List of Contributors

FUMIYOSHI ABE, Extremobiosphere Research Center, and Agency for Marine-Earth Science and Technology, 2-15 Natsushima-cho, Yokosuka 237-0061, Japan

GIOVANNI ADDOLORATO, Institute of Internal Medicine, Catholic University of Rome, L. go A. Gemelli 8, I-00168 Rome, Italy

PETER ALDRED, School of Science and Engineering, Institute of Food and Crop Science, Ballarat, Australia

R. ALLER, Institute of Endocrinology and Nutrition, Medicine School and Unit of Investigation, Hospital Rio Hortega, University of Valladolid, Valladolid, Spain

PAULO ALMEIDA, Department of Chemistry, Faculty of Science, University of Porto, Porto, Portugal

JESÚS-ROMÁN MARTÍNEZ ÁLVAREZ, Spanish Society of Dietetics and Food Science, Faculty of Medicine, Ciudad Universitaria 28040 Madrid, Spain

A.V. NIEUW AMERONGEN, Section of Oral Biochemistry, Department of Basic Dental Sciences, Academic Centre for Dentistry (ACTA), Amsterdam, The Netherlands

MOGENS L. ANDERSEN, Food Chemistry, Department of Food Science, University of Copenhagen, Rolighedsvej 30, Frederiksberg C DK-1958, Denmark

HITOSHI AOSHIMA, Applied Molecular Bioscience, Graduate School of Medicine, Yamaguchi University 1677-1 Yoshida, Yamaguchi 753-8512, Japan

SAKAE ARIMOTO-KOBAYASHI, Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama University, 1-1-1 Tsushima, Okayama 700-8530, Japan

ALEMAYEHU ASFAW, Department of Chemistry, University of Oslo, Oslo, Norway

ERICA WEINTRAUB AUSTIN, Edward R. Murrow School of Communication, Washington State University, Pullman, WA, USA

WERNER BACK, Lehrstuhl für Technologie der Brauerei I, Weihenstephaner Steig 20, Freising-Weihenstephan D-85354, Germany

SEUNG JOON BAEK, Laboratory of Environmental Carcinogenesis, Department of Pathobiology, College of Veterinary Medicine, University of Tennessee, 2407 River Drive, Knoxville, TN 37996, USA

WANDA BAER-DUBOWSKA, Department of Pharmaceutical Biochemistry, Poznań University of Medical Sciences, Swieckiego 4, 60780 Poznań, Poland

AQUILES A. BARROS, Requimte/Departamento de Química, Faculdade de Ciências, da Universidade Do Porto, Rua do Campo Alegre 687, Porto 4169-007, Portugal

HANS BECKER, Pharmakognosie und Analytische Phytochemie, der Universitat des Saarlandes, Saarbrúcken D 66041, Germany

BAKAN BÉNÉDICTE, INRA Unité Biopolymères, Interactions, Assemblages, Nantes cedex, France

STEFANIE BERWANGER, Pharmakognosie und Analytische Phytochemie der Universität des Saarlandes, Saarbrücken, Germany

STEFAN BLEICH, Department of Psychiatry and Psychotherapy, University Hospital Erlangen, Germany

JEFFREY B. BLUMBERG, Antioxidants Research Laboratory, Jean Mayer USDA Human Nutrition Research Center on Aging, Tufts University, Boston, MA, USA

JERINA BOELENS, Department of Hematology, Ghent University Hospital, Ghent, Belgium

GREGOR BOHR, Pharmakognosie und Analytische Phytochemie, der Universität des Saarlandes, Saarbrücken, Germany

MARC BRACKE, Laboratory of Experimental Cancer Research, Department of Radiotherapy and Nuclear Medicine, Ghent University Hospital, De Pintelaan 185, Gent B-9000, Begium

H.S. BRAND, Department of Oral Biochemistry, Academic Centre for Dentistry Amsterdam (ACTA), Amsterdam, van der Boechorststraat 7, Amsterdam 1081 BT, The Netherlands

M.L. BRUINS, Section of Oral Biochemistry, Department of Basic Dental Sciences, Academic Centre for Dentistry (ACTA), Amsterdam, The Netherlands

STEFANO BUIATTI, Department of Food Science, University of Udine, Via Marangoni 97, 33100 Udine, Italy

RODRIGO R. CATHARINO, Thomson Mass Spectrometry Laboratory, Institute of Chemistry, State University of Campinas, Campinas, SP 13083-970, Brazil

M. LUISA CERVERA, Department of Analytical Chemistry, Edificio de Investigacion, University of Valencia, E-46100 Burjassot, Valencia, Spain

CHUNG-YEN CHEN, Antioxidants Research Laboratory, Jean Mayer USDA Human Nutrition Research Center on Aging, Tufts University, 711 Washington Street, Boston, MA 02111, USA

QIAO QIAO CHEN, Unidade de Nutrição e Metabolismo, Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal

YUONNES CHEN, Edward R. Murrow School of Communication, Washington State University, Pullman, WA, USA

GIUSEPPE COMI, Department of Food Science, University of Udine, Via Marangoni 97, 33100 Udine, Italy

SONIA CORTACERO-RAMÍREZ, Department of Analytical Chemistry, Faculty of Sciences, University of Granada, Granada, Spain

L. DAENEN, Centre for Malting and Brewing Sciences, Catholic University of Leuven, Kasteelpark, Arenberg 22, PO Box 02463, Heverlee 3001, Belgium

L. De COOMAN, Laboratory of Enzyme and Brewing Technology, KaHo St-Lieven, Gent, Belgium

D.A. De LUIS, Institute of Endocrinology and Nutrition, University of Valladolid Medical School, c/Los perales 16 (URB Las Acenas), Simancas E-47130, Valladolid, Spain

D.P. De SCHUTTER, Department of Microbial and Molecular Systems, Centre for Malting and Brewing Science, Catholic University of Leuven, Kasteelpark, Arenberg 22, PO Box 02463, Heverlee 3001, Belgium

MAX L. DEINZER, Department of Chemistry, Oregon State University, Gilbert Hall 153, Corvallis, OR 97330, USA

F. DELVAUX, Department of Microbial and Molecular Systems, Centre for Malting and Brewing Science, Catholic University of Leuven, Kasteelpark, Arenberg 22, PO Box 02463, Heverlee 3001, Belgium

RALF DEMMEL, Department of Clinical Psychology, University of Muenster, Fliednerstr. 21, Muenster 48149, Germany

G. DERDELINCKX, Department of Microbial and Molecular Systems, Centre for Malting and Brewing Science, Catholic University of Leuven, Kasteelpark, Arenberg 22, PO Box 02463, Heverlee 3001, Belgium

ESTERA SZWAJCER DEY, Pure and Applied Biochemistry, Lund University, Lund, Sweden

M.E. DÍAZ-RUBIO, Department of Metabolism and Nutrition, CSIC, Ciudad Universitaria, C/Jose Antonio Novais 10, 28040 Madrid, Spain

J. RICHARD DICKINSON Cardiff School of Biosciences, Cardiff University, PO Box 915, Cardiff CF10 3TL, UK

MARION DIDIER, INRA, Unite Biopolymeres, Interactions, Assemblages, rue de la Geraudiere, Nantes BP71627 44316, Cedex 03, France

FRIEDHELM DIEL, IUG and University of Applied Sciencies, Hochschule Fulda, Fb:Oe, Marquardstrasse 35, Fulda D-36039, Germany

SUSANNE DIEL, Institut für Umwelt und Gesundheit (IUG) and University of Applied Sciences, FB:Oe, Biochemistry, Fulda, Germany

REINHARD A. DILLER, Institute of Technology of Biogenic Resources, Technical University of Munich, Straubing, Germany

ZODWA DLAMINI, Faculty of Health Sciences, School of Anatomical Sciences, University of the Witwatersrand, 7 York Road, Johannesburg 2193, South Africa

AGNIESZKA DOBROWOLSKA-ZACHWIEJA, Department of Gastroenterology and Human Nutrition, Poznań University of Medical Sciences, Poznań, Poland

JEAN-PIERRE DUFOUR, Department of Food Science, University of Otago, Dunedin, New Zealand

MARCOS N. EBERLIN, Thomson Mass Spectrometry Laboratory, Institute of Chemistry, State University of Campinas, UNICAMP, Campinas, SP, Brazil

KATHARINA E. EFFENBERGER, Department of Tumor Biology, Center of Experimental Medicine, University Medical Center Hamburg-Eppendorf, Martinistreet 52, Hamburg D-20246, Germany

GRAHAM EYRES, Department of Food Science, University of Otago, PO Box 56, Dunedin, New Zealand

PAOLO FANTOZZI, Italian Brewing Research Centre, CERB (Centro di Eccellenza per la Ricerca sulla Birra), University of Perugia, Via S. Costanzo, 06126 Perugia, Italy

JUSTIN A. FEGREDO, Department of Nutrition and Dietetics, King's College London, Franklin Wilkins Building, 150 Stamford Street, London SE1 9NH, UK

PETER FEICK, Department of Medicine II (Gastroenterology, Hepatology and Infectious Diseases), University Hospital of Heidelberg at Mannheim, Mannheim, Germany

ALBERTO FERNÁNDEZ-GUTIÉRREZ, Department of Analytical Chemistry, Faculty of Sciences, University of Granada, Granada, Spain

ISABEL M.P.L.V.O. FERREIRA, REQUIMTE, Servico de Bromatologia, Faculdade de Farmacia, Universidade do Porto, R. Anibal Cunha, Porto 4050-047, Portugal

ANNA FERRULLI, Institutes of Internal Medicine, Catholic University of Rome, Rome, Italy

MARTA FONTANA, Department of Agriculture and Environmental Sciences, University of Udine, Via delle Scienze 208, 33100 Udine, Italy

GLEN P. FOX, Plant Science-Wheat, Barley and Oats, PO Box 2282, Toowoomba Qld, 4350, Australia

JOSÉ Da CRUZ FRANCISCO, Pure and Applied Biochemistry, Lund University, Lund, Sweden

NORBERT FRANK, German Cancer Research Center (DKFZ) Chemoprevention, Im Neuenheimer Feld, Heidelberg, Germany

ANDREAS FRANKE, Department of Medicine II (Gastroenterology, Hepatology and Infectious Diseases), University Hospital of Heidelberg at Mannheim, Mannheim, Germany

GARY FREEMAN, BRI, Lyttel Hall, Nutfield, Surrey, UK

CORAZON FRIAS, Department of Pediatric Oncology/Hematology, University Medical Center Charité, Campus Virchow, Berlin, Germany

SONJA FRÖLICH, Institut für Pharmazie (Pharmazeutische Biologie), Freie Universität Berlin, Berlin, Germany

DIETMAR FUCHS, Division of Biological Chemistry, Innsbruck Medical University, Ludwig Boltzmann Institute of AIDS-Research, Fritz Pregl Strasse 3, A-6020 Innsbruck, Austria

ANDRZEJ GAMIAN, Institute of Immunology and Experimental Therapy, Polish Academy of Sciences, Wrocław; Department of Medical Biochemistry, Wrocław Medical University, Wrocław, Poland

S. GARCÍA-FALCÓN, Nutrition and Bromatology Group, Department of Analytical and Food Chemistry, Food Science and Technology Faculty, University of Vigo, Ourense Campus, Ourense, Spain

SALVADOR GARRIGUES, Department of Analytical Chemistry, Edificio de Investigacion, University of Valencia, 50 Dr. Moliner Street, Burjassot E-46100, Valencia, Spain

ANTONIO GASBARRINI, Institutes of Pathology, Catholic University of Rome, Rome, Italy

GIOVANNI GASBARRINI, Institutes of Internal Medicine, Catholic University of Rome, Rome, Italy

CLARISSA GERHÄUSER, Deutsches Krebsforschungszentrum (DKFZ), Abteilung Toxikologie und Krebsrisikofaktoren, Workgroup Chemoprevention, Im Neuenheimer Feld 280, Heidelberg D-69120, Germany

ANDREAS GERLOFF, Department of Medicine II (Gastroenterology, Hepatology and Infectious Diseases), University Hospital of Heidelberg at Mannheim, Mannheim, Germany

ANDREA GHISELLI, National Research Institute for Food and Nutrition Research, Via Ardeatina, Rome, Italy

A.M. GIL, Department of Chemistry, University of Aveiro, Campus de Santiago, Aveiro 3810-193, Portugal

I. GOÑI, Unidad Asociada Nutrición y Salud Gastrointestinal (UCM-CSIC), Dpt. Nutrición I. Facultad de Farmacia, Ciudad Universitaria, Madrid, Spain

STANISLAVA GORJANOVIĆ, Institute of General and Physical Chemistry, Studentski trg 12-16/V, PO Box 551, 11001 Belgrade, Serbia

MIGUEL de la GUARDIA, Department of Analytical Chemistry, Edificio de Investigacion, University of Valencia, E-46100 Burjassot, Valencia, Spain

N.P. GUERRA, Nutrition and Bromatology Group, Department of Analytical and Food Chemistry, Food Science and Technology Faculty, University of Vigo, Ourense Campus, Ourense, Spain

LUIS F. GUIDO, Requimte/Departamento de Química, Faculdade de Ciências, da Universidade Do Porto, Rua do Campo Alegre 687, Porto 4169-007, Portugal

SANJAY GUPTA, Department of Urology, Case Western Reserve University, University Hospitals Case Medical Center and Case Comprehensive Cancer Center, Cleveland, OH, USA

LINDA HELLBORG, Department of Cell and Organism Biology, Lund University, Biologihuset Solvegatan 35, Lund S-223 62, Sweden

GÜNTER HENZE, Department of Pediatric Oncology/Hematology, University Medical Center Charité, Campus Virchow, Berlin, Germany

MARÍA PURIFICACIÓN HERNÁNDEZ-ARTIGA, Department of Analytical Chemistry, Faculty of Sciences, University of Cadiz, Apdo. 40, Puerto Real 11510, Cadiz, Spain

JAVIER HERNÁNDEZ-BORGES, Department of Analytical Chemistry, Nutrition and Food Science, University of La Laguna, Avda, Astrofisico Fco. Sánchez s/n°, 38071 La Laguna, Tenerife, Canary Islands, Spain

MARIA HERWALD, Institut für Umwelt und Gesundheit (IUG) and University of Applied Sciences, FB:Oe, Biochemistry, Fulda, Germany

THOMAS HILLEMACHER, Department of Psychiatry and Psychotherapy, University of Erlangen-Nuremberg, Schwabachanlage 6, Erlangen D-91054, Germany

SHEIKH JULFIKAR HOSSAIN, Applied Molecular Bioscience, Graduate School of Medicine, Yamaguchi University 1677-1 Yoshida, Yamaguchi 753-8512, Japan

PAUL HUGHES, School of Life Sciences, International Centre for Brewing and Distilling, Heriot-Watt University, Riccarton, Edinburgh EH14 4AS, UK

STACEY J.T. HUST, Edward R. Murrow School of Communication, Communication Addition 101, PO Box 642520, Washington State University, Pullman, WA 99164-2520, USA.

KEVIN HUVAERE, Food Chemistry, Department of Food Science, University of Copenhagen, Frederiksberg C, Denmark

GIUSEPPE IACOMINO, Institute of Food Sciences, National Research Council, Avellino, Italy

EWA IGNATOWICZ, Department of Pharmaceutical Biochemistry, Poznań University of Medical Sciences, ul. Swiecickiego 4, 60780 Poznań, Poland

KATSUMI IKEDA, Department of Health and Bio-pharmaceutical Sciences, School of Pharmacy and Pharmaceutical Sciences, Mukogawa Women's University, Nishinomiya, Japan

PAVEL JANDERA, Department of Analytical Chemistry, Faculty of Chemical Technology, University of Pardubice, Nam. Cs. Legii 565, Pardubice CZ-532 10, Czech Republic

KRISTINA JENETT-SIEMS, Institut für Pharmazie, Freie Universitat Berlin, Konigin-Luise- Str. 2-4, D-14195 Berlin, Germany

RAVIN JUGDAOHSINGH, MRC Human Nutrition Research, Elsie Widdowson Laboratory, Fulbourn Road, Cambridge CB1 9NL, UK

MASATO KAWASAKI, Research Laboratories for Brewing, Technology Development Department, Production Division, Kirin Brewery Co., Limited, 1-17-1 Namamugi, Tsurumi-ku, Yokohama 230-8628, Japan

WILLIAM C. KERR, Alcohol Research Group, 6475 Christie Avenue, Suite 400, Emeryville, CA 94608, USA

IGOR KHMELINSKII, Universidade do Algarve, FCT, DQBF, Campus de Gambelas, Faro, Portugal

YOSHINOBU KISO, Institute for Health Care Science, Suntory Limited, Wakayamadai, Shimamoto-cho, Mishima-gun, Osaka, Japan

HIROFUMI KODA, Institute for Health Care Science, Suntory Limited, Wakayamadai, Shimamoto-cho, Mishima-gun, Osaka, Japan

M. KOMAITIS, Laboratory of Food Chemistry, Agricultural University of Athens, Iera Odo 75, Athens 118 55, Greece

KEIJI KONDO, Central Laboratories for Frontier Technology, Research Section for Applied Food Science, Kirin Brewery Co., Ltd.,Takasaki, Gunma, Japan

VIOLETTA KRAJKA-KUŹNIAK, Department of Pharmaceutical Biochemistry, Poznań University of Medical Sciences, Swieckiego 4, 60780 Poznań, Poland

ROBERTO KRATKY, Department of Food Science, University of Udine, Via Marangoni, 97, 33100 Udine, Italy

L. DARREN KRUISSELBRINK, School of Recreation Management and Kinesiology, Acadia University, 550 Main St., Wolfville, NS B4P 2R6, Canada

ALAN K.H. LAI, Department of Nutrition and Dietetics, King's College London, London, UK

M. LEDOCHOWSKI, Department of Internal Medicine, Innsbruck Medical University, Innsbruck, Austria

SEONG-HO LEE, Department of Pathobiology, College of Veterinary Medicine, University of Tennessee, Knoxville, TN, USA

LORENZO LEGGIO, Institutes of Internal Medicine, Catholic University of Rome, Rome, Italy

HUI-JING LI, Department of Chemistry, Oregon State University, Corvallis, OR, USA

KRIENGSAK LIRDPRAPAMONGKOL, Department of Biochemistry, Faculty of Science, Mahidol University and Laboratory of Biochemistry, Chulabhorn Research Institute, Bangkok, Thailand

ALEX G. LITTLE, Department of Surgery, Boonshoft School of Medicine, Wright State University, Dayton, OH, USA

C. LÓPEZ-MACÍAS, Nutrition and Bromatology Group, Department of Analytical and Food Chemistry, Food Science and Technology Faculty, University of Vigo, Ourense Campus, Ourense, Spain

SUZANNE LORET, Department of Biology, Faculty of Sciences, University of Namur (FUNDP), Rue de Bruxelles 61, B-5000 NAMUR, Belgium

ZACHARENIA LOUKOU, General Chemical States Laboratory, Kavala Division, Karaoli Square, Kavala, Greece

VALENTIN LOZANOV, Department of Chemistry and Biochemistry, Medical University of Sofia, Sofia 1431, Bulgaria

SOFIE LUST, Department of Hematology, Ghent University Hospital, Ghent, Belgium

JEAN ROBERT MABIALA-BABELA, Centre Hospitalier Universitaire,Service de Pediatrie Nourrissons, Brazzaville BP 32, Congo

MARISA MANZANO, Department of Food Science, University of Udine, Via Marangoni 97, 33100 UDINE, Italy

OMBRETTA MARCONI, Italian Brewing Research Centre, CERB (Centro di Eccellenza per la Ricerca sulla Birra), University of Perugia, Via S. Costanzo, 06126 Perugia, Italy

PEDRO MARQUES-VIDAL, Institut Universitaire de Medecine Sociale et Preventive, 17, rue du Bugnon, Lausanne CH-1005, Switzerland

PEDRO MARQUES-VIDAL, Unidade de Nutrição e Metabolismo, Instituto de Medicina Molecular, Faculdade de Medicina da Universidade de Lisboa, Av. Professor Egas Moniz, Lisboa 1649-028, Portugal

COLIN R. MARTIN, Psychology Group, School of Health and Human Services, Faculty of Health Leeds Metropolitan University, Civic Quarter, Leeds LS1 3HE, UK

E. MARTÍNEZ-CARBALLO, Nutrition and Bromatology Group, Department of Analytical and Food Chemistry, Food Science and Technology Faculty, University of Vigo, Ourense Campus, Ourense, Spain

ALPHONSE MASSAMBA, Centre Hospitalier et Universitaire, Service de Pediatrie Nourrissons, Brazzaville, Congo

HEIDI MAYER, Italian Brewing Research Centre, CERB (Centro di Eccellenza per la Ricerca sulla Birra), University of Perugia, Via S. Costanzo, 06126 Perugia, Italy

ZUKILE MBITA, University of the Witwatersrand, Wits Medical School, Johannesburg, South Africa

ADELE Mc KINNEY, School of Psychology, Life and Health Sciences, University of Ulster, Magee Camous, Derry BT48 7JL, Northern Ireland, UK

NIALL McCRAE, Health Services Research Department, Institute of Psychiatry, Denmark Hill, De Crespigny Park, PO Box 26, London SE5 8AF, UK

GARRY MENZ, School of Science and Engineering, Institute of Food and Crop Science, Ballarat, Australia

RACHEL MEYNELL, Department of Nutrition and Dietetics, King's College London, Franklin Wilkins Building, 150 Stamford Street, London SE1 9NH, UK

DOLORES BELLIDO MILLA, Department of Analytical Chemistry, Faculty of Sciences, University of Cádiz, Cádiz, Spain

STUART R. MILLIGAN, Division of Reproduction and Endocrinology, School of Biomedical Sciences, King's College London, Guy's Campus, Room 2.11N Hodgkin Building, London Bridge, London SE1 1UL, UK

LUIGI MONTANARI, Italian Brewing Research Centre, CERB (Centro di Eccellenza per la Ricerca sulla Birra), University of Perugia, Via S. Costanzo, 06126 Perugia, Italy

FRANCISCO J. MORALES, Consejo Sup. de Invest. Cie., Instituto del Frio (CSIC), Jose Antonio Novais 10, Madrid E-28040

YUJI MORIWAKI, Division of Endocrinology and Metabolism, Department of Internal Medicine, Hyogo College of Medicine, Mukogawa-cho 1-1, Nishinomiya Hyogo 663-8501, Japan

KENNETH J. MUKAMAL, Division of General Medicine and Primary Care, Beth Israel Deaconess Medical Center, 330 Brookline Avenue, Boston, MA 02215, USA

RENÉ J.L. MURPHY, School of Recreation Management and Kinesiology, Acadia University, Wolfville, NS, Canada

MAOURA NANADOUM, Laboratoire de Recherche sur les Substances Naturelles, Faculté des Sciences, Exactes et Appliquées BP, N'Djaména 1027, Tchad

MIRELLA NARDINI, Free Radical Research Group, National Institute for Food and Nutrition (INRAN), Via Ardeatina, 546, 00178 Rome, Italy

FAUSTA NATELLA, National Research Institute for Food and Nutrition Research, Via Ardeatina, Rome, Italy

SIMÓN NAVARRO, Department of Agricultural Chemistry, Geology and Pedology, School of Chemistry, University of Murcia, Campus Universitario de Espinardo, Murcia E-30100, Spain

JENNIFER NICOLAI, Department of Clinical Psychology, University of Münster, Münster, Germany

HAJIME NOZAWA, Central Laboratories for Frontier Technology, Kirin Brewery Co. Ltd., 3 Miyahara, Takasaki, Gunma 370-1295, Japan

FRITZ OFFNER, Department of Hematology, Ghent University Hospital, Ghent, Belgium

L.M. PASTRANA-CASTRO, Nutrition and Bromatology Group, Department of Analytical and Food Chemistry, Food Science and Technology Faculty, University of Vigo, Ourense Campus, Ourense, Spain

DOUGLAS E. PAULL, Department of Surgery, Wright State University School of Medicine, VA Medical Center, 4100 W. Third St. #112, Dayton, OH 45428, USA

ANDREA PAVSLER, Department of Food Science, University of Udine, Via Marangoni 97, 33100 Udine, Italy

C. PEHL, Department of Gastroenterology, Academic Teaching Hospital Bogenhausen, Englschalkinger Street 77, Munich 81935, Germany

JARA PÉREZ-JIMÉNEZ, Department of Metabolism and Nutrition, CSIC, Ciudad Universitaria, Madrid, Spain

BRUCE E. PINKLETON, Edward R. Murrow School of Communication, Washington State University, Pullman, WA, USA

JURE PISKUR, Department of Cell and Organism Biology, Lund University, Biologihuset Solvegatan 35, Lund S-223 62, Sweden

PAWEL POHL, Division of Analytical Chemistry, Faculty of Chemistry, Wroclaw University of Technology, Wybrzeze Stanislawa Wyspianskiego 27, 50-370 Wroclaw, Poland

SAM POSSEMIERS, Laboratory of Microbial Ecology and Technology (LabMET), Ghent University, Gent, Belgium

JACQUES POURQUIE, UMR Microbiologie et Genetique Moleculaire, CNRS/INA-PG/INRA, CBAI BP 01, 78 850, Thiverval Grignon, France

JONATHAN J. POWELL, MRC Human Nutrition Research, Elsie Widdowson Laboratory, Fulbourn Road, Cambridge CB1 9NL, UK

VICTOR R. PREEDY, Department of Nutrition and Dietetics, King's College London, Franklin-Wilkins Building, 150 Stamford Street, London SE1 9NH, UK

C. PROESTOS, Laboratory of Food Chemistry, Agricultural University of Athens, Iera Odos, Athens, Greece

ARAM PROKOP, Department of Pediatric Oncology/Hematology, University Medical Center Charité, Campus Virchow, Berlin, Germany

SANDRA RAINIERI, Department of Agricultural Sciences, University of Modena and Reggio Emilia, Via J. F. Kennedy, 17, 42100 Reggio Emilia, Italy

RAJKUMAR RAJENDRAM, Nutritional Sciences Research Division, School of Life Sciences, King's College, and Departments of General Medicine and Intensive Care, John Radcliffe Hospital, Oxford OX3 0JH, UK

BRITTANY B. RAYBURN, Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, School of Medicine, University of New Mexico, Albuquerque, NM, USA

WILLIAM F. RAYBURN, Department of Obstetrics and Gynecology, University of New Mexico School of Medicine, MSC 10 5580, 1 University of New Mexico, Albuquerque, NM 87131, USA

HERBERT M. RIEPL, Institute of Technology for Biogenic Resources, Technical University of Munich, Petersgasse 18, Straubing D-94315, Germany

JOSÉ RODRIGUES, Departamento de Quimica, Faculdade de Ciencias, Universidade Do Porto, Rua do Campo Alegre, 687, Porto 4169-007, Portugal

MIGUEL ÁNGEL RODRIGUEZ-DELGADO, Department of Analytical Chemistry, Nutrition and Food Science, University of La Laguna, Avda, Astrofisico Fco. Sánchez s/n°, 38071 La Laguna, Tenerife, Canary Islands, Spain

OLIVER ROSE, Department of Pediatric Oncology/Hematology, University Medical Center Charité, Campus Virchow, Berlin, Germany

PREFACE

Evidence for the brewing of beer dates back to over 8,000 years and since then, its pattern and consumption has changed considerably: from a beverage of warriors to a cheap and affordable commodity. Like most alcoholic drinks, it has been prone to abuse and in some countries, the high per capita consumption of beer has led to considerable health risks. However, current science indicates that, in moderate or low amounts, the consumption of beer may be beneficial to good health.

Beer in Health and Disease Prevention addresses the need for a single, coherent volume presenting this spectrum of information. The book is composed of four main sections:

1. General aspects of beer and constituents
2. General effects on metabolism and body systems
3. Specific effects of selective beer-related components
4. Assay methods and techniques used for investigating beer and related compounds

Studying specific instances where beer consumption may have a positive impact on health, this book presents a comprehensive overview of both beer and its constituents, and their relationship to disease. For example, some cancers like bladder cancers and the incidence of cardiovascular disease are reported to be lower in moderate beer drinkers. These findings have led to the suggestion that beer contains substances that may be protective against disease. This has been shown to be true to the extent that compounds derived from beer and hops are protective against damaged cells. Xanthohumol and isoxanthohumol are just two examples of potential anticancer agents.

Furthermore, there is a considerable body of emerging evidence to show that the antioxidant capacity of beers is high. It has been argued by some that the total antioxidants ingested in some beer drinkers equates to that consumed by red wine drinkers. However, beer is a complex beverage with well over 1,000 identifiable compounds and there is a continual drive to identify and characterize new compounds that might also have potential pharmacological effects.

However, beer may also contain carcinogenic compounds, such as nitrosamines, even asbestos fibers from beer filters. All this requires a holistic understanding of beer and beer-related science from brewing to the isolation beer-related compounds.

This book is designed to provide insight into the possibilities of the role of beer in health maintenance as well as prevention of diseases. Contributors are authors of international and national standing, leaders in the field and trend-setters. Emerging fields of science and important discoveries relating to beer have been incorporated in *Beer in Health and Disease Prevention*, and this resource will be essential reading for nutritionists, pharmacologists, health care professionals, research scientists, cancer workers, cardiologists, pathologists, molecular or cellular biochemists, general practitioners as well as those interested in beer or alcohol studies in general.

FOREWORD

In recent years few issues have hit the public health agenda as hard as alcohol abuse. Excessive alcohol consumption carries an attributable risk to public disorder, violent crime, road traffic accidents, hospital admissions and social instability. The government purse, filled by every taxpayer, is increasingly called upon for alcohol-related health care and law enforcement. The public face of alcohol consumption comprises bars, clubs, pubs and various social and sporting events – and synonymous with these is beer. So from where does a sincere, scientific book arrive entitled *Beer in Health and Disease Prevention*? The answer, in large part, lies in the now famous J-shaped curve that links alcohol ingestion to risk for a number of diseases. In short, moderate alcohol consumers not only appear to have better long-term health outcomes than excessive alcohol consumers but they can also fare better than abstainers. In other words, for some diseases, the graph relating alcohol intake to morbidity has a J shape with the nadir corresponding to moderate alcohol consumption. Study after study has shown this; most famously for cardiovascular disease but additionally, for example, for bone disease, cognitive decline, Type II diabetes and even overall mortality. On balance, beer appears at least as effective as wine at protecting against disease, when either are enjoyed in moderation, and our research has suggested that this effect may not only be attributable to beer's ethanol content but also to cereal and hop-related components such as silicic acid (silicon) and certain phenolics. But there are two significant issues with the J-shaped curve: the first is one of scientific endeavor and the second of social implication.

The observation that moderate alcohol consumers enjoy better health than abstainers may be confounded by co-linear patterns of behavior, social class and education. Put simply, the argument is that moderate consumers are moderate individuals who enjoy moderate life styles (exercise, balanced diet, low prevalence of smoking, high education and general health awareness). In contrast, continues the argument, abstainers of alcohol also miss out elsewhere, including exercise, diet balance and health education. This debate is not easily resolved. In most areas of medical science an "intervention study" would allow consensus to be reached but ethically and practically it is all but impossible to supplement abstainers with alcohol in moderation to see if this leads to an improvement in long-term health. Thus, we must reply on population survey studies, with their inherent limitations noted above. A major step in addressing whether the "moderate alcohol-better health" picture is confounded or not is the identification of underlying mechanisms. If biological pathways exist that explain the observations, then greater confidence can be drawn from the survey data. *Beer in Health and Disease Prevention* provides extensive data on the underlying science that can link moderate ethanol consumption, or other components of beer, to biological responses thus explaining some of the epidemiological observations. It also provides a framework around which further scientific studies can be built and, therefore, paves the way in providing quantification or "attributable benefit" to the associations.

However, if the J-shaped curve is proven beyond reasonable doubt what then do governments and health organizations do with the data? Will this not simply fuel further excessive drinking? It, of course, depends on how the message is handled and the context in which it is delivered. The message of abstention (or less-is-better) is not working in certain quarters. The concept that responsible drinking could be well regarded in all circles of society while irresponsible drinking becomes socially unacceptable, again at all levels, has its merit. Industry, governments, health organizations, alcohol organizations and health care professionals will need to pull together with respect to taxation, acceptable beverage types and marketing strategies, serving sizes, alcohol content, sales policies, definition of moderation, and public dissemination of responsible drinking messages. As such the J-shaped curve may have a role to play in addressing one of the most pressing public health issues of our time. Beer has probably been around, in one form or another, since Neolithic times. It has, over millennia, provided clean, uninfected hydration and nutrition for many populations when water supplies and some foods have failed in this respect. It gently crosses geography, creed and culture and is enjoyed by hundreds of millions of people across the world. *Beer in Health and Disease Prevention* not only pushes our thinking on the breadth of the alcohol–health debate, but it is also a timely reminder to society of the more gentle face of Janus when it comes to the complex, ancient but humble pint.

Overview of Manufacturing Beer: Ingredients, Processes, and Quality Criteria

Sascha Wunderlich and Werner Back Lehrstuhl für Technologie der Brauerei I, Freising-Weihenstephan, Germany

Abstract

Brewers worldwide produce beer at an advanced technological level while keeping in mind the importance of tradition. The basic ingredients are water, malted barley, hops, and yeast, as it is fixed in Germany by the legislation governing commercial brewing, the *Reinheitsgebot* (Purity Law) (BGB1, 1993). Brewing technologies worldwide are based on this recipe, although brewers in other countries have more flexibility, for example in selection of starch supply. Nevertheless, barley is commonly used as the source of starch but it has to be malted to dissolve starch in the grains prior to brewing. Malting steps are steeping, germination, and kilning. Enzymes digest grain contents during these processes and prepare starch for further processes. Heating during kilning produces coloring and flavoring substances. Further enzymes convert the starch of milled malt to fermentable sugars during mashing. This procedure results in wort that is boiled. Hops are added in this stage of boiling. Yeast converts sugars to alcohol during fermentation of cooled wort. After maturation and storage, beer is filtered and stabilized to inhibit quality deficiencies. These may be turbidity, decrease of flavor stability, or decrease of foam stability. Each production step influences decisively the resulting beer. So, an enormous variety of beers is possible that are all tasty, thirst-quenching and healthy.

List of Abbreviations

4-VG	Vinylguaiacol
°dH	Degree of hardness
DMS	Dimethyl sulfite
DMS-P	Dimethyl sulfite precursor
FAN	Free amino nitrogen
POC	Phenolic off-flavor
PVPP	Polyvinylpolypyrrolidon

Introduction

Beer is one of the oldest cultural achievements of mankind and one of the most popular beverages all over the world.

From the technological point of view, beer has four main properties based on its contents and manufacturing processes. It is (i) pure, (ii) wholesome, (iii) valuable, and (iv) it displays a variety of styles and genres:

(a) The purity is guaranteed by the natural ingredients: hops, malt, yeast, and water. No pathogenic germs are found in beer because of the pH-value, presence of hop substances, the anaerobic environment, the alcohol content and also the fact that yeast metabolizes nearly all fermentable sugars. Therefore, other micro-organisms experience a food shortage. Additionally, the manufacturing process is a clarifying process. Mashing, lautering, boiling, fermentation, and filtration separate harmful or exogenous substances.

(b) Beer is wholesome because of the variability and the balance of its contents. For example, 1l of beer has low carbohydrate contents and fewer calories than the equivalent amount of apple juice or milk. It contains no preserving agents but valuable amino acids at a moderate acidity. Generally, its alcohol content is in a physiologically advantageous relation to its water content.

(c) Beer is a valuable source of vitamins (especially in form of B-complexes), minerals and antioxidants. Beer is, *inter alia*, an excellent source of bio-available silicon. Further, gallic acid, quercetin, xanthohumol, and Maillard products like pronyl-lysine have been implicated in contributing to the wholesome nature of beer.

(d) All over the world more than 100 beer varieties are produced, from Pilsener to lager and wheat beer, as well as non-alcoholic varieties. Differences are based on the careful selection of raw materials and variations of the brewing process. Selected contents can be emphasized by special manufacturing methods (Back, 2005a; Bamforth, 2004).

Raw Materials

Water, malt, hops, and yeast are the four main ingredients for manufacturing beer. Quality and suitability of these ingredients is absolutely vital for a tasty and beneficial

product, as they are for cooking. Purchasing of raw materials for the brewery needs to strictly observe predefined quality criteria. These criteria are as variable as the different types of beer on the market (Kunze, 1999; Heyse, 2000; Bamforth, 2003; Briggs *et al.*, 2004).

Water

Water is the main component of beer and so breweries often stress the purity and originality of their brewing liquor. Water quality for brewing beer is often determined by legislation. It has to be potable, pure, and free of pathogens, as measured by chemical and microbial analyses. Additionally, there are ancillary quality requirements for water used for brewing. The pH-value is especially important because different production steps only take place optimally at defined pH-values. Substantial amounts of ions are released from malt during mashing. These ions react with water ions that cause changes in the pH-value. Alkaline earth metals (in first order Ca^{2+} and Mg^{2+}) are important for the aspect of hardness in brewing liquor. Others like K^+ often play a minor role. Generally, Ca^{2+} and Mg^{2+} are responsible for decreasing the pH-value. It is increased by hydrogen carbonate ions. Reactions with primary, secondary, and tertiary phosphates originating from malt inhibit this effect, but partly can also stimulate it. The relationship of pH-value increasing and decreasing ions finds its expression in the residual alkalinity of brewing water. It describes the effect that 3.5 mol Ca^{2+} or 7 mol Mg^{2+} can compensate the pH-value increasing effect of 1 mol hydrogen carbonate ions.

$$\text{Residual alkalinity} = \text{total alkalinity} - (\text{hardness of } Ca^{2+} + 0.5 \times \text{hardness of } Mg^{2+})/3.5$$

Total alkalinity represents hardness of carbonates, which is the content of carbonate and hydrogen carbonate ions. The contribution of carbonates to a conventional water pH-value below 8.2 is marginal and can be neglected. Traditionally, residual alkalinity is given in country-specific degrees of hardness. For example, in Germany 1 degree of hardness (°dH) is $10\,CaO\,mg/l$ or $0.36\,mmol/l$. In mash, an increased pH-value can be expected with increasing residual alkalinity. An increase of the residual alkalinity of 10 °dH is accompanied by an increase of the pH-value of 0.3 as a guideline in Germany. Water with a residual alkalinity of 0 does not influence the pH-value in mash. It acts in a similar way to distilled water. A residual alkalinity <5 °dH (better below 2 °dH) is recommended for pale brews. Dark brews can take a residual alkalinity <10 °dH, which complements the more flavorsome character of dark beer. Most water has to be conditioned for brewing. This happens, for example by ion exchange using synthetic resins or by the addition of brewing gypsum ($CaSO_4$). In the latter case, the evolving K_2SO_4 is unfavorable from a sensory point of view. Amounts exceeding $30\,mg$ $CaSO_4/hl$ should be avoided. Other mineral ions also influence the brewing process or taste. Sulfate, for example, can cause a hard and dry taste but favors a hop bouquet. Iron and manganese contents of more than $0.2\,mg/l$ result in an unfavorable color and taste. Calcium protects α-amylase from early inactivation during mashing. Zinc stimulates yeast growth and fermentation; these processes are inhibited by nitrates (Narziss, 1992; Heyse, 2000).

Barley and other cereals

Generally, barley (*Hordeum vulgare*) is – after water – quantitatively the second most important ingredient for beer. Brewers admire barley because it prospers even in adverse growing conditions. Germination may be easily adjusted during malting. Enzymes and other brewing technology-relevant substances that are produced are favorable from a process point of view. Two-row barley is preferred in Germany for its extract content. In general, barley with more rows has less developed grains but higher protein content and enzymatic strength. This is advantageous for adjunct brewing (brewing outside Germany).

Other crops like wheat, rye, triticale, spelt, and emmer are also suitable for brewing. Mostly they are added to barley malt. Bavarian wheat beer needs wheat as an adjunct in excess of 50%. Recently, first trials in assessing alternative cereals and pseudo-cereals like sorghum for their suitability in malting were conducted. They resulted in brews with novel sensory and health aspects (Back, 2005a). Alternative starch suppliers (malt substitutes) are interesting for their availability, profitability, and their special color and aroma contribution. Often raw materials, like unmalted barley, wheat, rice, or corn are used. Sometimes starch, saccharine, glucose, and corresponding syrups are also used (Bamforth, 2003; Briggs *et al.*, 2004). Their application is regulated in every country. In Germany, the use of malt substitutes is prohibited according to the *Reinheitsgebot* (the Purity Law governing commercial brewing). The United States allows an input of unmalted cereals of up to 34% and an input of sugars or syrups of up to 2.5% of the total grist (Back, 2005a).

Grain Contents   *Starch* is the most important content in grain for brewers. It is produced during photosynthesis and is stored as starch granules in the endosperm (Figure 1.1). About 63% of the grain's dry weight is starch. It is a food source for the embryo until it is a self-sufficient producer of metabolites. Starch consists of amylose (20–25%) and amylopectin (75–80%) that are α-(1,4) glycosidic bonds of glucose molecules. Amylopectin is a more complex molecule than amylase and can absorb water into its macromolecular structure for easier enzymatic degradation. Amylose does not agglutinate. Thus, enzymatic degradation is therefore more difficult.

Cellulose is the crude fiber that represents about 6% of the grain's dry weight. It is mostly detected in the grain covering husks (Figure 1.1). Traces are also found in the embryo, pericarp, and testa. It consists of glucose molecules as β-(1,4) glycosidic bonds. Cellulose is flavor neutral. It does not dissolve
Figure 1.1 Grain morphology: 1–3 coating (1: husk, 2: pericarp and testa, 3: furrow); 4 and 5 endosperm (4: protein (gluten) layer, 5: starch granules); 6–9 embryo (6: epithelium, 7: shield, 8: acrospire, 9: root).

Figure 1.2 Hop morphology, 1: hop cone, 2: axis, 3: lupulin glands, 4: leaf, 5: lupulin gland.

in water and survives the malting and brewing process intact. In husks cellulose is strengthened by lignin. It acts as a filter during lautering. *Hemicelluloses* mostly occur in membranes of starch granules in the endosperm, where they act as structural substances. They can also be found in husks to a lesser degree (Figure 1.1). Hemicelluloses are soluble in bases. The hot water soluble fractions are *gums*. Hemicelluloses and gums are polysaccharides and consist of glucose, hexurone acids and pentosans. β-Glucan is the most important factor in barley that influences the viscosity of wort and beer. *Protein* content in barley ranges between 8% and 13.5%. One-third may end up in the final beer. Protein is found in the embryo and mostly in the endosperm (Figure 1.1). It is divided into four fractions: albumins, soluble in distilled water; globulins, soluble in weak hydrochloric acid; prolamins, soluble in alcoholic solutions; and gutelins, soluble in weak bases. Prolamins and gutelins are storage proteins. Albumins and globulins are important for foam and colloidal characteristics of beer. *Minerals* originate in the embryo and the aleurone layer in the endosperm (Figure 1.1). They constitute 3% of the grain dry weight and are organically bound to about 80%. The most important minerals are silicon, potassium, and phosphorus as part of nucleic acids and phytin acid. Free phosphates influence the pH-value of the mash and downstream during fermentation. *Lipids* also occur in the embryo and the aleurone layer (about 3% grain dry weight). They may affect the taste and foam stability of beer. Especially, sterols may be regarded as pacemakers for starting fermentation. Barley and malt are rich in *vitamins*. These are mostly located in the embryo but also in the aleurone layer (Figure 1.1). Cereals also contain vitamin C, as do virtually all aerobically respiring forms of life. Most of the vitamins found belong to the B-complexes though. Vitamins can be nurtured and enhanced during malting. *Polyphenols* have numerous impacts on brewing. They influence color, foam, taste, and haze formation in beer. Husks, pericarp, and testa contain polyphenols in amounts between 0.1% and 0.3%
grain dry weight (Figure 1.1). Some phenolic carbon acids act in larger amounts as inhibitors for germination (cumarin, vanillic acid, ferulic acid). In smaller amounts they can also stimulate it. Ferulic acid, additionally, is involved in the typical wheat beer aroma by its metabolite 4-vinylguaiacol. Monomer polyphenols originating from flavan, like delphinidin and catechin (anthocyanogens), are able to fix oxygen. They are transformed into protein precipitating, polymer condensation products that can cause haze problems (Briggs, 1998; Narziss, 1999; Heyse, 2000; Bamforth, 2003).

Hop

Hop (*Humulus lupulus L.*) gives beer its typical bitterness and hop aroma. Traditionally, it is also added during brewing because of its preserving effects. Further, hop contains pharmacologically active substances, for example it is said to be soporific, or sleep inducing. All over the world hop is cultivated between the 35th and 55th parallels of latitude, north and south. The largest cultivation areas are in Germany (Hallertau, Elbe-Saale, Tettnang, Spalt) and the United States (Washington, Oregon, Idaho). In hop gardens, or hop fields, only unfertilized female plants are grown. They develop cones from their blossoms (Figure 1.2). Of interest to the brewer are lupulin glands, with the exception of the tannins. Lupulin glands are located between spindle and bracts (Figure 1.2).

Hop Contents Three groups of substances are especially interesting from the brewing technological point of view: hop resins, flavoring agents, and polyphenols. Hop resins constitute about 10–20% of the hop dry weight. They represent the sum of all bittering substances. Their important components are the α- and β-acids, whose bittering potential differs markedly. α-Acids are transformed into iso-α-acids during boiling. These iso-α-acids and their derivates have significant bittering potential. β-Acids have a low solubility in wort and beer. Thus, they contribute only a little to bitterness. Hop resins enhance physiological digestibility, foam stability, and bacteriostatic nature of wort and beer over and above the bittering potential.

Hop possesses approximately 0.4–2.0% flavoring agents per dry weight. These are essential oils that are responsible for the hop aroma and bouquet. More than 300 volatile substances have been identified up to now. Polyphenols (4–14% hop dry weight) also impact on beer quality. Additionally, low molecular polyphenols show antioxidative properties among their benefits. The hop polyphenol xanthohumol has been identified as a possible anticarcinogenic agent (Piendl, 2000; Back, 2005a). Amounts of polyphenols and composition depend on hop variety, cultivation area, and climatic conditions (Narziss, 1992).

Hop Products for the Brewery Brewers often stick to selected hop products because it gives their beer its special and predictable character. Generally, a differentiation is made between aroma hop and bitter hop. Flavor hops have lower α-acid contents but higher contents of essential oils. The flavor of each of these hop varieties has its own quality. Bitter hops have higher α-acid contents but lower contents of essential oils. Then there are different hop products. Breweries rarely use hop cones these days but pellets and hop extracts. Pellets are made from raw hops that are dried, ground, mixed, and pelletized. Hop extracts result from extraction with ethanol or carbon dioxide. After the extraction procedure, solvents are removed as far as possible. The resulting residue is a resin-like sticky substance. Extracted substances differ in their chemical make-up according to which solvent was used in extraction. In isomerized products α-acids are already transformed into iso-α-acids. These products can be added during wort boiling (kettle products) or before filtration (downstream products). It is possible to bitter a beer post-brewhouse or to give a hop aroma with special oils or emulsions. Special extracts can also be used for enrichment of hop substances, for example xanthohumol. Other products inhibit light-struck flavor or can be used to enhance foam. It should be noted that these special products have different sensory properties. An ancillary dosage regime is recommended (Narziss, 1992; Heyse, 2000).

Yeast

The following are the main criteria for a good brewing yeast: fermentation behavior (bottom or top fermentation), flocculation (powdery or flocculent yeast), fermentation performance (fermentation rate, degree of fermentation), production, and degradation of side products (aroma development, diacetyl removal), as well as intensity of propagation. Generally, yeasts are *Saccharomyces* yeasts and many breweries have their own yeast strains. In speciality beers different yeasts like *Brettanomyces* yeasts may also be used (Bamforth, 2003; Briggs *et al.*, 2004; Back, 2005b; Narziss, 2005). In the brewery, bottom fermenting yeast mostly is cultivated at 8–14°C. Pilsener or lager is general representatives of this genre. Top fermenting yeast mostly is cultivated at 15–26°C. Temperature increases during fermentation

and creates a fruity, estery flavor (e.g. Bavarian wheat beer). Appropriate yeast propagation and fast fermentation are essential for good quality brewing. Yeast has to be at an optimal nutritional state and conditions for metabolism have to be optimized accordingly.

Yeast Nutrition All malt wort is the ideal nutrient solution for yeast. *Carbohydrates* occur as utilizable sugars (fructose, glucose, sucrose, maltose, maltotriose). *Nitrogen* is important for synthesis of proteins and therefore essential for yeast propagation and fermentation. In wort, nitrogen mostly occurs in amino acids, peptides, and proteins. Concentrations of 900–1,200 mg/l total soluble nitrogen are considered to be sufficient. A rate of 20–25% should occur as free amino nitrogen (FAN). Different amino acids are utilized at different rates. This is important when an amino acid (e.g. valine) is slowly taken up but is immediately needed for propagation. The amino acid has to be synthesized by the yeast itself. By-products like alpha-aceto-lactate (diacetyl precursor) are synthesized that may have an impact on beer quality. Yeasts need minerals for enzyme activation (mostly potassium for kinases and dehydrogenates) and propagation (magnesium > 40 mg/l). Magnesium acts as a link between phosphate structures and enzymes (phosphorylation) and is also needed for enzyme activation. Calcium helps propagation and slows down degeneration. Sodium is needed for potassium transport and enzyme synthesis. Trace elements like iron, zinc, manganese, and copper are also involved in cell construction and enzyme reactions. Propagation, fermentation activity, and flocculation decreases, if yeast is depleted in zinc levels. Yeast can be enriched by repeated generations in zinc rich wort because of accrual. Additionally, sufficient manganese content is positive for yeast metabolism. It is considered as a potentially substituting element for zinc. Oxygen is needed for synthesis of sterols (mostly ergosterol) and fatty acids (e.g. palmitic acid, oleic acid), although respiration is considered unimportant for yeast. Most of the oxygen is immediately esterified. So a sterol pool is built up for yeast propagation. Oxygen is also part of porphyrin synthesis, regulation of gene expression, and the development of mitochondria. Aeration with 8–12 mg O_2/l is considered as sufficient for standard gravity worts. Further nutrients that are needed in small amounts and are present in all malt wort are vitamins (mostly biotin, pantothenic acid, nicotinic acid, thiamine for synthesis of coenzymes), purines, pyrimidines, nucleosines, nucleotides (RNA and DNA synthesis), fatty acids (lipid synthesis), sulfur (for cysteine and methionine synthesis), and phosphorus (in phospholipids, for phosphorylation) (Heyse, 2000; Briggs *et al.*, 2004; Back, 2005a; Narziss, 2005).

Yeast Metabolism Alcoholic fermentation is the main metabolic pathway during brewing. Ethanol and CO_2 originate from glucose. The so named "Crabtree-effect" inhibits aerobic metabolism in the presence of oxygen due to glucose repression. Further quality-determining beer contents are

produced during fermentation besides alcohol and CO_2, for example diacetyl, higher alcohols, esters, vinylguaiacol (4-VG), and SO_2. Higher alcohols like 2- or 3-methyl butanol and 2-phenyl ethanol may strongly influence the beer aroma. Mostly alcoholic, floral to solvent-like flavor notes are ascribed to higher alcohols. Esters are the most important aroma component in top fermented beers. They give fruity flavor notes and are divided into two groups: (i) acetate ester that result from acetyl-CoA and alcohol and (ii) fatty acid ester that result from fatty acids and ethanol. Important representatives are ethyl-acetate and isoamyl-acetate. 4-VG is a phenolic substance that mostly characterizes wheat beer. The origin of phenolic substances is regulated via POC (phenolic off-flavor) gene. It occurs in every yeast but is not expressed in bottom fermenting yeast. 4-VG results from ferulic acid. SO_2 is a natural antioxidant that is produced during fermentation. It contributes to flavor stability in beer. Sulfate originated from wort is enzymatically reduced to sulfite. This is used for amino acid synthesis or is released from cells. Reserve carbohydrates (glycogen, trehalose) are created at the beginning of nutrient shortage. They are said to be important for starting the fermentation, especially when repitching yeast (Heyse, 2000; Back, 2005a).

Demands on Yeast for Brewing Yeast for fermentation should be at peak condition. It has to have a high viability and vitality. Viability is the alive–dead rate of yeast cells. Vitality characterizes physiological condition of alive cells. In breweries different strategies are used to ensure optimal yeast condition. Brewers have to decide whether pure culture yeast or (also) repitched yeast is used. Repitched yeast characterizes yeast that has had prior exposure to fermenting wort (sometimes repeatedly). There are also different methods for yeast propagation before starting fermentation. The resulting yeast is always examined for viability and vitality (Heyse, 2000; Briggs *et al.*, 2004; Back, 2005a).

Making Beer

The production of beer includes malting and brewing. It is a value chain in which every step has an impact on the quality properties of the resulting beer.

Malting

Barley is a natural product. Its composition differs depending on variety, growing area, climate, harvesting conditions, preselection, and so on. Barley is rarely directly delivered from fields to maltings. Grain merchants normally act as go-betweens being responsible for pre-cleaning the crop and having samples analyzed in a laboratory.

Demands on Barley by the Maltster At first the maltster conducts a visual assessment of the crop at hand. This requires some experience, but often it is decisive in terms of the acceptance or rejection of a batch besides other analyses. Visual assessment values odor, color, homogeneity, brilliance, and husk quality. Additionally, it gives the counts of half grains, seeds of weeds, and alien elements that reduce the price. Crops with pest infestation, like grain weevil or grain moth, should definitely be rejected. Visual assessment may also discover grain defects that mostly result from adverse weather before cropping. Such a defect is, for example sprouting that occurs after seasons with hot weather during maturation. It accelerates the end of dormancy. Considerable precipitation causes germination of the grain just at the ear of the grain plant. Such grains are often dead and show an increased rate of microbial infection. There are percentage limits for grain defects that justify rejection. Other important criteria are germinative capacity, water content, and protein content. They are determined at delivery to the maltings by rapid tests. Germinative capacity is the percentage of alive to dead grains and should be >95% in rapid tests; >96% after cleaning and sorting in storage. Non-germinating grains retained as raw during malting may become infected by mildew and bacteria. Higher molecular β-glucan is dissolved from such grains during mashing. This can cause lautering and filtration problems downstream. Additionally, there may be a shortage of FAN. This may cause an insufficient fermentation and concomitant reduction in beer quality. Further non-germinating grains show a lower saccharification. So, only low final attenuations may be recorded. Water content should be no more than 13%. The higher the water content, the higher the respiration losses. Mildew infection may be the result. Grains with higher water content have to be dried. Protein content should be between 9.5% and 10% (water-free), so that beer can be brewed that shows resilience to long distance delivery or has better colloidal stability. Lower protein contents result in reduced foam stability, body, or flavor stability. Additionally, yeast nutrition may be reduced in assimilable nitrogen that may cause unfavorable fermentation by-products. Protein content varies between 10% and 11% (in the case of very bright beers of the Pilsener type). Protein contents between 11% and 11.5% are sufficient for conventional beers. Protein contents in the range of 11–12% are suitable for dark malt brews containing Münchner malt and darker due to its color and flavor. Barley that has a higher protein content may be the cause of colloidal instability in beer. These require an intensive, heavily malting with increased losses. Another criterion is the purity of the grade of barley. This is determined after cleaning and sorting. Grains should have diameters >2.2 mm, better >2.5 mm (full barley) at a rate of >90%. Malting with grains of different sizes results in heterogeneous malt because small grains have increased protein contents and germinate faster compared to larger ones. In a brewery, heterogeneous malt causes problems during processing and reduces beer quality (Briggs, 1998; Narziss, 1999; Heyse, 2000; Back, 2005a).

Figure 1.3 Malting process schematically. *Source*: Modified from Gesellschaft für Öffentlichkeitsarbeit, Deutscher Brauerbund.

Storage The crop is stored in aerated and cooled silos. Barley needs a time frame between 4 and 8 weeks after storage until it can be reprocessed. Grain is protected against early germination at the stem during this dormancy. Maturity of germination is determined via germinative energy prior to further processing. It is the percentage rate of grains that would germinate at the time of examination and should be >96% (Narziss, 1998; Heyse, 2000; Back, 2005a).

Malting Process Malting is the artificially induced germination of a crop. The maltster's aim is controlled dissolution of grain. Enough enzymes have to be activated and produced, so grain contents are homogeneously dissolved. Kilning follows steeping and germination to fix substantial translations and to create typical malt character (Figure 1.3).

Steeping and Germination Barley needs sufficient oxygen, heat, and humidity for germination. Water input induces changes in grain. Water content in grain of between 42% and 48% has to occur for the desired substantial translations within a defined time frame. Germination temperatures range between 14°C and 18°C. Oxygen is essential for respiration, otherwise the embryo dies. CO_2 has to be removed. At first, development of the embryo is visible at the root germ and acrospire (Figure 1.2). The main root breaks through the grain and emerges between husks (chit). Further side roots emerge (fork). Acrospire grows between pericarp, testa, and back husk. Reserving substances are degraded by enzymes and transferred into soluble forms in endosperm. Other substances are produced for energy supply and tissue. Solution processes increase, thus the grain

becomes more and more brittle. Steeping and germination may differ depending on technical equipment, crop variety, and annual set. Six days are considered to be optimum for steeping and germination.

Biochemical Processes During Malting Following and regulating degradation of the three main groups of substances are the most important criteria during the malting and brewing process. These groups are starch (amylolysis), proteins (proteolysis), and structural substances (cytolysis). Further degradation processes are lipid and phosphate degradation.

Substances in starch granules coatings are degraded during *cytolysis*. This is the prerequisite for facilitating digestion of starch granules by enzymes during mashing. Insufficient cytolysis results in yield losses and release of higher molecular β-glucan. Proteins are transformed into soluble low, medium, and high molecular substances during *proteolysis*. Insufficient degradation results in shortage of assimilable nitrogen for yeast. Consequences may be problems during fermentation and maturation like production of unfavorable side products (mostly diacetyl). High molecular protein is missed at excessive proteolysis that reduces foam and flavor stability. Starch is digested by amylolytic enzymes during *amylolysis*. α- and β-Amylases are the most important representatives.

Enzymes that are important for malting and mashing are displayed in Table 1.1. Different enzymes are subdivided into endo- and exo-peptidases. Hydrolytic enzymes like α-amylase, limit dextrinase, and endo-peptidase are produced during germination (*de novo*). This enzyme induction is provided by gibberellins acid and gibberellins A1.

Table 1.1 Occurrence of important enzymes during malting and mashing

	Enzyme	Substrate	Product	Malting					Mashing	
				Barley	Green malt	Cured malt	Optimum temperature (°C)	Optimum pH	Optimum temperature (°C)	Optimum pH
Zytolysis	β-Glucan-solubilase	Matrix bound β-glucan	Soluble high molecular β-glucan	++	+++	++	62	4.6–7.0	62–65	6.8
	Endo-1,3-β-glucanase	Soluble high molecular β-glucan	Low molecular β-glucan, cellobiose, lamiaribiose	0	+++++	++++	60	4.6–5.5	<60	4.6
	Endo-1,4-β-glucanase	Soluble high molecular β-glucan	Low molecular β-glucan, cellobiose, lamiaribiose	+	++++	+++	40–45	4.5–4.8	40–45	4.5–4.8
	Exo-β-glucanase	Cellobiose, lamiaribiose	Glucose	+	++++	−	<40	4.5	<40	4.5
Proteolysis	Endo peptidase	Proteins	Peptides, free amino acids	+(+)	+++++	++++	40–55	5.0–5.2	45–50	3.9–5.5
	Carboxy peptidase	Proteins, peptides	Free amino acids	+	++++	+++	50–60	5.2	50	4.8–5.6
	Amino peptidase	Proteins, peptides	Free amino acids	++	+++	++	40–45	7.2	45	7.0–7.2
	Dipeptidase	Dipeptides	Free amino acids	+(+)	+++	+++	40–50	7.7–8.2	45	8.8
Amylolysis	α-Amylase	High and low molecular α-glucan	Melagosaccharids, oligosaccharids	0	++++	+++	70–75	5.6–5.8	65–75	5.6–5.8
	β-Amylase	α-Glucan	Maltose	+(+)	++++	++	60–65	5.4–5.6	60–65	5.4–5.6
	Maltase	Maltose	Glucose	+(+)	+++	++	34–40	6.0	35–40	6.0
	Limit dextrinase	Limit dextrine	Dextrine	(+)	+++	++	55–60	5.5	55–60	5.1
Further relevant enzymes	Lipase	Lipids, lipid hydro peroxides	Glycerine + free long chain fatty acids, fatty acid hydro peroxides	0	+++	+	15–18		55–60	6.8–7.0
	Lipoxygenase	Free long chain fatty acids	Fatty acid hydro peroxides	(+)	++++	−	12–15		45–55	6.5–7.0
	Polyphenoloxidase	Polyphenols	Oxidized polyphenols	++	+++	++	15		60–65	6.5–7.0
	Peroxidase	Organic + inorganic substrates	Free radicals	(+)	++	+	15		>60	6.2
	Phosphatase	Organically bound phosphate	Inorganic phosphate	+(+)	++++	++	15	5.6–6.1	50–53	5.0

These growth promoters (hormones) are led from embryo via shield to aleuronic epithelium. There and in shield enzymes are released. Endo-peptidase stimulates release of endo-β-glucanase and endo-xylanase. Other enzymes like acidic phosphatase are not released from aleurone but activated by water intake. Enzyme capacity and thus speed of dissolution processes is increased by addition of, for example, gibberellin acid, although this is not permitted in Germany under the *Reinheitsgebot*.

Kilning Malt   Kilning removes water, fixes substantial translations, and creates typical malt colors and aromas. Green malt loses its raw grain character. Kilning is subdivided into withering and curing. Water content of from 45% to 10% is reduced at low temperatures during withering. Curing needs temperatures in a range between 80°C and 105°C. Duration and intensity of withering and curing depends on strived malt. Drying continues until water content reaches 3.5–4% in pale malts and 1.5–2% in dark malts. An amount of 100 kg barley results in about 160 kg green malt and about 80 kg cured malt after drying. The volume of green malt should be conserved. Essential chemical transformations take place during kilning. Growing is ongoing at temperatures below 40°C and water content above 20% (growing phase). Enzymes cause dissolution of the grain and the amount of degradation products increases. Further enzymatic degradation occurs at temperatures between 40°C and 70°C (enzymatic phase). Degradation processes stop with decreasing water content. The embryo's growth is discontinued and degradation products accumulate. Losses of enzymes increase with increasing humidity and temperature of malt. Coagulation and reduced dispersion of colloidal nitrogen substances occurs at temperatures >70°C (chemical phase). Properties of β-glucan change by production of low molecular substances at low viscosity. Intensive Maillard reaction takes place at temperatures >95°C. Color and aroma components arise from low molecular substances (sugars and amino acids). Dimethyl sulfite (DMS) is an important quality criterion in malt. It is a sulfur-containing, odor- and taste-intensive substance. The higher the curing temperature, the lower the contents of DMS precursors (DMS-P). Thus, dark malt has lower contents of DMS-P. Reduction of DMS-P in pale malts results from low temperatures for a longer time thus increased coloring is inhibited. Homogeneous inferior malt may be brewed to a pleasing beer by an adapted brewing process. In contrast, mixtures of high- and low-quality malt are insufficient. Radicles are removed after kilning because it rapidly adsorbs water again. Additionally, it causes bitter taste and increased coloring. Afterwards the malt is stored. Further physical and chemical changes during storage facilitate the reprocessing of malt (Briggs, 1998; Kunze, 1999; Narziss, 1999; Back, 2005a).

Different Malts   Production of pale malt significantly differs from production of dark malt. Barley for dark malt needs higher protein content and more intensive handling (high degree of steeping, higher germination temperatures) for grain dissolution and enrichment of precursors for coloring and aroma. The moisture of green malt is slowly reduced during withering of dark malt. Thus, dissolution is ongoing and enough educts arise for Maillard reaction. High curing temperatures (>95°C) result in a typical dark malt aroma. Inverse processes are used for pale malt. Water in green malt is rapidly reduced by fresh air. Curing temperatures range between 76°C and 80°C for pale color and conserving enzymes.

There are many special malts and kilned raw grain that are similarly produced. All of them have a special impact on beer character:

- Pale or dark wheat malt is used for wheat beer at grist ratios >50%. Flavor precursors get into wort and result in typical wheat beer aroma by top fermentation.
- Caramel malt awards beer a mouthfilling, malty character, and dark color. They are used in grist ratios between 2% and 10%.
- Roasted malt is added in grist ratios between 0.5% and 5%. It gives dark color and roasting flavor.
- Roasted barley, roasted rye, and others originate from unmalted, but roasted crops. Resulting beers have a roasting, raw grain-like character. They are mostly used for stout and ale (Briggs, 1998; Narziss, 1999; Heyse, 2000).

Brewing process

There are four main steps during the brewing process: (i) wort preparation that includes mashing and boiling, (ii) fermentation, (iii) maturation, and (iv) filtration and/or stabilization (Figure 1.4).

Milling   Prior to mashing malt has to be milled. Therefore, dust, stones, and metals are removed from malt to avoid damage at the milling cylinder or dust explosion. Generally malt mixtures are used for one brew. Milling increases reactive surfaces for enzymes, thus malt ingredients are easier to dissolve. Husk should be saved because it serves as filtration layer during lautering. In some breweries, mash filter is used as an alternative to the lauter tun in which no husk or coarse pieces are necessary. Malt can be fine milled in a hammer mill. The quality of milling has an impact on mashing and lautering and thus on quality of the resulting beer. For example, undissolved malt should be milled finer than well-dissolved malt because physical and enzymatic degradation processes are eased then (Narziss, 1992; Kunze, 1999; Briggs *et al.*, 2004).

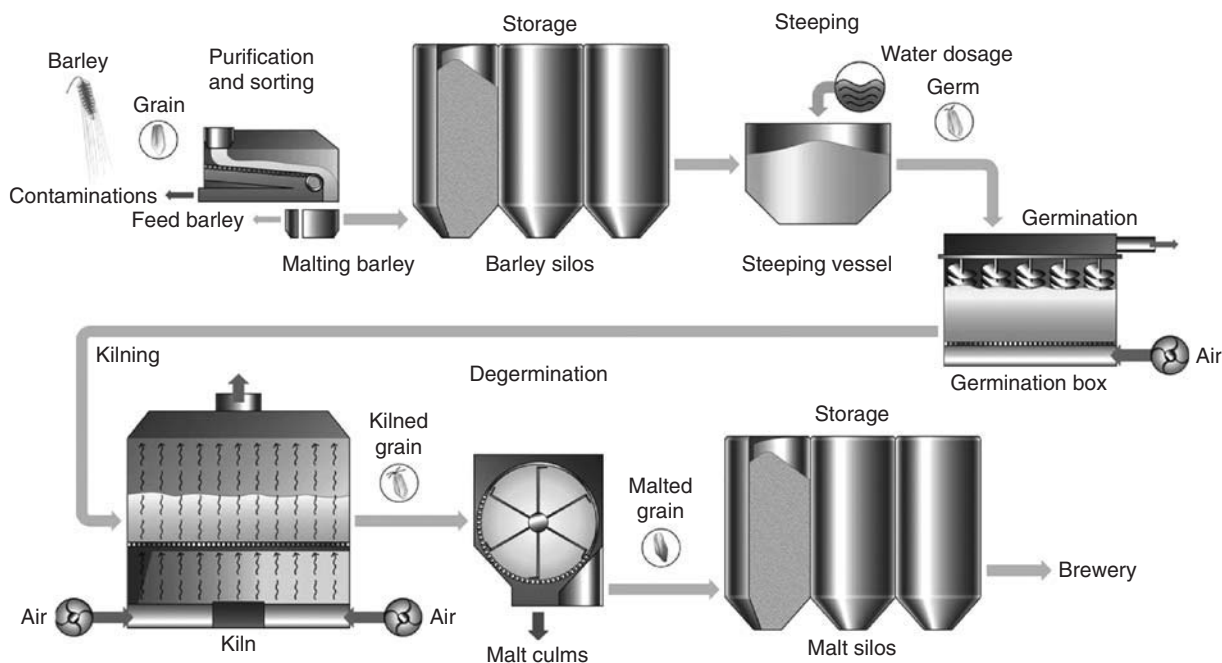
Mashing   Grist is mixed with water during mashing. Enzymes dissolute malt substances. Processes are regulated by temperature and its residence time (rest), pH-value, and water grist ratio (affusion). Generally, the same enzymatic processes take place as during malting; amylolysis, proteolysis, and cytolysis (section "Biochemical processes during malting" in Chapter 3).


Figure 1.4 Brewing process schematically. *Source*: Modified from Gesellschaft für Öffentlichkeitsarbeit, Deutscher Brauerbund.

Amylolysis Starch occurs as amylose and amylopectin. Their dissolution proceeds in three steps: (1) gelatinizing starch, (2) liquefaction, and (3) saccharification. Starch molecules adsorb water during gelatinizing. They first swell and later explode. Gelatinizing temperature depends on the type of corn and occurrence of amylases. Starch originated from malt gelatinizes at 60°C with the presence of amylases. Other starch suppliers like rice, corn, rye, sorghum, etc., have different optimum temperatures for gelatinization. Availability, economy, and special color or flavor contribution increase interest in so-called adjuncts. Often they are used in raw, unmalted form. Special technologies like cereal cookers or addition of enzymes may be necessary for conversion to sugar. Pre-gelatinized products are used, too. Countries have fixed different maximum amounts of adjuncts for beer production. In United States, for example 34% of grist load may be unmalted cereals. In Germany use of adjuncts is prohibited. Gelatinized starch is mostly digested by amylases during liquefaction. α-Amylase splits α-1,4 bonds of amylose and amylopectin. Starch cracks from the inside and larger fragments result. Viscosity decreases at the same time and new reactive surfaces are created for β-amylase. Dextrins are broken down to maltose during saccharification.

Brewers control starch breakdown by 0.2 N iodine tincture. This iodine test is based on the coloring effect of iodine solution. Starch and larger dextrins result in blue to red color. Sugar and small dextrins show no color. In this case, mash is "iodine normal."

Proteolysis In contrast to low-ordered starch molecules, proteins occur in mash as a mix of different sized molecular groups. There are high molecular substances as well as amino acids. Enzymes for proteolysis are divided in endo- and exo-peptidases and are characterized by different effective optima. Endo-peptidases break down proteins from the inner and increase soluble nitrogen content. Exo-enzymes attack ends of protein chains and set free amino acids. Some proteins precipitate already during mashing as a result of temperature and pH-value. Dissolution processes of proteins are accelerated during mashing compared to malting (10 to 14 to fold). The greatest protein degradation occurs at 50°C but special protein rest is not necessary if well-dissolved malts are used. Medium and high molecular breakdown products arise at 60–70°C and are important for fullness of flavor and foam. These quality criteria as well as carbonation decrease if protein degradation is extended too far. Additionally, risk increases for turbidity in beer. Insufficient protein degradation results in shortage of assimilable nitrogen. Fermentation is heavy and unwished-for side products arise. Proteases may be set free that decrease foam stability.

Cytolysis Breakdown products of hemicelluloses dissolute and increase viscosity during cytolysis. Main breakdown occurs at temperatures below 50°C. Breakdown decreases rapidly with increasing temperature. β-Glucan degradation stops at temperatures in a range between 60°C and 70°C but it is set free by β-glucan-solubiase. Hydrogen bonds of higher

ordered β-glucan molecules break during heating and boiling. Hydrogen bonds conjugate to gels if increased shearing forces occur and viscosity of mash increases. Increased viscosity may result in problems at lautern and filtration. Use of well-dissolved malt and minimizing shearing forces avoids these problems. Mostly lipids are insoluble and are removed via spent grist. Lipases split a small part into glycerine and fatty acids. Especially, non-saturated fatty acids result from reactions with oxygen or enzymatic breakdown into carbonyls by lipoxygenase. They decrease flavor stability already at low concentrations. Milling under inert gas and oxygen-deficient handling avoids these processes. Processes are additionally minimized by mashing at temperatures above 60°C and mash pH-value below 5.2. *Polyphenol* dissolution from husks and endosperm increases with increasing mashing duration and temperature. Peroxidases and polyphenoloxidases digest them enzymatically. Oxidation by oxygen occurs, too. Polymerization of polyphenols decreases the antioxidative potential of beer. This includes reduction of flavor stability. The use of high mashing temperatures and intensively kilned malts reduces peroxidase contents in mash and polyphenols originated from malts are saved. *Organic phosphates* are broken down enzymatically by phosphatases. Products are phosphate and primary phosphates. They decrease pH-value and increase buffering capacity. Lowest pH-values and lowest buffering capacity result at mashing temperatures in a range of 62–65°C. These conditions also promote welcome pH-fall during fermentation. *Zinc* content of wort is also fixed during mashing. It is one product from alcohol dehydrogenase. Low mash pH-values, low mashing temperatures (45–50°C), as well as reduced mash liquor favor zinc release. Zinc concentrations in a range between 0.1 and 0.15 mg/l are recommended.

Generally, most mashing processes go on better at low pH-values. So some brewers do "biological mash acidification." This procedure includes fermentation of first wort with malt borne *Lactobacillus amylovorus* or *L. amylolyticus*. Result is a 2% lactic acid which may be added to mash for decreasing pH-value. International brewers add substances including glucoamylase to mash to increase conversion of starch to fermentable sugar. It is heat-resistant, cops off glucose (like maltase), and has also an exo-action (like β-amylase).

Mash is prepared in special mashing containers (mash tun). Addition of much water (3–4 hl/kg malt) accelerates enzymatic reactions. Such "thin mash" is used for pale brews. Dark brews get by with 3–3.5 hl/kg malt. Generally, there are two types of mashing:

1. Infusion mashing indicates only enzymatic digestion at different temperatures and durations (rests).
2. Decoction mashing includes additionally thermal degradation. Part of the mash is removed, boiled, and returned. This procedure is recommended for use of unmalted cereals.

Well-dissolved malt should be mash in at higher temperatures as mentioned earlier. This results in technological and economic advantages. An adequate mashing procedure is

the "high-short-mashing-procedure." It includes mash in at 60–63°C. This temperature is kept for 30–45 min. Then mash is heated at 1°C/min to 72°C. Rest at this temperature is retained until iodine normality is reached (Narziss, 1992; Bamforth, 2003; Briggs *et al.*, 2004; Back, 2005a).

Lautering   The aim of lautern is separation of liquids (wort) and solids (spent grist). Husks act as a filter during this procedure. At first, liquid drains off (first wort, extract content: 16–20%). Then, residual spent grist is flushed several times with hot water (last runnings, last extract concentration: 0.5–1%). First wort and last runnings represent wort. The volume of last runnings depends on aimed extract concentration. Temperature is important during lautern, because increasing temperature decreases viscosity and lautern is accelerated. However, temperatures above 80°C are unfavorable. Then, α-amylase is destroyed and undissolved starch cannot be saccharified. Wort will not be iodine normal and starch haze will result in beer.

Generally, lautern is processed in a lauter tun or mash filter. Mash has to rest after transfer into the lauter tun to build a grain bed. First wort run off contains a lot of particles, so it is removed into the lauter tun. Then, first wort runs off and water is added continuously or stepwise for last runnings. Polypropylene filter sheets separate wort and spent grist in a mash filter. This procedure is independent of particle size. Extract content in spent grist fixes the end of lautern. Final extract content in spent grist has to be below 0.8% (Narziss, 1992; Kunze, 1999; Birgss *et al.*, 2004).

Wort Boiling   After lautern, wort is transferred to a boiling device (kettle). International brewers may add liquid sugar adjuncts like invert, dextrose, corn syrup, etc., in country specific maximum amounts (e.g. United States 2.5%). Aims of wort boiling are:

- water evaporation, adjustment of extract content in cast wort (original gravity),
- evaporation of unwanted flavor substances like DMS,
- formation of color and flavor substances,
- isomerization of hop bitter substances,
- precipitation of coagulated proteins (flocculation),
- wort sterilization,
- enzyme inactivation.

Here, three points are discussed in more detail.

1. Evaporation of *DMS* that gives a cabbage and vegetable-like flavor. Its concentration in all malt beer should be below the taste threshold of 100 μg/l. Transformation of DMS-P into DMS and evaporation of DMS increase with continued wort boiling.
2. Formation of *color and flavor substances*. Wanted melanoidins arise during boiling, which have antioxidative effects. But unwanted Strecker aldehydes are built up too, and these are precursors for stale flavor. The thermal stress

is characterized by thiobarbitur acid value that should be as low as possible.

3. *Flocculation.* Too much protein in beer results in turbidity. Too little protein is bad for foam and full taste. Concentration of coagulated nitrogen is an indicator that should be in a range of 15 and 25 mg/l. These three parameters have to be optimized for each system.

Hop is added during wort boiling. Brewers do this at the beginning or end of boiling or dose hop into the whirlpool. Hop dosage at the beginning of wort boiling serves for bittering and is generally carried out with bitter hop. A second dosage at the end of boiling or into the whirlpool gives a favorable hop dose. Few brewers add hop cones after fermentation (filling hop). Isomerized hop products may be added after fermentation or before filtration by brewers operating outside the German *Reinheitsgebot*.

Natural lactate acid may be added to wort (analogous to biological mash acidification). This is carried out at the end of wort boiling because isomerization and DMS degradation are decreased at low pH-values. Biological wort acidification facilitates protein precipitation and accelerates pH-fall during fermentation. Substances in lactate acid like zinc and vitamins stimulate yeast vitality. Generally, resulting beers are of increased quality. Taste is rounded off, full, and soft. Carbonation is fresh and sparkling. Brews show a high chemical–physical stability as well as high foam and flavor stability.

Commonly, original gravity is in a range between 11% and 12% at the end of boiling. Output of boiling is increased by so-called high gravity brewing. There, original gravity is up to 16%. Adjustment of alcohol content and residual extract takes place subsequently and mostly before filtration by addition of degassed water. It is an internationally applied procedure used mostly in larger breweries.

Formation of technical elements depends on brewers' demands:

- Use as wort tun only – or additionally as mash container, whirlpool, etc.
- Type of heating – base heating, internal or external boiling, etc.
- Hop and sour property dosage – often an additional container is necessary.
- Boiling under atmospheric pressure – above or below.

Stepwise boiling below atmospheric pressure facilitates evaporation of unwanted substances at reduced energy input. Boiling above atmospheric pressure can proceed continuously and accelerates chemical and physical processes.

Hot trub (hop particles and precipitated proteins) has to be removed after boiling. It can aggravate yeast metabolism, clarification of green beer, and filtration. Mostly a whirlpool separates hot trub. Hot trub settles down in the middle by resulting rotation (tea cup effect). The wort has to be cooled down as fast as possible to minimize infection

risk. The temperatures aimed at are 5–10°C for bottom fermentation and 15–25°C for top fermentation. Nowadays, heat is exchanged with the temperature of icy water in a stainless steel plate cooler. Proteins precipitate in wort again at temperatures below 60°C. Particles of this "*cold trub*" (0.5–1 μm) are smaller than those of hot trub (0.5–500 μm). It is removed by separation, filtration, or flotation (aeration of wort). Recent studies show that cold trub is advantageous for fermentation in less recycled yeast.

Aeration of wort is necessary for yeast propagation. Oxygen concentration should be 8–9 mg/l. It has to be added excessively because not all oxygen dissolves in wort (Narziss, 1992; Heyse, 2000; Bamforth, 2003; Briggs *et al.*, 2004; Back, 2005a).

Fermentation, Maturation, and Storage Cooled and aerated wort has to be mixed rapidly with yeast (pitching) for reduced bacteria development. A common yeast dosage is 15–20,000,000 cells/ml at good yeast vitality. Dosages in amounts of 30,000,000 cells/ml are recommended for strong ales or high gravity brews. Yeast is aerated continuously after pitching, which additionally secures homogeneous distribution. The fermentation tank may be open or closed. Larger breweries mostly prefer closed tanks. There brewers may regulate fermentation by pressure and CO_2. *Fermentation temperature* is the decisive factor for fermentation: the higher the temperature, the faster the processes, and the higher the side product concentrations. Applied pressure reduces yeast propagation and decreases formation of side products. Movement in the fermentation tank can also be controlled by temperature. Adapted convection secures good contact between wort and yeast and allows sedimentation for clarifying green beer at the end of fermentation. *Final attenuation* fixes the end of fermentation. It describes the amount of fermentable sugars in wort. No fermentable sugars (*residual extract*) should be left in final beer. This would increase infection risk and decrease digestibility. Generally, green beer has residual extract in a range of 6–10%. This secures sufficient formation of CO_2 during maturation. It may be significantly lower if one tank processes or "krausening" are applied. A further important process is development of pH-value. It should decrease from 5.6 to 4.5 during fermentation (pH-fall). Sour milieu inhibits infections in final beer. *Maturation* serves fermentation of the residual extract. Volatile substances like aldehydes and sulfur compounds are removed by CO_2 bubbles (CO_2-wash). Degradation of alpha-aceto-lactate and especially diacetyl takes place. Sedimentation of yeast clarifies the brew. Degradation of diacetyl as far as possible fixes the end of maturation. *Storage* at low temperatures (0°C and lower, beer freezes at approximately −2°C) serves for further clarification and stabilization of beer. It binds CO_2 and rounds off-flavor. Residual, settled yeast should be removed if not wished otherwise. Dead cells release substances during decomposition that influence flavor and stability of beer. Sometimes international brewers use wooden spans for homogeneous distribution and flotation of yeast during

fermentation. Extra zinc addition to yeast equalizes potential shortage. Addition of enzymes during maturation and storage serves filtration and colloidal stability of beer in countries other than Germany. In traditional ale production, finings, such as isinglass (the swim bladder of fish) or Irish moss (a seaweed), are placed in the cask to drag down the yeast and clear the beer (Heyse, 2000; Bamforth, 2003; Briggs *et al.*, 2004; Back, 2005a; Narziss, 2005).

Filtration and Stabilization   Consumers expect not only immaculate taste but also a clear or sparkling beverage. Often storage alone does not suffice. Artificial *clarification* takes place by filtration or centrifugation. One, or a combination, of three different processes serves artificial clarification:

1. Coarse, dispersed particles settle down by *sedimentation* or centrifugal force during centrifugation. Colloids remain in beer.
2. *Sieving effect* retains all particles bigger than pore size of filter. Trub particles and larger colloids as well as beer spoiling bacteria remain depending on pore size.
3. Particles and also dissolved substances can be removed by *adsorption*. It is based on affinity of substances to filter material.

Grade of filtration and intensity of stabilization depend on demands of shelf life. *Kieselguhr* filtration alone may be sufficient for a shelf life of 2 months. *Stabilization* via PVPP (polyvinylpolypyrrolidon) and/or silica gel is recommended for a shelf life of 6 months and more. Outside Germany, proteins may be hydrolyzed by papain (enzyme from paw paw).

Yeast, bacteria, and colloids are almost completely removed from beer depending on the selected filtration plate. Filtration plates consist of cellulose fibers from different types of wood, *kieselguhr*, perlite, synthetic fibers, and resins that increase stability of filters. Large surfaces serve optimum adsorption of trub substances. PVPP removes polyphenols, silica gel removes proteins. The last one is applied before filtration. PVPP is added between *kieselguhr* and plate filtration. Recently, membrane filtrations have been developed because *kieselguhr* resources will run short and disposal costs will increase. Membranes consist of polyester, nylon, etc. Filtration is based on sieving effect at membrane surfaces and may be used for sterile filtration, if sufficient pore sizes are chosen (Bamforth, 2003; Briggs *et al.*, 2004; Narziss, 2005).

Filling   The aim of filling is to conserve beer quality and to give an attractive appearance for consumers. It is the most expensive process in the brewery (costs and labor). Basics that have to be considered during filling are:

- *Filling under pressure*. CO_2 containing beverages release CO_2 if partial pressure of dissolved CO_2 is fallen below.
- *Avoiding air contact*. Low oxygen concentrations in beer (0.01 mg O_2/l) result in decreased flavor and colloidal stability of beer.

- *Axhaustive cleaning*. Cleaning and disinfection inhibit contamination by beer spoiling organisms (Kunze, 1999; Heyse, 2000; Back, 2005a; Narziss, 2005).

Quality Criteria of Beer

Microbial stability

Microbial stability describes the susceptibility of beer to contamination by micro-organisms. Beer has several selective properties:

- anaerobic conditions (CO_2 containing beverage),
- low pH-value (approximately 4.5),
- alcohol content (approximately 5% per volume),
- hop bitter substances and hop oils,
- shortage of easily digestible sugars and amino acids,
- low temperatures during manufacturing process.

Weakening of these properties by, for example, lack of alcohol or decreased tidiness may cause adverse effects. Beer spoiling organisms decrease aroma and taste quality and cause haze and precipitations after a certain adaptation phase. *Saccharomyces diastaticus*, for example, is an "over fermentating" yeast that digests dextrins, too. The resulting beer tastes blank, strangely bitter, and tends to foam over. Contamination by bacteria like *Megasphera cerevisia* causes a sewer-like smell. An increased butterscotch aroma indicates high diacetyl levels that may be due to an infection by *Pediococcus* or *Lactobacillus* bacteria. It is important to note that basically no pathogenic germs grow in beer. Beer can be treated thermally to increase microbial stability. Commonly, a short period of heating before filling or a subsequent pasteurization is applied (Back, 2005a; Back, 2005b; Narziss, 2005).

Flavor stability

The taste and aroma of beer are not stable. An aged impression arises from the loss of positive flavoring substances and development of an aged flavor. The main reason is contamination with oxygen, which is unavoidable in spite of the latest filling systems. International brewers may add sulfites or ascorbic acid to reduce oxygen impact besides oxygen-poor operation. Beer flavor changes within few days after filling and lasts for several years. Aging starts with a "ribes flavor" that turns into a "cardboard flavor." Flavor impression further changes from a bread-like taste to caramel, a honey-like flavor, and finally to a sherry-, or whiskey-like character (Briggs *et al.*, 2004; Back, 2005a; Narziss, 2005).

Colloidal stability

Colloidal stability (turbidity) describes precipitation of protein-tanning agent compounds after filling and aging of

beer. Instability depends on oxygen content, temperature (heat), movement, light, and presence of metal ions in beer. There are several methods to increase colloidal stability by removal of proteins or tanning agents (polyphenols, see section "Filtration and stabilization"). Biological acidification, oxygen-poor operation, etc. affects colloidal stability (Heyse, 2000; Briggs *et al.*, 2004; Back, 2005a; Narziss, 2005).

Foam stability

Often consumers expect stable foam on their beer. Foam is the result of the complex collaboration between technology and gastronomy. Selection of malt, mashing above protein rest, reduced boiling intensity, or yeast management influences foam development and stability. International brewers additionally may add adjuncts based on alginates to increase foam stability. Attention in gastronomy should especially be stressed on the tidiness of glasses. Fatty residues (e.g. lipstick) or residues of cleaning and disinfectant solutions decrease foam stability. Lastly, the kind of drawing is decisive for optimum presentation. A white, airy head results from CO_2 that also occurs in the drawing device. Manual pumping is applied on brews with less CO_2 that should not develop a distinct head. Drawing with nitrogen gas imparts a tight, creamy head, and a creamy texture (Briggs *et al.*, 2004; Back, 2005a; Narziss, 2005).

Non-alcoholic beer and other brewing technologies

Worldwide interest in non-alcoholic beer is increasing. Athletes appreciate beer's typical properties, reduced calories, and the isotonic properties of most non-alcoholic beers. Legally fixed maximum alcohol contents differ in countries. Arabic countries demand contents below 0.05% per volume. Germany allows contents below 0.5% per volume. Two procedures especially have been established for manufacturing non-alcoholic beer. On the one hand, thermal removal of alcohol is applied subsequently to brewing conventional beer. On the other hand, "cold contact procedure" involves contact of yeast with wort at 0°C or stopping fermentation before the alcohol limit is reached. Brews, according to the second procedure, differ in composition and sensorial properties because no complete fermentation took place. Beers produced by stopped fermentation may have a sweet wort character. Others often show a blank, untypical sour character. A combination of both procedures increases flavor quality.

It is possible to emphasize certain properties of beer by variations of brewing technology. As brewing technologists, we see a chance to improve the image of beer because health awareness increases continuously. Recently, special technologies were developed, for example, for enrichment of folic acid or xanthohumol in beer. Innovations like this, in addition to publicizing the healthy effects of beer ingredients, may strengthen consumer interest in a tasty and healthy beer (Back, 2005a; Narziss, 2005).

Summary Points

- Manufacturing beer is a complex mixture of technical and (bio-)technological processes.
- Main ingredients of most beers are:
  – water
  – barley
  – hops
  – yeast.
- Commonly, barley and other starch suppliers have to be malted to facilitate starch dissolution. This takes place during:
  – steeping (wetting grains, activation of enzymes)
  – germination
  – kilning (drying grains).
- Brewing itself is subdivided into:
  – mashing (activation of enzymes, dissolution of starch, conversion to sugars) and lautering (removal of solids)
  – boiling (thermal and enzymatic processes, addition of hops)
  – fermentation (conversion of sugars to alcohol), maturation (degradation of undesirable side products), and storage (development and fixation of CO_2)
  – filtration and stabilization (removal of residual yeast, causes of haze, and further unwanted substances for shelf-life).
- Every production step influences the resulting beer.
- Every beer variety has to fulfill quality criteria of:
  – microbial stability (no infections)
  – flavor stability (conservation of the original taste and aroma as long as possible)
  – colloidal stability (no haze)
  – foam stability.

2
Non-lager Beer

Andrea Pavsler and Stefano Buiatti Department of Food Science, University of Udine, Udine, Italy

Abstract

Many thousands of different beer brands are produced worldwide and most of them can be classified into defined beer styles which have developed over the course of time in different countries or regions. Depending on the process used, a first classification can be made according to the fermentation process in top and bottom fermentation beers. Top fermented beers represent only a small percentage of the total beer consumption. Top fermented beers are very common in Britain, Germany, Canada's eastern provinces, United States and, last but not least, Belgium. However, lager (the term generally used for bottom fermented beer) is the dominant style in almost all countries and represents more than 90% of the beer produced worldwide. Until the sixteenth century, ale (the term generally used for top fermentation beers) was the main type of beer in Europe. Traditionally, ales are fermented with the use of top-cropping yeasts which rise to the top of the beer in the head of foam at temperatures between 16°C and 24°C. At these temperatures, the yeast produces significant amounts of esters and other secondary flavor and aromatic products, and the result is often a beer with slightly "fruity" compounds. Typical ales have a sweeter, fuller body than lagers.

Introduction

The birthplace of beer is generally known to be the Middle East and Egypt. The first detailed mention of beer was made more than 5,000 years ago by the Sumerians. By the medieval period, the practice of brewing had spread into Europe, bringing a competitor for wine. Until the sixteenth century, ales (the generic name for beers produced by top fermentation) were the main type of beer in Europe. Historically, in the Middle Ages, the words *Ale* and *Beer* had two different meanings, ale describing a non-hopped malt beverage (also called *spiced ale*) as opposed to hopped beer, introduced to Britain by Flanders workers possibly not very keen about the sweet taste of English beers. In fact, in the sixteenth century (when hops had been used for many centuries in Germany), during the reign of Henry the VIII, hops were still considered a "*… wicked and pernicious weed*" (Bamforth, 2003). Nowadays top fermented beers represent only a small percentage of the total beer consumption. Nevertheless, ales are very common in Britain, Germany, Canada's eastern provinces, United States and Belgium. However, lager beer is the dominant type of beer in almost all countries and represents more than 90% of beer produced worldwide.

Top fermented beer is typically fermented at temperatures between 16°C and 24°C. At these temperatures, yeast produces significant amounts of esters and other secondary flavor and aroma products, and the result is often a beer with slightly "fruity" compounds resembling but not limited to apple, pear, pineapple, banana, plum or prune. Typical ales have a sweeter, fuller body than lagers.

Top Fermented Beer Production

- **Malting is the controlled germination of cereals, followed by a termination of this natural process by the application of heat.**

Malt is a cereal grain, usually barley, that has been germinated for limited period of time, and finally dried. During germination, the endosperm is degraded by enzymes that attack the cell walls, starch granules and the protein matrix. Usually, the malt used to produce ales is more and better modified than malt for lagers.

During kilning when the temperature is increased, destruction of malt enzymes is accelerated, and color and flavor are developed; consequently there are several malt types that can be used to provide appropriate substrates and enzymes to yield a soluble extract or simply as wort coloring agents (specialty malt) (Hough, 1985; Freeman, 1999).

- **Milling and mashing are the most critical operations in the brewing process.**

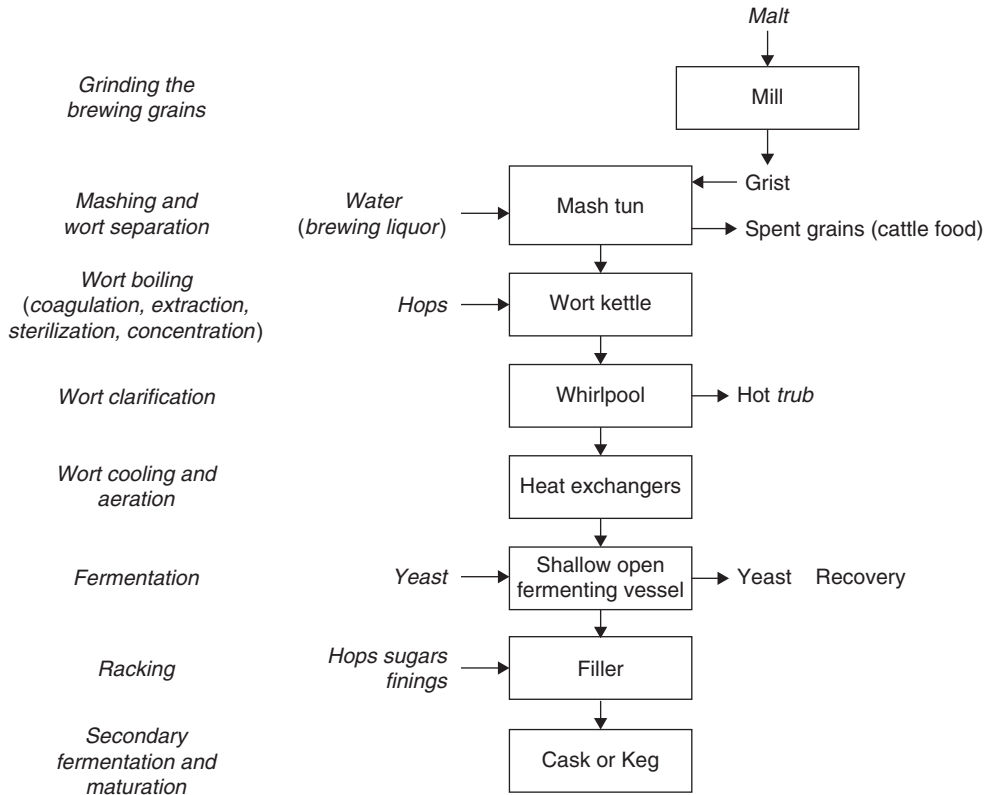
Milling increases the surface area of the malt and makes the starch more accessible to enzymic attack. An important objective is to keep the malt husk as intact as possible, to have an open filter bed that helps wort separation (Briggs *et al.*, 2004). Mashing is the most critical operation in the brewhouse because it directly determines both


Figure 2.1   The traditional ale brewing process.
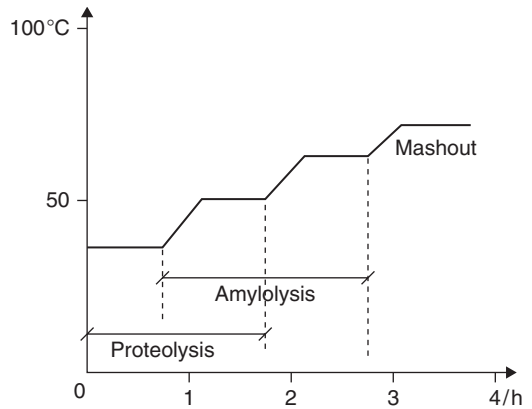
Figure 2.2   Mash tun.


Figure 2.3   Infusion mashing system.

chemical properties – yeast nutrients, alcohol content, peptide and amino acid profile, and concentration of unfermented carbohydrates; as well as the physical properties – color, foam and clarity (Ryder and Power, 1994). Usually, in top fermented beer production a more modified malt is used, with a lower protein content than bottom fermented beers (lager style). The infusion mashing system is commonly associated with the production of ales and stouts (Figure 2.1). It requires a single and unstirred

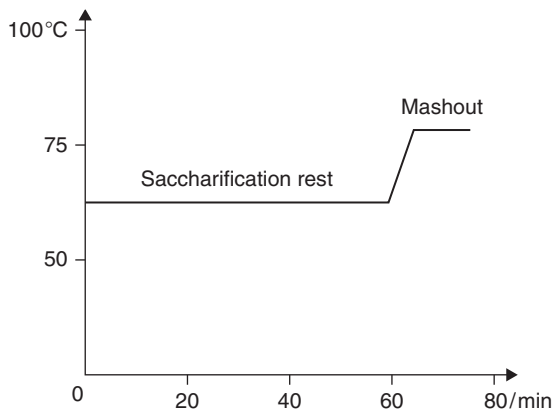
vessel, equipped with a false bottom, called a "mash tun" (Figure 2.2). In this vessel the total mash is always kept together and heated with rests being used at a temperature determined by enzyme properties (Figure 2.3) (Lewis and Young, 1995). The single-step infusion mash is the simplest mash schedule and is used extensively in ale brewing (Figure 2.4). At a mash temperature range of 65–70°C, enzymes in the malt activate and convert complex starches to simple sugar molecules (saccharification rest).


Figure 2.4 Single-step infusion mashing system. A single-step infusion mash is the simplest kind of mash. During the saccharification rest, malt enzymes convert the grain's starch into fermentable sugars.

Table 2.1 Flavour compounds associated with yeast metabolism in lager and ale

Class of volatile	Name	Lager (mg/l)	Ale (mg/l)
Higher alcohols	Ethanol	23–25 (g/l)	27–32 (g/l)
	Isopentanol	32–57	47–61
	β-Phenylethanol	25–32	36–53
	n-Propanol	5.0–10	31–48
	Isobutanol	6.0–11	18–33
	2-Methylbutanol	8.0–16	14–19
Esters	Ethyl acetate	8.0–14	14–23
	Isopentylacetate	1.5–2.0	1.4–3.3
Diketone	Diacetyl	0.02–0.08	0.06–0.30
	Pentane-2,3-dione	0.01–0.05	0.01–0.20
Sulfur compounds	Hydrogen sulfide (H_2S)	0.0015–0.008	0.0015–0.008
	Dimethyl sulfide (DMS)	15+ (μg/l)	15+ (μg/l)

Source: Modified from Hough (1994).

- **During mashing there is usually no "protein rest" because ale malts present a good modification and degradation of protein.**

Since the malts used to produce ales are better modified with protein (more degraded) there is no "protein rest" (near 50°C) which is typical in a multiple-step infusion. Therefore, a protein rest is used when the endosperm of the malt used is less enzymically degraded and requires more extensive enzymic action (e.g. in lager production) (Briggs *et al.*, 1982; Goldammer, 1999; Briggs *et al.*, 2004).

- **After the mash and before the boil, the wort must be separated from the mash.**

The objectives are to collect as much sugar from the mash as possible while leaving behind as many undesirable compounds as possible, and to make the wort as clear as possible. Filtration is directly run in the mash tun (Figure 2.2) which has a false bottom that allows efficient separation of wort from the spent grain (Lewis and Young, 1995). The sweet wort is transferred to a vessel (boiling kettle) where it is boiled with hops usually for 60–90 min. The boiling process is often associated with the addition of sugars or syrups, and hops or bitter products derived from hops. When hopped wort is clarified, it must be cooled as quickly as possible to fermentation temperatures (16–24°C) through a plate heat exchanger before yeast is pitched (Kunze, 1996). After cooling, it is usual to oxygenate or aerate the wort to provide oxygen for the yeast in the initial stages of fermentation (Briggs *et al.*, 2004).

- **To produce ale, strains of *Saccharomyces cerevisiae* are commonly used in the range of 16–24°C.**

To produce top fermented beers, strains of *Saccharomyces cerevisiae* are commonly used in the range of 16–24°C.

The inoculation of wort is called "pitching," and the pitching rate depends on fermentation temperature (pitching rate in ale is lower than lager beer), wort gravity, yeast strain and other variables (Munroe, 1994). As a rule of thumb, the pitching rate is 1×10^6 cells per Plato (°P) per ml of wort (Knudsen, 1999). The pitching rate is very important as it affects both beer flavor and fermentation rate. As shown in Table 2.1, the ester content in ale is higher than in lager beer. It is generally accepted that top fermented beer is more aromatic than bottom fermented beer, both having an identical original gravity. Top fermented beers, with their typically higher fermentation temperatures (16–24°C) and different yeast strains, usually contain more esters and fusel alcohols, and they often have a higher alcohol content (Derdelinckx and Neven, 1996).

Traditionally, ales are fermented with "top yeasts" that rise to the top of the beer in the head of foam. Major differences between ales and lagers do exist in the process conditions, traditional fermentation vessels and methods of yeast recovery. Ale fermentation uses the top-cropping yeast strain *S. cerevisiae*, which is used at higher temperatures than lagers, so the fermentation is faster. It rises to the top of the beer toward the end of the fermentation because the yeast flocs entrap carbon dioxide (CO_2), making them buoyant. The yeast is either removed by suction or by skimming and the fermenter may be the shallow open type (Munroe, 1994). With the development of cylindroconical vessels, the distinction between top and bottom yeasts tends to disappear. With this kind of vessel, brewers may use a bottom-cropping *S. cerevisiae* strain to produce ales. Therefore, the flocculating behavior of yeast is no longer used to exclusively distinguish between strains (Hough, 1985). Ale wort is pitched at about 16°C and fermentation is carried out at 16–24°C. The higher temperature than in lager fermentation

causes ale primary fermentation to be completed in much less time (2–3 days) (Briggs *et al.*, 2004).

- **Cask conditioning is the oldest method for maturation and conditioning of ale.**

The oldest method for maturation and conditioning of ale is cask conditioning. At the end of fermentation, which occurs either when the beer has achieved the required present gravity or the gravity has not changed for 24 h (about 2–3 days after fermentation starts), the beer is ready for cooling at 8–10°C to assist in removing any surplus yeast. The beer is then ready for racking into casks, where the maturation or secondary fermentation takes place. To achieve an effective secondary fermentation the beer requires a fermentable residue, and active cell in suspension of about 0.35–2.00×10^6 cells/ml, so the beer is rarely filtered. This additional carbonation is necessary if primary fermentation takes place in a shallow open-type vessel. To clarify beer, isinglass finings are added to bring the yeast out of suspension. A further addition may be hop products (dry hopping). The benefit with dry hopping is that the brewer can get as much flavor and aroma as possible into the final beer, due to the fact that no volatile oils are boiled off. This addition does not contribute to the bitterness because boiling is necessary to extract and isomerize the bitter resins. After packaging, the beer has to be kept between 12°C and 14°C (Hough, 1985; Carry and Grossman, 2006).

Refermentation of top fermenting beers in bottles is a frequently used process in Belgium. Mature beer is mixed with yeast and fermentable extract and subsequently bottled (Landschoot *et al.*, 2004). Historically, the origin of beer conditioning is related with the transport of beer kegs from brewery to pubs. Due to warm climatic conditions, remaining unfermented sugars in beer were fermented in the kegs. Carbonation gives a refreshing taste, creates foam and causes flavor compounds to escape from the glass (Vanderhaegen *et al.*, 2002).

- **Lambic is a beer produced by spontaneous fermentation.**

Lambic is a very distinctive style of beer brewed only in the Pajottenland region of Belgium (southwest of Brussels). Unlike conventional ales which are fermented by strains of *S. cerevisiae*, lambics are produced by spontaneous fermentation with airborne wild yeast and bacteria. Up to 86 microorganisms have been identified in lambic beer, the most significant ones being *Brettanomyces bruxellensis* and *Brettanomyces lambicus*. The process is generally only possible between October and May, because in summer, there are too many unfavorable organisms in the air that could spoil the beer. Another important feature of lambic is the raw material used to brew it. It is generally made from a grist containing approximately 55% barley malt and 35%

unmalted wheat. The temperature of mashing is increased by two or three decoctions and then, the wort is boiled for about 3–6 h, with the addition of aged hop. Hop aging leads to loss of much of its bitterness, but its antiseptic properties are still present. Consequently, lambics often have a strong cheese-like aroma, derived from oxidation of α-acids and β-acids and consequent low-molecular weight acids production (Lewis and Young, 1995). Before it was discovered that hops were a preservative and spice, all types of fruits, herbs and other seasonings were used to flavor the wort of barley and wheat. Cooling and aeration of wort is conducted in the cooling tun at a depth of 20–25 cm where it is exposed to the open air so that fermentation may occur spontaneously (Goldammer, 1999). It is this unusual process which gives the beer its distinctive flavor: dry, vinous and cidery, with a slightly sour aftertaste. The lambic style of beer includes many different sub-categories, such as lambic, gueuze, faro, fruit lambics and Kriek. The most significant ones are described in the section "Beer types."

- **A Trappist beer is a top fermented bottle-conditioned beer, brewed by or under the control of Trappist monks.**

To be called Trappist, the beer must be brewed within the walls of a Trappist abbey, by or under the control of Trappist monks. Trappist beer is therefore not so much a style as an appellation of origin. Trappists, or Order of Cistercians of the Strict Observance (O.C.S.O. or *Ordo Cisterciensis Strictioris Observantiae*), are a contemplative Roman Catholic religious order and their life follows the Rule of St. Benedict written in the sixth century. They originated in the Cistercian monastery of La Trappe, France, in reaction to the relaxation of practices in many Cistercian Monasteries. The Trappists live a life of prayer and penance. Their day is divided between work and prayer. Manual work is preferred over other types of work, and Trappist monasteries generally provide for themselves through the sale of goods produced in the monastery. One of the Rules of St. Benedict states "*You are only really a monk when you live from the work of your hands.*" By this rule, most Trappist monasteries produce goods that are then sold to provide an income for the monastery. The order does not require abstention from alcohol, and the goods produced are beer, cheese, bread and other foodstuffs. The Trappists, like many other religious people, brewed beer to fund their work, and monastery brewhouses existed all over Europe. Among these monastic breweries, the Trappists were certainly the most active brewers. In 1997, eight Trappist abbeys – six from Belgium (Orval, Chimay, Westvleteren, Rochefort, Westmalle and Achel), one from The Netherlands (Koningshoeven) and one from Germany (Mariawald) – founded the International Trappist Association (ITA) to prevent non-Trappist commercial companies from abusing the Trappist name. This private association created a logo that is assigned to goods (cheese, beer, wine and liquors)

that respect their precise production criteria. For beers, the rules are the following:

- The beer must be brewed within the walls of a Trappist abbey, by or under control of Trappist monks.
- The brewery, the choices of brewing and the commercial orientations must obviously depend on the monastic community.
- The economic purpose of the brewery must be directed toward assistance and not toward financial profit.

There are currently seven breweries (six in Belgium, one in The Netherlands) that are allowed to have their products bear the Authentic Trappist Product logo. These are Chimay, Orval, Rochefort, Westmalle, Westvleteren and Achel in Belgium and De Koningshoeven in The Netherlands. The brewery De Koningshoeven produces the only Dutch Trappist beer that is able to carry the "Authentic Trappist Product" logo. However, between 1999 and October 2005 their use of the logo was withdrawn. Trappist beers have become quite famous and are considered by many beer critics to be amongst the finest in the world.

Unlike Trappist beers, abbey beers are not made under the control of monks. Officially recognized abbey beers are made under license by a commercial brewery, using the name and recipes of an abbey that has ceased brewing itself. Only a couple of brands, including Val-Dieu and Abbaye d'Aulne, are actually made within the walls of an abbey.

Beer Types

There are many thousands of different beer brands throughout the world, many of which can be classified into defined beer types which have developed over the course of time in a few countries or regions. Depending on the process used, a first classification could be made into top fermentation and bottom fermentation beer types. Table 2.2 gives a breakdown of some principal beer types.

Top fermentation beer types

The sections below contain a list of top fermentation beer types (BJCP, 2004). Beer strength may be defined in several ways; and in order to explain the vital statistics of each style, the content of hop bitter substances (IBU, International Bitterness Units), the color (EBC, European Brewery Convention), the specific gravity of wort before fermentation (OG, original gravity) and post-fermentation (FG, final gravity), and the alcohol content (ABV or alcohol by volume) are used.

Table 2.2   Some principal beer types

Types of beers	Origin	Characteristics	Typical range of alcohol (% by vol.)
Top fermentation			
Standard/ordinary bitter	Britain	Low gravity, low alcohol levels	3.2–3.8
English pale ale	Britain	Dry hop, bitter, estery, malty, low carbonation	4.6–6.2
Mild	Britain	Refreshing, yet flavorful	2.8–4.2
Brown Porter	Britain	English dark ale with restrained roasty characteristics	4.0–5.4
Robust Porter	Britain	Malty dark ale	4.8–6.0
Dry stout	Ireland	Dark, roasty, bitter, creamy ale	4.0–5.0
Sweet stout	Britain	Dark, sweet, full-bodied, slightly roasty ale	4.0–6.0
Kölsch	Germany (Cologne)	Smooth and crisp	4.4–5.2
Lambic	Belgium	Fermented by a variety of Belgian microbiota	5.0–7.0
Rauchbier	Germany	Smoky aroma and flavor and a somewhat dark color	4.8–6.0
Weizen/Weissbier	Germany	Pale, spicy, fruity, refreshing wheat-based ale	4.3–5.6
Bottom fermentation			
German Pilsner (Pils)	Germany	Crisp, clean, refreshing beer	4.4–5.2
Bohemian Pilsener	Czech Republic	Crisp, complex and well-rounded yet refreshing	4.2–5.4
Classic American Pilsner	United States	Rice contributes a crisper, more neutral character	4.5–6.0
Vienna Lager	Austria	Soft, elegant maltiness	4.5–5.7
Oktoberfest/Märzen	Germany	Depth of malt character	4.8–5.7
Dark American Lager	United States	Sweeter version of standard lager	4.2–6.0
Munich Dunkel	Germany	Depth and complexity	4.5–5.6
Schwarzbier (Black Beer)	Germany	Probably a variant of the Munich *Dunkel* style	4.4–5.4
Maibock/Helles Bock	Germany	Pale, strong, malty lager beer	6.3–7.4
Traditional Bock	Germany	Dark, strong, malty lager beer	6.3–7.2
Doppelbock	Germany	Strong and rich lager	7.0–10+
Eisbock	Germany	An extremely strong, full and malty dark lager	9.0–14+

Source: Most of the data in this table is from the BJCP Style Guidelines (2004).

American Ale

American Pale Ale

Overall impression: Refreshing and hoppy, yet with sufficient supporting malt.

History: An American adaptation of English pale ale, reflecting indigenous ingredients (hops, malt, yeast and water). Often lighter in color, cleaner in fermentation by-products and having less caramel flavors than English counterparts.

Comments: There is some overlap in color between American pale ale and American amber ale. The American pale ale will generally be cleaner, have a less caramelly malt profile, less body and often more finishing hops.

Ingredients: Pale ale malt, typically American two-row. American hops, often but not always ones with a citrus character, American ale yeast. Water can vary in sulfate content, but carbonate content should be relatively low. Specialty grains may add character and complexity, but generally make up a relatively small portion of the grist. Grains that add malt flavor and richness, light sweetness, and toasty or bready notes are often used (along with late hops) to differentiate brands.

Vital statistics:	OG: 1.045–1.060 (11.2–14.7 °P)
IBUs: 30–45+	FG: 1.010–1.015
EBC: 9.8–27.6	ABV: 4.5–6%

Commercial examples: Sierra Nevada Pale Ale, Stone Pale Ale, Great Lakes Burning River Pale Ale, Full Sail Pale Ale, Three Floyds X-Tra Pale Ale, Anderson Valley Poleeko Gold Pale Ale, Left Hand Brewing Jackman's Pale Ale, Pyramid Pale Ale, Deschutes Mirror Pond.

American Amber Ale

Overall impression: Like an American pale ale with more body, more caramel richness and a balance more toward malt than hops (although hop rates can be significant).

History: Known simply as Red Ales in some regions, these beers were popularized in the hop-loving Northern California and the Pacific Northwest areas before spreading nationwide.

Comments: Can overlap in color with American pale ales. However, American amber ales differ from American pale ales not only by being usually darker in color, but also by having more caramel flavor, more body and usually being balanced more evenly between malt and bitterness. Should not have a strong chocolate or roast character that might suggest an American brown ale (although small amounts are OK).

Ingredients: Pale ale malt, typically American two-row. Medium to dark crystal malts. May also contain specialty grains which add additional character and uniqueness. American hops, often with citrus flavors, are common but others may also be used. Water can vary in sulfate and carbonate content.

Vital statistics:	OG: 1.045–1.060 (11.2–14.7 °P)
IBUs: 25–40+	FG: 1.010–1.015
EBC: 19.7–33.5	ABV: 4.5–6%

Commercial examples: Mendocino Red Tail Ale, North Coast Red Seal Ale, St. Rogue Red Ale, Avery Redpoint Ale, Anderson Valley Boont Amber Ale, Bell's Amber, Hoptown Paint the Town Red, McNeill's Firehouse Amber Ale.

American Brown Ale

Overall impression: Can be considered a bigger, maltier, hoppier interpretation of Northern English Brown Ale or a hoppier, less malty Brown Porter, often including the citrus-accented hop presence that is characteristic of American hop varieties.

History/comments: A strongly flavored, hoppy brown beer originated by American homebrewers. Related to American Pale and American Amber Ales, although with more of a caramel and chocolate character, which tends to balance the hop bitterness and finish. Most commercial American Browns are not as aggressive as the original home-brewed versions and some modern craft-brewed examples. India Pale Ale (IPA)-strength brown ales should be entered in the Specialty category.

Ingredients: Well-modified pale malt, either American or Continental, plus crystal and darker malts should complete the malt bill. American hops are typical, but UK or noble hops can also be used. Moderate carbonate water would appropriately balance the dark malt acidity.

Vital statistics:	OG: 1.045–1.060 (11.2–14.7 °P)
IBUs: 20–40+	FG: 1.010–1.016
EBC: 35.5–68.9	ABV: 4.3–6.2%

Commercial examples: Brooklyn Brown Ale, Great Lakes Cleveland Brown Ale, Avery Ellie's Brown Ale, Left Hand Deep Cover Brown Ale, Bell's Best Brown, North Coast Acme Brown, Lost Coast Downtown Brown, Big Sky Moose Drool Brown Ale.

English Pale Ale

Standard/Ordinary Bitter

Overall impression: Low gravity, low alcohol levels and low carbonation make this an easy-drinking beer. Some examples can be more malt balanced, but this should not override the overall bitter impression. Drinkability is a critical component of the style; emphasis is still on the bittering hop addition as opposed to the aggressive middle and late hopping seen in American ales.

History: Originally a draft ale served very fresh under no pressure (gravity or hand pump only) at cellar temperatures

(i.e. "real ale"). Bitter was created as a draft alternative (i.e. running beer) to country-brewed pale ale around the start of the twentieth century and became widespread once brewers understood how to "Burtonize" their water to successfully brew pale beers and to use crystal malts to add a fullness and roundness of palate.

Ingredients: Pale ale, amber and/or crystal malts may use a touch of black malt for color adjustment. May use sugar adjuncts, corn or wheat. English hops most typical, although American and European varieties are becoming more common (particularly in the paler examples). Characterful English yeast. Often medium sulfate water is used.

> *Vital statistics*: OG: 1.032–1.040 (8.0–10.0 °P)
> IBUs: 25–35 FG: 1.007–1.011
> EBC: 7.9–27.6 ABV: 3.2–3.8%

Commercial examples: Boddington's Pub Draught, Fuller's Chiswick Bitter, Oakham Jeffrey Hudson Bitter (JHB), Young's Bitter, Brakspear Bitter, Adnams Bitter.

Extra Special/Strong Bitter (English Pale Ale)
Overall impression: An average-strength to moderately strong English ale. The balance may be fairly even between malt and hops to somewhat bitter. Drinkability is a critical component of the style; emphasis is still on the bittering hop addition as opposed to the aggressive middle and late hopping seen in American ales. A rather broad style that allows for considerable interpretation by the brewer.

History: Strong bitters can be seen as a higher-gravity version of best bitters (although not necessarily "more premium," since best bitters are traditionally the brewer's finest product). Since beer is sold by strength in the United Kingdom, these beers often have some alcohol flavor (perhaps to let the consumer know they are getting their due). In England today, "ESB" is a brand unique to Fullers; in America, the name has been co-opted to describe a malty, bitter, reddish, standard-strength (for the United States) English-type ale. Hopping can be English or a combination of English and American.

Ingredients: Pale ale, amber and/or crystal malts, may use a touch of black malt for color adjustment. May use sugar adjuncts, corn or wheat. English hops most typical, although American and European varieties are becoming more common (particularly in the paler examples). Characterful English yeast. "Burton" versions use medium to high sulfate water.

> *Vital statistics*: OG: 1.048–1.060+ (11.9–14.7 °P+)
> IBUs: 30–50+ FG: 1.010–1.016
> EBC: 11.8–35.5 ABV: 4.6–6.2%

Commercial examples: Fullers ESB, Adnams Broadside, Shepherd Neame Bishop's Finger, Samuel Smith's Old Brewery Pale Ale, Bass Ale, Whitbread Pale Ale, Shepherd Neame Spitfire, Marston's Pedigree, Black Sheep Ale, Vintage Henley, Mordue Workie Ticket, Morland Old

Speckled Hen, Greene King Abbot Ale, Bateman's XXXB, Gale's Hordean Special Bitter (HSB), Ushers 1824 Particular Ale, Hopback Summer Lightning, Redhook ESB, Great Lakes Moondog Ale, Shipyard Old Thumper, Alaskan ESB, Geary's Pale Ale, Cooperstown Old Slugger.

English Brown Ale

Mild
Overall impression: A light-flavored, malt-accented beer that is readily suited to drinking in quantity. Refreshing, yet flavorful. Some versions may seem like lower gravity Brown Porters.

History: May have evolved as one of the elements of early porters. In modern terms, the name "mild" refers to the relative lack of hop bitterness (i.e. less hoppy than a pale ale, and not so strong). Originally, the "mildness" may have referred to the fact that this beer was young and did not yet have the moderate sourness that aged batches had. Somewhat rare in England, good versions may still be found in the Midlands around Birmingham.

Ingredients: Pale English base malts (often fairly dextrinous), crystal and darker malts should comprise the grist. May use sugar adjuncts. English hop varieties would be most suitable, though their character is muted. Characterful English ale yeast.

> *Vital statistics*: OG: 1.030–1.038 (7.6–9.5 °P)
> IBUs: 10–25 FG: 1.008–1.013
> EBC: 23.6–49.2 ABV: 2.8–4.5%

Commercial examples: Moorhouse Black Cat, Highgate Mild, Brain's Dark, Banks's Mild, Coach House Gunpowder Strong Mild, Gale's Festival Mild, Woodforde's Norfolk Nog, Goose Island PMD Mild.

Southern English Brown
Overall impression: A luscious, malt-oriented brown ale, with a caramel, dark fruit complexity of malt flavor. May seem somewhat like a smaller version of a sweet stout or a sweet version of a dark mild.

History: English brown ales are generally split into sub-styles along geographic lines. Southern English (or "London-style") Brown Ales are darker, sweeter and lower gravity than their Northern cousins.

Ingredients: English pale ale malt as a base with a healthy proportion of darker caramel malts and often some roasted malts. Moderate to high carbonate water would appropriately balance the dark malt acidity. English hop varieties are most authentic, although with low flavor and bitterness almost any type could be used.

> *Vital statistics*: OG: 1.035–1.042 (8.8–10.5 °P)
> IBUs: 12–20 FG: 1.011–1.014
> EBC: 37.4–68.9 ABV: 2.8–4.2%

Commercial examples: Mann's Brown Ale (bottled, but not available in the United States), Tolly Cobbold Cobnut Nut Brown Ale.

Northern English Brown Ale
Overall impression: Drier and more hop-oriented than Southern English Brown Ale, with a nutty character rather than caramel.

History/comments: English brown ales are generally split into sub-styles along geographic lines.

Ingredients: English mild ale or pale ale malt base with caramel malts. May also have small amounts of darker malts (e.g. chocolate) to provide color and the nutty character. English hop varieties are most authentic. Moderate carbonate water.

Vital statistics: OG: 1.040–1.052 (10.0–12.9 °P)
IBUs: 20–30   FG: 1.008–1.013
EBC: 23.6–43.3   ABV: 4.2–5.4%

Commercial examples: Newcastle Brown Ale, Samuel Smith's Nut Brown Ale, Tolly Cobbold Cobnut Special Nut Brown Ale, Goose Island Hex Nut Brown Ale.

Porter

Brown Porter
Overall impression: A fairly substantial English dark ale with restrained roasty characteristics.

History: Originating in England, porter evolved from a blend of beers or gyles known as "Entire." A precursor to stout. Said to have been favored by porters and other physical laborers.

Ingredients: English ingredients are most common. May contain several malts, including chocolate and/or other dark roasted malts and caramel-type malts. Historical versions would use a significant amount of brown malt. Usually does not contain large amounts of black patent malt or roasted barley. English hops are most common, but are usually subdued. London- or Dublin-type water (moderate carbonate hardness) is traditional. English or Irish ale yeast, or occasionally lager yeast, is used. May contain a moderate amount of adjuncts (sugars, maize, molasses, treacle, etc.).

Vital statistics: OG: 1.040–1.052 (10.0–12.9 °P)
IBUs: 18–35   FG: 1.008–1.014
EBC: 39.4–59.1   ABV: 4–5.4%

Commercial examples: Samuel Smith Taddy Porter, Fuller's London Porter, Burton Bridge Burton Porter, Nethergate Old Growler Porter, Nick Stafford's Nightmare Yorkshire Porter, St. Peters Old-Style Porter, Bateman's Salem Porter, Shepherd Neame Original Porter, Flag Porter, Yuengling Porter, Geary's London Style Porter.

Robust Porter
Overall impression: A substantial, malty dark ale with a complex and flavorful roasty character.

History: Stronger, hoppier and/or roastier version of porter designed as either a historical throwback or an American interpretation of the style. Traditional versions will have a more subtle hop character (often English), whereas modern versions may be considerably more aggressive. Both types are equally valid.

Ingredients: May contain several malts, prominently dark roasted malts and grains, which often include black patent malt (chocolate malt and/or roasted barley may also be used in some versions). Hops are used for bittering, flavor and/or aroma, and are frequently UK or US varieties. Water with moderate to high carbonate hardness is typical. Ale yeast can either be clean US versions or characterful English varieties.

Vital statistics: OG: 1.048–1.065 (11.9–15.9 °P)
IBUs: 25–50+   FG: 1.012–1.016
EBC: 43.3–68.9+   ABV: 4.8–6%

Commercial examples: Anchor Porter, Great Lakes Edmund Fitzgerald Porter, Sierra Nevada Porter, Bell's Porter, Thirsty Dog Old Leghumper, Otter Creek Stovepipe Porter, Portland Haystack Black Porter, Avery New World Porter, Deschutes Black Butte Porter, Redhook Blackhook Porter.

Stout

Dry Stout
Overall impression: A very dark, roasty, bitter, creamy ale.

History: The style evolved from attempts to capitalize on the success of London porters, but originally reflected a fuller, creamier, more "stout" body and strength. When a brewery offered a stout and a porter, the stout was always the stronger beer (it was originally called a "Stout Porter"). Modern versions are brewed from a lower OG and no longer reflect a higher strength than porters.

Ingredients: The dryness comes from the use of roasted unmalted barley in addition to pale malt, moderate to high hop bitterness and good attenuation. Flaked unmalted barley may also be used to add creaminess. A small percentage (perhaps 3%) of soured beer is sometimes added for complexity (generally by Guinness only). Water typically has moderate carbonate hardness, although high levels will not give the classic dry finish.

Vital statistics: OG: 1.036–1.050 (9.0–12.4 °P)
IBUs: 30–45   FG: 1.007–1.011
EBC: 49.2–78.8+   ABV: 4–5%

Commercial examples: Guinness Draught Stout (also canned), Murphy's Stout, Beamish Stout, O'Hara's Celtic Stout, Dorothy Goodbody's Wholesome Stout, Orkney

Dragonhead Stout, Brooklyn Dry Stout, Old Dominion Stout, Goose Island Dublin Stout, Arbor Brewing Faricy Fest Irish Stout.

Sweet Stout

Overall impression: A very dark, sweet, full-bodied, slightly roasty ale. Often tastes like sweetened espresso.

History: An English style of stout. Historically known as "Milk" or "Cream" stouts, legally this designation is no longer permitted in England (but is acceptable elsewhere). The "milk" name is derived from the use of lactose, or milk sugar, as a sweetener.

Comments: Gravities are low in England, higher in exported and US products. Variations exist in the level of residual sweetness, the intensity of the roast character, and the balance between the two being the variables most subject to interpretation.

Ingredients: The sweetness in most sweet stouts comes from a lower bitterness level than dry stouts and a high percentage of unfermentable dextrins. Lactose, an unfermentable sugar, is frequently added to provide additional residual sweetness. Base of pale malt, and may use roasted barley, black malt, chocolate malt, crystal malt, and adjuncts such as maize or treacle. High carbonate water is common.

Vital statistics: OG: 1.042–1.056 (10.5–13.8 °P)
IBUs: 25–40   FG: 1.010–1.023
EBC: 59.1–78.8+   ABV: 4–6%

Commercial examples: Mackeson's XXX Stout, Watney's Cream Stout, St. Peter's Cream Stout, Marston's Oyster Stout, Samuel Adams Cream Stout, Left Hand Milk Stout.

India Pale Ale

English IPA

Overall impression: A hoppy, moderately strong pale ale that features characteristics consistent with the use of English malt, hops and yeast. Has less hop character and a more pronounced malt flavor than American versions.

History: Brewed to survive the voyage from England to India. The temperature extremes and rolling of the seas resulted in a highly attenuated beer upon arrival. English pale ales were derived from IPA.

Ingredients: Pale ale malt (well modified and suitable for single-temperature infusion mashing); English hops; English yeast that can give a fruity or sulfury/minerally profile. Refined sugar may be used in some versions. High sulfate and low carbonate water is essential to achieve a pleasant hop bitterness in authentic Burton versions, although not all examples will exhibit the strong sulfate character.

Vital statistics: OG: 1.050–1.075 (12.4–18.20 °P)
IBUs: 40–60   FG: 1.010–1.018
EBC: 15.8–27.6   ABV: 5–7.5%

Commercial examples: Freeminer Trafalgar IPA, Hampshire Pride of Romsey IPA, Burton Bridge Empire IPA, Samuel Smith's India Ale, Fuller's IPA, King & Barnes IPA, Brooklyn East India Pale Ale, Shipyard Fuggles IPA, Goose Island IPA.

American IPA

Overall impression: A decidedly hoppy and bitter, moderately strong American pale ale.

History: An American version of the historical English style, brewed using American ingredients and attitude.

Ingredients: Pale ale malt (well modified and suitable for single-temperature infusion mashing); American hops; American yeast that can give a clean or slightly fruity profile. Generally all-malt, but mashed at lower temperatures for high attenuation. Water character varies from soft to moderately sulfate.

Vital statistics: OG: 1.056–1.075 (13.8–18.20 °P)
IBUs: 40–60+   FG: 1.010–1.018
EBC: 11.8–29.5   ABV: 5.5–7.5%

Commercial examples: Stone IPA, Victory Hop Devil, Anderson Valley Hop Ottin', Anchor Liberty Ale, Sierra Nevada Celebration Ale, Three Floyds Alpha King, Harpoon IPA, Bell's Two-Hearted Ale, Avery IPA, Founder's Centennial IPA, Mendocino White Hawk Select IPA.

Imperial IPA

Overall impression: An intensely hoppy, very strong pale ale without the big maltiness and/or deeper malt flavors of an American barleywine. Strongly hopped, but clean, lacking harshness and a tribute to historical IPAs.

History: A recent American innovation reflecting the trend of American craft brewers "pushing the envelope" to satisfy the need of hop aficionados for increasingly intense products. Category may be stretched to cover historical and modern American stock ales that are stronger, hoppier ales without the malt intensity of barleywines. The adjective "Imperial" is arbitrary and simply implies a stronger version of an IPA; "double," "extra," "extreme" or any other variety of adjectives would be equally valid.

Ingredients: Pale ale malt (well modified and suitable for single-temperature infusion mashing); can use a complex variety of hops (English, American, noble). American yeast that can give a clean or slightly fruity profile. Generally all-malt, but mashed at lower temperatures for high attenuation. Water character varies from soft to moderately sulfate.

Vital statistics: OG: 1.075–1.090+
IBUs: 60–100+   FG: 1.012–1.020 (3.07–5.0 °P)
EBC: 15.8–29.5   ABV: 7.5–10%+

Commercial examples: Dogfish Head 90-min IPA, Rogue I²PA, Stone Ruination IPA, Three Floyd's Dreadnaught, Russian River Pliny the Elder, Moylan's Moylander Double

IPA. Stock ales include examples such as Stone Arrogant Bastard and Mendocino Eye of the Hawk.

German Wheat and Rye Beer

Weizen/Weissbier
Overall impression: A pale, spicy, fruity, refreshing wheat-based ale.

History: A traditional wheat-based ale originating in Southern Germany that is a specialty for summer consumption, but generally produced year round.

Ingredients: By German law, at least 50% of the grist must be malted wheat, although some versions use up to 70%; the remainder is Pilsner malt. A traditional decoction mash gives the appropriate body without cloying sweetness. Weizen ale yeasts produce the typical spicy and fruity character, although extreme fermentation temperatures can affect the balance and produce off-flavors. A small amount of noble hops are used only for bitterness.

    Vital statistics: OG: 1.044–1.052 (11.0–12.9 °P)
    IBUs: 8–15   FG: 1.010–1.014
    EBC: 3.9–15.8   ABV: 4.3–5.6%

Commercial examples: Schneider Weisse, Paulaner Hefe-Weizen, Hacker-Pschorr Weisse, Franziskaner Hefe-Weisse, Penn Weizen, Capitol Kloster Weizen, Sudwerk Hefeweizen, Brooklyner Weisse, Barrelhouse Hocking Hills HefeWeizen, Sprecher Hefeweizen.

Dunkelweizen
Overall impression: A moderately dark, spicy, fruity, malty, refreshing wheat-based ale. Reflecting the best yeast and wheat character of a Hefeweizen blended with the malty richness of a Munich dunkel.

History: Old-fashioned Bavarian wheat beer was often dark. In the 1950s and 1960s, wheat beers did not have a youthful image, since most older people drank them for their percieved health-giving qualities. Today, the lighter Hefeweizen is more common.

Ingredients: By German law, at least 50% of the grist must be malted wheat, although some versions use up to 70%; the remainder is usually Munich and/or Vienna malt. A traditional decoction mash gives the appropriate body without cloying sweetness. Weizen ale yeasts produce the typical spicy and fruity character, although extreme fermentation temperatures can affect the balance and produce off-flavors. A small amount of noble hops are used only for bitterness.

    Vital statistics: OG: 1.044–1.056 (11.0–13.8 °P)
    IBUs: 10–18   FG: 1.010–1.014
    EBC: 27.6–45.3 ABV: 4.3–5.6%

Commercial examples: Franziskaner Dunkel Hefe-Weisse, Hacker-Pschorr Weisse Dark, Schneider Dunkel Weiss, Tucher Dunkles Hefe Weizen, Ayinger Ur-Weisse, Brooklyner Dunkel-Weisse.

Belgian and French Ale

Witbier
Overall impression: A refreshing, elegant, tasty, moderate-strength wheat-based ale.

History: A 400-year-old beer style that died out in the 1950s; it was later revived by Pierre Celis at Hoegaarden, and has grown steadily in popularity over time.

Ingredients: About 50% unmalted wheat (traditionally soft white winter wheat) and 50% pale barley malt (usually Pils malt) constitute the grist. In some versions, up to 5–10% raw oats may be used. Spices of freshly ground coriander and Curaçao or sometimes sweet orange peel complement the sweet aroma and are quite characteristic. Other spices (e.g. chamomile, cumin, cinnamon, Grains of Paradise) may be used for complexity but are much less prominent. Ale yeast prone to the production of mild, spicy flavors is very characteristic. In some instances a very limited lactic fermentation, or the actual addition of lactic acid, is done.

    Vital statistics: OG: 1.044–1.052 (11.0–12.9 °P)
    IBUs: 10–20   FG: 1.008–1.012
    EBC: 3.9–7.9   ABV: 4.5–5.5% (5% is most typical)

Commercial examples: Hoegaarden Wit, Vuuve 5, Blanche de Bruges, Blanche de Bruxelles, Brugs Tarwebier, Sterkens White Ale, Celis White (now made in Michigan), Blanche de Brooklyn, Great Lakes Holy Moses, Unibroue Blanche de Chambly, Blue Moon Belgian White.

Belgian Pale Ale
Overall impression: A fruity, moderately malty, somewhat spicy, easy-drinking, copper-colored ale.

History: Produced by breweries with roots as far back as the mid-1700s, the most well-known examples were perfected after World War II with some influence from Britain, including hops and yeast strains.

Ingredients: Pilsner or pale ale malt contributes the bulk of the grist with Vienna and Munich malts adding color, body and complexity. Candy sugar is not commonly used as high gravity is not desired. Noble hops, Styrian Goldings, East Kent Goldings or Fuggles are commonly used. Yeasts prone to moderate production of phenols are often used but fermentation temperatures should be kept moderate to limit this character.

    Vital statistics: OG: 1.048–1.054 (11.9–13.3 °P)
    IBUs: 20–30   FG: 1.010–1.014
    EBC: 15.8–27.6 ABV: 4.8–5.5%

Commercial examples: De Koninck, Speciale Palm, Dobble Palm, Ginder Ale, Op-Ale, Vieux-Temps, Brewer's Art

House Pale Ale, Ommegang Rare Vos (unusual in its 6.5% ABV strength).

Saison
Overall impression: A medium to strong ale with a distinctive yellowish-orange color, highly carbonated, well hopped, fruity and dry with a quenching acidity.

History: A seasonal summer style produced in Wallonia, the French-speaking part of Belgium. Originally brewed at the end of the cool season to last through the warmer months before refrigeration was common. It had to be sturdy enough to last for months but not too strong to be quenching and refreshing in the summer. It is now brewed year round in tiny, artisanal breweries whose buildings reflect their origins as farmhouses.

Ingredients: Pilsner malt dominates the grist though a portion of Vienna and/or Munich malt contributes color and complexity. Adjuncts such as candy sugar and honey can also serve to add complexity and thin the body. Hop bitterness and flavor may be more noticeable than in many other Belgian styles. A saison is sometimes dry-hopped. Noble hops, Styrian or East Kent Goldings are commonly used. A wide variety of herbs and spices are generally used to add complexity and uniqueness in the stronger versions. Varying degrees of acidity and/or sourness can be created by the use of gypsum, acidulated malt, a sour mash or *Lactobacillus*. Hard water, common to most of Wallonia, can accentuate the bitterness and dry finish.

Vital statistics:	OG: 1.048–1.080 (11.9–19.3 °P)
IBUs: 25–45	FG: 1.010–1.016
EBC: 9.8–23.6	ABV: 5–8.5%

Commercial examples: Saison Dupont, Foret and Moinette Blonde; Fantome Saison(s); Saison de Pipaix and La Folie; Saison Silly; Saison Regal; Saison Voisin; Lefebvre Saison 1900; Ellezelloise Saison 2000; Brooklyn Saison; Southampton Saison; New Belgium Saison; Pizza Port-Carlsbad Saison.

Belgian Specialty Ale
Overall impression: This category encompasses a wide range of Belgian ales produced by truly artisanal brewers more concerned with creating unique products than in increasing sales.

History: Unique beers of small, independent Belgian breweries that have come to enjoy local popularity but may be far less well-known outside of their own regions. Many have attained "cult status" in the US (and other parts of the world) and now owe a significant portion of their sales to export.

Ingredients: May include herbs and/or spices. May include unusual grains and malts, though the grain character should be apparent if it is a key ingredient. May include adjuncts such as candy sugar and honey. May include

Belgian microbiota such as *Brettanomyces* or *Lactobacillus*. Unusual techniques, such as blending, may be used though primarily to arrive at a particular result. The process alone does not make a beer unique to a blind judging panel if the final product does not taste different.

Vital statistics:	OG: varies
IBUs: varies	FG: varies
EBC: varies	ABV: varies

Commercial examples: Orval; De Dolle's Arabier, Oerbier, Boskeun and Still Nacht; La Chouffe, McChouffe, Chouffe Bok and N'ice Chouffe; Ellezelloise Hercule Stout and Quintine Amber; Unibroue Ephemere, Maudite, Don de Dieu, etc.; Minty; Zatte Bie; Caracole Amber, Saxo and Nostradomus; Silenrieu Sara and Joseph; Fantôme Black Ghost and Speciale Noël; St. Fullien Noël; Gouden Carolus Noël; Affligem Nöel; Guldenburg and Pere Noël; De Ranke XX Bitter; Bush (Scaldis); Grottenbier; La Trappe Quadrupel; Weyerbacher QUAD; Bière de Miel; Verboden Vrucht; New Belgium 1554 Black Ale; Cantillon Iris and many more.

Sour Ale

Berliner Weisse
Overall impression: A very pale, sour, refreshing, low-alcohol wheat ale.

History: A regional specialty of Berlin; referred to by Napoleon's troops in 1809 as "the Champagne of the North" due to its lively and elegant character. Only two traditional breweries still produce the product.

Comments: In Germany, it is classified as a *Schankbier* denoting a small beer of starting gravity in the range 7−8 °P. Often served with the addition of a shot of sugar syrups (mit schuss) flavored with raspberry (himbeer) or woodruff (waldmeister) or even mixed with Pils to counter the substantial sourness. Has been described by some as the most purely refreshing beer in the world.

Ingredients: Wheat malt content is typically well under 50% of the grist (generally 30%) with the remainder being Pilsner malt. A symbiotic fermentation with top fermenting yeast and *Lactobacillus delbruckii* provides the sharp sourness, which may be enhanced by blending of beers of different ages during fermentation and by extended cool aging. Low head and carbonation may be incorrectly caused by the yeast's adverse reaction to elevated levels of lactic acid. Hop bitterness is extremely low. A turbid mash is traditional, although some homebrewers use a sour mash.

Vital statistics:	OG: 1.028–1.032 (7.1–8.0 °P)
IBUs: 3–8	FG: 1.004–1.006
EBC: 3.9–5.9	ABV: 2.8–3.6%

Commercial examples: Schultheiss Berliner Weisse, Berliner Kindl Weisse, Nodding Head Berliner Weisse.

Flanders Red Ale
Overall impression: A complex, sour, red wine-like Belgian-style ale.

History: The indigenous beer of West Flanders, typified by the products of the Rodenbach brewery, established in 1820 in West Flanders but reflective of earlier brewing traditions. The beer is aged for up to 2 years, often in huge oaken barrels which contain the resident bacteria necessary to sour the beer. It was once common in Belgium and England to blend old beer with young to balance the sourness and acidity found in aged beer. Although blending of batches for consistency is now common among larger breweries, this type of blending is a fading art.

Comments: Long aging and blending of young and well-aged beer often occurs, adding to the smoothness and complexity, though the aged product is sometimes released as a connoisseur's beer. Known as the Burgundy of Belgium, it is more wine-like than any other beer style. The reddish color is a product of the malt although an extended, less-than-rolling portion of the boil may help add an attractive Burgundy hue. Aging will also darken the beer. The Flanders red is more acetic and the fruity flavors more reminiscent of a red wine than an Oud Bruin.

Ingredients: A base of Vienna and/or Munich malts and a small amount of Special B are used with up to 20% flaked corn or corn grits. Low alpha acid continental or British hops are commonly used (avoid high alpha or distinctive American hops). *Saccharomyces*, *Lactobacillus* and *Brettanomyces* (and acetobacters) contribute to the fermentation and eventual flavor.

Vital statistics:	OG: 1.046–1.054 (11.4–13.3 °P)
IBUs: 15–25	FG: 1.008–1.016
EBC: 19.7–31.5	ABV: 5–5.5%

Commercial examples: Rodenbach Klassiek, Rodenbach Grand Cru, Bellegems Bruin, Duchesse de Bourgogne, New Belgium La Folie, Petrus Oud Bruin, Southampton Publick House Flanders Red Ale, Verhaege Vichtenaar.

Flanders Brown Ale/Oud Bruin
Overall impression: A malty, fruity, aged, somewhat sour Belgian-style brown ale.

History: An "old ale" tradition, indigenous to East Flanders, typified by the products of the Liefman brewery (now owned by Riva), which has roots back to the 1600s. Historically brewed as a "provision beer" that would develop some sourness as it aged. These beers were typically more sour than current commercial examples. Although Flanders red beers are aged in oak, the brown beers are not.

Comments: Long aging and blending of young and aged beer may occur, adding smoothness and complexity and balancing any harsh, sour character. A deeper malt character distinguishes these beers from Flanders red ales. This style was designed to lay down, so examples with a moderate-aged character are considered superior to younger examples. As in fruit lambics, Oud Bruin can be used as a base for fruit-flavored beers such as kriek (cherries) or frambozen (raspberries), although these should be entered in the classic-style fruit beer category. The Oud Bruin is less acetic and maltier than a Flanders red, and the fruity flavors are more malt-oriented.

Ingredients: A base of Pils malt with judicious amounts of crystal malt and a tiny bit of black or roast malt. Low alpha acid continental or British hops are typical (avoid high alpha or distinctive American hops). *Saccharomyces* and *Lactobacillus* (and acetobacters) contribute to the fermentation and eventual flavor. *Lactobacillus* reacts poorly to elevated levels of alcohol. A sour mash or acidulated malt may also be used to develop the sour character without introducing *Lactobacillus*. Water high in carbonates is typical of its home region and will buffer the acidity of darker malts and the lactic sourness. Magnesium in the water accentuates the sourness.

Vital statistics:	OG: 1.043–1.077 (10.7–18.7 °P)
IBUs: 15–25	FG: 1.012–1.016
EBC: 29.6–39.4	ABV: 4–8%

Commercial examples: Liefman's Goudenband, Liefman's Odnar, Liefman's Oud Bruin, Ichtegem Old Brown.

Straight (Unblended) Lambic
Overall impression: Complex, sour/acidic, pale, wheat-based ale fermented by a variety of Belgian microbiota.

History: Spontaneously fermented sour ales from the area in and around Brussels (the Senne Valley) stem from a farmhouse brewing tradition several centuries old. Their numbers are constantly dwindling.

Comments: Straight lambics are single-batch, unblended beers. Since they are unblended, the straight lambic is often a true product of the "house character" of a brewery and will be more variable than a gueuze. They are generally served young (6 months) and on tap as cheap, easy-drinking beers without any filling carbonation. Younger versions tend to be one-dimensionally sour since a complex Brett character often takes upward of a year to develop. An enteric character is often indicative of a lambic that is too young. A noticeable vinegary or cidery character is considered a fault by Belgian brewers. Since the wild yeast and bacteria will ferment ALL sugars, they are bottled only when they have completely fermented. Lambic is served uncarbonated, while gueuze is served effervescent.

Ingredients: Unmalted wheat (30–40%), Pilsner malt and aged (surannes) hops (3 years) are used. The aged hops are used more for preservative effects than bitterness, and makes actual bitterness levels difficult to estimate. Traditionally these beers are spontaneously fermented with naturally occurring yeast and bacteria in predominately oaken barrels. Home- and craft-brewed versions are more typically made with pure cultures of yeast, commonly including

Saccharomyces, *Brettanomyces*, *Pediococcus* and *Lactobacillus*, in an attempt to recreate the effects of the dominant microbiota of Brussels and the surrounding countryside of the Senne River valley. Cultures taken from bottles are sometimes used but there is no simple way of knowing which organisms are still viable.

> *Vital statistics*:   OG: 1.040–1.054 (10.0–13.3 °P)
> IBUs: Up to 10   FG: 1.000–1.010
> EBC: 5.9–13.8   ABV: 5–6.5%

Commercial examples: The only bottled version readily available is Cantillon Grand Cru Bruocsella of whatever single batch vintage the brewer deems worthy to bottle. De Cam sometimes bottles their very old (5 years) lambic. In and around Brussels there are specialty cafes that often have draft lambics from traditional brewers/blenders such as Boon, De Cam, Cantillon, Drie Fonteinen, Lindemans and Girardin.

Gueuze
Overall impression: Complex, pleasantly sour/acidic, balanced, pale, wheat-based ale fermented by a variety of Belgian microbiota.

History: Spontaneously fermented sour ales from the area in and around Brussels (the Senne Valley) that stem from a farmhouse brewing tradition several centuries old. Their numbers are constantly dwindling and some are untraditionally sweetening their products (post-fermentation) to make them more palatable to a wider audience.

Comments: Gueuze is traditionally produced by mixing 1- to 3-year-old lambic. "Young" lambic contains fermentable sugars whereas old lambic has the characteristic "wild" taste of the Senne River valley. A good gueuze is not the most pungent, but possesses a full and tantalizing bouquet, a sharp aroma and a soft, velvety flavor. Lambic is served uncarbonated, whereas gueuze is served effervescent.

Ingredients: Unmalted wheat (30–40%), Pilsner malt and aged (surannes) hops (3 years) are used. The aged hops are used more for preservative effects than bitterness, and makes actual bitterness levels difficult to estimate. Traditionally these beers are spontaneously fermented with naturally occurring yeast and bacteria in predominately oaken barrels. Home- and craft-brewed versions are more typically made with pure cultures of yeast commonly including *Saccharomyces*, *Brettanomyces*, *Pediococcus* and *Lactobacillus* in an attempt to recreate the effects of the dominant microbiota of Brussels and the surrounding countryside of the Senne River valley. Cultures taken from bottles are sometimes used but there is no simple way of knowing which organisms are still viable.

> *Vital statistics*:   OG: 1.040–1.060 (10.0–14.4 °P)
> IBUs: Up to 10   FG: 1.000–1.006
> EBC: 5.9–13.8   ABV: 5–8%

Commercial examples: Boon Oude Gueuze, Boon Oude Gueuze Mariage Parfait, De Cam Gueuze, De Cam/Drei Fonteinen Millennium Gueuze, Drie Fonteinen Oud Gueuze, Cantillon Gueuze, Hanssens Gueuze, Lindemans Gueuze Cuvée René, Girardin Gueuze (Black Label), Mort Subite (Unfiltered) Gueuze, Oud Beersel Oude Gueuze.

Fruit Lambic
Overall impression: Complex, fruity, pleasantly sour/acidic, balanced, pale, wheat-based ale fermented by a variety of Belgian microbiota. A lambic with fruit, not just a fruit beer.

History: Spontaneously fermented sour ales from the area in and around Brussels (the Senne Valley) that stem from a farmhouse brewing tradition several centuries old. Their numbers are constantly dwindling and some are untraditionally sweetening their products (post-fermentation) with sugar or sweet fruit to make them more palatable to a wider audience. Fruit was traditionally added to lambic or gueuze, either by the blender or publican, to increase the variety of beers available in local cafes.

Comments: Fruit-based lambics are often produced like gueuze by mixing 1- to 3-year-old lambic. "Young" lambic contains fermentable sugars while old lambic has the characteristic "wild" taste of the Senne River valley. Fruit is commonly added halfway through aging and the yeast and bacteria will ferment all sugars from the fruit. Fruit may also be added to unblended lambic. The most traditional styles of fruit lambics include kriek (cherries), framboise (raspberries) and druivenlambik (Muscat grapes).

Ingredients: Unmalted wheat (30–40%), Pilsner malt and aged (surannes) hops (3 years) are used. The aged hops are used more for preservative effects than bitterness, and makes actual bitterness levels difficult to estimate. Fruits traditionally used include tart cherries (with pits), raspberries or Muscat grapes. More recent examples include peaches, apricots or merlot grapes. Tart or acidic fruit is traditionally used as its purpose is not to sweeten the beer but to add a new dimension. Traditionally these beers are spontaneously fermented with naturally occurring yeast and bacteria in predominately oaken barrels. Home- and craft-brewed versions are more typically made with pure cultures of yeast commonly including *Saccharomyces*, *Brettanomyces*, *Pediococcus* and *Lactobacillus* in an attempt to recreate the effects of the dominant microbiota of Brussels and the surrounding countryside of the Senne River valley. Cultures taken from bottles are sometimes used but there is no simple way of knowing which organisms are still viable.

> *Vital statistics*:   OG: 1.040–1.060 (10.0–14.4 °P)
> IBUs: Up to 10   FG: 1.000–1.010
> EBC: 5.9–13.8   ABV: 5–7%

Commercial examples: Boon Framboise Marriage Parfait, Boon Kriek Mariage Parfait, Boon Oude Kriek, Cantillon Fou' Foune (apricot), Cantillon Kriek, Cantillon Lou Pepe

Kriek, Cantillon Lou Pepe Framboise, Cantillon Rose de Gambrinus, Cantillon St. Lamvinus (merlot grape), Cantillon Vigneronne (Muscat grape), De Cam Oude Kriek, Drie Fonteinen Kriek, Girardin Kriek, Hanssens Oude Kriek, Oud Beersel Kriek.

Lager Beer

Andrea Pavsler and Stefano Buiatti Department of Food Science, University of Udine, Udine, Italy

Abstract

Beer is one of the world's oldest alcoholic beverages. Brewing industry is a huge global business, consisting of several multi-national companies and many thousands of smaller producers ranging from brewpubs to regional breweries. A great many of different types, or style, of beer are brewed across the world. For this reason, it is difficult to generalize on the relationship between beer and relative impact on nutrient intake because the composition of beers will range quite considerably depending on raw materials and how they are produced. Lager represents more than 90% of beer produced worldwide. It is typically brewed at low temperatures (bottom fermentation) in cool conditions using a particular yeast, and then stored (the word "lager" comes from the German *lagern* meaning "to store") in cool conditions to have maturation or improvement of its organoleptic characteristics. Until the sixteenth century ale (top fermentation) was the main type of beer in Europe. So it is only a myth that lager-style products have always been the characteristic beer in Germany. The monks of Bavaria were responsible for an innovation that was to change the face of beer brewing, the "bottom fermentation." The Bavarian monasteries first attempted to store beer for long periods in cool cellar. At lower temperatures, instead of frothing to the top of the fermenting vessel, the yeast sank to the bottom end fermenting more slowly. The Bavarian lager was still different from the widely known modern lager. They remained a fairly conventional dark brown or amber-red color, until 1842, when Joseph Groll mashed his first batch of beer in *Plzeň* (in Czech Republic) and the world's first ever golden colored lager was born.

OG	Original gravity
°P	Plato
PVPP	Polyvinylpolypyrrolidone
SO_2	Sulfur dioxide
SMM	*S*-methyl methionine
VDKs	Vicinal diketones

Introduction

Until the sixteenth century ale (top fermentation) was the main type of beer in Europe. So it is only a myth that lager-style products have always been the characteristic beer in Germany. The monks of Bavaria were responsible for an innovation that was to change the face of beer brewing, the "bottom fermentation." At the time, during summer, fermentation was likely to run out of control and bacteria could spoil the drink. The problem was so great that in Germany in 1533, Prince Maximilian I ordained that anyone wishing to brew between April 23 and September 29 had to obtain special permission. This edict was one of the main driving forces for the development of lager beer type. The Bavarian monasteries first attempted to store beer for long periods in cool cellar. This storage method caused some yeasts to change their character. At lower temperatures, instead of frothing to the top of the fermenting vessel, the yeast sank to the bottom end fermenting more slowly. Actually, the most apparent difference between ales and lagers is that lagers use bottom-fermenting yeast. In 1836, Gabriel Sedlmayr took over the running of the *Spaten* Brewery in Munich and developed the art of producing more stable, bottom-fermented beer through cold storage. The Bavarian lager was still different from the widely known modern lager. They remained a fairly conventional dark brown or amber-red color, until 1842, when Joseph Groll mashed his first batch of beer in *Plzeň* (in Czech Republic) and the world's first ever golden colored lager was born.

The development of the present bottom fermentation beer types did not occur until the end of the nineteenth century. This depended on some circumstances such as the invention of the refrigerating machine by Linde in 1871,

Table 3.1 Beverage beer consumption (2004)

Country	Total consumption (million liters)
China	286.40

countries beer is consumed more when compared to wine, but Italy and France drink considerably more wine than beer.

The Czech Republic has the highest *per capita* consumption of beer, over 33 l more than that of their nearest challenger, Germany. Table 3.3 shows that in Europe the first country in beer production is Germany, followed by United Kingdom and Holland (Bamforth, 2003).

Beer Production

- **The first step of brewing process is the milling of malt followed by mashing in which water is added to ground malt.**

In the brewing process, the first step is the milling of the malt (Figure 3.1). The objective is to break up malt and adjuncts to such an extent that the greatest yield of extract is produced in the shortest time in the mashing equipment in use. With most wort separation systems an important objective is to keep malt husk as intact as possible, in order to have an open filter bed that helps wort separation (Briggs *et al.*, 2004).

Ground malt represents a rich source of carbohydrate, degraded protein, various B vitamins, inorganic materials and many enzymes which progressively catalyze the hydrolysis of insoluble polymers (proteins, nucleic acids and carbohydrates) to give soluble products (Hough *et al.*, 1982). The preparation of the malt mash is the most critical operation in the brew house. The malting process will directly determine both chemical properties such as yeast nutrients, alcohol content, peptide and amino acid profile, concentration of unfermented carbohydrates and physical properties such as color, foam and clarity (Ryder and Power, 1994).

There are several methods of mashing to obtain satisfactory wort (an aqueous extract of the malt). In all cases, a mash should be held at a chosen temperature (or at successive different temperatures), for pre-determined times, to allow enzymes to degrade substances. At the end of mashing the sweet or unhopped wort is separated from the undissolved solids,

the development of mechanical glassblowing to manufacture cheap bottles and the invention of beer filtration in 1878 (Kunze, 1996). Every year more than 1,500 millions of hectoliters (1 hl equals 100 l) are consumed in the world (Table 3.1). Lager beers are by far the most widespread beer type throughout the world. As shown in Table 3.2, beer consumption statistics differ enormously among countries. In most

Figure 3.1   The lager brewing process. *Source*: Modified from Buiatti (2004).

the spent grains. The single-step infusion mashing system, commonly associated with the production of ales and stouts, involves the intimate mixing of the ground material, or grist as it is called, with hot water. In brewing, water is commonly known as liquor. The temperature of about 63–65°C is held constant (called "conversion temperature") for a period which may be as short as 30 min or may extend up to 60–90 min. In order to wash virtually all the sweet wort from the undegraded material (the spent grains), further supplies of hot water at say 78–80°C are sprayed over the surface of the mash. The single temperature mashing system is best for the highly modified malt produced in Britain (Briggs *et al.*, 1982), that require only a saccharification rest and no protein rest. Advantages are simplicity of operation and lower capital, energy cost compared to other mashing systems (Goldammer, 1999).

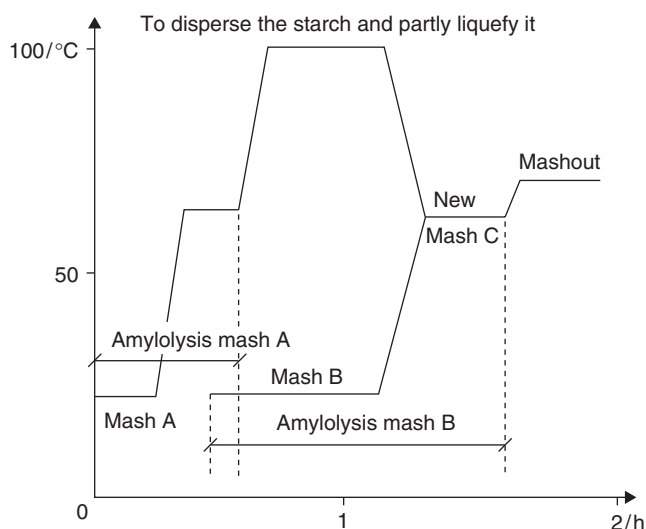
The decoction mashing system is traditional for mainland European lager brewers (Figure 3.2). It differs from infusion mashing in several aspects. The endosperm of the malt used is usually less enzymically degraded and requires more extensive enzymic action in mashing. To aid this, the
Figure 3.2   A temperature scheme for a typical two-decoction mashing program. Two portions of the mash are boiled separately.


Figure 3.3 Typical temperature schedule of double mash infusion process. A scheme of the temperatures using a cereal cooker. (A) the temperature of the adjuncts/grits mash in the cereal cooker, (B) temperature in the malt mash and in the combined mash during and after mixing and (C) mash obtained mixing mashes A and B.

malt is both ground more finely than in infusion process and mixed with water of lower temperature, at 35–40°C. Extensive proteolysis and solubilization occur. During the conversion a portion of the mash (often one-third) is boiled. On return to the main mash, the temperature rises to about 50°C. Later a further third of the mash is withdrawn and boiled; when it is sent back to the main mash, the temperature increases to about 65°C and hydrolysis of carbohydrates (amylolysis) now occurs rapidly. After a last decoction all enzyme activity ceases (mashout) in the consolidated mash at 75°C.

The double mash infusion system (Figure 3.3), common in North American practice, is a method having features in common with infusion and decoction. This is called double mashing because the mash starts as two separate mashes which are later combined. A cereal cooker for boiling adjuncts and a mash tun for well-modified malts is used. The malt is ground and mixed with water to obtain a mash at 38°C (peptonizing rest). After about 20 min, the temperature is rose to 50°C. Unmalted cereal in the form of maize (corn) or rice grits is mixed with a little malt and/or a preparation of microbial enzymes (if permitted by countries regulations), milled and carefully heated in a cereal cooker to 100°C to disperse the starch and partly liquefy it. The two mashes are then mixed together to achieve about 65–72°C, for about 30–40 min. Upon completion of saccharification, temperature rose to a "mashing out" temperature (75–77°C). The wort is then separated from the grain in a process known as lautering. Additional water may be sprinkled on the grains to extract additional sugars (Briggs *et al.*, 1982; Goldammer, 1999).

- **At the end of mash filtration the wort is boiled, clarified, cooled and aerated.**

The sweet wort is transferred to a vessel, boiling kettle, where it is boiled with hops or hop preparations, usually for 60–90 min in order to arrest further enzymes action, sterilize and concentrate the wort and precipitate some of the proteinaceous material as a coarse coagulum (hot *trub*). The boiling process is often associated with the addition of sugars or syrups, and hops or bitter products derived from hops. Additions may be regulated by weight or by α-acid content, and several additions may be made at different stages of the boil. The bitter resins of the hops are extracted during the boil, and particular attention is paid to levels of humulones (α-acids) and lupulones (β-acids). During wort boiling the humulones are isomerized to isohumulones which are more bitter and water soluble. The hot *trub* and any insoluble material from hop is taken out of the wort by centrifugation or by a whirlpool tank. When hopped wort is clarified, it must be brought down to fermentation temperatures before yeast is added through a plate heat exchanger. Further protein and tannin material tend to come out from solution. This precipitation is called cold break (cold *trub*). During the cooling, it is usual to oxygenate or aerate the wort to provide oxygen for the yeast in the initial stages of fermentation (Briggs *et al.*, 2004).

- **After boiling the cooled and aerated wort is pitched with yeast.**

The yeasts used in breweries are conventionally divided into two main classes, top-fermenting and bottom-fermenting. Beer is also divided into two very broad categories according to which yeast is used, respectively, lager and ale. Lager yeast, known as *Saccharomyces pastorianus* or *Saccharomyces carlsbergensis*, runs the fermentation at cool temperatures (8–15°C), and forms a cloudy mass (flocculates) on the bottom of the vessel (Bamforth, 2003). The beers so produced are called bottom fermented. Lager term therefore refers to the secondary fermentation, maturation and storage which these beers traditionally receive after primary fermentation. To produce ale beers, strains of *Saccharomyces cerevisiae* are commonly used in the temperature range of 16–24°C. The inoculation of wort is called "pitching," and the pitching rate depends on fermentation temperature (so lager and ale are different), wort gravity, yeast strain and other variables (Munroe, 1994). A pitching range of $10\text{--}25 \times 10^6$ cells/ml is normally used. As a rule of thumb, the pitching rate is 1×10^6 cells per Plato (°P) per milliliter of wort (Knudsen, 1999). The pitching rate is very important and affects both beer flavor and fermentation rate. Compared to low pitching rates, higher pitching rates will lead to a lower number of cells doubling under fixed oxygen supply. As the pitching rate becomes too low, the oxygen requested to synthesize sterols for new cells is lower and overall growth is lowered.

Poor yeast can also lead to high sulfur dioxide (SO_2) concentrations (Munroe, 1994).

- **The fermentation process starts after 4–6 h, depending on the temperature.**

Lager beers produced by bottom-fermenting yeasts are the most widespread beer types throughout the world (more than 90%). Lager yeast typically undergoes primary fermentation at 8–15°C, followed by a long secondary fermentation between −1°C and +4°C (the "lagering phase"), by having some 1% remaining fermentable extract and also about $1–4 \times 10^6$ cells/ml of yeast in suspension. Now, with modern improved fermentation control, most lager breweries use only short periods of cold storage, typically 1–3 weeks.

- **Lager beer after primary fermentation is stored in cool conditions to have maturation with improvement of its flavor.**

This period causes proteins to coagulate and settle out with the yeast giving improved beer stability. During the maturation, the yeast continues to attack the residual fermentable material, and the carbon dioxide (CO_2) produced is effective in purging any air out of the beer and also much of hydrogen sulfide (H_2S, odor of rotten eggs), sulfur dioxide (SO_2) and dimethyl sulfide (DMS). These are all the results of yeast metabolism, although the majority of DMS comes from *S*-methyl methionine (SMM), an amino acid present in malt, when wort is heated or malt is kilned. In general, for bottom-fermented beers, the technique of maturation must ensure the production of a balanced beer flavor with the minimum concentration of diacetyl (2,3-butanedione). Diacetyl and the related compound 2,3-pentanedione are called vicinal diketones (VDKs). They are generally undesidered contributors to the flavor of lager beers. VDKs are originated by yeast as it synthesizes the amino acids, valine and leucine (Figure 3.4). In this pathway, α-acetolactate is transported out of the cell, where it is non-enzymically converted in diacetyl, compound with a negative buttery flavor. This chemical reaction is accelerated by higher temperature and lower pH. Diacetyl is later converted to 2,3-butanediol by the yeast, compounds having a lower flavor impact (Munroe, 1994). Still another possibility is to add to the lager tank fermenting wort at the *Kräusen* stage (phase in which yeast shows its maximum activity). This addition of fermentable extract at the rate of 5–10% by volume is called "Kräusening" (Hough *et al.*, 1982). The active yeast from the *Kräusen* beer can reduce the diacetyl level in the original beer in shortest time.

- **After fermentation beer is extremely turbid, due to the presence of residual yeast and colloidal haze. The purpose of filtration is to obtain a beer stable for a long time.**
Figure 3.4   Formation of diacetyl and its conversion.

There are various processing techniques for clarification (gravity sedimentation, centrifugation and filtration), but only filtration is able to give the brilliance required in the marketplace. Several chillproofing techniques are employed in order to remove proteins and tannins present in beer which tend to combine together slowly and form colloidal haze. Insoluble polyvinylpolypyrrolidone (PVPP) is, for example, an effective adsorbent of tannins and it is normally added to a tank of pre-filtered beer. Other media used are silica gels and diatomaceous earth (*Kieselguhr*). Silica gels have been successfully used as protein adsorbents, so they cannot combine with polyphenols. *Kieselguhr* selectively removes particles of a certain size and is the filtering coadjutant most commonly used to remove yeast cells. The small diatoms, deposited upon a filter septum, form a rigid and porous filter cake which sieves out the particulate matter in beer. The precoats, made of cellulose and/or *Kieselguhr* of different sizes, would soon become blocked with the suspended particles in the beer, but this is avoided by regular injections of fresh *Kieselguhr* (Patino, 1999).

- **The yeast, besides ethanol and CO_2, produces several by-products that have a great effect on the flavor of beer.**

Fermentation by-products have a great effect on the flavor and aroma of the beer, and the factors which influence their formation are very important to the brewer. As previously described, diacetyl is the most important aroma of not mature beer, and the technique of maturation must ensure the production of a balanced beer flavor with the minimum concentration of diacetyl. Moreover, sulfur compounds (H_2S, SO_2, DMS, see above) have a very strong smell taste. The CO_2 produced during the fermentation is effective in purging any air out of the beer. On the other hand, there are other

Table 3.4 Flavor compounds associated with yeast metabolism in lager and ale

Class of volatile	Name	Lager (mg/l)	Ale (mg/l)
Higher alcohols	Ethanol	23–25 (g/l)	27–32 (g/l)
	2-methylbutanol	8–16	14–19

flavor compounds such as higher alcohol (or fusel alcohols) and esters that contribute directly to final product aroma.

Most of higher alcohols are formed during primary fermentation. They can be formed from amino acids, from sugars and by other biosynthetic ways (Kunze, 1996). The most important higher alcohols are reported in Table 3.4. The lower temperature fermentations of lagers, limit the production of fusel alcohols (Goldammer, 1999).

Esters, which are produced during fermentation by esterification of fatty acids by ethanol or, in small amounts, by higher alcohols, have long been recognized as important flavor determinants in beers, with many being present at or near their sensory thresholds (Engan, 1981; Kunze, 1996). In general they impart fruity taste to beer. The production of esters is dependent on several factors, such as fermentation temperature, oxygen content, original gravity, pitching rates and yeast strain (Lewis and Bamforth, 2006). As showed in Table 3.4, the ester content in ale is higher than lager beer. It is generally accepted that top-fermented beer is more aromatic than a bottom-fermented beer, both having an identical original gravity (OG). Top-fermented beers, with their typically higher fermentation temperatures (16–24°C) and different yeast strains, usually contain more esters and fusel alcohols, and they often have higher alcohol content (Derdelinckx and Neven, 1996).

- **The microbiological stabilization, through pasteurization or sterile filtration, are the last operations before packaging.**

The term "microbiological stabilization" describes a process whereby spoilage mechanisms, such as bacteria and yeast, are destroyed or removed from the product. These spoilage mechanisms can cause off-flavor and hazing in the final beer and affect the expected shelf-life. Thus, it is important

that such contaminants are removed. A traditional method used to destroy the number of microorganisms is pasteurization. The basis of this process is the heating of the beer to a specific temperature for a pre-determined period of time to attain the minimum degree of pasteurization necessary to inactivate beer-spoiling bacteria. The two main pasteurization techniques used are "flash" and "tunnel". Flash pasteurization is used for the continuous treatment of bulk beer prior to filling kegs. It is typically carried out in a plate heat exchanger, with steam as the heat exchange medium. The beer is heated to between 72°C and 74°C and held in this temperature range for 15–30 s.

Tunnel pasteurization, on the other hand, is applied after the bottles and cans have been filled and sealed. The bottles are loaded at one end of the pasteurizer and passed under sprays of hot water as they move along the conveyor. The sprays are arranged so that the bottles are subjected to increasingly hot water until the beer in the bottles reaches the pasteurization temperature of 60°C. The bottles are then cooled gradually with water until they are discharged from the end of the pasteurizer. The temperature changes are made in stages to prevent the bottles from breaking. The heating and cooling of the bottles are performed using various water circulation paths to enable the reuse of the recovered heat. In this way, the energy usage by the tunnel pasteurizer can be kept to a minimum. Although disagreement exists within the brewing community, one criticism leveled against the use of pasteurization is the risk of damaging the flavor of the beer with the heat treatment. An alternative to pasteurization that has been used for many years is sterile filtration. This process has the obvious advantage over pasteurization of eliminating the risk of adversely affecting the beer's flavor characteristics, while at the same time effectively removing the spoilage microorganisms (Scanlon, 2004; Lewis and Bamforth, 2006).

Beer Types

There are many thousands of different beer brands throughout the world, many of which can be classified in defined beer types which have developed in the course of time in a few countries or regions. Depending on the process used, a first classification could be made into top fermentation and bottom fermentation beer types. Table 3.5 gives a breakdown of some principal beer types.

Bottom fermentation beer types

In the text below, there are reported a list of bottom fermentation beer types (BJCP, 2004). Beer strength may be defined in several ways; to explain the vital statistics of each style, it is used to explain the content of hop bitter substances (IBU, International Bitterness Units), the color

Table 3.5 Some principal beer types

Types of beers	Origin	Characteristics	Typical range of alcohol (% by vol.)
Bottom fermentation			
German Pilsner (Pils)	Germany	Crisp, clean, refreshing beer	4.4–5.2
Bohemian Pilsner	Czech Republic	Crisp, complex and well rounded yet refreshing	4.2–5.4
Classic American Pilsner	United States	Rice contributes a crisper, more neutral character	4.5–6.0
Vienna lager	Austria	Soft, elegant maltiness	4.5–5.7
Oktoberfest/Märzen	Germany	Depth of malt character	4.8–5.7
Dark American lager	United States	Sweeter version of standard lager	4.2–6.0
Munich Dunkel	Germany	Depth and complexity	4.5–5.6
Schwarzbier (black beer)	Germany	Probably a variant of the Munich *Dunkel* style	4.4–5.4
Maibock/Helles bock	Germany	Pale, strong, malty lager beer	6.3–7.4
Traditional bock	Germany	Dark, strong, malty lager beer	6.3–7.2
Doppelbock	Germany	Strong and rich lager	7–10+
Eisbock	Germany	An extremely strong, full and malty dark lager	9–14+
Top fermentation			
Standard/ordinary bitter	Britain	Low gravity, low alcohol levels	3.2–3.8
English Pale Ale	Britain	Dry hop, bitter, estery, malty, low carbonation	4.6–6.2
Mild	Britain	Refreshing, yet flavorful	2.8–4.2
Brown Porter	Britain	English dark ale with restrained roasty characteristics	4.0–5.4
Robust Porter	Britain	Malty dark ale	4.8–6.0
Dry Stout	Ireland	Dark, roasty, bitter, creamy ale	4.0–5.0
Sweet Stout	Britain	Dark, sweet, full-bodied, slightly roasty ale	4.0–6.0
Kölsch	Germany (Cologne)	Smooth and crisp	4.4–5.2
Lambic	Belgium	Fermented by a variety of Belgian microbiota	5.0–7.0
Rauchbier	Germany	Smoky aroma and flavor and a somewhat dark color	4.8–6.0
Weizen/Weissbier	Germany	Pale, spicy, fruity, refreshing wheat-based ale	4.3–5.6
Weizenbock	Germany	Strong, malty, fruity, wheat-based ale	6.5–8.0+

Source: Most of the data in this table is from BJCP Style Guidelines (2004).

(EBC, European Brewery Convention), the specific gravity of wort before fermentation (OG, original gravity) and after fermentation (FG, final gravity), and the alcohol content (ABV or alcohol by volume).

Pilsner

German Pilsner (pils)

Aroma: Typically features a light grainy malt character and distinctive flowery or spicy noble hops. Clean, no fruity esters, no diacetyl. May have an initial sulfuric aroma (from water and/or yeast) and a low background note of DMS (from pils malt).

Appearance: Straw to light gold, brilliant to very clear, with a creamy, long-lasting white head.

Flavor: Crisp and bitter, with a dry to medium-dry finish. Moderate to moderately low yet well-attenuated maltiness, although some grainy flavors and slight malt sweetness are acceptable. Hop bitterness dominates taste and continues through the finish and lingers into the aftertaste. Hop flavor can range from low to high but should only be derived from German noble hops. Clean, no fruity esters, no diacetyl.

Mouthfeel: Medium-light body, medium to high carbonation.

Overall impression: Crisp, clean, refreshing beer that prominently features noble German hop bitterness accentuated by sulfates in the water.

History: A copy of Bohemian Pilsner adapted to brewing conditions in Germany.

Comments: Drier and crisper than a Bohemian Pilsner with a bitterness that tends to linger more in the aftertaste due to higher attenuation and higher sulfate water. Lighter in body and color, and with higher carbonation than a Bohemian Pilsner.

Ingredients: Pilsner malt, German hop varieties (especially noble varieties such as Hallertauer, Tettnanger and Spalt for taste and aroma), medium sulfate water, German lager yeast.

Vital statistics: OG: 1.044–1.050 (11.0–12.4 °P)
IBUs: 25–45   FG: 1.008–1.013
EBC: 3.9–9.8   ABV: 4.4–5.2%

Commercial examples: Bitburger, Warsteiner, König Pilsner, Jever Pils, Holsten Pils, Spaten Pils, Victory Prima Pils, Brooklyn Pilsner.

Bohemian Pilsner

Aroma: Rich with complex malt and a spicy, floral Saaz hop bouquet. Some diacetyl is acceptable, but need not be present. Otherwise clean, with no fruity esters.

Appearance: Very pale gold to deep burnished gold, brilliant to very clear, with a dense, long-lasting, creamy white head.

Flavor: Rich, complex maltiness combined with a pronounced yet soft and rounded bitterness and flavor from Saaz hops. Some diacetyl is acceptable, but need not be present. Bitterness is prominent but never harsh, and does not linger. The aftertaste is balanced between malt and hops. Clean, no fruity esters.

Mouthfeel: Medium-bodied (although diacetyl, if present, may make it seem medium-full), medium carbonation.

Overall impression: Crisp, complex and well rounded yet refreshing.

History: First brewed in 1842, this style was the original clear, light-colored beer.

Comments: Uses Moravian malted barley and a decoction mash for rich, malt character. Saaz hops and low sulfate, low carbonate water provide a distinctively soft, rounded hop profile. Traditional yeast sometimes can provide a background diacetyl note. Dextrins provide additional body, and diacetyl enhances the perception of a fuller palate.

Ingredients: Soft water with low mineral content, Saaz hops, Moravian malted barley, Czech lager yeast.

Vital statistics: OG: 1.044–1.056 (11.0–13.8 °P)
IBUs: 35–45   FG: 1.013–1.017
EBC: 6.9–11.8   ABV: 4.2–5.4%

Commercial examples: Pilsner Urquell, Budweiser Budvar (Czechvar in the United States), Czech Rebel, Staropramen, Gambrinus Pilsner, Dock Street Bohemian Pilsner.

Classic American Pilsner

Aroma: Low to medium grainy, corn-like or sweet maltiness may be evident (although rice-based beers are more neutral). Medium to moderately high hop aroma, often classic noble hops. Clean lager character, with no fruitiness or diacetyl. Some DMS is acceptable.

Appearance: Yellow to deep gold color. Substantial, long-lasting white head. Bright clarity.

Flavor: Moderate to moderately high maltiness similar in character to the Continental Pilsners but somewhat lighter in intensity due to the use of up to 30% flaked maize (corn) or rice used as an adjunct. Slight grainy, corn-like sweetness from the use of maize with substantial offsetting hop bitterness. Rice-based versions are crisper, drier, and often lack corn-like flavors. Medium to high hop flavor from noble hops (either late addition or first-wort hopped).

Mouthfeel: Medium body and rich, creamy mouthfeel. Medium to high carbonation levels.

Overall impression: A substantial Pilsner that can stand up to the classic European Pilsners, but exhibiting the native American grains and hops available to German brewers who initially brewed it in the United States. Refreshing, but with the underlying malt and hops that stand out when compared to other modern American light lagers. Maize lends a distinctive grainy sweetness.

History: A version of Pilsner brewed in the United States by immigrant German brewers who brought the process and yeast with them when they settled in America. They worked with the ingredients that were native to America to create a unique version of the original Pilsner. This style died out after prohibition but was resurrected as a home-brewed style by advocates of the hobby.

Comments: The classic American Pilsner brewed both pre-prohibition and post-prohibition with some differences. OGs of 1.050–1.060 would have been appropriate for pre-prohibition beers while gravities dropped to 1.044–1.048 after prohibition. Corresponding IBUs dropped from a pre-prohibition level of 30–40 to 25–30 after prohibition.

Ingredients: Six-row barley with 20–30% flaked maize to dilute the excessive protein levels. Native American hops such as Clusters, traditional continental noble hops or modern noble crosses (Ultra, Liberty, Crystal) are also appropriate. Water with a high mineral content can lead to an inappropriate coarseness in flavor and harshness in aftertaste.

Vital statistics: OG: 1.044–1.060 (11.0–14.7 °P)
IBUs: 25–40   FG: 1.010–1.015
EBC: 5.9–11.8   ABV: 4.5–6%

Commercial examples: Occasional brewpub and micro-brewery specials.

European Amber Lager

Vienna lager

Aroma: Moderately rich German malt aroma (of Vienna and/or Munich malt). A light-toasted malt aroma may be present. Similar, though less intense than Oktoberfest. Clean lager character, with no fruity esters or diacetyl. Noble hop aroma may be low to none. Caramel aroma is inappropriate.

Appearance: Light reddish amber to copper color. Bright clarity. Large, off-white, persistent head.

Flavor: Soft, elegant malt complexity is in the forefront, with a firm enough hop bitterness to provide a balanced finish. Some toasted character from the use of Vienna malt. No roasted or caramel flavor. Fairly dry finish, with both malt and hop bitterness present in the aftertaste. Noble hop flavor may be low to none.

Mouthfeel: Medium-light to medium body, with a gentle creaminess. Moderate carbonation. Smooth. Moderately crisp finish. May have a bit of alcohol warming.

Overall impression: Characterized by soft, elegant maltiness that dries out in the finish to avoid becoming sweet.

History: The original amber lager developed by Anton Dreher shortly after the isolation of lager yeast. Nearly extinct in its area of origin, the style continues in Mexico where it was brought by Santiago Graf and other Austrian immigrant brewers in the late 1800s. Regrettably, most modern examples use adjuncts which lessen the rich malt complexity characteristic of the best examples of this style. The style owes much of its character to the method of malting (Vienna malt).

Comments: American versions can be a bit stronger, drier and more bitter, while European versions tend to be sweeter. Many Mexican amber and dark lagers used to be more authentic, but unfortunately are now more like sweet, adjunct-laden American Dark Lagers.

Ingredients: Vienna malt provides a lightly toasty and complex, melanoidin-rich malt profile. As with Oktoberfests, only the finest quality malt should be used, along with continental hops (preferably noble varieties). Moderately hard, carbonate-rich water. Can use some caramel malts and/or darker malts to add color and sweetness, but caramel malts should not add significant aroma and flavor, and dark malts should not provide any roasted character.

Vital statistics: OG: 1.046–1.052 (11.4–12.9 °P)
IBUs: 18–30   FG: 1.010–1.014
EBC: 11.0–31.5   ABV: 4.5–5.7%

Commercial examples: Great Lakes Eliot Ness (unusual in its 6.2% strength and 35 IBUs), Gösser Dark, Noche Buena, Negra Modelo, Samuel Adams Vienna Style Lager, Old Dominion Aviator Amber Lager, Gordon Biersch Vienna Lager, Capital Wisconsin Amber.

Oktoberfest/Märzen

Aroma: Rich German malt aroma (of Vienna and/or Munich malt). A light- to moderate-toasted malt aroma is often present. Clean lager aroma with no fruity esters or diacetyl. No hop aroma. Caramel aroma is inappropriate.

Appearance: Dark gold to deep orange-red color. Bright clarity, with solid foam stand.

Flavor: Initial malty sweetness, but finish is moderately dry. Distinctive and complex maltiness often includes a toasted aspect. Hop bitterness is moderate, and noble hop flavor is low to none. Balance is toward malt, though the finish is not sweet. Noticeable caramel or roasted flavors are inappropriate. Clean lager character with no diacetyl or fruity esters.

Mouthfeel: Medium body, with a creamy texture and medium carbonation. Smooth. Fully fermented, without a cloying finish.

Overall impression: Smooth, clean and rather rich with a depth of malt character. This is one of the classic malty styles, with a maltiness that is often described as soft, complex and elegant but never cloying.

History: Origin is credited to Gabriel Sedlmayr, based on an adaptation of the Vienna style developed by Anton Dreher around 1840, shortly after lager yeast was first isolated. Typically, brewed in the spring, signaling the end of the traditional brewing season and stored in cold caves or cellars during the warm summer months. Served in autumn amidst traditional celebrations.

Ingredients: Grist varies, although German Vienna malt is often the backbone of the grain bill, with some Munich malt, Pils malt and possibly some crystal malt. All malt should derive from the finest quality two-row barley. Continental hops, especially noble varieties, are most authentic. Somewhat alkaline water (up to 300 ppm) with significant carbonate content is welcome. A decoction mash can help to develop the rich malt profile.

Vital statistics: OG: 1.050–1.056 (12.4–13.8 °P)
IBUs: 20–28   FG: 1.012–1.016
EBC: 13.8–27.6   ABV: 4.8–5.7%

Commercial examples: Paulaner Oktoberfest, Hacker-Pschorr Original Oktoberfest, Ayinger Oktoberfest-Märzen, Hofbräu Oktoberfest, Spaten Oktoberfest, Eggenberger Märzen, Goose Island Oktoberfest, Capital Oktoberfest, Gordon Biersch Märzen, Samuel Adams Oktoberfest (a bit unusual in its late hopping).

Dark Lager

Dark American lager

Aroma: Little to no malt aroma. Medium-low to no roast and caramel malt aroma. Hop aroma may range from none to light spicy or floral hop presence. Hop aroma may range from none to light, spicy or floral hop presence. Can have low levels of yeast character (green apples, DMS or fruitiness). No diacetyl.

Appearance: Deep amber to dark brown with bright clarity and ruby highlights. Foam stand may not be long lasting, and is usually light tan in color.

Flavor: Moderately crisp with some low to moderate levels of sweetness. Medium-low to no caramel and/or roasted malt flavors (and may include hints of coffee, molasses or cocoa). Hop flavor ranges from none to low levels. Hop bitterness at low to medium levels. No diacetyl. May have a very light fruitiness. Burnt or moderately strong roasted malt flavors are a defect.

Mouthfeel: Light to somewhat medium body. Smooth, although a highly carbonated beer.

Overall impression: A somewhat sweeter version of standard/premium lager with a little more body and flavor.

Comments: A broad range of international lagers that are darker than pale, and not assertively bitter and/or roasted.

Ingredients: Two- or six-row barley, corn or rice as adjuncts. Light use of caramel and darker malts. May use coloring agents.

Vital statistics: OG: 1.044–1.056 (11.0–13.8 °P)
IBUs: 8–20 FG: 1.008–1.012
EBC: 27.6–43.3   ABV: 4.2–6%

Commercial examples: Dixie Blackened Voodoo, Shiner Bock, San Miguel Dark, Beck's Dark, Saint Pauli Girl Dark, Warsteiner Dunkel, Crystal Diplomat Dark Beer.

Munich Dunkel

Aroma: Rich, Munich malt sweetness, like bread crusts (and sometimes toast.) Hints of chocolate, nuts, caramel and/or toffee are also acceptable. No fruity esters or diacetyl should be detected, but a slight noble hop aroma is acceptable.

Appearance: Deep copper to dark brown, often with a red or garnet tint. Creamy, light to medium tan head. Usually clear, although murky unfiltered versions exist.

Flavor: Dominated by the rich and complex flavor of Munich malt, usually with melanoidins reminiscent of bread crusts. The taste can be moderately sweet, although it should not be overwhelming or cloying. Hints of caramel, chocolate, toast or nuttiness may be present in the background. Burnt or bitter flavors from roasted malts are inappropriate, as are pronounced caramel flavors from crystal malt. Hop bitterness is moderately low but perceptible, with the balance tipped firmly toward maltiness.

Mouthfeel: Medium to medium-full body, providing a firm and dextrinous mouthfeel without being heavy or cloying. Moderate carbonation. May have a light astringency and a slight alcohol warming.

Overall impression: Characterized by depth and complexity of Munich malt and the accompanying melanoidins. Rich Munich flavors, but not as intense as a bock or as roasted as a *Schwarzbier*.

History: The classic brown lager style of Munich which developed as a darker, malt-accented beer in part because of the moderately carbonate water.

Comments: Unfiltered versions from Germany can taste like liquid bread, with a yeasty, earthy richness not found in exported filtered *Dunkels*.

Ingredients: Grist is primarily made up of German Munich malt (up to 100% in some cases) with the remainder German Pilsner malt. Very small amounts of crystal malt can add dextrins and color but should not introduce excessive sweetness. Very slight additions of roasted malts (such as Carafa or chocolate) may be used to improve color but should not add any flavor. Noble German hop varieties and German lager yeast strains should be used. Moderately carbonate water.

Vital statistics: OG: 1.048–1.056 (11.9–13.8 °P)
IBUs: 18–28   FG: 1.010–1.016
EBC: 27.6–55.1   ABV: 4.5–5.6%

Commercial examples: Ayinger Altbairisch Dunkel, Hacker-Pschorr Alt Munich Dark, Paulaner Alt Münchner Dunkel, Weltenburger Kloster Barock-Dunkel, Penn Dark Lager, Capital Munich Dark, Harpoon Munich-type Dark Beer, Gordon Biersch Dunkels, Dinkel Acker Dark.

Schwarzbier (black beer)

Aroma: Low to moderate malt, with low aromatic sweetness and/or hints of roast malt often apparent. The malt can be clean and neutral or rich and Munich-like, and may have a hint of caramel. The roast can be coffee-like but should never be burnt. A low noble hop aroma is optional. Clean lager yeast character (light sulfur possible) with no fruity esters or diacetyl.

Appearance: Medium to very dark brown in color, often with deep ruby to garnet highlights, yet almost never truly black. Very clear. Large, persistent, tan-colored head.

Flavor: Light to moderate malt flavor, which can have a clean, neutral character to a rich, sweet, Munich-like intensity. Light to moderate roasted malt flavors can give a bitter-chocolate palate that lasts into the finish, but which are never burnt. Medium-low to medium bitterness, which can last till the end. Light to moderate noble hop flavor. Clean lager character with no fruity esters or diacetyl.

Mouthfeel: Medium-light to medium body. Moderate to moderately high carbonation. Smooth. No harshness or astringency, despite the use of dark, roasted malts.

Overall impression: A dark German Lager that balances roasted yet smooth malt flavors with moderate hop bitterness.

History: A regional specialty from southern Thuringen and northern Franconia in Germany, and probably a variant of the Munich Dunkel style.

Comments: In comparison with a Munich Dunkel, usually darker in color, drier on the palate and with a noticeable (but not high) roasted malt edge to balance the malt base. While sometimes called a "black pils," the beer is rarely that dark; do not expect strongly roasted, porter-like flavors.

Ingredients: German Munich malt and Pilsner malts for the base, supplemented by a small amount of roasted malts (such as Carafa) for the dark color and subtle roast flavors. Noble-type German hop varieties and clean German lager yeasts are preferred.

Vital statistics: OG: 1.046–1.052 (11.4–12.5 °P)
IBUs: 22–32   FG: 1.010–1.016
EBC: 27.6–55.1+   ABV: 4.4–5.4%

Commercial examples: Köstritzer Schwarzbier, Kulmbacher Mönchshof Premium Schwarzbier, Einbecker Schwarzbier, Weeping Radish Black Radish Dark Lager, Sprecher Black Bavarian, Sapporo Black Beer.

Bock

Maibock/Helles bock

Aroma: Moderate to strong malt aroma, often with a lightly toasted quality and low melanoidins. Moderately low to no noble hop aroma, often with a spicy quality. Clean. No

diacetyl. Fruity esters should be low to none. Some alcohol may be noticeable. May have a light DMS aroma from pils malt.

Appearance: Deep gold to light amber in color. Lagering should provide good clarity. Large, creamy, persistent, white head.

Flavor: The rich flavor of continental European pale malts dominates (pils malt flavor with some toasty notes and/or melanoidins). Little to no caramelization. May have a light DMS flavor from pils malt. Moderate to no noble hop flavor. May have a low spicy or peppery quality from hops and/or alcohol. Moderate hop bitterness (more so in the balance than in other bocks).

Mouthfeel: Medium-bodied. Moderate to moderately high carbonation. Smooth and clean with no harshness or astringency, despite the increased hop bitterness. Some alcohol warming may be present.

Overall impression: A relatively pale, strong, malty lager beer. Designed to walk a fine line between blandness and too much color. Hop character is generally more apparent than in other bocks.

History: A fairly recent development in comparison to the other members of the bock family. The serving of Maibock is specifically associated with springtime and the month of May.

Comments: Can be thought of as either a pale version of a traditional bock or a Munich Helles brewed to bock strength. While quite malty, this beer typically has less dark and rich malt flavors than a traditional bock. May also be drier, more hopped and more bitter than a traditional bock. The hops compensate for the lower level of melanoidins. There is some dispute whether Helles (pale) Bock and Mai (May) Bock are synonymous.

Ingredients: Base of pils and/or Vienna malt with some Munich malt to add character (although much less than in a traditional bock). No non-malt adjuncts. Noble hops. Soft water preferred so as to avoid harshness. Clean lager yeast. Decoction mash is typical, but boiling is less than in traditional bocks to restrain color development.

Vital statistics: OG: 1.064–1.072 (15.7–17.5 °P)
IBUs: 23–35+   FG: 1.011–1.018
EBC: 11.8–21.7   ABV: 6.3–7.4%

Commercial examples: Ayinger Maibock, Hacker-Pschorr Hubertus Bock, Einbecker Mai-Urbock, Augustiner Hellerbock, Hofbräu Maibock, Capital Maibock, Victory St. Boisterous, Gordon Biersch Blonde Bock.

Traditional bock

Aroma: Strong malt aroma, often with moderate amounts of rich melanoidins and/or toasty overtones. Virtually no hop aroma. Some alcohol may be noticeable. Clean. No diacetyl. Low to no fruity esters.

Appearance: Light copper to brown color, often with attractive garnet highlights. Lagering should provide good

clarity despite the dark color. Large, creamy, persistent, off-white head.

Flavor: Complex maltiness is dominated by the rich flavors of Munich and Vienna malts, which contribute melanoidins and toasty flavors. Some caramel notes may be present from decoction mashing and a long boil. Hop bitterness is generally only high enough to support the malt flavors, allowing a bit of sweetness to linger into the finish. Well attenuated, not cloying. Clean, with no esters or diacetyl. No hop flavor. No roasted or burnt character.

Mouthfeel: Medium to medium-full bodied. Moderate to moderately low carbonation. Some alcohol warmth may be found, but should never be hot. Smooth, without harshness or astringency.

Overall impression: A dark, strong, malty lager beer.

History: Originated in the Northern German city of Einbeck, which was a brewing center and popular exporter in the days of the Hanseatic League (fourteenth to seventeenth centuries). Recreated in Munich starting in the seventeenth century. The name "bock" is based on a corruption of the name "Einbeck" in the Bavarian dialect, and was thus only used after the beer came to Munich. "Bock" also means "billy-goat" in German, and is often used in logos and advertisements.

Comments: Decoction mashing and long boiling plays an important part of flavor development, as it enhances the caramel and melanoidin flavor aspects of the malt. Any fruitiness is due to Munich and other specialty malts, not yeast-derived esters developed during fermentation.

Ingredients: Munich and Vienna malts, rarely a tiny bit of dark roasted malts for color adjustment, never any non-malt adjuncts. Continental European hop varieties are used. Clean lager yeast. Water hardness can vary, although moderately carbonate water is typical of Munich.

Vital statistics: OG: 1.064–1.072 (15.7–17.5 °P)
IBUs: 20–27   FG: 1.013–1.019
EBC: 27.6–43.3   ABV: 6.3–7.2%

Commercial examples: Einbecker Ur-Bock Dunkel, Aass Bock, Great Lakes Rockefeller Bock.

Doppelbock

Aroma: Very strong maltiness. Darker versions will have significant melanoidins and often some toasty aromas. A light caramel flavor from a long boil is acceptable. Lighter versions will have a strong malt presence with some melanoidins and toasty notes. Virtually no hop aroma, although a light noble hop aroma is acceptable in pale versions. No diacetyl. A very slight chocolate-like aroma may be present in darker versions, but no roasted or burned aromatics should ever be present. Moderate alcohol aroma may be present.

Appearance: Deep gold to dark brown in color. Darker versions often have ruby highlights. Lagering should provide good clarity. Large, creamy, persistent head (color varies

with base style: white for pale versions, off-white for dark varieties). Stronger versions might have impaired head retention, and can display noticeable legs.

Flavor: Very rich and malty. Darker versions will have significant melanoidins and often some toasty flavors. Lighter versions will have a strong malt flavor with some melanoidins and toasty notes. A very slight chocolate flavor is optional in darker versions, but should never be perceived as roasty or burnt. Clean lager flavor with no diacetyl. Some fruitiness (prune, plum or grape) is optional in darker versions. Invariably there will be an impression of alcoholic strength, but this should be smooth and warming rather than harsh or burning.

Mouthfeel: Medium-full to full body. Moderate to moderately low carbonation. Very smooth without harshness or astringency.

Overall impression: A very strong and rich lager. A bigger version of either a traditional bock or a helles bock.

History: A Bavarian specialty first brewed in Munich by the monks of St. Francis of Paula. Historical versions were less well attenuated than modern interpretations, with consequently higher sweetness and lower alcohol levels (and hence was considered "liquid bread" by the monks). The term "doppel (double) bock" was coined by Munich consumers. Many doppelbocks have names ending in "-ator," either as a tribute to the prototypical Salvator or to take advantage of the beer's popularity.

Comments: Most versions are dark colored and may display the caramelizing and melanoidin effect of decoction mashing, but excellent pale versions also exist. The pale versions will not have the same richness and darker malt flavors of the dark versions, and may be a bit drier, more hopped and more bitter.

Ingredients: Pils and/or Vienna malt for pale versions (with some Munich), Munich and Vienna malts for darker ones and occasionally a tiny bit of darker color malts (such as Carafa). Noble hops. Water hardness varies from soft to moderately carbonate. Clean lager yeast. Decoction mashing is traditional.

Vital Statistics:	OG: 1.072–1.096+ (17.5–22.9+ °P)
IBUs: 16–26+	FG: 1.016–1.024+
EBC: 11.8–49.2	ABV: 7–10+%

Commercial examples: Paulaner Salvator, Ayinger Celebrator, Spaten Optimator, Tucher Bajuvator, Augustiner Maximator, Weihenstephaner Korbinian, Weltenburger Kloster Asam-Bock, EKU 28, Eggenberg Urbock 23°, Samichlaus, Bell's Consecrator, Moretti La Rossa.

Eisbock

Aroma: Dominated by a balance of rich, intense malt and a definite alcohol presence. No hop aroma. No diacetyl. May have significant fruity esters, particularly those reminiscent of plum, prune or grape. Alcohol aromas should not be harsh or solvency.

Appearance: Deep copper to dark brown in color, often with attractive ruby highlights. Lagering should provide good clarity. Head retention may be impaired by higher-than-average alcohol content and low carbonation. Pronounced legs are often evident.

Flavor: Rich, sweet malt balanced by a significant alcohol presence. The malt can have melanoidins, toasty qualities, some caramel and occasionally a slight chocolate flavor. No hop flavor. Hop bitterness just offsets the malt sweetness enough to avoid a cloying character. No diacetyl. May have significant fruity esters, particularly those reminiscent of plum, prune or grape.

Mouthfeel: Full to very full bodied. Low carbonation. Significant alcohol warmth without sharp hotness. Very smooth without harsh edges from alcohol, bitterness, fusels or other concentrated flavors.

Overall impression: An extremely strong, full and malty dark lager.

History: A traditional Kulmbach specialty brewed by freezing a doppelbock and removing the ice to concentrate the flavor and alcohol content (as well as any defects).

Comments: Eisbocks are not simply stronger doppelbocks; the name refers to the process of freezing and concentrating the beer. Some doppelbocks are stronger than Eisbocks. Extended lagering is often needed post-freezing to smooth the alcohol and enhance the malt and alcohol balance. Any fruitiness is due to Munich and other specialty malts, not yeast-derived esters developed during fermentation.

Ingredients: Same as doppelbock. Commercial eisbocks are generally concentrated anywhere from 7% to 33% (by volume).

Vital statistics:	OG: 1.078–1.120+ (18.9–28.1+°P)
IBUs: 25–35+	FG: 1.020–1.035+
EBC: 35.5–59.1+	ABV: 9–14+%

Commercial examples: Kulmbacher Reichelbräu Eisbock, Eggenberg Urbock Dunkel Eisbock, Niagara Eisbock, Southampton Eisbock.

The information about the bottom fermentation beer types comes from the 2004 BJCP Style Guidelines, which are Copyright © 2004, Beer Judge Certification Program, Inc. The most current version of the guidelines is found on the BJCP website (http://www.bjcp.org).

Traditional and Modern Japanese Beers: Methods of Production and Composition

Masato Kawasaki Research Laboratories for Brewing, Technology Development Department, Production Division, Kirin Brewery Company, Limited, Yokohama, Japan
Shuso Sakuma Quality Assurance Center for Alcoholic Beverages, Quality Assurance Department, Production Division, Kirin Brewery Company, Limited, Yokohama, Japan

Abstract

We can trace the roots of Japanese beer industry to the early Meiji Era (1868–1912), as well as note the significant growth of the industry after the conclusion of World War II. Traditional Japanese beer is a Pilsner-style lager developed during the early Showa Era (1926–1989), relying on hops, and being pasteurized before packaging in bottles. The major difference between traditional Japanese beer and that of Europe is the use of adjuncts. The prevalent modern Japanese beer is a highly fermented beverage, using weakened hops, being fermented in cylindro-conical tanks, and then aged. While characteristically unpasteurized, modern Japanese beer is subjected to membrane filtration before being shipped for consumption. Over the past 10 years or so, techniques related to the use of adjuncts have changed significantly, resulting in the introduction of happo-shu (low-malt beer) with low malt ratios and so-called "New Genre" products containing no malt whatsoever. These products feature a fresher/crisper flavor with low levels of bitterness. However, the industry will continue to develop a wider variety of beer products and techniques to meet the increasingly diverse customer taste preferences.

Introduction

The origin of Japan's beer industry can be traced back to the early Meiji Era (1868–1912). Initially, the Japanese produced both a German-style beer and an English-style beer. However, gradually, well-capitalized manufacturers of German-style beer became prevalent. During this time, the Japanese introduced the use of adjuncts, forming the archetype of traditional and modern Japanese beers. Beer production underwent major growth during the post-war economic boom, including a transition from returnable bottle packaging to cans, and a move away from pasteurization to membrane filtration for "draft" beer. Over the past 20 years, the advent of highly fermented dry beers, the lifting of bans on microbreweries, and the birth of new

products called happo-shu and "New Genre" have all significantly changed the structure of the market in Japan. In this chapter, we will introduce the history of the beer business in Japan, changes in manufacturing methods of beer, happo-shu (low-malt beer), and "New Genre" products, and trends in beer composition.

Japanese Beer Production and Consumption Volumes

In 2004, worldwide beer production was approximately 1.5 billion hl. Japan's production volume for that year, including happo-shu, was 66 million hl, helping Japan to reach the No. 7 spot behind China, America, Germany, Brazil, Russia, and Mexico, accounting for 4.3% of the world's beer production volume. Total consumption of beer in Japan was 65.5 million hl, placing Japan in the 6th place worldwide after China, America, Germany, Brazil, and Russia. However, on a per-individual basis, Japanese consumed 51.3l of beer for that year, placing Japan on the 32nd position among the world's beer-consuming countries (Brewers Association of Japan, 2006). At present, Japan is home to five major beer-manufacturing companies, with approximately 200 small-scale "microbreweries." However, microbrewery production of beer only accounts for about 1% of Japan's total beer production. The main beer product in Japan is a Pilsner-style beverage, but Japan's microbreweries produce a diverse mix of beers, ale, dark ale, Weizen, Kölsch, etc. In 2005, happo-shu, introduced to the market in 1993, accounted for 27% of all beer sales at 17.6 million hl. The year 2005 also saw the introduction of "New Genre" products, that is, a beer-type happo-shu not using malt, representing 16% of all beer sales at 10.1 million hl. Commercial-use beer sales represented 44.7% of the market, while beer for home/private consumption was 55.3%. Four percent of happo-shu was sold for commercial purposes, with 96% consumed at home. The entire amount of "New Genre" product sold during 2005

was consumed at home. As for packaging, 27% of Japan's beer sales in 2005 were bottles, 44% cans, and the remaining 29% kegs. About 96% of happo-shu was sold in cans with 4% sold in kegs. All "New Genre" sales were sold in cans (Jozo Sangyo News, 2006). It is apparent that most of the beer for home consumption is purchased in cans.

History of Japanese Beer

In the Edo Period, prior to the opening of Japan to global trade in 1854, the Dutch people were the only westerners allowed to trade with Japan. These foreigners brought beer to the Land of the Rising Sun, which was apparently enjoyed by a certain number of Japanese who were specializing in western learning. When Perry reached Japan in 1853, it is said that, Komin Kawamoto a doctor of western medicine, saw descriptions of beer noted in western texts, and became the first Japanese to attempt to brew beer in Japan (Hashimoto, 1997). Later, in 1868, the Edo Shogunate collapsed, ushering in the advent of Japan as a modern nation. It was in 1870 that the first serious commercial production of beer was engaged. The setting was at Yokohama, and it was William Copeland, a Norwegian-American, who took on the endeavor. As a young man, Copeland studied brewing for 5 years at the foot of a German brewer. Copeland subsequently traveled to Yokohama when he was 30 years of age. There, he observed a plot of land in the Yamate foreigner's residential area of Yokohama that featured a clear water spring. Copeland built a brewery on this location, calling the facility "Spring Valley Brewery." William Copeland's beer was tremendously popular among the foreigners living in Yokohama, and was even known among the local Japanese, who called the product "Amanuma Beer Sake."

Shozaburo Shibutani is said to be the first Japanese to seriously engage in the beer production and sales in the Osaka area beginning in 1872. In 1874, Mitsu Uroko Beer was founded in Kofu. Later, in 1876, the Hokkaido Kaitakushi Sapporo Brewery was established as a government-run enterprise in Hokkaido. The following year, Sapporo Beer was introduced to the Japanese market. In 1887, the Japan Beer Brewery Company was founded, purchasing brewing equipment and malt from Germany. The company brought in brewing specialists from overseas, and introduced Ebisu Beer to Japan in 1890. In connection with government divestment in 1886, the Sapporo Brewery was granted to the Okura Group from the Hokkaido Prefectural Government; the Sapporo Beer Company was later formed in 1888. In 1885, the land and buildings of the Spring Valley Brewery were carried over to the Japan Brewery Company, Limited, and in 1888, the company began selling Kirin Beer. Asahi Beer was introduced to the Japanese market in 1892 by the Osaka Beer Company, Limited, which was established in 1889. At one point in Japan's history, more than 100 different labels of beer were for sale in the market. Most of the smaller beer breweries produced English-style beer without the need to use refrigeration equipment. At that time, the

price of one large bottle of beer was very expensive, equivalent to 4,000 yen in today's terms.

At the time, the Japanese government had yet to assess a liquor tax on beer. However, Japanese military expansion precipitated a tax on beer, beginning in 1901. The combination of high-quality German-style beers produced by well-funded manufacturers and the commencement of tax levies on beer forced a wave of bankruptcies among smaller breweries, leaving only the larger producers to continue. In 1906, the Japan Beer Brewery Company merged with the Osaka Beer Company and the Sapporo Beer Company to form the Dai-Nippon Beer Company, Limited, which continued to expand. In 1907, Kirin Brewery was established, taking over the business operations of the Japan Brewery Company, Limited. It was about this point in time that some breweries began to use rice as an adjunct, with the use of such being recognized in the Revised Liquor Tax Law of 1904. World War I broke out in 1914, but Japan experienced an economic boom due to its fortunate geographical location. The war was also a blessing for Japan's beer industry, which used this opportunity to penetrate into the Southeast Asian and Indian markets suffering from interrupted supplies of beer from Europe. Beer prices were not immune to postwar deflation, and while prices could have been considered somewhat geared for the mass market, overall beer consumption did not increase to a great extent. Rather than recovering, beer sales declined even further during the subsequent period of Japanese militarization. The price of a large bottle of beer in 1918 was the equivalent to 1,500 yen in today's prices. Beer consumption volume in 1939 marked the highest levels at 3.1 million hl before World War II, half of which was consumed by the military. World War II broke out in 1939. Beer price controls were instituted at the time, and home consumption of beer was rationed. The Pacific War made it extremely difficult for Japanese breweries to procure barley and hops, leading to decreases in beer production. War-time shortages in 1940 resulted in an increase in the volume of adjuncts used in beer, leading to standards still in use today. In the year following the war, total beer production volume had fallen to one-fourth of pre-war levels. The rationing system was abolished after the war in 1949, and Dai-Nippon Beer was separated into today's Asahi Breweries and Sapporo Breweries under the terms of the Law for the Elimination of Excessive Concentration of Economic Power. Japan had ample access to supplies of raw materials, fuel, and building materials after the outbreak of the Korean War in 1950, and with the abolition of raw material controls in 1952, beer production for 1953 outpaced any production level of pre-war times. After that point, the growth of Japan's beer industry was remarkable, growing approximately 15 times between 1955 and 1975, and reaching nearly 40 million hl of annual production. In 1987, total beer production in Japan exceeded 50 million hl, reaching 60 million hl by 1989, and a record of 71 million hl by 1994. The spread of access to beer throughout Japan due to pre-war rationing system, soldiers, who developed a taste for beer, returning to

Japan from battlefields overseas, and mass production resulting in more accessible beer prices can all be cited as underlying reasons for the rapid increase in beer consumption in Japan (Hashimoto, 2003). The availability of electric refrigerators from around 1960 was another major factor behind the increased beer consumption.

Canned beer, first introduced to Japan in 1958, represented only 16% of beer sales in Japan as of 1985 (Beverage Japan, 1990). By 1995, however, the ratio of canned beer had risen to 45% of the market, even outpacing bottled beer sales (Packpia, 1995). Today, most beer consumption at home is of the canned product (Jozo Sangyo News, 2006). Suntory entered the beer market in 1963, and began selling all of their beer products as membrane-filtered draft beer in 1968 (Sasaki, 1983). In 1989, membrane-filtered bottled/canned draft beer represented 63% of the market (Hashimoto, 1990), and at present, most bottled/canned beer is of the draft variety. The Japanese diet included an increasing preference for meat, and the volume of animal fat consumption increased accordingly. As a result, a lighter option was sought for accompanying dishes and drinks.

In this way, we see that the taste preferences and beer consumption patterns were changing in Japan, and in 1987, a dry beer concept called "karakuchi" was introduced. The "dry" beer featured a smooth sensation at first, with a refreshing aftertaste, and was designed to keep the interest of consumers in their 20s and 30s (Usuba, 1996).

In 1994, government deregulatory policies led to the revision of the Liquor Tax Law, under which annual minimum beer production volume was reduced from 20,000 to 600 hl. This swung the gates to beer production wide open in Japan, with new microbreweries springing up all over the country. According to the National Tax Agency, Japan was home to 232 microbreweries in 2002 (National Tax Agency Japan, 2006). Besides Pilsner-style beer, Japan's microbreweries produce several other types, including ales, dark ales, Weizen, Kölsch, etc.

The strong yen valuation of the 1990s brought a flood of cheap beer from overseas. At that time, domestically produced canned beer was sold for 225 yen, whereas a major supermarket chain was contracting with a Belgian beer maker, offering canned beer for 128 yen retail. Meanwhile, thanks to deregulation, discount liquor stores were popping up all around the country, destroying the foundation of the fixed-price sales system that had been an industry practice for many years. The market-share growth of imported beers in Japan was remarkable, reaching 4.2% in 1994 (Packpia, 1995). To compete with cheap beer imports, the ratio of malt was reduced to 65% to be exempted from high taxation on beer, and the sales of happo-shu (low-malt beer) at a significantly lower price point of 180 yen was initiated. With the Revised Liquor Tax Law in 1994, beer containing more than 66.7% malt was assessed a high tax of 77.7 yen per 350 ml, but happo-shu containing less than 66.7% malt enjoyed a 31% reduction in liquor taxes. The line drawn at 66.7% for malt usage ratio defining beer on one side and happo-shu on the other, with the difference consisting of only a few percent, seemed quite arbitrary. Accordingly, the Revised Liquor Tax Law of 1997 reduced tax rates only on two types of happo-shu, one containing less than 50% malt and the other containing less than 25% malt. Later, the Liquor Tax Law was further revised; at present, most happo-shu contains less than 25% malt. Happo-shu is a cheaper alternative to beer, and has been warmly accepted by consumers as a light, easy to drink option (Hashimoto, 1998).

The 2003 revision of the Liquor Tax Law increased the tax on happo-shu by approximately 10 yen per 350 ml. In response to this change in law, a version of happo-shu without malt was introduced in Japan. This new product has come to be known as "New Genre" in Japan. According to Japanese Liquor Tax Law as of 2006, happo-shu without malt is categorized as "Other Sparkling Spirits," taxed at 28 yen per 350 ml, a lower rate compared to the 46.99 yen levy on happo-shu with less than 25% malt, or the 77 yen assessment on beer using 66.7% or greater malt. Since "New Genre" products do not use malt, they have a fresher/crisper flavor compared to regular happo-shu (Kashiwada and Oono, 2004; Nakamura, 2005) (Table 4.1).

Table 4.1 Beer category definitions and taxes according to Japan's Liquor Tax Law

Category	Malt ratio (%)	Tax (yen/350 ml)
Beer	≥66.7	77.0
Happo-shu	≥50	77.0
Happo-shu	50>, ≥25	62.3
Happo-shu	25>	46.9
"New Genre"	None	28.0

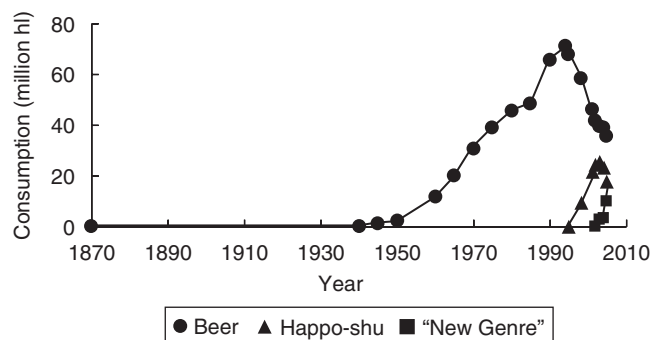
Note: According to Japanese Liquor Tax Law in 2006, beer is defined as beer made from malt more than 66.7%. The tax for beer is 77 yen/350 ml. Beer made from malt less than 66.7% is defined as Happo-shu (low-malt beer). The tax for Happo-shu that made from malt more than 50% is 77 yen/350 ml. The tax for Happo-shu that made from malt between 25% and 50% is 62.3 yen/350 ml. The tax for Happo-shu that made from malt less than 25% is 46.9 yen/350 ml. Happo-shu not containing malt is categorized as "New Genre." The tax for "New Genre" is 28 yen/350 ml.


Figure 4.1 Consumption trends for beer, happo-shu, and "New Genre."

Table 4.2 History of beer production in Japan

Year	Details
1853	Beer first brewed in Japan by Komin Kawamoto, a practitioner of western medicine
1870	Norwegian-American William Copeland establishes the Spring Valley Brewery in Yokohama
1876	Government-run Hokkaido Kaitakushi Sapporo Brewery established
1885	Copeland's Spring Valley Brewery taken over by Japan Brewery Company Limited
1887	Japan Beer Brewery Company founded
1887	Sapporo Beer Company (successor of Sapporo Brewery) established
1889	Osaka Beer Company Limited established
1901	Beer tax instituted in conjunction with Japanese military expansion
1904	Revised Beer Tax Law allows addition of rice (up to 30% vs. malt volume)
1906	Dai-Nippon Beer Company Limited established with merger of Japan Beer Brewery Company, Osaka Beer Company, and Sapporo Beer Company
1907	Kirin Brewery established, taking over business of Japan Brewery Company Limited
1940	Allowed adjuncts ratio increased to 50%
1949	Dai-Nippon Beer Company Limited separated into Asahi Breweries and Sapporo Breweries under the Law for the Elimination of Excessive Concentration of Economic Power
1967	First "draft beer" marketed; precision filtered and bottled, rather than pasteurized
1987	"Dry" type beer ("karakuchi") introduced
1994	Revised Liquor Tax Law reduces minimum production from 20,000 to 600 hl; many new microbreweries enter the market
1994	Happo-shu (65% malt) introduced
1995	25% malt happo-shu introduced
2004	Beer-flavored "New Genre" beverages containing 0% malt introduced

Figure 4.1 shows the trend for beer, happo-shu, and "New Genre" consumption in Japan. The increasing consumption of happo-shu has led directly to a decrease in beer consumption, while the introduction of "New Genre" products has eaten into consumption of both beer and happo-shu. Beer consumption in 2005 was 36.2 million hl, while happo-shu consumption was 22.1 million hl, and "New Genre" consumption was 10.1 million hl (Jozo Sangyo News, 2006). Table 4.2 shows the history of beer production in Japan.

The consumption of beer increased rapidly during the post-war economic boom and went up to 71.0 million hl in 1994. Happo-shu was put on sale in 1994. The increasing consumption of happo-shu has led directly to a decrease in beer consumption. "New Genre" that was put on sale in 2004 has eaten into consumption of both beer and happo-shu. Beer consumption in 2005 was 36.2 million hl, while happo-shu consumption was 22.1 million hl, and "New Genre" consumption was 10.1 million hl.

Traditional Japanese Beer Production Methods

Traditional Japanese beer is the hops-infused Pilsner-style lager that was created during the early Showa Era (1926–1989). It is a pasteurized, bottled product, but one that uses adjuncts, marking a difference between the Japanese version and the Pilsner-style beer of Europe. The consumption of beer in Japan increased dramatically during the post-war economic boom (1960s through 1970s), and all of Japan's beer manufacturers were busy building new production facilities. Generally speaking, traditional Japanese beer was brewed of malt of 76–82% extract, a Kolbach Index of between 34% and 42%, and a fermentability of between 78% and 85%. Baled hops were used most often with rice, starch, and even corn grits, following the pattern used in America, as adjuncts.

Saccharification was generally achieved through decoction, while wort filtration was conducted via lauter tun or mash filtration. A plate cooler was used for wort cooling. Two- to three-meter tall fermentation tanks made of steel, aluminum, or stainless steel, using either an open or closed type system, were installed inside the fermentation room. The fermentation room itself was cooled. The temperature of the maturation room was kept between 0°C and 2°C, with the room usually located directly beneath the fermentation room. The maturation tanks used were of the horizontal type, similar to the fermentation tanks. To improve haze stability, an exogenous enzyme such as papain was also used. The standard maturation period was 2 months. Beer filtration was performed through a combination of a filter using filter cotton, which is called "Schalenfilter" and a sheet filter using filter paper. Filled and capped bottles were sent through a pasteurizer for low-temperature pasteurization.

Modern Beer Production Methods

Characteristics of Japan's beer production methods

In the modern era, most beer produced in Japan is still of the Pilsner style. The following are particular characteristics of beer produced in Japan. Most of the beer now produced in Japan is not pasteurized, but is rather precisely sterilized under membrane filtration before shipping. This type of beer was first bottled and shipped as "draft beer" in 1967 (Sasaki, 1983), with more manufacturers following suit in 1977. Beginning in 1980, beer not subjected to pasteurization was advertised as "draft beer." In Japan, the sense behind the term "draft" is to imply an image of freshness, which is considered as one factor behind the popularization of the phrase "draft beer." While avoiding pasteurization does preserve the enzymatic activity of invertase and so on, there is no other clearly recognized effect on flavor.

The second characteristic of modern Japanese beer production is the use of adjuncts. Beer produced in 1876 by Japanese technicians holding formal manufacturing licenses from Germany consisted of 100% malt; however, the use of adjuncts was gradually adopted subsequently. In 1904, the Liquor Tax Law recognized the addition of up to 30% rice, and the Revised Liquor Tax Law in 1953 defined the usage of rice, corn, starches, and other adjuncts of up to 50% malt. Presently, regular beer uses rice, corn grits, starch, or other adjuncts; however, the purpose of these ingredients is to adjust the flavor and richness of the beer. Even premium beers in the higher-priced segments consist of both all-malt versions and versions using adjuncts. One could say that adjuncts are an indispensable part of producing a beer product that meets the taste preferences of the Japanese.

A third characteristic of modern Japanese beer is the advent of happo-shu (low-malt beer) and "New Genre" beers. While the category originally emerged in response to needs for a low-cost product, it also developed in response to changing taste preferences amid regulatory restrictions related to malt usage ratios.

Beer

Japan's brewery facilities built before the 1970s underwent wholesale renovations, focusing on scale and automation. The prevailing form of modern beer in Japan is fermented and aged in cylindro-conical tanks, highly fermented, and made of weakened hops. Most modern beer is not pasteurized, but rather subjected to membrane filtration. Most malt used in Japan is imported from overseas, having a Kolbach Index of between 40% and 45%. Malt having a high enzymatic capacity and high fermentability is used to produce beer with a high degree of fermentation (Usuba, 1996). Saccharification is achieved through decoction, as well as infusion for highly fermented wort production. The mashing process incorporates a mechanism to minimize contact with oxygen to improve flavor stability (Kimura and Araki, 2000). Removing air from the water used in the brewing process, and slowly inserting/removing wort from the bottom of the mash vessels ensures that the mixing in of air is kept to a minimum. Lauter tun is the prevalent form of mash separation used in modern beer manufacturing in Japan. During mash separation, the initial liquid produced is the first wort, while the second wort is collected by reintroducing hot water, and then recovering the remaining extract.

Due to the ratio of tannin components seeping out of the husk of the malt is high, the first wort gives rise to a refined, refreshing taste, and a straight-forward drinkability, while second wort imbues beer with a rich, stimulating drinking experience. Normally, first and second worts are blended and fermented; however, some beers are manufactured solely with first wort to produce a light, refreshing flavor. The practice of using hops in both pellet and extract form is increasing; however, there are also cases of hops being used in cone form.

Yeast is selected according to the characteristics of the product in question; however, to produce a beer with a high degree of fermentation, yeast with a strong fermentability is used. Under traditional production methods, fermentation and maturation tanks are installed indoors, but today, outdoor cylindro-conical tanks are prevalent. Some production tanks exceed 5,000 hl in volume. Since refrigeration units are directly wound around the tanks, the temperatures inside the tank can be precisely controlled, and it is even possible to promote the maturation process. This is a process whereby, during the course of maturation, the oxidative decarboxylation of α-acetolactic acid to diacetyl is accelerated through high temperatures, shortening the maturation period. The maturation period varies according to the type of beer in question, but the shortest method takes approximately 2 weeks. High gravity brewing is being tested at the pilot plant level; however, production has not spread to the extent found in the United States and Europe.

After kieselguhr filtration, beer is normally subjected to precise filtration via membrane. Sometimes silica gel and PVPP are added during kieselguhr filtration to remove proteins and polyphenols that cause chill haze. Membrane filtration can produce beer products that can be stored for lengthy periods of time, even without pasteurization.

Happo-shu (low-malt beer)

Under Japan's Liquor Tax Law, alcoholic beverages fermented using malt, hops, and water as raw materials, or alcoholic beverages fermented using malt, hops, water, and barley, rice, corn, kaoliang (type of sorghum), potatoes, starches, and/or sugars in a volume by weight of less than half of that of malt are defined as "beer." Alcoholic beverages other than beer that use malt or barley as a portion of ingredients having effervescent properties are defined

as happo-shu (low-malt beer). In 1994, happo-shu was reintroduced to the market. Happo-shu containing 65% malt was first marketed to compete with the low-priced import beer being sold in Japan. In the following year, happo-shu utilizing a malt ratio of less than 25% was brought to the market. At that time, only two companies were producing happo-shu; but later, in 1998 and then in 2001, other manufacturers entered the market, and all four of Japan's major beer producers began selling happo-shu.

The biggest challenge in developing happo-shu is restricted malt ratios. The questions were how to maintain original beer flavor while having a low-malt component, as well as how to compensate in the production process for reduced fermentability caused by lower levels of malt nutrients. With most happo-shu on the market, malted barley comprises less than 25% of the total raw materials, while the treatment of adjuncts, such as rice, corn, or starches is what determines the flavor of the product. To compensate for reduced malt levels, manufacturers use ungerminated barley and/or extract from barley as adjuncts. Manufacturers also use mineral-enriched deep ocean water to ensure that the yeast has enough required nutrients. A reduction in malt composition also results in a reduction in saccharification enzyme activity; however, the addition of liquid sugar as well as starches is frequently used as an adjunct. The production of happo-shu is virtually identical to that of beer, with the exception of malt ratio and the techniques for using adjuncts. The results of the techniques described above have produced a product having a taste equal to beer. Another characteristic of happo-shu is a reduced level of nitrogen in comparison to beer.

"New Genre"

Beer taste preferences in Japan have changed. While beers with rich and deep flavors were once the main characteristic of such beverages in Japan, Japanese tastes have turned to prefer beers with a fresher, crisper flavor profile. In 2004, a beer-flavored beverage using no malt was introduced to the Japanese market (Kashiwada and Oono, 2004). In 2005, three other companies marketed a similar beverage, and these products have come to be known as "New Genre" beers in Japan. With no malt component, liquid sugars are used as a carbon source, which means there is no need for the saccharification process to be conducted, as normally would be the case. Just as with beer production, hops are added and boiled, the liquid is cooled, yeast is added for fermentation, and then the liquid is matured. As malt is not used, the most important issue is to ensure that there is enough nitrogen for yeast propagation. After a process of trial-and-error using different raw materials, manufacturers settled on using pea proteins, soybean proteins, soy peptides, and/or corn. Yeast extract is also used at times to make up for the nitrogen deficiency. Under the current Liquor Tax Law, beverages consisting of spirits added to happo-shu are included in this "New Genre" category.

The lack of malt in "New Genre" beers also affects the color of the product. Most of beer color derives from the malt, and some pigmentation is a by-product of the Maillard Reaction that occurs during the wort boiling process. Since no malt is used for "New Genre" products, caramel coloring is used more often than not to adjust the color of the beverage.

"New Genre" products are noted for a fresh, crisp taste; however, some "New Genre" products are designed specifically for "flavor." One such product is manufactured by adding sugars to peptides/amino acids derived from soy proteins. The mixture is heated, and then the Maillard Reaction imparts a deep flavor, distinct in its richness. Since an amber color is added through the Maillard Reaction, there is no need to add any caramel coloring (Ohta and Sasaki, 2006). Compared to traditional beers, "New Genre" beers were developed with the clear concept of providing a fresh, crisp taste to the consumer. The concept was practically realized by lowering the nitrogen content in the beverage, and reducing the bitterness value (Figures 4.2 and 4.3).

Figure 4.2 shows the total nitrogen levels in Japanese major beer, happo-shu, and "New Genre" brands. Each bar indicates the average value of the major brand of each manufacturer. The levels of total nitrogen in happo-shu and "New Genre" are lower than beer as a result of their low malt ratio.

Figure 4.3 shows the bitterness levels in Japanese major beer, happo-shu, and "New Genre" brands. Each bar indicates

the average value of the major brand of each manufacturer. The concept of fresh, crisp taste of "New Genre" was realized by reducing the bitterness level.

Changes in Beer Composition

Table 4.3 shows changes in the main indices used in beer analysis. While the levels of original extract and alcohol concentration have remained almost unchanged, real degree of fermentation have increased, and real extract, total nitrogen, bitterness, and polyphenol levels have decreased. Beers of the Meiji Era were Pilsner-style beers brewed without adjuncts, adopted during a period when beer brewing techniques were brought to Japan from Germany. The beer of that day contained high levels of original extract and nitrogen components, with strong richness and body. With the introduction of low-polyphenol grains, corn or rice, for example as adjuncts replacing a portion of malt, the polyphenol levels in the beer decreased, and the haze problem in the beer improved. At the same time, nitrogen components such as proteins and amino acids also decreased, causing a lightness in the flavor of the beer. The bitterness of different beers can be compared using beverage unit (BU). During the Meiji Era, beer BU was greater than 30; however, consumers reacted negatively to strong bitterness as beer flavors became lighter, resulting in gradually decreasing bitterness in beer through time. The "dry" beers put on market in 1987 used a reduced amount of malt, and increased degree of fermentation, leading to a crisp, very drinkable flavor (Hashimoto, 1998). Happo-shu, for which the malt ratio is less than 25%, uses exogenous enzymes to make up for the lack of malt. Liquid sugar, barley, and other adjuncts are used to generate a more "beer-like" flavor. The low levels of nitrogen in happo-shu result in a light, agreeable flavor, with an elegant, easygoing flavor that matched perfectly to the hint of bitterness. "New Genre" beverages use peas, soybeans, or corn as a nitrogen source (Nakamura, 2005). Most beers derive their color from malt, with pigmentation also created by the Maillard Reaction occurring in the brewing process. To generate a "beer-like" color in "New Genre" products, which use no malt, caramel is added, and the so-called Browning process is utilized to promote the Maillard Reaction by boiling sugar and proteins during the mashing process, as described earlier (Ohta and Sasaki, 2006). The complete lack of malt in "New Genre" beverages results in a fresher, crisper flavor compared to happo-shu.

Beer caloric content depends on the amount of alcohol and extract contained. For example, beer with a 3.2% extract, 5% alcohol content contains approximately 42 kcal per 100 ml. Assuming that the daily caloric requirements of an adult averages to 2,500 kcal, the caloric content of 1 l of beer represents approximately one-sixth of the daily requirement. The harmful effects of alcohol on the human body appear due to excessive consumption particularly for highly concentrated alcoholic beverages, while no ill effects are a concern as related to low-alcohol beverages. Appropriate alcohol consumption enhances the appetite, helps digestive organ and heart function, and aids in recovery from muscle fatigue. In addition, beer contains vitamins B1, B2, B6, niacin, pantothenic acid, biotin, folic acid, and other helpful nutrients, as well as rutin, vital salts such as phosphoric acid, and calcium (Takahashi, 2000). Research into the effects of beer on preventing lifestyle-related diseases have variously reported that xanthohumol, a component in hops, demonstrates anti-cancer activity; that iso-humulones improve insulin resistance and fat metabolism; that iso-xanthohumols help resist bone-density decline; and that polyphenols demonstrate antioxidant properties in living organisms (Kondo, 2004). The reduction in malt and hops content made in response to consumer taste preferences have reduced the efficacy of beer as a healthful food. Purines contained in beer are considered as a cause of gout, and doctors recommend that persons with high levels of uric acid avoid beer altogether. In response, purines-free beers have been developed, warmly received by persons with high levels of uric acid (Fujino and Sakuma, 2006).

[c] RDF: Real degree of fermentation.

Summary Points

- Traditional Japanese beer is a Pilsner-style lager developed during the early Showa Era (1926–1989), relying on hops, and being pasteurized before packaging in bottles. The major difference from that of Europe is the use of adjuncts. Most modern Japanese beer is not pasteurized, but rather subjected to membrane filtration, and then filled in cans.
- Together with the wide-spread adoption of cylindro-conical tanks, beers featuring a high fermentation level and weakened hops have become prevalent over the past 20 years.
- Over the past 10 or so years, happo-shu (using low amounts of malt) and "New Genre" beers (using no malt at all) have been developed to compete against low-cost imported beer.
- Since beer was first produced in Japan, the trend has been increasing real degree of fermentation with lowering bitterness. Happo-shu and "New Genre" beers feature a cleaner, crisper flavor than traditional beer, with less bitterness.

Sorghum Beer: Production, Nutritional Value and Impact upon Human Health

Maoura Nanadoum Laboratoire de Recherche sur les Substances Naturelles, Faculté des Sciences Exactes et Appliquées N'Djaména, Tchad
Jacques Pourquie UMR Microbiologie et Génétique Moléculaire, CNRS/INA-PG/INRA, CBAI, Thiverval-Grignon, France

Abstract

In Africa, traditional SMM (sorghum, millet, maize) beers are typically consumed by people who do not have access to sufficient dietary intake. These so-called opaque beers provide their consumers with significant amounts of valuable nutrients (calories, proteins, minerals and vitamins) which they would have difficulty in obtaining from other sources. They are produced in a home-made manner on a very small scale but by numerous individual brewers. They thus support an economic activity which brings cash money to an underpaid part of the population (sorghum growers, firewood collectors and especially women brewers). For example, we discuss bili bili sorghum beer which is produced and consumed in the Republic of Chad. We describe the technical and socioeconomic aspects of its making, and also discuss how the nutritional value of the starting cereal is improved through the different steps of the brewing process. From a risk–benefit point of view, despite their alcoholic content and the very poor sanitary conditions under which they are made, these beverages contribute more to sustain a minimum welfare to their consumers than to add an extra health hazard.

Introduction

The history of beer making is as long and as rich as the history of humankind. Many kinds of sorghum or millet beers, known as opaque beers, have been reported across African countries (Table 5.1) (Périsse *et al.*, 1959; Bismuth and Ménage, 1961; Adrien and Jacquot, 1964; Odunfa, 1985; Novellie and De Chaepdrijver, 1986; Haggblade and Holzapfel, 1989; Sanni *et al.*, 1999; Seignobos, 2002). They are produced and sold on village scale markets and in many cities. They form the basis of a significant economic activity, providing both a source of nutrients to undernourished people and an additional income to an otherwise underpaid

Table 5.1 Typical names of traditional African beers

population. Although this activity is disparaged by non-governmental organizations (NGOs), religious parties and local administrations which consider that the production of sorghum beers is one of the causes of malnutrition, alcoholism, juvenile delinquency and deforestation, its nutritional, economic and social importance cannot be denied (Nanadoum, 2001; Magrin and Mbayhoudel, 2002).

This chapter will focus on the example of the Republic of Chad, where the local traditional beer is called bili bili. We will first give a short overview of the economic and social aspects of bili bili making and consumption. We will then give a technical description of the currently employed process and also discuss the biochemical and microbiological transformations occurring and how these transformations affect the quality of the beer and the health of the consumers.

Sorghum Beer in the Present Chad Society

In ancient times, sorghum beer had a sacred value and its consumption was strictly restricted to social events and work parties. This strong social connotation has progressively vanished; today, sorghum beer production has become a significant economic activity and its consumption is commonplace.

Bili bili beer is obtained by fermentation of malted sorghum and millet. It is an opaque beer which has to be consumed on the very day of its production. It is produced in a home-made manner using a procedure which is roughly similar to that of the production process of European type beers, and the details of which are transmitted orally from generation to generation. It is made exclusively by adult women who individually perform, on a weekly basis, the series of operations which in 2–3 days lead from the sorghum grain to the fermented beer. It demands great physical efforts and the production of each batch is thus limited to an average volume of 150 l.

There are no national statistical figures concerning the total annual production of bili bili, but some studies have been performed on a regional scale in the main cities of the south of Chad (ECOSIT 1, 1998; Ngardiguim and Digali, 2003). They show that around 70% of the local production of sorghum and millet is transformed into bili bili by women brewers who represent 0.5% of the total population. Most important is the flow of cash money which is induced by this transformation; in 2001, it has been estimated that in the town of Moundou (145,000 inhabitants), 840 million CFA Francs ($1.2 million) has been distributed between grain producers and traders, brewers, hirers of taverns and local administration (Magrin and Mbayhoudel, 2002). As a significant part of this money goes to the women brewers who get from this activity an average monthly income of 25,000 CFA ($35), beer production can be regarded as a way to redistribute to women a part of the cotton production income from which they tend to be excluded by the still strongly non-egalitarian structure of the Chad society.

- Bili bili making is a significant source of cash for African women and underpaid people.

Bili bili making

- Sorghum is the fifth largely grown cereal crop in the world. It is a graminaceous annual plant from the Poaceae family. It is well adapted to grow in arid lands and under hot climates; it is much more resistant to drought than any other major cereal. Sorghum and maize have similar nutritional values though sorghum is richer in protein and poorer in lipids.
- Millet is a generic name which encompasses various graminaceous species. Their agronomical and nutritional characteristics are similar to sorghum but their seeds are much smaller.

Bili bili is exclusively prepared by adult women. A survey among 71 of these women brewers (Nanadoum, 2001) has shown that 90% of them use the process which is depicted in Figure 5.1. As shown in this figure, this process encompasses the same basic steps as those of an industrial production (sprouting, malting, mashing and fermentation), but of course these steps are operated under very different conditions.

Sprouting and Malting   Great care is taken of the quality of the grain. Seeds which are too old or too young are not used. Although many varieties are available, the most frequently used is djigari, a tannin rich red variety to which small amounts of maize are sometimes added. The kourgho variety, with a lower content of tannins, is considered superior, but its use is limited by its high cost and lesser availability.

Using large earthenware jars, grains are soaked for 10–18 h in water to remove husks and soil impurities, and to reach the optimal moisture content. They are then placed in wooden baskets or porous bags, and washed once or twice before draining. They are then heaped up in a vat until sprouting starts. Sprouting is favored by the rise of temperature inside the heap, caused by endogenous metabolism. During the warm season, this heaping-up step is often omitted.

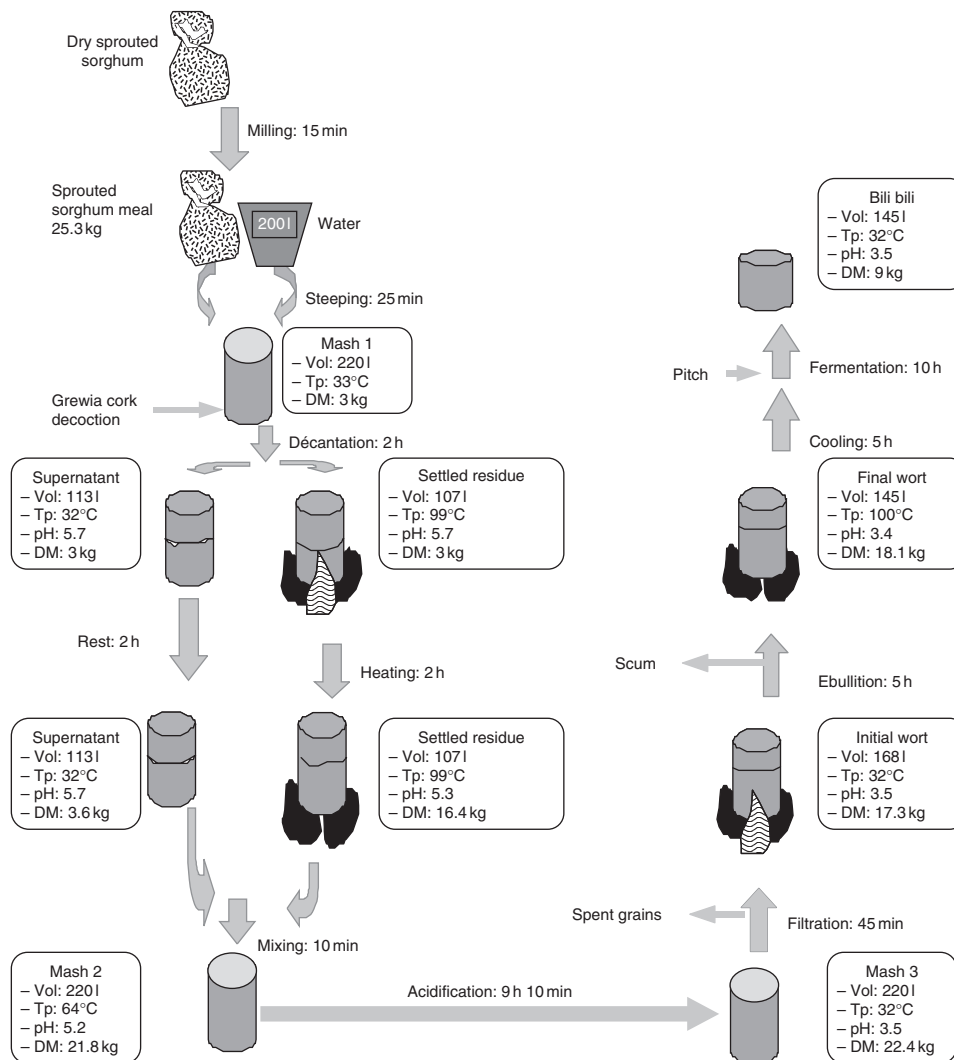
Grains are then spread on a plastic sheet to form a layer 1–2 in. thickness, and kept covered. Green plantain leaves are still used in some villages in place of plastic sheets. If needed, initial moisture is maintained by spraying with water. Sprouting takes 2–3 days after which germinated grains are heaped up again and set aside overnight. This step results in withering of the plantlets due to the heat evolved within the heap and to an acidification, which is considered as a prerequisite to the correct flavor of the product.


Figure 5.1 Bili bili making. Dry matter (DM) was measured in the liquid phase. *Source*: Nanadoum *et al.* (2005).

Germinated grains are then sun dried. Thin layers of germinated grains are spread over rush mats, corrugated iron or even clean soil, and frequently turned over. They are stored under protection during the night to avoid rehydration. This drying step takes 2–3 days depending on the intensity of sunlight. Due to quality losses during storage, the malting step is always scheduled to allow for an immediate usage of the malt.

Mash Preparation

Milling   Once dried, the malt is crushed in a mortar or milled over a millstone to produce a coarse flour. In urban areas, the use of mechanical, gasoline or fuel oil powered hammer mills is becoming more frequent.

Steeping: The steeping step usually starts around 4 p.m. The whole milled malt corresponding to a minimum weight of 35 kg is mixed with 200 l of water in a vessel, either a metal drum or a jar, devoted to this exclusive use, and stirred with a wooden stick. A decoction of *Grewia mollis* bark is often added to promote the sedimentation of insoluble matter and subsequently the filterability of the mash. An opaque mash is obtained which corresponds to the mash obtained in the brewing industry. This mash is left to stand for at least 2 h during which time decantation occurs yielding a supernatant phase and a settled residue. Using a calabash, the supernatant phase is carefully collected from the settled phase and set aside at ambient temperature. This cloudy tea-colored liquid has a slight sour sweet taste.

Cooking of the residue: The settled residue is then cooked over a wood fire. This cooking step is thought to aid the gelatinization of the starch. Depending on the quality of the wood and the thermal conductivity of the vessel, the duration of this cooking step may vary widely around an average of 2 h. While still boiling, the thick mash obtained

is poured into the supernatant phase which had been set aside and the temperature of this mix drops to 65–70°C.

Souring – Filtration: This reconstituted mash is thoroughly homogenized and stands overnight in the open air. During this time the temperature falls to 32–40°C, decantation occurs and acidity develops progressively. This acidification is considered to be a critical step of the process and is therefore assessed by frequent tasting. When the brewer considers that it has reached the correct value, she carefully withdraws the supernatant phase with a calabash. More liquid is recovered from the decanted residue using a rudimentary press filter made of a nylon cloth stretched over a bowl and raked with a wooden stick. The semi-solid residue which is obtained is sold as a livestock feed; the liquid which is recovered is mixed with the supernatant phase to constitute the wort. Due to the crude filtration process, an appreciable amount of insoluble material goes into the filtrate and contributes to the typical opaqueness of these beers. In the earlier days, filtration was performed in a woven basket filled with grass in the bottom. Although the obtained filtrate was much clearer, this process was time consuming and has been abandoned.

When the tasted acidity is considered as too strong, the brewer may decide to neutralize it by adding ash or potash, a procedure which results in some degradation of the organoleptic quality of the beer.

Boiling: The wort is boiled in jars or, more and more frequently, metal drums for an average time of 5 h. During this step, a foam, called *ngôph*, is formed on the top. As its nutritive value is high, it is continuously skimmed to be used as an infant gruel. Often, at the end of boiling, brewers drop burning charcoals into the mash, believing that this will "purify" it and clear out bad germs and unpleasant odors. Apart from charcoal, nothing should be added to the mash during its cooking. However, it is suspected that some brewers add bran of penicillary millet or bark of *Kaya senegalensis* to increase the bitterness of the beer.

At the end of this step, the total volume of the mash is reduced to two-thirds of its initial value.

Cooling: To reduce the cooling time, the mash is distributed between small 20 l and 30 l vessels. During this cooling phase, a pitch is prepared by mixing a volume of around 2.5 l of fresh mash with one-tenth volume of a former preparation of beer. This culture is put to stand at ambient temperature.

Fermentation   Brewers know by experience that when the fermentation is started at a very high temperature, it takes a longer time to develop. This is probably due to the killing or inactivation of the pitch culture and the replacement by a spontaneous flora which requires some time to become installed.

When they consider that the mash has cooled to the correct temperature, they gather the formerly distributed aliquots in a clean drum and add the pitch which they mix carefully with a calabash reserved for this purpose. Fermentation then takes place at ambient temperature. It is necessary that the fermentation be started in the evening to be able to sell the beer the next morning.

After 2–3 h, the mash becomes effervescent and foam develops, this being considered to be an indication of a good and rapid fermentation. The next morning, at around 5 a.m., the bili bili is covered with a thick head of foam typical of a successful preparation. The beer is then strained and distributed in large aluminum vessels called *tawas* which can be hermetically closed. These *tawas* have replaced earthenware jars. Bili bili is ready to be sold but brewers usually let it rest for two more hours to ensure a good further development of the foam and to afford them with enough time to prepare for the sale. Beer is thus sold from 8 a.m. to 20 p.m. by which time the brewer must clear the market stand. Beer which is left over is distilled at the brewer's home.

As it is the case with many home-made productions, bili bili production associates a precise protocol, transmitted orally from generation to generation, with significant sources of variability resulting from to the variety of operators, raw materials, tools and energy sources, and a complete absence of instrumental and analytical controls. A detailed study (Nanadoum, 2001; Nanadoum *et al.*, 2005) based on a thorough survey of more than 70 brewers and analyses of their intermediate and final products has pinpointed the most invariant features of this process. It has allowed for a chemical and microbiological characterization of the different steps of the transformation of the raw material. Based on this characterization, the specific technological functions of these steps have been identified. We discuss below these main functions.

From germination to malting: This step results in a malt endowed with the required amylolytic properties but also enriched with an abundant lactic flora. Three functions can be assigned to this flora:

1. Lactic acid production lowers the pH to values that are more favorable to amylolytic activities.
2. Supplementary amylolytic activities are produced by the lactic flora as it is usual in many homemade African transformations of starchy foods such as cassava (Daeschel, 1989; Giraud *et al.*, 1991).
3. Amensalistic interactions provide protection against pathogenic or unwanted spoilage flora.

From steeping to sedimentation: As no significant solubilization of the total dry matter is observed, the functions to be assigned to this step are: the preservation of the amylolytic activities and of the lactic flora which would otherwise be impaired by heat, and the decrease in the total volume of material to be submitted to cooking.

Setting aside of the supernatant phase: This standing of the liquid results in a strong acidification the role of which is unclear.

Cooking of the settled phase: This step results in a significant solubilization of the total dry matter mostly due to the gelatinization, dextrinization and hydrolysis of the starch content. Forty-four percent of the dry matter is converted into soluble sugar. By analogy with industrial brewing, it cannot be excluded that other transformations occur, which do not significantly affect the mass balance but are important from both technological and organoleptic points of view (precipitation of proteins, phytates and tannins, hydrolysis of β-glucans, etc.).

Mixing of the supernatant and cooked settled phases: This mixing results in a significant increase of the total concentration in fermentable sugars which amount up to 65% of the total dry weight, probably due to the immediate action of the amylolytic enzymes of the supernatant phase upon the dextrins which have been produced during the cooking step.

Acidification: Due to the continued hydrolysis of dextrins, total fermentable sugar concentration rises to 80% of the total dry weight. An increase in lactic acid concentrations and in counts of lactic acid bacteria suggests that there is development of a vigorous lactic fermentation. The responsible flora probably originates from the flora which developed in the supernatant phase and survived the thermal shock caused by the mixing operation.

Wort cooking: Three main functions have to be assigned to this step:

1. Reduction of the total volume due to water evaporation
2. Precipitation of proteins and tannins
3. Disinfection of the wort

Given the absence of sterile procedures during subsequent stages of production, the main interest of disinfection is probably to free the wort from any bacterial populations which could compete with the intentionally added populations during the fermentation step.

Final fermentation: Both microbiological examinations (parallel development of yeasts and lactic bacteria counts) and analytical assays (parallel productions of lactic acid and ethanol) show that lactic and ethanolic fermentation develop concurrently during this step. The identification and typing of yeast strains isolated from bili bili have shown that these strains belong predominantly to the *Saccharomyces cerevisiae* species, to display a strong inter-strain polymorphism and to be accompanied by low numbers of genera and species such as *Kluyveromyces marxianus*, *Candida albidus* and *Debaryomyces hansenii* (Nanadoum *et al.*, 2005).

When compared to European brewing technologies (Table 5.2), bili bili production displays three main differences:

1. The operating procedure and complexity of the mashing step are probably justified by the rudimentary heating technique. And it does not allow for a tight control of the specific temperatures which would be required for the specific needs of gelatinization, dextrinization and hydrolysis of the various components.
2. The presence and activity of an abundant indigenous lactic bacterial flora throughout the process.
3. The shortness of the final fermentation step which is performed under higher-temperature conditions.

Table 5.2 Comparison of traditional African beer with industrial European beers

		Beer		
		Industrial European	*Bili bili from Chad*	*Dolo from Burkina*
Starting materials	Starchy substrate	Barley malt	Sorghum or millet malt	Sorghum malt

Characteristics of bili bili sorghum beer

As do many traditional African sorghum beers, bili bili beer displays a number of features which make it distinct from more conventional beers. It is a viscous liquid, slightly cloudy as it has still retained part of the yeast and cellulosic impurities. This is why it is named "opaque beer" in contrast with European beers which are often filtered and pasteurized. Its color varies from brown to golden yellow depending on the sorghum variety which has been used. It is a sparkling and foamy beverage which does not contain any extraneous aromatic compound. This acidic drink (pH 3.5) displays a pronounced sourness associated with fruity overtones.

The alcoholic content is around 4.2% (w/v) but the beer is also rich in soluble sugars (30.4 g/l), soluble protein (10.1 g/l) and lactic acid (12.6 g/l). It is served while still warm during a time period which does not exceed 24 h because of rapid spoilage. It is sold at a price 10 times lower than that of the industrial domestic beer.

Nutritional Value and Impact upon Human Health

In terms of total volume consumed, sorghum beer is the alcoholic beverage most commonly drunk in the Sahel, but it also plays an important role in the nutrition of low-income urban as well as of rural populations. Consumption of the drink begins at teenage, for both men and women. This consumption is frequent since this beverage, which is often called "eat drink," is considered as both nourishing and euphoriant. Thus the question posed by Novellie (1963) "is this beer a food or an alcoholic drink?" is still open.

In the course of our survey in N'djamena (Nanadoum *et al.*, 2006), we noted that the majority of regular consumers were low-salaried civil servants, unemployed people, students and rural people. They appear to be in as good health as are drinkers of the domestic industrial Gala beer which is marketed in Chad. Some consumers stated that they often went for 2 or 3 days drinking sorghum beer as their only source of nutrition. A similar observation was made by Dirar (1993) who noted that 40% of construction workers in Sudan substituted two or three daily meals by consumption of merrissa ("merrissa" is the Arab name for sorghum beer). Platt (1964) also reports that half of the annual consumption of beer in African villages occurs during cooperative works where it constitutes 35% of the caloric intake. According to these statements, sorghum beer can be regarded as an important and safe food.

Nutritional value of the raw material

Cereals such as sorghum, millet or maize which are used for traditional beer production display similar gross chemical compositions (Table 5.3). The digestible form of sugar, mainly as starch, amounts to 65–70% of the total dry weight, corresponding to a caloric value of 3.3–3.8 kcal/g.

Table 5.3   Comparison of sorghum, millet and maize compositions

Constituents	Sorghum	Millet	Maize
Protein (g)	11	10.6	9.5
Lipids (g)	3.2	4.1	4.0
Available sugars (g)	59.3	73.2	66
Dietary fibers (g)	14.5	Nd	0
Calcium (mg)	26	22	16
Phosphorus (mg)	330	286	220
Iron (mg)	10.6	20.7	3.6
Vitamin B1 thiamine (mg)	0.30	0.30	0.33
Vitamin B2 riboflavin (mg)	0.15	0.22	0.10
Vitamin PP (vitamin B3) nicotinamide (mg)	5.3	4.7	3.1
Vitamin B12 (mg)	Nd	Nd	0.4
Vitamin B5 pantothenic acid (mg)	1.2	1.25	0.65

Note: Values expressed for 100 g of grain at 10% moisture. Nd, not determined.

Source: FAO (1974).

Dietary fibers content varies over a large range from 2% to 30% depending on the size of the grain, the proportion of husk being higher in the smallest ones.

Protein content varies between 6% and 18%, but most frequently between 8% and 13%. Despite these somewhat low figures, the protein contribution of these cereals is most important as they make up the major staple diet of numerous populations. The qualitative nutritional value of this protein contribution is rather poor as their content in lysine and tryptophan is low.

Lipids are scarce but of high value due to their richness in polyunsaturated fatty acids.

Mineral content is low and most ions (Fe, Mg, Zn, etc.) are complexed by phytic acid as total calcium is too low to neutralize these acids.

Vitamin C is lacking as well as, except for few species, vitamin A. Group B (except B12) vitamins are present but they are often lost during husking.

Most importantly, digestibility and biological availability of these various nutrients are impaired by the presence of two classes of inhibitors of digestion: phytic acid and tannins.

Nutritional value of the beer

Numerous studies have been devoted to the nutritional interest of African cereal beers (Richards, 1939; Périsse *et al.*, 1959; Novellie, 1963, 1966b; Platt, 1964; Chevassus-Agnes *et al.*, 1976; Van Heerden, 1985; Novellie and De Chaepdrijver, 1986; Van Heerden and Glennie, 1987; Haggblade and Holzapfel, 1989; Dirar, 1993).

The significant dry matter losses due to alcoholic fermentation seem to be balanced by the improvement in protein and amino-acid digestibility, mineral availability and vitamin content (Tables 5.4 and 5.5).

According to Taylor (1983), sprouting increases the digestive availability of essential amino acids tenfold, which is preserved in the subsequent stages of production.

Table 5.4   Evolution of the contents in soluble materials during the production of bili bili

| | Malt | Production steps | | | |
		Mash 1	Mash 3	Final wort	Beer
Soluble starch	3.8	0.11	0.1	0.43	0.27
Soluble sugar	5.2	10.82	94.41	110.4	30.43

Sprouting also leads to a decrease in phytic phosphorus which results in a significant increase in ionizable iron and zinc (Malleshi and Desikachar, 1986b; Udayasekhara Rao and Deosthale, 1988).

Phenolic compounds and tannins confer to the grains of brown sorghum a strong astringency which renders them both mold resistant and repellent for birds. But these compounds also impair the nutritional value by sequestering exogenous and endogenous proteins in the form of indigestible complexes (Eggum and Christensen, 1975; Griffiths, 1985; Asquith and Butler, 1986). It has been reported that germination (Osuntogun *et al.*, 1989), cooking (Price *et al.*, 1980) and fermentation (Dhankher and Chauhan, 1987) removed significant amounts of tannins.

Finally, proliferation of lactic acid bacteria and yeasts gives important additional properties to the final product, in relation to increased vitamin content and also probiotic effects.

- Through the improvements in protein and mineral availability and the enrichment in vitamins content, bili bili has a better nutritional value than crude cereal grains.

Hygienic quality and potential hazards

The survey (Nanadoum *et al.*, 2006) conducted among bili bili consumers has stressed the fact that their prevailing complaint was concern about the poor sanitary conditions during beer production: open air operation, incomplete washing, and lack of disinfection. Yet most of them recognize that they never experienced any health problem after having taken bili bili. A small minority stated that they did sometimes suffer from diarrhea, vomiting or headache after having consumed some bad tasting products.

With respect to the mycotoxin hazard, analysis performed in other countries (Okafor, 1966; Lovelace and Nyathi, 1977; Novellie and De Schaepdrijvers, 1986; Odhav and Naicker, 2002; Isaacson, 2005; Nkwe *et al.*, 2005) have shown quite high amounts in maize grains and maize malts but somewhat lower in maize beers. Sorghum malts were found to be weakly contaminated while sorghum beers were devoid of any mycotoxin.

No pathogenic bacteria could be isolated from the bacterial flora of African SMM beers. This is probably due to the strong amensalistic interactions exerted by the lactic flora against pathogenic invaders through the establishment of acidic conditions and bacteriocin excretion.

- Sorghum beers are pathogen- and mycotoxin-free.

Conclusion

Bili bili beer suffers from two important drawbacks:

1. It is prepared under quite poor sanitary conditions.
2. It is an alcoholic drink.

Yet it remains an important and cheap source of calories, digestible proteins, minerals and vitamins. It contributes to sustain the nourishment of a significant part of an urban population, too poor to access other sources of transformed food and for many of them without any means to prepare their own home-made food. This contribution is obtained at an epidemiological cost which is undoubtedly lower than

the cost of infectious, parasitic and other diseases which arise in this undernourished population.

It is our opinion that, as long as economic conditions do not improve up to a point where safe and well-balanced food becomes available to the poorest part of the population, bili bili consumption, if moderate, will play a positive role in providing these people with the essential nutrients they could not obtain elsewhere.

Production of Alcohol-Free Beer

Luigi Montanari, Ombretta Marconi, Heidi Mayer and Paolo Fantozzi Italian Brewing Research Centre (CERB), University of Perugia, Via San Costanzo, Perugia, Italy

Abstract

With greater interest in health and concern about weight and considering the warnings about alcohol abuse, especially when driving, consumer preference for low-alcohol and alcohol-free beer is increasing, but the definitions of "low-alcohol" and "alcohol-free" beers vary in different countries as well as their composition.

Low-alcohol or any other word or description which implies that the drink being described is low in alcohol may not be applied to any alcoholic drink unless: (a) the drink has an alcoholic strength by volume of not more than 1.2% and (b) the drink is marked or labeled with an indication of its maximum alcoholic strength immediately preceded by the word "not more than."

The most common way to produce non-alcoholic beers is to modify the normal brewing process so that fermentation is limited and almost no ethanol is produced. There are several techniques for determining alcohol concentration by controlling the extent of fermentation. Moreover, beers produced in a traditional way and in different brands can be made alcohol-free by using physical methods to remove the alcohol at the end of the production process.

The biological methods used to produce alcohol-free beers do not usually require special extra plant, but rather a more accurately controlled process to prevent an overproduction of alcohol.

List of Abbreviations

% (v/v) of alcohol	Alcohol concentration % by volume
°C	Celsius degree
°P	Plato degree
ADH	Alcohol dehydrogenase
Ca	Calcium
CCP	Cold contact process
CO_2	Carbon dioxide
DMS	Dimethyl sulfide
EBC	European Brewing Convention
EBU	European Bitterness Unit
EU	European Union
g	Gram
h	Hour
HG	High gravity
hPa	hectopascal
HPLC	High-performance liquid chromatography
IBC	International Bitterness Unit
ml	Milliliter
n.d.	Not detectable
N_2	Nitrogen
NAD	Nicotinamide adenine dinucleotide
NADP	Nicotinamide adenine dinucleotide phosphate
ppb	Parts per billion
ppm	Parts per million
S. ludwigii	*Saccharomycodes ludwigii*
SHG	Super high gravity
wt%	Percent in weight

Introduction

With greater interest in health and concern about weight and considering the warnings about alcohol abuse, especially when driving, consumer preference for low-alcohol and alcohol-free beers is increasing. The definitions of "low-alcohol" and "alcohol-free" vary in different countries (Table 6.1).

The European Union (EU) has no law that refers to "low-alcohol" and "alcohol-free" beers, but each country has its own legislation. In many countries such as Germany, Switzerland, Austria, Finland and Portugal, the ethanol content of alcohol-free beer is restricted to 0.5% (v/v). In Belgian legislation, "alcohol-free" is used for a beer with less than 0.5% (v/v) alcohol and a specific gravity higher than 2.2°P, while the alcohol

Table 6.1 Data related to relation to alcohol content and energy in beers from different countries

Country	Light beer (% v/v alcohol)[a]	Low-alcohol beer (% v/v alcohol)	Alcohol-free beer (% v/v alcohol)	Reference
Austria	≤3.7	>0.5 and ≤1.9	≤0.5	Codex Alimentarius Austriacus Kapitel B 13, April 1998
Belgium	Gravity ≥1° and ≤4°P[b] 30% energy reduction	>0.5 and ≤1.2 and gravity ≥2.2°P	≤0.5 and gravity ≥2.2°P	Real Decree March 31, 1993
Denmark	<2.8		<0.1	None
Finland	30% less energy content	<2.8	≤0.5	Finnish food legislation
France			≤1.2	Decree n° 92–307 of March 31, 1992
Germany	30% energy reduction	>0.5 and ≤1.2	≤0.5	Nährwert – Kennzeichnungsverordnung, Diät – Verordnung

The Netherlands	33% less calorific value	>0.1 and ≤1.2	≤0.1	Beer Ordinance 2003, Commodity Board for Beverage
Portugal		>0.5 and ≤1.2	<0.5	Decree n° 1/96 of January 3, 1996
Spain	30% energy reduction	From 1 to 3	<1	Real Decree 53/1999 of 20 January and agreement with Ministry of Health and Consumption dated 1990
Sweden		≥2.25		Alcohol low and agreement with Ombudsman regarding advertising (i.e. self-regulation)
United Kingdom		≤1.2	≤0.05	Statutory Instrument 1996 n° 1499
United States		≤2.5	Absolutely no alcohol is present[c]	

[a] Alcohol concentration % by volume.
[b] 1°P is equal to 1 g of sugar/100 g wort.
[c] non-alcoholic beer <0.5% v/v alcohol.
Source: The Brewers of Europe (2004).

content % (v/v) ranges from 0.5% to 1.2% for low-alcohol beers. Other countries, like Italy and France, consider beer as "alcohol-free" if it has less than 1.2% (v/v) of alcohol and as light beer if it has 1.2–3.5%. (v/v) of alcohol In France, Decree n° 92–307 of March 31, 1992 states that "bier sans alcool" is not a claim but a sales denomination. In Denmark and The Netherlands the term "alcohol-free" may be applied to beer with less than 0.1% (v/v) of alcohol. In the United Kingdom, the Statutory Instrument 1996 n° 1499 established that the term "alcohol-free" may not be applied to any drink from which alcohol has been extracted unless (The Brewers of Europe, 2004):

(a) the drink has an alcoholic strength by volume of not more than 0.05%;
(b) the drink is marked or labeled with an indication of its maximum alcoholic content immediately preceded by the word "not more than" or, if appropriate, with an indication that it contains no alcohol.

Low-alcohol or any other word or description which implies that the drink being described is low in alcohol may not be applied to any alcoholic drink unless:

(a) The drink has an alcoholic strength by volume of not more than 1.2%;
(b) The drink is marked or labeled with an indication of its maximum alcoholic strength immediately preceded by the word "not more than."

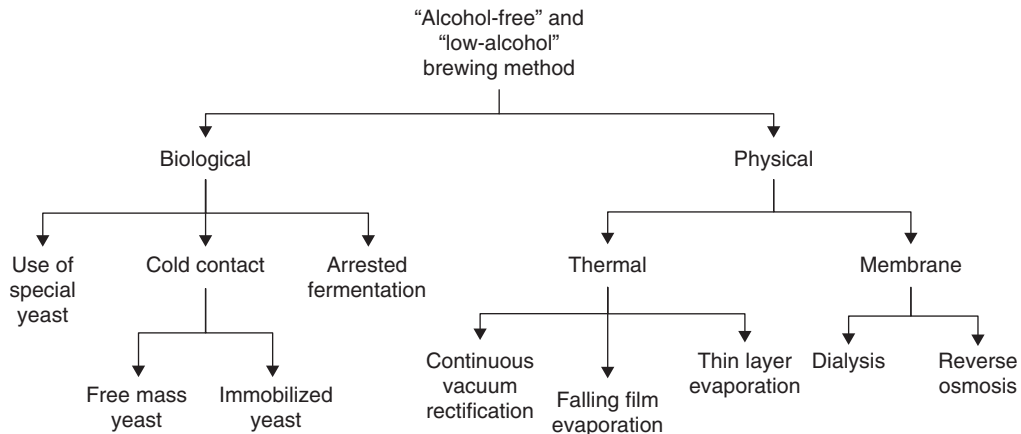
"Low-alcohol beer" or "reduced-alcohol beer" is defined by the US Government as a beer with less than 2.5% (v/v) of alcohol. Furthermore, in the United States, "near-beer" or non-alcoholic beer means that it contains less than 0.5% (v/v) of


Figure 6.1 The scheme of alcohol-free and low-alcohol beer production methods. Biological and physical processes exist for producing alcohol-free beer. The biological processes include the use of special yeasts, arrested fermentation and CCP. The physical processes include thermal processes and membrane processes.

alcohol by volume, while "alcohol-free" means that there is absolutely no alcohol present (Munroe, 1995), that is to say, below the common analytical detection limit which is 0.05 (v/v) % of alcohol. Islamic countries also demand absolutely no alcohol (Caluwaerts, 1995).

This chapter deals with "alcohol-free" and "low-alcohol" beers production technologies, as well as with their chemical, physical and sensorial characteristics. Over the last few years, several methods, listed below, have been developed for the production of low-alcohol or alcohol-free beer (Scott and Huxtable, 1995) (Figure 6.1).

The biological processes include:

1. use of special yeasts (*S. ludwigii*);
2. arrested fermentation;
3. cold contact process (CCP).

The physical processes include thermal and membrane processes such as:

1. thin-layer evaporation;
2. falling film vacuum evaporation;
3. continuous vacuum rectification;
4. reverse osmosis;
5. dialysis.

Less used processes include pervaporation, freeze concentration, extraction processes, such as extraction with organic solvents and extraction with carbon dioxide, as well as adsorption on special kieselgels or on special adsorbent resins (Von Hodenberg, 1991). An alternative technique for producing beer with a reduced ethanol content is the use of a genetically modified yeast strain that forms less ethanol during complete fermentation of wort sugars (Nevoigt *et al.*, 2002). Technologically, it is possible to produce beer with less than 0.05% (v/v) of alcohol. The alcohol

Table 6.2 Alcohol-free beers obtained with different production technologies

Brewing method	% (v/v) alcohol	References
Arrested fermentation and dilution	0.3–1.0	Zasio (1996)

Dialysis	0.4	Zufall and Wackerbauer (2000b)

concentration of beer obtained from the different methods is reported in Table 6.2.

Production Technologies

Biological methods

The most common way to produce non-alcoholic beers is to modify the normal brewing process so that fermentation is limited and almost no ethanol is produced. There are several techniques for determining alcohol concentration by controlling the extent of fermentation. Generally, worts with a low concentration of fermentable carbohydrates are used for all of these techniques. Such worts can be produced by using a high-temperature mash cycle that involves removing and boiling a portion of the mash (the decoction); it is then returned to the main mash to increase the

temperature. Briefly, the grist is mashed with hot water at 52°C. The first decoction is performed by removing a part of the mash which is then heated to boiling and then mixed again with the main mash to obtain a temperature of 76°C. This temperature, used for mashing, lautering and sparging, inactivates the amylases (mainly β-amylase) which prevents the formation of normal concentrations of fermentable sugars. The mashing process is dependent on the different biochemical characteristics of the enzymes involved. The enzyme α-amylase is largely responsible for the breakdown of starch into lower-molecular-weight sugars and dextrins. Some of these sugars are fermentable but the dextrins, that are the majority, are not. The other important enzyme is β-amylase that attacks dextrins and soluble starch at the non-reducing chain ends to form fermentable sugar maltose. These enzymes have different thermal stabilities; α-amylase is more stable than β-amylase at high temperatures. These properties can be exploited to control the carbohydrate composition and the fermentability of the final wort (Montanari *et al.*, 2005). In the brewing environment, it is necessary to produce a wort fermentability of about 25–30% to produce a low-alcohol beer (Muller, 2000), whereas a wort fermentability of 80% is needed to obtain pale beers (Kunze, 2004). The different fermentable sugar composition of two worts with 1.040 gravity produced at a mashing temperature of 65°C and 85°C is reported in Table 6.3. The worts had the same total carbohydrate content, but the amount of fermentable sugars found in the wort produced at 85°C was considerably lower than that obtained at 65°C. The fermentable sugar composition was determined using high-performance liquid chromatography (HPLC) (Muller, 1991; Floridi *et al.*, 2001).

A further decrease in the alcohol concentration in the final beer can be obtained by fermenting worts produced by high gravity (HG) (15°P) or super high gravity (SHG) (18°P) (Younis and Stewart, 1999) followed by dilution. Biological processes for alcohol-free beer production include:

1. the use of weakly fermenting yeast strains or of yeast strain mixtures which cannot ferment maltose (Von Hodenberg, 1991);

2. stopped fermentation techniques that halt conventional beer fermentation at a low-alcohol level by suddenly increasing the pressure or lowering the temperature;
3. cold contact process.

Use of Special Yeasts   Alcohol-free beer with an alcohol concentration not lower than 0.05% by volume can be obtained with this technique. *Saccharomycodes ludwigii* yeast is closely related to *Saccharomyces uvarum*, but it is capable of fermenting glucose, sucrose and fructose sugars but not maltose, because it does not have invertase and maltase. Considering that *S. ludwigii* attenuates very slowly Narziss *et al.* (1992) obtained an alcohol-free beer by carrying out the fermentation of a wort with 11.5 wt% at 20°C, then reduced the temperature to 0°C during the last fermentation day. After a fermentation time of 120 h at 20°C *S. ludwigii* had formed 0.68 wt% of ethanol. With a dilution to 7.5% of the original gravity, about 0.45% ethanol would have been formed. This yeast has the advantage of being easy to handle – at least during fermentation – and does not require continuous monitoring of the extract reduction.

Stopped Fermentation Methods   Stopped fermentation, where the yeast is removed before full attenuation, can be distinguished from limited fermentation, in which yeast metabolism is restrained. The fermentation may be stopped by removing the yeast cells or by rapidly cooling the fermenting wort. This technique requires worts with a low concentration of fermentable carbohydrates. The fermentation step is conducted at low temperatures, about 2–3°C, with a contact time of about 150–200 h. During fermentation, the wort is not aerated to prevent yeast reproduction and to lengthen the lag-phase where the yeast consumes and metabolizes, but does not propagate or produce ethanol. The metabolites produced during the lag phase influence beer flavor. These beers are characterized by high level of sulfur compounds which do not completely evaporate during the wort boiling. Dimethyl sulfide (DMS) could therefore be used as an analytical marker. Recent experiments have attempted to strip wort in the presence of carbon dioxide or nitrogen. After cooling the wort to about 20°C, it is stripped under pressure to avoid foam production. This method allows a good quality beer with less than 0.2% of alcohol by volume to be produced, but it requires accurate analytical control. The yeast mass and alcohol content must be checked every 8 h. The beers are produced using HG or SHG processes. In the SHG production starting from 18°P, 6°P is obtained after centrifugation at about 0.2–0.3°C and dilution, before or after final filtration, with desalinated water to reach the alcoholic and saccharometric level desired. When producing non-alcoholic beers by means of arrested fermentation, the predominant objective is to reduce the worty flavor impression or limit it from the beginning. When fermentation is arrested at an early stage, the short active phase of the

Table 6.3   Wort sugars analysis

Sugar	Low fermentability	Normal fermentability
Glucose	0.17	0.58
Sucrose	0.27	0.38
Maltose	0.38	4.41
Maltoriose	0.14	0.81
Total	0.96	5.96

Note: Two worts (gravity 1.040) were prepared at 65°C (normal fermentability) and at 85°C (low fermentability) and the single fermentable sugars were determined by HPLC (g/100 g).

yeasts can contribute to the formation of fermentation by-products that influence the taste of the beer. When producing non-alcoholic beer by using stopped fermentation factors, it is necessary to consider the composition of added malt, the time of dilution, the time and extent of acidification, the fermentation conditions in relation to the yeast type, as well as the fermentation time and temperature (Narziss *et al.*, 1992). The following is an example of a method used to produce a beer with 0.31 wt% of ethanol. A brew was diluted so that the finished wort contained 8% extract, which was then divided into two parts and boiled. One part was fermented with the top fermentation yeast and the other with the bottom fermentation yeast. After a "whirlpool rest," the worts were cooled to 10°C and then to 0°C and then pitched without aeration. Once an attenuation of 10% was reached, the products were filtered, stored and carbonated; after a 3-week storage period, they were bottled. At the fermentation temperatures applied (about 0°C), the top-fermenting yeast took effect rather slowly so that attenuations were considerably lower than for the bottom yeast. The use of top fermentation instead of bottom-yeast fermentation results in the formation of more fermentation by-products such as higher alcohols and esters as well as more diacetyl. When bottom yeasts are used, a higher fermentation temperature is more advantageous despite the short fermentation time and the diacetyl level is reduced if the same temperature is used as that used for top-fermenting yeasts (Table 6.4).

Malt composition influences the final alcohol-free beer obtained with stopped fermentation. Compared to the brew pitched with 100% pale malt, the beers with the special malts clearly contained more beer flavor substances. In particular, pale caramel malt contributed the highest amount of furfural; when a slight excess of caramel malt was added the beer had an unusual color. In conclusion, special malts contribute positive taste characteristics and

these beers have a less worty flavor impression than beers produced exclusively with pale malt.

Cold Contact Process   In 1983, Schur (1983) proposed a "CCP" combining a long fermentation time with low temperature thus limiting fermentation. During this process, high temperatures (15–20°C) are sometimes combined with short fermentation times (0.5–8 h). However, low temperatures are used (0–5°C), often in combination with longer fermentation times (up to 24 h) (Huige *et al.*, 1990). No ethanol is produced under these conditions, but the yeast exhibit moderate metabolism such as the production of ester and fusel alcohol or carbonyl reduction. During CCP, alcohol-free beers are produced starting from a normal wort cooled to 0–1°C before pitching. In most cases, a high yeast cell concentration is used ($>10^8$ cells/ml); thus thick yeast slurry is mixed with a HG wort. One disadvantage of this method is that the yeast slurry used for inoculation may have a relatively high ethanol concentration (6.5% v/v) (Schur and Sauer, 1990). Primary metabolism is slow under these conditions, although many biochemical reactions can take place. Carbonyl compounds, suspected of imparting the worty flavor, are partially reduced, while some esters are synthesized. The pH is not as low as usual, so the wort must be acidified either chemically or by immobilized lactic bacteria (Perpete and Collin, 1999).

The CCP is currently applied in two ways:

1. Free mass yeast
2. Immobilized yeast.

CCP with Free Mass Yeast   Worts with low concentration of fermentable sugars are stripped at a low temperature and under pressure with CO_2 or N_2 to eliminate the sulfur compounds which were not evaporated during wort boiling. Generally, the yeasts eliminate them during normal

Table 6.4   Influence of yeast type and fermentation temperature on beer composition

fermentation, but in CCP yeast metabolism is limited. The use of CO_2 rather than N_2 is preferable because CO_2 is present in the final beer at a concentration of 5/6 g/l. CO_2 prevents spontaneous fermentation. This technique is characterized by a contact time of 50–100 h and stripping with CO_2 at a temperature of 0°C. Stripping improves the contact of yeast with the wort because of convective movements. Using an SHG process, this method produces beer with less than 0.1% alcohol by volume. It is an economical method but requires considerable analytical control; the yeast and alcohol production must be checked every 8 h.

CCP with Immobilized Yeast   CCP is currently applied to low-density worts in immobilized yeast reactors. Arrested batch fermentation is a simple operation, but is difficult to control when producing alcohol-free beers. The use of immobilized yeast is currently of great interest to brewers. Fermentation takes a very short time, but the yeast can be used for a long time. A decisive factor is the immobilization of the yeast on a macroporous carrier material (Kunze, 2004). In general, four immobilization technique categories can be distinguished, based on the physical mechanism of cell localization and on the nature of the support mechanisms (Karel *et al.*, 1985; Verbelen *et al.*, 2006):

1. *Attachment to a surface*: The yeast cells are allowed to attach to a solid support. Many different carrier materials are being used. Cellular attachment to the carrier can be induced using linking agents (such as metal oxides, glutaraldehyde or amilosilanes).
2. *Entrapment within a porous matrix*: Two methods of entrapment exist. In the first one, cells are allowed to diffuse into a pre-formed porous matrix. After the cells begin to grow, their mobility is hindered by the presence of other cells and by the matrix, and they are entrapped (Baron and Willaert, 2004). In the second one, the porous matrix is synthesized *in situ* around the cells. Natural and synthetic polymeric hydrogels such as Ca-alginate, *k*-carrageenan, agar, polyurethane, polystyrene and polyvinyl alcohol are being used.
3. *Containment behind a barrier*: This can be attained either by using microporous membrane filters or by entrapping cells in microcapsules. This type of immobilization is most suitable when a cell-free product is required, or when high-molecular-weight products need to be separated from the effluent.
4. *Self-aggregation*: Yeast flocculation is a reversible, asexual and calcium-dependent process in which cells adhere to form flocs consisting of thousands of cells (Bony *et al.*, 1997). Because of their macroscopic size and mass, the yeast flocs settled out rapidly from the fermenting medium, thereby the cells are immobilized naturally. The use of flocculating yeast is simple and cheap.

Immobilization carriers must be inert, cheap, stable, reusable and usually non-toxic, and support a high yeast cell concentration. In brewing, the carriers are usually calcium alginate, carrageenan beads for gel entrapment, DEAE cellulose as an inert support and sintered glass for entrapment in a pre-formed carrier. Other techniques, such as covalent attachment and cell aggregation are mentioned, but not applied. The attachment of yeast cells to suitable carrier materials allows a controlled use of the enzyme potential of the yeast, especially during the exponential and stationary phases of fermentation, and consequently of the formation and removal of fermentation by-products. Currently, only beer maturation and alcohol-free beer production are carried out in commercial-scale immobilized yeast reactors. The main objective during fermentation of alcohol-free beer is to reduce wort carbonyl flavors by yeast, without the formation of alcohol. Traditionally, alcohol-free beer has been produced by arresting fermentation. By keeping the yeast in an optimal steady state condition at low temperature leads to a more complete reduction of wort carbonyl with minimum alcohol formation (Verbelen *et al.*, 2006). In the continuous production of non-alcoholic beer by immobilized yeast at low temperature three aspects are important:

1. The Cultor carrier, a DEAE-cellulose-based granular material, is used in a packed bed reactor, which is operated under down-flow. The yeast cells bind to the rough surface in a monolayer, and the cells are not subject to starvation by substrate limitation. By packing the carrier particles in a bed reactor, and operating under down-flow, a flexible and easily controlled system is obtained.
2. A low temperature (2–4°C) is used. Yeast growth, which could clog the reactor after long production periods, is suppressed and metabolism is limited; however, substrate conversion and product formation are still sufficient. Because of the low temperature, viability remains high over long periods.
3. Anaerobic conditions are maintained, which suppress yeast growth and prevent oxidation of wort lipids that give carbonyl off-flavors.

The combined stress factors thus suppress yeast growth and sugar metabolism, and decrease the risk of contaminants developing in the reactor. In this system, the yeast is made to form a colony on the carrier material. The growth rate in the bioreactor depends on the temperature (Figure 6.2).

S. cerevisiae were grown at very low temperatures, with growth rates of 0.007 and 0.022 h⁻¹ at 2°C and 4°C, respectively, in two batch cultures. In a bioreactor, Van Iersel *et al.* (1995) calculated a growth rate of 0.012/h, in agreement with the rates determined in the above-mentioned batch cultures. The temperature and square root of the growth rate are linearly related. In the reactor, combined stress factors,
Figure 6.2 Scanning-electron micrograph of yeast cells immobilized on a carrier particle. Bar represents $10\,zm^{-1}$. In the yeast immobilized system, the yeast forms a colony on the carrier material. The growth rate in the bioreactor depends on the temperature. *Source*: Van Iersel *et al.* (1995).

Table 6.5 Fermentable sugar concentrations (g/100 g) in the wort and in non-alcoholic beer, produced by an immobilized yeast/CCP

Sugars	In-flowing wort	Out-flowing wort	Change in concentration
Glucose	0.58 ± 0.01	0.61 ± 0.02	+0.03
Fructose	0.10 ± 0.10	0.25 ± 0.01	+0.15

such as low temperature (2–4°C) and anaerobic conditions, limit cell metabolism. Growth at low temperatures requires changes in the cell physiology. Inhibition of transport processes might be responsible for the absence of growth. Yeast cells metabolize glucose and reduce numerous wort components to alcohols and esters. Starting from a wort of 12°P which contained approximately 7.05 g/100 g of fermentable sugar, and operating at a temperature of 3°C with a flow rate of $1\,m^3/h$, a non-alcoholic beer with approximately the same amount of sugars and a concentration of ethanol of less than 0.1% (v/v) was obtained (Table 6.5).

S. cerevisiae takes up glucose more than other sugars. This yeast uses invertase to hydrolyze sucrose in a mixture of various sugars. Due to glucose repression of the maltose and maltotriose transport system, these sugars are not metabolized. At low temperature, regulation of sugar metabolism is apparently centered around glucose which is metabolized preferentially. During fermentation with immobilized yeast at low temperature under anaerobic conditions, yeast cells reduce wort off-flavors and produce beer flavor. The main wort off-flavors are given by aldehydes, such as 2- and 3-methylbutanal, hexanal and heptanal which are reduced to the corresponding alcohols. In addition, aldehydes, formed as intermediates in cell metabolism, are reduced to fusel alcohols (e.g. 1-propanol, isobutanol and isoamyl alcohol). Aldehydes are reduced by alcohol dehydrogenase (ADH). Several ADHs are present in yeast, most of which are dependent on the coenzyme nicotinamide adenine dinucleotide. ADH1 is the main fermentative enzyme and its functioning is essential under anaerobic condition. ADH2 is glucose-repressed, but when cells grow on ethanol, it is the main enzyme that oxidizes ethanol to acetaldehyde. Under physiological conditions, this enzyme uses NADPH

primarily. In addition, NAD phosphate (NADP) specific activity increased slightly during alcohol-free beer production. Overall, NADP-specific activity was 3–5 times higher in immobilized cells compared to suspended cells under anaerobic conditions (Van Iersel *et al.*, 2000). The Bavaria Brewery (The Netherlands) uses a packed bed immobilized yeast bioreactor with a production capacity of 150,000 hl of alcohol-free beer per year (Van Dieren, 1995), and according to information from the company, the bioreactor operates for months without problems with no biomass being formed. Further advantages of this method are considered to be:

- better utilization of raw materials;
- no losses;
- no environmental problems;
- very rapid start-up phase.

Physical methods

Beers produced in a traditional way and in different brands can be made alcohol-free by using physical methods to remove the alcohol at the end of the production process. But in comparison with the original beer, there can be a great loss of flavor, body and freshness; this can be mitigated by adding krausen, green beer or fully mature beer up to the permissible alcohol content. While, according to Zufall and Wackerbauer (2000a), beers produced with a manipulated fermentation often have a worty and sweet flavor (Kunze, 2004). Generally, two types of physical processes can be distinguished: thermal and membrane processes. Both require an extra process step with additional costs compared to manipulated fermentation.

Thermal Processes Distillation at atmospheric pressure is the simplest method for making "alcohol-free" and "low-alcohol" beer. The beer is heated to boiling and the volatile substances are separated in the vapor phase and the non-volatile substances are concentrated in the liquid phase. Maintaining a high temperature for a long period degrades the beer quality by increasing the color, caramelizing the

naturally occurring sugars and eliminating or damaging the flavor notes. The resulting beer is completely different from the original one; this technology is no longer in use. Nowadays, a vacuum is applied which decreases the boiling temperature and thus reduces the thermal stress on the beer. Most vacuum distillation systems evaporate the beer at temperatures between 30°C and 60°C at pressures of 40–200 hPa absolute (Zufall and Wackerbauer, 2000a). Besides alcohol, other volatile aroma substances like esters and higher alcohols which contribute to a good beer flavor are transferred into the distillate or extracted by vacuum pump. To compensate for these disadvantages, many breweries use a modified brewing technology to produce a more aromatic original beer. Another way to compensate for sensory disadvantages is to blend de-alcoholized beer with a small quantity of original beer or with a beer aroma extract that is recovered from the evaporation plants with rectification columns (Zürcher *et al.*, 2005). The end product of all thermal processes is an alcohol-free beer concentrate to which water and CO_2 must be added.

Continuous Vacuum Rectification   A modern, thermal process for gentle removal of alcohol in beer is the SIGMATEC process (API Schmidt-Bretten, 2004). The beer is degassed and then pre-heated in a plate heat exchanger. The beer is fed to the stripping section of a rectifying column. The fluid flows down the column at a temperature between 43°C and 48°C. In counterflow, the product comes in contact with rising vapors which bring about the selective separation of alcohol from the product. The alcohol-free beer is then fed into an evaporator from the bottom of the column. In the evaporator, vapors necessary for the rectification process are produced and then redirected into the column. The completely de-alcoholized product is pumped out of the plant after passing through a cooler. The alcohol-rich vapors pass from the stripping section to the rectification section where they are concentrated. In an aroma recovery unit, aroma components are recovered and redirected into the beer. So, through the de-alcoholization process, the alcohol level can be reduced to less than 0.1%. In trials performed by Zürcher *et al.* (2005) in an industrial vacuum evaporation plant equipped with a rectification column in which very low-alcohol concentrations are achieved, the levels of most of the aroma compounds of the de-alcoholized beer were below the detection limits. The reduction levels were influenced minimally by the temperature of the process (Table 6.6).

The quality of the separation depends on the equilibrium of the vapor and liquid phases as well as on the time that the beer is on the heat exchange surface which is minimized when the liquid layer is reduced. Thin-layer evaporators with gravimetric (falling film evaporator) or mechanically (vacuum rotation evaporator) operated surfaces are mainly used.

Thin-Layer Evaporation   An example of a thin-layer evaporator is the Centritherm system (Flavourtech Company). It

is a single-effect, centrifugal evaporator that operates under vacuum and uses steam as the heating medium. The heating surface is the underside of a hollow, rotating cone. The full-fermented beer enters the evaporator through a feed tube, and injection nozzles distribute the product to the heating surface. Centrifugal force instantaneously spreads the beer over the entire heating surface in an extremely thin layer (0.1 mm). The beer passes across the heating surface in less than 1 s and collects at the outer edge of the cone and then leaves the evaporator through the stationary paring tube. The product vapor removed from the extract rises through the center of the cone stack and enters an exhaust pipe that transfers it to an external condenser. Steam is supplied to the steam chamber inside each hollow cone through a hollow spindle. As the steam condenses, the condensate is immediately projected to the upper wall of the hollow steam chamber through a channel and is removed from the evaporator by way of a paring tube (Figure 6.3).

The Centritherm evaporator has minimal thermal impact compared to other types of evaporators due to its short delay time and low operating temperatures (35–60°C). The product contacts the heating surface for approximately 1 s. In other evaporation systems contact time is often greater than 30 s. The only negative aspect is the risk of oxygen being introduced into the moving system (Zufall and Wackerbauer, 2000a).

Falling Film Evaporator   The falling film evaporator is, according to Zufall and Wackerbauer (2000a), the cheapest
Figure 6.3 Thin-layer evaporator: Centritherm process. The full-fermented beer enters the evaporator through a feed tube and injection nozzles distribute the product to the heating surface. The beer passes across the heating surface in less than 1 s and collects at the outer edge of the cone and then leaves the evaporator through the stationary paring tube. (1) product feed; (2) steam/condensate; (3) vapor to condenser and (4) product concentrate (Centritherm process, Flavourtech., www.ft-tech.net).

Figure 6.4 Thin-layer evaporator: falling film evaporator. In falling film evaporators, the original beer is pre-heated to boiling. Then even thin film enters the heating tubes through a distribution device in the head of the evaporator, flows downward at boiling temperature and is partially evaporated. The beer therefore has a very short product contact time, generally just a few seconds per pass. The alcohol is removed in a separator connected to the outlet of the evaporator and is finally condensed in a condenser. (1) head, (A) product, (2) calandria, (B) vapor, (3) calandria, lower part, (C) concentrate, (4) mixing channel, (D) heating steam, (5) vapor separator, (E) condensate.

technology that uses thermal processes to produce alcohol-free beer because of its simple construction and great efficiency. Investment and regular operating costs are cheaper than the thin-layer evaporator systems. They are easier to clean and there are no moving parts and no wear. In falling film evaporators the original beer is pre-heated to boiling which occurs at a lower temperature because the whole system is kept under defined vacuum conditions. Even thin film enters the heating tubes through a distribution device in the head of the evaporator, flows downward at boiling temperature and is partially evaporated. This gravity-induced downward movement is augmented by the co-current vapor flow. The beer therefore has a very short product contact time, generally just a few seconds per pass. The contact time is slightly longer than in the thin-layer evaporator. From the beginning to the end of the tube, the layer of the beer becomes thinner because the vapor mass increases while the liquid mass decreases. The alcohol is removed in a separator connected to the outlet of the evaporator and is finally condensed in a condenser (Figure 6.4).

Zufall and Wackerbauer (2000a) examined some parameters and found that conventional analysis does not show important changes, except for the ethanol content. The de-alcoholized beer has only slightly more color and slightly lower concentrations of hop-bittering substances than the original beer. The pH of the de-alcoholized beer is 0.18 higher than that of the original beer which could be due to the loss of volatile organic acids (Table 6.7).

In contrast, the aromatic substances are considerably reduced (Table 6.8).

Table 6.7 Conventional analysis before and after falling film evaporation

	Original beer	*De-alcoholized beer*
Original gravity (wt%)	11.57	4.54

Source: Zufall and Wackerbauer (2000a).

Two- or Three-Stage Falling Film Evaporator The equipment consists of two or three falling film evaporators. According to Zufall and Wackerbauer (2000a), energy can be saved with this kind of plant because the alcohol-containing vapor of the first evaporator is used as heating steam for the second, while the alcohol-containing vapor of the second evaporator is used as heating steam for the third. One disadvantage is the relatively high evaporation temperature of the first evaporator which is necessary to

have enough energy for the evaporation in the last falling film evaporator. There is a significant thermal impact on the beer because the temperature of the beer in the first stage is normally about 60°C and 35–40°C in the last one.

Membrane Processes All of the membrane processes have less thermal impact on the beer (Pilipovic and Riverol, 2005). The alcohol is removed with the aid of a semipermeable membrane which separates a full-fermented beer

Table 6.8 Aromatic substances before and after falling film evaporation

from an alcohol-free liquid; only small molecules like ethanol and water are allowed to pass from the beer to the other liquid. The membranes are placed in modules. Generally, the membranes used are made of cellulose acetate with hollow fiber membranes or the newer spiral-wound membranes. Two types of membrane processes can be distinguished: dialysis and reverse osmosis. These systems are very expensive when alcohol is removed to a content of 0.7% by volume (Zasio, 1996).

Dialysis In a dialysis process, the exchange of substances (Bandel *et al.*, 1986) from different liquids through a semipermeable membrane occurs almost exclusively practically only by means of diffusion (Figure 6.5).

The degree of compound exchange is therefore determined by the concentration gradient at the membrane as well as by the contact time between beer and dialysate. The concentration of all the dissolved substances on both sides of the membrane try to come into equilibrium. In this case, the beer passes along a dialysis membrane at a low-pressure differential, while an alcohol-free dialysate liquid simultaneously flows in counter-current along the other side of the membrane. The principle of counter-current flow guarantees a high concentration gradient between the dialysate and the beer in terms of the alcoholic content so that an optimal diffusion can be obtained (Donhauser *et al.*, 1991). The alcohol escapes from the fermented beer through the membrane into the dialysate liquid. However, a portion of the low-molecular-weight components such as higher alcohols also diffuse with the alcohol weakens the taste of the beer. The esters and higher alcohols are almost completely eliminated (Table 6.9) and only 50% of the short-chain fatty acids remain (Table 6.10).

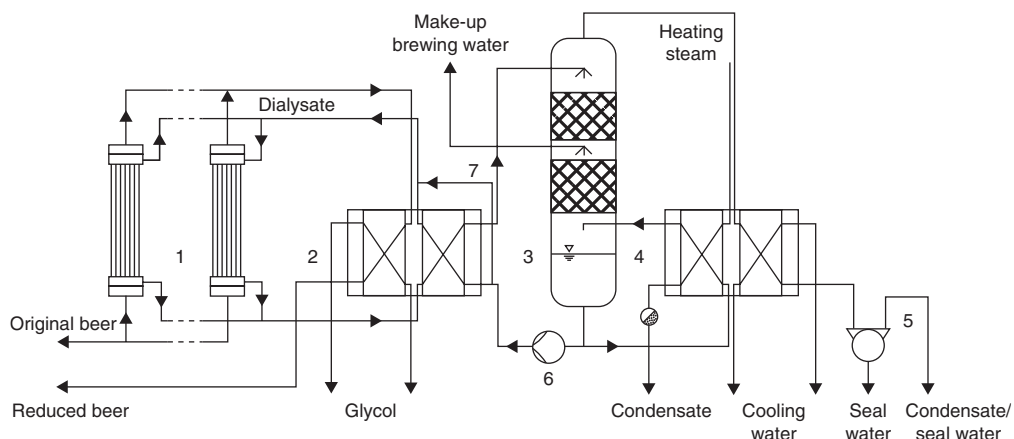

Figure 6.5 Flow diagram of the production of non-alcoholic beer by dialysis. The beer passes along a dialysis membrane at a low-pressure differential, while an alcohol-free dialysate liquid simultaneously flows in counter-current along the other side of the membrane. The alcohol escapes from the fermented beer through the membrane into the dialysate liquid. The alcohol is removed again from the alcohol-enriched dialysate in a rectification column and the dialysate is then pumped back into the module by a dialysate pump. (1) Dialysis membrane module, (2) Plate heat exchanger/low-temperature cooling plant, (3) stripper column, (4) evaporator/condenser, (5) vacuum pump, (6) dialysate pump and (7) temperature control for dialysate infeed. *Source*: Donhauser *et al.* (1991).

This loss of taste components can be prevented if the dialysate liquid has a composition similar to fully fermented beer. For example, alcohol-free beer could be used as the dialysate liquid or the dialysate could be recovered after dialysis, enriched with beer substances and then made alcohol-free in a rectification column and recirculated. On the other hand, substances from the dialysate can also pass into the beer, namely salts (sodium, calcium, nitrate) in the water which are concentrated in the dialysate during rectification and then pass into the beer during dialysis, thus increasing the final values (Donhauser *et al.*, 1991). The beer:dialysate flow ratio determines the amount of ethanol removed. US Patent 4581236 reports a beer:dialysate flow ratio of 1:0.4 that will reduce the alcohol content by 30% lowering the contents of extractive matter by about 10% only with a taste that is fully comparable to the initial beer. By lowering the throughput of beer to 1:1.2 and keeping the amount of dialysate liquid unchanged, a 65% reduction of the alcohol content is obtained, giving a so-called low-alcohol beer. If an alcohol-free beer is desired,

the throughput of beer has to be reduced further. The beer: dialysate flow ratio needed is about 1:2.3, but, according to Zufall and Wackerbauer (2000b), with these proportions the efficiency of the plant decreased noticeably and the energy costs for the rectification of the dialysate increased too much. They proposed a mixed production of de-alcoholized beer by manipulated fermentation followed by removal of ethanol by dialysis to less than 0.5% (v/v) of alcohol. The body, freshness and flavor of these beers are of good quality and the production costs are reasonable. The membranes in a dialysis unit are usually hollow fiber membranes and the process fluids flow at high velocity parallel to the membrane surface. The resulting turbulent flow continuously cleans the membrane surface allowing it to be consistently permeated at the highest possible output for any given feed concentration level. The total pressure in the system is generally slightly overpressure, but it has to be increased above the saturation level of the carbon dioxide in the fully fermented beer to keep the carbon dioxide that is still in solution at the membrane surface and to prevent gas formation in the case of carbon dioxide permeating through the membrane. Carbon dioxide may be dissolved in the dialysate liquid in an amount corresponding to the amount of carbon dioxide in the fermented beer which is subjected to analysis (Bandel *et al.*, 1986). In this way, the beer leaves the dialysis plant with the normal content of carbon dioxide. In comparison with reverse osmosis, in the dialysis method there is no concentration for the beer (Zufall and Wackerbauer, 2000b), there is no post-carbonating of the alcohol-free beer, and no need of a high-pressure pump. Therefore, the costs are lower.

Reverse Osmosis In a reverse osmosis process, the pressure differential of the different liquids is the determining factor for the passage of substances through the membrane and must be substantially higher than the osmotic pressure. An example is the Carlsberg brewery described by Von Hodenberg (1991) (Figure 6.6).

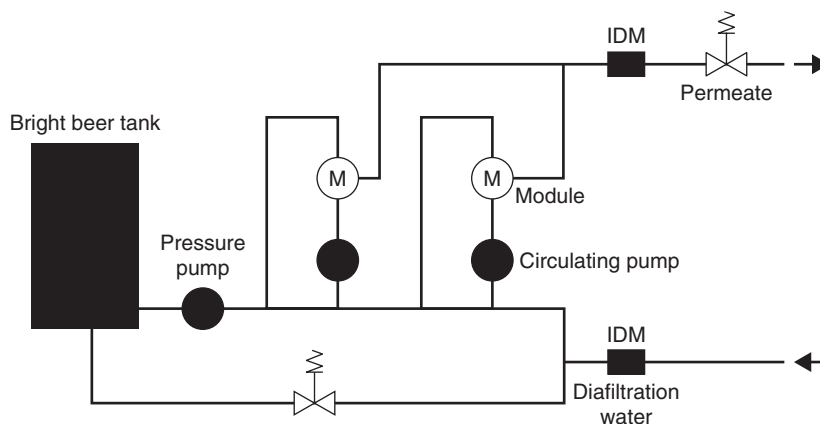
A fully fermented and filtered beer led to the reverse osmosis plant by a feed pump and a valve battery. A pressure of 40 bar is generated by a high-pressure piston pump on the side of the retentate. The beer is passed through a semipermeable membrane, that is a flat cellulose–acetate membrane installed between a spacer and a support plate. During alcohol removal, the beer (concentrate) runs between the membrane and the spacer. The alcohol–water mixture (permeate) goes through the membrane in the direction of the support plate and from there into the void area of the plate; it is then taken away by a hose. One module is made up of 380 membranes. Six modules constitute a unit in a loop. A circulating pump is installed ahead of each loop because the beer must flow past the membrane at a high velocity to avoid that substances such as proteins, α-glucans and β-glucans from being deposited on the membrane and blocking the pores or decreasing the


Figure 6.6   Flow diagram of the production of non-alcoholic beer by reverse osmosis. A fully fermented and filtered beer is led to the reverse osmosis plant by a feed pump and a valve battery. The beer is passed through a semi-permeable membrane. During alcohol removal, the beer (concentrate) runs between the membrane and the spacer. flow capacity during reverse osmosis. Especially, developed cleansers and disinfectants are used to clear the membranes. Cellulose–acetate membranes can only be used in the pH 2–8 range and up to a maximum of 30°C. Careless treatment with excess temperatures or excessive pH leads to a structural change in the membrane and a change in the pores, which makes the membrane unusable. Proven cleansing agents contain β-glucanase and proteinase. Due to the high pressure, the temperature of the beer increases and ice water is used as a cooling medium. Tubular heat exchangers are used in the line downstream of the circulating pump. There are three separate phases: the concentration phase, the diafiltration phase and the make-up phase. During the concentration phase, the permeate (water, alcohol, CO_2 and aromatic substances) is removed from the beer which concentrates the beer and causes an apparent increase in the alcoholic content. At a particular concentration, the beer constituents, for example, the β-glucan gel, reduce the permeability. The following factors are responsible for this: shear forces (arising from the circulating pump), alcoholic content (higher than the original level of the starting beer) and temperature. The lower the temperature during alcohol removal, the more the β-glucan gel that is formed in conjunction with other factors. The concentration phase ends after a defined quantity of permeate is removed which is proportionally replaced by diafiltration water in the diafiltration phase. The diafiltration water has to be sterile, completely de-mineralized and have an oxygen content of less than 0.1 ppm. For storing, only CO_2 may be used as a propellant. Should air be used, oxygen would diffuse into the water by virtue of the partial pressure gradient. The carbon dioxide contained in the beer can also go through the membrane, so there has to be a pressure reducer to maintain a pressure sufficient to prevent carbon dioxide from

being released into the permeate. Bubble-free permeate is required to have an accurate measurement of the quantity. This phase continues until the desired alcoholic content in the concentrate has been reached. Following this, during the make-up phase, the concentrate is brought up to the original volume of the starting beer with diafiltration water. Because of reverse osmosis and of the makeup with diafiltration water, little carbon dioxide is present in the beer, therefore carbonation to the required CO_2 level is necessary. According to Pilipovic *et al.* (2005), the reverse osmosis is not economically feasible for the production of beer with an alcohol percentage less than 0.45.

Chemical Composition and Sensorial Properties of Alcohol-Free and Low-Alcohol Beers

Chemical composition

The chemical composition of commercial alcohol-free beers is reported in Table 6.11.

The real beer extract which is usually brewed with an initial gravity of 4.13–7.4°P often remains above 4.11–6.60°P. Comparing alcohol-free beer and lager beer, however, is complex. Alcohol-free beer has no more than 0.1% ethanol but contains dextrins and fermentable sugars. Lager beer usually contains around 5% ethanol, residual dextrins up to 3°P, but no more fermentable sugars if attenuation is complete (Perpete and Collins, 2000; Floridi *et al.*, 2001). The alcohol-free beers have a higher pH than regular beers. The beers obtained using special yeasts have less bitter substances (EBU) than the beer obtained with arrested fermentation and they have a high concentration of DMS.

Table 6.11 Conventional analysis of commercial alcohol-free beers. Minimum, maximum and average values

	Minimum	Maximum	Average
Original gravity (wt%)	4.13	7.42	6.63
Ethanol (wt%)	0.01	0.54	0.30
Apparent extract (wt%)	4.11	6.43	5.82
Real extract (wt%)	4.11	6.60	6.03
Attenuation (wt%)	0.5	18	12
Color (EBC)	6.6	11.5	8.6
pH	4.25	5.10	4.59
Bitter substances (EBC)	12.1	29.1	22.9
DMS (μg/l)	10	60	28
Acetoin (mg/l)	1.80	9.00	4.70
Total diacetyl (mg/l)	0.04	1.4	0.24
2,3-pentadione (mg/l)	Traces	0.06	0.03

Note: Alcohol-free beer has no more than 0.1% ethanol and attenuation average of 12 wt%. The alcohol-free beers have a higher pH than regular beers with value of 4.59.
Source: Narziss *et al.* (1992).

Sensorial properties

The sensorial properties of an alcohol-free beer are quite different from a full-fermented beer because alcohol is an important flavor contributor. Notwithstanding, alcohol-free beers are of good quality even if they have worty off-flavors and lack the pleasant fruity or ester aroma found in regular beers. Such defects in the process of manipulated fermentation may be due to a fermentation procedure that fails to reduce the chemical compounds responsible for the worty flavor and to produce fusel alcohol and esters. Several carbonyl compounds may contribute to the worty off-flavor, while esters are known to impart the fruity flavor to regular beers. A comparison of the ester and fusel alcohol concentrations of regular and alcohol-free beers shows that alcohol-free beers have little fruity aroma (Perpete and Collin, 1994). The total ester content is below 1 ppm after CCP fermentation (Schur, 1983) (Table 6.12).

S. cerevisiae usually produce high levels of estery flavors. The final level in the end product depends on factors such as high sugar concentrations, temperature increases and low oxygen level. The acetate esters, such as ethyl acetate and isoamyl acetate, are synthesized by alcoholysis of acetyl-coenzyme A (CoA) which is closely linked to the metabolism of lipids. The production of acetate ester is low during the growth phase when lipids are accumulated and is enhanced as the acetyl-CoA increases during the stationary phase. During the production of alcohol-free beer with immobilized *S. cerevisiae* at a temperature of 12°C, the production rate of ethyl acetate is 2–4 times higher compared to rates at 2°C. The beer flavor is strongly affected by the amount of acetalactate because during storage it is converted into a diacetyl that gives a strong off-flavor. At a temperature of 12°C a high level of acetalactate is produced in a short time. An optimal and constant alcohol-free beer

Table 6.12 Concentration (ppb) of fusel alcohols and esters in a CCP before and after fermentation

Compounds	Initial concentration	Final concentration
Isobutanol	150	350
Isopentanol	180	380
2-phenylethanol	210	130
Isoamyl acetate	0	70
Ethyl butyrate	0	10
Ethyl caprylate	0	60
Ethyl caprylate	0	75
Isoamyl caproate	0	6
Phenylethylacetate	0	6
Total	540	1,102

Note: The concentration of esters and fusel alcohols in the CCP increases during the fermentation. The total ester level after fermentation is below 1 ppm.

profile can be achieved by introducing a regular aerobic period to stimulate yeast growth. Temperature can be used to control the rate of growth and the rate of flavor formation (Van Iersel *et al.*, 1999). Wort carbonyl compounds have long been considered responsible for worty aroma in alcohol-free beer. The main carbonyl compounds present in wort are formed by three different reactions: Maillard reactions between amino acids and sugar, Strecker degradation of amino acids and degradation of lipids (Debourg *et al.*, 1994). During the production of alcohol-free beer, wort aldehydes are reduced by the activity of alcohol dehydrogenases of the yeast (Table 6.13).

Isobutanal, 3- and 2-methylbutanal are reduced by alcohol dehydrogenases and aldehyde dehydrogenase using either NADH or NADPH as cofactors. There is

a 77.9% and 70% reduction of 3-methylbutanal and 2-methylbutanal, respectively, but worty flavor imparting compounds remain after fermentation. The worty off-flavor of alcohol-free beers produced by a CCP was attributed to insufficient aldehyde reduction by yeast enzymes due to a limited fermentation. It appears, however, that perception of the aldehydes responsible for the worty flavor is influenced by the medium. In a typical lager beer, ethanol increases aldehyde retention, while in alcohol-free beers, both the absence of ethanol and the higher sugar level could strengthen worty off-flavors (Perpete and Collin, 2000). On the other hand, beers gently de-alcoholized by thermal and membrane processes do not have any off-flavor, except the mild caramel aroma when a thermal process is used. Moreover, they are characterized by the loss of flavor and body. Only an unpleasant sourness was noted in the case of the alcohol-free beer produced by dialysis. Of prime importance is the quality of the original beer (Zürcher *et al.*, 2005). All of the above-mentioned techniques are used and the combination of manipulated fermentation with a process which removes alcohol from a slightly fermented beer can produce very good results.

Technological Evaluation

The biological methods used to produce alcohol-free beers do not usually require an extra plant or process, but rather a more accurate control (Perpete and Collin, 1999). It is extremely important to control the fermentation to prevent an overproduction of alcohol. The use of special yeasts (e.g. *S. Ludwigii*) requires a particular attention to avoid yeast contamination of either the special yeast or the normal brewery yeast. On the other hand, the physical methods require another step in the process which increases the cost for equipment and management (energy and water service). The thermal methods produce an alcohol-free beer with up to 0.05% alcohol by volume, but the colloidal stability of this product is less than the beers made with membrane processes. Furthermore, they have a light caramel flavor due to the thermal impact and a high value of the tiobarbituric acid number. The thermal methods are less selective than membrane methods because they eliminate all of the volatile compounds which can then be recovered by rectification and redirected into the alcohol-free beer. The flavors of beers produced by membrane processes have less body and a low aromatic profile, while the beers obtained by biological methods have a sweet and worty off-flavor.

Summary Points

- There are several different ways to intend "low-alcohol" and "alcohol-free" beers.

- The production of "low-alcohol" and "alcohol-free" beers has different regulation in different countries, therefore the composition of these beers could change from country to country.
- Table 6.1 reports some data related to alcohol content and energy in beers from different countries.
- Over the last few years, biological and physical methods have been developed for the production of low-alcohol or alcohol-free beer.
- The main biological processes include: (1) use of special yeasts (*S. ludwigii*); (2) arrested fermentation and (3) CCP.
- The physical processes include thermal and membrane processes such as: (1) thin-layer evaporation; (2) falling film vacuum evaporation; (3) continuous vacuum rectification; (4) reverse osmosis and (5) dialysis.
- Less used processes include pervaporation, freeze concentration, extraction processes, such as extraction with organic solvents and extraction with carbon dioxide, as well as adsorption on special kieselgels or on special adsorbent resins.
- Alternative techniques for producing beer with a reduced ethanol content include the use of genetically modified yeast strain that forms less ethanol during complete fermentation of worth.
- Technologically, it is possible to produce beer with less than 0.05% (v/v) of alcohol. The alcohol concentration of beer obtained from the different methods is reported in Table 6.2.
- A common chemical composition of commercial alcohol-free beers is reported in Table 6.11.
- The biological methods used to produce alcohol-free beers do not usually require an extra plant or process, but they need a more accurately controlled process. It is extremely important to control the fermentation to prevent an overproduction of alcohol.
- The use of special yeasts (e.g. *S. Ludwigii*) requires a particular attention to avoid yeast contamination of either the special yeast or the normal brewery yeast.
- The physical methods require another step in the process which increases the cost for equipment and management (energy and water service).
- The thermal methods produce an alcohol-free beer with up to 0.05% alcohol by volume, but the colloidal stability of this product is less than the beers made with membrane processes. Furthermore, they have a light caramel flavor due to the thermal impact and have a high level of tiobarbituric acid.
- The thermal methods are less selective than membrane methods because they eliminate all volatile compounds which can then be recovered by rectification and redirected into the alcohol-free beer.
- The flavors of beers produced by membrane processes have less body and a low aromatic profile, while the beers obtained by biological methods have a sweet and worty off-flavor.

Yeast Diversity in the Brewing Industry

Linda Hellborg and Jure Piškur Department of Cell and Organism Biology, Lund University, Lund, Sweden

Abstract

Yeast strains involved in the fermentation greatly influence the beer characteristics. The importance of these unicellular organisms for beer industry is due to their ability to ferment various substrates into ethanol and secondary metabolites. The variation in nature is enormous with over 1,000 different yeast species recognized and many more strains. Taking this into account the possibility of forming even new variants in the laboratory is immense. The best characterized yeast is *Saccharomyces cerevisiae*, and it is also the most common top-fermenting brewer's yeast. The most common bottom-fermenting lager yeast is *Saccharomyces pastorianus*, a hybrid between *Saccharomyces cerevisiae* and *Saccharomyces bayanus* – like yeast. The genomes from these two yeasts and around 20 other yeasts have now been fully sequenced, and a few more are partially done. From these sequences different post-genomics tools have been derived and can now be used, in combination with other genetic and molecular biology tools, to study and manipulate certain yeast traits that are important for beer industry.

List of Abbreviations

ARS	Autonomous replicating sequence
C	Cytosine
DNA	Deoxyribonucleic acid
GMO	Gene modified organisms
G	Guanine
mRNA	Messenger RNA
mtDNA	mitochondrial DNA
NADH	Reduced form of nicotinamide adenine dinucleotide
rDNA	Ribosomal DNA
SHAM	Salicylhydroxamic acid

Introduction

The change from hunters to farmers approximately 10,000 years ago was one of the largest evolutionary steps for mankind and made our lifestyle of today possible. This step included growing cereals and developing two of the oldest food technologies that we still use today, baking and brewing.

The brewing technology provided early societies with a nutritious and relatively safe drink that also acted as an intoxicant. The necessary ingredient for both baking and brewing is unicellular yeast. Yeasts are therefore one of the earliest domesticated species (Fay and Benavides, 2005). Chemical tests of ancient pottery jars reveal that a fermented beverage of rice, honey and fruit was made in China 7000 before Christ (BC). This was refined into different beverages fermented from different raw materials and described in the earliest texts from the Shang and Zhou Dynasty, in China 1200–200 BC. Residues from wine have also been found on pottery from Egypt dating back to 3150 BC (Cavalieri *et al.*, 2003; McGovern *et al.*, 2004). Beer was also brewed in Mesopotamia 3000 BC, but not until first century AD in Europe (Corran, 1975).

In the mid-1600 Antoine van Leuwenhoek made the first observation of yeast cells, but the importance of yeast in the food and beverage industries was not realized until 200 years later (1850–1900). Scientists like Louis Pasteur (1822–1895), Hermann Emil Fisher (1852–1919) and Emil Christian Hansen (1842–1909), and their discoveries on yeast have importantly influenced the modern brewing industry (reviewed in Barnett, 2000).

Louis Pasteur, a French chemist and biologist, solved the mysteries of rabies, anthrax, chicken cholera and silkworm diseases, and contributed to the development of the first vaccines. He also discovered that fermentation is caused by microorganisms and thereby contributed a scientific explanation for wine making and brewing of beer. This insight led to the process of pasteurization (as reviewed by Barnett, 2003).

Emil Fischer was a German chemist and the founder of carbohydrate chemistry in the late nineteenth century. His father had a brewery in Dortmund, where young Emil Fischer made his first experiments with beer yeast to ferment different sugars. He as well as Louis Pasteur found that yeast utilized only one of the two optical forms of sugar, and Emil Fischer also discovered that different yeasts fermented different sugars. This led to his famous conclusion about enzyme and corresponding substrate that have to fit like a lock and key to affect each other. He also speculated about differentiation of main keys and special keys referring to enzymes with a broad and narrow substrate range (reviewed in Barnett, 2003).

Emil Christian Hansen, a Danish biologist, was employed by the Carlsberg Laboratories in Copenhagen. He discovered a way to isolate and culture a pure yeast strain, and by this method he described a number of new yeast species. He also developed a standardized procedure of using clones from bottom-fermenting yeast in the production of beer. A clone isolated from the Carlsberg brewery called Carlsberg bottom yeast no. 1 gave consistently good beer (Barnett and Lichtenthaler, 2001). *This yeast has become known as Saccharomyces carlsbergensis* but its "true" name is *Saccharomyces pastorianus* (Kurtzman and Robnett, 1998).

Yeast Biodiversity

Yeasts are unicellular fungi (Figure 7.1a) that can be classified into two phylogenetic groups: ascomycetous yeasts and basidiomycetous yeasts. Phylogenetics is derived from Greek *phylon* = tribe, race and *genetikos* = relative to birth, from *genesis* = birth, and is the study of evolutionary relatedness among various groups of organisms. The distinction between the two groups of fungi is not easy if they do not reproduce sexually. In the old days these yeast were called fungi imperfecti. Ascomycetous yeasts produce

sexually by forming asci (sing. ascus), sacks where the spores are produced by a simple meios like the bakers yeast (*Saccharomyces cerevisiae*). The Basidiomycetes on the other hand produce basidia (sing. basidium), which are the cells on which sexual spores are produced. There is a great range of variation in morphology of the basidium, the number of spores formed and how the spores are borne on the surface of the basidium (Ingold, 1991). The two phyla separated from each other probably over 1,000 million years ago (Ma) (Heckman *et al.*, 2001). The per cent of the two bases guanine (G) and cytosine (C) in the nuclear deoxyribonucleic acid (DNA) is very different where ascomycetous yeast strains have a gas chromatography (GC) content between 28% and 50% and Basidiomycetes range from 50% to 70% (Price *et al.*, 1978; Kurtzman and Phaff, 1987) (Figure 7.1b).

Today the classification is made by sequence analysis of a region in ribosomal DNA (rDNA). A major advantage of rDNA is that it is present in all living organisms, has a

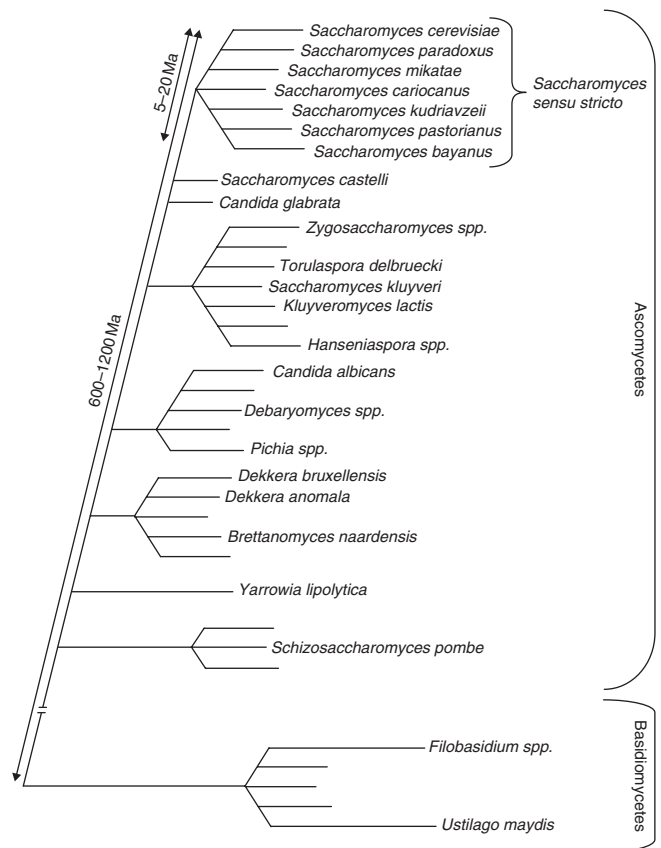

Figure 7.1a Cells from a wine-spoilage yeast *Dekkera bruxellensis*, which is also found in some Belgian beers (kindly provided by A. Merico and C. Compagno).

Figure 7.1b A simplified phylogenetic tree of yeast and some other fungi representing the species mentioned in this chapter. The empty branches are a reminder of known species omitted from the figure. The numbers on the vertical branch indicate times of divergence of the species indicated by the arrows. *Source*: Adapted from Kurtzman and Phaff (1987), Heckman *et al.* (2001), Kellis *et al.* (2003), Kurtzman and Robnett (2003), Kurtzman and Fell (2006) and Woolfit *et al.*, 2007.

common evolutionary origin, occurs in multiple copies and is easy to sequence because primer pairs for conserved regions can generally be used for all organisms. It has been suggested that in fungi the intraspecies (within a species) differences are between 0 and 3 bases per 600 nucleotides (0–0.5%) and a strain differing in more than 6 bases (1%) is considered a separate species (Kurtzman and Robnett, 1998; Fell *et al.*, 2000). Intermediate base substitutions are showing the intermediates between subspecies and fully recognized species. Given time these could evolve to a true species level. With this classification system the number of recognized species of fungi has increased and during the last years doubled the number of recognized yeast species. Although more than 1,000 species of ascomycetous yeast and over 30,000 species of basidiomycetous yeast have been described, it is likely that they are just the top of the iceberg constituting less than 1% of the natural flora. This assumption can be inferred from the high frequency of long single-species branches in the phylogenetic tree implying that there are a lot of genera and species missing (Figure 7.1b) (Kurtzman and Fell, 2006).

One of the best studied eukaryotes is *S. cerevisiae*. Its genome together with its closest relatives has been sequenced and form a group of their own called the *Saccharomyces sensu stricto*. They are supposed to have diverged from each other between 5 and 20 Ma (Kellis *et al.*, 2003). In this group three of the most important species for the beer industry are found: *S. cerevisiae*, *S. bayanus* and a hybrid, *S. pastorianus*. In this group, gene transfer and hybridization between different species is possible, resulting in new variants (Marinoni *et al.*, 1999). The progress of classifying old species and the discovery of new ones has led to many changes in the taxonomy, and a considerable number of species has recently been renamed.

Comparative genomics

Comparative genomics is a branch of genetics that is becoming more and more useful and sophisticated thanks to the growing number of DNA sequences from different organisms. By 2006 the complete sequences of more than 400 genomes have become available, and some 1,600 additional genomes are currently being sequenced. The number of sequenced yeast genomes is increasing strongly due to the industrial and scientific importance of this group of organisms and also because of their small genome sizes (Axelson-Fisk and Sunnerhagen, 2006). Within these sequences lie answers to questions on biological features, the evolution of species and their phylogenetic relation to other organisms. The quest for the "Tree of Life" in which all organisms on earth today will find their ancestors and be connected to one another biologically is getting closer. However, it is complicated by the fact that yeast and bacteria can transfer genetic material between very distantly related species, invalidating previous simple assumptions on the inheritance of a gene (Rokas, 2006). These horizontally transferred DNA fragments could be very important, such as the *URA1*

gene coding for dihydroorotate dehydrogenase in *S. cerevisiae,* which allows its owner to live almost without oxygen and thereby promote the development into good brewing strains (Nagy *et al.*, 1992; Gojkovic *et al.*, 2004). Genetic material can also be transferred between much more closely related species, as seen in the *Saccharomyces sensu stricto* group, which will be described later.

Large-scale comparisons of genomes (Sunnerhagen and Piskur, 2006 and references cited therein) can also suggest answers to many basic questions about genes, like the number of functional genes in a species, identification of species-specific genes, distribution of genes among functional families, gene density, preservation of gene order, mechanisms of genome reshuffling, the rate of sequence divergence, etc. The sequence of a gene determines also its function, and generally, the more similar the sequences, the more similar are the functions. By comparing an unknown sequence from a gene to already annotated gene sequences, the function can be distinguished. In this way a lot of experimental work is reduced.

In 2006, more than 20 different yeast species had been fully sequenced, and the sequences had been published (Sunnerhagen and Piskur, 2006). Apart from yeast a few other fungi have been sequenced. The first genome to be fully sequenced in 1996 was that of *S. cerevisiae*. In the *Saccharomyces sensu stricto* group, *S. paradoxus, S. mikatae, S. bayanus* and *S. kudriavzevii* are now also completely sequenced. From the rest of the Ascomycete group we can find the whole genome sequences from *S. castelli, Candida albicans, Candida glabrata, Yarrowia lipolytica, Debaryomyces hansenii, Kluyveromyces lactis, Kluyveromyces waltii, Hansenula polymorpha, Ashbya gossypii, Aspergillus nidulans, Giberella zea, Magnaporthe grisea, Neurospora crassa* and *Schizosaccharomyces pombe*. In Basidiomycetes three genome sequences are currently available, from *Phanerochaete chrysosporium, Ustilago maydis* and *Cryptococcus neoformans*. The genome size is between 8.7 Mb in *A. gossypii* and 38.9 Mb in *N. crassa*. The number of genes is correlated with genome size and is found to be between 4,718 in *A. gossypii* and 10,082 in *N. crassa* (reviewed in Axelson-Fisk and Sunnerhagen, 2006). *S. cerevisiae* has a genome size of 12.5 Mb divided into approximately 5,777 genes and intergenic regions (Goffeau *et al.*, 1996). The genome sequences are a strong basis for development of a wide array of tools, including tools for manipulation of the corresponding yeasts.

Comparative genomics is also a very good tool to elucidate evolutionary events, like the whole genome duplication in an ancestor of the *Saccharomyces* clade and the subsequent loss and refinements of pathways leading to the species of today (see Figure 7.2) (Piskur *et al.*, 2006).

Why are they here to serve us?

At the end of the Cretaceous age 140–64 Ma, an excess of different fruits developed, and with them an increased

amounts of sugars. These sugars, mostly hexoses (C_6), were used as substrates by many microbes (Friis and Crepet, 1987). The ability of some microorganism to ferment these sugars into ethanol, a two-carbon molecule (C_2), plus carbon dioxide, coupled with a high ethanol tolerance, was probably a winning strategy to inhibit the growth

of competing organisms by high ethanol concentrations (Piskur *et al.*, 2006 and references cited therein). This feature was invented by ancestors of *Saccharomyces* yeasts (see Figure 7.3). However, the degradation of glucose to ethanol instead of a full oxidation to carbon dioxide (CO_2) and water is a very inefficient use of the carbon source. This "peculiarity" is circumvented by a change in the metabolism called the diauxic shift. This strategy involves shifting substrate from glucose to ethanol when the consumption of hexoses has depleted the sugar storage and generated ethanol instead. The accumulated ethanol is now "digested" (the "make-accumulate-consume" strategy) and oxidized into CO_2 (Pronk *et al.*, 1996; Johnston, 1999; Verstrepen *et al.*, 2004).

The ability to produce ethanol in an anaerobic (absence of oxygen) environment is probably a very old trait, originating more than 200 Ma before the yeast lineage (Ascomycetes) diverged. All studied yeasts belonging to Ascomycetes have both the genes responsible for consuming ethanol and also the reverse reaction, production of ethanol in the absence of oxygen. In the presence of oxygen the respiratory pathway can oxidize the sugars to CO_2.

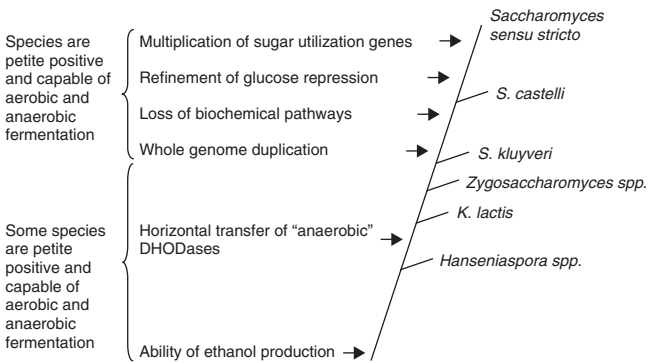

Figure 7.2 Evolutionary tree of important genomic events in Saccharomycetae. *Source*: Modified from Piskur and Langkjaer (2004) and Merico *et al*. (2007).

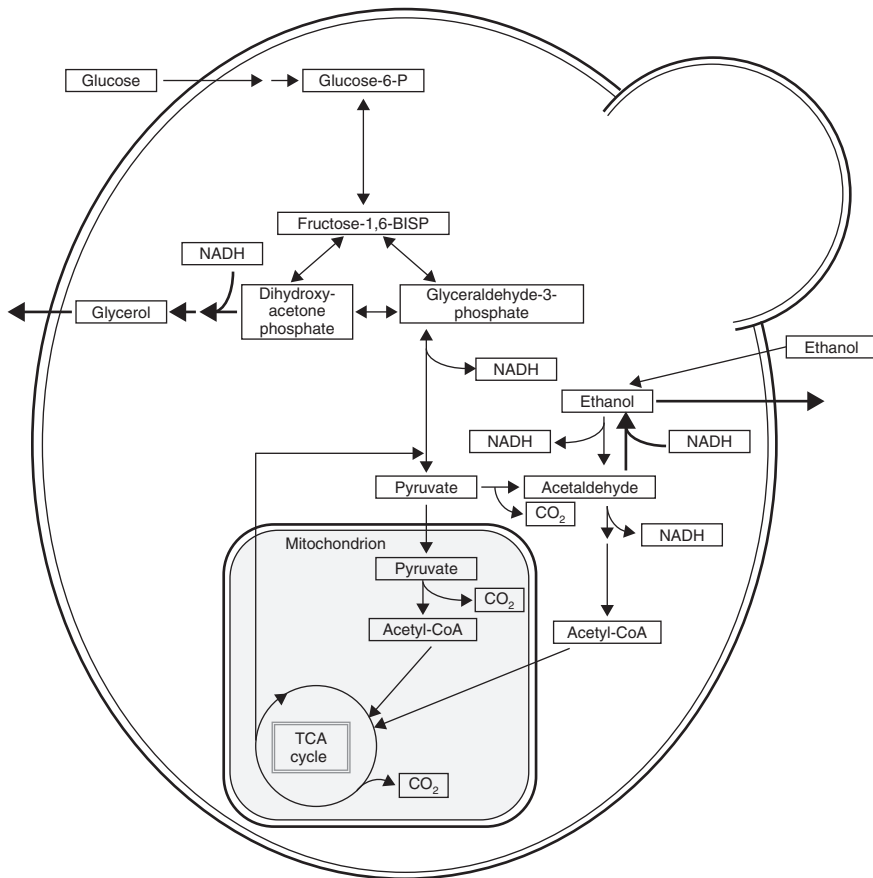

Figure 7.3 Pathways involved in glucose and ethanol assimilation under aerobic conditions, underlining the differences between a Crabtree-negative yeast *Kluyveromyces lactis* (thin arrows), which degrades hexoses directly to CO_2, and a Crabtree-positive yeast, *Saccharomyces cerevisiae* (thin and thick arrows), which can accumulate ethanol. P: phosphate; TCA cycle: tri-carboxylic acid cycle. *Source*: Modified from Piskur *et al.* (2006).

But some yeast lineages, like the *Saccharomyces sensu stricto* group, have developed the ability to suppress the respiratory metabolism in the presence of glucose and oxygen, and can thereby accumulate ethanol even under aerobic conditions. This feature is called the Crabtree effect, and all organisms capable of it are called Crabtree positive (De Deken, 1966).

Species Involved in Brewing

Traditionally ale and lager yeast were differentiated by the ability to ferment melibiose, and whether the yeast was at the top (top fermenting) or the bottom (bottom fermenting) of the fermentation tank after the primary fermentation (see Table 7.1). The lager yeasts produced the extracellular enzyme melibiase (α-galactosidase), which catalyzes the hydrolysis of melibiose into galactose and glucose. The lager yeasts could thereby ferment melibiose, whereas ale strains did not (Tornai-Lehoczki and Dlauchy, 2000; Hornsey, 2004). The ale yeasts used to be all top-fermenting yeasts, where the yeast cells flocculated and floated on the top of the fermentation tank and could easily be removed by carefully scraping them off the surface. These yeasts are mostly closely related to *S. cerevisiae*. The lager brewing yeasts are hybrids between *S. cerevisiae* and other *Saccharomyces* species and usually called *Saccharomyces pastorianus*. They flocculate and sink to the bottom, thereby the name bottom fermenting (Vaughan-Martini and Martini, 1987).

The fermenting temperatures of ales are between 15°C and 23°C, and lager beers has a primary fermentation at 7–12°C and a long second fermentation between 4°C and 7°C. The long second fermentation in lager is the "lagering phase" where the beer clears and mellows resulting in a "crisper" and "cleaner" tasting beer.

The yeast chosen for ale production:

1. ferments more quickly than lager yeasts;
2. converts less sugar to alcohol, which results in a sweeter and fuller body;
3. produces esters, which usually add a fruity taste;
4. produces diacetyl, which provides the beer with a buttery taste.

Table 7.1 Traditional differences in production of lager and ale

	Lager	*Ale*
Yeast species used	*S. pastorianus*	*S. cerevisiae*
Hops used	Yes	No (till seventeenth century)
Ferment meliobiose	Yes	No
Fermenting temperature	4–12°C	14–25°C
Collection of yeast	Bottom	Top
"Taste"	"Clean" beer	Flavor compounds produced

Source: Tornai-Lehoczki and Dlauchy (2000) and Hornsey (2004).

Today 99% of all beer is lager and only 1% is ale, and the brewing yeasts are mainly selected for their uptake capabilities of carbohydrates and other compounds and the conversion of these compounds into alcohol, energy and aroma compounds. Other features that are selected for are the sedimentation characteristics, stress response, vitality and viability. This has led to an almost never-ending search for the ultimate strain, in which certain properties are optimized for different beer characteristics.

Saccharomyces sensu stricto

This group includes *S. bayanus*, *S. cariocanus*, *S. cerevisiae*, *S. kudriavzevii*, *S. mikatae* and *S. paradoxus* (Kurtzman and Robnett, 2003) and are by far the most used in the brewing industry. They have several properties that make them outstanding for industrial use and especially the brewing industry, including fast growth, good ability to produce ethanol and a tolerance for several environmental stresses, such as high ethanol concentration and low oxygen levels (as reviewed by Piskur and Langkjaer, 2004). Within this group, hybridization between two or more species is common, resulting in new sets of genes and new metabolic characteristics (see Figure 7.4a). Rainieri *et al.* (2006) tested different strains isolated from beer and compared the genomes to

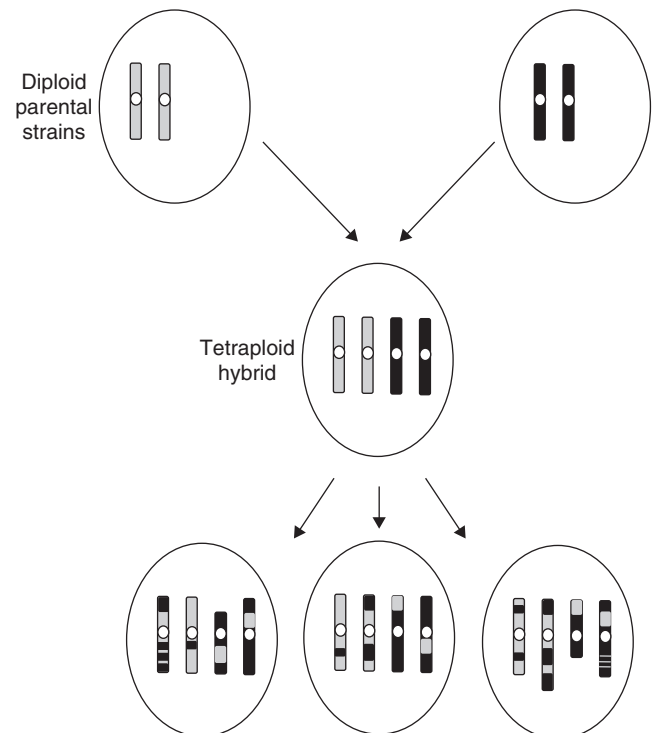

Figure 7.4a Hybridization between two diploid yeast cells forming an allotetraploid progeny and its possible further evolution by genetic events such as homologous recombination, chromosomal translocation, inversion, deletion, duplication and other mutations, making lineages more and more genetically divergent.
Figure 7.4b *Genomes in the polyploid brewing strains, here represented by example 1, 2 and 3. In the brewing strains four different progenitor genomes could be found: Saccharomyces cerevisae, S.c. ▢, Saccharomyces bayanus, S.b. ▨, Saccharomyces uvarum, S.u. ▮ and a fourth called "lager" ◺. Source: Modified from Rainieri et al. (2006).*

the well established *S. cerevisiae*, *S. bayanus* and a third, non-hybrid strain derived from an ancestor of *S. bayanus*, called *S. uvarum*. Within the brewery strains, all of these three different genomes could be found in different hybrid compositions, but a diverged fragment could also be detected in some chromosomes not deriving from any of the three non-hybrid strains mentioned above. The authors refer to this fourth ancestor as the "lager" type (see Figure 7.4b). Three different hybrid groups were found, one containing genomic parts from *S. bayanus*/*S. cerevisiae*/lager, another with genes from all four types, and the last one with genetic compositions of *S. bayanus*/*S. uvarum*/lager. The authors also suggest that the hybrids containing *S. cerevisiae* should all be referred as *S. pastorianus* since this is the scientific name for the most common yeast found in lager brewing (see below).

Saccharomyces cerevisiae   *S. cerevisiae* is the most common top-fermenting brewery species, but the variation in this species is large. The different strains are carefully tested and chosen for their unique characteristics in the fermentation of a brew made from grain and hops into a specific brand of beer. In this species we also find spoilers, typically producing too much of some flavor compound that is not wanted in the beverages. In a recent study (Douglas *et al.*, 2006), different *S. cerevisiae* strains and their effect on the fermentation products from a chemically defined, simulated wort and a hopped ale or stout wort were tested. The choice of strain was found to affect all tested parameters, like foam, filterability and haze characteristics of the final beer.

The search for a better strain is a never-ending task of the yeast engineers, and the number of improvements seems endless. Below are only a few examples breeding efforts on brewery strains of *S. cerevisiae*.

Nevoigt *et al.* (2002) tried to lower the ethanol content in beer to get a healthier and safer (regarding driving and drinking) beverage with the same taste. They over-expressed the gene *GPD1*, which encodes glycerol-3-phosphate dehydrogenase, thereby favoring the production of glycerol at the cost of ethanol production. They managed to increase

the glycerol content 5.6 times, and ethanol was decreased by 18% when compared to the wild type. Over-expression of *GPD1* did not affect the consumption of wort sugars and caused only minor changes in the concentration of higher alcohols, esters and fatty acids. However, the concentrations of several other unwanted by-products, particularly acetoin, diacetyl and acetaldehyde, were considerably increased.

β-glucan is a polysaccharide found in the barley cell walls, causing reduced filterability, formation of gels and hazes in the beer, if not broken down by β-glucanase during the grain modification associated by malting. The adverse effects of the presence of β-glucan in the mash from insufficiently modified malt may be remedied by addition of bacterial β-glucanase produced from, for example, *Bacillus subtilis*. In a genetically engineered *S. cerevisiae* strain where the β-glucanase from *Trichoderma reesei* was expressed, the β-glucans were digested very efficiently, resulting in a reduction of beer viscosity. *Trichoderma reesei's* β-glucanase has a lower pH optimum more suited for *S. cerevisiae* than *B. subtilis'* β-glucanase (Penttila *et al.*, 1987, 1988; Penttilä *et al.*, 1987; Suihko *et al.*, 1990, 1991).

Saccharomyces pastorianus   In 1883 Emil Christian Hansen isolated a single cell from *Saccharomyces carlsbergensis*, or *S. pastorianus* as it is called today. This was the first time someone generated a pure yeast culture from one single, isolated cell, which was then used as a starter culture in the production of beer. Together with its close relatives it is the most studied lager brewing yeast. The strains are often non-maters, they sporulate poorly and they have very low spore viability. The lager brewing yeast, *S. pastorianus* has a mosaic genome with parts deriving from other members in the *Saccharomyces* group (Kodama *et al.*, 2006).

In eukaryotes two different sets of genomes exist, one in the nucleus, and one in an organelle called the mitochondrion (mtDNA). If the cell only contains one set of chromosomes in its nucleus, it is called a haploid cell, and if it contains two sets of chromosomes, the cell is diploid, three sets triploid, four sets tetraploid and so on. The DNA in the nucleus is usually inherited with a haploid set from one parent and a haploid set from the other parent, resulting in a diploid progeny cell. The mtDNA on the other hand is usually only inherited from one parent, but sometimes it can be inherited as a recombinant of that of the two parents.

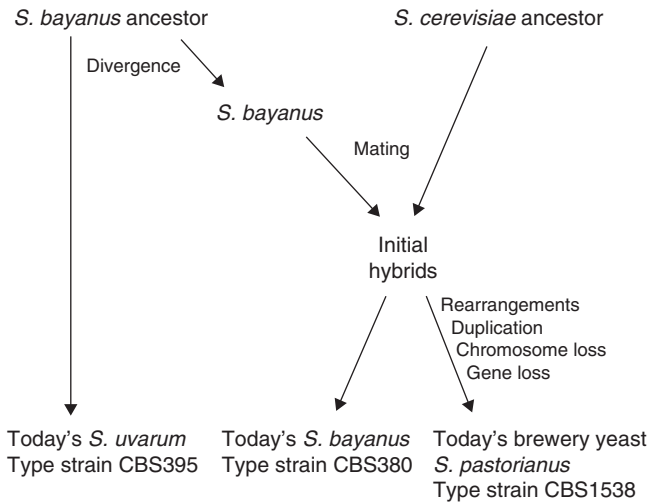
As initially found for a single linkage group (Nilsson-Tillgren *et al.*, 1981), *S. pastorianus* strains are allopolyploid with chromosomes derived from different species (reviewed by Kielland-Brandt *et al.*, 1995). The whole genome of a lager brewing yeast has been sequenced recently (Nakao *et al.*, 2003; Kodama *et al.*, 2006). The hybrid nature of the lager strain has been first proposed on the basis of chromosome III transfer studies (Nilsson-Tillgren *et al.*, 1981). Several studies have tried to identify the parental strains of *S. pastorianus* and from DNA–DNA reassociation with members


Figure 7.4c Schematic representation of the evolution of the modern brewing strains. *Source*: Modified from Casaregola *et al.* (2001) and Kodama *et al.* (2006).

of the *Saccharomyces sensu stricto* group. Vaughan-Martini and Kurtzman (1985) suggested that lager brewing yeasts are hybrids between *S. cerevisiae* and *S. bayanus*. A competing hypothesis was at the time a hybridization between *S. cerevisiae* and *Saccharomyces monacensis* (now classified as a *S. pastorianus* strain), a brewing yeast also isolated by Emil Christian Hansen in the Carlsberg breweries. The reason for this was that several genes (*HIS4*, *LEU2*, *MET2* and *ACB1*) are represented by two different alleles in *S. carlsbergensis*, one identical to *S. cerevisiae* and the other to *S. monacensis* (Pedersen, 1983, 1986; Hansen & Kielland-Brandt, 1994; Borsting *et al.*, 1997). A comprehensive analysis by Casaregola *et al.* (2001) of the different yeast strains involved in developing the lager brewing strains suggested a complex pedigree where today's *S. bayanus* diverged into two different strains, of which one mated with *S. cerevisiae* and evolved into *S. pastorianus* and the other became today's *S. uvarum* (see Figure 7.4c). However, the nature of the participating parental strains and the offspring is still debated. Today's *S. pastorianus* is composed of two whole sets of genomes, one from an *S. cerevisiae* ancestor and a second from an ancestor of *S. bayanus*. The combination of genomes from *S. bayanus*, *S. cerevisiae*, *S. uvarum* and lager has been rearranged, duplicated and some parts lost, and resulted in the modern allotetraploid genome, *S. pastorianus*. The mitochondrial genome was only inherited from the non-*cerevisiae* part, which in itself is odd because all experiments on mitochondrial hybridization between *S. cerevisiae* and *S. bayanus* have resulted in a daughter cell sharing the nuclear genome between the two parents, but the mtDNA molecule only from the *S. cerevisiae* parent (Marinoni *et al.*, 1999).

Since *S. pastorianus* is an allopolyploid yeast, it is more difficult to genetically engineer it compared to the haploid *S. cerevisiae* laboratory strains. However, it can be done (Hansen & Kielland-Brandt, 1996).

Saccharomyces bayanus An important characteristic of *S. bayanus* is its ability to grow and ferment at low temperature. It can still utilize substrates at 2°C, which is impossible for *S. cerevisiae*. To improve the fermentation capability of *S. cerevisiae* at low temperature, this yeast has been hybridized with *S. bayanus*, resulting in hybrids capable of growing and fermenting at 7°C (Kishimoto, 1994; Sato *et al.*, 2002).

The yeasts within the *S. bayanus* have been subdivided further into two groups (Nguyen and Gaillardin, 1997; Rainieri *et al.*, 1999; Naumov, 2000; Nguyen *et al.*, 2000), *S. bayanus*, which contains a miscellany of various hybrids, and *S. uvarum*, which contains strains of non-hybrid origin, usually isolated from grapes or wine fermentations (Naumov *et al.*, 2000, 2002; Demuyter *et al.*, 2004). *S. uvarum* is the only group found in the above described species in which all strains have equal and consistent characteristics (Giudici *et al.*, 1998; Pulvirenti *et al.*, 2000; Rainieri *et al.*, 2003; Nguyen and Gaillardin, 2005). The *S. bayanus* genome has been sequenced (Kellis *et al.*, 2003), and a lot of studies comparing it to its more famous relative *S. cerevisiae* have been carried out (Beltrao and Serrano, 2005; Hall *et al.*, 2005; Naumova *et al.*, 2005; Romov *et al.*, 2006).

Torulaspora delbrueckii

Torulaspora delbrueckii, *Saccharomyces delbrueckii* and *Saccharomyces fermentati* are all names for the same species of yeast. This yeast, along with *S. cerevisiae* and *Kluyveromyces lactis*, is used in vinification and brewing. They have the ability to transform a range of monoterpene alcohols using a variety of reactions (King and Dickinson, 2000). Since monoterpenoids are found in hops, they have a strong influence on the aroma quality of the beer (Ribéreau-Gayon *et al.*, 1975; Bauer *et al.*, 1990), so the yeast transformation of these compounds into other compounds is very important for the flavor (see Table 7.2).

In a study by King and Dickinson (2000) the reactions catalyzed by these yeasts led mainly to the formation of linalool and α-terpineol, but the different yeast strains would influence the beer differently. For example, *T. delbrueckii* forms linalool from geraniol, with no citronellol production (see Figure 7.5). Therefore, using *T. delbrueckii* may produce beers with an aroma more like that of the Muscat wines, characterized by a high linalool content. The modifications of the terpenoids may not only alter the type of aroma, but also the intensity. For example, conversion of linalool to α-terpineol may have a negative effect, as its sensory threshold is 4.6 times lower and then the beer would loose some of its aroma. On the other hand, conversion of nerol to linalool would be expected to be beneficial for the floral flavor.

Table 7.2   Properties of monoterpenoids produced by yeast

Compound	Aroma	Systematic name	Sensory threshold ($\mu g/l$)
Geraniol	Floral, rose-like, citrus	3,7-Dimethyl-*trans*-2,6-octadien-1-ol	132
Citronellol	Sweet, rose-like citrus	3,7-Dimethyl-6-octen-1-ol	100
Linalool	Floral, fresh, coriander	3,7-Dimethyl-1,6-octadien-3-ol	100
Nerol	Floral, fresh, green	3,7-Dimethyl-*cis*-2,6-octadien-1-ol	400
α-Terpinol	Lilac	1-*p*-Menthen-8-ol	460

Source: Aroma data from Bauer *et al.* (1990) and sensory threshold data (in water) from Ribéreau-Gayon *et al.* (1975).

1. Reduction of geraniol to citronellol (except *T. delbrueckii*)
2. Isomerization of geraniol to linalool
3. Isomerization of nerol to linalool
4. Isomerization of linalool to α-terpineol
5. Isomerization of nerol to α-terpineol
6. Hydration of α-terpineol to terpin hydrate
7. Isomerization of nerol to geraniol (except *S. cerevisiae*)

Figure 7.5   Biotransformations of monoterpenoids catalyzed by *S. cerevisiae*, *T. delbrueckii* and *K. lactis. Source*: Modified from King and Dickinson (2000).

Torulaspora delbrueckii has until recently been only poorly studied, but the academic interest in the yeast has increased notably due to its high resistance to several types of stress, including salt and osmotic imbalance. Now genetic tools, such as transformation protocols and knock-out studies, have been developed to study its unique properties (Hernandez-Lopez *et al.*, 2006a,b).

Dekkera/Brettanomyces

Dekkera and *Brettanomyces* are present in spontaneously fermented Belgian lambic and gueuze beer types. They belong to the same genus, where *Dekkera* species are fungi perfecti (reproduce sexually) and *Brettanomyces* species are fungi imperfecti (reproduce asexually). The genus includes the species *D. bruxellensis*, *D. anomala*, *B. naardensis*, *B. custersianus* and *B. nanus* (Walt, 1998). This group is not closely related to *Saccharomyces* (Woolfit *et al.*, 2007), but at least *D. bruxellensis* exhibits a physiology similar to very characteristic features of *S. cerevisiae* and other *Saccharomyces sensu stricto* strains, such as the Crabtree effect, anaerobic growth, the ability to produce respiratory deficient petite mutants, and to produce and tolerate high ethanol concentrations. However, the species is a well-known spoiler of wine and beer, generating off-flavors in the maturation part of the beverage. These off-flavors are often called "brett" flavors and are mainly due to three different compounds produced by *Dekkera/Brettanomyces*:

1. 4-ethylphenol smells like: band-aids, barnyard, horse stable, antiseptic;
2. 4-ethylguaiacol smells like: bacon, spice, cloves, smoky;
3. isovaleric acid smells like: sweaty saddle, cheese, rancidity.

Recently 40% of the genome of a *D. bruxellensis* strain has been sequenced and analyzed (Woolfit *et al.*, 2007). Approximately 2,700 genes, among them a lot of transporters and genes involved in nitrogen and lipid metabolism have been identified. A somewhat surprising finding was the presence of a salicylhydroxamic acid (SHAM) sensitive alternative oxidase (*AOX1*). This gene is connected with the ability of an alternative respiration pathway. There are two known responses to glycolytic overflow in the presence of high levels of glucose, namely aerobic fermentation (leading to the formation of ethanol, defining Crabtree-positive yeasts) and alternative respiration (Crabtree-negative yeast). Both pathways reoxidize NADH (reduced form of nicotinamide adenine dinucleotide) that is overproduced from the glycolysis to NAD^+, either by reduction of pyruvate to ethanol (Crabtree positive) or to reduce oxygen to water by alternative oxidase (Crabtree negative). Another alternative that could be used to reoxidize NADH to NAD^+ is to form glycerol from pyruvate (see Figure 7.3). At the moment it is unclear what the function of the *D. bruxellensis*' SHAM pathway is.

Despite the importance of this yeast species as a spoiler of wine not much is known about its physiology, ecology and variation. There are currently no published studies how to genetically manipulate this yeast, even if it may represent a valuable resource of various aromatic compounds.

Other yeasts

The wort in beer production is a rich growth medium for a number of yeast species. Yeasts not deliberately used

in the brewery and thus uncontrolled are called wild yeast (Holm and Poulsen, 1888; Priest, 1981). These unwanted organisms can produce substances that will alter the quality and the flavor of the beer even in concentration as low as one wild yeast per 10^5-10^6 of the culture yeast. The wild yeasts are traditionally divided into non-*Saccharomyces* and *Saccharomyces* yeasts (Back, 1987). The non-*Saccharomyces* wild yeasts belong to different genera such as *Brettanomyces*, *Candida*, *Debaryomyces*, *Filobasidium*, *Hanseniaspora*, *Kluyveromyces*, *Pichia*, *Torulaspora* and *Zygosaccharomyces* (Ingledew and Casey, 1982; Campbell and Msongo, 1991; Campbell, 1996). The majority of the *Saccharomyces* wild yeasts belong to *S. cerevisiae*, but other *Saccharomyces* species have also been reported (Lawrence, 1988; Campbell, 1996). The *Saccharomyces* wild yeasts are often regarded as the most hazardous wild yeasts. The diversity of spoilage yeasts means that no general description can be given and no general detection method can be used.

Methods to Increase the Diversity

Nature has provided us with an enormous number of species that can ferment ethanol (Merico *et al.*, 2007). However, additional diversity has been and can be created by employment of genetic and molecular methods (reviewed in Polaina, 2002; Hansen and Piskur, 2004).

Selective breeding

Many beer strains are polyploid (have more than two sets of chromosomes) which makes it very hard to manipulate the genome with only molecular methods. As demonstrated by Gjermansen and Sigsgaard (1981), one may circumvent this problem by sporulating and breeding them under specific conditions (Kielland-Brandt *et al.*, 1995). Yeast lineages can be selected for desired characteristics, sporulated and crossed, thereby producing different strains with different characteristics. However, the sporulation ability can be limited. "Rare mating" is another approach, in which haploid maters are mixed with a population of brewing yeasts; this technique may produce rare hybrids that can be selected. Another approach is fusion of yeast cells after the cell wall has been taken away, producing cells with whole or parts of the genome from both of the fused cells. These mating techniques involve the transfer of many genes or parts of the whole genomes, and the outcome is very unpredictable (reviewed in Hansen and Piskur, 2004).

Hybrids

Hybridization, the genetic combination from two different yeast strains to form a progeny, is relatively easy to carry out in the laboratory. Interspecific hybridization offers almost unlimited variation and has only been poorly explored, and the future outcome can only be speculated upon. Another approach to novel and improved brewing strains is the transfer of limited amounts of genetic material within the *Saccharomyces* yeasts by molecular techniques.

One example of combining two different species to get enhanced brewing yeast has been given by Mukai *et al.* (2001). They took a lysine auxotrophic mutant of sake yeast and fused it with a respiratory deficient mutant of a top-fermenting brewer's yeast. The different mutations in the parents are supposed to complement each other in the fused yeast cells, so only progeny with both parental genomes will survive on a selective medium. The rationale for the fusion rested on the ability of the Sake yeast to produce a fruity flavor and its tolerance to higher concentrations of ethanol (Mukai *et al.*, 1998). The characteristics of the fused hybrid have been intermediate compared to the parents, in both ethanol tolerance and production. The content of isoamyl acetate in the beer brewed using the hybrid increased by 1.5-fold compared to the parental yeast. In addition, the content of acetic acid in the beer decreased significantly. The beer brewed using the hybrid had a strong fruity aroma and a sharp aftertaste compared to the beer brewed by the parental yeast (Mukai *et al.*, 2001).

Molecular techniques

To manipulate and alter the characteristics of yeast, methods have been developed for eliminating the function of a gene (gene deletion or disruption) or insert a new gene from another species, to give the organism a new function. These procedures can rely on homologous recombination where a specific target in the genome can be replaced by a functional gene or disrupted to destroy the function of an existing gene. The transformation of genetic material can also be done by a plasmid (small circular DNA), which usually contains a specific gene, a selection gene and an autonomous replicating sequence (ARS). When the plasmid is introduced into the cell, the ARS enables the plasmid to replicate itself (reviewed in Hansen and Piskur, 2004). There are many variants of these two methods, and of course they can be combined to delete an unwanted gene and replace it with a desired functional one at the same time (Amberg *et al.*, 2005). These methods can also generate novel strains with potentially improved traits for the brewing industry. So far, many recombinant strains have been developed but have only rarely been used in the breweries because of an unfavorable attitude toward gene modified organisms (GMO) in the general public.

Post-genomic methods

The sequenced genomes generated from organisms have been a basis for so-called post-genomic methods developed to find out more about the cell physiology and biochemistry. An example is the DNA microarrays, in which the principle is to hybridize (bind) different messenger RNAs (mRNA)

to short sequences of known DNA; the results show different concentrations of the mRNA produced in the cell. These concentration differences are compared against a standard and in this way deviating concentrations of a specific mRNA is recognized. mRNA is the link between DNA and protein, and for those proteins required in the cell at a specific condition, the corresponding mRNA will often be produced in higher amounts. The mRNA signal for a protein can also be completely absent under a certain condition where the protein is not needed (Kumar and Snyder, 2001; Bochner, 2003; Panda *et al.*, 2003; Steinmetz and Davis, 2004). Microarrays detect the expression of the whole genomic set of genes, and not just a single gene.

The mRNA is, as mentioned above, only a link between the instructors (DNA) and the workers (protein), and there is no absolute correlation between the two. Protein microarray technology, on the other hand, has just been introduced, but it has already been successfully applied for the identification, quantification and functional analysis of proteins (reviewed in Poetz *et al.*, 2005). There are a number of different approaches depending on the field of application, but the principle is based on the specific interaction between an antibody and a protein. When attached to each other, a measurable signal, correlated quantitatively with the number of binding pairs, can be detected. These genes can then be manipulated using standard molecular techniques.

Future Trends

The breweries are constantly trying to improve their beers and to find new kinds with other flavors and enhanced characteristics, like foam and color. To do this all components involved in the brewing process are meticulously checked and improved if possible, including the yeast. Yeasts represent a very important part for the final quality of the beer, and not surprisingly there has been lot of research to improve the strains already used and to find new ones. A lot of tools are available to modify the yeast, and a lot of improved strains have been made (reviewed in Dequin, 2001). However, despite the remarkable progress in this field only a limited number of genetically modified brewery strains have been approved officially (Hammond, 1995). An organism is considered a GMO if it has been modified by molecular tools (recombinant DNA technology) described above. It is however not considered a GMO if one uses the selective breeding approach where specific mutations are selected for and crossed with each other or other strains with desirable mutations. The difference at the end is basically precision and the time spent in the laboratory; whereas the recombinant DNA technology is a precise and very fast technique, the breeding process is an often very time-consuming approach. The concern about the GMO is generally due to limited knowledge in the general public about recombinant DNA technology, the benefit for

the public and the potential risk of a release into nature. In most beers (not the unfiltered beers) the yeast has been filtered away, so only the product of the yeast will be engulfed and not the yeast itself.

Another way to enhance the beer variability could be to add different yeast strains during the fermentation process to get a specific flavor or degrade a specific substrate. The more we learn about different yeast strains, the more we can use their potentials. An example could be the "brett" flavors produced by *Dekkera/Brettanomyces*, which in small amounts are desired in particular products. If this yeast is added toward the end of fermentation, the amount of volatile phenols (flavors) produced will be less than if it was added from the beginning of fermentation. In this way the taste could be varied enormously.

Summary Points

- Yeasts are essential in beer production.
- There are over 1,000 different yeast species.
- The different yeasts have different characteristics, which can be studied by various approaches.
- Selective breeding and recombinant DNA technology are different ways of modifying yeast and generating more diversity.
- *Saccharomyces sensu stricto* is a group of well-known yeasts and brewing species.
- *Saccharomyces cerevisiae* is the best characterized yeast and the most common top-fermenting species.
- *Saccharomyces pastorianus* is an allopolyploid yeast derived from *S. cerevisiae* and *S. bayanus-like* and the most common bottom-fermenting lager yeast.
- Other important yeasts include *Saccharomyces bayanus*, *Torulaspora delbrueckii*, *Dekkera/Brettanomyces* and hybrids.
- Improvements have been developed in different yeast strains using recombinant DNA technology, but because of the resistance toward GMO, they have not been used in the brewing industry.

The Brewer's Yeast Genome: From Its Origins to Our Current Knowledge

Sandra Rainieri Department of Agricultural Sciences, University of Modena and Reggio Emilia, Reggio Emilia, Italy

Abstract

Brewing yeasts play the fundamental role of converting malt sugars into ethanol, carrying out the alcoholic fermentation that is at the basis of beer manufacturing. Their metabolism is of major importance for establishing the technological and nutritional characteristics of beer, therefore the understanding of their genome is an essential step for optimizing the brewing process, as well as improving the overall beer quality. Many microorganisms and different yeast species can grow and ferment spontaneously in a rich media such as malted barley juice, the fermentation substrate of beer. However, only two types of yeasts have been selected over the years and are currently employed for industrial beer production: ale and lager yeasts.

Ale yeasts are polyploid *Saccharomyces cerevisiae* that differ from *S. cerevisiae* laboratory strains and show a high degree of interspecific polymorphism. Lager yeasts are now considered as part of the *Saccharomyces pastorianus* species, even though their classification has always been controversial. Their genome is very complex and seems to be composed of at least two different genomes: one nearly identical to *S. cerevisiae* and one originating from a non-*S. cerevisiae* yeast, closely related to *Saccharomyces bayanus*. This chapter illustrates the development of the complex taxonomical grouping of ale and lager brewing yeasts; it describes the steps that led to the current knowledge on the characteristics of their genome; and finally it attempts at elucidating the way they possibly originated and developed.

Introduction

Beer is the product resulting from the fermentation of the juice extracted from malted barley (the wort), carried out by yeasts. Yeasts play the fundamental role of converting the fermentable sugars of wort into ethanol and CO_2, moreover they release a number of minor fermentation by-products that are critical for defining the general aromatic characteristics of beer.

Far before the existence and the role of yeast was even suspected, its ability of converting sugars into ethanol has been exploited by mankind and has been used for guaranteeing the preservation of foodstuff, providing men with safe and nutritious food supplies. An ancestor of beer was already produced more than 5,000 years ago in Mesopotamia (Corran, 1975); for centuries beer represented a good source of nutrients (such as vitamins, proteins and sugars) and its inebriating effect was probably sought for to overcome years of darkness, famine and fear.

Nowadays, beer is one of the most popular fermented beverages in the world. Two different brewing techniques are currently employed for industrial beer production: (1) lager brewing, the worldwide major technique, contributing to 90% of the global beer production and (2) ale brewing, contributing to a 5% of the total world beer production. The remaining 5% is represented by other minor productions generally manufactured at artisan level (Dufour *et al.*, 2003) that will not be discussed in this chapter.

Ale brewing

Ale brewing is probably the earliest technique used for beer manufacturing and the ancestor of beer was most likely produced in this way. Wort is fermented at 20–25°C; yeasts remain in suspension during the fermentation but, toward the end of the process, the cells adhere to the ascending CO_2 bubbles of the foam and are then carried to the surface of the fermenting wort. The fermentation process is completed within a few days and the product is then ready for consumption. In former times, the foam of the best batches used to be manually transferred to start the fermentation of new batches, thus acting as a natural starter.

Currently, ale brewing is used for producing ales and stouts, which are products generally regarded as a specialty beers mainly produced and consumed in United Kingdom and Ireland.

Lager brewing

The lager brewing technique originated in Bavaria (Germany) during the mid-nineteenth century from the practice of storing food into caves, with the scope of preservation. As a matter of fact, the origin of the name "lager" reflects this practice (in German "to store" = "lagern"). In lager brewing, wort is fermented at 8–15°C; the yeasts stay in suspension during the fermentation, but tend to deposit at the bottom of the fermentation vessel once the fermentation has terminated. These deposited yeasts are used again to ferment new batches. After fermentation, lager beer is generally matured at low temperatures for several weeks; during this period, a secondary fermentation occurs, refining the taste and the quality of the product. Lager beer is then filtered and commercialized.

Yeast cultures in brewing

Until the end of the nineteenth century, yeast was not identified as the fermentation agent of wort, and beer was traditionally obtained by the action of a miscellanea of unidentified microorganisms, mainly represented by yeasts and bacteria, that were perpetuated from one batch to the other. It was thanks to the studies of E.C. Hansen from Carlsberg Brewery (Denmark) that yeast cultures could be individually studied. Hansen was the first to apply the pure culture technique (a practice originally elaborated by R. Koch for bacteria) ensuring that isolated cultures were not a mixture of different microorganisms, but individual entities. This allowed Hansen to establish the basis for using selected yeast strains as starter cultures in brewing. Thanks to Hansen's approach, Carlsberg Brewery started the first industrial production of lager beer in 1883 employing a selected starter culture (Polaina, 2002). Figure 8.1 shows an example of cells originating from a pure yeast culture of *S. cerevisiae*.

Figure 8.1 Example of brewing yeast cells originating from a pure culture of *S. cerevisiae*. Yeast pure cultures originate from the multiplication of one single cell, therefore all the daughter cells will be genetically identical to the mother cells and identical among them. This pictures has been taken under an optic microscope with a 1,000 times magnification.

It became soon clear that the two brewing techniques, ale and lager, implied the activity of two different types of yeasts. On the basis of the analysis of some phenotypic characteristics, Hansen was the first to define ale brewing yeasts and to distinguish them from lager brewing yeasts (Hansen, 1883). In particular, Hansen named ale yeasts as *S. cerevisiae* and lager yeasts as *Saccharomyces carlsbergensis* (Hansen, 1908).

Ale and lager yeasts are also commonly known as top and bottom fermenting yeasts, respectively. These names reflect the aforementioned property of ale cells to be carried to the top of the fermentation vessel and of lager cells to precipitate to the bottom of the vessel. The difference in this behavior seems to be related to the fact that ale cells have a higher content of surface protein, which makes them highly hydrophobic thus facilitating their adherence to the bubbles of CO_2 (Dengis and Rouxhet, 1997).

Objective of This Chapter

With the exception of some rare cases, such as some traditional Belgian beers (e.g. Lambic beer) that are still fermented with the natural microflora of wort, industrial ales and lagers are currently produced employing specific yeast starter cultures that have been selected to guarantee a product with constant, programmable and desired characteristics. The study of the genome of brewing yeasts is at the basis for the understanding of their metabolic and physiological processes, which are indispensable for the efficient selection and manipulation of industrial strains.

In this light, the objectives of this chapter are: (1) to provide an updated description of the genome of ale and lager yeast and (2) to attempt at tracking the origin of these genomes.

In Table 8.1, some of the technical terms used in this chapter are defined and explained.

Table 8.1   Definitions and explanation of some of the technical terms used through the chapter

Terms used in the text	Definition
Allele	One of the alternative forms of a gene that occupies a specific position on a chromosome (genetic locus).
Cloned genes	Genes of interest can be isolated among a population of many different genes. Each isolated gene is then perpetuated through insertion into a vector (plasmid) and insertion of the vector into a host organism (a bacterial cell). The obtained cloned gene can be studied, sequenced, etc.
DNA probes	DNA fragments that are denatured, labeled enzymatically (employing a chemioluminescence detection system) or with radioactivity, and used to detect the presence of a DNA fragment bearing a complementary sequence by Southern hybridization. Probes can be gene fragments or entire genes.
DNA reassociation	Pairing of complementary single-strand DNA to form a double helix. This technique is used as a taxonomic tool to distinguish yeast species and bacterial species and is expressed in percentage.
Flow cytometry analysis	Analysis of biological material by detection of the light-absorbing or fluorescing properties of cells or subcellular fractions such as chromosomes, passing in a narrow stream through a laser beam. Through this measurement it is possible to estimate the ploidy of a yeast.
Genome	All of the hereditary information encoded in the DNA possessed by an organism.
Genomics	Science that studies genes and their function, attempting at understanding the structure of the genome, the gene products, and how, when and why these products are synthesized.
Meiosis	Nuclear division which results in daughter nuclei, each containing half the number of chromosomes of the parent.
Microarray	A device consisting of different DNA probes that are chemically attached to a substrate (e.g. a microchip, a glass slide or a microsphere-sized bead). This device is used to analyze the information contained within an entire genome by hybridization.
PCR and PCR-based techniques (AFLP, PCR–RFLP and RAPD)	Polymerase chain reaction, a technique for selectively replicating and producing a large amount of a specific stretch of DNA *in vitro* starting from a DNA sample. PCR-based techniques: AFLP = following restriction enzyme digestion of DNA, a subset of DNA fragments is selected for PCR amplification and visualization. It is a high sensitive method for detecting polymorphisms in DNA. PCR–RFLP = amplification by PCR of a specific DNA fragment and its subsequent digestion with selected enzymes that produce fragments of different lengths reflecting differences in the DNA nucleotide sequence. RAPD = amplification by PCR of undefined regions of a template DNA. Many fragments are generated from a single reaction and are later separated by agarose or polyacrylamide gel electrophoresis.
Ploidy (includes the terms: haploid, diploid, allopolyploid, aneuploid, polyploid)	Ploidy = number of sets of chromosomes in a cell. Haploid = cells having one set of chromosomes; diploid = cells having two sets of chromosomes; polyploid = cell with more than two chromosome sets; allopolyploid = polyploidy produced by a hybrid between two or more different species therefore possessing two or more different sets of chromosomes; aneuploid = cell having more or fewer of the exact multiple of the haploid number of chromosomes.
Proteomics	The analysis of the expression, locations, functions and interactions of the proteins expressed by the genetic material of an organism.
Southern hybridization	Technique for the detection of specific sequences among DNA fragments. Fragments are separated by gel electrophoresis and then blotted onto a sheet of nitrocellulose for detection with labeled nucleic acid probes.
Starter cultures	Microorganisms selected for their optimal fermentation characteristics and used to initiate and guide a fermentation process.
Type strain	The first strain isolated and characterized of a microbial species. In some cases, it is not the most representative strain of the species but possesses an historical value.

Note: Important biological terms required for the understanding of this chapter are collected here.

Brewing Yeasts Taxonomy and Nomenclature

The taxonomy of the *Saccharomyces sensu stricto* species complex

Ale and lager brewing yeasts belong to the *Saccharomyces sensu stricto* species complex, a grouping originally based on the ability of yeasts to give vigorous alcoholic fermentations (Van der Walt, 1970). The taxonomy of *Saccharomyces sensu stricto* yeasts has always been controversial, particularly at species level. Over the years, this group has undergone many changes that were a consequence of the development of the techniques employed for yeasts classification. At the early stage of yeast taxonomy, the only tests employed to identify yeasts were basically colony and cell morphology, the ability to sporulate and to ferment some carbon sources. With the development of new techniques, the system of yeast classification was progressively enlarged; the number of physiological tests, based on fermentation and assimilation of carbon and nitrogen sources, increased, and some biochemical characteristics

Note: Yeast important for the Fermentation Industry belong to the *Saccharomyces sensu stricto* species complex. The classification of these species has undergone numerous changes depending on the classification technique employed. Over the years, species have been created, eliminated and fused, causing confusion among yeast scientists and technologists. In this table are reported the *Saccharomyces sensu stricto* species acknowledged from the first yeast classification of Guillermond (1912) to the currently accepted classification (Kurtzman, 2003). In bold are marked the species involved in the lager brewing yeast genome.

were also being evaluated. With the further development of molecular based techniques, such as nucleotide sequencing and polymerase chain reaction (PCR), yeast grouping has been carried out in an increasingly accurate way. However, depending on the tests employed, yeasts ended up being grouped in different ways and the number of species within the *Saccharomyces sensu stricto* complex changed accordingly (Rainieri *et al.*, 2003). This situation contributed to confuse yeast scientists and technologists. Table 8.2 shows the development of the changes within the *Saccharomyces sensu stricto* yeasts, starting from the first published study on yeast taxonomy to the currently accepted classification.

Saccharomyces bayanus and *Saccharomyces pastorianus* taxonomy

In spite of the sophisticated taxonomic techniques now available and in spite of the importance that some of

these species have for the Fermentation Industry, the most recent yeast classification is not yet considered sufficiently accurate. This is especially true for the species *S. bayanus* and *S. pastorianus*, which are the most relevant for the Fermentation Industry as they include wine, brewing and cider strains. Isolates belonging to these two species are very heterogeneous, as they include cultures of hybrid nature, which make difficult their exact taxonomic collocation. Some authors (Nguyen and Gaillardin, 1997; Rainieri *et al.*, 1999; Nguyen *et al.*, 2000) divided the *S. bayanus* species into two groups: (1) *S. bayanus* variety *bayanus*, a group containing the current type strain (CBS 380) and a miscellanea of hybrid strains not generally isolated in natural environments, but preserved in Cultures Collections and (2) *S. bayanus* variety *uvarum*, commonly referred to as *Saccharomyces uvarum*, which contains strains of non-hybrid origin, widespread in nature, especially in the oenological environment (Naumov *et al.*, 2000; Naumov *et al.*, 2002; Demuyter *et al.*, 2004). *S. uvarum* is the only group within the two species that shows homogeneous and consistent genetic and metabolic characteristics (Giudici *et al.*, 1998; Pulvirenti *et al.*, 2000; Nguyen and Gaillardin, 2005) and because of this, a representative of this group has been chosen to be fully sequenced (Kellis *et al.*, 2003). *S. pastorianus* also contains strains of hybrid origin that possess very variable characteristics and are therefore very difficult to group (Yamagishi and Ogata, 1999; Casaregola *et al.*, 2001). Lager brewing strains are currently classified as *S. pastorianus*.

Current developments of brewing yeasts classification

Recently, Rainieri *et al.* (2006) studied the genetic variability of *S. bayanus* and *S. pastorianus* yeasts and concluded that indeed five distinct groups of yeasts contribute to form these two species, namely; (a) two pure genetic lines, represented by: (1) *S. uvarum* and (2) a novel *S. bayanus* non-hybrid group typified by strain NITE Biological Resource Center (NBRC) 1948 and (b) three multiple genetic lines: (1) containing both the *S. bayanus* and the *S. uvarum* genome plus a novel genome referred to as Lager (Lg genome), (2) containing the *S. cerevisiae*, the *S. bayanus* and the Lg genome and (3) containing the *S. cerevisiae*, the *S. bayanus*, the *S. uvarum* and the Lg genome (Rainieri *et al.*, 2006). According to this grouping, lager brewing strains are part of multiple genetic line containing the *S. cerevisiae*, the *S. bayanus* and the Lg genomes. Table 8.3 shows the details of this grouping.

This controversial taxonomic situation has affected differently the two types of brewing yeasts: ale yeasts have been classified by Hansen as *S. cerevisiae* more than one century ago, and still today this grouping has proved to be valid. On the contrary, lager brewing yeasts have been classified in several different ways over the years. Hansen

Table 8.3 Grouping of *S. bayanus* and *S. pastorianus* yeasts according to their genome constitution

Genetic line	Genome	Representative strain	Species according to current classification
Pure line 1	*S. uvarum*	CBS[a] 7001	
Pure line 2	*S. bayanus*	NBRC[b] 1948	*S. bayanus*
Hybrid line 1	*S. bayanus* + *S. uvarum* + Lg[c]	CBS 380	
Hybrid line 2	*S. cerevisiae* + *S. bayanus* + Lg	Lager yeasts	*S. pastorianus*
Hybrid line 3	*S. cerevisiae* + *S. bayanus* + *S. uvarum* + Lg	Hybrid wine yeasts	

Notes: *S. bayanus* and *S. pastorianus* are important species for the Fermentation Industry as they include wine, cider and lager brewing strains. In spite of their importance, they have not yet been satisfactorily classified. In fact, they are highly heterogeneous species containing strains of hybrid and non-hybrid nature. A detailed study on the genome constitution of these two species carried out on a high number of strains, highlighted that they can be subdivided into five genetic groups: (a) two pure genetic lines (formed by strains that are not a product of interspecific hybridization) and (b) three hybrid lines (formed by strains that are the product of multiple hybridization). The hybrid lines containing the *S. cerevisiae* genome are currently considered as a part of the *S. pastorianus* species, whereas both pure lines and the hybrid line not containing the *S. cerevisiae* genome are part of the *S. bayanus* species. A representative strain of reference is shown for each group.

[c] Lg (Lager type genome, a type of genome recently detected in lager yeast that differs from the *S. bayanus* and *S. uvarum* genomes and is present in various portions of the non-*S. cerevisiae* genome of lager yeasts).

Source: Rainieri *et al.* (2006).

initially classified them as *S. carlsbergensis* (Hansen, 1908); however, in the 1970s this species was not considered valid any longer and lager yeasts were referred to as *S. uvarum* (Van der Walt, 1970). In the following yeasts classification, all *Saccharomyces* species were gathered under the only species *S. cerevisiae*, which was subdivided into 17 physiological races, and lager yeasts became *S. cerevisiae* physiological race *uvarum* (Yarrow, 1984). Since 1998, lager yeasts have been classified as *S. pastorianus* (Vaughan-Martini and Martini, 1998).

Brewing scientists and technologist have generally faced the problem of lager yeast taxonomy in a very practical and sensible way: still today, in fact, in the brewery, lager strains are generally referred to as *S. carlsbergensis*, the original name assigned by Hansen to these cultures.

Characteristics of Ale and Lager Yeasts

Ale yeasts

Phenotypic Characteristics   Ale yeasts generally form branched chains of cells, do not ferment melibiose, have an optimal fermentation temperature of 20–25°C and can grow above 37°C (Tornai-Lehoczki and Daluchy, 2000).

One of the distinctive technological traits of ale yeasts is their ability to produce high concentrations of esters, compounds that impart a fruity aroma to beer; ale beers are, in fact, often described as "fruity" (Stewart *et al.*, 1977). Another characteristic that within brewing strains has been detected only in some ale strains, is the ability to decarboxylate phenolic acids producing some compounds considered off-flavors such as 4-vinylguaiacol (McMurrough *et al.*, 1996). This trait is generally negative; however, it is acceptable for some specialty beer such as the German wheat beer (Bamforth, 2000). Table 8.4 summarizes some of the most important phenotypic characteristics and technological features of ale yeasts in comparison to lager yeasts.

Genomic Characteristics   All in all, not many studies have been carried out to define the genome of ale yeasts and this is probably due to the fact that ale beers represent a minor production compared to lager beers.

With no doubt, ale strains belong to the *S. cerevisiae* species. Investigations carried out by Pedersen (1986) demonstrated that they are closely related to the *S. cerevisiae* laboratory strain S288C. A number of further studies investigating the entire genome of ale yeasts using the Amplified Fragment Length Polymorphism (AFLP) analysis (Azumi and Goto-Yamamoto, 2001), Random Amplified Polymorphic DNA (RAPD) analysis (Tornai-Lehoczki and Daluchy, 2000), as well as the chromosomal banding pattern obtained by Contour-Clamped Homogeneous Electric Field (CHEF) analysis (Johnston *et al.*, 1989), and more recently the construction of a two-dimensional protein map specific for ale strains (Kobi *et al.*, 2004), have confirmed this association. All these studies have also highlighted a high degree of interspecific heterogeneity in ale yeasts.

In spite of having a genome that is highly similar to *S. cerevisiae* laboratory strains, ale yeasts also show a number of characteristics that make them unique among *Saccharomyces* yeasts. These features have probably evolved as a consequence of adaptation to the fermentation substrate, the fermentation technique, and are also a consequence of the artificial selection carried out by brewers, who would chose and perpetuate only the cultures providing a final product with highly desirable characteristics. While laboratory *S. cerevisiae* strains are mainly haploid or diploid, *S. cerevisiae* ale strains, as the majority of industrial *Saccharomyces* yeasts, are polyploid (Stewart *et al.*, 1977). Moreover, they sporulate very poorly and the rare spores are generally non-viable.

Lager yeasts

Phenotypic Characteristics   Among the distinctive physiological characteristics of lager brewing strains are the ability to use melibiose as a carbon source; the ability to ferment well at low temperatures (8–10°C); the inability to grow above 37°C; and the presence of an active system in the cell for fructose transport (Rodrigues de Sousa *et al.*,

Table 8.4   Some of the major characteristics typical of ale and lager yeasts

Ale yeasts	Lager yeasts
Species specific characteristics	
S. cerevisiae polyploid strain	*S. pastorianus* allotetraploid strains
Single genome	Multiple genome
Do not ferment the sugar melibiose	Generally ferment the sugar melibiose
Grow above 37°C	Do not grow above 37°C
Absence of fructose transport system	Presence of fructose transport system
Characteristics influencing technological process of brewing	
Ferment well at 25°C	Ferment well at 10°C
Highly hydrophobic cells	Low hydrophobic cells
Slow uptake of maltotriose	Efficient uptake of maltotriose
Characteristics influencing the final product	
Can decarboxilate phenolic acids → off-flavors	Unable to decarboxilate phenolic acids → no off-flavors
High esters production	Low esters production
Low amount sulfite production	High amount sulfite production

Note: Ale and lager yeasts are the agents of alcoholic fermentation in brewing. They belong to two different species, namely *S. cerevisiae* and *S. pastorianus*, and are employed in two different brewing techniques: ale brewing (where fermentation is carried out at 20–25°C) and lager brewing (where fermentation is carried out at 8–10°C). These yeasts show different characteristics; (i) some of these reflect the traits typical of the species, (ii) others are exploited by the technique of production and (iii) others are responsible for the distinctive traits of the beer obtained. Species-specific traits are also used taxonomically to distinguish yeasts at species level, in particular the ability to grow above 37°C, the ability to ferment the sugar melibiose and the presence of an active transport system for fructose. Important characteristics exploited by the different technological use of the two types of yeasts are: the ability to carry out efficient fermentation at the temperature employed in the two different brewing techniques (10°C and 25°C for lager and ale, respectively), the high hydrophobicity of ale cells that make them adhere to the CO_2 particles of the foam and to be carried to the top of the vessel, and the efficient uptake by lager yeasts of maltotriose, which is the most abundant but less efficiently metabolized sugar of wort. Important traits that influence the characteristics of the final product are the inability of lager yeasts, and actually of most brewing yeasts, to decarboxilate phenolic acid, this decarboxilation causes the release of unwanted off-flavors in beer. The effect of this decarboxilation is acceptable in wheat beer. Esters are compounds imparting a fruity aroma in beer; they are specifically produced by ale yeasts that impart to is beer a specific fruity aroma. Sulfites play in beer an antioxidant activity and contribute to flavor stability, lager yeast produce more sulfites than ale, and lager beer are generally regarded as "sulfury" beers.

1995). These features have been used for years to differentiate lager yeasts from other *Saccharomyces* yeasts, including ale strains (Vaughan-Martini and Martini, 1993).

Some of the most important brewing characteristics that are considered typical of lager yeasts are an efficient uptake of maltotriose, and a high production of sulfite. The efficient uptake of maltotriose is a very important trait. Actually, maltotriose is one of the most abundant sugars in wort; however, it has the lowest priority of uptake compared to the other sugars and its slow metabolization is often the cause of reduced fermentation activity. Lager yeasts utilize maltotriose faster compared to ale yeasts (Zheng *et al.*, 1994) and this seem to be due to a difference in the sugar transport system. Ale yeasts possess broad substrate-specificity transporters that could cause competition between the uptake of different sugars, whereas lager strains possess a more specific transport system for sugars (Vidgren *et al.*, 2005). Sulfite plays an antioxidant activity in beer and is also a key compound for beer flavor stability. Lager yeasts produce higher amounts of sulfite compared to ale yeasts and lager beer is often described as a type of beer with a "sulfury aroma" (Stewart *et al.*, 1977), see Table 8.4.

Genomic Characteristics   A high number of studies have been carried out over the years to elucidate the genome and the functionality of lager brewing yeasts; these studies have led to interesting findings not only under the technological point of view, but have also set the basis for the development of studies on the evolution of industrial yeasts.

The Multiple Genome of Lager Brewing Strains   Many works have supported the hypothesis that the genome of lager brewing yeasts is composed of at least two divergent genomes; a *S. cerevisiae*-type and a non-*S. cerevisiae*-type genome, very likely related to the genome of the *S. bayanus* species. Table 8.5 summarizes some of the most important

Notes: Many studies have confirmed that lager brewing yeast is composed by at least two different genomes; one nearly identical to *S. cerevisiae* and one similar to *S. bayanus*. Most of the approaches taken were based on the Southern hybridization analysis of lager yeast DNA employing DNA probes made with genes isolated from *S. cerevisiae*. A number of genes relevant for the brewing process and located in different chromosomes have been cloned from *S. cerevisiae* and used as probes to detect the presence of complementary DNA fragments in lager yeasts, these complementary fragments have been subsequently characterized by PCR–RFLP or sequencing. In all cases, the genome of lager yeasts showed two types of genes corresponding to the *S. cerevisiae* gene probe; one nearly identical to *S. cerevisiae* and one showing a high similarity to *S. bayanus*. Results confirming this finding have been obtained also by other techniques, such as Southern hybridization of *S. cerevisiae* probes on the chromosomes separated on an agarose gel (CHEF technique), the *S. cerevisiae* genome hybridization to a lager yeasts (DNA reassociation analysis), AFLP and PCR–RFLP analysis on areas covering the entire genome, the detection of all the proteins expressed in comparison with those expressed by *S. cerevisiae* and *S. bayanus* (proteome analysis), until the total nucleotide sequencing of a representative lager yeasts. A brief description of all the techniques mentioned here is given in Table 8.1.

strategies adopted over the years to investigate lager yeast genome. Most of the approaches taken were based on the Southern hybridization analysis of lager yeast DNA employing DNA probes made with genes isolated from *S. cerevisiae*. A number of genes relevant for the brewing process and located in different chromosomes have been cloned from *S. cerevisiae* and used as probes to detect the presence of complementary DNA fragments in lager yeasts, these complementary fragments have been subsequently characterized by PCR–RFLP (restriction fragment length polymorphism) or sequencing. In all cases, the *S. cerevisiae* probe could detect two types of genes in lager yeasts; one nearly identical to *S. cerevisiae* and one showing a high similarity to *S. bayanus*. Works based on the study of the entire genome using different PCR-based techniques such as RFLP, RAPD, AFLP, corroborated this evidence. In the year 2000, the release of a protein profile specific for lager brewing strains provided further evidence of the co-existence of two types of genomes, as two co-existing protein profiles, one identical to *S. cerevisiae* and one highly similar to *S. bayanus*, were detected (Joubert *et al.*, 2000).

The Chromosomal Set Up of Lager Brewing Yeasts   The existence of two divergent genomes in lager brewing yeasts implies also the presence of a multiple chromosomal set made of at least two types of chromosomes: one representing the *S. cerevisiae* genome and the other the non-*S. cerevisiae* genome. Since the 1980s, the co-existence of two types of chromosomes have been investigated at the Carlsberg Laboratories; some pioneer techniques were developed to enable the transfer of individual lager strains chromosomes into laboratory well-defined *S. cerevisiae* strains (Nilsson-Tillgren *et al.*, 1981; Nilsson-Tillgren *et al.*, 1986; Casey *et al.*, 1986b; Petersen *et al.*, 1987; Kielland-Brandt *et al.*, 1995). The study of the meiosis product of such artificial strains enabled these Authors to identify three types of chromosomes in lager brewing strains:

1. Chromosomes that could recombine efficiently with *S. cerevisiae* (homologous chromosomes).
2. Chromosomes that could recombine with difficulty with *S. cerevisiae* (homeologous chromosomes).
3. Chromosomes composed of parts of recombining and not recombining portions (mosaic chromosomes).

The existence of a multiple set of chromosomes has also been demonstrated by studies carried out by Tamai *et al.* (1998) and Yamagishi and Ogata (1999) based on the hybridization of DNA probes on the lager yeasts chromosomes separated by pulsed-field electrophoresis. Both studies confirmed the co-existence of *S. cerevisiae*-type and *S. bayanus*-type chromosomes in lager brewing strains.

In their recent studies, Rainieri *et al.* (2006) investigated the genome composition of several lager brewing strains, by PCR–RFLP or sequencing of 48 genes fragments from three distinct areas of each of the 16 chromosomes corresponding to the *S. cerevisiae* chromosomal set. This investigation, besides confirming the co-existence of the two different genomes (*S. cerevisiae*-type and *S. bayanus*-type), also highlighted the existence of a third type of genome, never detected before, referred to as Lg genome. Table 8.6 shows the genome composition detected with this study for some representative lager strains compared to the genome of *S. bayanus* and *S. uvarum* representative strains.

The Total Genome Sequence of a Representative Lager Yeast   One of the most important efforts in elucidating the nature of lager yeasts has been the completion of the total nucleotide sequence of a representative lager brewing strain (Weihenstephan 34/70) carried out at the Institute of Fundamental Research of Suntory Research Center of Osaka (Japan). The details of this sequence have not been made public yet; however, the approach taken and the major implications of this outstanding scientific achievement are described by Nakao *et al.* (2003) and Kodama *et al.* (2006). The sequencing of a lager yeasts has revealed instrumental in: (a) definitely proving the co-existence of at least two genomes in lager yeasts; (b) defining how these two co-existing genomes are organized in the lager yeast; cell: and in (c) characterizing the complex chromosome structure of lager yeasts.

According to the results obtained with this sequencing, the presence of at least two genomes in lager yeasts was confirmed, as well as the existence of three types of chromosomes. Moreover, this investigation highlighted that lager brewing strains contain at least eight mosaic chromosomes and that in chromosomes VIII, X and XI, mosaic chromosomes co-exists with homologous and homeologous chromosomes (Kodama *et al.*, 2006). This complex situation has been confirmed also by competitive comparative genome hybridization of lager yeasts to the *S. cerevisiae* genome (Bond *et al.*, 2004).

Interspecific Diversity of Lager Brewing Strains   The comparison of several lager brewing strains by comparative genomic hybridization with a *S. cerevisiae* DNA microarray revealed a very high degree of genetic diversity, and highlighted how the chromosomal set up can vary for lager yeasts at strain level (Kodama *et al.*, 2006). The major degrees of diversity have been detected between ancient lager strains (such as the first lager strains studied by Hansen referred to as *S. pastorianus*-type and *S. carlsbergensis* type strains) and strains currently used at industrial level for lager beer production. In particular, the ancient strains seem to have lost most of the *S. cerevisiae* genome that remains present in modern brewing yeasts. These findings are in agreement with the results of DNA reassociation experiments carried out in the 1980s, showing that the values of reassociation to *S. bayanus* are similar for most lager strains, while the values of reassociation to *S. cerevisiae* can differ greatly and are particularly low for the *S. pastorianus*-type strain (Vaughan-Martini and Martini, 1987).

Note: PCR–RFLP and sequencing was carried out on the genome of some selected yeasts involved in the genome constitution of lager brewing strains. These include *S. cerevisiae*, *S. bayanus*, *S. uvarum*, ancient representatives of lager brewing strains (*S. pastorianus* and *S. carlsbergensis*) and a representative strain of lager yeasts currently employed in lager beer production. For each strain, gene fragments located in three different areas for each of the 16 chromosomes corresponding to the *S. cerevisiae* chromosome set (left, center and right area, indicated as L, C and R, respectively), were amplified by PCR and distinguished by RFLP or sequencing. *S. cerevisiae*, *S. bayanus* and *S. uvarum* resulted pure genetic lines (with a single genome) whereas the lager strains tested showed a combination of the genomes of *S. cerevisiae*, *S. bayanus* and of a new genome never detected before and indicated as Lg (lager type genome). The genome of *S. uvarum* was never detected in the lager brewing strains analyzed. In the Table, for each chromosome location it is indicated which type/s of genome was found (Sc = *S. cerevisiae* type genome; Sb = *S. bayanus* type genome; Su = *S. uvarum* type genome; Lg = lager type genome). Chr. = chromosome; L = left telomere of chromosome; C = centromere area; R = right telomere area.

The Ploidy of Lager Brewing Strains   In the light of these reports, establishing the exact ploidy of lager strains seems quite an arduous task. Flow cytometry analysis on some ancient lager yeasts (including the type strains of *S. pastorianus*, *S. carlsbergensis*, and *S. monacensis*), showed different ploidy for different strains; the type strains of *S. pastorianus* and *S. monacensis* resulting diploid, and the *S. carlsbergensis*-type strain resulting triploid (Naumova *et al.*, 2005). Bond *et al.* (2004) examined the copy number of *S. cerevisiae*-like genes in two lager yeasts: the detection of two copies in most cases, but also some discrete changes at distinct loci, led these Authors to conclude that lager yeasts should be aneuploid organisms. Considering all the data reported, including the new sequencing data and the latest microarray hybridization results, it seems reasonable to consider lager strains allopolyploid yeasts, with a highly irregular chromosomal set up that is aneuploid for some regions and that is variable for each strain. As a consequence of the allopolyploid and aneuploid nature, lager yeast do not generally show sexual reproduction, therefore they do not sporulate, and this makes very difficult to perform genetic studies, or to set up programs of genetic improvement using traditional genetic techniques.

Aneuploidy, polyploidy, and lack of sporulation are common traits of industrial yeasts, as mentioned already for ale yeasts. This condition, in spite of hampering the development of improvement programs, shows some advantages. The presence of multiple copies of the same gene, in fact,

reduces the possible negative effects of mutations that very unlikely will affect all the existing gene copies; polyploid non-sporulating cultures are generally very stable and this feature guarantees that they do not modify their metabolic properties during subsequent use, a practice commonly employed in brewing (Dufour *et al.*, 2003).

The Origin of the Non-*S. cerevisiae*-Type Genome and the Shaping of Lager Brewing Yeast Genome   The co-existence of at least two genomes in lager brewing strains has definitely been established; however, it still remains to clarify which is the exact contribution coming from each of these genomes. To achieve this, the understanding of the non-*S. cerevisiae* genome portion of lager yeasts is crucial. In fact, it is likely that the most useful features of lager brewing strains originated from specific traits of this part of the genome. So far, the nature of this portion is not fully clear; a number of studies revealed that it has a high similarity to the *S. bayanus* genome; nevertheless, a representative *S. bayanus* strain contributing to the lager genome has not been identified.

The Interaction Between Wine and Brewing Yeasts   Rainieri *et al.* (2006) demonstrated that the only strains that are not the result of inter- or intraspecific hybridizations within the *S. bayanus* species are *S. uvarum* strains and one type of *S. bayanus* typified by strain NBRC 1948. Their work demonstrates that the genome of *S. uvarum* is not directly involved in the genetic composition of lager brewing strains. On the other hand, *S. bayanus* strain NBRC 1948 shares the same PCR–RFLP pattern as lager brewing strains in 67% of the 48 gene fragments that they examined.

S. uvarum is typically found in oenological environments, whereas *S. bayanus* strain NBRC 1948 was originally isolated from a brewing environment. These two groups of strains seem to have evolved from a common ancestor that diverged into two groups probably to become better suited to different nutritional habitats; oenological and brewing, respectively. In support of this hypothesis is the fact that the bottom fermenting brewing technique was originally created in Bavaria (Germany) towards the end of the nineteenth century when beer was cold conditioned in caves and the use of yeast cultures started becoming popular for bottom fermenting beer. The use of caves for preserving food was a common ancient practice. Bavaria has long been a wine producing area, and wines that were made in those days were also traditionally fermented and stored in the same caves were the lager brewing batches were kept. A cold fermenting type of strain was very likely responsible for the fermentation of such wines, as the low temperature inside caves (8–10°C) should have favored the development and activity of *S. uvarum*-like yeasts. Ecological studies on the distribution of *S. uvarum* strains have confirmed, in fact, that these yeasts are associated with low temperature climatic conditions and dominate wine fermentations

conducted at low temperatures (Naumov *et al.*, 2000; Naumov *et al.*, 2002; Demuyter *et al.*, 2004). It is therefore very likely that *S. uvarum* strains could have contaminated the brewing batch or that the same type of yeast acted as the fermentation agent of both products (beer and wine) and differentiated at a later stage probably to adapt to the different nutritional habitat of the brewing environment. This hypothesis is sustained by physiological, metabolic, and molecular traits that are common to the *S. uvarum*, *S. bayanus* and *S. pastorianus* yeasts. For example, all these yeasts have an optimal temperature for growth that is lower compared to other *Saccharomyces* yeasts and are not able to grow above 37°C. Furthermore, it has recently been proved that only strains belonging to these species have a gene (*FSY1*), which is specifically designed to promote an active transport inside the cell of fructose and consequently to optimize its utilization (Goncalves *et al.*, 2000). Fructose is one of the major sugars of grape juice; however, its concentration is not relevant in wort. The presence of an optimized system for fructose transport in lager brewing strains could simply represent a function inherited from a *S. uvarum*-like wine strain that, in a brewing habitat, gradually lost its role and scope.

The Lg Genome   The nature of the non-*S. cerevisiae*-type genome of lager brewing strains is very complex and does not seem to be associated to any specific single strain or any pure genetic line. At least two types of complements seem to be composing this portion; namely, the *S. bayanus* genome and the Lg genome detected for the first time by Rainieri *et al.* (2006). The Lg genome has not yet been attributed to other existing *Saccharomyces* pure genetic lines and so far it has only been detected in association with other genomes; namely *S. cerevisiae*, *S. bayanus* and/or *S. uvarum* (see Table 8.5). In lager brewing strains, the Lg genome was detected exactly in all the cases when RFLP analysis was not sufficient to distinguish the *S. uvarum* from the *S. bayanus* genome and this could indicate that perhaps in lager brewing strains the *S. uvarum* genome (or the ancestral genome that originated both *S. bayanus* and *S. uvarum*) was gradually substituted by or gradually evolved to the Lg genome and therefore there might not be in nature a pure genetic line containing solely Lg genome.

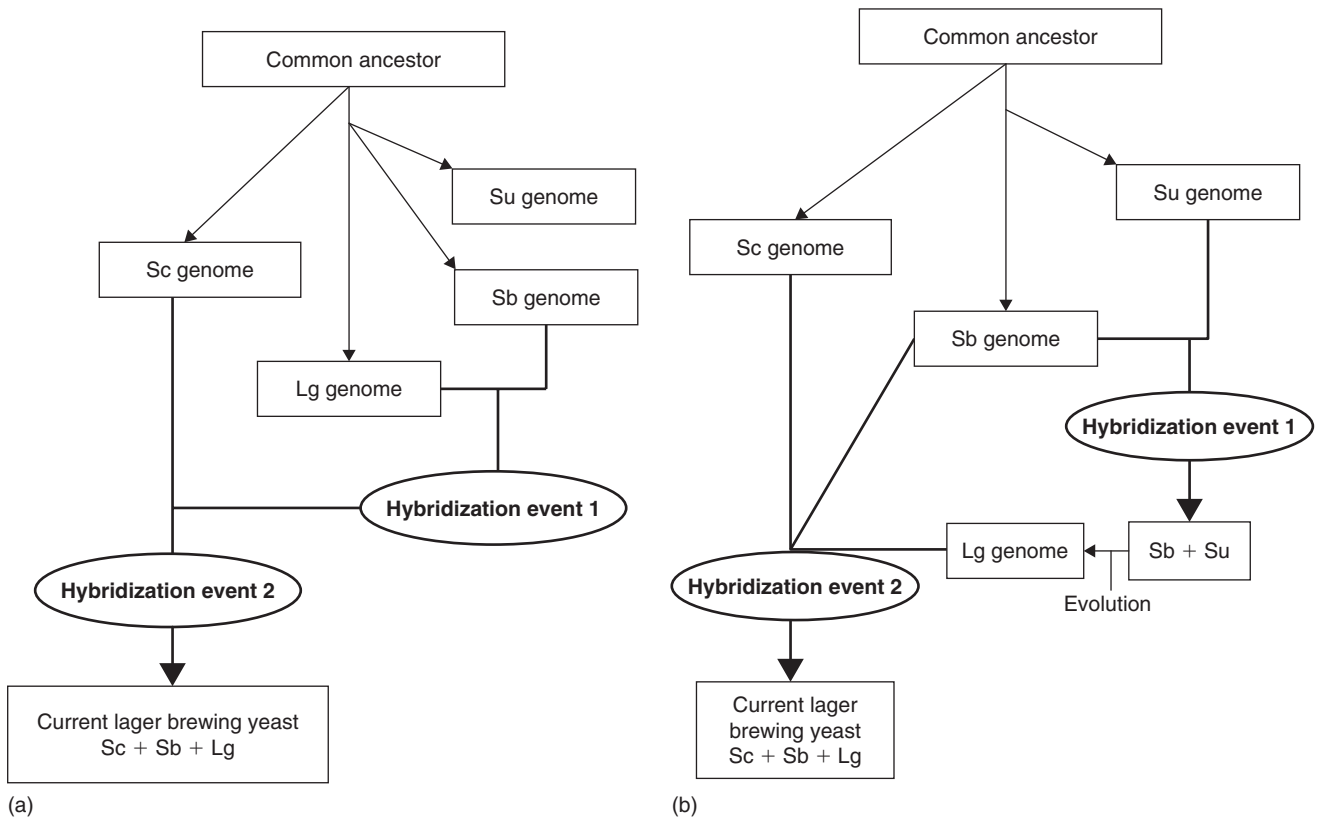
The Hybrid Nature of the Non-S. cerevisiae Portion of Lager Brewing Yeast Genome   The aforementioned findings suggest that lager brewing strains could have originated via a multiple hybridization event. De Barros Lopes *et al.* (2002) demonstrated that multiple hybridization events are possible in *Saccharomyces* yeasts. These authors proposed that lager brewing strains originated from a double hybridization event; one occurring between a *S. cerevisiae*- and a *S. bayanus*-like strain to form *S. pastorianus*, and one between this new formed *S. pastorianus* and a *S. cerevisiae* ale strain. A multiple hybridization event followed by chromosomal loss and rearrangements


Figure 8.2 Two hypothesis on the origin of lager brewing yeast and on the lager-type genome (Lg genome) formation. Lager brewing yeasts are composed of at least two divergent genomes: one nearly identical to *S. cerevisiae* and one similar to *S. bayanus*. Recently, a new genome has been detected as a further portion of lager brewing genome by Rainieri *et al*. (2006) and was named Lg genome. The two hypothesis described in the figure attempt to establish the origin of lager yeasts and of this newly detected genome. *Saccharomyces* yeasts could have originated from a common ancestor, here only the species related to lager brewing strains are shown; *S. cerevisiae* diversified from *S. bayanus* and *S. uvarum* branched out from *S. bayanus* (or the other way around). (a) Hypothesis 1: The Lg genome evolved independently from the common ancestor of *Saccharomyces* yeasts, it hybridized with *S. bayanus* (first hybridization event) and the result of this mating hybridized a second time with a *S. cerevisiae* strain (second hybridization event). (b) Hypothesis 2: *S. bayanus* hybridized with *S. uvarum* (hybridization event 1) and the result of this hybridization underwent some evolutionary rearrangements that lead to the conversion of the *S. uvarum* genome to the Lg type genome. A second multiple hybridization event occurred between *S. cerevisiae*, the newly formed Lg genome and the *S. bayanus* genome (hybridization event 2) that formed the current lager brewing strains. Sc genome = genome from *S. cerevisiae*; Sb genome = genome from *S. bayanus*; Su genome = genome from *S. uvarum*; Lg genome = newly detected genome referred to as Lager genome or Lg genome. In bold are marked the possible ways to the hybridization events.

is a common mechanism of yeast genome evolution (Wolfe and Shields, 1997) and could also be at the basis of the non-*S. cerevisiae*-type genome in lager yeasts. Figure 8.2 shows two of the possible hypothesis on how current lager strains could have originated and on how the Lg genome portion could have evolved. Assuming that all *Saccharomyces* yeast originate from a common ancestor, Figure 8.2(a) shows hypothesis 1: the Lg genome evolved independently from the common ancestor of *Saccharomyces* yeasts, it hybridized with *S. bayanus* and the result of this mating hybridized a second time with a *S. cerevisiae* strain. Figure 8.2(b) shows hypothesis 2: *S. bayanus* hybridized with *S. uvarum* and the result of this hybridization underwent some evolutionary rearrangements that lead to the conversion of the *S. uvarum* genome to the Lg genome. A second multiple hybridization event occurred

between *S. cerevisiae,* the newly formed Lg genome and the *S. bayanus* genome.

The alternative hypothesis of lager yeast being itself the common ancestor that originated the species composing or related to its genome (*S. cerevisiae*, *S. bayanus*, and *S. uvarum*) cannot be excluded.

Conclusions

The study of the origin and the characteristics of industrial yeast genomes is critical for understanding the metabolic properties of cultures guiding the fermentation processes. In brewing, as well as in any other fermented food, this knowledge is at the basis for the development of genetic

improvement programs aimed at selecting and constructing yeasts targeted to optimize the brewing process and the overall beer quality. The case of lager brewing strains is particularly challenging and at the same time exciting. These strains represent, in fact, a unique example in yeast genetics, where the genome has evolved through the rearrangement of divergent genomes in a favorable and stable combination particularly suited to the brewing environment. In the light of the most recent scientific achievements, such as the genome sequence of a representative lager yeast, genomics and proteomics represent a great potential that can be exploited not only for the efficient manipulation of industrial yeasts, but also for the counteraction of pathogenic or undesirable cultures.

Summary Points

- Currently two types of beer are produced industrially: ale and lager beer. Lager beer contributes to the 90% of the global beer production, ale beer to the 5%. These two products are obtained by fermentation of malted barley juice (the wort) at 20–25°C and 8–10°C, respectively, by the activity of two types of yeasts named ale and lager yeasts.
- Ale yeasts are classified as *S. cerevisiae*; they differ from lager yeasts for their phenotypic and genomic characteristics. Among the major distinctive traits of these yeasts are the ability to ferment well at 20–25°C and to produce high concentrations of esters, thus imparting to ale beer a typical fruity aroma.
- Lager yeasts are currently classified as *S. pastorianus*, however, their name has changed several times over the years and their taxonomy is still controversial. Lager strains generally cannot grow above 37°C and ferment well at 8–10°C. They commonly produce a higher concentration of sulfites compared to ale yeasts, thus contributing to enhance the flavor stability of lager beer.
- The genome of lager yeasts is very complex and this is probably the cause of their difficult taxonomic collocation as well as their technological properties. The lager yeast genome is a multiple genome, composed by two portions: a *S. cerevisiae* portion and a non-*S. cerevisiae* portion. The latter is composed by two types of genomes: a *S. bayanus*-like genome and a newly discovered genome referred to as Lg genome. So far the Lg genome has not been associated to any existing yeast species; however, it seems genetically related to other cold fermenting *Saccharomyces* yeasts, such as *S. uvarum* wine strains.
- The multiple genome of lager yeasts seems to have originated from a series of hybridization events that involved the hybridization of the *S. cerevisiae* to the non-*S. cerevisiae* genome. The non-*S. cerevisiae* genome seems to be itself the product of hybridization.
- Three types of chromosomes can be detected in lager yeasts, *S. cerevisiae*-type chromosomes, *S. bayanus*-type chromosomes, and mosaic chromosomes between the two. The cells of lager yeasts are allopolyploid, with an irregular chromosomal set up that is aneuploid for some regions and variable for each strain. The total genome sequence of a representative lager brewing strain has recently confirmed the complex nature of the lager yeast genome and elucidated its chromosomes organization.
- The exploitation of these findings in studies of expression analysis, comparative genomics, and structural analysis will provide novel insight into the improvement of brewing production and beer quality as well as in elucidating beer beneficial characteristics.

Flocculation in *Saccharomyces Cerevisiae*

Eduardo V. Soares Chemical Engineering Department, Superior Institute of
Engineering from Porto Polytechnic Institute, Porto, Portugal
IBB-Institute for Biotechnology and Bioengineering, Centre for Biological Engineering,
Universidade do Minho, Braga, Portugal

Abstract

Yeast flocculation is a reversible, non-sexual and multivalent process of cell aggregation into multicellular masses, called flocs, with the subsequent rapid removal of flocs from the medium in which they are suspended. Traditionally associated with beer production, flocculation might also be useful in modern biotechnology as a low cost and easy method of cell separation. Flocculation characteristics, namely the degree and the time of onset of flocculation, are of exceptional interest to brewing industry because they can affect beer characteristics.

Flocculent cells have a specific lectin-like protein, which sticks out of the yeast cell wall, recognizes and interacts with the carbohydrates residues of α-mannan (receptors) of adjoining cell walls; calcium ions are required to activate the lectin. Taking into account the sugar sensitiveness and ethanol dependence, four flocculation phenotypes have been described: Flo1 phenotype, NewFlo phenotype, mannose insensitive (MI) phenotype and strains whose flocculation requires the presence of ethanol.

Yeast flocculation is a complex process, influenced by multiple factors, namely: cell surface characteristics, chemical characteristics of the medium, fermentation conditions and the expression of several specific genes such as *FLO1*, *FLO5*, *FLO8* and *Lg-FLO1*.

This work reviews, discusses and updates the current knowledge on yeast flocculation with particular attention to the aspects related with brewing yeasts. The loss and the onset of flocculation in brewing yeasts belonging to NewFlo phenotype are also examined and discussed. Finally, the possibility of flocculation to constitute a long-term survival mechanism or a means of protection against an unfavorable environment is discussed.

List of Abbreviations

$[Ca^{2+}]_f$	Free calcium concentration
Con A	Concanavalin A
CSH	Cell surface hydrophobicity
EDTA	Ethylenediaminetetraacetic acid
GPI	Glycosylphosphatidylinositol
Kbp	Kilobase pair
MI	Mannose insensitive
mnn mutants	Mannan synthesis mutants
NCYC	National Collection of Yeast Culture
PCR	Polymerase chain reaction
S. cerevisiae	*Saccharomyces cerevisiae*
YEPD	Yeast extract, peptone, dextrose
YNB	Yeast nitrogen base

Introduction

Cellular aggregation is a well-known phenomenon in higher organisms and widespread in microbial world, being observed within bacteria, yeasts, filamentous fungi, algae and protozoa (Calleja, 1987). Yeast flocculation has been traditionally used in many fermentation processes, like wine making or in the brewing industry. Nevertheless, this property might also be useful in modern biotechnology, as in the production of heterologous proteins or ethanol in continuous fermentations (Domingues *et al.*, 2000, 2005; Verbelen *et al.*, 2006), since it is a natural, easy, eco-friendly and a low cost method of cell separation from the fermentation broth (Figure 9.1), thus facilitating further downstream processing.

Although flocculation is fundamentally linked with the yeast *Saccharomyces cerevisiae* and particularly with brewing yeast strains, it seems to be a more generalized phenomena, being found in other yeast genera, namely *Candida utilis, Hansenula anomala, Kluyveromyces marxianus, Pichia pastoris, Saccharomycodes ludwigii, Schizosaccharomyces pombe* and *Zygosaccharomyces* sp. (Stratford, 1992c).

The present contribution concerns almost exclusively to the present knowledge of flocculation in *S. cerevisiae,* with particular attention to the aspects related to its use in brewing industry. Recent reviews of yeast adhesion and yeast flocculation specifically, where complementary viewpoints can be found, were performed by Jin and Speers (1998), Domingues *et al.* (2000), Verstrepen *et al.* (2003) and Verstrepen and

Klis (2006). For an earlier work, the reader may consult the reviews by Calleja (1987) and Stratford (1992a, c).

Types of Yeast Aggregation

Cellular aggregation can be defined as a meeting of several units in order to form a large unit called the aggregate. The aggregates formation implicates the cell movement, which is initially as a form of isolated cells, and the establishment of reversible multicellular contacts. The aggregation process should be spontaneous and compatible with the life of the cells (Calleja, 1987). Common examples of yeast aggregation, which should be distinguished from flocculation, are sexual aggregation and chain formation (Table 9.1); however, the last phenomenon does not fulfill the definition of aggregation.

Yeast flocculation can be defined as a reversible, multivalent and non-sexual aggregation of yeast cells into multicellular masses (called flocs) (Figure 9.2), dispersible by ethylenediaminetetraacetic acid (EDTA) or specific sugars, with subsequent fast sedimentation of these flocs from the medium in which they were suspended (Table 9.1) (Stewart, 1975; Calleja, 1987). The word floc derives from the Latin word *floccus*, which means a lock of wool. The cells with the ability to form flocs are called flocculants and look like tufts of wool (Figure 9.1), while the cells not able to form flocs are usually known as powdery.

Although Amory *et al.* (1988) made a distinction between flocculence and flocculation, in the present work, the expressions, flocculation, flocculence, aggregation, adhesion and cell–cell interactions will be used indiscriminately to designate the flocculation phenomenon.

Yeast Flocculation and Beer Production

The flocculation characteristics of a brewing yeast strain, namely the timing (during the fermentation cycle) of the

Table 9.1 Different types of *S. cerevisiae* aggregation

	Sexual aggregation	Chain formation	Flocculation
Type of cells involved	Two	One	One
Mechanism	Protein–protein bonding	Covalent linked	Lectin–carbohydrate bonding
Aggregate dispersion	EDTA and sugar insensitive	Mechanical shear; reaggregation not possible	By EDTA (Ca^{2+} sensitive), sugars or heat

Note: Aggregation can be formed between complementary mating types cells (α and a) after exchange of pheromones, a and α factors, respectively (sexual aggregation), due to a failure of buds to separate from mother cell (chain formation) or within single strains (flocculation).

onset of flocculation as well as the degree of flocculation, are of exceptional commercial interest to the brewing industry because they can determine the extent of attenuation (conversion of sugars into ethanol) of the wort. Ideal brewing yeasts should grow and ferment wort sugars, as free cells, and flocculate after its metabolic role has finished. Classically, ale strains raise to the top of the fermenter, probably due to the affinity for the CO_2 bubbles (top fermentation), while the lager strains settle in the bottom of the fermenter (bottom fermentation) (Stewart and Russell, 1981).

The onset of flocculation marks, as a rule, the end of primary fermentation, limits the wort nutrients to yeast cells and leads to a decrease of the number of cells to secondary fermentation. Early or premature flocculation is one of the common causes of "hung" or "stuck" fermentations giving rise to sweeter and less fermented beers (with low alcohol contents). A delay or a lack of flocculation can cause filtration difficulties and some problems occur for obtaining
Figure 9.2 Photomicrographs of non-flocculent and flocculent cells of *S. cerevisiae*. (a) Non-flocculent cells of *S. cerevisiae* S646-8D; (b) flocculated cells of the ale-brewing strain of *S. cerevisiae* NCYC 1364; (c) detail of figure (b).

a bright sparkling beer; moreover, the presence of excess yeast in beer during aging can cause off-flavors due to yeast autolysis (Stewart and Russell, 1981).

Measurement of Yeast Flocculation

Sedimentation test

The sedimentation method described by Burns (1937) is the base of most of the flocculation assays reported in the literature. This method has been modified and refined by many authors in order to standardize the steps and turn it quantitative (Helm *et al.*, 1953; Stewart, 1975; Bendiak, 1994; Soares and Mota, 1997; D'Hautcourt and Smart, 1999). Basically, it consists of the separation, by sedimentation, of the flocs from the free cells. After a defined period of settling (usually between 6 and 10 min), free cells remaining in suspension are determined spectrophotometrically (600 nm) without (Bendiak, 1994) or with a previous deflocculation step (Soares and Mota, 1997). The fraction of flocculated cells is calculated by subtracting the fraction remaining in suspension from the total cell count previously determined.

In these tests, cells are removed from the growth medium, washed and then flocculation is promoted, usually, in 150 mmol/l acetate buffer, at pH 4.5, with about 4 mmol/l Ca^{2+} (ASBC, 1996). In order to become more close to fermentation conditions and take into account ethanol–flocculation dependence shown by several yeast strains, some authors proposed the inclusion of 4% ethanol in the buffer solution (Speers and Ritcey, 1995; D'Hautcourt and Smart, 1999).

Other methods of measurement

In the years 1980 and 1990, a more detailed analysis of the influence of the initial cell concentration and agitation in the quantification of yeast flocculation was performed (Miki *et al.*, 1982b; Stratford and Keenan, 1987, 1988; Soares and Mota, 1997). Yeast cells are usually negatively charged leading to its dispersion; mechanical agitation gives enough energy to yeast cells to overcome this repulsion barrier, allowing the establishment of a flocculent bond (Stratford, 1992a). The colloidal aspects of yeast flocculation, particularly concerning to predict the cell–cell interaction energies and the rate at which cells collide and associate, were reviewed by Jin and Speers (1998).

Stratford and co-workers described a standardized method, in which the cell suspension was shaken in Erlenmeyer flasks during several hours (4–6 h) until the equilibrium between the fraction of flocculated and free cells had reached (Stratford and Keenan, 1987; Stratford *et al.*, 1988). A comparative study between Stratford test and a sedimentation test has shown that the results obtained by both methods are not significantly different, having the sedimentation method the advantage of being much faster (Soares and Mota, 1997).

Beyond the tests reported above, other methods were developed based on the dispersion of the flocculated yeast's suspensions by the action of sugars (Eddy, 1955), heat (Taylor and Orton, 1975) or EDTA (Stahl *et al.*, 1983). On-line measurement of yeast flocculation has been attempted by several authors (Van Hamersveld *et al.*, 1993; Mas and Ghommidh, 2001). Recently, a new method was proposed by Jibiki *et al.* (2001) based on polymerase chain reaction (PCR) amplification of the *FLO5* gene.

Physiology of Yeast Flocculation

pH and presence of ions

Changing the pH value of the solution can cause a reversible dispersion of the flocs in a strain-dependent process (Figure 9.3). For several laboratory and industrial strains, flocculation occurs over a broad pH range, 2.5–9.0; conversely, many brewing yeasts only flocculate within a narrow pH range, with an optimum pH value between 3.0 and 5.0 (Figure 9.3) (Stratford, 1996; Soares and Seynaeve, 2000b).

There is a general agreement that Ca^{2+} is the most effective ion in the promotion of flocculation (Miki *et al.*,
Figure 9.3 Influence of pH on the flocculation. Flocculation of the ale-brewing strains *S. cerevisiae* NCYC 1214 (○) (narrow pH range) and NCYC 1364 (●) (broad pH range). Flocculation was evaluated in standard conditions, in buffer containing Ca^{2+}. Insert: Influence of pH in the free Ca^{2+} concentration ($[Ca^{2+}]_f$). Theoretical calculations of variation of $[Ca^{2+}]_f$ with the pH in the presence of 8 mmol/l of total Ca^{2+} concentration and a ligand (50 mmol/l of succinic acid). *Source*: Reprinted with permission of the editor; from Soares and Seynaeve (2000b).

1982a; Stratford, 1989). For some strains, trace amounts of Ca^{2+} (10^{-5}–10^{-8} mol/l) are sufficient to induce flocculation (Taylor and Orton, 1975), while other strains require a higher amount (5×10^{-4} mol/l) of Ca^{2+} (Soares and Seynaeve, 2000b). More important than the total Ca^{2+} concentration present in the media is the available Ca^{2+} (the free and labile Ca^{2+}); this fraction is the only one which is able to induce the correct conformation of the lectins, and is influenced, among other factors, by the pH, as it can be seen in the insert of Figure 9.3 (Soares and Seynaeve, 2000b). The promotion of flocculation by other ions, such as Rb^+, Cs^+, Fe^{2+}, Co^{2+}, Al^{3+} and particularly Mg^{2+} and Mn^{2+} was also reported (Miki *et al.*, 1982a; Nishihara *et al.*, 1982; Sousa *et al.*, 1992).

Ba^{2+}, Sr^{2+}, Pb^{2+} and with less intensity Na^+ inhibit competitively yeast flocculation, probably due to the similarity of their ionic ratio to Ca^{2+} (Nishihara *et al.*, 1982; Gouveia and Soares, 2004); most likely, these cations compete for the same "calcium binding site" of flocculation lectins, being not able to activate the lectin-like component of yeast flocculation.

Ethanol and ionic strength

Flocculation of the majority of brewing strains is not affected by ethanol (Stratford, 1992c); for some strains, where flocculation mechanism is most likely different from the lectin-like model, flocculation increases with ethanol concentration or only occurs in the presence of ethanol (Mill, 1964b; Dengis *et al.*, 1995; Dengis and Rouxhet, 1997). Conversely, a negative effect of ethanol in yeast flocculation was reported (Kamada and Murata, 1984). It has

been suggested that the positive effect of ethanol is due to its adsorption at cell surface, which may cause a reduced local dielectric constant, leading to a decrease of cell–cell electrostatic repulsion; alternatively, ethanol can allow the protrusion of polymer chains into the liquid phase, carrying binding sites for non-specific (hydrogen binding) or specific interactions (Amory *et al.*, 1988; Dengis *et al.*, 1995). Ethanol seems to produce a pronounced effect in the promotion of flocculation in yeast strains with a strong surface hydrophobicity (Jin and Speers, 2000).

The increasing of ionic strength seems to have a negative impact on yeast flocculation, both for Flo1 and NewFlo phenotype strains, probably due to modifications in the conformation of flocculation lectins (Kamada and Murata, 1984; Jin and Speers, 2000).

Cell surface charge and hydrophobicity

Factors that facilitate cell–cell contact, namely the increase of cell surface hydrophobicity (CSH) or the decrease of cell surface charge, could play an important role on flocculation. However, no clear relationship between electrical properties and the onset of flocculation was found (Amory *et al.*, 1988; Dengis *et al.*, 1995; Dengis and Rouxhet, 1997).

Although an extensive research about the role of CSH on yeast flocculation has been undertaken, a controversy still exists. For instance, CSH and more recently the presence of 3-hydroxy fatty acids (3-OH oxylipins) on yeast cell wall has been positively correlated with the onset of flocculation (Straver *et al.*, 1993; Jin *et al.*, 2001; Strauss *et al.*, 2005). However, other authors described no significant differences in CSH or surface concentrations of proteins, polysaccharides or hydrocarbons between flocculent and non-flocculent cells at stationary and exponential phases of growth, respectively (Dengis *et al.*, 1995; Dengis and Rouxhet, 1997).

Temperature

Temperature affects a multiplicity of factors complicating the interpretation of its effect on the flocculation process. The lowering of fermentation temperature reduces the level of yeast metabolism and the production of CO_2 with the consequent reduction of turbulence favoring yeast sedimentation. Temperature also acts at surface level, in the cell–cell interactions, promoting a reversible dispersion of the flocs at 50–60°C (Mill, 1964b; Taylor and Orton, 1975). Additionally, the growing temperature seems to have a deep impact on yeast flocculation expression. A brief heat shock (52°C, 5 min) in brewing strains in exponential phase of growth delayed the onset of flocculation; a permanent mild heat stress (incubation at a supra-optimum temperature) impair or delay the triggering of flocculation (Williams *et al.*, 1992; Garsoux *et al.*, 1993; Soares *et al.*,

1994; Claro *et al.*, 2007). Probably, a continuous mild heat stress can act directly on the mitochondrial activity and indirectly on the cell membrane structure, affecting the secretion of flocculation lectins with the consequent reduction of flocculation (Soares *et al.*, 1994).

Sugars and nitrogen source

The floc dispersion effect of sugars is well documented in the literature (Mill, 1964b; Taylor and Orton, 1978). A detailed study of the effect of sugars and their derivatives on the floc dispersion promotion has shown the existence of three flocculent phenotypes: Flo1, NewFlo and mannose insensitive (MI) phenotype (see section "Flocculation phenotypes") (Stratford and Assinder, 1991; Masy *et al.*, 1992). On the other hand, the presence of sugars in the wort or culture medium can provoke a loss or a modification in yeast flocculation ability by affecting the expression of *FLO* genes (see section "The flocculation cycle").

High molecular weight polysaccharides from wort rich in arabinose and xylose have been implicated in premature flocculation (Herrera and Axcell, 1991). These polysaccharides have a higher affinity than sugars present in medium for yeast flocculation lectins inducing premature yeast settling by acting as a bridge between cells (Stratford, 1992a).

Strains grown in worts with high level of assimilable nitrogen or in medium supplemented with basic amino acids or ammonia showed a delay on the onset of flocculation (Mill, 1964a; Baker and Kirsop, 1972). Many ale strains do not flocculate in chemically defined media yeast nitrogen base (YNB) or in rich media yeast extract, peptone, dextrose (YEPD), being only flocculent in wort. It was proposed that these strains require the addition of nitrogen compounds (gelatine, peptones or yeast extract) to YNB in order to flocculate (Stewart, 1975; Beavan *et al.*, 1979). More recent works have shown that the lack of flocculation can be explained by the narrow pH range of flocculation of these strains (see above, effect of pH) plus the limited available Ca^{2+} in solution (Stratford, 1996; Soares and Seynaeve, 2000b). YNB has a small buffer capacity and consequently the pH falls rapidly to near 2.0 during yeast growth. On the other hand, the pH at the end of growth in YEPD (near 5.5–6.0) do not correspond to the pH range where these strains flocculate; in these culture media, flocculation is restored by Ca^{2+} addition and/or by correcting the pH to a suitable value (Soares and Seynaeve, 2000a, b).

Oxygen

The presence/absence of O_2 seems to have a deep effect on yeast flocculation. A moderate aeration produces a benefit effect, while a strong aeration leads to a lack of flocculation (Kida *et al.*, 1989; Soares *et al.*, 1991). On the other hand, the absence of oxygen seems to lead to a reduction of flocculation in laboratory and industrial strains (Miki *et al.*, 1982b; Soares *et al.*, 1991; Straver *et al.*, 1993; Iung *et al.*, 1999). In anaerobic conditions, the integrity and functionality of plasma membrane of *S. cerevisiae* can be affected, influencing the secretion of flocculation lectins and consequently yeast flocculation.

Cell age

It was proposed that flocculation increased with the genealogical age, being the bottom part of the yeast crop constituted by the more flocculent and aged cells (Hough, 1961). Thus, the brewing practice of cell reuse (repitching) leads to the constant selection of the more flocculating cells. Powell *et al.* (2003) have shown that virgin and non-virgin cells are both flocculent, the aged being more flocculent than the younger counterparts. However, the analysis of the distribution of the genealogical age of settled and cells remaining in suspension did not detect any difference (Gyllang and Martinson, 1971).

A more recent and detailed analysis of the different zones of the cone of the fermenter has shown cell populations with an extensive heterogeneity of flocculation, cell size and replicative age (Powell *et al.*, 2004).

Since flocculation of cells with zero genealogical age is not so different from the parent cells, it was suggested that daughter (virgins) and parent (old) cells should be flocculent or non-flocculent, depending on the growth phase (Soares and Mota, 1996). The genealogical distribution throughout the growth was essentially identical comprising 44–54% of daughter cells; in this way, the onset of flocculation observed toward the end of exponential phase of growth can hardly be explained by the genealogical age of the cells (Soares and Mota, 1996).

Genetic Control of Yeast Flocculation

The best known flocculation gene is *FLO1*, which has been cloned and sequenced by different groups (Teunissen *et al.*, 1993a, b; Watari *et al.*, 1994). The *FLO1* is a dominant gene localized at 24 kbp from the right end of chromosome I (Teunissen *et al.*, 1993a) and encodes a cell wall protein involved in flocculation process of *S. cerevisiae* (Watari *et al.*, 1994; Bony *et al.*, 1997). Other *FLO* genes are *FLO2* and *FLO4*, which are in fact alleles of *FLO1*, and the genes *FLO5*, *FLO9* and *FLO10*, which are highly homologous to *FLO1*; thus, the *FLO5* and *FLO9* gene products are 96% and 94% similar to *FLO1* product, respectively, while *FLO10* and *FLO1* gene products are 58% similar (Teunissen and Steensma, 1995). Expression of *FLO1* gene causes flocculation of Flo1 phenotype (Watari *et al.*, 1994). A new *FLO1* homolog, named *Lg-FLO1*, was isolated and it is believed that it encodes to an adhesine responsible for the NewFlo phenotype of brewer's yeasts

(Kobayashi *et al.*, 1998; Sato *et al.*, 2002). The analysis of the N-terminal region of Flo1 protein and Lg-Flo1 protein suggested that threonine 202 in Lg-Flo1 protein interacts with mannose and glucose, while tryptophan 228 and its neighboring amino acids residues in Flo1 protein recognize C-2 hydroxyl group of mannose but do not recognize the C-2 hydroxyl group of glucose (Kobayashi *et al.*, 1998).

It was proposed that *FLO1* gene is transcriptionally regulated by the proteic complex Ssn6–Tup1 that acts as global repressor in a regulatory cascade (Teunissen *et al.*, 1995). It was shown that the Swi–Snf coactivator and Tup1–Ssn6 corepressor control an extensive chromatin domain in which regulation of the *FLO1* gene takes place (Fleming and Pennings, 2001). The *FLO8* gene encodes a transcriptional activator *FLO1*, *FLO11* and *STA1* genes (Kobayashi *et al.*, 1996, 1999). Recently, it was shown that the transcription factor Mss11p, together with the Flo8p, is required for the induction of flocculation, controlled by *FLO1* gene (Bester *et al.*, 2006).

The *FLO11* gene encodes a protein critical for diploid pseudohyphal development and haploid invasive growth (Guo *et al.*, 2000; Lo and Dranginis, 1998). Expression of *FLO11* has been shown to be controlled by several major pathways, including the mitogen-activated protein (MAP) kinase pathway and the protein kinaseA/cAMP pathway (Verstrepen and Klis, 2006).

Besides the dominant genes, recessive/semi-dominant genes *flo3*, *flo6*, *flo7* have been described (Teunissen and Steensma, 1995). Several lines of evidence suggest that the expression of *FLO1* may be inhibited by suppressor genes: *fsu1*, *fsu2* and *fsu3* (Teunissen and Steensma, 1995). Additionally, many mutations give rise to flocculation involving regulatory, mitochondrial or genes implicated in the cell wall biosynthesis; these mutations and their pleiotropic effects were listed and reviewed by Teunissen and Steensma (1995).

Mechanism of Yeast Flocculation

The presence of proteins

The cell wall of *S. cerevisiae* has a layered structure, consisting of an amorphous inner layer and a fibrillar outer layer. The inner layer is mainly composed by β-glucan and chitin, whereas the outer layer consists predominantly of α-mannan associated with proteins (Lesage and Bussey, 2006).

Yeast flocculation is an intrinsic surface phenomenon, as isolated cell walls from flocculent strains are able to flocculate (Nishihara *et al.*, 1982; Sousa *et al.*, 1992). The outer mannoprotein layer of yeast cell wall is involved in the flocculation process because the treatment of flocculent cells with proteases as well as chemical modification of functional groups of amino acids residues, promote the irreversible desaggregation of the flocs (Nishihara *et al.*, 1977, 1982). The addition of a protein synthesis inhibitor (cycloheximide) impairs the onset of flocculation, which

clearly shows that flocculation is a protein-dependent process (Baker and Kirsop, 1972; Stratford, 1993).

The Flo1 protein

The open reading frame of *FLO1* gene is composed by 4.6 kbp, which encodes for a protein of 1,537 amino acids (Watari *et al.*, 1994). Flo1 protein contains many repeated sequences, a large number of serine and threonine residues (which provide sites for *O*-glycosylation) and 14 potential *N*-glycosylation sites (Teunissen *et al.*, 1993b; Watari *et al.*, 1994). Flo1 protein is a structural protein localized at yeast cell surface (Bidard *et al.*, 1995; Bony *et al.*, 1997, 1998) and is directly involved in the flocculation process (Bony *et al.*, 1997). The functional analysis of the major repeated sequence showed that the degree of flocculation can be modulated by adjusting the number of repeated sequences in the Flo1 protein (Bidard *et al.*, 1995).

Flo1 protein has a hydrophobic C-terminal region, which likely corresponds to a glycosylphosphatidylinositol (GPI) anchor signal addition (Watari *et al.*, 1994). Deletion of this hydrophobic region prevents cell surface anchorage of the protein, resulting in the loss of flocculation and the release of the protein in the culture medium (Bony *et al.*, 1997).

Prediction of the secondary structure of Flo1 protein shows that it is almost composed by β sheets and coils, being the α-helix found only at N- and C-terminal regions (Watari *et al.*, 1994). As a consequence of *O*-glycosylation of serine and threonine residues, the Flo1 protein would increase the stiffness and adopt an extended conformation, being the N-terminus exposed toward the cell surface (Teunissen *et al.*, 1993b; Watari *et al.*, 1994). The truncated form of Flo1 protein, in which the N-terminal region was deleted, could not develop a flocculent phenotype, although it can be detected in the cell wall (Bony *et al.*, 1997). It was shown that the N-terminal region of Flo1 protein contains the sugar recognition domain (Kobayashi *et al.*, 1998).

The involvement of α-mannan

Reversible inhibition of flocculation by mannose and mannosyl derivatives suggests the involvement of the α-mannan in the flocculation (Taylor and Orton, 1978); in the same line, the blocking or chemical modification of α-mannan also prevents flocculation (Miki *et al.*, 1982a; Nishihara *et al.*, 2000).

Flocculation theories

Calcium Bridge Theory The calcium bridge theory was dominant in 60–70 years and proposed that flocculent cells were linked by calcium bridges formed by the carboxylic groups (Mill, 1964b; Beavan *et al.*, 1979) or the phosphate

groups (Lyons and Hough, 1970, 1971) of the cells involved. This theory is unsatisfactory to explain the flocculation inhibition by the action of bivalent ions like Sr^{2+}, Ba^{2+} or Pb^{2+} (Nishihara *et al.*, 1982; Gouveia and Soares, 2004), as well as by sugars (Taylor and Orton, 1978) or concanavalin A (Con A) (Miki *et al.*, 1982a).

Lectin-Like Mechanism   The lectin-like theory was formally proposed in the beginning of the 80 years and is the theory that prevailed until now in almost all of its basic concepts.

The term lectin derives from the Latin word *legere*, which means to choose, pick up or select. Lectins are glycoproteins of non-immune origin that bind sugars, often with high specificity (Goldstein *et al.*, 1980). In lectin-like model (Miki *et al.*, 1982a), it was proposed that a specific lectin (only present on flocculent cells) recognize and interact with carbohydrate residues of α-mannans (receptors) of adjoining cells (Figure 9.4). The calcium ion has the role to assure the correct conformation of the lectin (Miki *et al.*, 1982a; Stratford, 1989). The receptors are present both in flocculent and non-flocculent cells (Miki *et al.*, 1982a; Soares *et al.*, 1992), since *S. cerevisiae* cells have mannans on the outer part of cell wall. A detailed analysis of the inhibitory action of sugars and the use of *mnn* mutants and Con A suggests that flocculation receptors of Flo1 and NewFlo phenotype are the non-reducing termini of α(1→3)-linked mannan side branches, two or three mannopyranose residues in length (Stratford and Assinder, 1991; Stratford, 1992b).

Using atomic force microscopy, adhesion forces of $121 \pm 53\,pN$ were measured; these forces reflect the specific interactions between cell surface flocculation lectins

Figure 9.4   Lectin-like model for yeast flocculation. A specific lectin-like protein, previously activated by calcium ions, sticks out of the yeast cell wall, recognizes and interacts selectively with the mannose residues (receptors) of adjoining cells.

and sugar residues (receptors) (Touhami *et al.*, 2003). It was suggested that the specific interactions (lectin-receptor) were stabilized by non-specific interactions: hydrogen bonds and hydrophobic interactions (Amory *et al.*, 1988; Dengis *et al.*, 1995; Jin and Speers, 2000; Jin *et al.*, 2001).

Flocculation phenotypes

Taking into account the flocculation reversible inhibition by sugars, salt and proteases sensitiveness, two main types of flocculent yeast cells were found: Flo1 phenotype, comprises strains where cell–cell interactions are specifically inhibited by mannose and derivatives; NewFlo phenotype, is composed mostly by ale-brewing strains where flocculation is reversibly inhibited by mannose, maltose, glucose and sucrose, but not by galactose (Stratford and Assinder, 1991).These phenotypes also possess different sensitiveness to culture conditions, namely temperature, pH and glucose availability (Soares *et al.*, 1994; Soares and Mota, 1996; Stratford, 1996; Soares and Seynaeve, 2000b).

Later on, two other phenotypes have been described: MI phenotype, composed by strains where flocculation is not inhibited by sugars, including mannose (Masy *et al.*, 1992), and a fourth phenotype, comprising strains whose flocculation occurs in the presence of sufficiently high ethanol concentration (Dengis *et al.*, 1995; Dengis and Rouxhet, 1997). The exact mechanism of aggregation of these strains is far from being understood.

The Flocculation Cycle

Although the Flo1 phenotype flocculation is generally constitutively expressed throughout growth (Figure 9.5a), the majority of brewer yeast strains belong to the NewFlo phenotype and possess cyclic flocculation ability (Stratford and Assinder, 1991; Soares and Mota, 1996). NewFlo strains progressively lose their flocculation in the early period of growth (Figure 9.5b) and become flocculent toward the end of logarithmic phase of growth (Stratford and Carter, 1993; Soares and Mota, 1996; Soares *et al.*, 2004, Sampermans *et al.*, 2005). Flocculation receptors were found in all stages of growth (Stratford, 1993; Soares and Mota, 1996), while Flo 1 protein is not permanently present at the cell surface, increasing at the end of the exponential phase growth (Bony *et al.*, 1998). These facts, together, indicate that the availability of Flo proteins in the cell wall determines the flocculation level.

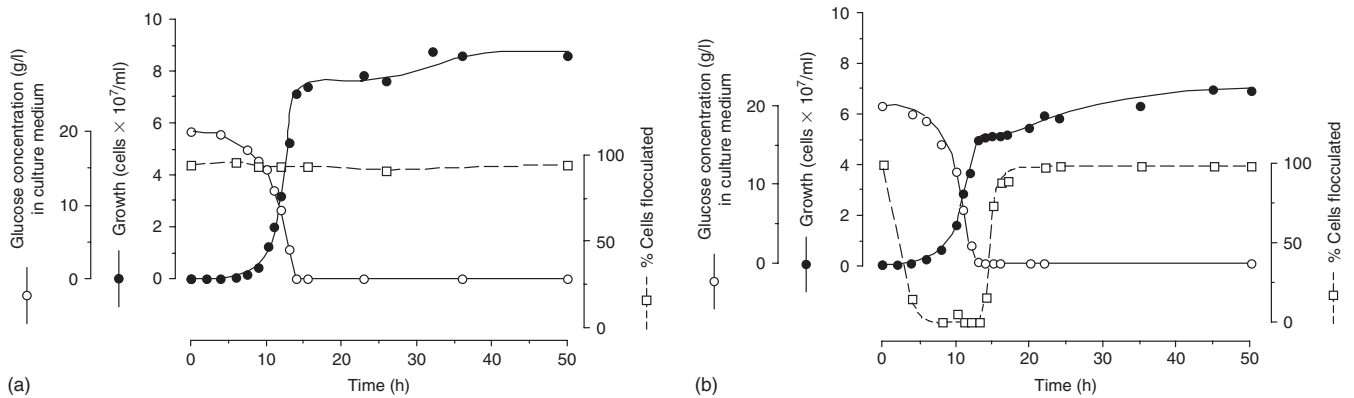
The loss and triggering of flocculation can be influenced by many and varied factors that can act at different stages. The action of culture medium components on cell–cell interactions and the disappearance/emergence of flocculation lectins on yeast cell surface are two important levels of control of flocculation cycle. On the other hand, the presence of active lectins on yeast cell surface can be controlled at different levels: by transcriptional control of *FLO* genes


Figure 9.5 Flocculation and glucose utilization during the growth of Flo1 and NewFlo phenotype strains. (a) *S. cerevisiae* NCYC 869 (Flo1 phenotype) flocculates during all phases of growth, being insensitive to the presence of nutrients. (b) *S. cerevisiae* NCYC 1195 (NewFlo phenotype) lose flocculation ability in the early phase of growth, occurring the onset of flocculation at the end of exponential phase. This phenomenon coincides with the attainment of the lowest amount of glucose in the culture medium. Flocculation was evaluated in standard conditions, in buffer containing Ca^{2+}. *Source*: Reprinted with permission of the editor; from Soares and Mota (1996).

or during the secretion process. This means that the regulation of flocculation cycle of *S. cerevisiae* is not a straightforward mechanism.

The loss of flocculation

Fermentable sugars (glucose, maltose and sucrose), present in commercial worts as well as in most culture media, cause the dispersion of flocculated yeasts of NewFlo phenotype. With the fermentation progress, sugars are consumed and their inhibitory effect decreases. Recently, it has been shown that, besides this surface level action, sugars have a central role in the induction of flocculation loss both in starved cells (Soares and Duarte, 2002; Soares and Vroman, 2003) and in growing conditions (Figure 9.5b) (Soares and Mota, 1996; Soares *et al.*, 2004), most likely via the yeast metabolism. The loss of flocculation is an energy-dependent process, influenced by carbon source metabolism, and requires *de novo* protein synthesis by an unknown mechanism; probably, different proteases are involved on the dismantling of flocculation mechanism because the presence of protease inhibitors prevented partially or completely flocculation loss induced by glucose (Soares and Vroman, 2003; Soares *et al.*, 2004).

The onset of flocculation

The pH value, Ca^{2+} availability, residual concentration of sugars or nitrogen and the presence of ethanol are important factors on the controlling of the onset of flocculation. In brewing conditions, the pH of the wort falls from 5.2–5.8 to 4.0–4.4, which seems to be enough to induce flocculation in strains that flocculate in a narrow (3.0–5.0) pH range (Figure 9.3) (Stratford, 1996; Soares and Seynaeve, 2000b). In addition, available Ca^{2+} (the free and labile Ca^{2+}) increases as a consequence of pH decrease (insert

of Figure 9.3), which favors the triggering of flocculation (Soares and Seynaeve, 2000a, b).

The onset of flocculation occurs at the end of exponential phase of growth, when a low sugar (Figure 9.5b) and/or nitrogen concentration is reached in the culture media (Smit *et al.*, 1992; Soares and Mota, 1996; Sampermans *et al.*, 2005). The triggering of flocculation is an energetic-dependent process, requiring a residual external carbon source, most likely for the production of energy required for the secretory pathway (Mill, 1964a; Stratford, 1992a; Soares and Mota, 1996); conversely, it does not require an external source of nitrogen (Sampermans *et al.*, 2005). The nutrients shortage combined with the presence of ethanol, which in a small amount has a positive effect on yeast flocculation, may be the signal nutrient that induces the onset of flocculation (Sampermans *et al.*, 2005; Claro *et al.*, 2007).

Nutrients availability or limitations may directly repress or induce, respectively, *FLO* genes in NewFlo phenotype strains (Verstrepen *et al.*, 2003; Verstrepen and Klis, 2006). It was proposed that *FLO1* gene is regulated at the transcriptional level by the proteic complex Ssn6–Tup1 (Teunissen *et al.*, 1995). However, nothing is known about the regulation of the *Lg-FLO1*, which is believed to encode the lectin responsible for the NewFlo phenotype. Although much information has been obtained last year about the flocculation cycle of NewFlo phenotype strains, the upstream sensors as well as the signaling pathway(s) of regulation of NewFlo phenotype flocculation in laboratory and brewing conditions remain unknown.

To Be or Not to Be Flocculent: The Art of Survival?

Why do yeast cells, which suffer from nutrient limitations under flocculating conditions, keep on insisting in separating from the culture medium?

In nature, the majority of biomass is under starving conditions and the multicellular lifestyle of microorganisms appears to be prevalent (Palková and Váchová, 2006). Brewing yeasts belonging to NewFlo phenotype, in the presence of available nutrients, are preferentially under the form of individual cells (Soares *et al.*, 2004). Interestingly, the nutrient shortage, probably combined with the presence of ethanol, induces the triggering of flocculation (Sampermans *et al.*, 2005); thus, the cells aggregated in flocs do not have anything to lose, under a nutritional viewpoint. On contrary, they can cooperate within a multicellular structure (floc) and in this case the union may be the basis of the strength. The autolysis of some cells of the center of the floc will originate compounds that can support the survival of the other cells of the floc. Herker *et al.* (2004) proposed that yeast cells commit altruistic suicide (apoptosis – programed cell death) in order to provide nutrients for the others, probably younger and healthy cells. In this way, flocculation can be seen as a form of making possibly a long-term survival of a cellular community in an unfavorable environment with a limited nutrient supply, as it was suggested by B. F. Johnson (personal communication to Stewart and Russell (1981).

Flocculation can also be seen as a means of protection against a harmful environment (Stratford, 1992c). Brewing yeasts are usually exposed to different detrimental conditions during beer production. In this perspective, flocculation can be a strategy of survival, as the cells outside the floc can offer some protection to external adverse environmental conditions to the cells inside.

Although the question raised above remains without a straight and definitive answer, future work, namely about the regulation of yeast flocculation as well as the impact of stress on the triggering of flocculation, could give a little more light on these conjectures.

Summary Points

- Yeast flocculation is a reversible process of cell aggregation into multicellular masses called flocs.
- Traditionally associated with beer production, flocculation might also be useful in modern biotechnology as a low cost and easy method of cell separation.
- Yeast flocculation is affected by multiple factors, namely pH, Ca^{2+} availability, temperature, sugars and nitrogen sources and dissolved oxygen.
- Brewing flocculent strains have a specific lectin-like protein, which interacts with the sugars (receptors) of adjoining cells; calcium ions are required to activate the lectin.
- Four flocculation phenotypes have been described: Flo1, NewFlo, MI and strains whose flocculation requires the presence of ethanol.
- Several dominant, recessive and suppressor genes have been described. Expression of *FLO1* and *Lg-FLO1* genes causes flocculation of Flo1 or NewFlo phenotype, respectively.

- In brewing NewFlo phenotype strains, sugars induce the loss of flocculation in the early period of growth; the onset of flocculation occurs toward the end of logarithmic phase when low sugar and/or nitrogen concentration is reached in the culture medium.
- Yeast flocculation can constitute a long-term survival mechanism or a means of protection against a harmful environment.

Use of Amylolytic Enzymes in Brewing

N.P. Guerra, A. Torrado-Agrasar, C. López-Macías, E. Martínez-Carballo, S. García-Falcón, J. Simal-Gándara and L.M. Pastrana-Castro Nutrition and Bromatology Group, Department of Analytical and Food Chemistry, Food Science and Technology Faculty, Ourense Campus, University of Vigo, Ourense, Spain

Abstract

One of the main problems in the production of fermented alcoholic beverages from amylaceous raw materials is the efficient conversion of starch into fermentable sugars for *Saccharomyces cerevisiae*. α-Amylase, β-amylase, α-glucosidase, and limit dextrinase are the enzymes responsible for the hydrolysis of starch into maltose and glucose in beer elaboration.

Two different strategies are used in traditional brewing: to favor the activity of the endogenous enzymes that are present in the ingredients during the malting and mashing steps (beer in Western countries), or to use amylolytic microorganisms in a previous step to yeast fermentation (koji in Eastern countries). More recently, the development of technologies for the efficient production of enzymes, mainly of microbial origin, has allowed the application of exogenous amylases in beer elaboration to improve classical brewing by compensating enzymatic deficits in poor malts and by reducing the needs of malt for mashing. But, moreover, the addition of exogenous enzymes has also allowed the use of new starchy materials with low amylolytic potential and the preparation of worts with adequate sugars composition to elaborate new kinds of beer with interesting functional properties, as low-caloric and gluten-free beers for celiac people.

The importance of the amylolytic potential of the amylaceous material, the synergic activity of the three main enzymes (α-amylase, β-amylase, and limit dextrinase) involved in starch hydrolysis during mashing, and the need of a correct performance of the malting and mashing steps to maximize the expression and activity of these enzymes and to minimize the losses of enzymatic activity due to the thermal treatments applied during brewing are here described, paying special attention to the use of barley and sorghum as the most used starchy substrates and sources of amylases. Finally, examples of the application of exogenous enzymes in brewing for the use of new starchy materials as chestnut, and for the elaboration of new kinds of functional beers, are also included.

Introduction

Brewing is one of the best examples of the important role of enzymes in the elaboration of traditional food and beverages.

Briefly, beer can be defined as the alcoholic beverage elaborated by means of yeast fermentation with *Saccharomyces cerevisiae* of a starch-based material. The most used material is barley, although there are also beers made from wheat, rice, oats, rye, corn, sorghum, potato, cassava root, or agave among others. Hop is added to give bitterness. Adjuncts can also be added as additional sources of fermentable sugars and nutrients for yeast development during the fermentation stage.

Starch is the molecule of sugar storage in plants. It is the main component of cereal grains and tubercles. Starch can be defined as the mixture of two polymers of glucose: amylose – a linear molecule of D-glucose linked by α-1,4-glucosidic bonds; and amylopectin – a branched molecule of α-1,4-glucose residues and α-1,6-glucose bonds at the branching points (Figure 10.1).

The inability of *Saccharomyces* to directly utilize the starch molecule as a carbon source makes necessary the previous hydrolysis of the polymer into smaller sugars, preferably the monomeric (glucose) and dimeric (maltose) molecules. The same happens with the proteins present in starchy materials since they must be hydrolyzed to amino acids to be used by the yeast as nitrogen sources.

According to that, the first steps in beer elaboration are directed to allow the hydrolysis of both starch and proteins; amylases, limit dextrinase (LD), and proteases are the enzymes responsible for it. The fermentability of the wort (Figure 10.2) and the final levels of alcohol and remaining sugars in beer are strongly dependent on the activity of these enzymes.

Amylases, limit dextrinase, and proteases are naturally present in the cereal grains or in the tubercles during germination. Therefore, traditional brewing takes advantage of it stimulating the synthesis and activity of these endogenous enzymes. Still more, the election of barley as the most used material for brewing is not surprising, considering the high content of this cereal in amylases.

Figure 10.2 shows the main stages in beer elaboration, indicating those in which enzymes are implied for a correct brewing.

During the first stage (*steeping*) of barley *malting*, the grains are soaked in water for 1–3 days at 10–15°C to increase the humidity of the cereal. Afterwards, the steeping water is drained away and the grain is spread out to allow germination for 4–7 days with periodical aeration. During this phase proteases and the starch-degrading enzymes are accumulated. At this step proteases also contribute to starch degradation releasing bound β-amylase from starch
Figure 10.1 Amylopectin structure and hydrolysis points depending on the different enzymes involved in starch hydrolysis. RE, reducing end; N-RE, non-reducing end.

(Loreti *et al.*, 1998) and releasing the inactive limit dextrinase forms from their inhibitors (Longstaff and Bryce, 1993; McCafferty *et al.*, 2004).

Final drying (*kilning*) provides brown coloring and flavor by the Maillard reaction. In the case of malt storage, kilning also allows malt stabilization by stopping the enzymatic reactions and inhibiting an undesirable microbial growth by decreasing the water activity. This malt is still not readily fermentable by *S. cerevisiae*. Since hydrolysis must be continued in the next stage of brewing, kilning is a critical step because an intensive heating treatment can lead to enzymes deactivation.

The next step (*mashing*) is performed to obtain the wort. Mashing starts by milling and mixing the malt with water in ratios between 3:1 and 4:1. Extra carbon and nitrogen sources can be added at this point as adjuncts. Mashing is a critical operation in brewing. Hydrolysis of starch and proteins must be completed at this stage by continuation of the enzymatic hydrolysis, which had started during germination, to allow next the fermentation. This stage ends heating at 75–80°C to inactivate the enzymes, and filtering to eliminate the residual solids. The resulting wort is thus enriched in low molecular weight compounds, mainly maltose, glucose, and amino acids, and also in starch dextrins that were not hydrolyzed by the endogenous amylases. Mashing is the last step for starch and protein hydrolysis.

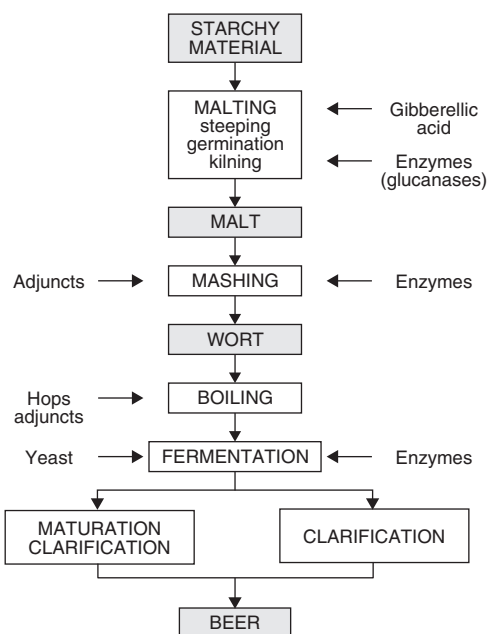
Before yeast inoculation, hop and adjuncts are added to the filtered wort, which is finally boiled to inactivate residual enzymatic activities, to sterilize the medium, to coagulate proteins, and to give flavor by improving hop extraction and inducing Maillard reactions.


Figure 10.2   Stages in beer elaboration.

Besides the central role of amylases, limit dextrinase, and proteases in wort fermentability and beer composition, there are other enzymes implied in brewing. β-Glucanases are the enzymes responsible for the solubilization and hydrolysis of the β-glucans, which are major components of the cell wall of the starchy endosperm of barley. The synthesis and activity of these enzymes during germination is essential in brewing to improve the extraction of the grain components (mainly starch and proteins). During mashing these enzymes continue the hydrolysis of the solubilized β-glucans, which increase the viscosity of the medium and make difficult the operations of filtering (Georg-Kraemer *et al.*, 2004; Kuusela *et al.*, 2004).

Amylases in Traditional Brewing

The efficient extraction and transformation of starch into fermentable sugars is the critical step in brewing. Hence, amylases and limit dextrinase expression, stability, and performance under the conditions applied by the malting and brewing industries are critical.

The concentration of fermentable and non-fermentable starch-derived sugars in the wort defines the quality of the beer in terms of alcoholic degree and caloric content. The elaboration of high ethanol beers employs worts with high concentrations of fermentable sugars, which can be achieved by addition of adjuncts rich in fermentable sugars and by extensive hydrolysis of the starch coming from malt and adjuncts. On the opposite, low ethanol beers are elaborated by limiting the activity of the enzymes during mashing to reduce the amount of fermentable sugars.

Among the starch-derived sugars, only the monosaccharide (glucose) and the lineal disaccharide (maltose) are readily fermentable by *S. cerevisiae*, while the α-1,6-disaccharide (isomaltose) and the lineal trisaccharide (maltotriose) are only partially consumed (Yoon *et al.*, 2003). The lineal and branched oligosaccharides of higher degree of polymerization are not fermentable for this yeast. Fructose and saccharose, which are not starch sugars but are present in many starchy materials, are also good carbon sources for *S. cerevisiae*. A high degree of hydrolysis of the starch molecule is then necessary to obtain high concentrations of fermentable sugars.

The enzymatic hydrolysis of starch is carried out by the joint action of three amylases (α-amylase, β-amylase, and α-glucosidase) and of limit dextrinase (Table 10.1 and Figure 10.1). α-Amylase (EC 3.2.1.1) is an endo-acting enzyme that rapidly and randomly attacks the α-1,4-glucosidic linkages of starch and related oligosaccharides to produce linear and branched oligosaccharides. The final products of the exhaustive hydrolysis of starch by α-amylase are maltose, glucose, and α-limit dextrins, which contain the α-1,6-glucosidic linkages of the branched molecules of starch. The action of the α-amylase on starch produces a

Table 10.1 Enzymes involved in starch degradation during brewing according to the IUBMB nomenclature

Trivial name	Systematic name	Code number	Reaction	Substrates	Products
α-Amylase, alpha-amylase, glycogenase, endoamylase, Taka-amylase A	1,4-α-D-glucan glucanohydrolase	EC 3.2.1.1	Random endohydrolysis of 1,4-α-D-glucosidic linkages	Starch, glycogen and related polysaccharides, and oligosaccharides with three or more 1,4-α-linked D-glucose units	α-Oligosaccharides, α-maltose, α-glucose (low amounts), α-limit dextrin
β-Amylase, beta-amylase, saccharogen amylase, glycogenase	1,4-β-D-glucan maltohydrolase	EC 3.2.1.2	Successive hydrolysis of 1,4-α-D-glucosidic linkages to remove β-maltose units from the non-reducing ends of the chains	Starch, glycogen and related polysaccharides, and oligosaccharides	β-maltose, β-limit dextrin
α-Glucosidase, maltase, glucoinvertase, glucosidoinvertase, maltase-glucoamylase, α-glucoside hydrolase, glucosidosucrase, α-Glucopyranosidase	α-D-glucoside glucohydrolase	EC 3.2.1.20	Successive hydrolysis of terminal non-reducing 1,4-linked α-D-glucose residues with release of α-D-glucose	Polysaccharides Oligosaccharides (more rapidly)	α-D-glucose
Glucoamylase, amyloglucosidase, glucose amylase, exo-1,4-α-glucosidase, γ-amylase, acid maltase, γ-1,4-glucan glucohydrolase, lysosomal α-glucosidase	1,4-γ-D-glucan glucohydrolase	EC 3.2.1.3	Successive hydrolysis of terminal non-reducing 1,4-linked α-D-glucose residues with release of β-D-glucose Hydrolysis of terminal 1,6- α-D-glucosidic linkages when the next bond in the sequence is 1,4	Polysaccharides (more rapidly) Oligosaccharides	β-D-glucose
Limit dextrinase, R-enzyme, amylopectin-1,6-glucosidase	Dextrin α-1,6-glucanohydrolase	EC 3.2.1.142	Hydrolysis of 1,6-α-D-glucosidic linkages	α- and β-limit dextrins of amylopectin (complete reaction), amylopectin (incomplete reaction)	Oligosaccharides, maltose (as the smallest sugar released)

fast reduction of the viscosity of the medium. For that reason α-amylase is also called liquefying amylase. β-Amylase (EC 3.2.1.2) is an exo-acting enzyme that cleaves β-maltose from the non-reducing ends of the lineal chains, but does not hydrolyze the α-1,6-glucosidic linkages. Consequently, the final products of starch hydrolysis by β-amylase are β-maltose and β-limit dextrins. α-Glucosidase (EC 3.2.1.20) is also an exo-acting enzyme that cleaves non-reducing α-1,4-linkages liberating glucose. This amylase participates in starch hydrolysis mainly during the early stages of starch degradation in germinating barley seeds (Sun and Henson, 1991). β-Amylase and α-glucosidase are also called saccharifying amylases. Limit dextrinase (EC 3.2.1.142) is an endo-acting enzyme that removes the α-1,6-linkages in α- and β-limit dextrins to allow their further hydrolysis by β-amylase.

The activity of mainly α-amylase, β-amylase, and limit dextrinase is collectively called "diastatic power" (DP). In the brewing industry, DP is a key parameter of malting quality since it is an estimate of the capacity of the malt to degrade starch into fermentable sugars (Delcour and Verschaeve, 1987). Methods for estimating the diastatic activity of malt are generally based on its ability to generate reducing sugars. The main units and criteria used to measure the DP of a malted cereal are:

- Degrees Lintner (°L), defined by the JECFA (the Joint FAO/WHO Expert Committee on Food Additives) and the IoB (Institute of Brewing) as follows: "A malt has a diastatic power of 100°L if 0.1 ml of a clear 5% infusion of the malt, acting on 100 ml of a 2% starch solution at 20°C for 1 h, produces sufficient reducing sugars to reduce completely 5 ml of Fehling's solution." For a complete description of the method see http://www.fao.org/ag/agn/jecfa-additives/specs/Monograph1/Additive-270.pdf. The DP is around 35–40 for standard barley malts, but it can be as high as 100–125 for lager malts, and over 160 for some high-protein North American malts which have far more enzymatic power than they require to hydrolyze the starch from the malt. Therefore, they enable the brewer to use these malts as an amylases source in the case of unmalted starch adjuncts addition (The BREWER Inter-national, 2002, p. 29).
- Degrees Windisch–Kolbach (°WK), used by the EBC (European Brewery Convention), which can be converted to Lintner units as follows:

$$DPL = \frac{°WK + 16}{3.5}$$

- Sorghum diastatic units (SDU), used by the SABS (South African Bureau of Standards) especially for sorghum, and not easily comparable to °L and °WK (EtokAkpan, 2004).

Next, the importance of every stage during brewing to enhance the activity of the enzymes and to obtain an adequate wort for beer elaboration is briefly described.

Malting: Germination and Kilning   The first step of germination is critical in the brewing process if no exogenous enzymes are added. At this stage, all the enzymes must be expressed and activated to start the process of starch solubilization and hydrolysis. α-Amylase, α-glucosidase, and bound limit dextrinase are synthesized *de novo* during seed germination, while β-amylase (Ziegler, 1999) and free limit dextrinase are activated by endogenous proteases. In addition to the effect of the genotype on enzymes expression, the main factors that affect both expression and activation of these enzymes during germination are temperature, water/solid ratio, oxygen availability, and concentration of gibberellic acid (GA3) – the hormone that stimulates the synthesis of α-amylase and other hydrolases.

α-Amylase synthesis is synergically improved with the increase in temperature from 20–25°C to 30–35°C and the addition of exogenous GA3 (Singh *et al.*, 1988). β-Amylase, which is synthesized during the development of the grain and accumulated in an inactive starch-bound form, is released from starch and activated by a proteolytic process. Anoxic conditions during germination prevent the production of the endoprotease involved in β-amylase activation. Oxygen deficit also inhibits α-amylase synthesis (Hanson and Jacobsen, 1984; Loreti *et al.*, 1998). Limit dextrinase in barley is partially synthesized following germination (Hardie, 1975) under the influence of GA3 (Lee and Pyler, 1984) and the hydration conditions. Continuous humectation during germination produces higher levels of limit dextrinase than addition of water at the beginning (Pratt *et al.*, 1978; Longstaff and Bryce, 1993; Stenholm, 1997). Nevertheless, limit dextrinase activity is usually low in malted cereals, making up less than 20% of the potential total activity (Longstaff and Bryce, 1991) and leading to high concentrations of non-fermentable limit dextrins. This low activity is due to the major presence of LD as inactive forms of the enzyme bound to endogenous proteinaceous inhibitors (MacGregor *et al.*, 2000). LD activation probably occurs by proteolysis of these inhibitors by endogenous thiol proteases (Longstaff and Bryce, 1993) and/or specific reduction of inhibitors by thioredoxin (Cho *et al.*, 1999). In agreement with it, anaerobically germinated grain, following a period of normal malting, produced grains containing a limit dextrinase activity constituting over 80% of the potential total limit dextrinase activity (McCafferty *et al.*, 2004) due to the application of reducing conditions that could improve the activity of cysteine proteases (McCafferty *et al.*, 2000). In consequence, considering the high levels of limit dextrinase inhibitors usually present in malt, it does not seem suitable to improve the levels of this enzyme in the wort by selecting cereal lines with a high potential for limit dextrinase synthesis. It will

be more effective to optimize those malting and mashing conditions that promote the release of free enzyme from the inhibitors-bound enzyme (MacGregor *et al.*, 1999).

In spite of enzymes synthesis and activation during germination, at this stage the starch is attacked only in a small extent because starch in the grain is in a crystalline non-soluble form that shows resistance to the enzymatic hydrolysis. α-Amylase and α-glucosidase are the only enzymes that are able to partially attack native (not boiled) starch (Sun and Henson, 1990). Consequently, the enzymes present in the germinated grain must retain their activity during the heating treatment of kilning to be active in the next step of mashing. Kilning is then a critical operation in brewing because excessive temperatures will lead to dramatic losses of the amylolytic ability of the malt. The thermostability of the synthesized and activated enzymes during germination is also of great importance for correct mashing. It depends on the enzyme, its origin, and even on the variety of the starchy material (Evans *et al.*, 2003). Under a typical kilning regimen, approximately 30% of the β-amylase activity is irreversibly deactivated (Evans *et al.*, 1997). α-Amylase, α-glucosidase, and limit dextrinase are also negatively affected, although the inhibitor-bound forms of this last enzyme are more resistant to thermal degradation (Sissons *et al.*, 1995).

Mashing   At this stage starch hydrolysis must be completed to produce wort with an adequate composition of fermentable sugars. The use of malt with high DP will be the first requirement if no exogenous enzymes are added. Nevertheless, some considerations must be made at this respect.

The DP of a malted starchy material depends on the total and relative amounts of enzymes present in the malt. In the case of barley, β-amylase has been significantly correlated to DP (Gibson *et al.*, 1995; Clarke *et al.*, 1998), what is in agreement with the presence of maltose in barley wort as the major fermentable sugar (typically >55%) (Kunze, 1996) and with the presence of β-amylase as the enzyme that contributes in a greater extent to the total amylolytic activity in barley malt. Nevertheless, the levels and composition of fermentable sugars depend on not only the β-amylase but also the synergistic interaction between all the enzymes that are involved in starch degradation in such a way that, for the same content in β-amylase, the differences in α-amylase and limit dextrinase activities will be responsible for the differences in the levels of non-fermentable sugars in the wort (MacGregor *et al.*, 1999). In effect, in spite of the importance of β-amylase to generate maltose, the activity of this enzyme is positively affected by α-amylase, which improves synergically the activity of the β-amylase providing it oligosaccharides of adequate molecular weight for this saccharifying enzyme. On the other hand, limit dextrinase is the only enzyme capable of hydrolyzing α-1,6-linkages. Since high levels of limit dextrins, which can constitute as much as 25% of total carbohydrates, often remain in the wort as

non-fermentable sugars (Enevoldsen and Schmidt, 1974), wort fermentability also depends strongly on the activity of the free limit dextrinase (Stenholm and Home, 1999). Nevertheless, this enzyme cannot attack starch granules without the previous action of α-amylase on starch (Maeda *et al.*, 1978). On the other hand, high levels of maltose, produced by the intensive action of β-amylase, can inhibit the activity of the free limit dextrinase during the mashing stage of brewing (MacGregor *et al.*, 2002). In conclusion, optimal starch hydrolysis will require an adequate equilibrium between α- and β-amylases and free limit dextrinase, which reflects the empirical model obtained by MacGregor *et al.* (1999) including the main effects of α- and β-amylases, as well as the interactions between these enzymes and the free limit dextrinase.

The relative ratio and total amounts and activity of each enzyme in malt depends first of all on the genotypic characteristics of the starchy material, the variety, the cultivar, and the malting conditions, as commented before. Nevertheless, the activity of the enzymes during mashing is strongly affected by the conditions of pH, which must be in the range 5–6 – as usual in the wort – by the presence of Ca^{2+} that is necessary for the activity and stability of the α-amylase, and mainly by the temperature and time of operation.

During mashing, temperature must reach at least 60°C to ensure starch gelatinization that makes it adequate for the enzymatic hydrolysis (Slack and Wainwright, 1980). This increase of temperature affects the activity of every enzyme in a different extent depending on their specific activities at each temperature and on their resistant to thermal denaturation, these effects being stronger as the time of operation increases. This way, an adequate amount and ratio of the enzymes could be suboptimal if the conditions of mashing are particularly inadequate for one of them. In general terms, α-amylase is the most resistant enzyme to heat inactivation and an amylase with higher optimal temperature (around 70°C). β-Amylase and limit dextrinase show maximum enzymatic activities at 60–62.5°C (Stenholm and Home, 1999), but while limit dextrinase retains most of its activity at these temperatures, especially under conditions of high gravity mashing (Stenholm, 1997), β-amylase suffers an important inactivation. This is in agreement with the apparent excess of β-amylase needed in malt compared to *in vitro* assays, what could be explained by the need of higher amounts of this enzyme to counterpart the loss of activity due to heat inactivation during mashing (MacGregor *et al.*, 1999). In this sense, there is already some evidence that improving the heat stability of β-amylase may be more beneficial than selecting barleys with higher β-amylase levels to increase the levels of fermentable sugars in the wort (MacGregor *et al.*, 1999).

Mashing can be performed isothermally at approximately 65°C (infusion mash) or by using a ramped temperature profile from approximately 45°C–70°C (temperature

programmed mash). The time of operation is usually between 1 and 3 h. According to all that, an accurate selection of the mashing conditions of temperature and time of operation must be carefully done depending on malt and adjuncts composition (if added), and on the cereal enzymes profile, to improve the activity of the enzymes that control the extent of starch hydrolysis (Brandam et al., 2003), according to the desired final characteristics of the beer, and to optimize extraction from malt. This way, when it is necessary to reduce the amount of non-fermentable sugars in the wort to obtain beers with high levels of alcohol or a low-caloric content, different mashing temperature profiles can be assayed to minimize limit dextrinase and β-amylase thermal losses by avoiding long periods of high temperature. On the contrary, in the case of low ethanol beers, low levels of fermentable sugars are needed in the wort and, consequently, mashing at high temperature can be a good strategy to reduce the activity of β-amylase and limit dextrinase.

Consequently with all of it, it is suggested to add, to the conventional malt quality DP criterion, the description of the individual enzymatic activities, mainly for α-amylase, β-amylase, and free limit dextrinase, to make easier to brewers the choice of the kind of malt and the mashing conditions that will allow the elaboration of good quality and special beers (Evans et al., 2003).

Koji

Koji can be considered the substitute of malt in the Eastern World. Koji elaboration consists of the solid-state culture of molds on seeds to produce hydrolytic enzymes, including amylases and proteases. The koji thus obtained can be used as source of enzymes for the hydrolysis of starchy materials as a previous step in the manufacture of a variety of Oriental fermented foods as sake (the traditional alcoholic beverage of Japan made from rice), soy sauce, or sufu (soybean cheese). There are different kinds of koji depending on the material used (mainly rice and soybean, but also barley), the mold inoculated (mainly *Aspergillus oryzae*, but also *Aspergillus flavus* and species belonging to *Zygomycetous* spp.), and the final use of the koji. In all cases the growth of microorganisms is not only a source of enzymes, but also of vitamins and flavors that give the particular organoleptic character to the final food or beverage.

The Role of Amylases in Modern Brewing

Nowadays, the development of the enzyme technology has allowed optimizing the enzymatic steps of brewing to secure an adequate and constant quality of the wort (see at The BREWER International, 2002, p. 17) a "first enzymatic aid kit" to solve different problems that can appear during all the brewing process). In addition to the optimization of temperature and time conditions during the enzymatic steps, the addition of exogenous enzymes, especially thermostable amylases, has been introduced in brewing to compensate enzymatic deficits in case of incomplete germination or in case of materials with low enzyme production. This has allowed the extending of the number of starchy materials suitable for beer elaboration, offering the possibility to use local cultivars for brewing and to elaborate new beers with special tastes and nutritional characteristics, as gluten-free beers for celiac people, made from gluten-free starchy materials with low DP, as sorghum (Maccagnan et al., 1999).

The use of exogenous enzymes has also allowed elaborating beer for diabetics (Curin et al., 1988), or diet (low caloric) beers (Annemueller and Schober, 1999) with a caloric-content reduction between 15% and 50%. Considering that the caloric content in beer can be calculated approximately as (Lewis and Young, 1995)

$$\text{Calories in 10 cl} = 4 \times \% \text{ (w/v) solids} \times 7 \\ \times \% \text{ (w/v) alcohol} \tag{10.1}$$

and considering that in a typical beer residual dextrins account for 75% of the solids, diet beers are elaborated by reducing the remaining non-fermentable dextrins with the addition of exogenous enzymes, mainly glucoamylase.

Substitution of the malting step by addition of all the necessary amylolytic enzymes to avoid the synthesis of β-glucanases during germination is also described as a strategy to elaborate functional beers, mainly from oats or barley, with beneficial coronary effects due to the high content of soluble glucans in these cereals (Triantafylloy, 2000) (Table 10.2).

The most used amylases in beer elaboration are α-amylase, α-glucosidase, and glucoamylase (see Table 10.1), although the use of these two last enzymes can affect negatively the fermentation of mashing worts with high concentrations of maltose since the presence of high concentrations of glucose as a result of the action of these amylases could inhibit maltose consumption in some yeast strains (Stewart et al., 1979; Phaweni et al., 1993). β-Amylase is also added, especially in case of those materials, as sorghum, lacking this enzyme.

The addition of limit dextrinase is not suitable since the inhibitors present in the malt will complex and deactivate part of the added enzyme (Stenholm, 1997). Pullulanase (EC 3.2.1.41) can substitute limit dextrinase in brewing (Enevoldsen, 1970; Odibo and Obi, 1989) since this enzyme is not inhibited as limit dextrinase. However, pullulanase is commonly used in the production of syrup adjuncts, but it is not approved for use in brewing in many countries (MacGregor et al., 1999). Exogenous hydrolysis of α-1,6-linkages can be performed by glucoamylase, which offers the advantage over α-glucosidase of also hydrolyzing α-1,6-glucosidic bonds when the next bond is α-1,4. Care must be taken in the use of thermostable glucoamylases (many

Table 10.2   List of patents including the use of exogenous enzymes in brewing for different purposes

Patent number	Title
General brewing; starch sources for brewing	
US2005095315	Process for the production of alcoholic beverages using maltseed
DD99179	Highly fermented beer manufacture with barley processing
ZA9803237	Process for brewing beer
WO2002074895	Improved fermentation process
CN1594525	Method for manufacturing barley extracts for beer production
DE2153151	Starch degradation for the manufacture of ethanol beverages
ZA2003009381	A method of producing a fermentable wort
RU2190012	Method for manufacture of beer Arsenal'noe Temnoe 4
FR2203875	Manufacturing beer
DE2352906	Enzymes in beer wort manufacture
ZA7004735	Brewers' wort for making beer
NL7713669	Brewer's wort
SU379615	Beer
US3066026	Wort treatment with hectorite and enzyme
CN1616636	Preparation of a potato syrup for special use in beer
ZA6900044	Production of beer
WO9805788	Improved process for the production of alcoholic beverages using maltseed
DD109400	Beer wort after substitution of traditional raw materials
JP2004024151	Beer-like alcoholic beverages brewing from wheat starch
Enzymatic preparations	
DE10027915	Methods for isolation from malted grain of enzymes and enzyme mixtures and their application in beer and food production
DE10241647	Preparation of enzymes and culture media components from malted grain for use in beverage and food industries
WO9742839	Enzyme granulate for use in food technology
US6031155	Isolation and characterization of barley endoxylanase gene and products and their use to enhance arabinoxylan degradation in brewing processes
FR2676456	Thermostable variants of *Bacillus amyloliquefaciens* α-amylase and their preparation and use
Special new beers with nutritional benefits	
CN1740301	Method for producing dry beer from oats
WO2000024864	Preparation of wort and beer of high nutritional value, and corresponding products
CN1116652	Method for brewing health beer series not containing carcinogen but containing anticarcinogen
CN1401754	Enzymatic transglycosylation method for producing bifidus factor beer
US4355047	Low-calorie beer
EP949329	Gluten-free beer
CS236212	Method of manufacturing a light beer for diabetics by treating the mash with amylase
US4251630	Preparation of malt high in alpha-1,6-hydrolase
US4666718	Preparation of low calorie beer

commercial fungal glucoamylases) since they can retain some activity even after beer pasteurization, thus increasing the sweetness of the beer in the bottle at the expense of residual dextrins (James and Lee, 1997). Therefore, yeast thermolabile glucoamylases are usually applied.

These enzymes can be added individually or in enzymatic mixtures that generally include other enzymes not directly involved in starch hydrolysis (Souppe and Beudeker, 1998; Annemueller et al., 2001; Annemueller et al., 2004) such as glucanases and xylanases, which contribute to the filterability of the wort (Dale et al., 1990) and to improve starch solubilization through the hydrolysis of cell wall polymers in the case that glucanases are added during the germination step (Grujic, 1998). Proteases are usually added with amylases to increase nitrogen availability for fermentation.

The exogenous enzymes applied in brewing can be of plant origin. Examples are the addition of *Curculigo pilosa* as an exogenous β-amylase source in the traditional elaboration of sorghum beer in West Africa, which additionally offers the advantage of high activity and stability, and the ability to attack raw starch from wheat, corn, potato, and rice (Dicko et al., 1999), the employ of β-amylase from sweet potato for partial replacement of malt in brewing (Jiang et al., 1994), or the use of multienzymatic preparations obtained from malted cereals (Annemueller et al., 2001). Nevertheless, the exogenous enzymes applied in brewing are usually of microbial origin due to the advantages that fermentation offers in comparison to plant enzymes recovery, as higher yields and less time-consuming procedures. Microbial enzymatic preparations containing one or several amylases are obtained from GRAS ("generally recognized as safe") bacteria or fungi in cultures made on starch, as bacterial and fungal α-amylases (Sobral and De Vasconcelos, 1983; Imayasu et al., 1989; Goode et al., 2002; Goode et al., 2003), bacterial β-amylases (Xu et al., 1994), yeast glucoamylases (Lowery et al., 1987), or bacterial pullulanases (Odibo and Obi, 1989).

Several strategies can be applied for exogenous enzyme enrichment. Generally, enzymes are added during mashing to complete the hydrolysis of starch before the enzyme deactivation that takes place during wort pasteurization. But there is also the possibility to include exogenous enzymes during fermentation (Dickscheit et al., 1973; Mizuno et al., 2004) to progressively release glucose and/or maltose, thus avoiding substrate inhibition of the yeast during the elaboration of beers with high ethanol degree.

Finally, there are other possibilities for the use of exogenous enzymes. They include the use of transgenic seeds and recombinant *Saccharomyces* strains, which will express heterologous enzymes during malting in the first case, and during fermentation in the second situation. The modification of barley seeds by inclusion of a fungal thermotolerant endo-1,4-beta-glucanase (EC 3.2.1.4) from microbial origin (*Trichoderma reesei*) to reduce wort viscosity and improve beer filtration (Nuutila et al., 1999) is already reported. The construction of different amylolytic brewing yeasts (S. cerevisiae and S. pastorianus) by transformation of the wild strains with yeast and fungal α-amylase and glucoamylase genes that allow growth on starch as sole carbon source for the manufacture of low-carbohydrate diet beers (Hollenberg and Strasser, 1990; Liu et al., 2004) is also described. The transformation of laboratory strains of S. cerevisiae and brewers' and distillers' yeasts with both genes encoding a glucoamylase from S. diastaticus and an α-amylase from *Bacillus amyloliquefaciens*, and the synergistic effect of the co-expression of both genes into the same strain to improve starch assimilation with an efficiency as high as 93% is also reported (Steyn and Pretorius, 1991).

Starchy materials for brewing other than barley

As commented before, adding exogenous enzymes during mashing allows to extent the possibilities of brewing with starchy materials that show low DP and difficulties for correct starch hydrolysis during mashing, whenever the fermentability of the wort and the organoleptic quality of the beer thus elaborated are adequate.

In these cases three strategies can be applied: partial addition of malted cereals as source of enzymes during mashing, addition of exogenous enzymes, mainly during mashing or even during the fermentation step, and use of an amylolytic microorganism that grows on the starchy material in a first stage, producing the amylases needed to hydrolyze in a second stage the starch present in the fresh material.

Addition of malted barley as source of enzymes has the advantage of contributing to color and flavor in the beer if the main starch material gives no enough adequate organoleptic profile to the beer. But even in that case, exogenous enzymes can be added to reinforce the amylolytic ability of barley (Goode et al., 2000; Goode and Arendt, 2003). Addition of exogenous enzymes has the advantage of allowing to regulate the degree of starch hydrolysis needed depending on the type of beer, as well as correcting the levels of assimilable nitrogen and the filterability of the wort if proteases and glucanases are also applied. The possibility of using amylolytic microorganisms constitutes the basis for koji elaboration, as commented before.

Next, two examples of exogenous enzyme applications in beer elaboration with starchy materials other than barley are exposed.

Sorghum Beer   A good example of exogenous enzyme application in brewing is the case of sorghum beer elaboration. Sorghum is the world's fifth most important cereal grain and constitutes a strategic natural food resource in areas subject to hot and dry agroecologies, where it is difficult to grow other grains. In fact, 90% of the world's sorghum area lies in the developing countries, mainly in Africa and Asia (FAO and ICRISAT, 1996).

For that reason sorghum has been widely used for several traditional food purposes, including brewing of African beers as burukutu (Faparusi, 1970; Novellie, 1977; Ogundiwin and Tehinse, 1981). Recently, sorghum beer brewing has also developed into a major industry for European-type lager beer elaboration, especially in the case of Nigeria, where barley importations have been restricted since 1988 (EtokAkpan, 2004).

There are several studies about the use of sorghum in brewing (Owuama, 1997; Agu and Palmer, 1998; Jani et al., 1999; Obeta et al., 2000; Okungbowa et al., 2002; Goode and Arendt, 2003; EtokAkpan, 2005). As well as economic reasons, sorghum offers an interesting potential as raw material for brewing due to its high starch content and the absence of gluten, what makes it suitable for the elaboration of gluten-free beers for celiac people. Nevertheless, there are some inherent problems associated with sorghum that must be solved to better compete with barley in the elaboration of European-type beer.

A major disadvantage for the use of malted sorghum in brewing is the usual low DP and amylolytic activity during mashing. Although α-amylase isoenzymes are *de novo* synthesized during sorghum germination, very low (Dufour et al., 1992; Taylor and Robbins, 1993) or even total absence (Uriyo and Eigel, 2000) of β-amylase levels are detected, causing incomplete saccharification of starch and low levels of maltose in comparison to barley wort (Dicko et al., 2006). In addition, the higher gelatinization temperature of sorghum starch with regard to barley increases thermal deactivation of the enzymes (Jani et al., 1999).

Several studies have been developed to improve α- and β-amylase activities in malted sorghum in relation with variety, cultivar, steep regime, steep liquor composition, and kilning temperature (Taylor and Robbins, 1993; Jani et al., 1999; Obeta et al., 2000; Okungbowa et al., 2002). Nevertheless, the best solution to reduce the levels of nonfermentable sugars in sorghum worts is the use of mixtures of malted barley with sorghum during mashing (Goode and Arendt, 2003), or the addition of exogenous enzymes such as α-amylase and amyloglucosidase (Clayton, 1969), β-amylase from potato (Etim and EtokAkpan, 1992), or microbial α-amylases (Goode et al., 2003), to the unmalted sorghum. In this last case it is also reported the convenience of including a percentage of malted sorghum as source of endogenous proteases to avoid the need of adding these enzymes since a poor foam retention has been associated to commercial proteolytic enzymes (Agu and Palmer, 1998).

Chestnut in Brewing   Among the above-mentioned seeds used as raw materials for the preparation of fermented drinks, other indigenous crops like chestnut can constitute local alternative sources of starches for industrial purposes (especially sugar and alcohol manufacture) and lead to the conservation of agriculturally marginal lands. In fact, it is already described the elaboration of a new Chinese chestnut beer with beneficial health effects such as anti-cancer, reducing blood sugar, and lowering blood fat activities (Li et al., 2005). Therefore, chestnut is here studied as a source of starch for brewing.

As sorghum, chestnut has no gluten but shows low endogenous amylolytic activity. According to it, chestnut is included in the elaboration of a kind of koji as a prior stage to ethanol fermentation for the elaboration of wine (Iwasaki et al., 2002) or shochu (a Japanese popular distilled light alcoholic drink produced from steamed cereals, mainly rice and barley, but also from sweet potato soba (buckwheat), and chestnut in a lesser extent). Addition of malt (Li et al., 2005) is also reported as a source of exogenous enzymes to complete chestnut starch hydrolysis.

Another strategy for brewing chestnut consists on substituting koji by direct addition of exogenous enzymes. This alternative takes as basis the two-step industrial process for starch hydrolysis. In the first stage simultaneous gelatinization and liquefaction of starch with a high-temperature α-amylase are performed. The maltodextrins thus generated are then saccharified with a glucoamylase in the second stage (Slominska, 1993). Optimal reaction conditions depend on the amylases used, as well as on the starch origin, which affects the composition, viscosity, and degradation resistance of the polysaccharides.

In our laboratory, we have optimized the enzymatic hydrolysis of chestnut starch in solid (chopped) and submerged (aqueous liquid pastes) operation in a single step with an enzymatic mixture of a commercial heat resistant α-amylase (Termamyl 120L(S)) and a glucoamylase (AMG 300L), both purchased by Novo Nordisk A/S Industries (López et al., 2004, 2005, 2006). Some details of these enzymatic processes are next briefly described as an example of practical application and optimization of the addition of exogenous enzymes in brewing of new starchy materials.

The submerged process of hydrolysis was performed at 70°C to reduce purée viscosity. In these conditions total conversion of starch to glucose in a single step was only achieved when an adequate concentration and composition of the enzymatic mixture of α-amylase/glucoamylase was present in the reaction medium (López et al., 2004). Figure 10.3 shows the linear increasing effect of the concentration of the enzymes on chestnut starch solubilization and hydrolysis, being the best the higher value assayed (60 EU/g raw chestnut, corresponding to 10.5 EU/ml), and the second order effect of the ratio of α-amylase/glucoamylase, which implies the existence of an optimum value corresponding to glucoamylase enriched mixtures (α-amylase/glucoamylase ratio of 0.35/0.75 EU). Sugar profile in this hydrolyzate corresponded to glucose (as the only final product of starch hydrolysis) and saccharose (present in chestnut) in concentrations of 70 and 15 g/l respectively.
Figure 10.3 Combined effect of the enzyme concentration and the ratio of α-amylase/glucoamylase (in codified values) on the solubilization, hydrolysis, and glucose release from chestnut purée with a mixture of amylases. E, enzyme concentration; R, ratio of α-amylase/glucoamylase in the mixture. Published with permission of the American Chemical Society (Copyright 2004).
Figure 10.4 Thermal loss of amylolytic activity of a mixture of α-amylase and glucoamylase (respective ratio: 0.35/0.65) at 70°C in (a) 50 mM citric–phosphate buffer pH 4.75 and (b) 225 g/l pH 4.75 buffered chestnut purée. AA, total amylolytic activity expressed as percentages referred to the initial value (1.35 EU/ml). Symbols represent the mean values of two experimental points; dashed and solid lines represent, respectively, the fittings to a first order model and to model (10.3).

Incomplete starch conversion at low enzyme concentrations was attributed to product and substrate inhibition, as well as thermal deactivation (López *et al.*, 2006). In effect, substrate and product inhibition were confirmed and modeled by equation (10.2), this derived from Michaelis–Menten and Briggs–Haldane's models considering simultaneous competitive and non-competitive product inhibition, and substrate inhibition:

$$v = \frac{v'_m S}{\left(K'_m \left(1 + \dfrac{I}{K'_{iC}} \right) + S + K'_S S^2 \right) \left(1 + \dfrac{I}{K'_{iNC}} \right)} \quad (10.2)$$

where v and v'_m are respectively initial and maximal initial reaction rates of the enzyme mixture in chestnut purée, S is the substrate concentration, K'_m and K'_s represent operational Michaelis–Menten and substrate inhibition constants, respectively, I is the inhibitor (glucose) concentration, and K'_{iC} and K'_{iNC} are operational competitive and non-competitive product inhibition constants, respectively.

Anyway, substrate and glucose inhibition was not strong enough to explain the low percentage of hydrolysis reached at low enzyme concentration. Consequently, thermal deactivation of the α-amylase and glucoamylase mixture at low enzyme concentration was also studied in presence and absence of substrate (Figure 10.4), and the losses of amylolytic activity were fitted to model (10.3), based on Aymard and Belarbi's one for an enzymatic mixture (Aymard and Belarbi, 2000), and modified to include a synergistic effect between these two enzymes (López *et al.*, 2006):

$$AA_t = AA_\alpha + ae^{-kat} + be^{-kbt} + S_1 AA_\alpha (ae^{-kat}) + S_2 AA_\alpha (be^{-kbt}) \quad (10.3)$$

where AA_t represents the total amylolytic activity (expressed as percentage referred to the initial total activity) of the mixture at time t, AA_α is the α-amylase activity expressed as percentage, a and b, and ka and kb are, respectively, pre-exponential parameters and first order constants for each glucoamylase form present in the commercial enzyme (Amirul *et al.*, 1996), and S_1 and S_2 are the synergism terms between the α-amylase and each glucoamylase form.

Experimental and modeled data showed a strong decrease of the enzymatic activity in both cases, which reflects the important role of enzyme thermal deactivation as a reason for incomplete starch hydrolysis. Glucoamylase, following a biexponential kinetics pattern, was only responsible for the thermal deactivation of the mixture, while the α-amylase kept 100% of the initial activity at the end of the incubation in these conditions. Therefore, the slightly retarded addition of glucoamylase with regard to α-amylase, to reduce the exposure of this enzyme to high temperatures while taking advantage of the synergic action of both enzymes working together, was finally proposed as an alternative to reduce the need of high concentrations of enzymes, especially of glucoamylase (López *et al.*, 2004).

Two main factors prevent the achievement of high-glucose hydrolyzates from chestnut, they condition the utility of chestnut as an adequate starchy material for use in brewing or as adjunct. They are the low concentration of starch in raw chestnut (around 30%) and the impossibility of working with chestnut purée concentrations higher than 300 g/l due to their viscosity. Therefore, two procedures were developed to increase the glucose levels in chestnut hydrolyzates.

In a way, the elaboration of hydrolyzates in consecutive cycles of submerged one-step hydrolysis of chestnut purée, carried out by using the hydrolyzate obtained in the first cycle – free of solids – to make a new chestnut pureé for the next cycle of hydrolysis, led to a 65% increase of the glucose concentration in the hydrolyzate obtained after three cycles of operation (López *et al.*, 2004) with regard to the simple one-step operation.

On the other hand, solid state hydrolysis, performed with chopped-wet chestnut without free water, also showed the suitability of this mode of operation to increase the levels of glucose in the hydrolyzates obtained after one-step solid state operation and posterior aqueous extraction (López *et al.*, 2005). Applying the same optimal enzyme concentration and α-amylase/glucoamylase ratio defined for the submerged operation, total hydrolysis was achieved operating in solid state at 70°C (López *et al.*, 2005) (Figure 10.5), what led to a 50% increase of the glucose concentration in the hydrolyzate comparing to the submerged process. The assays performed at lower temperatures to check the possibility to develop a process of simultaneous hydrolysis and fermentation showed the inability of the system to achieve total hydrolysis of the chestnut starch (Figure 10.5) as a consequence of mass transfer restrictions (López *et al.*, 2005).
Figure 10.5 Kinetics of the one-step solid-state hydrolysis of chestnut with a mixture of 0.35/0.65 α-amylase/glucoamylase and 60 EU/g of raw chestnut at three temperatures: 70°C (triangles), 30°C (circles) and 17°C (squares). Published with permission of the American Chemical Society (Copyright 2005).

Summary Points

- Enzymes are the underlying responsible for all the biochemical reactions that take part in the elaboration of many foodstuffs. Beer is an example of that.
- Amylases are, together with limit dextrinase and proteases, the main enzymes implicated in brewing. Their action during the stages of malting and mashing allows the degradation of the starch and proteins present in the cereal grain to transform them into yeast assimilable sugars and amino acids.
- The fermentability of the wort and the final levels of alcohol and remaining sugars in beer are strongly dependent on the activity of the starch degrading enzymes (amylases and limit dextrinase). Low levels of enzymes or inadequate conditions of pH, temperature, and time of operation during malting and mashing can lead to low-quality beers.
- The profile of cereal endogenous starch degrading enzymes includes α-amylase, β-amylase, α-glucosidase, and limit dextrinase. It depends mainly on the cereal, although variety, cultivar, and malting conditions also affect the levels of the enzymes synthesized. They are accumulated during the malting step by *de novo* synthesis or by proteolytic transformation into active forms.
- The main amylases in barley and sorghum are β- and α-amylase. The former is the major amylase in barley. It is an exoenzyme that liberates β-maltose from starch, providing a readily fermentable substrate for the yeast. The latter is the major amylase in sorghum. It is an endoenzyme that reduces starch viscosity breaking the starch molecule in lower weight non-directly assimilable oligosaccharides, maltose, and glucose in low amounts. The only action of α-amylase on starch provides low levels of fermentable

sugars. Therefore, this enzyme needs the following action of β-amylase or α-glucosidase as saccharifying amylases.

- Limit dextrinase is the debranching enzyme responsible for the hydrolysis of the α-1,6-linkages in α- and β-limit dextrins resulting from the exhaustive action of α- and β-amylases on starch. The activity of this enzyme during mashing is usually low in malted cereals, making up less than 20% of its potential total activity due to the major presence of limit dextrinase as inactive forms of the enzyme bound to endogenous proteinaceous inhibitors.

- Exogenous amylases (mainly α-amylase, α-glucosidase, and glucoamylase) can be added during the mashing stage to reinforce the action of the endogenous enzymes. This strategy has interesting operational benefits increasing the wort fermentability of poorly modified malts, reducing the need of malt for mashing, and allowing the use of other non-easily maltable starchy sources as chestnut.

- New kinds of beers with interesting nutritional characteristics can be obtained by different strategies related to the role of amylases:
  - Beers with low ethanol content can be obtained by limiting the activity of the endogenous enzymes during mashing to reduce the amount of fermentable sugars in the wort.
  - Beers for diabetics, light or diet beers, which are characterized by low levels of residual sugars in the final product, can be elaborated increasing the extent of starch hydrolysis during mashing by adding amylase-rich multienzyme preparations.
  - Beers for celiac people can be elaborated employing gluten-free starchy sources with low DP (as sorghum) in combination with the addition of exogenous enzymes.

Trends of Beer Drinking in Europe

Pedro Marques-Vidal Unidade de Nutrição e Metabolismo, Faculdade de
Medicina da Universidade de Lisboa, Lisboa, Portugal

Abstract

The trends in beer drinking in Europe were assessed from the
food balance sheets of the Food and Agriculture Organization
and the brewers in Europe, together with available national or
international studies. In Nordic countries, beer consumption
decreased in some countries but increased in others. In Southern
European countries, beer consumption tended to increase, whereas
in Central European countries beer consumption declined stead-
ily. Finally, in Eastern European countries, no concise pattern
could be drawn, although an increase in the consumption
was found in most countries studied. Overall, the available
data indicate that beer consumption decreases in the Center
and North of Europe, while it tends to increase in the
Southern and Eastern Europe. The reasons for such changes
are multiple, including global market, tax and law enforce-
ment, local supply and trendy fashion.

Introduction

Alcohol drinking can be influenced by several factors at the
population level: price policies (Ponicki *et al.*, 1997; Heeb
et al., 2003; Kuo *et al.*, 2003), law enforcement (Kubicka
et al., 1998; Nordic Council for Alcohol and Drug Research,
2002; Wallin *et al.*, 2005), local availability (Ólafsdóttir,
1998) and fashion (Simpura *et al.*, 1995). Further, assessing
the trends in alcohol (and beer) consumption is a relatively
challenging task, as there are little longitudinal studies, and
the methods used to quantify alcohol consumption do not
provide homogeneous results (Giovannucci *et al.*, 1991;
Casswell *et al.*, 2002; Koppes *et al.*, 2002). Since earlier

trends have already been reported (Leifman, 2000), this
chapter will focus mainly on the trends in beer availability as
reported in the Food and Agriculture Organization (FAO)
food balance sheets (Food and Agriculture Organization,
2006), and by national brewer's associations. The FAO food
balance sheets enable the estimation of a per capita supply
of different types of foodstuffs for a given period based on
the available supply and the population size,[1] but do not
take into account the individual imports or home-made
alcoholic drinks (Nordlund and Osterberg, 2000; Leifman
et al., 2002). Whenever possible, data from national or
international studies on the trends of beer drinking will be
provided. Regarding adolescents, data from the European
School survey Project on Alcohol and other Drugs (ESPAD)
study (Hibell *et al.*, 1997, 2004) will be reported; the
ESPAD study is a multinational study focusing on alco-
hol and other drug use among students, encompassing 35
European countries, and provides estimates of the preva-
lence of adolescents aged 15–16 years who consumed beer
at least thrice during 30 days prior to the interview. It
should be stressed that the results obtained using the FAO
food balance sheets, the per capita consumption as provided
by brewer's associations and the data from population stud-
ies might differ, as the methodologies are not comparable.

Also, since drinking patterns differ considerably accord-
ing to geographical region (Sieri *et al.*, 2002), trends will
be provided for four regions: Nordic, traditionally spirit-
drinking countries; Central, beer-drinking countries, and
Southern European, wine-drinking countries (Leifman,
2000); and lastly, the trends in beer consumption will be
assessed in the former USSR, Eastern European countries,
for which only limited data regarding trends are available.

Results will be expressed in annual per capita consump-
tion (in liters), mean daily beer-related ethanol consumption
(in grams of ethanol) and as percentage of overall ethanol
consumption. For each country, a linear regression was per-
formed using beer consumption parameters as dependent var-
iable and year as independent variable; this enables to assess

whether the beer availability and/or consumption increased, remained stable or decreased during the time period studied.

Nordic Countries

Nordic countries (Denmark, Finland, Iceland, Norway and Sweden) are characterized by high spirit consumption. Beer is also a common beverage, and its alcohol content varies between less than 2.8% (light beer) to nearly 7% (strong beer). Interestingly, although alcoholic beverage sales is a state monopoly, light beer can be found in supermarkets, and changes in sales policies as imposed by European Union (EU) might considerably influence consumption trends (Holder et al., 1995). Most of the beer is consumed in private houses, less than 25% being consumed in restaurants or other premises, and no significant trend was noted (Table 11.1).

Denmark

Denmark is a relatively modest producer of beer in Europe, ranking behind Austria and before Portugal (Table 11.2). Per capita consumption decreased from 128 l per year in 1992 to 85 l in 2004; this decrease being also found for the average daily consumption and the percent of total ethanol consumption as reported by the food balance sheets (Table 11.3). Those findings are in agreement with other authors, and are the result of efforts of some Nordic countries to promote Southern European drinking style, replacing beer and spirits by wine (Gerdes et al., 2002; Nordic Council for Alcohol and Drug Research, 2002). Still, those findings might not apply to all the Danish population, as a recent survey found that alcohol consumption has remained relatively stable in 15–16-year olds for the period 1995–2003

(44% in 1995, 53% in 1999 and 44% in 2003) (Hibell et al., 2004) or even increased in middle-aged and elderly Danes (Bjork et al., 2006).

Finland

Contrary to Denmark, beer consumption in Finland increased in the 1980s (Simpura et al., 1995) and remained stable afterward (Table 11.3). In 1992, the per capita consumption was 88 l per year, with only a slight decrease to 84 l in 2004; similar conclusions can be drawn from the FAO food balance sheet data. Beer represents circa two-thirds of all ethanol consumed, and this figure has remained stable for the period studied (Table 11.3). It should be noted that there is no information available regarding unrecorded beer consumption, such as home-made beer or importing from abroad (Leifman et al., 2002). Also, as in Denmark, total alcohol consumption appears to be increasing among elderly subjects (Sulander et al., 2004), although no information regarding whether this consumption of beer or other types of alcoholic beverages was provided. The prevalence of adolescents who consumed beer three times or more during the last 30 days also increased slightly from 15% in 1995 to 17% in 2003 (Hibell et al., 2004).

Iceland

There is little information regarding the trends in beer consumption for Iceland. A previous study has shown that the consumption of beer increased after the introduction of strong beer in 1989, but leveled off afterward (Ólafsdóttir, 1998). Still, people started shifting from spirits to beer since, and data from the FAO indicate that the consumption of beer increased during 1992–2004: in 1992, beer represented less than 40% of total alcohol consumed, whereas in 2003 it was over 60%. Beer-related ethanol consumption also doubled during that period (Table 11.3), and a slight, non-significant increase in the prevalence of beer drinkers was also noted in the ESPAD study: 17% in 1995 and 1999, 19% in 2003 (Hibell et al., 2004).

Norway

The mean beer-related ethanol consumption increased slightly from 1992 to 2003 (Table 11.3) a trend also observed in the ESPAD study for adolescents (9% in 1995, 17% in 1999, 14% in 2003) (Hibell et al., 2004). Conversely, the share of beer among alcoholic beverages decreased from 70% to 56% (Table 11.3). Those findings indicate that beer consumption is increasing at a lower pace than total alcohol consumption (Strand and Steiro, 2003).

Sweden

As for Denmark, the consumption of beer has been declining in Sweden. Per capita consumption decreased from 64 l in

1992 to 51 l per year in 2004, a trend similar to the percentage of total ethanol (Table 11.3). Again, this trend might be related to the promotion of a Southern European drinking style, replacing beer and spirits by wine (Gerdes *et al.*, 2002; Nordic Council for Alcohol and Drug Research, 2002; Eiben *et al.*, 2004). Still, recent changes regarding alcoholic beverage trading might counter this favorable trend (Berggren and Nystedt, 2006), namely regarding the consumption of strong beer among teenagers (Andersson *et al.*, 2002) and adults (Berg *et al.*, 2005). Interestingly, the ESPAD study showed a relative stabilization in the prevalence of beer drinkers: 19% in 1995, 21% in 1999 and 20% in 2003 (Hibell *et al.*, 2004).

Central European Countries

Central European countries (Austria, Belgium, Germany, Ireland, The Netherlands and the United Kingdom) are traditionally beer-producing and beer-drinking countries. Although Switzerland cannot be considered as a traditional beer-drinking country, it can be considered as a Central European country, and will be analyzed accordingly. It should also be noted that people from Belgium, Ireland and the United Kingdom tend to consume beer mostly outside home, whereas the opposite trend is found for Austrians, Germans and Swiss; still, a slight trend toward a higher home consumption can be noted for all countries (Table 11.1).

Austria

Mirroring the decrease in beer production (Table 11.2), the per capita consumption of beer decreased from 23.3 l

in 1992 to 22.4 l per year in 2004 (Table 11.4). This trend could not be confirmed by the data from the food balance sheets, although the share of total alcohol consumption decreased slightly, indicating a possible shift from beer to other alcoholic beverages (Table 11.5).

Belgium–Luxembourg

Contrary to beer production, which increased in Belgium and decreased in Luxembourg (Table 11.2), the per capita consumption decreased considerably in Belgium from 114 l in 1992 to 85 l per year in 2004, whereas it remained stable in Luxembourg (Table 11.4). A possible explanation might be the sales of alcoholic beverages to foreign tourists, although a real stability in the consumption of beer cannot be ruled out. Taking both countries together, the average consumption of beer remained stable, as the share of total alcohol consumption (Table 11.5).

Germany

Germany is the biggest beer producer in Europe (Table 11.2) and one of the biggest in the world. Still, the overall production and consumption of beer have been declining steadily. Per capita consumption dropped from 144 l in 1992 to 120 l in 2004 (Table 11.4), whereas verage beer-derived alcohol consumption also decreased (Table 11.5). Interestingly, the share of beer among total alcohol consumption also decreased from 67% to 61% (Table 11.5), indicating a slight but consistent shift in drinking patterns. Those findings are further confirmed by population studies, which also showed a downward trend in alcohol and beer consumption (Schaeffler *et al.*, 1996;

NA, not available.
Source: Data from the Food and Agriculture Organization food balance sheets (Food and Agriculture Organization, 2006).

Bloomfield, 1998). Thus, the available information indicates that the Germans are replacing beer with other alcoholic drinks, mostly with wine.

Ireland

The per capita consumption of beer in Ireland has remained stable between 1992 and 2004, although with a slight decrease in the recent years (Table 11.4). Similar findings were obtained among adolescents aged 15–16 years for the period 1995–2003, with a prevalence of beer consumers between 34% and 36% (Hibell *et al.*, 2004). Still, the overall beer production has increased (Table 11.2), as the average consumption expressed in grams of ethanol (Table 11.5). Conversely, no changes were found regarding the percentage of total alcohol consumption for beer, although a slight increase might be apparent for the period 1996–2003

(Table 11.5). Those findings indicate that beer is the preferred alcoholic beverage in Ireland, accounting for circa three quarters of total alcohol consumed.

The Netherlands

The Netherlands is the fourth biggest beer producer in the former EU, and the production has increased in the beginning of the twenty-first century relative to the beginning of the 1990s (Table 11.2). Still, the per capita consumption has decreased from 90 l in 1992 to 78 l per year in 2004 (Table 11.4), a decrease which was not found regarding beer availability, although the average consumption in the 2000s was lower than in the 1990s; a possible explanation is that the increased production of beer is for exports, thus reducing the actual amount of beer available for local consumption.

The share of total alcohol consumption increased in the beginning of the 1990s to decrease afterward (Table 11.5), thus making the overall trend non-significant. Those findings might indicate temporal changes in drinking patterns, although other reasons cannot be ruled out.

Switzerland

Switzerland is a wine-producing country, and beer consumption remained stable between 1992 and 2003, although a decrease was noted between 1992 and 2000 (Table 11.5). This decrease in beer consumption was also found in population studies (Schmid and Gmel, 1996), and was paralleled by a decrease followed by a slight increase in the share of total alcohol consumption (Table 11.5). This decrease can partly be due to the increased spirit consumption following price changes (Kuo *et al.*, 2003; Mohler-Kuo *et al.*, 2004), with a stable consumption of wine and beer (Heeb *et al.*, 2003).

United Kingdom

In the United Kingdom, most of the beer consumption occurs outside home (Table 11.1), mainly in public bars (McKinney and Coyle, 2005). The per capita consumption has decreased in the 1990s, with a slight recovery in the beginning of the new millennium (Table 11.4). Opposite trends were found for adolescents who consumed beer three or more times during the last 30 days, with an increase from 30% in 1995 to 37% in 1999, followed by a decrease to 31% in 2003 (Hibell *et al.*, 2004). Still, the availability of

beer remained rather stable, whereas the share in total alcohol consumption decreased slightly (Table 11.5).

Southern European Countries

Southern European countries (France, Greece, Italy, Portugal and Spain) are usually considered as wine-producing, wine-consuming countries, with a Mediterranean-style diet. Still, in the early 1990s some authors have suggested that alcohol consumption patterns were shifting, with an increased consumption of beer (Pyörälä, 1990; Smart, 1991), but no recent data were available.

France

The production of beer has declined in France, being overcome by Belgium in 2004. This decrease in production has been paralleled by a decrease in consumption from 40.9 l per year in 1992 to 33.7 l in 2004 (Table 11.6) (The Brewers of Europe, 2006). Other sources indicate a 15% decrease in the consumption of beer and cider between 1980 (51.7 l per year) and 1995 (44.2 l per year) (Haut Comité de la Santé Publique, 2000). Indeed, the percentage of French students consuming beer at least thrice during the past 30 days is the lowest when compared to the other countries, and also decreased from 25% in 1999 to 20% in 2003 (Hibell *et al.*, 2004). Conversely, the share of beer has remained relatively stable (Table 11.6), indicating that the decrease in beer consumption might partly be due to the decrease in total alcohol consumption.

In France, and contrary to Greece, Portugal and Spain, most of beer is consumed in private homes (Table 11.1). Possible explanations include the high consumption of beer by tourists visiting those countries (increased beer consumed in bars, restaurants and other premises) associated with higher weather temperatures, although other reasons related to marketing or drinking patterns cannot be ruled out.

Greece

Greece is usually considered as a minor producer of beer, but in 2004 the Greek production was higher than Sweden (Table 11.2). The per capita consumption has remained stable for 10 years at 40 l per year, half of the EU average, but higher than France or Italy (Table 11.6). This relatively high per capita consumption might partly be due to tourists, as only one-third of beer sales are consumed in private homes (Table 11.1).

Mean consumption remained stable, whereas the share of total alcohol consumption decreased from 40% in 1992 to 33% in 2003 (Table 11.7). A decrease was also found in the ESPAD study for adolescents, from 35% in 1999 to 28% in 2003 (Hibell *et al.*, 2004). Those findings might indicate that, contrary to the other Southern European countries, the Greeks are slowly shifting from beer to other alcoholic beverages, such as wine or spirits.

Italy

Italy has a relatively small production of beer, ranking seventh in front of Ireland, Austria and Denmark. As for France, circa 60% of all beer sales are consumed in private households (Table 11.1). The per capita consumption of beer is the lowest among Europe (29.6 l per year in 2004), with an increase in the recent years (Table 11.6). Those findings are confirmed by the ESPAD reports, where the percentage of male students consuming beer at least thrice

during the past 30 days increased from 36% in 1995 to 45% in 2003 (Hibell *et al.*, 1997, 2004); conversely, the authors reported a relative stability of the number of female students consuming beer (21% in 1995 and 22% in 2003), and for the overall sample, no significant trend was observed (Hibell *et al.*, 2004).

Beer consumption shows a seasonal pattern in Italy, being three times higher in summer than in winter (Table 11.7), with no significant change for almost a decade (Associazione degli Industriali della Birra e del Malto, 2002, 2003, 2004, 2005). Those findings might be related to weather temperature, as beer can be consumed as a refreshing beverage, or due to increased number of incoming tourists.

Portugal

The Portuguese production of beer has been increasing regularly since 1992 and, according to the FAO food balance sheets, exceeded wine production in 2003 (Food and Agriculture Organization, 2006). The per capita consumption in 2004 was 61.7 l, the second highest among Southern European countries, although a slight downward trend was noted. Still, no significant evolution was noted using data from the food balance sheets, neither for average consumption nor for the share of total alcohol consumption (Table 11.6). Conversely, individual data from the national health surveys actually showed an increase in beer consumption: in men, beer represented 20% of alcohol consumption in 1995/96 and 22% in 1998/99, the corresponding figures for women being 9% and 35%, respectively (Marques-Vidal and Dias, 2005). Finally, data from the ESPAD report also confirms those trends, with a slight increase in the percentage of male students who consumed beer at least thrice during the past 30 days (25% in 1995 and 27% in 2003); conversely, the percentage of female students reporting a similar consumption decreased slightly

Table 11.7 Monthly consumption of beer in Italy

Figure 11.1 Trends in beer consumption in Spain. Squares: overall consumption (Spanish citizens + tourists); circles: Spanish citizens only. *Source*: Adapted from Cerveceros de España (2004).

(12% in 1995 and 10% in 2003), making the overall trend non-significant (Hibell *et al.*, 1997, 2004). Finally, the share of beer sales consumed in private homes increased dramatically between 2003 and 2004 (Table 11.1); those data might indicate that beer is increasingly becoming a popular beverage among households, possibly at the expense of other alcoholic beverages.

Spain

Spain is the third biggest beer producer in the EU and the ninth in the world, ranking in front of Ireland and The Netherlands. Still, the per capita consumption of beer in 2004 was just at the European average (80 l per year, Table 11.6). According to the Spanish Ministry of Agriculture, Fisheries and Food, the per capita consumption of beer in 2003 was 57.5 l, whereas according to the Spanish Beer Producers, this consumption was around 78 l (Cerveceros de España, 2004). Those differences are mainly due to tourists visiting Spain, which account to circa one-third of beer consumption. Indeed, most of the tourists come from traditionally beer-drinking countries such as the United Kingdom and Germany, their per capita consumption is significantly higher than the Spanish. Thus, considering the 1991–2003 period, the consumption of beer has actually declined from 71 to 57.5 l among Spanish citizens, whereas the overall consumption (Spanish citizens + tourists) has slightly increased from 71 to 78 l (80 in 2004 – Figure 11.1). Those findings might also explain the relatively low share of total beer sales consumed in private homes, which decreased between 2002 and 2003 (Table 11.1), possibly indicating that beer is increasingly consumed in bars or other premises open to tourists. Still, data from the food balance sheets suggest that the average consumption of beer-related ethanol has remained stable, and that beer has

actually increased its share of total alcohol consumed: since 1999, beer accounts for half of all alcohol consumed in Spain (Table 11.6).

The consumption of beer varies according to region, with a South to North gradient. In 2003, the per capita consumption of beer in the South (Andalucía and Extremadura) was 89 l, whereas the corresponding consumption in the North (Galìcia, Asturias and León) was only 38 l (Cerveceros de España, 2004). Those differences are mainly due to the number of tourists visiting the region and to local weather temperatures, as beer is normally consumed as a refreshing beverage. Indeed, the heat wave that struck Southern Europe in the summer of 2003 is considered as one of the main reasons for the increase in beer consumption between 2002 and 2003. The highest increase was noted in the Northern regions, although it is currently unknown whether this increase was for Spanish citizens or due to the higher number of tourists.

Former USSR and Eastern European Countries

There is little information regarding the trends in the consumption of alcoholic beverages in Eastern European countries. Further, the types of alcohol consumed differ according to country, and it is possible to define spirit-drinking (Russian Federation, Belarus), wine-drinking and beer-drinking (Ukraine) countries (Pomerleau *et al.*, 2005); the prevalence of alcohol drinkers also varies considerably (McKee *et al.*, 2000).

In the Czech Republic, the increase in alcohol consumption following political changes in 1993 (Kubicka *et al.*, 1998) appears to have stabilized, as the mean amount of ethanol and also the share of beer among alcoholic beverages did not show any significant trend (Tables 11.8 and 11.9). Similar findings were obtained in the ESPAD survey: the prevalence of adolescents who consumed beer thrice or more, the previous 30 days increased from 31% in 1995 to 40% in 1999, but remained stable afterward (39% in 2003) (Hibell *et al.*, 2004). Also, no significant trends were found for the period studied for Belarus, Bulgaria and Slovakia (Tables 11.8 and 11.9), although in Slovakia a decrease in alcohol consumption was observed since 1990 (Szantova *et al.*, 1997). Regarding consumption by adolescents, the ESPAD data indicate that the prevalence of subjects who consumed beer thrice or more the previous 30 days increased from 27% in 1999 to 43% in 2003 in Bulgaria, and from 16% in 1995 to 22% in 2003 in Slovakia (Hibell *et al.*, 2004).

Bosnia, Croatia, Estonia, Poland, Romania, the Russian Federation, Serbia–Montenegro and Ukraine showed an increase in beer consumption, both in grams of ethanol and as percentage of all alcoholic beverages, indicating a possible shift of drinking patterns (Tables 11.8 and 11.9).

Source: Data from the Food and Agriculture Organization food balance sheets (Food and Agriculture Organization, 2006).

Those findings are in agreement with the literature, where beer has become the preferred alcoholic beverage among adolescents in the Baltic countries (Zaborskis *et al.*, 2006). Also, the ESPAD study noted an increase in the prevalence of beer drinkers in most countries: Croatia (from 13% in 1995 to 28% in 2003), Estonia (from 12% in 1995 to 25% in 2003), Poland (from 25% in 1995 to 41% in 2003), Romania (from 20% in 1999 to 32% in 2003) and Ukraine (from 12% in 1995 to 34% in 2003), whereas no increasing trend was found for Russia (40% in 1999 and 38% in 2003) (Hibell *et al.*, 2004). Interestingly, for Southern European countries, the consumption of beer in

Estonia is significantly related with weather temperature, being higher in summer (Silm and Ahas, 2005).

In Lithuania, the per capita consumption was 75.5l in 2003 and increased to 81.2l in 2004 (The Brewers of Europe, 2006), in agreement with data from the FAO (Table 11.8), the ESPAD (from 9% in 1995 to 28% in 2003) (Hibell *et al.*, 2004) and previous findings from an urban sample of subjects aged 35–64 years (Tamoshiunas *et al.*, 2005) in adolescents (Grabauskas *et al.*, 2004) and in school-aged children (Sumskas and Zaborskis, 2004). Beer is consumed mostly at home (Table 11.1), and the share of total alcohol from beer remained stable, suggesting an increase in total alcohol consumption (Table 11.9). Conversely, beer has become the most popular alcohol drink in school-aged children (Sumskas and Zaborskis, 2004), indicating that the penetration of beer in the Lithuanian population might differ according to age group. Also, for Latvia, an increase in the average consumption of beer was noted (Table 11.8), although data from the ESPAD showed no significant trend in adolescents (30% of subjects with a consumption ≥ 3 units the previous 30 days in 1999, 32% in 2003); further, no significant change in the share of alcoholic beverages was noted (Table 11.9).

Only three countries registered a decrease in the average consumption of beer: Hungary, Macedonia and Slovenia. In Slovenia, total alcohol consumption decreased significantly (Sesok, 2004); data from the ESPAD study actually showed an increase in the percentage of adolescents consuming beer from 21% in 1995 to 27% in 1999, followed by a decrease to 21% in 2003 (Hibell *et al.*, 2004). The share of beer actually increased, indicating a probable shift in drinking patterns, people preferring beer to other alcoholic beverages (Tables 11.8 and 11.9). The opposite conclusion can be derived for Hungary, where the share of beer tended to decrease, suggesting that beer is being substituted by other alcoholic beverages, although the percentage of adolescents consuming beer increased from 12% in 1999 to 17% in 2003 (Hibell *et al.*, 2004). Finally, data from Macedonia indicate that beer consumption is decreasing but that its share of alcoholic beverages is relatively stable (Tables 11.8 and 11.9).

Conclusion

During the last decade, the consumption of beer showed different trends according to geographical region: mostly a decrease in Nordic and Central European countries, with a concomitant increase in Southern and Eastern European countries. Those trends can be found using data from different sources (FAO, European brewers, ESPAD study), suggesting that beer consumption is slowly coming toward uniformity among European countries, as reported by other authors (Pyorälä, 1990; Gual and Colom, 1997; Walsh, 1997). The reasons for such changes are multiple, such as

global marketing, price policies (Ponicki *et al.*, 1997; Heeb *et al.*, 2003; Kuo *et al.*, 2003), law enforcement (Kubicka *et al.*, 1998; Nordic Council for Alcohol and Drug Research, 2002; Wallin *et al.*, 2005) and local availability (Ólafsdóttir, 1998) just to cite a few. Of particular concern is the fact that beer (and alcohol) consumption is increasing among adolescents in a considerable number of European countries, with possible deleterious health consequences in the future.

Summary Points

- The consumption of beer decreased in Nordic and Central European countries, and increased in Southern and Eastern European countries.
- Those trends can also be found for adolescents aged 15–16 years.
- The reasons for those different trends are multiple and include global marketing, price policies, European or local regulations and fashion, and might be different according to country.
- The increase in beer (and total alcohol) consumption in Eastern European countries and in adolescents is of concern.

Trends of Beer Drinking: Rest of the World

Qiao Qiao Chen Unidade de Nutrição e Metabolismo, Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal
Pedro Marques-Vidal Institut Universitaire de Médecine Sociale et Préventive, Lausanne, Switzerland

Abstract

The trends in beer drinking worldwide were assessed from the food balance sheets of the Food and Agriculture Organization, together with available national or international studies. Overall, the data indicate that beer consumption is decreasing in industrialized countries such as Australia, Canada, Japan, New Zealand and the United States, whereas the opposite trend is observed for developing countries. This increase is particularly strong in Asia, namely in China and Thailand. Conversely, no definite trends were found in other regions such as Latin America or Africa. Although social and religious factors considerably influence alcohol and beer drinking, their effects appear to be lessening in the younger generations, which appear as the major consumers of beer.

FAO   Food and Agriculture Organization of the United Nations
USA   United States of America

Introduction

In this chapter, it was decided to present only data from countries where alcohol consumption is common in the population. Thus, data from predominantly Muslim countries were not included. Further, while most industrialized countries have reliable data on beer production and consumption, this is not the case for most developing countries, where estimates have to be performed. Thus, some trends should be regarded with caution, as Food and Agriculture Organization of the United Nation (FAO) data do not take into account home-made alcoholic beverages, which are quite common and popular in developing countries (Carlini-Cotrim, 1999; Mohan *et al.*, 2001).

North America

Canada

Canada ranks 12th in beer production worldwide (Brewers Association of Japan, 2004a) but only 19th as regards the per capita consumption of beer (Brewers Association of Japan, 2004b). Overall, the per capita consumption of beer has decreased in the last years from 93l in 1995 to 88l in 2005 (Table 12.1), but this decrease was not observed in some provinces such as Québec and Yukon (Table 12.1). It should also be noted that the per capita beer consumption varies considerably between provinces, from less than 80l per year in Manitoba and Saskatchewan to over 100l in Newfoundland and 150l in Yukon (Table 12.1) (The Brewers Association of Canada, 2007b, c). Expressed in percentage of overall ethanol consumption, the importance of beer has also decreased slightly from 85% in 1995 to 80% in 2005 (Table 12.1). Those findings are partly confirmed by the FAO data (Table 12.2), namely as regards the relative importance of beer; conversely, no significant trend was found regarding the amount of beer-derived ethanol consumption (Table 12.2).

The type of beer package also showed differential trends, cans being more frequently purchased, while bottles and draft beer showed a slight decrease (Figure 12.1) (The Brewers Association of Canada, 2007a).

United States of America

The United States were until recently the main producers of beer worldwide, but have been overpowered by China (Brewers Association of Japan, 2004a).

Data from the National Institute on Alcohol Abuse and Alcoholism indicate that the overall consumption of beer has decreased in the recent decades (Figure 12.2) (National Institute on Alcohol Abuse and Alcoholism), a trend also confirmed by the FAO data (Table 12.2) and the USDA

Economic Research Service (Table 12.3) (USDA Economic Research Service Data Sets, 2006). Overall, beer represented between 67% and 54% of all ethanol consumed, and this percentage also tended to decrease in all datasets analyzed. Interestingly, the consumption of beer is not evenly distributed in the United States, representing over 50% of total alcohol consumption in the Midwest and South regions, vs. less than 50% in the Northeast and the West (Table 12.3).

Data from the National Alcohol Surveys showed that the frequency of beer drinkers decreased from 51.5% in 1984 to 45.2% in 1990, but increased slightly to 48% in 1995

(Greenfield *et al.*, 2000); since no consumption data were available, it cannot be assessed whether this slight increase in drinkers was associated with a concomitant increase in individual consumption.

The 2001–2002 National Epidemiologic Survey on Alcohol and Related Conditions provided very interesting data regarding the factors related to beer preference. Overall, beer is the most preferred alcoholic beverage, but considerable gender, ethnicity, education, family income and age differences exist. For instance, 50% of men indicate beer as their preferred alcoholic beverage, vs. 19% of women (National Institute on Alcohol Abuse and Alcoholism, 2006); beer is

cited by 45% of Hispano or Latino subjects, vs. 37.5% for American Indians/Alaska Natives and 33.8% in Whites (National Institute on Alcohol Abuse and Alcoholism, 2006). Further, over 51% of subjects with 11 years or less of education prefer beer, vs. 33.5% of subjects with 13–15 years and 25.6% of those with 16 years or more of education (National Institute on Alcohol Abuse and Alcoholism, 2006). Among families with less than $20,000 annual income, beer is the preferred beverage for 40.4%, 36.5% for families with incomes between $35,000 and $59,999 and less than 30% for families with an annual income of $60,000 or more (National Institute on Alcohol Abuse and Alcoholism, 2006). Regarding age, 36% of subjects aged 18–24 years report beer as the preferred beverage, vs. 24% of subjects aged over 65 years (National Institute on Alcohol Abuse and Alcoholism, 2006). Finally, 45.5% of current smokers preferred beer, vs. 31.3% for non-smokers, and heavy drinkers reported more frequently preferring beer than light drinkers (National Institute on Alcohol Abuse and Alcoholism, 2006).

Mexico

In 1994, beer was estimated to represent 87% of the Mexican market of alcohol (Medina-Mora *et al.*, 2000)

and accounted for 54% of all ethanol consumed (Medina-Mora *et al.*, 1998). Beer is the most frequently consumed alcoholic beverage (78% of drinkers) followed by spirits (72%) (Medina-Mora *et al.*, 2000), although in rural areas it comes second after the traditional *pulque* (Medina-Mora, 1999). Men consume more than women; in men, beer is mainly consumed by high/excessive drinkers, whereas in women it is mainly consumed by low/high drinkers (Medina-Mora *et al.*, 2000). Consumption is irregular and occurs on special occasions such as weekends, paydays and festivities (*fiestas*) (Medina-Mora *et al.*, 2000, 2001) where high amounts can be consumed.

Both beer production and imports have increased considerably; for instance, beer imports increased from only 304l in 1970 to more than 30 million in 1993 (Medina-Mora, 1999). Although the data from FAO do not support an increase in beer consumption (in absolute ethanol/day), still the relative impact of beer among alcoholic beverages has increased (Table 12.2). It should be noted that those figures do not take into account home-made alcoholic beverages, which might represent as much as 40% of the total volume of ethanol consumed in the country (Medina-Mora, 1999; Medina-Mora *et al.*, 2000).

Central America and the Caribbean

There is little information regarding the trends in beer consumption in Central America and the Caribbean. Data from beer production (Table 12.4) and the FAO (Table 12.5) indicate that the amount of beer-derived alcohol has increased in some countries, namely in Cuba and the Dominican Republic. The highest consumptions are observed for the latter country and Panama, possibly due to a North American influence.

With the exception of Costa Rica and El Salvador, beer accounted for almost half of the ethanol consumption, and increased in Cuba, the Dominican Republic and Nicaragua, whereas it tended to decrease in El Salvador and Panama (Table 12.5).

South America

Argentina

Argentina is traditionally among the countries with the highest per capita wine production, with a relatively low production of beer. Still, in the last decades this balance has shifted, with a considerable increase in the production of beer (Figure 12.3, Tables 12.6 and 12.7) (Camara de la Industria Cervecera y Maltera Argentina, 2007) and a decrease in wine consumption (Munné, 2005). Beer is the preferred alcoholic drink among adolescents, namely boys (Jerez and Coviello, 1998). Although the total amount of beer (expressed in grams of ethanol/day) remained stable in Argentina for period 1993–2003 (Table 12.7), the

percentage of ethanol consumed as beer actually increased, from less than one-quarter to almost one-third (Table 12.8). A possible explanation is the recent economic crisis, which led to considerable changes in drinking patterns, people shifting to lower-quality alcoholic drinks and going less frequently to bars (Munné, 2005), although the long-term effects of this crisis on patterns of alcohol consumption remain to be assessed.

Interestingly, beer consumption in Argentina follows a seasonal pattern (Camara de la Industria Cervecera y Maltera Argentina, 2007), opposite to that observed in Italy (Associazione degli Industriali della Birra e del Malto, 2004) (Table 12.9). Thus, the months of November to January account for one-third of all beer consumed, almost twice the amount of the consumption observed in June to August; the most likely explanation is weather, with increased temperatures during the summer months of the Southern hemisphere.

Brazil

Brazil ranks among the biggest producers of beer worldwide, with an increasing production from 51 millions of hectoliters in 1993 to 80 million in 1999 (Cervesia, 2003) (Table 12.6). The production is unevenly distributed throughout the country, the Southeast region accounting for more than half of the overall brewing capacity (Cervesia, 2003). Beer ranks first in the Brazilian consumption by volume, being second after spirits (*cachaça*) regarding the amount of ethanol consumed (Carlini-Cotrim, 1999).

Beer is the most popular alcoholic drink among adolescents (Pechansky, 1995; Galduróz and Caetano, 2004; Oliveira de Souza *et al.*, 2005) and also in the general population, namely among men, higher educated and non-white subjects (Almeida-Filho *et al.*, 2004). The per capita consumption of beer doubled between 1985 and 1995 (Carlini-Cotrim, 1999), but no significant trend was found afterwards (Table 12.8). In 2003, beer represented slightly more than half of total ethanol consumption (Table 12.8), but this figure should be interpreted with caution as the local, unreported home production of spirits is not considered in the FAO data.

Venezuela

Venezuela is the third biggest producer of beer in South America after Brazil and Colombia (Table 12.6). Still, reported on a per capita basis, Venezuela has the highest per capita production and consumption rates (Cerveceros latinoamericanos, 2007b) (Table 12.7). Those findings are in agreement with data from the FAO (Food and Agriculture Organization, 2006), although the differences between countries are not so stringent. Expressed in grams of ethanol/day, Venezuela has the highest consumptions, comparable to those found in European countries (Table 12.8). Beer

represents more than half of total ethanol consumption (Table 12.8), but this ratio has remained relatively stable for period 1993–2003. Conversely, beer has replaced other traditional alcoholic drinks such as corn liquor; currently beer is the most frequently consumed alcoholic beverage among the indigenous population (Seale *et al.*, 2002a, b).

Other countries

The production and per capita consumption of beer show wide variations between countries in the other South American countries (Tables 12.6 and 12.7). Expressed in grams of ethanol/day, Paraguay has the second highest consumption, comparable to those found in European countries, whereas the consumption in the other South American countries is much lower. Beer represented more than half of total ethanol consumption in Bolivia and principally Ecuador, where it represented two-thirds of all ethanol consumption (Table 12.8).

Regarding trends, beer consumption (expressed in grams of ethanol) increased in Bolivia, decreased in Colombia and Peru, and remained stable in the other countries. Expressed as percentage of total ethanol consumption, an increase was

observed in Bolivia and Paraguay, a decrease in Colombia and Peru, while non-significant trends were found for the other countries (Table 12.8). Finally, in Chile, beer is the most popular drink among students, together with spirits (Araneda *et al.*, 1996).

Asia-Pacific Region

The Asia-pacific region is characterized by two main and differential trends: a decreased consumption in Australia and New Zealand, paralleled by a considerable increase in the consumption among emerging Asiatic economies such as China and Thailand.

China

China is the main beer producer worldwide (Brewers Association of Japan, 2004a), and both the amount of beer-derived alcohol and the percentage of total ethanol from beer have increased considerably, almost doubling during the period 1993–2003 (Table 12.10). Beer is the most consumed alcoholic beverage among Chinese adolescents (Li *et al.*, 1996) and the second most consumed among adults (Wei *et al.*, 2001).

India

In India the consumption of beer is very low, representing less than 5% of all ethanol consumption, and no significant

trend was noted (Table 12.10). Beer consumption is much lower than country-made liquor or spirits, and might be even lower since there is no good estimation of the amount of illicit, home-produced spirits (Mohan *et al.*, 2001). The very low consumption of beer is probably due to its high price (Gupta *et al.*, 2003), which make this beverage more frequent among middle and upper economic classes and also among the urban youngsters (Saxena, 1999).

Japan

Japan is the sixth biggest beer producer worldwide (Brewers Association of Japan, 2004a) but only the 31st regarding the per capita consumption (Brewers Association of Japan, 2004b). Beer is the most popular alcoholic drink among policemen (Ohno, 1995), male adolescents (Osaki *et al.*, 1999) and adult women (Sobue *et al.*, 2001). Still, beer consumption showed a considerable decrease for period 1993–2003, both in absolute and relative terms (Table 12.10).

Malaysia

In Malaysia, beer and *samsu*, a local distilled alcoholic drink, are the most popular drinks by volume of absolute alcohol (Jernigan and Indran, 1999). Still, the high price of beer precludes its consumption by the lower socio-economic groups of the population (Jernigan and Indran, 1997, 1999). Based on FAO data, the average per capita consumption of beer is very low and has remained constant throughout the

period 1993–2003 (Table 12.10). Those figures should be analyzed with caution, since beer and alcohol consumption is unevenly distributed in the population, being almost none among the Muslims and much higher among Chinese (Jernigan and Indran, 1999). Further, and as reported for other countries, the high percentage of alcohol consumed as beer is probably overestimated, since the local, home-based production of spirits cannot be taken into account (Jernigan and Indran, 1999).

Australia

Slightly more than half of all alcohol consumed in Australia is in some form of beer, mostly beer with more than 4.5% alcohol by volume (Chikritzhs *et al.*, 2003), which represents 80% of beer-derived ethanol consumption and an even greater percentage as regards beverage volume (Catalano *et al.*, 2001). Although beer is still considered as the most popular alcoholic drink (Pidd *et al.*, 2006), its consumption has decreased (Drinkwise Australia, 2007), and this decrease is also patent in FAO data, both in absolute and relative terms (Table 12.10). Interestingly, the amount of full strength beer consumed has decreased by 14% while light alcohol beer has increased by 25% over the past one to two decades (Stockwell, 2004), no differences between urban and rural subjects (Dunsire and Baldwin, 1999). Among adolescents, beer consumption is decreasing, being replaced by spirits (King *et al.*, 2005); similar findings among middle-aged women, where beer consumption is lower than consumption of wine or spirits (Young and Powers, 2005). Finally, beer consumption is higher among risky and high-risk drinkers compared to low risk level drinkers (Australian Bureau of Statistics, 2006).

Other countries

In South Korea, beer is a popular alcoholic drink, together with local traditional beverages such as soju and makkolli (Chung, 2004); for period 1993–2003, no significant trends were found regarding the absolute and relative consumption of beer (Table 12.10).

In Thailand and Vietnam, the absolute amount of beer more than doubled during period 1993–2003; in Thailand, the percentage of ethanol consumed as beer increased considerably, whereas no changes were found in Vietnam (Table 12.10).

In Papua New Guinea, locally brewed lager beer is the most popular alcoholic beverage, followed by rum (Marshall, 1999). Men consume more than women, and usually do so in groups. In rural areas consumption is lower and, interestingly, beer is used in exchange ceremonies between kin groups (Marshall, 1999). Finally, in New Zealand, both the total amount as the relative part of beer-derived alcohol decreased (Table 12.10).

Mediterranean Non-European Countries

Only two countries were assessed, Turkey and Israel. In Turkey, the amount of beer-derived ethanol is low and increased only slightly, whereas the percentage of total ethanol from beer showed a steeper increase, from 48% in 1993 to 59% in 2003 (Table 12.11).

In Israel, the amount of beer-derived ethanol remained stable between 1993 and 2003, while the percentage of total ethanol from beer showed a decreased trend, from 56% in 1993 to less than half in 2003 (Table 12.11). A possible explanation might be related to alcoholic beverage preference of Russian emigrants, who tend to prefer spirits and disregard beer; indeed, no difference regarding beer consumption was found between Russian emigrants and other Israeli Jews (Rahav *et al.*, 1999). Finally, among college students, beer and wine were more popular than spirits and consumed in similar frequencies (Isralowitz and Peleg, 1996).

Africa

With the exception of the Seychelles and South Africa, the consumption of beer is very low in African countries.

Table 12.11   Trends in beer consumption in non-European Mediterranean countries

Year	1993	1994	1995	1996	1997	1998	1999	2000	2001	2002	2003	Trend

Source: Data from the Food and Agriculture Organization food balance sheets (Food and Agriculture Organization, 2006).

Further, the figures are somewhat hampered by considerable fluctuations, probably due to economical or political changes, and there are few field studies on alcohol consumption. Further, home-made alcoholic beverages are quite common and are not integrated into the national statistics. Thus, the data presented should be interpreted with some caution.

Namibia

In Namibia, 67% of all alcohol is consumed as home-brewed beer and 15% as store-purchased beer (Mustonen *et al.*, 2001). In women, 73% of ethanol consumption comes from home-brewed beer, whereas the corresponding figure in men is 64% (Mustonen *et al.*, 2001); conversely, men tend to consume more store-purchased beer.

Based on FAO data, a considerable increase in the total amount and in the relative importance of beer-derived ethanol consumed was noted till 2002, with a considerable decrease afterwards (Table 12.12). The reasons for such a decrease are not straightforward and might be related to economic or political changes.

Nigeria

In Nigeria, stout beer accounts for 80% and lager beer for 20% of total beer volume sales (Gureje, 1999), and more than 40 brands of locally brewed lager and stout are available (Obot, 2000). Beer is the most common alcoholic beverage, above local traditional beverages made of palm wine: 44% of adults in the middle-belt region and northern part of Nigeria reported consuming beer, vs. 21% for palm wine (Gureje, 1999). Indeed, expressed in volume, beer production is almost double of soft drinks, with a much steeper annual increase (Obot, 2000) (Figure 12.4). Possible reasons for such popularity are the relatively low price of beer, which is also considered a modern and stigma-free alcoholic beverage, and the availability in small-scale, street-corner shops (Gureje, 1999). Still, the consumption of beer and alcohol is unevenly distributed throughout the country, the predominantly Muslim North region being characterized by a very low consumption (Gureje, 1999). According to FAO data, no significant trends were found for both the

Source: Data from the Food and Agriculture Organization food balance sheets (Food and Agriculture Organization, 2006).

overall and the relative amount of beer-derived ethanol consumption (Table 12.12); the relatively low percentage of total ethanol consumed as beer might be related to the low alcohol content of beer relative to the other alcoholic drinks.

Data from the FAO food balance sheets indicate a slight, borderline significant increase in the amount of beer-derived ethanol, whereas no significant trend was found regarding the relative importance of beer among alcoholic beverages (Table 12.12). Based on FAO data, beer accounted for one-sixth (15%) of all ethanol consumed.

Seychelles

Beer is the most frequently consumed alcoholic beverage in the Seychelles: circa 45% of men aged 25–64 years report being regular drinkers (Perdrix *et al.*, 1999; Bovet, 2001). Conversely, beer-derived ethanol consumption is only 31%, the main percentage coming from local distilled beverages such as *baka* (Perdrix *et al.*, 1999). Men consume considerably more than women (17.6 vs. 1.1 ml ethanol/day), and alcoholic beverages are consumed mainly outside home (Perdrix *et al.*, 1999; Bovet, 2001). Beer consumption has been estimated to be 3 million liters for the entire population, although in the year 1994 5.54 million liters of beer were sold (Perdrix *et al.*, 1999; Bovet, 2001). Indeed, FAO data indicate considerable but stable beer consumption (over 45 g of ethanol/day), which accounts for more than 75% of all ethanol consumed (Table 12.12).

South Africa

Two-thirds of the absolute ethanol consumption in South Africa is in the form of malt or sorghum beer, and from 1970 to 1995 the greatest market growth was in malt beer (Parry and Bennetts, 1999). Those figures are not in agreement with the FAO data, which indicates that beer accounts for only 40% of total ethanol consumed (Table 12.12). The most likely explanation is that home-brewed beer production is not considered in the FAO report, thus underestimating the importance of this beverage. Consumers are shifting from sorghum to malt and home-brewed beer, since they contain more alcohol (Parry and Bennetts, 1999). In 1997, malt beer accounted for 44% of the alcoholic beverage market, followed by sorghum beer with 20% (Parry and Bennetts, 1999); this popularity is partly due to the fact that beer prices have been maintained below the inflation rate, making beer more affordable (Parry and Bennetts, 1999). Thus, between 1970 and 1991, the per capita consumption of malt beer increased by over 300, from 13.7 to 58 l per year (Parry and Bennetts, 1999). Based on FAO data, this increase has been contained, since no significant trend was found regarding both absolute and relative ethanol consumption (Table 12.12); again, the

unaccounted for home-brewed production might explain part of those differences.

Gender differences regarding the consumption of alcoholic beverages have also been noted, men consuming mainly beer while women consume other alcoholic drinks (Parry and Bennetts, 1999); a similar pattern is also found among teenagers (Madu and Matla, 2003). Interestingly, beer is the preferred alcoholic beverage in men irrespective of race (Parry and Bennetts, 1999).

Zimbabwe

In Zimbabwe, traditional African or opaque beer is the most consumed alcoholic beverage, followed by lager beer (Jernigan, 1999). Consumption is mostly driven by economic forces, people consuming the less expensive beverages, and the industry has kept the price of beer behind the pace of inflation to promote sales (Jernigan, 1999). Indeed, data from the FAO indicate that both the absolute and relative amounts of beer-derived ethanol have increased, beer representing less than one-tenth of all ethanol consumed in 1993 and one-quarter in 2003 (Table 12.12). Women consume very little alcoholic beverages, while the per capita consumption of opaque beer has been estimated to be over 11 l of pure ethanol a year in the 1970s (Jernigan, 1999). Taking into account that in 1995 the beer produced by the country's legal breweries amounted to only 4 l of pure ethanol per capita, the difference between the legal production and the actual per capita consumption is mainly due to illegal, home-brewed beer (Jernigan, 1999).

Other countries

The consumption of beer increased in Angola and Egypt; in Angola it increased from one-third to half of all ethanol consumed (Table 12.12). Conversely, in Mozambique, no trend was found regarding absolute beer consumption, whereas the relative part of beer-derived ethanol consumption showed a slight decreasing trend. Overall, beer accounted for more than half of total ethanol consumption in those three countries (Table 12.12).

Conclusion

The epidemiology of beer drinking worldwide is hampered by the lack of reliable data for most developing countries. The local, home-made and mostly illegal alcoholic beverages (including beer) are difficult to assess and might considerably bias the estimates. Conversely, in industrialized countries, the available data might provide different estimates for the prevalence of beer drinking or the amount of beer consumed; thus, the data source must be properly cited when single estimates are provided.

Still, based on the available information, it can be inferred that the consumption of beer is decreasing in most industrialized countries, while the opposite trend is found in developing countries, namely due to low prices and strong marketing forces. Also in developing countries, traditional and religious beliefs strongly influence beer (and alcohol) consumption. Asia is the continent where the increase in beer consumption is steeper, namely due to China. Finally, in almost all countries, beer consumption is closely linked to male gender and younger age groups.

Summary Points

- Beer accounts for 58–67% of total alcohol consumption in North America; 15–59% in Central America and the Caribbean; 29–58% in South America; 28–91% in Asia-Pacific countries, and 9–88% in selected African countries.
- Beer consumption is increasing in developing countries whereas the opposite trend is observed among industrialized countries.
- This increase is stronger in Asia (China and Thailand) than in other parts of the world.
- This increase is also stronger among younger generations.
- Social and religious factors considerably influence beer consumption, but their effect appears to be lessening.
- In many developing countries, the lack of reliable field studies and the local non-declared production of beer lead to an underestimation of the per capita consumption.

Beer Consumption Patterns in Northern Ireland

Adele Mc Kinney School of Psychology, Life and Health Sciences, University of Ulster, Magee Campus, Derry

Abstract

Alcohol has a long history of use, and due to its ability to promote feelings of joviality it is associated with celebrations. Northern Ireland has a distinct binge drinking culture where excessive amounts of alcohol are consumed at one sitting. The Health Promotion Agency of Northern Ireland (HPA, 2002) revealed that 37% of male drinkers exceeded 21 units per week and 20% of female drinkers exceeded 14 units per week, and this alcohol consumption is concentrated to the weekend. Another characteristic of Northern Irish male drinkers is their preference for beer consumption compared to wine consumption which is more popular in the wider European community. The HPA (2002) observed that the main drink of choice for men is beer (77%). For women the main choice of drink is wine (50%) closely followed by spirits (42%). One further distinctive pattern within Northern Ireland is the high level of abstinence. A Northern Ireland Community Health Study (Blaney and Mc Kenzie, 1978) found that 40% did not drink and of those 37% were life-long abstainers. However this level of abstinence is gradually decreasing. The continuous household survey (NISRA – Northern Ireland Statistics and Research Agency) revealed that the level of abstainers had decreased to 24% in 2002–2003. These drinking patterns are evident in all age groups and all socioeconomic classes of Northern Irish drinkers.

Introduction

To address the topic of "beer consumption patterns" it is important to identify what is meant by patterns. Patterns of beer consumption can relate to where beer is consumed, how much beer is consumed, when beer is consumed and in what environment. Patterns of alcohol consumption may also refer to the differences in beer consumption among different socioeconomic groups, age groups and gender. This chapter aims to address these interpretations of pattern of consumption.

It has been well established that the United Kingdom and in particular Northern Ireland are essentially beer drinking cultures. Another aspect of alcohol consumption in Northern Ireland is the tendency to drink large quantities of alcohol in one sitting, binge drinking. This chapter will compare the drinking patterns in Northern Ireland with other European countries to highlight the binge drinking culture.

Beer is the drink of choice in Northern Ireland especially for males; however, it is important to put the beer drinking into context and describe general drinking habits in Northern Ireland. This chapter will endeavor to describe drinking habits in Northern Ireland in relation to other countries and then focus on the beer drinking culture within the distinctive drinking culture of Northern Ireland.

Alcohol Use/Misuse in Northern Ireland

The classification of problem drinkers is questionable but different research studies have used units of alcohol consumption as a criterion. The recommended weekly intake of alcohol is 14 units for females and 21 units for males. The percentage of females, in Northern Ireland, consuming more than 14 units is reported to have decreased from 12% to 11% between 1987 and 1989, the percentage of males consuming more than 21 units decreased from 33% to 26% during the same period (Sweeney *et al.*, 1990). More recent statistics from NISRA (Northern Ireland Statistics and Research Agency) indicate that this slight decrease in Northern Irish drinking more than the recommended weekly limit has been reversed and 33% of males and

11% of females in Northern Ireland consume more than the recommended weekly limit in 2002–2003.

Females consuming more than 35 units per week and males consuming more than 50 units per week are classified as heavy problem drinkers. According to this classification, in 1987 and 1989, only 1% of female drinkers were above the upper risk of 35 units per week (Sweeney et al., 1990). This is in accordance with the figures from "the continuous household survey" and this rate was maintained during the period 1988–1998. However the percentage of females consuming alcohol to a "dangerous" level has increased to 2% in 2002–2003. The percentage of males consuming above the upper risk limit of 50 units per week decreased from 9% in 1987 to 6% in 1989, and this had decreased to 4% in 1989. However there has been a marked increase and the level of "dangerous" drinking in the male population of Northern Ireland from 9% in 2001 to 11% in 2003.

A recent study carried out by the Health Promotion Agency of Northern Ireland (HPA, 2002) confirmed that daily drinking limits are not regularly exceeded by Northern Irish drinkers but that drinking is concentrated. It was observed that 48% of men and 35% of women had a binge drinking session in the previous week. A binge drinking session was defined in this study as 10 units for men and 7 units for women. This study also revealed that 37% of male drinkers and 20% of female drinkers exceeded their weekly sensible drinking limit (21 units for men and 14 units for women) and could be referred to as risk drinkers. These figures are slightly higher than those obtained in the continuous household survey but confirm the fact that an increasing number of people in Northern Ireland are drinking beyond the recommended weekly limits.

Social aspects of alcohol consumption

The media has an influential role in people's lives and has been concerned with the effects of alcohol. One example of an extensively reported problem, associated with alcohol consumption, was the mass media depiction of "lager louts." The heavy drinking was associated with public disorder among young people, especially males (British Medical Association, 1986). Another area of mass media concern is driving while under the influence of alcohol. Driving while under the influence of alcohol is currently the principle cause of road traffic deaths in Northern Ireland and was responsible for 25% of road fatalities in 1996 (DHSS, 1998); this figure has not changed and other dramatic figures related to alcohol consumption include 30% of drowning, 30% of murders, 33% of accidents in the home, 40% of incidents of domestic violence, 44% of theft charges and 88% of criminal damage arrests (HPA, 2002).

The alcohol-related death rate in the United Kingdom increased from 6.9 per 100,000 population in 1991 to 13.0 in 2004, it was also observed that death rates are much higher for males than females and in recent years the gap between the sexes has widened. In 2004 the male death rate was 13.7 deaths per 100,000 while females was 8.5 deaths per 100,000 (NISRA).

A relationship between the type of beverage consumed and the likelihood of driving after the consumption of alcohol has been suggested. Perrine (1970) found that 58% of the Vermont drivers arrested for drink-driving reported daily beer drinking, but only 12% were daily spirit drinkers and 3% reported drinking wine. However the proposed link between beverage choice and drinking-driving may be confounded by the sex and age characteristics of the drinking-driver. Gruenewald et al. (2000) investigated the association between beer drinking and driving under the influence. The results failed to establish a relationship between beverage preference and driving while under the influence of alcohol. However the demographic information revealed that the beer drinkers in the sample were from a sub-population of heavy drinking young men with a preference for drinking in bars. Thus they had to travel to and from the place of alcohol consumption.

Cultural variations in beliefs about alcohol effects

The level of social acceptance of alcohol consumption varies between cultures. Within the United Kingdom, Northern Ireland has been associated with a distinctive drinking style. The differences may be due to numerous factors among which are alcohol expectancies. O'Connor (1978) showed that Northern Irish adults expect the consumption of alcohol to reduce anxiety and enhance sociability. In contrast English adults simply view alcohol consumption as a social activity. In a recent qualitative study carried out by the HPA (2002) the participants-perceived benefits of alcohol consumption included reduce stress, increase confidence, strengthens relationships and facilitates meeting new people. The majority of the participants are not aware of any safe drinking guidelines and are shocked to be told that the general definition of binge drinking used in UK studies was 10 and 7 units for men and women respectively. An example of a females' definition of binge drinking was "A binge is when you drink for 3 or 4 days constantly." Another quote from the survey relating to how participants define binge drinking was "If you go for a week or two and drink non-stop." This type of definition was in keeping with the responses from the majority of the sample. The conclusions drawn placed the Irish at greater risk of alcohol-related problems due to the attitudes attached to alcohol consumption. These findings indicate that the change in recommendations by the UK government to update the sensible drinking guidelines from a weekly to a daily limit to discourage saving units for the "weekend binge" Bennett et al. (1995) have had little effect in

decreasing the pattern of binge drinking for Northern Ireland drinkers.

In Europe it is common for people to consume small amounts of alcohol frequently. In contrast Northern Ireland is associated with a more concentrated drinking style. Marques-Vidal *et al.* (2001) observed that alcohol consumption in France was homogeneous throughout the week with a slight increase at the weekend, this is in contrast to the pattern observed in the Northern Irish drinkers, were 66% of the total drinking occurred on Friday and Saturday. They also observed that the men in the French sample consumed on average 317 ± 249 ml/week compared to Northern Irish men consuming 325 ± 333 ml/week thus Northern Irish men consume more in 2 days than French men consume in 7 days. The second interesting observation is the volume of each type of beverage consumed, wine consumption accounted for 216 ml/week in the French sample but only accounted for 18 ml/week in the Northern Irish sample, spirits accounted for 28 ml/week in the French sample and 91 ml/week in the Northern Irish sample and the beverage of choice in the Northern Irish sample was beer which accounted for 215 ml/week compared to 72 ml/week in the French sample. Thus confirming two facts about the drinking habits in Northern Ireland: (1) there is a tendency to concentrate all drinking to the weekend and (2) the beverage of choice for Northern Irish males in beer.

Drinking habits in Northern Ireland

There have been a few large-scale investigation of drinking habits in Northern Ireland and a distinctive pattern of drinking has emerged. It has been well documented that Northern Ireland has one of the highest levels of abstinence in Europe, with 30% of adults who do not drink at all. However recent research has identified that this abstinence rate is decreasing and that 24% of people are non-drinkers in 2002–2003 (continuous household survey). However within its population of drinkers drinking tends to be less frequent with greater quantities. When considering the identified drinking patterns in Northern Ireland the investigations which look at the consumption of alcohol per capita of population are misleading, due to the high level of abstinence. This causes the consumption within the population as a whole to be artificially deflated. The other factor, which is concealed, is the concentrated drinking. Studies looking at the amount of alcohol consumed per annum fail to identify the tendency, within Northern Ireland, to consume large quantities on few occasions.

Differences within cultures

Differences within cultures as well as between cultures have been identified. A focus of large-scale research has been placed on the examination of drinking practices in terms of user characteristics. Drinking practices have been found to vary according to age, sex, socioeconomic position, income, education, ethnicity, religious affiliation, marital status and urbanization (Cahalan *et al.*, 1969; Dight, 1976; Casswell, 1980). Thus when discussing drinking or beer consumption patterns it is important to take into consideration some of these factors. Recently attention has been directed toward the study of influential factors other than the characteristics of individuals. Situational and contextual variables differ according to demographic variables such as age and sex and have been found to be important determinants of alcohol consumption (Clark, 1977; Harford, 1983). Consequently a complete discussion of beer consumption patterns requires consideration of situational and contextual factors.

Beer Consumption

The Northern Irish have a beer and spirits drinking culture. In Northern Ireland the preferred beer is stout, always ordered by brand name, usually Guinness. Second to Guinness is lager. This is in contrast to England where the beer of choice is real ale, real ale is not popular in Northern Ireland and few bars even stock bitters on tap. The popularity of wine is increasing rapidly, but this trend is not yet evident in the majority of ordinary pubs. In other countries, adults decide when it is time to stop drinking and the public bars are open all night. In Northern Ireland the decision about when to stop drinking is taken out of the punters control and the bars are forced to close at 1.30 with 1/2 h drinking up time.

Drinking Patterns Among the Young People of Northern Ireland

The distinctive drinking patterns associated with Northern Ireland can be identified even at an early age. Three large-scale studies of children in year 8–12 (age 11–19 years) aimed to describe and compare young peoples drinking behavior. The Health Behaviour of School Children Survey (HSBC, 1997) was a cross, a national-research study conducted in collaboration with European Region of the World Health Organization (WHO), data was obtained from a representative sample of 5,607 in 1997, >80% response rate. The Young Persons' Behaviour and Attitudes Surveys (2000 and 2003) were a commissioned work carried out by NISRA. The response rates were 6,297 in 2000 (85%) and 7,223 in 2003 (89%). The results indicate that 41% of young people in the 2003 survey had never taken an alcoholic drink; however, the abstinence rate decreased with increasing age so that only 19% of 16-year olds had never taken an alcoholic drink.

Table 13.1   Choice of drink for those who currently drink

	1997				2000

Note: The HPA results for choice of drink for those young people aged 11–19 years who currently drink. The results are presented for both boys and girls due to the difference in drink preference. The table presents the percentage of girls and boys in each school year who drink each type of beverage.
Source: HPA (2004).

The HPA conducted secondary analysis on the HSBC (1997) and the Young Persons' Behaviour and Attitudes Surveys (2000, 2003) and revealed that beer was the most popular drink for boys in 1997, but by 2000 it has been overtaken by Alcopops. Alcopops are the main drink of choice for girls in both the 1997 and 2000 survey (see Table 13.1).

However the 2000 survey identified that this drinking preference changes with age (see Table 13.2). For 8-year-old boys who drink, Alcopops (63%) are the most popular; however, when the boys reach year 12 beer becomes the most popular drink (87%). There is a very strong sense of who should drink what in Northern Ireland, working class men can only drink beer or spirits in a pub everything else being effeminate. This could explain the move away from Alcopops when boys reach the age of 18/19 and become aware of the actual trend in drinking style when they can legally drink in a bar.

The percentage of girls choosing beer doubles from 21% in year 8 to 42% in year 9. This increased popularity is maintained and increases slightly to 49% in year 12; however, as can be seen from Table 13.2, the increase in popularity of Alcopops increases by 40% between year 8 and year 12.

Young Adult Drinkers in Northern Ireland

A study carried out by the HPA (2002) collected information on prevalence of drinking from a representative sample of 1,752 individuals aged 18–75 years; 922 individuals also completed a diary of drinking the week prior to the survey, only 7 individuals failed to complete the diary fully; thus the data relating to alcohol consumption in 1 week was based on 915 individuals.

This survey followed previous work and also supported previous findings of a very distinctive drinking pattern in
Figure 13.1   Drink of choice analyzed by sex. The graph displays the percentage of men and women who choose each type of alcoholic beverage. *Source*: HPA (2002).

Northern Ireland. One important aspect of drinking patterns is the type of drink consumed. This comprehensive survey confirmed that beer is the drink of choice for men in Northern Ireland. Figure 13.1 presents choice of drink by sex. The main drink of choice for men is beer (77%). For women the main choice of drink is wine (50%) closely followed by spirits (42%).

When investigating drinking patterns other determinants need to be taken into consideration. The HPA (2002) identified some important determinants of choice of drink and subjected their findings to statistical analysis. Table 13.3 illustrates the influence of age group, marital status, socioeconomic group, household income, educational status and religious group on the choice of drink. Due to the observed difference in choice of drink between males and females the results were analyzed separately. It was observed that males under 44 years, manual workers, males educated to O level or commercial qualifications, and Catholic males were more likely to choose beer, these differences reached significance. Marital status had no impact on the choice of drinking beer.

The same analysis was performed on the responses from females and revealed that household income was the only factor to significantly influence the female's choice of drinking beer with females in the lower income categories (<£14,999) choosing to drink beer more than the females in the higher income groups (>£15,000) (see Table 13.4).

Another important factor when considering beer drinking patterns is the days of the week that alcohol is consumed. The HPA addressed this issue and revealed that beer was the most popular choice of alcoholic drink for men on each day of the week with a slight increase in popularity on a Saturday and a small decrease in popularity on a Sunday. Table 13.5 illustrates the popularity for males of each type of beverage on each day of the week.

To clarify these results further the HPA ranked the most popular drinks (see Table 13.6) on each day of the week and as expected beer is the most popular each day.

For females it was observed that wine (see Table 13.7) was the most popular choice of drink each day; however, this was closely followed by spirits. Beer was also very popular especially on a Saturday.

To clarify these results further the Health Promotion Agency ranked the most popular drinks (see Table 13.8) on each day of the week and as expected wine was the most popular drink each day with beer being ranked third each day.

Quantity of Consumption

As identified in previous studies Northern Ireland has a tendency to binge drinking so it is important to investigate the quantity of alcohol consumed at one sitting, when investigating beer consumption patterns. A questionnaire survey carried out in Northern Ireland in 1998 (McKinney and Coyle, 2005) employed an opportunistic sampling technique, aiming to represent students and non-students; 239 questionnaires (39.8% response rate) were returned, 108 (45.2%) from males and 131 (54.8%) from females.

The study employed a short self-report questionnaire (after Knight and Longmore, 1994, p. 97) inquiring about alcohol consumed in the previous month. The focus of this questionnaire was on identifying social drinkers in terms of volume and type of alcohol consumed, days of the week

that alcohol is consumed and places where alcohol is consumed. Frequency of drinking, using the previous month as a reference, was assessed using a five-point scale. The five-point scale ranged from consuming alcohol no days in the previous month to 6–7 days per week. This information was obtained for each type of beverage beer, wine and spirits. Respondents also provided information concerning the amount of each alcoholic beverage consumed at one sitting, this ranged from no pints of beer to 8 or more pints, no glasses of wine to 15 or more and no measures of spirits to 15 or more. The question concerning place of alcohol consumption provided four choices in which alcohol is usually consumed: pub or bar, at home or the home of friends or relatives, a club or disco, somewhere else. Using the last week as a reference respondents reported on which day(s) of the week they had consumed alcohol.

Of the alcohol consumers it was revealed that Friday and Saturday are the most popular days for alcohol consumption; 59% of respondents have a drink on Friday and 73.6% have a drink on Saturday. Five-hundred and ninety one drinking events were reported for the total sample within the last month, 54% of all drinking events occur on the weekend, Friday (24%) and Saturday (30%). Thus the prevalence of weekend alcohol consumption is slightly greater than week–day alcohol consumption.

The participants who report beer consumption have the highest volume of consumption on any one occasion.

As shown in Table 13.9, 32% of respondents reported the consumption of 7 or more pints (>14 units) of beer at one sitting. The highest percentage of spirit consumers also falls in the highest range, that is, 15% consume 7 or more measures of spirits. The most popular quantity of wine consumption is four glasses accounting for 11% of respondents. However 10% of respondents report wine consumption of two glasses. Thus 21% of the wine drinkers consume four or less glasses of wine at any one sitting. Thus the volume of wine consumed on any one occasion is typically lower than the volume of beer or spirits consumed on any one occasion.

Mixed Drinks

Almost half the sample reports mixing drinks (45%), that is the consumption of, for example, beer, wine and spirits on any one occasion. The most popular mix of drinks is beer and spirits accounting for 17%. A large proportion of people report consuming all three beverage types – beer, wine and spirits 12% (see Table 13.10). The least popular mix of drinks on any one drinking occasion is wine and spirits with only 6%. This is closely followed by the combination of beer and wine (9%). However the highest representation is for the consumption of beer alone (31%). That is beer drinking alone is almost twice as popular as the most popular mix of drinks (beer and spirits).

Table 13.8   Drink rating through the week – top three for females

Rank	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
1	Wine	Wine	Wine	Wine	Wine	Wine	Wine
2	Spirits	Spirits	Spirits	Spirits	Spirits	Spirits	Spirits
3	Beer	Beer	Beer	Beer	Beer	Beer	Beer

Note: The table illustrates the rank order of drink of choice of alcoholic drink preference for females for each day of the week.

≥7	76	31.8	≥7	14	5.9	≥7	36	15

Note: The table illustrates the number and percentage respondents who drink each quantity ranging from 0 units to greater than or equal to 7 units of beer, wine and spirits.

Gender

Quantity Independent sample *t*-tests employed to investigate the relationship between gender and alcohol consumption. It was revealed that men consumed significantly (t (237) = 9.689, p < 0.001) more beer than women (female mean, 4.32 SD 5.4; male mean, 11.28 SD 5.62)

Table 13.10 The number and percentage of participants who reported consuming each combination of mixed drinks on any drinking occasion

	N	%
Beer	74	31
Wine	26	10.9
Spirits	21	8.8
Beer and wine	16	6.7
Beer and spirits	40	16.7
Wine and spirits	14	5.9
Beer, wine and spirits	29	12.1

Note: It was observed that respondents mix their drinks. The table illustrates the number and percentage of respondents who consume each mix of beer, wine and spirits.

per drinking occasion. And women consumed significantly (t (237) = −4.071, p < 0.001) more wine than men (female mean, 2.22 SD 3.10, male mean, 0.7824 SD 2.17) per drinking occasion. No difference in the volume of spirits was observed (t (237) = 0.833, p > 0.05). This is shown in Table 13.11.

Frequency Independent sample *t*-tests indicated that males drank beer significantly more often than females (t (237) = −7.519, p < 0.001) and that females drank wine significantly more often than males (t (237) = 3.950, p < 0.001). Table 13.12 shows, 39% of men consume beer 6–7 days a week compared to 11% of women who consume beer daily. No significant difference between genders was revealed for the frequency of consuming spirits (t (237) = 0.240, p > 0.05).

Students/Non-students

Investigation into the volume of alcohol consumed revealed no difference in the volume of beer (t (220) = −0.304, p > 0.05) and volume of wine (t (209.280) = −1.015, p > 0.05)

Table 13.11 The percentage of male and female respondents who consume each volume of each beverage

Quantity Units	Beer		Wine		Spirits	
	Male	Female	Male	Female	Male	Female
0	14 (13.0)	67 (51.1)	87 (80.6)	66 (50.4)	64 (59.3)	70 (53.4)
2	3 (2.8)	15 (11.5)	9 (8.3)	15 (11.5)	10 (9.3)	9 (6.9)
4	15 (13.9)	20 (15.3)	5 (4.6)	21 (16.0)	10 (9.3)	18 (13.7)
6	15 (13.9)	14 (10.7)	5 (4.6)	13 (9.9)	10 (9.3)	12 (9.2)
≥7	61 (56.5)	15 (11.5)	2 (1.9)	16 (12.3)	14 (12.9)	22 (16.8)

Note: The table illustrates the number and percentage of males and females who drink each quantity (0 to >7 units) of beer, wine and spirits.

Table 13.12 The percentage of people who drink each mix of alcoholic beverage and the place(s) they consume alcohol

	Bar (%)	Home (%)	Club (%)	Other (%)
Beer	24	12	12	4
Wine	4	7	3	0
Spirits	6	4	6	0
Beer and wine	5	3	2	0
Beer and spirits	13	7	7	2
Wine and spirits	5	2	3	1
Beer, wine and spirits	10	5	4	1

Note: It was observed that almost half the sample, mix their drinks on any one drinking occasion. It was also observed that people consume alcohol in more than one place. This illustrates the places people consume alcohol, this is presented in terms of mix of drinks to illustrate that beer is the most popular choice of drink in all locations but especially in a public bar setting.

between students and non-students. However the difference in reported volume of spirits (t (220) = 2.579, p < 0.05) indicates that students consume more spirits than non-students. It was also observed that the frequency of drinking spirits was higher for students than non-students (t (220) = 2.14, p < 0.05); however, this increased frequency was not observed in beer (t (220) = −0.154, p > 0.05) or wine (t (220) = −1.395, p > 0.05) drinking.

Place of Alcohol Consumption

It has been shown that respondents tend to mix their drinks with 45% consuming more than one type of alcoholic beverage at any one sitting. It was also observed that respondent consume alcohol in more than one place. They may start drinking in their own home or the home of family or friends, then continue drinking in a pub and even proceed to a club. Table 13.12 illustrates the percentage of people who consume alcohol in either their own home or the home of family or friend, in a public bar in a club or disco or in another place. This is presented in terms of their mix of drink.

It was also observed that participants consume alcohol in more than one place. For example they may start drinking wine in their own home then continue to drink spirits in the public bar. Thus the mixing of drinks could be influenced by the place of alcohol consumption. The present author revealed that the consumption of alcohol in the pub is the most popular single setting accounting for 29% of the respondents; 14% consume alcohol only in the home and 9% consume alcohol only in a club setting; 37% consume alcohol in a pub setting in conjunction with a home setting and/or a club setting. Thus 66% of respondents consume alcohol in a pub. The choice of drink(s) and place of alcohol consumption are presented in Table 13.12. This illustrates that beer is the drink of choice for people who drink in a bar.

Conclusion

This chapter has presented evidence of the very distinctive style of drinking in Northern Ireland. It has highlighted the high, but decreasing abstinence rate. It has also highlighted the prevalence of binge drinking and the preference of beer over other beverages especially for the male alcohol consumers of Northern Ireland.

Summary Points

- 37% of male drinkers and 20% of female drinkers exceeded their weekly sensible drinking limit (21 units for men and 14 units for women) and could be referred to as risk drinkers.
- Northern Irish adults expect the consumption of alcohol to reduce anxiety and enhance sociability.

- There is a high level of abstinence in Northern Ireland approximately 30%.
- There is a high level of abnormal, problem or heavy drinking in Northern Ireland.
- A distinctive style of drinking in which more is consumed on fewer drinking occasions has also been observed.
- Beer was the most popular drink for boys in 1997, but by 2000 it has been overtaken by Alcopops.
- For 8-year-old boys who drink, Alcopops (63%) are the most popular; however, when the boys reach year 12 beer becomes the most popular drink (87%).
- In Northern Ireland the main drink of choice for men is beer (77%). For women the main choice of drink is wine (50%) closely followed by spirits (42%).
- Friday and Saturday are the most popular days for alcohol consumption; 59% of respondents have a drink on Friday and 73.6% have a drink on Saturday.
- The participants who report beer consumption have the highest volume of consumption on any one occasion, 31.8% of respondents reported the consumption of 7 or more pints (>14 units) of beer at one sitting.
- The most popular mix of drinks is beer and spirits.

Beer Consumption in Teenagers in Brazzaville (Congo)

Jean Robert Mabiala Babela, Alphonse Massamba and Senga Prosper Centre Hospitalier et Universitaire, Service de Pediatrie Nourrissons, Brazzaville, Congo
Rajaventhan Srirajaskanthan Department of Nutrition and Dietetics, Kings College, London, UK

Abstract

Brazzaville is the capital of Congo, which is a central African country with a population of around 3 million. Alcohol consumption has been prevalent in the Brazzaville since the colonial period. Beer was introduced to the region during the 1950s. The annual consumption of alcohol is estimated to be 5.2l per person over the age of 15 years, however, a large proportion of the population are teenagers. Following a study done by our group we identified the extent of beer consumption amongst the teenage population. Factors such as non-schooling teenagers and orphans have a higher beer intake than teenagers attending school or teenagers with parents. Furthermore, those who practice religion have a significantly lower prevalence of beer consumption than those who do not. Within 15–19 year old age groups, the consumption of beer is marked and this leads to concerns about long-term health implications. In view of the high incidence of beer consumption, efforts to control drinking patterns amongst teenagers in Brazzaville would be prudent.

Introduction

Congo is a central African country, located across the equator covering an area 342,000 km^2; the climate is consistently warm throughout the year. The population is approximately 3 million with 47% of the population being under the age of 18 years (WHO, 2004). There is a high level of urbanization with over 50% of the population living in four main cities: Brazzaville, Point Noire, Dolisie and Nkayi.

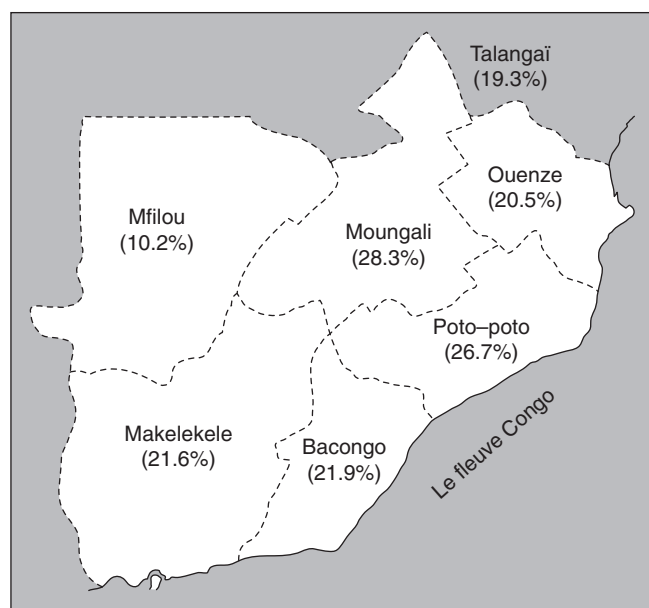
The consumption of alcohol in Congo is not a new phenomenon. Initially during the colonial period, the Congolese people consumed alcoholic drinks which were produced by fermentation of cooked cereals, palm wine or fruit juices (Bonnafe, 1988). Following the incursion of the French and Portuguese, wine, liquors and strong drinks were introduced into the region, initially in the costal regions before spreading inland (Vennetier, 1968; Phillis, 1972). Beer was introduced to the region in the 1950s. In 2002, most different types of beverage had become available in Congo, there were two breweries and wine and spirits were openly available.

Alcohol Consumption in Brazzaville

The annual consumption of alcohol is estimated to be 5.2l of alcohol per person over the age of 15 years (CNSEE, 1997). However, as stated earlier a large proportion of the Congalese population are under 15 years of age. Furthermore, in 1994 a survey of the World Health Organization (WHO) about the health of Congolese adolescents revealed that more than a third of 12 year olds from all social backgrounds are involved in the use of lawful drugs (WHO, 1994). The 2004 Global Alcohol report from the WHO showed that 3.9% of drinkers in the Congo are heavy episodic young drinkers. Its consumption is not spread in a homogenous way throughout the different regions of the country. Furthermore, it seems that within a region there are some zones with a high prevalence of youth alcohol consumption. This is associated with social deviation and/or disruption linked to alcohol consumption; one of these areas is Brazzaville, the capital city of Congo. There are a multitude of socio-economic factors that are at the origin of this phenomenon, mainly the repetition of armed conflicts which Brazzaville city was a victim. This chapter analyzes the alcohol consumption, with a specific focus on beer, in teenagers within Brazzaville.

Beer Consumption Amongst Teenagers

A study conducted by our research group over a year period from October 2004 looked at the alcohol consumption in teenagers in the seven administrative divisions of Brazzaville (see Figure 14.1). We interviewed 4,315 adolescents from various regions of Brazzaville to give us an accurate representation of drinking habits throughout the entire capital city (Hambleton *et al.*, 1995; Schienger and Dervaux, 2000). All the children and parents gave informed consent prior to interview, and interviews were carried out in the absence of parents. The study group was composed of 2,334 boys and 1,981 girls; the age range was 10–19 years.

Among the 4,315 adolescents questioned, 984 (22.8%) were drinking beer. The prevalence of beer consumption among adolescents in the seven administrative regions varied from 10.2% in Mfilou (a semi-urban area) to 28.3% in Moungali (cosmopolitan area), see Figure 14.1. This prevalence of alcohol consumption is much lower than in European countries, for example, a study by Hibbel *et al.* (1997) showed that the prevalence of alcohol consumption in 16 year olds in Denmark is 50%, Great Britain 39% and 30% in United States. There was no gender difference in the groups that were drinking. Age was a significant variable with regards to beer consumption amongst teenagers. The older the adolescent, the higher the consumption of beer ($p < 0.001$), see Table 14.1. The first contact with beer often occurred by the age of 14 years; 74.1% of children questioned had drunk beer by age of 14 years. This usually occurred in a controlled environment, for example, an anniversary, communion or gathering with peers.


There was significantly higher consumption of beer in adolescents that did not attend school than those that did attend school ($p < 0.01$), see Table 14.2. Also, as would be expected there is a significantly higher percentage of children consuming alcohol at secondary school than at primary school ($p < 0.01$).

Table 14.3 indicates the different prevalence found in accordance with the socio-demographic characteristics. The beer consumption frequency among non-schooling adolescents with a weekly or monthly income was higher than that of any other group ($p < 0.05$).

Table 14.1   Prevalence as a function of gender and age

	Sample (N)	Beer users (n)	Prevalence (%)
Gender			
Male	1,981	582	24.9
Female	2,334	402	20.3
Age			
10–14 years old	2,750	323	11.7
15–19 years old	1,565	661	42.2*

Notes: Shows the number of teenagers questioned and the prevalence of beer drinking within this cohort. There is a significant difference in beer consumption between the 10–14 and 15–10 age groups.

*Significant difference at $p < 0.001$.

Table 14.2   Beer consumption related to school attendance

	Sample (N)	Beer users (n)	Prevalence (%)
Schooling	3,622	701	19.3
Primary level	1,333	141	10.5
Secondary level	2,289	560	24.4
Non-schooling	693	283	40.8
With pocket money	384	164	42.7
No pocket money	309	119	38.5

Table 14.3   Prevalence as a function of socio-cultural status

	Sample (N)	Beer users (n)	Prevalence (%)
Religious practice			
Yes	4,168	894	21.4
No	147	90	61.2*
Parental structure			
Living with their parents	2,194	378	17.2
Divorced parents	1,114	259	23.2
Orphaned	1,007	347	34.4**

Notes: A significant difference was illustrated between those who practice religion and those that do not. Orphaned teenagers have a significantly higher prevalence of beer consumption than those with parents.

*Significant difference at $p < 0.05$.
**Significant difference at $p < 0.001$.

Figure 14.1   Map of Brazzaville showing the seven study sites. The prevalence of beer consumption among teenagers shown in brackets.

There was a significant (p < 0.001) relation between abstinence to beer consumption and religious practice, in that those that are religious have a lower rate of consuming beer, see Table 14.3. The consumption of beer was higher among adolescents with one or more parents deceased (p < 0.001); whilst children with united families presented a low prevalence 17.2%.

With regard to the types of beer consumption, see Table 14.4, they were variable amongst different groups. Moderate drinkers constituted the majority, whatever the light ale beer is the dominant in the regular consumption (95.4%). In those that use alcohol continually the most commonly used beer was mainly brown ale beer (4.6%). The regular and excessive consumption of beer was most commonly seen amongst boys in comparison to girls (p < 0.005). There was also a relation between the mode of consumption and the age.

Regular and excessive drinkers were found in a large number of subjects between 15 and 19 years of age. As for the regular weekly consumption of beer, it approached 100–300 g in 52.7% of cases, with the top volume of consumption of 1,000 g for 1.1% of teenagers. The average intake of beer was different amongst boys (17.4 ± 3.1 g/day) and girls (9.2 ± 0.7 g/day). The univariate analysis revealed that boys drunk more beer than the girls (p < 0.001). As for the frequency of becoming drunk, it was more important among boys: 49.2% of them confessed to have been drunk on beer more than twice, against 11.9% of girls. Finally, regular and excessive drinkers were found frequently (p < 0.01) amongst non-schooling young people.

Underlying Causes for Teenage Drinking

The consumption of beer increases with age (Arènes et al., 1998; Laure et al., 2001), this pattern is seen in other countries, for example, in Canada from 40% in 12 year olds to 84% in 19 year olds (Adlaf et al., 1999). The growth of prevalence with age is clearly connected to the psychological development stage of adolescents (Bandura, 1980; Damon, 1983).

Some variables can play the role of activator or of moderator in development of beer consumption, four clear variables have been identified, these are: school environment, family background, socio-economic status and way of life (Ferreol, 1999). It has been shown in other countries as well as in Brazzaville that children in primary and secondary school have lower consumption of beer compared to non-schoolers. However, this in part is due to the fact that non-school attenders are usually older. In the Congo, school is compulsory till the age of 15 years. Among non-schooling teenagers, there are multiple reasons for increased beer consumption, first, they usually work and earn an income, thereby, buying beer from their own income. Idleness amongst those without income can also lead to drinking.

A study by Isohanni et al. (1994) in Finland noted that the children whose parents are divorced or one of them deceased are more exposed to the consumption of beer and to the drunkenness experience. Our work has shown that the consumption of beer among the adolescents is influenced by those of close persons. It is in fact established that the alcoholism of parents has more impact than the one of the brothers or friends. This is a direct correlation between the ages a child has initial contact with individuals who abuse alcohol and the age at which the child starts consuming beverages. So children exposed to alcoholic parents or relatives at a young age start drinking at an earlier age.

Teenage drinking in Brazzaville follows certain patterns which are gender specific. These patterns pertain to types of beer consumed, frequency and volume of beer consumption and age of commencement of beer drinking (see Figures 14.2 and 14.3). These teenager gender specific patterns have been reported in other studies, for example Harford (1976), Donovan et al. (1983), Parquet et al. (1986) and Bailly (1999). The reasons for the underlying differences

Table 14.4 Survey of consumption

	Lager beer (%)	Brown ale beer (%)	Imported lager beer (%)	Imported brown beer (%)
Frequency				
Occasional	13.6	43.5	63.7	12.2
Moderate	57.4	35.2	24.1	81.6
Regular	23.9	20.8	11.8	2.3
Abuse	5.1	0.5	0.4	0.9
*Volume**				
<100 g	12.3	30.6	47.4	35.8
100–300 g	70.2	53.2	35.1	52.3
300–500 g	10.5	9.7	12.8	8.6
500–700 g	5.1	5.2	4.8	2.8
>700 g	1.9	1.3	0.9	0.5

Notes: Consumption of imported beer is relatively uncommon especially amongst those with the highest beer consumption. Imported beers are predominately consumed by occasional and moderate drinkers.

*Volume (in gram) of pure alcohol consumed in 1 week.
Figure 14.2 Evolution of alcoholic practices shown by gender. A larger percentage of men drink with a regular and heavy frequency than compared to women.
Figure 14.3 Evolution of alcoholic practices separated by age. The majority of 10–14 year olds that drink consume beer on a moderate basis. Heavy intake of beer is almost sorely amongst the 15–19 year old cohort.

between consumption patterns and between the sexes are complex. In part, it is thought to be that from an early age and throughout adolescence, children attain insight into the acceptable behavior and roles of each gender. The figures or role models that provide most of this insight are parents, siblings, peers and institutions. The children then learn to express their interpretation of accepted behavior patterns within society. Beer consumption is a specific type of behavior and different beer consumption practices are accepted for boys and girls. Furthermore, in Congo the social acceptance of the teenagers drinking behavior is almost more important than the legal aspects, since there is an absence of legal law and its enforcement with regards to alcohol consumption (Nsika Nkaya, 1985).

In view of this social system, it is unsurprising that teenagers that have finished school, who are therefore, likely to

be older have a higher alcohol intake than those at school. One would expect them to follow different social patterns and in some way follow adult behavior traits. Furthermore, differences seen in regional zones with regard to alcohol consumption would be expected, since they correlate with the socio-demographics and structural characteristics of the region (Sokal and Rohlf, 1969). The region with the highest number of teenage drinkers has the highest population density and the largest number of drink retailers. In addition, the less activities and sport venues available to teenagers have a higher number of regular teenager beer drinkers.

Type of Beer Consumption Amongst Teenagers

As stated earlier light ale beer is the most consumed drink in Brazzaville (Table 14.4); it is also advertised mainly on television. However, there is also a consumption of brown ale and imported beers. This is of some concern because brown ale locally brewed has higher alcohol content than the light ale. The light ale is usually 3–6% alcohol by volume, whilst the brown ale is 6–9% alcohol by volume. The consumption of the stronger beer by adolescents is associated with bad social behavior traits, as well as higher sexual activity and increased rates of delinquency. The price difference between the light beer (500 CFA) and the brown ale (600 CFA) is only 100 CFA, therefore, in teenagers that wish to become drunk, or suffer from alcohol dependence, there is only a relatively small price difference for much stronger beer.

Of some concern is that in 19 year old boys and girls the daily consumption that is being reported at 25.3 ± 2.8 g and 12.1 ± 0.5 g, respectively, is higher than that reported by in the same age group in France (Rigaud et al., 1997). Since France has one of the highest rates of alcohol consumption in the world, it is of concern that within the Congo where medical facilities are not the same, teenagers are consuming large volumes of alcohol. This could potentially lead to high rates of cirrhosis in this group of individuals over the next 10–15 years; unfortunately, they will not have access to the same quality of medical care and support that is available in European countries, with similar rates of alcohol consumption.

Conclusion

The consumption of beer amongst Congolese teenagers is alarming; especially, the high levels being consumed by non-school attending teenagers. If these teenagers continue this level of consumption, a large number will eventually develop medical complications related to alcohol abuse. Government need to address this emerging problem with the adoption of legislative measures to stop teenagers being able to purchase alcohol and also prohibit them from

entering drinking premises. In addition, there is a need for education amongst teenagers of the long-term detrimental effects of alcohol.

Summary Points

- Drinking amongst teenagers in Brazzaville increases with age in both boys and girls.
- The behavioral practices of boys and girls differ with regards to consumption of beer.
- There is increased incidence of teenagers drinking in poorer and more urbanized areas, with higher population density.
- In teenagers that do not attend school, the frequency and volume of beer consumption is highest.
- The total weekly consumption of 19 year olds in Brazzaville is comparable to that of Western European countries.
- Efforts to reduce teenage drinking within the Congo need to be implemented to tackle the problem of teenage drinking.

Personality Characteristics Associated with Drinking and Beverage Preference

Colin R. Martin Psychology Group, Faculty of Health, Leeds Metropolitan University, Leeds, UK

Abstract

The study of psychological aspects of alcohol consumption and, in particular, alcohol dependence and problem drinking has produced a vast and broad quantity of research findings over the past 50 years. However, in spite of the breadth of research conducted in this important area of applied psychology, comparatively little research has been conducted into the relationship of personality characteristics and beverage and beer preference. This chapter seeks to highlight some of the significant relationships that have been observed between alcohol beverage choice and selection and personality characteristics and style. Given the relative dearth of robust findings in the area of alcohol beverage choice and psychological factors, the context for this present state of affairs is also explored by highlighting competing and contrasting models of alcohol consumption and abuse in addition to highlighting areas of future research endeavor in this surprisingly under-researched area.

Introduction

This chapter will explore personality attributes associated with drinking behavior and drinking preferences, particularly the characteristics that may influence the main beverage choice of the individual, whether it be beer, wine or spirits. To explore these issues within a coherent psychological context, it is important to establish key factors which have been influential in the development of important personality insights central to the manifestation of drinking behavior and beverage preference. Psychology as a scientific and evidence-based discipline has attempted to determine these pertinent personality characteristics through experimentation and social and clinical observation. The psychological heritage in this area is extensive and complex; however, the milestones encountered in the understanding of drinking behavior from a psychological perspective have also highlighted fundamental omissions in the understanding of personality attributes in certain areas,

particularly beverage preferences. There are very good and rationale reasons why this has been the case to date but fortunately, the sophistication of methodological approaches used in this research arena have started to yield valuable and robust insights within the psychological processes and characteristics which influence beverage choice. To understand this fascinating and important story within a coherent and understandable context, the historical perspectives and contemporary approaches to understanding personality antecedents to drinking behavior and beverage preference will be explored. Examination of these factors within this framework will be invaluable in allowing the reader to develop an understanding of not only drinking style and beverage preferences as behavioral end-points, but also an appreciation of the contribution of psychology to separating the normal from the pathological, the hazardous from the hazard-free in the constellation of fundamental personality attributes enmeshed within the complex behavior known as drinking alcohol.

A Psychology of Drinking Behavior

Investigation of the personality and behavioral characteristics of abstinence, normative drinking and pathological drinking has been a key psychological endeavor for clinical researchers for decades (Martin and Bonner, 2005). The historical perspective of psychological study of drinking has, as a modus operandi, the main tenet of psychological science, namely to understand and predict behavior and ultimately to modify it. Unsurprisingly, this enterprise has had as a central focus, a pressing clinical agenda, brought into sharp relief by the huge social, occupational and health consequences of problematic drinking behavior, often encapsulated within the disease concept of "alcoholism" (Jellinek, 1960; Lender, 1979; Piazza and Wise, 1988). The disease model of alcoholism has created a lasting enigma for both the practice of evidence-based medicine and the provision of effective therapeutic intervention. The disease

model of alcoholism has also enabled and facilitated psychological science to develop alternative approaches to the disease model of alcoholism that have the identification of personality characteristics which are consistently associated with drinking behavior and preference choice. Prior to proceeding further, it is crucial to reflect on what the disease model of alcoholism is, why it has been needed, how it has endured and how it has facilitated and often driven the development of psychological alternatives to it.

The Disease Model of Alcoholism

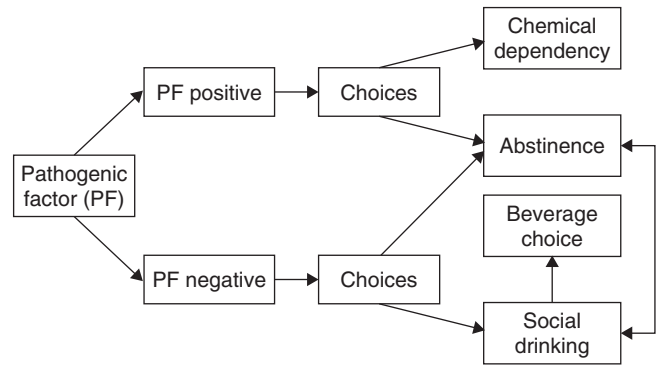
The disease model of alcoholism represents a paradox for modern medicine and indeed modern clinical science. The paradox is patently clear within the context of modern medical practice in the area as an evidence-based discipline. The disease model of alcoholism posits that there is a key biological characteristic that distinguishes those people that drink unproblematically and socially, from those that drink hazardously, abusively and ultimately chemically dependent (Jellinek, 1960). Despite the dominance of this model since at least the 1960s, there is absolutely no evidence at all for the notion of a unitary biological antecedent factor that causes the "disease of alcoholism." Jellinek's (1960) model and subsequent developments of it are paradoxical in many respects since the classification system proposed to identify clusters of drinkers includes definable group with critical psychological[1] rather than biological features of presentation (alpha alcoholism) and who could stop if the individual really wanted to! To put this in perspective, the model describes these sub-types in a progressive way leading through the sub-types to increasingly catastrophic drinking. Surprisingly, the focus of this model pays no head to the particular beverage of choice, only that the disease is specific to alcohol. It is readily acknowledged that there are genetic, social, biological and psychological features which may influence the development of problematic drinking (Wallace, 1990; Orford and Velleman, 1991; Zucker *et al.*, 1994); however, in no way could any of these characteristics can be described as having the attributes of a causative biological entity. The consequences of a disease model of alcoholism are highly constrictive to the patient with the "illness" since there is no "cure" to be had, only a lifestyle of abstinence from alcohol, punctuated with periods of "remission" and sadly, "relapse." The disease model does satisfy an agenda of offering treatment to those who have alcohol problems as a disease rather than through choice. Thus the disease model "gives permission" to offer treatment to individuals who would be unlikely to receive medical intervention if their drinking behavior was attributed to their own choice. The focus on the disease model notion


Figure 15.1   The disease model of alcoholism. Only in the case of the individual without the pathogenic factor for alcoholism does beverage choice have any salience.

that alcoholics have no choice or free will in their alcohol pursuits also by implication negates any issues of beverage preference, the goal of the alcoholic being to maintain a significant blood alcohol level. The disease model is described in Figure 15.1.

The medical model of alcoholism is still influential today and a central part of self-help organizations such as Alcoholics Anonymous. The insufficiencies in the evidence for a medical model have led to the development of a number of models of problematic drinking as either a psychodynamic issue or (more commonly) a behavioral problem (Wilson, 1977; Hays, 1985; Vuchinich and Tucker, 1988; Smith and Goldman, 1994; Leonard and Blane, 1999). Contemporary psychological models emphasize that hazardous and chemically dependent drinking is a behavioral problem and that the problem behavior can be modified and extinguished. This psychological perspective on the presentation of problem behavior has facilitated the development of a number of effective psychological interventions for those encountering problematic drinking (Thevos *et al.*, 2000; Ness and Oei, 2005; Kavanagh *et al.*, 2006). Importantly, these psychological interventions may have, as an end-point, a return to controlled responsible drinking, whereby the individual will have a choice over what to drink within firmly proscribed parameters of amount in units. However, even within the most sophisticated psychological models, including those that integrate psychological, personality and biological processes in describing problematic drinking, the issues associated with the choice of beverage is rarely seen. Indeed, the most recent model of psychobiological model of alcohol dependency that includes personality characteristics does not include beverage selection as an integral feature to its overall structure (see Figure 15.2).

Personality Traits and Beverage Choice

The main substantive psychological literature in relation to beverage selection concerns personality traits. The notion

---

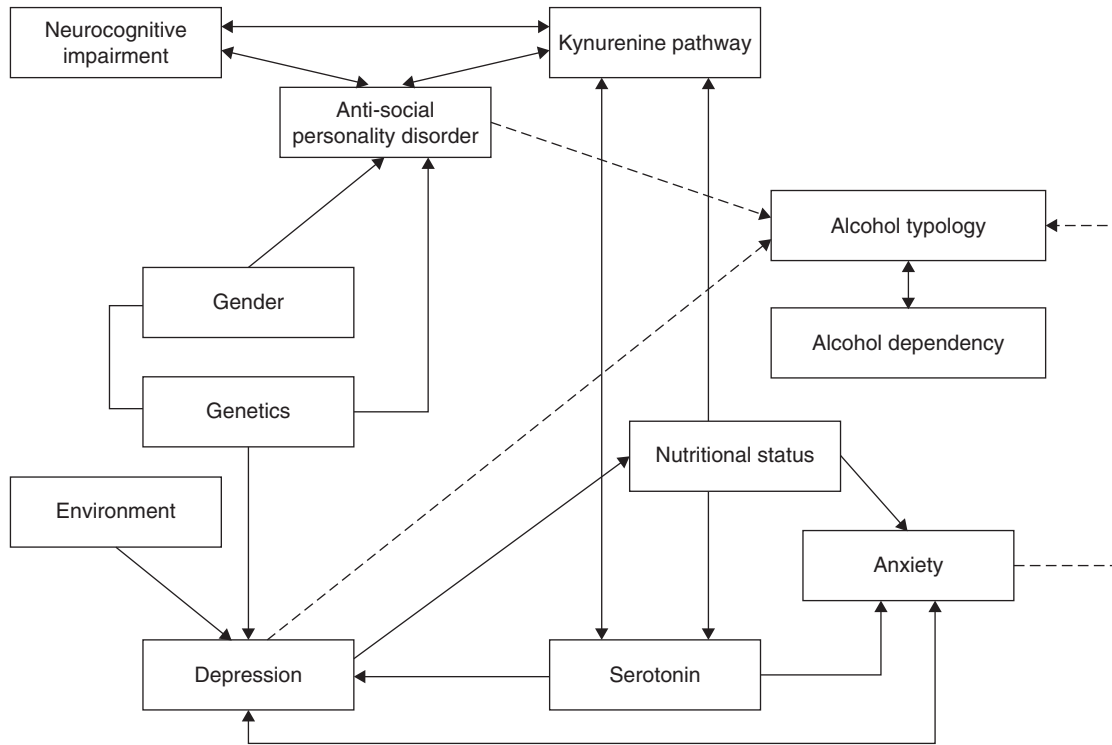
[1] Thus, it could be argued that Jellinek's model was actually a biopsychosocial model rather than a disease model *per se*.


Figure 15.2   Martin and Bonner's (2005) psychobiological model of alcohol dependency. Beverage choice selection is absent within the model, an omission common to psychological models of excessive drinking.
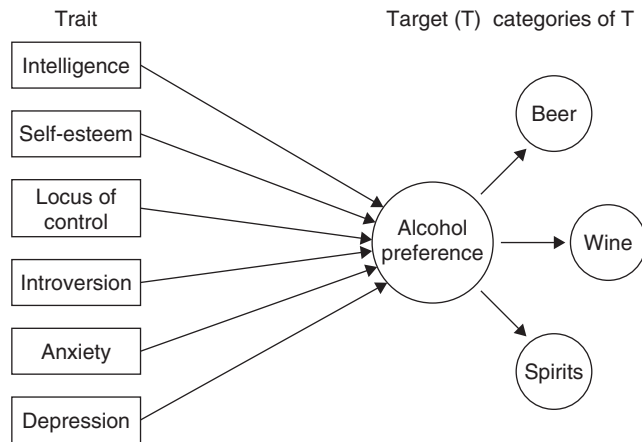

Figure 15.3   A multiple logistic regression predicting beverage preference from personality trait characteristics. The relative contribution of individual traits can be evaluated in terms of their influence on alcohol preference. Cumulative effects of traits can also be evaluated using regression modeling.

of the personality trait is important to psychology because it has a number of key functions. Personality traits do not seek to explain the whole personality, rather they seek to identify key attributes which are stable, measurable, behaviorally influential and predictive. The characteristics of the attributes described are very powerful elements in accounting

for behavioral outcomes and also for identifying between groups differences, for example intelligence is a trait personality characteristic and has been found to be predictive of the choice of beer individuals choose to drink (Mortensen *et al.*, 2005). Importantly, though personality traits generally represent uni-dimensional constructs, they can be usefully combined in predictive analysis to determine not only any (statistically) significant predictive value of a personality trait on a target behavior, but also the relative contribution of a personality trait, compared to other personality traits, in predicting a behavioral outcome. The statistical approach taken is multiple linear and multiple logistic regression. To explore which personality traits influenced drinking preference and how important they were to this target behavior, a multiple logistic regression would be used. A hypothetical model of multiple logistic regression model to determine the contribution of personality traits to alcoholic beverage choice is shown in Figure 15.3. Statistical *t*-values and p-values are calculated for each predictor variable (personality traits) in the model. The target variable comprises categorical classifications of beverage preference. Predictor variables are analogs to independent variables and the target variable is analogs to a dependent variable. This approach to modeling is very powerful and has been underutilized in research on alcohol beverage preference to date, though this situation is fortunately changing as the power of this approach becomes increasingly widely recognized.

Personality Characteristics Associated with Alcoholic Beverage Preference

A number of personality characteristics have been identified which discriminate between non-drinkers and drinkers, and drinkers with different beverage preferences. Some of these characteristics cover a number of personality, neurocognitive and neurophysiological domains. Intelligence is a key example of this, certainly, since it is recognized that intelligence does demonstrate the key characteristics of a personality trait including stability, measureability, and is often behaviorally predictive in combination with other personality traits.

Intelligence

Mortensen *et al.* (2005) conducted a large sample study (>1,700) following up men who had been tested for their intelligence quotient (IQ) in early adulthood and the relationship between this and drinking preferences several years later. These researchers found a significant association between IQ and later beverage preference. It was observed that a high IQ was associated with a preference for wine over both beer and spirits. Importantly, IQ was not found to be associated with heavy drinking nor was the IQ advantage of wine drinkers over beer and spirit drinkers associated with socio-economic factors. This important and indeed provocative study has highlighted robust and impressive evidence that beer and spirit drinkers have a lower intelligence than wine drinkers. The findings of this European study were limited by a participant population that was exclusively male; however, extension of this study design to females would be highly desirable to determine how generalizable this finding may be. Intelligence is a key individual differences variable and ultimately mediated by neurophysiological processes and structures. The findings from this study therefore would indicate that preference for beer over wine or vice versa may be potentially "hardwired" within the brain and involves genetic antecedents.

Contrasting with the findings of Mortensen *et al.* (2005), a study recently conducted in the United States by Paschall and Lipton (2005) revealed that beer drinkers were less educated than wine drinkers. A similar association between beer drinking and lower education was found by McCann *et al.* (2003). These findings may initially seem to support those of Mortensen *et al.* (2005); however, it should be acknowledged that more education is by no means equivalent to more IQ and may be more representative of social opportunity. This distinction also serves to remind that the implications of personality traits are of far greater significance than socio-demographic variables in understanding the intra-personal aspects of beverage preference. Further, the neurophysiological corollaries of personality traits such as intelligence also furnish a pathway between the psychology of beverage preference and the biology of problematic drinking.

It has, for example, been observed that beer drinkers are at greater risk of becoming excessive drinkers compared to wine drinkers (Jensen *et al.*, 2002). It would therefore be anticipated that personality variables that have associations between both beverage preference and biological substrates (e.g. intelligence) may be potent and useful markers of broader psychobiological processes. Indeed, this informed conjecture is central to the psychobiological model of alcohol dependency proposed by Martin and Bonner (2005).

Negative evaluation

Negative evaluation, the individuals' perception of how they are seen and evaluated by others, also has many characteristics common to a definition of a personality trait. Certainly, some individuals perceive and fear negative evaluation more than others, therefore negative evaluation represents an enduring individual differences variable. The concept of negative evaluation is also stable across time and conditions, thus confirming the status of the concept as a personality trait. Finally, consistent with personality traits, the fear of negative evaluation will influence behavior. Experimental work has identified a powerful effect of negative evaluation on beer selection specific to females. Corcoran and Segrist (1998) found that in a beverage selection experiment, females with elevated levels of fear of negative evaluation selected beer significantly less often from a selection that included beer among a selection of alcohol-free drinks such as Coke light, tonic water and pineapple juice. This behavioral effect of fear of negative evaluation was not observed in males suggesting an influential gender-specific role of this personality trait in beer selection. Further, research is required in this area to determine the impact of this pervasive trait on actual beer drinking behavior in social settings.

Depression

Depression is often considered within the context of clinical classification for diagnosis, but it should be borne in mind that there is a basal level of depression within the individual which is usually stable over time and a component part of human psychological functioning. Depression then is a personality characteristic and is related to other key psychological domains which also have enduring trait qualities, such as dispositional optimism, dispositional pessimism and anhedonia. Depression is often co-morbid with a diagnosis of alcohol dependency (Martin and Bonner, 2000; Le Fauve *et al.*, 2004; Pettinati, 2004; Lukassen and Beaudet, 2005) and there is consequently a rich ancestry of research exploring the relationship between depression and alcohol dependency. The role of depression on beverage selection is less well explored, however tantalizing insights into the role of depression on beverage selection can be deduced by examination of data from suicide rate studies. This is based on

the premise that depression and suicide are associated, since many individuals who chose to end their lives are clearly depressed. Gruenewald *et al.* (1995) in large-scale population study conducted in the United States found that suicide rates were not associated with beer drinking; however, a significant increase in suicides was associated with the purchase and consumption of spirits. This study highlights that it is not ethanol *per se* that impacts on the occurrence and prevalence of suicide, but the form of beverage itself is key. This leads to the very real consideration and possibility of an important association between increased depression and spirit preference compared to beer preference.

Anxiety

Anxiety is a key co-morbid clinical presentation associated with both alcohol dependence and alcohol abuse (Allan, 1995; Martin and Bonner, 2000; Schade *et al.*, 2003; Baigent, 2005). Importantly, anxiety in individuals with alcohol dependency commonly comprises two distinct components. These components are either physiological autonomic manifestations of anxiety symptoms, often exacerbated during withdrawal of alcohol and detoxification, in effect a central nervous system rebound effect. However, a more enduring anxiety component has been observed in individuals with alcohol dependency which represents a relative elevated trait characteristic that is largely independent of the level of alcohol in the bloodstream or the kinetic properties of alcohol metabolism during withdrawal or consumption. This component of anxiety has been associated with relapse as alcohol may be used as a maladaptive attempt at "self-medication" by the individual (Thomas *et al.*, 2003; Tomlinson *et al.*, 2006). Indeed, therapeutic programs aimed at reducing relapse emphasize the importance of anxiety management techniques as integral aspect of treatment. Given the importance and relevance of anxiety to alcohol-related problems, it is surprising to discover a relative dearth of research in the area of anxiety and alcohol preference. However, given the potent effect of alcohol as a central nervous system depressant, the type of beverage, beer, wine, spirits, etc. chosen may actually be immaterial as the goal-seeking behavior of the individual may be primarily geared toward access to ethanol rather than a specific beverage to exploit the potent central nervous system effects of ethanol as a depressant. Clearly, more research is necessary to explore the possible relationships between beverage type and anxiety in selection of a drink of choice and any interaction between alcohol type, anxiety and the problematic compared to non-problematic drinking style.

Motivation

Increasing over recent years within the clinical and health psychology, literature on individual differences factors in relation to health and disease behaviors is a focus on motivational aspects. The role of motivational factors in drinking behavior has been of relevance to the study of psychological aspects of drinking behavior is of particular relevance due to the concept of motivation being key in the treatment of individuals presenting with alcohol abuse and dependency. Motivation to drink has been associated with alcohol preference and as such motivation assumes key status as a behavioral variable of important interest to understanding both normative and problematic decision making in the realm of alcohol consumption. However, before elaborating further, it is of value to reflect that in the points made to beverage preference and anxiety and depression made earlier, motivational factors will inevitably be concurrent with the affective presentation of an individual. Beer and spirit consumption has been shown to be associated with problematic drinking styles compared to other types of alcohol (Clapp and Shillington, 2001). This is an interesting finding, since it immediately raises the issues of preference beyond the constraints of the physiological aspects of the blood alcohol curve, since the profile would be different between beer and spirits as a function of proof volume. However, motivation remains an illusive and multi-factorial construct psychologically, strongly influenced by dispositional, environmental and social factors and as such, robustly implicating motivational factors causally and uni-directionally within an alcohol preference model is likely to remain difficult for some time.

Summary

This chapter has highlighted some of the more interesting and relatively more important psychological dimensions that may have an influence of alcohol beverage and beer choice. A surprising finding is not only how little primary research has been conducted in the psychological arena on alcohol beverage and beer preference characteristics in relation to personality, but also the *relatively* small amount of research conducted compared to a strong body of evidence implicating personality characteristics and individual differences attributes with problem in drinking behavior. Consequently, no firm conclusions can be made regarding personality characteristics and beer preference. Where relationships are found to exist, these seem to represent psychological domains that often lie beyond the bounds of what may be termed exclusively a personality characteristic or attribute, for example in the case of intelligence.

It is enlightening that given the huge industrial base and financial rewards associated with alcohol and beer commercial enterprise, evaluation of personality characteristics which may be associated with beverage choice seems largely ignored and under-researched. In addressing such a vacuum of research and the need and desirability to redress this in the future, the author is minded to comment that such research enterprise should be approached with both investigative zeal

and moral responsibility since the relationship between non-problematic alcohol use and alcohol abuse can represent a gray and overlapping area.

A final recommendation is therefore that the issues of personality characteristics and beer preference require further systematic investigation to determine the relationship of these enduring psychological domains to alcoholic choice and beverage selection decision making and further, that such endeavor should be done within the context of a coherent theoretical account and psychological model.

Summary Points

- The relationship between alcohol beverage preference and personality characteristics is currently under-researched.
- A small number of personality characteristics have been found to be associated with beer/alcohol type preference.
- The focus of research into personality characteristics associated with alcohol consumption has largely ignored the issue of alcohol beverage type.
- The clinical/applied bias in research may be responsible for the dearth of research in the area of personality characteristics and alcohol beverage choice.
- There is a pressing need to address through systematic research the absence of robust and replicable findings in the area of personality characteristic and beverage choice.

Beer and Current Mood State

Ralf Demmel and Jennifer Nicolai Department of Clinical Psychology, University of Münster, Münster, Germany

Abstract

The consumption of beer is closely related to human affect. An individual's current mood state has been shown to act as an internal stimulus eliciting the urge to drink alcohol, thus activating positive outcome expectancies and drinking motives. An individual's beliefs regarding the effects of beer determine his or her labeling of mood states following the consumption of beer. The attribution of the perceived changes in current mood state to the effects of beer strengthens both an individual's alcohol expectancies and his or her drinking motives.

Introduction

An individual's alcohol use is closely related to his or her current mood state. For example, depressed mood may trigger cravings for alcohol in individuals anticipating mood-enhancing effects of alcohol use. Accordingly, high levels of negative affect have been shown to increase the risk for relapse following successful substance abuse treatment (e.g. Hodgins *et al.*, 1995). An individual's current mood state may in turn be the result of his or her previous alcohol use. For example, a low dose of alcohol may produce pleasurable feelings of mild euphoria (e.g. Martin *et al.*, 1993). Thus, changes in current mood state may be either the cause or the consequence of alcohol use.

Researchers in the field of alcohol studies are less intested in the mood effects of specific types of beverages. Administering a mixture of a non-alcoholic beverage and vodka is the standard procedure in alcohol challenge studies (e.g. Croissant *et al.*, 2006). Beer is rarely used as a pharmacological challenge in experimental research. Hence, scientific evidence on the relationship between beer consumption and current mood is limited. In contrast, common beliefs about the mood effects of beer consumption are richly reflected in folklore and art. For example, William Hogarth's famous engraving of Beer Street illustrates eighteenth century beliefs about the positive effects of beer consumption (Figure 16.1). When Hogarth's engraving was first published in 1751, a poem by the Reverend James Townley was included:

Beer, happy product of our Isle

Can sinewy strength impart,

And, wearied with fatigue and toil,

Can cheer each manly heart.

Labor and Art, upheld by thee,

Successfully advance;

We quaff thy balmy juice with glee,

And Water leave to France.

Genius of Health, thy grateful taste

Rivals the cup of Jove,

And warms each English generous breast

With Liberty and Love.

While the appreciation of beer had been echoed in the work of many nineteenth century artists (for a review, see

Figure 16.1 William Hogarth, Beer Street.

Jung, 1966), empirical research in the second half of the twentieth century started to challenge prevailing beliefs about the psychological effects of alcohol in general and beer in particular. Pharmacological studies proved alcohol to be a sedative rather than a stimulant (for a review, see Fromme and D'Amico, 1999). Psychological studies using the balanced placebo design (Figure 16.2) enabled researchers to separate placebo effects from pharmacological effects (e.g. Gross *et al.*, 2001). Animal studies led to the development of the tension reduction hypothesis stating that individuals use alcohol to gain relief from anxiety and stress, respectively (for a review, see Greeley and Oei, 1999). Recently, psychophysiological studies broadened the focus of alcohol research beyond the relationship between anxiety and alcohol use (for a review, see Lang *et al.*, 1999). To provide a conceptual framework for the interpretation of findings from different lines of research, we suggest a cognitive model of alcohol use taking into account the concepts of cue reactivity, outcome expectancies, drinking motives, and attributional processes (Figure 16.3). Alcohol-related cues such as the smell of beer or an individual's current mood state are assumed to act as stimuli eliciting the urge to drink alcohol. The perception of alcohol cues is likely to activate positive outcome expectancies. The anticipation of positive alcohol effects in turn will motivate the individual to initiate alcohol use. Finally, the model assumes that the attribution of mood enhancement to the effects of alcohol consolidates an individual's alcohol

expectancies, thus strengthening his or her drinking motives and making future alcohol use more likely. Before we discuss the model in more detail, we first provide a brief introduction to research on human affect.

Current Mood States

Since the 1980s, mood has become a very popular concept in psychology. In contrast to emotions, moods are defined as relatively diffuse and enduring affective states of low intensity. While emotions are assumed to be the consequence of specific circumstances, moods are, by definition, not induced by a salient event. Traditionally, research in the field of human affect has focused on the identification of discrete types of affect, such as anxiety, anger, and joy. However, measures of different types of affect have been shown to be strongly related to each other. For example, individuals feeling sad have been found to report high levels of fear as well (e.g. Watson and Clark, 1992). The non-specificity of affect led many researchers to prefer a dimensional approach to the assessment of affective states. Research based on non-self-report data, for example, the analysis of facial expression, identified two dimensions of affect labelled pleasantness vs. unpleasantness and activation/arousal (Figure 16.4). Findings from studies using self-report questionnaires suggest two independent dimensions of affect often labeled negative and positive. In experimental research so-called mood induction procedures are used for manipulating an individual's current mood state. For example, participants are asked to listen to a piece of serious classical music or to watch a funny movie (for a comprehensive review of research on the assessment of current mood states, see Watson and Clark, 1997). In an early study on the relationship between mood and alcohol consumption social drinkers were randomly assigned to interact with a child confederate trained to enact behaviors characteristic of either well-adjusted or mentally ill children. Interacting with a child confederate exhibiting externalizing behaviors induced negative mood in both males and females. Moreover, male participants anticipating another interaction with the same child consumed more beer during a 20 min

	Expected	
	Alcohol	No alcohol
Administered Alcohol	A	B
No alcohol	C	D

ad lib drinking period compared to their counterparts anticipating a second encounter with an apparently well-adjusted child (Lang *et al.*, 1989). These findings suggest that negative mood induced by a stressful social interaction may increase beer consumption.

Cue Reactivity

According to learning theory, a previously neutral stimulus becomes capable of eliciting a response from an organism by pairing it several times with either an aversive or a reinforcing stimulus. In other words, due to the repeated association with significant stimuli formerly non-significant stimuli may turn into signals or cues predicting important events, for example the availability of food and beverage. The capability of external alcohol cues, for example the smell and taste of beer, to elicit an appetitive response, that is craving for alcohol, from both non-problem and problem drinkers is well established (for a review, see Carter and Tiffany, 1999). Moreover, an individual's current mood state has been shown to act as an internal stimulus eliciting the urge to drink alcohol (e.g. Willner *et al.*, 1998). Most interestingly, individuals at high risk for alcohol-related disorders have been found to drink more beer following a negative mood induction when compared to low-risk individuals (Randall and Cox, 2001). These findings are in line with research demonstrating an increased sensitivity to the reinforcing effects of alcohol in high-risk individuals (e.g. Finn *et al.*, 1990).

Outcome Expectancies

Cognitive learning theories state that an individual's outcome expectancies determine his or her behavior. For example, the anticipated short-term effects of drinking are assumed to affect both the frequency and the quantity of alcohol use. In accordance with cognitive models of drinking and alcohol dependence, research using self-report questionnaires has consistently shown that alcohol outcome expectancies are related to drinking behavior (e.g. Demmel and Hagen, 2003). Findings from both cross-sectional and longitudinal studies indicate that positive alcohol expectancies enhance the level of alcohol use (for a review, see Jones *et al.*, 2001). Positive alcohol expectancies are beliefs about the reinforcing effects of alcohol such as social and sexual enhancement, tension reduction, and positive affect. In contrast, negative alcohol expectancies include the anticipation of cognitive impairment, physical discomfort, and interpersonal aggression. The strength of alcohol expectancies has been shown to vary with the number of drinks an individual expects to consume within a given time period and his or her current mood state. For example, social drinkers asked to think of how they would feel immediately after drinking four glasses of beer in 60 min anticipate higher levels of alcohol-induced sedation and stimulation than their counterparts expecting to have one glass of beer in 15 min (Demmel *et al.*, 2006). Moreover, those respondents feeling tired and worn out at the time of completing an expectancy questionnaire anticipate higher levels of beer-induced sedation (Demmel *et al.*, 2006). These findings suggest that current mood state may determine the level of beer consumption by altering the strength of outcome expectancies.

Drinking Motives

Drinking motives are assumed to be more proximal antecedents of alcohol use than outcome expectancies. While the term drinking motives refers to an individual's reasons for the initiation of alcohol use, alcohol outcome expectancies are defined as the anticipated short-term effects of alcohol. Drinking motives and alcohol outcome expectancies are – yet conceptually distinct – closely related to each other (for a detailed discussion, see Cox and Klinger, 2004). For example, drinking to cope with negative mood implies that an individual believes alcohol to have mood-altering effects. Findings from longitudinal studies suggest that the desire to regulate both positive and negative affect is the major motivation for alcohol use. While drinking to enhance positive affect seems to be a correlate of externalizing personality traits such as sensation seeking, drinking to cope with negative affect has been found to be related to depressed mood (Cooper *et al.*, 1995).

Attributional Processes

In cognitive psychology, the term attribution is often defined as the causal explanation of an event or an individual's behavior. Moreover, when used synonymously with blame, the term attribution refers to the responsibility for an event,

state, or behavior (for a detailed discussion, see Bell-Dolan and Anderson, 1999). Drunkenness has been shown to affect the attribution of responsibility. For example, studies using written acquaintance-rape scenarios revealed that females are considered more responsible for being raped when described as having had a couple of beers (e.g. Cameron and Stritzke, 2003). Findings from experimental studies suggest that attributional processes are also involved in human affect (e.g. Sinclair *et al.*, 1994). For example, an individual's beliefs regarding the effects of beer will determine his or her labeling of mood states following the consumption of beer. Mood states congruent with the anticipated outcomes are likely to be attributed to the effects of beer.

Summary Points

- Moods are relatively diffuse and enduring affective states of low intensity.
- Negative mood induced by a stressful social interaction may increase beer consumption.
- Individuals at high risk for alcohol-related disorders drink more beer following a negative mood induction when compared to low-risk individuals.
- An individual's current mood state may determine the level of beer consumption by altering the strength of his or her outcome expectancies.
- Changes in current mood state congruent with the anticipated outcomes are likely to be attributed to the effects of beer.

Female Beer Drinking and the Morning After

L. Darren Kruisselbrink and René J.L. Murphy School of Recreation Management and Kinesiology, Acadia University, Wolfville, NS, Canada

Abstract

The goal of this chapter is to review the drinking patterns and hangover effects of beer consumption in women. We first provide an overview of alcohol consumption and the experience of the alcohol hangover. Alcohol is a widely consumed drug. Beer is consumed by both men and women although women typically consume less than men. In North America, per capita consumption of beer has been stable over the past 20 years; total amount of pure alcohol consumed in beer is approximately 4–4.5 l/year. Given that beer contains ~5% alcohol by volume (~17 ml alcohol per 341 ml bottle), this represents the annual consumption of a large quantity of beer. Factors contributing to consumption including consumption rates, locations and social influences are reviewed, as there are some limitations of the methods used to collect these data. There are some differences in alcohol pharmacokinetics between women and men, however when these are controlled, sex does not appear to differentially affect the intoxication or hangover experience. Consumption of alcohol is often associated with negative delayed effects sometimes experienced as hangover symptoms. These delayed or hangover effects are difficult to standardize and have not been widely studied. Although there is little published work on the experience of hangover in women, the few reports that are available indicate that hangover effects on performance do not appear to differ between women and men. Furthermore, there are very few studies on the hangover effects of beer consumption in women. This chapter concludes with a summary of the known effects of beer hangover on physical and psychomotor performance in women, as well as general recommendations for future work.

List of Abbreviations

BAC — Blood alcohol concentration, estimated with an Alco-Sensor IV breathalyzer in grams of alcohol per 100 ml of blood
bpm — Beats per minute
CRT — Choice reaction time
freq. — Frequency
g — Grams
g% — Grams of pure alcohol (1 ml of alcohol weighs 0.79 g) per 100 ml of blood (e.g. in Canada the legal driving limit is set at 0.08 g%)
g/kg — Grams of alcohol per kilogram body weight
HR — Heart rate
kg — Kilograms
l — Liters
min — Minutes
ml/kg — Milliliters of alcohol per kilogram body weight
mmHg — Millimeters of mercury
ms — Milliseconds or 1/1000th of a second
n.s. — Non-significant
POMS — Profile of mood states, a questionnaire measuring negative and positive aspects of mood
RPE — Rating of perceived exertion
SRT — Simple reaction time

"I feel sorry for people who don't drink. When they wake up in the morning, that's as good as they're going to feel all day" (Frank Sinatra).

Hangover is a commonly experienced phenomenon following over zealous consumption of alcohol. Descriptions of the hangover state indicate feeling worse than would be expected if alcohol had not been consumed. The majority of quotations about the alcohol-induced hangover give the impression that it is a male-dominated experience. Perhaps because the temperance movement in the United States in the late 1800s and early 1900s was driven by women, the image of decent women drinking and experiencing hangovers has remained in the background of the North American cultural psyche. Alcohol consumption in twenty-first century North America, however, appears to be an equal opportunity vice, as a trip to many popular bar or lounge will undoubtedly attest. Although women tend to favor wine and spirits over beer, females still consume beer in substantial quantity. All this alcohol consumption suggests the inevitability of the hangover experience that typically follows.

The goal of this chapter is to review the experience and effects of alcohol hangover in females following consumption of beer. To achieve this purpose, we will begin by discussing North American alcohol consumption patterns to

provide a general context in which to consider hangover effects. We will also discuss differences in alcohol pharmacokinetics between females and males, as well as the experience and effects of alcohol hangover in females.

Consumption Patterns

Consuming alcohol creates the opportunity to experience a hangover. The alcohol-induced hangover is a commonly experienced phenomenon. In the following section, we outline the prevalence of alcohol consumption primarily in North America, the pros and cons of the methods used to gather these data, the location and frequency of drinking episodes, the average amount consumed per episode and the rate of consumption. Some of these data are provided in summary form in Table 17.1.

Prevalence

Alcohol is widely consumed. In Canada and the United States, various national surveys have reported that the proportion of the population who had consumed alcohol in the previous year ranged from 74% to 80%. Alcohol has been reported as the most used drug, with over 50% of teenagers and higher percentages of college students and adults having consumed alcohol in the past 12 months (Prendergast, 1994; World Health Organization, 2004). In the United States, 49% of adults over 18 years indicated that they were current drinkers ($\geq$12 drinks in the previous year; National Center for Health Statistics, 2006), while in Canada 53% rated themselves as regular drinkers ($\geq$1 drink/month in the previous year; Health Canada, 1999). Across North America, a greater percentage of males than females reported consuming alcohol regularly. Per capita alcohol consumption in both Canada and the United States has remained stable at approximately 8 l of pure alcohol (ethanol) per year since the mid-1990s, but has declined from a peak of over 10 l reported in the mid-1970s (World Health Organization, 2004). In contrast, North American consumption of ethanol in beer has been remarkably stable, totaling approximately 4 l since the early 1960s; recent data indicate that Americans and Canadians consume 3.9 and 4.6 l of ethanol, respectively, in beer (World Health Organization, 2004). The Brewers Association of

Table 17.1　Summary of alcohol consumption data in North America

Item	Male	Female	Total
Percentage of regular drinkers ($\geq$1 drink per month)			
United States 18+ years (National Center for Health Statistics, 2006)	58%	41%	49%
Canada 15+ years (Health Canada 1999; Statistics Canada, 2005)	63–69%	43–51%*	53%
Percentage heavy drinkers ($\geq$5 drinks per occasion $\geq$12 times per year)			
Canada 20+ years (Statistics Canada, 2004, 2006)	28–30%	10–12%	
Canada 20–34 years (Statistics Canada, 2004, 2006)	40–46%	18–22%

*Statistics Canada (2005) indicates that as of 2003, 55–60% of women aged 15–54 years were regular drinkers.
l = liters; freq. = frequency; min = minutes; ~ = approximately.

Canada estimated that between 1995 and 2005 the per capita consumption of beer was 83–87 l/year (Brewers Association of Canada, 2006). These estimates of drinking prevalence provide a general indication of the extent of alcohol consumption, however, they do not provide any information on the pattern of drinking or the problems that may be associated with drinking (Prendergast, 1994).

Location of drinking episodes

Alcohol consumption has been shown to vary by location. Engs and Hanson (1990), In their review, concluded that males drank most frequently in public places (e.g. ballgame, concert or a dormitory) while females drank most often in restaurants or lounges, nightclubs or bars. Storm and Cutler (1981) interviewed males and females at beer parlors and cocktail lounges, reporting that the number of drinking occasions and number of drinks consumed per occasion varied by sex and location. Specifically, men reported drinking more frequently than women. Women tended to report consuming fewer drinks per occasion in cocktail lounges vs. beer parlors whereas men reported consuming similar amounts in each setting. Compared to males, females were less likely to drink bottled beer in a lounge (16% vs. 4%; Storm and Cutler, 1981).

Drinking in private settings, including parties in private homes, is the location where drinking has been reported to occur most frequently (World Health Organization, 1999). Single and Wortley (1993) also reported that home consumption accounted for the greatest share of alcohol consumption. They concluded that drinking in licensed establishments represented only 25% of the total alcohol consumption.

Amount consumed per episode

Studies by a number of groups (e.g. Plant *et al.*, 1977; Storm and Cutler, 1981) have yielded remarkably similar findings on the number of drinks consumed per episode. On average, females have been reported to consume 1–3 drinks per episode while males typically consume 2–5 drinks per occasion. In the Melbourne Collaborative Cohort Study, Baglietto *et al.* (2006) reported that the majority of women who consumed alcohol tended to drink between 1 and 19 g/day; more men reported consuming alcohol and a greater percentage of those reported drinking larger quantities. By the way of contrast, most patrons observed at drinking establishments consumed a small number of drinks (average: 1.9–3.3 for women and 2.0–4.3 for men; Storm and Cutler, 1981). However, in interviews of men and women drinking in beer parlors and cocktail lounges, they reported consuming an average of 0.9–1.3 additional drinks other than those observed being consumed in the drinking establishment. Furthermore, 35% of women interviewed about their consumption pattern in a beer parlor reported drinking ≥9 drinks that evening while 50% reported drinking ≤4 drinks.

Social context also influences the amount of alcohol consumed. Gerstel (1975, as cited in Storm and Cutler, 1981) has reported that social drinkers are more likely to drink heavily in groups. Rosenbluth *et al.* (1978) also reported that individuals in larger groups drank more than individuals in pairs. Storm and Cutler (1981) observed that females tended to drink in groups of two or more, whereas males were more likely to drink alone in beer parlors. Moreover, they observed that one-third of females drinking in beer parlors in groups of six or more consumed ≥6 beers. Rosenbluth *et al.* (1978) reported that men drank less in the presence of women and women drank more in the presence of men.

The amount of alcohol consumed has also been shown to vary with age. In 2005, 25% of Canadian females and 38% of Canadian males aged 15–19 drank five or more drinks on one occasion, 12 or more times in a year (Statistics Canada, 2006). In the 20–24-year-old demographic, 32% and 55% of females and males, respectively, were heavy drinkers. Conversely, the incidence of heavy drinking in females and males aged 35–64 was in the range of 8–11% and 25–30%, respectively. In women drinking in a beer parlor, there was a significant relationship between age and number of drinks ($r = -0.37$; Storm and Cutler, 1981). Thus, it appears that for young adult women, the consumption of alcohol is a relatively widespread phenomenon.

Rate and duration of consumption

The rate of alcohol consumption observed in women drinking in beer parlors was 29.5 min per drink, whereas it was observed to be 19.7 min for men (Storm and Cutler, 1981). In cocktail lounges, Storm and Cutler (1981) observed the mean rate of consumption in females and males as 35.9 and 31.8 min, respectively. Storm and Cutler also noted that both men and women drank the first beer faster than subsequent ones. Similarly, our direct observations of alcohol consumption rates for female university students in a beer parlor indicated that, on average, women took approximately 30 min to consume the first couple of drinks whereas subsequent drinks were consumed at a rate of approximately 40 min each (reported in Kruisselbrink *et al.*, 2006).

By directly observing patrons drinking, Storm and Cutler (1981) have reported that the average duration of drinking episodes in men and women was ~88 and 106 min, respectively, in beer parlors while the observed duration in a lounge was ~62 min. Since not all drinking occurs in the setting chosen for observation, these data likely do not represent the full duration of the drinking episode.

Data collection methods

Estimates of alcohol consumption patterns have been obtained through direct observation, surveys and through calculations of total sales of alcohol. There are pros and cons to each approach. The benefit of directly observing drinking patterns in naturalistic settings is an accurate tally, however the observed drinking pattern may be unique to the location

and setting in which they were recorded, and are not representative of regular consumption patterns. For example, a survey conducted by Storm and Cutler (1981) following observation of drinking patterns in public places revealed that 40% of the respondents had consumed alcohol – sometimes a large volume of alcohol – prior to their arrival at (or after leaving) a public drinking establishment. Population surveys have been used to try to assess alcohol consumption patterns but most have focused on quantity and frequency of drinking and on indicators of problem drinking. These surveys are helpful in defining population tendencies but rarely provide information on location and social context of consumption or other factors like rate of consumption. Rehm *et al.* (1999) have also shown differences in the sensitivity of different methods of assessing alcohol consumption. Alternatively, total sales of alcoholic beverages are good estimates of the total amount of consumption in a region, but they do not provide accurate information on patterns of how, when and by whom alcohol is consumed, and do not take into account the alcohol produced privately or in brew pubs, for example (Brewers Association of Canada, 2006).

Clearly each data collection method provides useful information, however, the conclusions generated using data collected by a specific approach must focus on its strengths and care should be exercised when generalizing, especially when so many potential covariates are often ignored. For instance, it is important to note that alcohol consumption may vary from day to day and from week to week. Occasions of heavy drinking, following which hangovers are much more likely to result, may also account for a disproportionate amount of the total consumption compared to lighter consumption at regular intervals (Storm and Cutler, 1981). All these factors need to be considered and accurately compiled and reported.

Alcohol Pharmacokinetics

Differences in alcohol pharmacokinetics between females and males have the potential to affect the drinking experience of females, which in turn may affect their hangover experience. Research has shown that females have more body fat and less body water per kg of body weight than males. Thus, standardizing the amount of alcohol females and males consume by body weight will produce higher peak blood alcohol concentrations (BACs) in females than males (Goist Jr. and Sutker, 1985; Mumenthaler *et al.*, 1999). Standardizing the amount of alcohol given to females and males by volume of body water eliminates this difference. The available evidence also suggests that females eliminate alcohol faster than males (Lammers *et al.*, 1995).

The phase of menstrual cycle has been reported to alter females' sensitivity to alcohol (e.g. Jones and Jones, 1976). However, in more recent reviews of this literature, Mumenthaler *et al.* (1999) have stated that phase of menstrual cycle is unlikely to affect alcohol pharmacokinetics and performance in females, while Lammers *et al.* (1995) have stated that "for the time being, it cannot be concluded

that the human female menstrual cycle has a significant impact on the potency of alcohol" (p. 28).

Although there appear to be some differences in how the female and male body reacts to alcohol, these discrepancies have not produced sex differences in perceived intoxication (Goist Jr. and Sutker, 1985). Nonetheless, some performance differences between females and males have been reported while intoxicated. Jones and Jones (1977) found that short-term memory was affected to a greater degree in intoxicated females than males. Furthermore, Niaura *et al.* (1987) showed that females were slower to recover short-term memory following peak BAC as it returned to zero. Females also showed greater decrements in divided attention than males (Mills and Bisgrove, 1983); however, decrements in psychomotor performance while intoxicated have not been shown to vary according to sex (Mumenthaler *et al.*, 1999).

The Experience of Hangover

Introducing alcohol to the body initiates a number of short-term physiological adaptations including altered neural and endocrine functioning (Lemon, 1993). Hangover is thought to be caused, in part, by re-adaptation processes once alcohol has been fully metabolised and cleared. Hangover symptoms commence with the decline in BAC after drinking has stopped, and peak around the time that it reaches zero (Swift and Davidson, 1998). Following a bout of heavy drinking (1.50–1.75 g/kg ethanol), Anylian *et al.* (1978) have shown that ratings of hangover intensity were greatest (12–16 h) after drinking stopped.

While few would disagree that hangovers exist, generating a precise definition of it has been elusive. In fact, Wiese *et al.* (2000) state that "there is no consensus definition" (p. 897) for hangover. In general terms, Swift and Davidson (1998) state that "a hangover is characterized by the constellation of unpleasant physical and mental symptoms that occur after a bout of heavy alcohol drinking" (p. 55). The result of this lack of consensus in defining hangover is the use of a wide variety of descriptors in various combinations to characterize hangover symptomology. Table 17.2 lists hangover symptoms provided in a pair of recent hangover studies that included a rationale for the symptoms they included, as well as from a number of hangover reviews that included a summary of reported symptoms. While a comprehensive review of hangover symptoms is beyond the scope of this chapter, those gleaned from the literature that was sampled indicate a number of hangover symptoms that appear to be central to the hangover experience; headache, nausea, dry mouth/thirst, fatigue, dizziness/vertigo, tremulous/shakiness, depressed well being and anxiety were reported in >50% of the literature sampled. Other hangover symptoms appear more peripheral to the hangover experience, appearing in <50% of the literature sampled (see Table 17.2).

There appears to be little evidence that hangover severity differs amongst females and males. Verster *et al.* (2003) reported that hangover intensity was greater in females than males; however, sex differences in peak BAC were not

Table 17.2 Summary of hangover symptom descriptors and frequency of use in selected literature

assessed in their study. As ethanol consumption was standardized on the basis of body weight, females may have reached higher peak BACs than males (Goist Jr. and Sutker, 1985). Kruisselbrink *et al.* (2004) allowed females and males to consume alcohol *ad libitum* in the natural setting of their choice. Peak BACs were recorded upon termination of drinking and subjects rated the presence and intensity of eight hangover symptoms approximately 12 h later. Overall, lower mean peak BACs were recorded for females, who also rated their hangover as less severe than males. However, when peak BAC served as a covariate, there was no difference in hangover intensity between females and males (unpublished analysis). Thus, the presence of hangover appears to be independent of sex and more related to the volume of alcohol consumed.

Delayed (Hangover) Effects of Alcohol Consumption

Although a number of studies examining the relationship between hangover and performance have included females

as subjects, many of these do not report sex differences. Therefore, we can only assume that the delayed effects of alcohol on performance do not substantially differ between females and males. In general, the extant research is inconsistent in showing decrements in performance with hangover, prompting Lemon (1993) to state, "it must be noted that for nearly every performance difference found in the post-intoxication state, there is at least one other study using the same, or similar, tests which has reported no effect" (p. 309). For example, performance decrements on cognitive and psychomotor tasks such as divided attention, digit-symbol substitution, mental rotation, memory, strategic decision making, simple (SRT) and choice reaction time (CRT), compensatory tracking and fine motor movement have been found by some (Seppälä *et al.*, 1976; Kim *et al.*, 2003; McKinney and Coyle, 2004) but not others (Lemon *et al.*, 1993; Chait and Perry, 1994; Streufert *et al.*, 1995; Rohsenow *et al.*, 2006). Likewise, for longer duration psychomotor tasks such as simulated flying and driving, research indicates both the presence (Yesavage and Leirer, 1986; Yesavage *et al.*, 1994; Petros *et al.*, 2003) and absence (Törnros and Laurell, 1991;

Morrow *et al.*, 1993; Taylor *et al.*, 1996; Petros *et al.*, 2003) of significant decreases in performance. Similarly, some physiological variables (e.g. heart rate (HR), blood pressure and aerobic performance) have been shown to decrease (Karvinen *et al.*, 1962; O'Brien, 1993) whereas others (e.g. grip strength) have not (Karvinen *et al.*, 1962).

One factor that may influence the presence or absence of performance decrements post-intoxication is the peak BAC achieved while drinking. Petros *et al.* (2003) failed to find significant decreases in flight simulator performance following peak BACs of ~0.07 g% in males, but found some differences for the group of men that exceeded 0.10 g%. Similarly, Yesavage and Leirer (1986) and Morrow *et al.* (1993) reported some post-intoxication deficits on flight simulator performance following BACs of >0.10 g%, however Yesavage *et al.* (1994) did not. Törnros and Laurell (1991) also found no differences in post-intoxication driving simulator performance 14–16 h after achieving peak BACs ranging from 0.115–0.247 g%. More recently, despite reporting increases in hangover symptoms and perceived impairment of performance following consumption of beer, Rohsenow *et al.* (2006) reported no post-intoxication effect on ship engine simulator performance in young cadets following heavy drinking (mean peak BAC 0.115 g%). This suggests that peak BAC contributes to, but is not the sole cause of, the obtained results.

In their reviews of the hangover literature, Lemon (1993) and Gauvin *et al.* (1993) both have provided summary tables of the post-intoxication effects of alcohol on performance once BAC had returned to zero. When these data are considered together, the inconsistency in the pattern of results is evident. Table 17.3 is a similarly styled summary table of post-intoxication effects of alcohol on performance conducted since 1993; however, for the purposes of this chapter, we have only included those studies in which females have been included as subjects. Similar to previous patterns of results, an overview of the findings reported in Table 17.3 indicates an inconsistent pattern of results.

The only study to explicitly contrast the psychomotor performance of males and females post-intoxication was conducted by Taylor *et al.* (1996). They found no differences between females and males on flight simulator performance 8 h after drinking terminated. To date, there is no reason to believe that post-intoxication performance differs according to sex; however, this conclusion should be interpreted with caution as it is based on limited data.

The available data also do not provide conclusive evidence that beer hangovers are rated any differently than hangovers induced by other types of alcoholic beverages. Whereas Takala *et al.* (1958) compared a beer hangover to a hangover induced by brandy, no self-rated hangover data were reported. Finally,

Table 17.3 Summary of hangover studies published since 1993 that have included female participants

Study	Subjects	Dose	Peak BAC reported	Delay	Post-intoxication performance results
Kruisselbrink *et al.* (2006)	12 f	0, 27, 54 and 81 g (in beer)	0, 0.036, 0.070 and 0.106 g%	9 h	↑CRT errors; ↔HR, blood pressure, grip strength, 4 CRT, run to exhaustion
Rohsenow *et al.* (2006)	11 f, 50 m	To reach 0.10 g% (in beer)	0.100 g%	~10 h	↔Ship engine simulation; fell asleep faster, ↑self-rated impairment
Finnigan *et al.* (2005)	35 f, 36 m	*Ad libitum*	Not measured	Next day between 9 a.m. and 1 p.m.	↔Tracking-SRT dual task, ↔probed memory recall
McKinney and Coyle (2004, 2006)	33 f, 15 m	f average of 95 g, m average of 132 g	Not measured	Next day at 9 a.m., 11 a.m., 1 p.m.	↓Free recall 9 and 11 a.m., ↑SRT, ↔5CRT; less sleep, to bed later, fell asleep faster; sleep less satisfying, restful and refreshing; less alert at 11 a.m.
Verster *et al.* (2003)	24 f, 24 m	1.4 g/kg	0.155 g%	~10.5 h	↔Sleep quality; ↓rated alertness; ↔immediate recall, ↓delayed recall, ↔recognition, ↔vigilance
Anderson and Dawson (1999)	8 f, 8 m	*Ad libitum* (>1 g/kg)	Not measured	12–16 h	↓Focused attention, ↓divided attention
Taylor *et al.* (1996)	12 f, 11 m	m 0.8 ml/kg, f 12.5% less ml/kg	f 0.084 g%, m 0.087 g%	8 h	↔Change in flight simulator performance; n.s. gender effect
Chait and Perry (1994)	4 f, 10 m	f 0.5 g/kg, m 0.6 g/kg	0.088 g%	13.5 h	POMS fatigue ↑ in morning; ↔1 leg balancing, ↔digit substitution, ↔divided attention

Note: For subject and dose columns, f = female, m = male; g = grams; g% = grams of alcohol per 100 ml of blood; ml/kg = milliliters of alcohol per kilogram body weight; g/kg = grams of alcohol per kilogram body weight (1 ml of alcohol weighs 0.79 g); ↑ = increase; ↓ = decrease; ↔ = no change; CRT = choice reaction time; SRT = simple reaction time; HR = heart rate; n.s. = non-significant; POMS = profile of mood states, a questionnaire measuring negative and positive aspects of mood.

Source: For summaries of work prior to 1993, see Gauvin *et al.* (1993) and Lemon (1993).

Verster (2006) has recently suggested that beer hangovers are less intense than liquor-induced hangovers, however these data were generated from a survey in which participants were asked to recall post-intoxication experiences caused by beer vs. liquor rather than on more direct and objective state measures taken during the hangover state. Therefore, this finding must be interpreted with caution.

Search and Review of Articles on the Topic

There is a dearth of literature on the delayed effects of beer on physical and psychomotor performances. Moreover, few studies on the delayed effects of alcohol have included females or focused specifically on women. We searched the Web of Science, PsycInfo, PubMed and Google Scholar databases using various combinations of keywords related to alcohol- and beer-induced hangover in females to highlight the number of publications on the topic. The number of results returned from each search is shown in Table 17.4.

Given the dearth of research examining post-intoxication effects of alcohol on various measure of performance in females, the call for more hangover research on females (e.g. Gauvin *et al.*, 1993) and the relatively widespread consumption of beer by females, we investigated the effects of drinking beer on next morning performance in a group of female university students (Kruisselbrink *et al.*, 2006).

Beer-Induced Hangover and Performance in Females

In the only published report specifically assessing the post-intoxication effects of beer in women, Kruisselbrink *et al.* (2006) concluded that there are minimal short-term performance decrements following consumption of up to 6 beers. Kruisselbrink and colleagues reported that consuming moderate quantities of beer altered decision making but had limited effects on short-term physical and physiological variables measured during hangover. Specifically, 12 healthy, non-smoking female university students aged 22 ± 2.8 years completed four testing conditions where they consumed 0 (control), 2, 4 and 6 bottles of beer (341 ml, commercially brewed, 5% alcohol by volume, 13.5 g alcohol/bottle) in a laboratory setting. The rate of consumption was standardized according to typical drinking patterns of female university students in a social setting (30 min/beer for the first 2 bottles; 40 min/beer for subsequent bottles).

Results

In this study, the treatment, ranging from 0 to 6 beers, caused a dose-dependent significant increase in BAC of the female subjects, increasing from 0.000g% in the control (0 beer) to 0.106g% in the 6 beer condition (see Figure 17.1a). Although the amount of beer consumed was moderate and ingested over time in an ecologically valid manner, it was sufficient to induce some acute deficits in performance as well as some delayed (i.e. hangover) effects 9 h following the end of consumption. For example, in the acute phase (i.e. 15–30 min following the end of consumption), CRT increased as dose increased (Figure 17.1b), indicating a slowing of information processing speed; no differences in movement time emerged with increased dose (Figure 17.1c) which shows that subjects' ability to carry out the simple movement once triggered was unaffected by dose. BAC had returned to 0.000 in all subjects at the time of awakening and post-intoxication testing.

The morning after the control condition (no alcohol consumed), participants' responses on the Post-Intoxication Scale indicated that, for the most part, they experienced the absence of, or mild symptoms typically associated with hangover (77% and 20% of total responses, respectively; Table 17.5). Moreover, the frequency of rating hangover symptoms as mild or severe increased with dose (see Kruisselbrink *et al.*, 2006 for hangover intensity ratings).

Table 17.4   Number of articles identified in commonly used academic databases using various combinations of relevant keywords

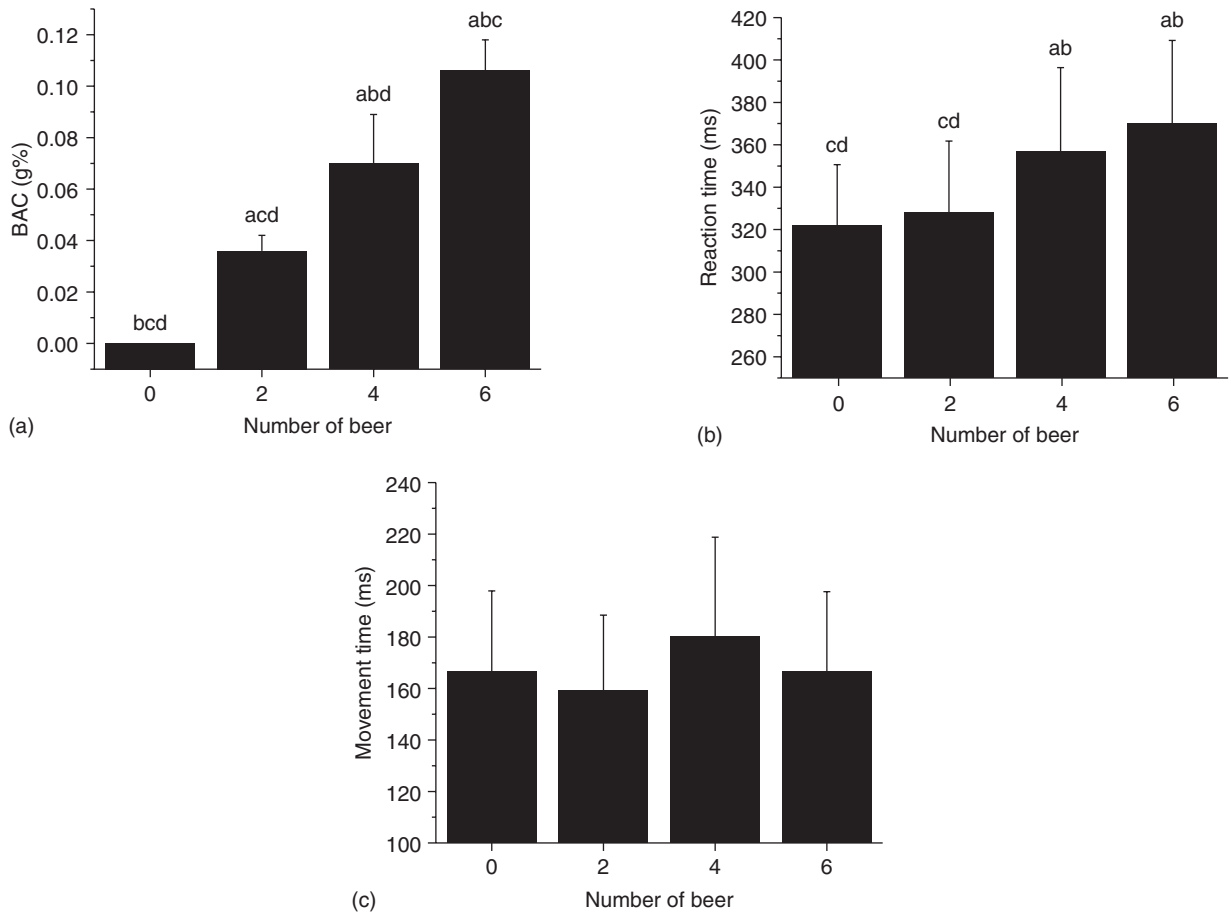
*Note that a large number of articles were not cited in this review because of non-human subjects, outcome measures used or relevance of the topic in the identified publications.


Figure 17.1   Peak mean BAC, four CRT and movement time within the hour following cessation of drinking. BAC = blood alcohol concentration, estimated with an Alco-Sensor IV breathalyzer in grams of alcohol per 100 ml of blood; error bars represent standard deviations; reaction time and movement time were obtained using four stimulus-response alternatives – following a cue, subjects released a central start key and moved up, down, right, left to depress a response key 15 cm away. ms = milliseconds or 1/1000th of a second. Repeated measures ANOVA and Tukey HSD *post hoc* analysis revealed significant differences (p < 0.05) between conditions. a, condition significantly different from 0 beer condition; b, condition significantly different from 2 beer condition; c, condition significantly different from 4 beer condition and d, condition significantly different from 6 beer condition.

Table 17.5   Frequency of rating hangover symptoms as absent, mild and severe by females (*n* = 12) the morning after consuming 0, 2, 4 and 6 bottles of beer

Hangover symptom	0 beer (0 g alcohol)			2 beer (27 g alcohol)			4 beer (54 g alcohol)			6 beer (81 g alcohol)		
	A	M	S	A	M	S	A	M	S	A	M	S
Headache	7	5	0	9	3	0	3	8	1	4	7	1
Nausea	12	0	0	8	4	0	10	2	0	6	4	2
Dry mouth/thirsty	7	4	1	3	8	1	2	9	1	0	5	7
Fatigue	3	7	2	4	4	4	3	7	2	1	6	5
Dizziness vertigo	11	1	0	6	6	0	6	6	0	4	5	3
Movement tremors	11	1	0	11	1	0	9	3	0	7	4	1
Upset stomach	12	0	0	9	2	1	12	0	0	6	3	3
Irritable	11	1	0	9	2	1	9	2	1	8	4	0
% of total responses	77	20	3	61	31	7	56	39	5	38	40	23

Note: Each bottle contained 341 ml of beer at 5% alcohol by volume which translates into 13.5 g of alcohol per bottle. Symptoms were rated on a 7 point Likert scale ranging from 0–6. A = absent, symptom given a rating of 0; M = mild, symptom given a rating of 1, 2 or 3; S = severe, symptom given a rating of 4, 5 or 6. Rounding errors are responsible for those conditions in which the % of total responses does not total 100%.

Table 17.6 Physiological and physical hangover effects of beer consumption in females ($n = 12$) the morning after consuming 0, 2, 4 and 6 bottles of beer

	Resting heart rate (bpm)	Blood pressure (mmHg)		Grip strength (kg)	Body weight (kg)
		Systolic	Diastolic		
0 beer (control)	66.8 (6.7)	114.5 (5.2)	73.4 (6.5)	64.8 (14.5)	66.4 (7.1)
2 beer	61.5 (7.1)	115.7 (6.9)	76.0 (10.7)	64.9 (13.1)	66.8 (6.7)
4 beer	63.8 (7.8)	114.3 (5.6)	74.4 (7.7)	65.4 (14.5)	67.0 (7.1)
6 beer	64.4 (11.3)	116.5 (8.3)	75.0 (8.3)	64.0 (13.9)	66.9 (6.9)

Note: bpm = beats per minute; mmHg = millimeters of mercury; kg = kilograms. For each condition, standard deviations are provided in parentheses following the mean value. Heart rate and blood pressure were measured in bed prior to standing. Grip strength is the sum of the better of two trials from each of the dominant and non-dominant hand.

Table 17.7 Hangover effects of beer consumption on physical performance in females ($n = 12$) the morning after consuming 0, 2, 4 and 6 bottles of beer

	Time to exhaustion (min:sec)	RPE* (Borg scale)		Blood glucose[†] (mM)			Blood lactate[†] (mM)		
		Submax	Max	Resting	Submax	Max	Resting	Submax	Max
0 beer (control)	12:44 (6:22)	12.7 (2.2)	17.7 (1.2)	4.8 (0.6)	4.6 (1.1)	6.0 (1.7)	1.3 (0.4)	2.7 (1.6)	7.7 (3.8)
2 beer	11:27 (5:39)	13.1 (2.7)	17.1 (1.9)	5.1 (1.5)	4.5 (1.9)	6.1 (1.9)	1.6 (1.7)	2.3 (1.4)	6.4 (2.3)
4 beer	12:53 (6:34)	13.1 (1.6)	17.9 (1.4)	4.9 (0.7)	5.0 (0.8)	6.1 (1.8)	1.5 (0.9)	3.4 (1.4)	8.1 (2.8)
6 beer	11:41 (5:24)	13.6 (2.1)	17.4 (1.4)	4.8 (0.8)	5.2 (1.3)	5.8 (1.5)	1.4 (0.8)	3.2 (1.9)	7.1 (2.2)

Notes: For each condition, standard deviations are provided in parentheses following the mean value. RPE = rating of perceived exertion; min:sec = minutes and seconds; mM = millimoles; submax = the 6 min submaximal portion of the treadmill run during which the treadmill operated at 6 miles per hour at a 0% grade – RPE, glucose and lactate were measured in the last minute; max = the maximal portion of the treadmill run during which the treadmill operated at 6 miles per hour at a 7% grade – RPE, glucose and lactate were measured immediately following termination.

*Dose of beer consumed produced a significant ($p < 0.05$) increase in the ratings of perceived exertion between the 2 and 4 beer conditions during maximal exercise but not during the submaximal run.

[†]indicates a significant ($p < 0.05$) increase with exercise intensity (from rest to submaximal exercise to maximal exercise).

Post-intoxication resting HR, systolic and diastolic blood pressure and body mass following consumption of 0, 2, 4 or 6 beers in young adult women are presented in Table 17.6. Neither resting HR, resting blood pressure nor body mass was affected by the amount of beer consumed the previous evening.

Physical testing was also performed the morning after consumption. Overall grip strength performance was not affected by dose conditions (Table 17.6) and further analysis demonstrated that grip strength in neither the dominant nor the non-dominant hand was affected by the amount of beer consumed by this group of women (unpublished observation). A submaximal treadmill run and a run to exhaustion were also completed. The effect of dose of beer in the time to exhaustion on the treadmill test the following morning is shown in Table 17.7. There was no statistically significant difference in time to exhaustion with an increasing dose of beer, and the dose of beer did not alter

HR in response to exercise in the female subjects the next morning. As expected, there was an increase in HR and perception of effort from submaximal to maximal treadmill exercise regardless of the amount of beer subjects had consumed (Table 17.7). While ratings of perceived effort varied significantly with the dose of beer consumed, the pattern did not follow a dose–response relationship as lower ratings of perceived effort were provided the morning after consuming 6 relative to 4 bottles of beer. As expected, blood glucose and blood lactate increased with exercise intensity but the amount of beer consumed did not alter this anticipated relationship in either variable (Table 17.7).

Psychomotor testing the next morning showed that the mean number of response errors made during CRT testing were greatest following consumption of the highest dose although neither reaction time nor movement time varied significantly with the amount of beer consumed the night before. This finding suggests that the time needed to

react to an event does not change when the event is perceived correctly, however at the highest dose the event was misperceived more often (Kruisselbrink *et al.*, 2006).

Conclusions

Overall, this first and only study on the effects of increasing, moderate doses of beer on physical, physiological and psychomotor variables in young female subjects indicates that, despite the moderate dose of beer consumed in a more ecologically valid fashion (i.e. 81 g alcohol in 6 beers over 2 h 40 min for the largest dose), very few performance characteristics were significantly altered. Cardiovascular physiology and aerobic performance, maximal muscle strength and metabolism during a submaximal and maximal run on a treadmill appear to be largely unaffected in healthy young adult women even after reaching BACs of approximately 0.10 g%. A number of variables may have contributed to the null results obtained in this study. These include the amount of beer consumed, age of subjects, tolerance to alcohol, rate of consumption, the laboratory conditions of drinking and sleeping, food consumed, hydration status, the delay between drinking and hangover testing, the relatively short duration of post-intoxication testing and the sensitivity of tests used. Moreover, anecdotally, in the debriefing for the study, a number of participants indicated that their mood likely played a larger role in their ability to perform than the amount of beer consumed the night before. Future studies should attempt to control as many of these variables as possible.

Summary Points

- Approximately 50% of alcohol (ethanol) consumed in North America is in the form of beer.
- To date the available literature shows that there appear to be differences in the consumption of beer by females and males, with females consuming less beer than males.
- The lower volume of body water combined with faster alcohol elimination rates in females will cause females to reach higher peak BACs than males of equal body weight, but they will also likely return to zero faster.
- Any differences in the way the bodies of females and males respond to alcohol appear to have little effect on the experience of drunkenness and hangover, given that females rate perceived intoxication and hangover severity similar to males.
- Physical testing of females has shown no significant impact of hangover on HR, blood pressure, grip strength, metabolism during exercise or running performance even when peak BAC had reached 0.10 g% 9 h previous.
- In the short term, neither physical nor psychomotor performance appears to be greatly compromised in women after consuming up to 6 beers to perform than the

amount of beer consumed the night before. No decreases in complex cognitive functioning have been reported; however, the increase in error rates on a CRT test suggests that the delayed effects of alcohol consumption may affect cognitive processing.

Recommendations

- The database of research examining hangover effects of beer consumption is extremely limited. Currently, little is known about whether a beer hangover is rated any differently from hangovers induced by wine or spirits, and if differences do exist, whether they alter performance. In addition to exposing the need for more research into the delayed effects of beer consumption, we also reinforce Gauvin *et al.*'s (1993) recommendation for more hangover research that includes female participants.
- Moreover, we recommend that researchers who include females as research participants in hangover studies provide an analysis of sex differences related to the experience and any effects of hangover, as Taylor *et al.* (1996) did.
- Many of the tasks used in hangover research, with the exception of some flight simulations, are short-duration tasks. Perhaps hangover effects can be overcome in the short term (e.g. 1 h) and emerge to a greater extent when the subject's attention and energy must be sustained over time. We recommend incorporating longer duration tasks into hangover testing batteries.
- We also recommend that researchers continue to search for tests that are sensitive to hangover effects. Perhaps the demands of many of the tests that produce inconsistent results simply do not place sufficient resource demands on hungover subjects.

Beer Consumption During Pregnancy

Brittany B. Rayburn and William F. Rayburn Division of Maternal-Fetal
Medicine, Department of Obstetrics and Gynecology, School of Medicine,
University of New Mexico, Albuquerque, NM, USA

Abstract

Beer is the most commonly chosen and most heavily consumed alcoholic beverage by reproductive-age women. Lower cost, easy access, and a perception by many as being less harmful favors this alcoholic beverage, even after pregnancy awareness. Routine prenatal questioning should focus on beer drinking patterns. Drinking several consecutive beers is a particularly troublesome pattern before and after pregnancy recognition. Some pregnant women, especially heavy drinkers, will continue to drink beer. In addition to abstention-oriented health messages, it is prudent for the obstetrician to educate patients about beverage equivalency and standard drink sizes. Brief interventions and referrals to alcohol treatment programs are urged to reduce exposure and potential harm to the vulnerable fetus. Although evidence is inconclusive about effects from social drinking on fetal growth and neurobehavior development, it is recommended that women limit or preferably cease any alcohol consumption during pregnancy.

Introduction

Maternal alcohol consumption is a leading preventable cause of birth defects and childhood neurobehavior disabilities in the United States (Ebrahim *et al.*, 1998; Centers for Disease Control and Prevention, 2004). Frequent alcohol use during pregnancy has not reduced significantly in the United States during the past 20 years (from 3.9% in 1988 to 3.5% in 1995) (Ebrahim *et al.*, 1998). Adverse fetal outcomes associated with excess alcohol exposure include morphologic, behavioral, cognitive, hormonal, immunologic abnormalities and death (Centers for Disease Control and Prevention, 1995).

Despite the widespread availability of home pregnancy tests, most women are usually unaware that they are pregnant until after the fifth week, once the pregnancy is established and the fetal organs are being formed (Cole *et al.*,

2004). A recent cross-sectional study in 2002, using survey data collected by the United States National Center for Health Statistics, revealed that half of all pregnant women drank alcohol during the 3 months before pregnancy recognition, with one in twenty drinking at moderate-to-heavy levels (National Survey on Drug Use and Health, 2005). In most surveys of women who drank, the number of drinking days decreased considerably once pregnancy was recognized. For example, the survey from the National Center indicated that confirmation of a pregnancy led to a decrease in alcohol use, especially heavy consumption (National Survey on Drug Use and Health, 2005) (Table 18.1).

The type of alcoholic beverage and how it is consumed during pregnancy may affect fetal outcome (Lancaster *et al.*, 1989; Graves and Kaskutas, 2002; Bailey *et al.*, 2004). Beer is consumed often by reproductive-aged women, particularly in a binge pattern (Graves and Kaskutas, 2002; Centers for Disease Control and Prevention, 2004); Bailey *et al.*, 2004). The objective of this chapter is to examine the prevalence of beer consumption before and after pregnancy awareness and to counsel about hazards and therapy.

Table 18.1 Level of consumption of different alcoholic beverages before pregnancy awareness. Beer was consumed more heavily (moderate or heavy) than wine alone ($p < 0.05$) or liquor alone ($p < 0.05$)

Beverage	Level of consumption*		
	Light (%)	Moderate (%)	Heavy (%)
Beer	5.5	28.8	65.8
Wine alone	25.0	75.0	0
Liquor alone	25.0	15.0	60.0
Wine and liquor combined	25.0	16.7	58.3

*Levels of drink units per drinking day: light (≤ 2 drinks); moderate (>2, <5 drinks); heavy (≥ 5 drinks).

Beer Preference During Pregnancy

Beverage preference during pregnancy is affected by women's attitudes about the relative safety of different kinds of alcoholic beverages. For example, Graves and Kaskutas (2002) found that more than one-fourth of their surveyed Native American and African-American pregnant patients in 2002 believed that beer and wine were safer than other kinds of alcoholic drinks. In another study, pregnant African-American women who drank beer thought it was safer than other alcoholic beverages (Graves and Kaskutas, 2002). These women thought that reducing their drinking during pregnancy might not prevent birth defects or other harmful fetal effects.

Worldwide, pregnant women appear to prefer beer than other types of alcohol. In a study of 2,913 antepartum gravidas in Cleveland, Ohio, Sokol *et al.* (1981) reported that 57% of the women who reportedly drank while pregnant preferred beer to other forms of alcohol. About 52% of pregnant participants in a study in Sweden reported drinking beer at least once weekly, with one to six bottles or cans per occasion (Halmesmaki *et al.*, 1987). Younger women expressed more tolerant attitudes toward alcohol use and drank more beer on any occasion. Another study in South Africa revealed that women who continued to drink after pregnancy awareness tended to drink beer or to binge (Croxford and Viljoen, 1999).

Beer also appears to be the alcoholic beverage of choice for hazardous pregnant drinkers regardless of ethnicity (Rayburn *et al.*, 2006). Many study populations are predominantly low income, and beer is popular because it is the least expensive alcoholic beverage. These results add to the literature that reported beer products to be the preferred alcoholic beverage in poor or lower income communities. In a 1-year cohort of 872 Swedish nulliparas, Dejin-Karlsson *et al.* (1997) noted that younger women or those with fewer years of education tended to continue drinking alcohol if it was beer. In contrast, we found that more educated women drank wine and in low quantities before pregnancy and negligibly after confirmation of gestation (Rayburn *et al.*, 2006).

Social vs. Heavy Alcohol Consumption

A safe threshold dose for alcohol use in general and for beer in particular during pregnancy has never been established. Women at highest risk to have affected children are those who chronically ingest large quantities and those who engage in binge drinking. For comparison in alcohol consumption, drinks may be converted into standard drink units of 0.5 oz. of ethanol. One unit of alcohol equals approximately 8 g of absolute alcohol which is equivalent to one-half pint of ordinary strength beer, lager or cider or to one-fourth pint of strong beer or lager (Royal College of Obstetricians and Gynecologists, 1996).

Most reproductive-age women consume alcohol at some time. Occasional alcohol consumption is socially acceptable and regarded as normal behavior. This social activity during pregnancy is often discouraged, although its consequences are less clear. Investigations are limited by the often inexact or underreporting of alcohol consumed and by confounding factors, such as other substance use, time of pregnancy awareness, and manner in which alcohol is consumed.

Data are, therefore, inconsistent about the effect of "social drinking" on many pregnancy outcomes such as spontaneous abortion or preterm delivery. There is no conclusive evidence of reduced fetal growth or IQ level with alcohol consumption below 120 g (15 units) per week (Royal College of Obstetricians and Gynecologists, 1996). Social alcohol consumption does have a small negative effect on fetal weight. Separate studies by Mills and Florey reported a 66–83 g deficit in birth weight for an average of two drinks per day (Mills *et al.*, 1984; Florey *et al.*, 1992).

Impairment of intelligence appears to occur at higher levels of alcohol consumption. The best information comes from the Seattle Pregnancy and Health Study as summarized in a 1993 review (Streissguth *et al.*, 1994). That group reported a decrease of five IQ points in children of mothers drinking greater than 250 g of alcohol (>30 units) per week, while 7-year-old children of mothers drinking greater than 165 g (>20 units) per week had a decrease of seven IQ points. Other neurodevelopment impairments included deficits in attention and memory, and difficulties with arithmetic and reading.

Jones *et al.* (1973) were the first to describe "fetal alcohol syndrome" (FAS). Heavy maternal alcohol consumption was associated with the following fetal impacts: (1) growth restriction, (2) central nervous system involvement (neurological abnormalities, development delay, intellectual impairment, head circumference below the third centile, brain malformation), and (3) facial deformities (short palpebral fissures, elongated mid-face, flattened cheek bone). This syndrome is rare with reported incidences of 1.7 per 1,000 and 3.3 per live births in Sweden and France, respectively (Guerri *et al.*, 1999).

Neither fetal alcohol spectral disorders nor fetal alcohol syndrome can be diagnosed prenatally. There is no correlation between alcohol use and ultrasonically detectable facial and intracranial biometrical measurements (Handmaker *et al.*, 2006). Shown in Table 18.2 are prenatal ultrasound findings associated with FAS. While heart defects or cleft lip can be diagnosed sonographically, failure to identify major organ defects does not preclude other alcohol effects.

The syndrome is not seen consistently in infants born to women who are heavy consumers of alcohol. Women ingesting eight or more drinks daily throughout pregnancy have a 30–50% risk of having a child with all features of the alcohol syndrome (Abel, 1999). Susceptibility of fetuses to heavy alcohol exposure is believed to be multifactorial,

Table 18.2   Prenatal ultrasound findings associated with FAS.

- Symmetrical smaller size for gestational age
- Organ defects (heart, kidney, widespread eyes)
- Skeletal and rib abnormalities (small jaw and foot length)
- Vascular abnormalities (single umbilical artery, excess amniotic fluid)

reflecting a complex interplay of genetic factors, social deprivation, nutritional deficiencies, tobacco, and other substance use (Royal College of Obstetricians and Gynecologists, 1996).

Binge Drinking During Pregnancy

Binge drinking, defined as greater than or equal to five drinking units per drinking day, is associated with an increased finding of unplanned pregnancy and continued drinking during pregnancy (Ebrahim *et al.*, 1999). Intermittent fetal exposure to these potentially high levels of alcohol can have important neurologic consequences. Fetuses exposed to binge drinking are at greater risk of cognitive deficits, delinquent behavior at 7 years of age, and IQ scores in the mentally retarded range (Streissguth *et al.*, 1990; Jacobson *et al.*, 1998; Naimi *et al.*, 2003). In addition, maternal consequences of binge drinking include unintentional injuries, exposure to domestic violence, unprotected and unplanned sexual intercourse, spontaneous abortion, and sexually transmitted diseases (Naimi *et al.*, 2003).

This pattern is particularly noteworthy for beer consumption rather than for wine or distilled spirits alone. Binge drinking is common among our hazardous beer drinkers before and after pregnancy recognition. The National Survey on Drug Use and Health reported that 4.1% of pregnant women binge drank during the past month (National Survey on Drug Use and Health, 2005). Ebrahim *et al.* reported that, between 1991 and 1995, binge drinking among pregnant women increased significantly from 0.9% to 3.5% (Figure 18.1), whereas the prevalence changed little for nonpregnant women (11.3% vs. 11.2%) (Lancaster *et al.*, 1989).

Although some studies indicate that fetal injury can result from consuming as little as one to two drinks per day, the effects of binge drinking may have been obscured by computing a daily average alcohol consumption. For example, Jacobson *et al.* (1993) reported that the threshold below which no alcohol-related effects occurred was 0.5 oz. of absolute alcohol per day. Most women with affected children actually drank four to six drinks per occasion, however, which averaged to be lower daily doses. Subsequently, Jacobson *et al.* (1998) found that 80% of functionally impaired infants were born to women who drank more than five drinks per occasion, on several occasions weekly.
Figure 18.1   Alcohol drinking by pregnant women in the month before the survey, United States, 1988–1995. Percentages were adjusted to the population distribution of pregnant women in 1988. Frequent drinking = binge drinking or at least seven drinks per week. *Source*: Abel (1999) with permission.

Limitations with Animal and Human Investigations

We were only able to locate laboratory investigations about beer specifically during pregnancy by Lancaster and his colleagues (Lancaster and Spiegel, 1989, 1992; Lancaster *et al.*, 1989). Their method for voluntary beer drinking by pregnant rats identified subtle consequences of maternal beer drinking. Their findings in rodents suggest beer to be more hazardous to the fetus than other alcoholic beverages. Lancaster observed in gravid rats that beer exposure led to adverse effects on the fetal development. Beer-exposed offspring were less active in the open field than nonexposed offspring and had excess body weight from birth until 21 days of age (Lancaster *et al.*, 1989). As shown in Figure 18.2, gravid rats exposed to beer also had greater weights of their body and specific organs (thymus, spleen, heart,

and liver) (Lancaster *et al.*, 1989; Lancaster and Spiegel, 1992).

Limitations of beer investigations in pregnant humans are noteworthy. Study populations may not be representative of all alcohol-exposed pregnancies. Hazardous drinkers often seek late or no prenatal care, and those who sought prenatal care early may not be representative. Many surveys rely on responses by pregnant drinkers to questionnaires to quantitate alcohol consumption. Their self-reported beer consumption is often underestimated (National Survey on Drug Use and Health, 2005).

There is no reliable laboratory technique in screening for long-term alcohol exposure. Alcohol and its metabolites are eliminated rapidly from the body, making them insensitive as biomarkers for chronic intermittent exposure (Bearer, 2001; Cook, 2003). Biological markers of excess alcohol consumption include blood gamma-glutamyl transferase, thiocyanate, and mean corpuscular volume (Bearer, 2001). None is precise, however, and better markers are being developed.

A limitation in counseling would be that it is not possible to focus solely on beer products and their harm to the mother or fetus. Most women drink beer with other alcoholic beverages before and after pregnancy awareness (Rayburn *et al.*, 2006). Furthermore, beer is often consumed with other substances such as cigarettes and marijuana (Rayburn *et al.*, 2006).

In addition to a brief alcohol intervention during initial prenatal care, the obstetrician or other healthcare provider is encouraged to offer a brochure, such as that published by the National Institute on Alcohol Abuse and Alcoholism, about the hazards of drinking during pregnancy. In addition, a list of local substance abuse and mental health treatment agencies, with a referral letter, are encouraged.

Prevention of Beer Drinking During Pregnancy

Prevention involves more than warning people about health hazards of alcohol abuse. It requires screening for early detection of alcohol abuse and providing patient-specific information. One method to screen for beer drinking is to include a prior week's diary of alcohol consumption, including lunchtime and early evening drinking. The T-ACE questionnaire, devised by Sokol *et al.* (1989), can be used to screen either the whole population or those women with growth-impaired fetuses. The survey consists of four questions:

1. **T** How many drinks does it take to make you feel high? (The patient is considered **t**olerant if it takes more than two drinks to her feel high) – 2 points
2. **A** Have people **a**nnoyed you by criticizing your drinking? – 1 point

3. **C** Have you ever felt you ought to **c**ut down your drinking? – 1 point
4. **E** Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (**e**ye opener)? – 1 point

A total score greater than or equal to two points is considered to be positive and correctly identifies approximately 70% of heavy drinkers during pregnancy.

Very brief physician interventions or trials of advice qualify as prevention or early intervention programs that can be easily offered in medical practice. Randomized trials proved this to be effective in reducing harmful levels of alcohol consumption (Fleming *et al.*, 1997). Individuals should know that their attitudes and behaviors will affect how their children and spouses drink. All should be cautioned that drinking is dangerous in dealing with insomnia and emotional problems.

Counseling During Pregnancy

Therapies can be classified as psychological, behavioral, or sociocultural. Selection is best done on an individualized basis to meet the patient's specific needs. Most programs use a combination of such modalities. The current emphasis is on outpatient care, except for treatment of severe acute withdrawal syndrome. Costly inpatient care remains an option for people who have failed other forms of treatment and who will not deal with the problems so long as they are in environments that maintain destructive drinking.

Alcoholism is associated with special needs that require the therapist to take a more active role than is typical in insight-oriented psychotherapy. One must provide structure, guidance, support, nurturance, and instruction on helping the patient control drinking while working on her underlying conflicts and dysfunctional defense mechanisms. Behavioral–cognitive therapies are based on the notion that alcoholism is a learned behavior that can be extinguished and reshaped. Behavioral therapy is often useful in dealing with problems involving role changes and in motivating behavior change in specific situations. Cognitive therapy attempts to identify the precipitants to abuse and the factors that maintain or perpetuate it.

The primary physician can perform a major service for these patients by understanding available specialized referral resources in one's community and matching them to the patient's needs. Sociocultural treatment emphasizes altering external factors. It includes residential care, halfway houses, and direct social manipulation, such as finding jobs, helping with shelter and money, and removing a person from her family. This is a treatment appropriate for homeless, jobless young people, and severe family problems. Any of these approaches and the community services that follow can be used as adjuncts to other treatments wherever

necessary. Alcoholics Anonymous is a community service that provides the critical elements of social support, caring, and structure, which are essential to many patients. Al-Anon and Alateen assist family members of the alcoholic, while Women for Sobriety stresses individual responsibility to boost self-esteem. Employee assistance programs and church organizations can be very helpful when motivation is high.

Drug Therapy During Pregnancy

Specific information about medication to curb beer drinking during pregnancy is unavailable. Drug therapy plays a supportive role in outpatient care, mainly by providing a temporary respite from alcohol consumption to engage in a more comprehensive and durable treatment program (Shaffer and Naranjo, 1998). The duration of therapy is individualized. Treatment should be terminated if the patient fails to keep appointments, resumes drinking, or develops abnormalities in liver function tests or cardiovascular status. Pharmacologic agents are prescribed to reduce the urge to drink, to blunt withdrawal symptoms, and to treat underlying psychiatric problems that may contribute to alcohol abuse. Treatment modalities when nonpregnant have been well summarized (Hanna, 2000).

Aversive therapy is seldom, if ever, used during pregnancy. Disulfiram (Antabuse) is an aversive drug not used during pregnancy. The drug sensitizes the patient to the effects of alcohol by inhibiting hepatic aldehyde-NAD oxidoreductase. Within minutes of taking as little as 1 oz. of alcohol, she can experience an increase in serum acetaldehyde concentration that leads to palpitations, flushing, tachypnea, tachycardia, and shortness of breath. Nausea, vomiting, and headache develop if a greater amount of alcohol is consumed. Symptoms last about 90 min but usually are self-limited. Naltrexone (Trexan), an opioid antagonist that appears to blunt the pleasurable effects of alcohol, is US Food and Drug Administration approved to reduce cravings.

Pharmacologic treatment of underlying psychopathology has been proposed as a means of cutting down on any form of drinking. Anxiolytic agents such as the benzodiazepines have been used with a modicum of short-term (less than 4 weeks) success in patients who drink because of an anxiety disorder. Buspirone has been effective in short trials as a treatment for severely anxious patients, but more work is required to clarify its effectiveness. Selective serotonin reuptake inhibitors may be effective when there is an underlying depression, especially when it is accompanied by neurovegetative symptoms. Lithium has been tried with lesser success.

The acute withdrawal syndrome and its severest manifestations and complications (seizures, hallucinations, and delirium tremens) are best prevented and treated during pregnancy by use of benzodiazepines or barbiturates such as phenobarbital (Hanna, 2000). The Clinical Institute Withdrawal Assessment – Alcohol, revised (CIWA-Ar) is the most validated instrument for objective assessment of withdrawal severity and risk. Women with moderate symptoms (e.g. CIWA-Ar score of 8–15) benefit symptomatically from treatment; those with severe symptoms (scores higher than 15) require pharmacologic therapy, because the risk of seizures is very high. Long-acting benzodiazepines (e.g. lorazepam, diazepam, chlordiazepoxide) appear to be more effective in preventing withdrawal seizures and in achieving a smoother withdrawal with fewer rebound symptoms than the short-acting agents; however, they are more likely to cause sedation. Fixed-dose, loading-dose, and symptom-triggered benzodiazepine regimens are effective when used as intended. Beta-blockers (e.g. atenolol, 50–100 mg/day) can help control adrenergic symptoms and reduce benzodiazepine requirements. Clonidine, a centrally acting inhibitor of noradrenergic activity, is an effective alternative to benzodiazepines in mild to moderate withdrawal syndrome when used in a tapered program. Outpatient administration is appropriate for those with mild symptoms of withdrawal.

Beer and Breastfeeding

Beer is used as a folk remedy to enhance lactation. However, a clinical study by Mennella and Beauchamp (1993) revealed that beer consumption by nursing women altered the sensory qualities of their milk and the short-term behavior of their infants during breastfeeding. The infants consumed significantly less milk shortly after their mothers drank beer. This reduced intake was not due to a decrease in the number of times the babies were fed. Despite this, the mothers believed that their infants had ingested enough milk, reported breast milk letdown while nursing, and felt that enough milk remained in their breasts at the end of most feedings.

Summary Points

- Beer is the most commonly chosen and most heavily consumed alcoholic beverage by reproductive-age women.
- Lower cost, easy access, and a perception by many as being less harmful favors this alcoholic beverage, even after pregnancy awareness.
- Routine prenatal questioning should focus on beer drinking patterns. Inquiring about malt liquor, drink size, and drink numbers is recommended for patients with a positive history of beer consumption.
- Binge drinking is a particularly troublesome pattern when beer is consumed before and after pregnancy recognition.
- In addition to abstention-oriented health messages, it is prudent for the provider to educate patients about beverage equivalency and standard drink sizes.

- Brief interventions and referrals to alcohol treatment programs are urged to reduce harm to the vulnerable fetus.
- Although evidence is inconclusive about effects from social drinking on fetal growth and neurobehavior development, it is recommended that a woman be careful or preferably cease any alcohol consumption during pregnancy.
- Beer consumption by nursing women may affect qualities of milk and short-term behavior of infants during breastfeeding. Decreased milk intake may result.

Beer and Other Alcoholic Beverages: Implications for Dependence, Craving and Relapse

Thomas Hillemacher and Stefan Bleich Department of Psychiatry and Psychotherapy, University Hospital Erlangen, Erlangen, Germany

Abstract

Beer and other types of alcoholic beverages play different roles in alcohol-mediated neurotoxicity, withdrawal symptoms, craving and relapse. This chapter will try to give an overview about pathophysiological mechanisms that are responsible for neurotoxicity and withdrawal symptoms, especially including the role of homocysteine and the glutamatergic system. In this context, differences between beverages and their influence on homocysteine-mediated toxicity are presented. Beer contains higher levels of folate than other alcoholic beverages. It has been found that consumers of beer had nearly consistent serum folate and moderately increased homocysteine levels compared to other patients with alcohol dependence. Also, neurobiological and particularly neuroendocrinological pathways are discussed in the pathogenesis of alcohol craving and relapse. Recently, differences between beverage types have been found to influence alcohol craving during withdrawal. We found that beer consumption was directly associated with the extent of craving, but not consumption of wine or spirits. A possible role of volume regulating mechanism with respect to a dysregulation of the hypothalamic–pituitary–adrenal axis will be discussed as a possible explication for these beverage-dependent differences. This may explain the found association between beer consumption and craving and may help to further understand neurobiological mechanisms of alcohol craving and relapse.

List of Abbreviations

ACTH	Adrenocorticotropic hormone
ANP	Atrial natriuretic peptide
CHD	Coronary heart disease
CRH	Corticotropin releasing hormone
HPA axis	Hypothalamic–pituitary–adrenal axis
ICD	International Classification of Diseases
MRI	Magnetic resonance imaging
MS	Methionine synthase
NF-κB	Natural killer-enhancing factor B
NMDA	N-methyl-D-aspartate
NMDAR	N-methyl-D-aspartate receptor
OCDS	Obsessive-compulsive drinking scale
PARP	Poly-ADP-ribose polymerase
ROS	Reactive oxygen species

Introduction

Alcohol dependence is, besides nicotine dependence, the clinically most important form of addiction. Lifetime prevalence is estimated in industrialized countries being about 3–6% for alcohol dependence and 4–16% for alcohol misuse. The differentiation between alcohol misuse and alcohol dependence is one first and important step because therapy differs regarding to the diagnosis. Referring to the international classification of diseases (ICD-10), alcohol dependence should be diagnosed if 3 of 6 criteria are positive: craving, loss of control, withdrawal symptoms, increasing tolerance regarding the effects of alcohol, neglect of social activities and interests, and to continue consuming alcohol in spite of damaging sequels. The amount of consumed alcohol or the type of consumed beverage is no criterion for alcohol dependence or misuse.

Excitatory amino acids, such as glutamate, aspartate and homocysteine, have been shown to be increased in patients with chronic alcoholism who underwent alcohol withdrawal. Furthermore, sustained hyperhomocysteinemia occurred in chronic alcoholics with an active drinking pattern. Excitotoxicity can be induced by increased homocysteine levels via rebound activation of N-methyl-D-aspartate receptor (NMDAR) mediated glutamatergic neurotransmission upon the removal of ethanol-evoked inhibition. Therefore, hyperhomocysteinemia may be responsible for the higher incidence of complications during alcohol withdrawal (e.g. seizures). In addition, an association between brain atrophy and increased levels of homocysteine in chronic alcoholism was shown. This may have important implications for the

pathogenesis of brain atrophy in alcoholics. However, there exist important differences regarding the consumption of different alcoholic beverages, particularly with respect to cardiovascular risks, neurotoxicity, craving and relapse.

Main Text

Homocysteine, alcoholic beverages and cardiovascular risk

Evidence from observational studies suggests that elevated levels of homocysteine are associated with an increased risk of cardiovascular diseases including coronary artery disease, cerebrovascular disease, peripheral vascular disease and venous thrombosis (Nygard et al., 1997). Furthermore, it has been observed that chronic alcoholism is associated with increased homocysteine levels (Bleich et al., 2000a, b, d, 2005; Cravo and Camilo, 2000) and could therefore be responsible for the increased incidence of stroke and myocardial infarction in this group (Bleich and Degner, 2000; Bleich et al., 2000c). The "French paradox" is the lower-than-expected rate of mortality from coronary heart disease (CHD) conferred by mild-to-moderate alcohol consumption in a country where traditional risk factors of CHD (hypertension, hyperlipidemia, smoking, diabetes) are not less prevalent than in other industrialized countries and where the diet is rich in animal saturated fat. Thus, various epidemiological studies suggested that moderate alcohol intake results in a U-shaped curve in which the equivalent of two drinks (20–40 g alcohol per day) of any kind of alcohol, especially red wine consumption, is associated with a decreased incidence of CHD compared with no drinks (St Leger et al., 1979; Renaud and de Lorgeril, 1992; Gronbaek et al., 1995). However, higher doses result in an increased risk of infarction and stroke (Numminen et al., 2000).

As shown in Figure 19.1 and Table 19.1, homocysteine levels are increased in social drinkers with daily alcohol consumption of beer, red wine or spirits (Bleich et al., 2001). The reasons for the significant correlation between blood alcohol concentration on the one hand, and plasma homocysteine on the other, regardless of whether beer, wine or
Figure 19.1 Homocysteine levels in dependence of beverage types (see Table 19.1).

Table 19.1 Homocysteine and other laboratory parameters in non-drinking controls and in subjects before and 6 weeks after daily consumption of beer, red wine or spirits

Parameter	Mineral water	Beer	Red wine	Spirits
Baseline				
Hcy (μmol/l)	9.06 ± 2.08	11.67 ± 2.17	12.69 ± 1.85	13.80 ± 2.22
Folate (μg/l)	12.3 ± 4.8	9.7 ± 3.3	9.2 ± 3.8	11.3 ± 5.3
B12 (ng/l)	512 ± 198	428 ± 118	612 ± 158	479 ± 87
B6 (μg/l)	11.3 ± 4.2	14.3 ± 6.2	9.9 ± 2.8	10.3 ± 4.1
After 6 weeks				
Hcy (μmol/l)	8.47 ± 1.42	14.58 ± 1.58*	15.61 ± 1.83*	16.25 ± 2.19*
Folate (μg/l)	11.5 ± 3.9	8.9 ± 4.1	7.1 ± 3.9**	9.1 ± 2.3**
B12 (ng/l)	578 ± 112	479 ± 77	543 ± 87	528 ± 115
B6 (μg/l)	9.8 ± 3.1	13.8 ± 4.7	8.4 ± 2.8	9.2 ± 3.9

Notes: Non-drinking individuals (n = 15) consumed mineral water whereas social drinkers (n = 15 per group) daily consumed 30 g alcohol in the form of beer, red wine or spirits over a period of 6 weeks. Homocysteine (Hcy) and vitamin levels (folate, B12, B6) were analyzed at baseline and after 6 weeks, respectively. Scores of folate (normal range: 4–17 μg/l), vitamins B6 (4–20 μg/l) and B12 (170–850 ng/l), and homocysteine (Hcy; 5–15 μmol/l). Homocysteine concentrations were significantly increased in social drinkers, especially in consumers of red wine and spirits (Mann–Whitney U-test, p < 0.01). The latter alcohol consumers also had significant lower folate levels (p < 0.02). Statistical details are summarized in the results section. Significant (p < 0.02) changes are marked:

*significant increase;
**significant decrease.

Source: Bleich et al. (2001).

spirits had been consumed (Bleich *et al.*, 2000c), are most likely complex ones in alcohol-dependent patients: impairment of remethylation of homocysteine is brought about on account of a dysfunction of methionine synthase (MS), due to an alcohol-induced vitamin deficiency (folic acid and vitamin B12), as well as a direct inhibition of MS due to acetaldehyde (Kenyon *et al.*, 1998), the product of oxidative degradation of alcohol. Regular consumers (daily alcohol intake over a period of 6 weeks) of red wine and spirits had significant lower folate levels when compared with concentrations at baseline (Bleich *et al.*, 2001). In addition, it has been known for many years that ethanol has an effect on folate metabolism, which could not be explained by an alcohol-induced low intake of folate (Sullivan and Herbert, 1964). The etiology of folate deficiency in alcoholism can be ascribed to several causes, such as low dietary intake, poor absorption, decreased hepatic uptake and retention, and increased urinary excretion of folate. Furthermore, beer is a rich source of folate (about 90–120 g/40 g alcohol) and vitamin B6 (about 0.3–0.5 mg/40 g alcohol), whereas red wine and spirits contain negligible amounts of these vitamins, which might explain that the consumers of beer had nearly consistent serum folate and moderately increased homocysteine levels (Bleich *et al.*, 2001). Additionally, abstinent individuals were shown to have significant higher levels of folate which might be explained by the lack of the alcohol-induced folate depletion, as described above.

Mildly elevated plasma homocysteine levels have been associated with an increased risk of CHD (Nygard *et al.*, 1997; Folsom *et al.*, 1998; Refsum *et al.*, 1998). Hence, it has been shown that homocysteine levels increase after 6 weeks consumption of red wine and spirits by 19% and 17%, respectively. The latter increase in homocysteine coincides with an increase of CHD risk of approximately 20% (Verhoef *et al.*, 1998). However, some other effects of alcohol may counteract the effect of homocysteine (Bleich *et al.*, 2000e; Paassilta *et al.*, 1998) and, in addition, other known risk factors for cardiovascular diseases (i.e. hypertension) must be taken into account. Furthermore, elevated plasma homocysteine levels may increase the risk for different types of vascular diseases (i.e. cerebral microangiopathy, brain infarction, peripheral vascular disease) whereby the exact mechanisms are largely unknown (Fassbender *et al.*, 1999).

Homocysteine and alcoholism: implications for neurotoxicity

More recent studies have demonstrated that the plasma homocysteine concentration is not only dependent on the type of alcoholic beverage, but especially on the amount of alcohol consumed and the blood alcohol concentration (Bleich *et al.*, 2000b, d). The degree of the plasma homocysteine levels is strongly determined by the degree of alcoholization. Whereas alcohol-dependent patients only have

minimally elevated or already normal homocysteine concentrations a few days after they have stopped drinking, the majority of alcoholized patients have plasma homocysteine levels two to three times higher than the upper normal value of 15 μmol/l (Bleich *et al.*, 2000b, c, e). Course measurements during an alcohol withdrawal treatment show a continuous reduction in plasma homocysteine levels, which return more or less to within the normal range after around 3–7 days (Hultberg *et al.*, 1993; Bleich *et al.*, 2000e). Before withdrawal a remarkable feature is the significant positive correlation between the degree of the plasma homocysteine level and the blood alcohol concentration as well as the significant inverse correlation between homocysteine and the serum folic acid level (Bleich *et al.*, 2000d). The plasma levels of vitamins B12 and B6 are mostly even in the upper normal range and have no effect on the plasma homocysteine concentration (Bleich *et al.*, 2000b, d, e). However, other studies have shown a deficiency of these vitamins (Cravo *et al.*, 1996; Cravo and Camilo, 2000). The interplay of these conditions is important for an understanding of alcoholism-associated hyperhomocysteinemia, since a single intoxication with large amounts of alcohol does not lead to a pathological increase in plasma homocysteine concentrations in healthy subjects (Bleich *et al.*, 2000c).

Several mechanisms of toxic action of homocysteine have been discussed. Homocysteine can act as an agonist at the glutamate binding site of the NMDAR (Lipton *et al.*, 1997) which are expressed in both neurons and astrocytes (Conti *et al.*, 1990). Furthermore, it has been found that astrocytes regulate the expression of NMDAR subtypes which increase neuronal sensitivity to glutamate toxicity (Daniels and Brown, 2001). Thus, homocysteine leads to an enhanced excitatory glutamatergic neurotransmission in different brain areas (Lipton *et al.*, 1997) whereby neuronal damage derives from excessive calcium influx and reactive oxygen generation (Kim and Pae, 1996; Lipton *et al.*, 1997). Homocysteine can induce neuronal apoptosis or apoptotic processes by a mechanism involving DNA damage, poly-ADP-ribose polymerase (PARP), and mitochondrial dysfunction by caspase-3 activation (Kruman II *et al.*, 2000; Anton *et al.*, 2006). Autooxidation of homocysteine is known to generate reactive oxygen species (ROS), whereby the prevention of homocysteine-induced toxicity by catalase, in cell cultures which were coincubated with homocysteine and Cu^{2+}, suggests that hydrogen peroxide acted as a mediator of oxidative injury leading to apoptosis (Huang *et al.*, 2005). In the present study, this mechanism of toxic action seems less probable as the culture media used contained only minimal concentrations of metal ions. Homocysteine also decreases the expression of the antioxidant enzymes glutathione peroxidase and natural killer-enhancing factor B (NF-κB) so that homocysteine could potentially enhance conditions known to cause oxidative stress (Outinen *et al.*, 1998). Like some structurally related excitotoxins homocysteine may competitively inhibit cystine uptake resulting in a decrease in glutathion

synthesis and reduced capabilities of blocking oxidative stress (Kato *et al.*, 1992; Meldrum, 1993).

Brain volumetric magnetic resonance imaging (MRI) studies on alcohol-dependent patients show a significant correlation between the degree of plasma homocysteine levels, on the one hand, and the hippocampal volume reduction or global alcoholism-associated brain atrophy, on the other (Bleich *et al.*, 2003; Bleich and Kornhuber, 2003). A new approach to explain the reversibility of "alcohol-induced" brain atrophy observed in many cases may be provided by transient ethanol-associated hyperhomocysteinemia. Accordingly, toxic hyperhomocysteinemia is to be discussed as being causative, but the influence of alcohol regarded as an indirect effect. These investigations are consistent with the observation that patients with hereditary homocystinuria, in addition to mental retardation, remarkably often display cerebral atrophy and suffer from epileptic seizures (Harris *et al.*, 2002). The latter fact is in line with more recent investigations showing that patients with moderate to severe hyperhomocysteinemia significantly more frequently suffer from alcohol withdrawal seizures (Bleich *et al.*, 2000a, 2006; Kurth *et al.*, 2001; Bayerlein *et al.*, 2005).

Craving and relapse in alcoholism

Craving is a well-studied phenomenon in patients with alcoholism (Geerlings and Lesch, 1999) and is known to be associated with a higher risk of relapse in patients suffering from alcohol dependence (Bottlender and Soyka, 2004). The manifestations of craving differ widely while obsession and compulsion have been described by many authors to be the most common characteristics (Modell *et al.*, 1992; Lesch *et al.*, 1997; Tiffany and Conklin, 2000). In fact, craving for alcohol shares many features with obsessive-compulsive disorders. Furthermore, it has much in common with other forms of craving, especially food craving (Pelchat, 2002). Craving is of high importance in treating addictive diseases and must be regarded as an important factor for relapse. Therefore, treatment of craving with psychotherapeutic or pharmacological interventions is of high interest in the therapeutic concept for patients with alcohol dependency. The efficacy of psychotherapeutic and pharmacological anticraving therapy has been described in various studies (Kranzler *et al.*, 1999; Rohsenow and Monti, 1999; Buerger *et al.*, 2002; Flannery *et al.*, 2003). Recently, the COMBINE-Study showed negative findings regarding the efficacy of acamprosate in relapse prevention (Anton *et al.*, 2006). However, the majority of existing studies and meta-analysis show significant effects for both, acamprosate and naltrexone (Kiefer *et al.*, 2003; Mann *et al.*, 2004). New substances like baclofen and topiramate have been studied to treat craving in alcoholism and have shown promising results (Johnson *et al.*, 2003; Addolorato *et al.*, 2006). While pharmacological anticraving therapy seems to be effective it is only one part of the therapeutic concept. An integrative therapeutic concept for relapse prevention should also include psychotherapeutic strategies differentiating in-patients and out-patients treatment, attendance in self-help groups, social activities and a tight connection with the therapist. Only if profiting of all these therapeutic possibilities, a low rate of relapse can be achieved.

The underlying mechanisms of alcohol craving are subject to intense research. Behavioral models intent to explain craving mainly by reinforcement as alcohol improves mood and reduces negative affective states. The mesocorticolimbic dopaminergic neurotransmission most probably is of crucial importance in cue-induced reinforcement (Wise, 1988; Heinz *et al.*, 2003b; Tupala and Tiihonen, 2004; Bowirrat and Oscar-Berman, 2005). Animal-experimental investigations have shown that alcohol directly stimulates dopaminergic neurons (Gessa *et al.*, 1966; Imperato and Di Chiara, 1986; Brodie *et al.*, 1995), while chronic consumption leads to a down-regulation of dopamine receptors. In human beings, reduced dopamine receptor activity has been reported in alcohol-dependent patients (Heinz *et al.*, 1995; Schmidt *et al.*, 2005). During detoxification, a normalization of down-regulated central dopaminergic receptors has been shown in recent studies (Markianos *et al.*, 2000). Furthermore, findings point toward a lower risk of relapse in patients with an increase of dopamine receptor responsivity (Markianos *et al.*, 2001).

Besides the dopaminergic system, recent studies have shown that also various neuroendocrinological conditions are associated with craving in alcoholism (Buerger *et al.*, 2002; Kiefer and Wiedemann, 2004). Many investigations showed that craving is associated with a disturbance of the hypothalamic–pituitary–adrenal (HPA) axis (Buerger *et al.*, 2002; Kiefer and Wiedemann, 2004). Higher craving was found to correlate with lower corticotropin releasing hormone (CRH) in patients suffering from alcohol dependency (Fahlke *et al.*, 1994; Olive *et al.*, 2003). Further studies showed, that also lowered cortisol- and ACTH-(adrenocorticotropic hormone)-serum levels are associated with higher craving and elevated relapse rates (Kiefer *et al.*, 2002; Junghanns *et al.*, 2003). Also changes of the prolactin secretion, possibly as sequel of a disturbed dopaminergic transmission in the tuberoinfundibular circuit, are associated with alcohol craving (Hillemacher *et al.*, 2005b; 2006a).

As described above, craving also shares many neurobiological pathways with food craving and appetite regulation. The peptide leptin, secreted by white adipocytes, is known to play an important role in hypothalamic appetite regulation (Kraus *et al.*, 2001). Kiefer *et al.* showed first evidence for an association between increased plasma concentration of leptin and craving for alcohol in 2001 (Kiefer *et al.*, 2001a, b). Since leptin plasma concentrations were shown to be elevated during chronic alcohol consumption (Nicolas *et al.*, 2001) and normalize during withdrawal and abstinence (Wurst *et al.*, 2003), leptin was discussed as a factor that mediates increased alcohol intake through increased urge to drink. Leptin is known to regulate the HPA axis and to

inhibit the cortisol-mediated stress response (Inui, 1999). Also other appetite regulating hormones such as grehlin have been investigated to be associated with alcohol craving without positive findings up to now (Kraus *et al.*, 2005).

Differences regarding alcoholic beverages

The majority of studies on craving and relapse refer to ethanol intake without differentiating the type of consumed beverages. However, recent findings suggest that important differences exist between the different types of alcoholic drinks. So, consumption of low-alcohol drinks such as so-called alcohol free beer was found to be associated with increased craving (Long and Cohen, 1989), which points toward a beverage-dependent effect besides the "pure" ethanol impact. In the study of Willner *et al.* increased craving after exposure to low-alcohol beer was found in male recreational drinkers, which points toward the importance of gender effects in craving (Willner *et al.*, 2003). In female patients, Willner *et al.* found no effect or decreased craving after consumption of low-alcohol beer. In an investigation of our own study group, we demonstrated that craving is not only associated with alcohol intake. Instead, we found that craving for alcohol also depends on the type of alcoholic beverage consumed. In this recent study, we found that beer consumption, in contrast to wine or spirits consumption, is associated with higher alcohol craving (Hillemacher *et al.*, 2005a). The differences between the consumption of different alcoholic drinks with respect to high and low craving (using a median-split division of the OCDS, obsessive-compulsive drinking scale; $N = 198$) are shown in Figure 19.2.

The findings of this study are in line with other investigations, observing an association between craving and intake of low-alcohol beer (so-called alcohol free beer) in problem drinkers (Long and Cohen, 1989) and in male recreational drinkers (Willner *et al.*, 2003). These results add evidence to the hypothesis that craving as an important factor for relapse in alcoholism may be a special phenomenon in beer drinkers. Alcoholic patients who prefer wine or spirits may have other risk factors leading toward relapse or may mainly suffer from craving dimensions other than obsession and compulsion (Lesch *et al.*, 1997; Geerlings and Lesch, 1999).

A different motivation for consuming beer may help to explain these findings. In contrast to wine or spirits, beer is often used to quench one's thirst. This may cause an additional reward effect on beer consumption apart from the ethanol impact. Reward effects in alcoholism and craving have been described in recent studies (Heinz *et al.*, 2003a). Also, the similarity between alcohol craving and food craving may help to elucidate our findings (Pelchat, 2002). In this context, the orbito-frontal cortex, which is especially implicated in obsessive-compulsive disorders and alcohol craving (Volkow and Fowler, 2000; Pelchat, 2002), may play an important role. In addition to that, different neurobiological factors such as endogenous
Figure 19.2 Differences regarding alcohol craving and consumption of different beverages. *Significant difference comparing low and high alcohol craving (OCDS median-split division) for beer consumption (Mann–Whitney U-test: $Z = -2.8$, $p = 0.004$), not for wine or spirits consumption; OCDS: obsessive-compulsive drinking scale.

opiates that have been described as a factor in food craving and alcohol craving, may contribute to this pathophysiologic model (Buerger *et al.*, 2002; Pelchat, 2002).

One other possible explication of these findings would be associated with the high volume intake in beer drinkers. Especially, beer-drinking patients with alcohol dependence tend to consume high amounts of volume. Therefore, we studied whether the volume intake of alcoholic beverages in general and in comparison to the pure ethanol intake is associated with craving (Hillemacher *et al.*, 2006b). We found that the daily volume intake is significantly associated with craving, independently of the ethanol intake. Of course, these results do not mean that ethanol consumption is not involved in craving but points toward an additional influence of volume intake.

The possible role of volume regulating mechanisms

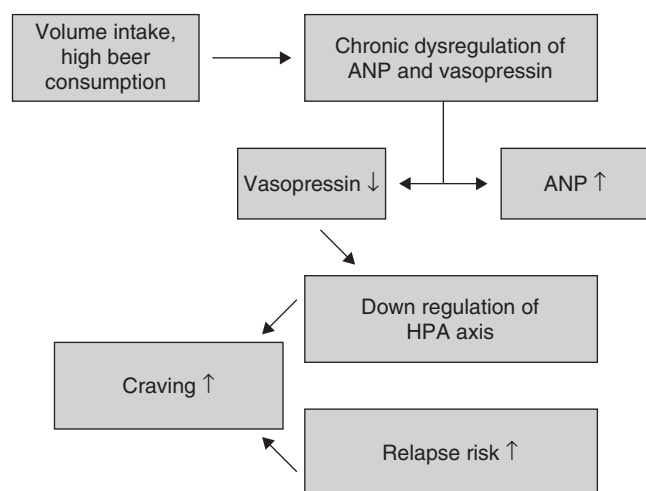
Changes in volume regulation during alcohol intoxication and withdrawal are well known and have been the focus of various studies (Eisenhofer *et al.*, 1985; Trabert *et al.*, 1992;


Figure 19.3 Volume regulating mechanisms.

Table 19.2 Lesch's typology of alcohol dependence

Lesch Type 1	Severe alcohol withdrawals, alcohol to ease withdrawal symptoms
Lesch Type 2	Alcohol consumption as self-medication in patients with comorbid anxiety disorder
Lesch Type 3	Patients using alcohol to treat an underlying mood disorder
Lesch Type 4	Infantile cerebral damage, behavioral disorders

Taivainen *et al.*, 1995; Buerger *et al.*, 2002). Recent investigations have shown that these alterations are persistent after detoxification in long-term abstinent alcoholics (Döring *et al.*, 2003; Jahn *et al.*, 2004). An association between craving and changes in volume regulation has been postulated (van Ree *et al.*, 1994; Döring *et al.*, 2003), but has not been studied in detail until recently.

In numerous studies, neuroendocrinological changes in alcohol dependency have been described (Kiefer and Wiedemann, 2004). We suppose that higher volume intake may lead to higher craving via changes in the vasopressin and atrial natriuretic peptide (ANP) metabolism. In alcohol craving, a role of the vasopressin metabolism and an involvement of the HPA axis has been suggested in different studies (Buerger *et al.*, 2002; Döring *et al.*, 2003; Hillemacher *et al.*, 2005b). The present results suggest that the described findings about the association of beer consumption with craving (Hillemacher *et al.*, 2005a) may be explained by a volume effect, as – evidently – beer consumption is associated with higher volume intake than wine or spirits consumption. This concept has much in common with concepts referring to similarities between alcohol craving and food craving, for example in patients suffering from binge eating disorder. For a schematic illustration of the proposed neurobiological mechanisms see Figure 19.3.

Patients with alcohol dependency can be subtyped not only referring to their consumed beverages but also taking into account other biological and psychosocial factors. In Europe, the Lesch's typology of alcohol dependence is widely used to distinguish different forms of alcohol dependency. The Lesch's typology is a well-established classification taking into account social, mental and somatic factors (Lesch *et al.*, 1990; Lesch and Walter, 1996). The typology differentiates four subtypes: type 1 (model of allergy) is characterized as patients with heavy alcohol detoxifications, who tend to use alcohol to weaken detoxification symptoms. Patients of type 2

(model of anxiety or conflict) use alcohol as self-medication because of anxiolytic effects. In patients of Lesch's type 3 an affective disorder is the main characteristic as origin of alcohol abuse (alcohol as an antidepressant). Instead, Type 4 patients (alcohol as adaptation) show pre-morbid cerebral defects, a high social burden and behavioral disorders.

We used the Lesch's typology to analyze whether the described association between volume intake and alcohol craving is more important in a patients subgroup than in other patients. The results show, that this association is of highest importance in Lesch type 2 patients. If proposing a dysregulation of vasopressin and ANP it is notable that ANP has been discussed to have an anxiolytic activity (Wiedemann *et al.*, 2001; Herrmann-Lingen *et al.*, 2003). Animal studies have proposed an involvement of ANP in fear-motivated learning processes (Bidzseranova *et al.*, 1992). Craving and anxiety have many features in common from a psychopathological point of view. Therefore, especially in patients with comorbid anxiety disorder, a dysfunction of volume regulating mechanisms might be important.

Perspectives

Understanding the neurobiological mechanisms is one important step to develop new and more effective therapeutic strategies for treating alcohol withdrawal and dependency. Homocysteine is increasingly regarded as a risk factor for patients to develop alcohol withdrawal seizures and is also already used in some centers as a biological marker to assess the individual seizure risk. Taking into account that high plasma homocysteine levels are helpful in the prediction of alcohol withdrawal seizures, early anticonvulsive therapy could prevent this severe complication. Prospective intervention studies may show whether the incidence of complications of alcohol withdrawal (e.g. withdrawal seizures) or alcoholism-associated damage (e.g. brain atrophy) can be reduced by therapeutic measures with early lowering of elevated homocysteine levels (e.g. folate administration). Supplementation of folate, a cofactor of the homocysteine catabolism, lowers raised homocysteine levels and therefore could be established as a new therapeutic strategy in alcohol withdrawal treatment. The results of various studies highlight the need for further research to prove whether alcoholics benefit from a reduced homocysteine

level with respect to both, alcohol-related disorders and alcohol withdrawal symptoms.

Regarding craving and relapse prevention, the described new findings show that relapse and craving not only depend on the amount of consumed ethanol but also differs in dependence of the consumed alcoholic beverages. This leads to new perspectives for research regarding the neurobiology of alcohol craving and may help to consider new therapeutic options in the future. Also, it shows that subtyping patients using specific typologies or just distinguishing different consumption patterns may be important to evaluate the efficacy of pharmacological interventions in future trials.

Summary Points

- Beer and other alcoholic beverages have different effect on the cardiovascular risk factor homocysteine.
- Homocysteine levels on admission may be a useful screening method to identify alcoholic patients at risk for withdrawal seizures.
- Alcohol consumption-associated increase of homocysteine provides new approaches for explaining the damaging consequences of dependent drinking.
- Craving in alcohol dependence differs with respect to the amount of consumed beer, wine or spirits.
- The volume regulating endocrinological system may be one important pathway in the neurobiology of alcohol craving due to a dysregulation of vasopressin and ANP.

Beer Composition: An Overview

Stefano Buiatti Department of Food Science, University of Udine, Udine, Italy

Abstract

The word beer comes from the old English *bēor*; but its roots are from late latin *biber* (meaning drink), from *bibere* (to drink) which is the source of English "imbibe" and "beverage" (Encarta World English Dictionary, 1999). Not surprisingly beer is not only the oldest alcoholic beverage but also the most important in terms of amount of volumes produced worldwide. In 2006 nearly 1,700,000,000 hl (one thousand and seven hundred million of hectoliters) of beer were drunk in the world. Hectoliter (hl) is equivalent to 100 l (175.98 UK pints or 211.29 US pints). The amount of wine, the other "historical" alcoholic beverage, produced in the world is about six times smaller (280,000,000 hl). Beers are quite similar in most respects but small differences in their composition can greatly affect both appearance and flavor. Apart from water which normally represents more than 90% of the beer, the only compound present with a concentration greater than 1 g/l are some carbohydrates not fermented by yeast, ethanol, carbon dioxide and glycerol. In spite of this fact beer, is a very complex beverage that contains, besides these compounds, about 800 organic compounds. Many of them have such a low level that only those having a flavor active impact can have a real influence on taste and smell perception. Most chemical compounds in beer were either present in the raw materials (malts, hops and water) or they are by-products of yeast metabolism during the fermentation and are responsible for most of the flavor character that is unique to beer.

List of Abbreviations

ABV	Alcohol by volume
DMS	Dimethyl sulfide
DMSO	Dimethyl-sulfoxide
DP	Degree of polymerization
IBU	International Bitterness Units
kDa	Kilo (thousand) Daltons
MBT	3-methyl-2-butene-1-thiol
SMM	*S*-methyl methionine
VDK	Vicinal diketones

Introduction

Beer is as old as civilization. The origins of beer are lost somewhere in the mists of time but, as one of the world's oldest drinks, it has played an important part in many of the major cultures of the past. It has been known for a long time that Middle East and Egypt were the birthplace of beer and that it can have an important role and contribution to the diet. In the ancient times beer production was strictly related to the baking of bread since they are both made with grain, water and yeast. During 6000 BC in the old cities of Mesopotamia (the area today covered by Iraq) the brewing of beer was well known. Although the great early Middle Eastern civilization did develop brewing to a fine art no one understood how the process of fermentation worked. These beers must have been very different from those we are used today; they probably were thicker, sweeter, lower in alcohol and higher in protein.

Greeks and Romans learned from Egyptians the art of brewing but when wine became the most common drink in the Mediterranean area beer migrated to the north. Throughout the medieval times beer was more than satisfying and warming refreshment, it also provided a safe drink in an age when the purity of water was uncertain and drinks like coffee and tea were unknown. The process of boiling, the antibacterial properties of alcohol and, after they were introduced in fifteenth century, hops kept away the main dangers of infection.

The main constituents of a beer are shown in Table 20.1.

Beer comprises hundreds of different compounds. Some of them are derived from raw materials and pass unchanged through the brewing process, others are produced during the process. Raw materials sources of chemicals in beer are water, malts (and its adjuncts), hops and yeast.

- **Water is quantitatively the main ingredient of beers: it forms more than 90% and often even more than 94% of the final product.**

Not surprisingly its composition is very important and of critical concern to the brewer. Any water that will end

Table 20.1 Composition of beer

Substances	Concentration	Number of compounds	Source or agent
Water	90–94%	1	–
Ethanol	3–5% v/v	1	Yeast, malt
Carbohydrates	1–6% w/v	~100	Malt
Carbon dioxide	3.5–4.5 g/l	1	Yeast, malt
Inorganic salts	500–4,000 mg/l	~25	Water, malt
Total nitrogen content	300–1,000 mg/l	~100	Yeast, malt
Organic acids	50–250 mg/l	~200	Yeast, malt
Higher alcohols	100–300 mg/l	80	Yeast, malt
Aldehydes	30–40 mg/l	~50	Yeast, hops
Esters	25–40 mg/l	~150	Yeast, malt, hops
Sulfur compounds	1–10 mg/l	~40	Yeast, malt, hops
Hop derivates	20–60 mg/l	>100	Hops
Vitamin B compounds	5.0–10 mg/l	13	Yeast, malt

Source: Modified from Hardwick (1995).

up in the bottle of beer must be of the highest chemical and microbiological quality. The water must fulfill all legal requirements both chemically and microbiologically as well as satisfy the brewer's standards for clarity, taste, smell and lack of color. Breweries need vast amount of water; for every liter of beer produced, at least five more are required for cleaning, cooling and heating. In some cases brewery might use as much as 20 times more water (Bamforth, 2003).

The mineral content of brewing water has a very large effect on the properties of beer and gives an important contribution to the flavor of the finished product. A wide range of brewing waters ("liquor" is the name given in breweries to the water used for brewing) is employed, giving rise to many classic styles of beers that over the centuries have become very famous. Certain mineral salts were identified in natural water supplies from various locations which produced superior beers of a particular type. Perhaps the best known brewing liquor is that of Burton-on-Trent, a town that became famous for its full flavored and excellent pale ales. This liquor is high in permanent hardness because of the high calcium sulfate (gypsum) content but it also has a lot of temporary hardness due to the high level of bicarbonate. Liquor treatment is the practice of adding or removing mineral salts, to give the brewing liquor properties similar to the most suitable natural supplies. For example, brewers in other parts of the country, with less suitable water supplies, were able to adjust the composition of their supplies to make them the same; the practice became known as Burtonisation. A good water source was a particular key requirement for the earliest breweries. Many of the great brewing towns sprang up around a good liquor supply. At one time most breweries had their own supply which varied

little in its mineral content and a liquor treatment could be done to suit the supply. At present, where a brewery is taking its supply from a water authority, water can be taken from several sources which are changed according to the demand of the customers and availability from the sources. Water supplied one day could be quite different in its mineral content the day after; some brewers find this problem so great that they remove all salts from the water and add what they require rather than try to adjust the amounts which are naturally present from day to day. Natural water supplies all contain some salts which are dissolved from the geological strata through which they have to pass. Besides Burton-on-Trent, other towns are famous for their waters: Munich, in Germany, has water poor in sulfates and chloride but contains bicarbonates, which are not very suitable for pale beers but ideal to produce darker, smoother lagers. The carbonates raise the pH during the mashing, producing a wort with a higher dextrin to maltose ratio. The water from Vienna (Austria) is more mineralized than that from Munich. The Bohemian Czech town of Plzen (Pilsen in German), where this famous classic style was first produced in 1842, has very soft water and produces beers renowned for their complex character with a flowery hop aroma and a dry finish. The water of Dortmund (Germany) contains noticeable amounts of both bicarbonate and chloride that aid in the production of full-bodied, malty lagers which are less aromatic than a Pilsner. The principal ions present in most brewing liquors are calcium, magnesium, sodium, potassium, sulfate, chloride, bicarbonate, carbonate and nitrate. Other elements are present but only in small amounts and are known as trace elements. It should be mentioned that brewing materials are also a source of some of these ions; most of the magnesium, potassium and phosphate in wort come from this source (Goldammer, 1999; Warnakulasuriya *et al.*, 2002)

- **Inorganic salts found in beer (Table 20.2) come from brewing water and/or malt and may have positive or negative effect on beer quality depending on their concentration and nature.**

Some ions may be precipitated during the brewing process on the break and others may be absorbed by the yeast; that means the inorganic salts present in beer are very different from those present in the brewing water used. The presence of some minerals (e.g. iron) is avoided by brewers because it can have a negative action as pro-oxidant and so accelerating the beer staling. On the other hand iron has been used as foam stabilizer but its addition to beer is not very common. Trace amounts of many metals are essential for yeast growth whereas larger amounts can be toxic and/or limited by regulations. When specific limit for beer is not indicated the limits for potable beer are usually applied. Beer is cited as being an important dietary source of selenium and the high potassium:sodium ratio (4:1) is consistent with a low sodium diet. Yeast is a source of a

Table 20.2 Inorganic compounds in beer

Inorganic compounds	Concentration (mg/l)	Inorganic compounds	Concentration (mg/l)
Potassium	200–450	Fluoride	0.08–0.71
Sodium	20–350	Hydrogen	0.2–0.3
Calcium	25–120	Iron	0.01–0.3
Magnesium	50–90	Lead	<0.01–0.1
Chloride	120–500	Manganese	0.03–0.2
Sulfate	100–430	Mercury	Negligible
Oxalate	5–30	Nickel	0.03–0.2
Phosphate	170–600	Nitrite	0–2
Nitrate	13–43	Nitrogen	1–14
Aluminum	0.1–2	Oxygen	0.4–4
Arsenic	0.02–0.05	Phosphorus	90–400
Bromine	0.2–0.4	Silica	10.2–22.4
Cadmium	0.03–0.68	Selenium	Negligible
Chromium	<0.04	Tin	0.01–0.02
Cobalt	0.01–0.11	Vanadium	0.03–0.15
Copper	0.01–1.55	Zinc	0.01–1.48

Source: Baxter and Hughes (2001) and Briggs *et al*. (2004).

chromium-containing complex (the so-called glucose tolerance factor) which may play an important role in the regulation of body glucose levels. Iron, tin, lead and zinc were found in beer at higher than minimal concentrations in three-piece tin plate cans that have soldered side seam. Three-piece welded cans are generally welded with a copper-based metal that can cause an increase in copper concentrations in beer. The UK Food Standard Committee recommends a limit for copper in beer of 7.0 mg/kg. In the 1960, cobalt was added to beer as foam enhancer and to prevent gushing but was found to cause heart diseases in heavy drinkers (more than 20 pints/day) and since then no brewer is employing cobalt as foam stabilizer (Hardwick, 1995; Briggs *et al.*, 2004)

- **Beer is mainly rich in magnesium, potassium, sodium and calcium (cations) and chloride, sulfate, nitrate and phosphate (anions).**

Calcium (Ca^{2+})

This ion is by far the most influential mineral in the brewing process because they affect the acidity of the wort; it can react with phosphates in the malt and can form primary, secondary or tertiary phosphates. The secondary phosphate is weakly soluble and the tertiary phosphate is not soluble at all. The more calcium present in the wort the more tertiary phosphate is produced which is accompanied by a release of hydrogen ions making the wort more acidic.

$$3Ca^{2+} + 2(HPO_4)^{2-} \rightarrow 2H^+ + Ca_3(PO_4)_2$$
The lowering of the pH is critical because it provides an ideal environment for α- and β-amylase, proteolytic enzymes. This in turn will increase saccharification and proteolysis, leading to an increase in extract yield and a rise in soluble nitrogen. The lowering of the pH may sufficiently reduce wort viscosity for faster filtration. Moreover, polyphenols (so-called tannins) are extracted to a lesser degree at a lower pH, resulting in less astringent beers with less color. Calcium during wort filtration aids rapid, bright filtration which diminishes the extraction of astringent and coloring substances. During boiling process calcium ions are essential to have a good break formation as it aids in the precipitation of proteins and other substances which might otherwise cause beer haze formation. Calcium enhances yeast flocculation and sedimentation during the primary fermentation and, during maturation, improves clarification, stability and flavor in the final product. Calcium ions initiate the precipitation of oxalate derived from malt which continues to precipitate during the brewing process. When these ions are not sufficient oxalate precipitation might be delayed and, in some cases, causes haze and foam problems in the finished beer. Usually a 4:1 ratio Ca:oxalate is recommended but some brewers advocate 10:1 ratio to prevent haze formation. Too much calcium, however, can lead to an intense precipitation of phosphates causing a wort poor of a vital yeast nutrient. High calcium content also tends to diminish the extraction of hop resins and delay the isomerization of α-acids.

Carbonate (CO_3)$^{2-}$ and Bicarbonate (HCO_3)$^{1-}$

These are not desiderable as they take up hydrogen ions (H^+) from the wort to produce water and carbon dioxide (CO_2). The decrease in acidity (higher pH) is not welcomed. When calcium bicarbonate is present in water producing temporary hardness the detrimental effects of the bicarbonate ions outweigh the beneficial effects of the calcium ions.

$$CaCO_3 \xrightarrow{Ca^{++}} (CO_3)^{2-} \xrightarrow{H^+} (HCO_3)^{1-} \xrightarrow{H^+} H_2O + CO_2$$
Alkalinity is a measure of the buffering capacity of the bicarbonate ions and, to a some extent, the carbonate and hydroxide ions of water. These three ions all react with hydrogen ions to reduce acidity and raise pH. Alkalinity is normally given in mg/l (mg/l) as calcium carbonate ($CaCO_3$) for all three ions. Usually water with more than 100 mg/l of calcium carbonate is considered alkaline and should be treated. Water with less than 100 mg/l of calcium carbonate is considered soft or just slightly alkaline. The pH raise caused by carbonate hardness opposes the pH lowering effect coming from other calcium and magnesium ions present as calcium chloride, calcium sulfate, magnesium chloride and magnesium sulfate. The bicarbonate ion is a very strong buffer and because of that

water with a high buffering capacity or alkalinity tends to have a pH very stable, even when bases or acids are added to it (Moll, 1995)

Total water hardness is the measure of the bicarbonate, calcium and magnesium ions present in the water and is measured in two ways: temporary and permanent. Temporary hardness is always strongly alkaline and permanent hardness is only weakly acidic. Total hardness is the combined effect of the two measurements.

The effect of carbonate ions in raising pH can give less fermentable worts due to a higher dextrin/maltose ratio, slow wort filtration and less efficient separation of protein–polyphenol compounds during the hot and cold breaks (indicated with the German word *trub* meaning turbid). Moreover high carbonate concentration can have a negative influence on hop flavor while hop bitterness becomes harsher. Usually carbonate concentration should not exceed 50 mg/l to avoid harsh and bitter flavors. Carbonate in excess of 200 mg/l is acceptable only when a dark roasted malt is used to buffer its excessive acidity.

Magnesium (Mg^{2+})

It has similar properties to calcium ions and also reacts with phosphates in the malt but the phosphates produced are more soluble. Thus fewer hydrogen ions are released and the increase in acidity is therefore less. Magnesium ions are important for the yeast metabolism being required in very small amounts as an enzyme cofactor. Usually, malt and water contain sufficient magnesium to supply the required amount. They can also impart a sour or bitter astringency to the beer in concentration over 15 mg/l.

Sodium (Na^+)

At low concentration it influences sweetness and smoothness (levels from 70 to 150 mg/l) which is most pleasant when paired with chloride ions than when associated with sulfate ions. Higher concentrations give a salty and unpleasant taste. When sodium sulfate is present in the brewing liquor the combined effect of the ions on the beer is an unpleasant harshness and sour taste; 150 mg/l is considered the upper limit of this salt for brewing water. In some, breweries is preferred adding potassium chloride rather than sodium chloride as potassium is free from the slightly sour flavor given by the sodium ion. However when sodium chloride is added at the correct concentration palate fullness is produced.

Potassium (K^+)

It has similar properties to sodium ions but does not give beer the sourness that sodium ions do. If chloride ions need adding in a water treatment potassium chloride is therefore often used in preference to sodium chloride. It is required for yeast metabolism and above 10 mg/l inhibits some mash enzymes and makes beers laxative. However, its concentration is rarely high enough to have any effect on beer flavor.

Sulfate ($SO_4)^{2-}$

This ion has a positive effect on starch and protein degradation which favor wort filtration and *trub* sedimentation. It can give a dry, crisp palate to beer and increase the perceived bitterness but if in excess, the final product may have a harsh, salty and laxative character. Light ales bitters and even mild ales benefit from the presence of sulfate in brewing water.

Chloride (Cl^-)

Calcium and magnesium chloride give sweetness, body, fullness to beers. Sodium chloride (common table salt) adds a certain roundness on the palate and this makes the salt suited for all types of sweet beers (e.g. Scotch Ales) and both dark beers and stouts. Concentrations of sodium chloride above 400 mg/l give to pale beers a pasty flavor and above 500 mg/l chloride has a negative effect on yeast metabolism and leads to poor clarification and a flat taste.

Nitrates ($NO_3)^{1-}$ and Nitrites ($NO_2)^{1-}$

Nitrate in itself is not a problem. The nitrate concentration in beer is usually below the legal limit of 50 mg/l for drinking water and is harmless. However nitrate can be converted to nitrite which is harmful to health. Moreover high nitrite levels may slow the fermentation rate and cause an increase of vicinal diketones (VDK) levels in beer. It has been reported that nitrite can cause gushing when it reacts with amino acids.

Trace Elements

Iron (Fe^{2+})

Iron salts above 0.2 mg/l can have a negative effect slowing the saccharification, resulting in hazy worts and reduced yeast activity. If its concentration is above 0.3 mg/l causes grayish foam and an increase in color and with more than 1 mg/l iron weakens yeast, increases haze problems and oxidation of tannins.

Copper (Cu^{2+})

This ion in concentration as low as 0.1 mg/l has an effect of catalyst of oxidants causing beer haze formation. When its concentration is above 10 mg/l copper becomes toxic to yeast.

Zinc (Zn^{2+})

Zinc has an important role in yeast metabolism and fermentation process with a positive action on protein synthesis and yeast growth. A zinc level between 0.08 and 0.2 mg/l is recommended to have positive effects on fermentation while zinc content above 0.6 mg/l can vice versa affect negatively fermentation and colloidal stability of beer. More than 1 mg/l zinc is toxic to yeast cells and inhibits enzymes. Like iron, zinc can give a metallic taste if present with too high concentrations.

Manganese (Mn^{2+})

Manganese has an important role as enzyme cofactor and a positive action on protein solubilization. This ion can inhibit yeast metabolism and affect negatively colloidal stability of beer. The manganese level should be from 0.1 to 0.2 mg/l in wort and in any case not more than 0.5 mg/l.

- **Malt is the germinated and dried barley and it is the grist component of more than 90% of beer produced in the world.**

The cultivated barley (*Hordeum vulgare*) belongs to the grass family (*Gramineae*). On average to produce 1 hl of beer 15–20 kg of malt are used. This raw material is the primary source of the protein, lipid, carbohydrate, polyphenols compounds present in beers. Most malt components are changed during mashing; protein degradation, for example, to peptones and peptides started during germination goes on in the mash vessel. Even if these composition changes are not really great they are significant and important to obtain a regular fermentation for the yeast growth and for the development and synthesis of flavor compounds that will be formed throughout the brewing process.

- **Substances different from barley malt which provide fermentable carbohydrates in addition to those from malt are known as adjuncts.**

Adjuncts are used to replace malt not only for economic reasons, being usually cheaper than barley malt, but also to modify the flavor. Thus, the resulting beers may have a lighter flavor and a less satiating impact (especially when sugars, as adjuncts, have been added) or an increased flavor depending on the adjunct (e.g. roasted raw barley) added to barley malt. These adjuncts are primarily cereals such as corn (maize), rice, wheat, rye, sorghum used as sources of starch. Also invert sugar (hydrolyzed cane or beet sugar) glucose syrups (derived from maize starch) or other cereal syrups are adjuncts. The starch coming from the cereals, once gelatinized, is hydrolyzed by malt enzymes in the same manner as malt starch. These adjuncts can be used as grits, flakes or torrefied products. Classification and substances which can be legally used vary from country to country and from time to time the lists and amounts permitted adjuncts change.

- **Barley malt and adjuncts are the sources of several constituents present in beer such as, nitrogenous compounds, lipids, carbohydrates and vitamins.**

Nitrogenous compounds: Nitrogenous compounds in beer are in the range of 0.3–1.0 g/l (equivalent to 0.11–0.63% protein multiplying by the conversion factor 6.3) and comprise amino acids, peptides and polypeptides, nucleic acid fragments, amines and heterocyclic compounds. Some strong beers (particularly the not filtered ones) can contain up to nearly 2,000 mg/l of total nitrogen equivalent to 1.26% protein; 80–85% of these nitrogen components are derived from the malt (10–15% are from the yeast). The total nitrogen content multiplied by the factor 6.25 is often expressed as "protein." It is suggested that peptides may contain up to 10 amino acids, polypeptides from 11 to 100 amino acids residues and proteins more than 100 amino acids. However Bamforth suggests that the term protein should be used only for undegraded molecules. On this basis only few proteins are still present in the finished product and most of the nitrogen as polypeptides (Briggs *et al.*, 2004).

During mashing, proteins and peptides in malt are broken down to amino acids thereby continuing the enzymatic degradation started during malting operations. As a consequence the level of nitrogenous compounds that will be available to the yeast later in fermentation is increased. Most of these amino acids will be used by the yeast for its multiplication, apart from proline which is not utilized by yeast in anaerobic conditions and carried out through the beer. The amino compounds found in beer are almost exclusively nitrogenous compounds that were not utilized by the yeast. Some wort amino acids are metabolized by yeast to form higher alcohols (or fusel alcohols) which are important flavor compounds in beer. In fact deamination and transamination reactions carried out by the yeast cell are responsible for the presence of several organic acids, aldehydes, alcohols and esters in beer; most of them are cast-out carbon skeleton of amino acids which were in wort. As already known malt contains different peptides and polypeptides which increase during mashing due to proteolytic enzyme action degrading malt protein and other complex polypeptides to smaller compounds. Some of these smaller units can be metabolized by yeast while the larger, more complex polypeptides, made up of hundreds of amino acids, are still soluble in beer. These compounds can give an important contribution to foam stability and to the mouthfeel of beer. The biggest polypeptides and the undegraded proteins will precipitate and eliminate during the brewing process.

Purines and pyrimidines as well as nucleotides and nucleosides are present in beer as degradation products of nucleic acids which took place during malting and mashing. Their concentration is included between 0.2 and 139 μg/ml and

guanosine, uridine and cytosine are the major constituents. Other nitrogenous constituents of beer are choline, tryptophol and nicotinic acid which are a B vitamin, essential for human growth.

Other nitrogenous constituents are the heterocyclic compounds originated mainly from the Maillard reaction which took place during the malt kilning. Above 80°C the reducing sugars and amino acids can react to form a great group of compounds referred generically as Maillard reaction products, which are coloring and with a strong flavor. The intermediate compounds called Amadori rearrangements products will decompose to various chemicals such as 2-acetylfuran and other compound carrying the furan ring. Substitution of nitrogen or sulfur into the furan ring structure results in the formation of pyridines, pyrrolizines, pyrroles, maltoxazines, thiazolines, thiazoles and thiophenes; other heterocyclic compounds are the pyrazines, alkyl-substituted pyrazines, furyl pyrazines and cyclopentapyrazines responsible for a nutty, toffee, green wood, burnt, roasted odors. These compounds have a concentration between 2 and 400 mg/l. Biogenic amines are also present in beer and polyamines that, at low concentrations found in beer, do not have a very significant influence on the flavor of beer. Dimethylamine is the major component of this class; tyramine, obtained from the decarboxylation of tyrosine, has been detected in beer. People under treatment with monoamine oxidase inhibitors (antidepressant) do not have to drink due to the build up of toxic levels of tyramine. Even ethyl carbamate (urethane), which is reported to be carcinogenic, has been detected in many fermented and spirits beverages, but according to Canas *et al.* (1989) could be found only in few beers. Secondary amines, such as dimethylamine, can react with oxides of nitrogen to form carcinogenic *N*-nitrosamines. Some of these compounds have been detected in beers and after several studies it was finally found that the nitrosamines were formed during the direct fired kilning of malts (e.g. as in the German *Rauchmalz*, smoked malt); the oxides of nitrogen (NO_X) react with amines such as hordenine to form nitrosamine. Since then (mid-1970s) the level of these compounds has been strongly reduced and today the level set by the American Food and Drug Administration is not more than 5 μg/l of *N*-nitrosodimethylamine in beer.

Lipids: Lipids in beer come mainly from barley malt and are fatty acids, diglyceraldehydes and triglyceraldehydes. In fact barley contains approximately 3% w/w lipid, present in the living tissues (embryo and aleurone layer) but only very little is still present in the final product making this beverage basically a fat-free food, beers in fact contain trace amounts of lipids. The concentration of the lipids is very low, less than 0.1%, and the yeast metabolism can affect the presence of these compounds and modify them. The effect of lipids is negative for the shelf life of beers and particularly a fatty aldehyde, the *trans*-2-nonenal, is a very flavor potent compound, detectable in beer at less

Table 20.3 Unfermented carbohydrates in beer

Carbohydrates	Concentration (g/l)
Fructose	0–0.19
Glucose	0.04–1.1
Sucrose	0–3.3[a]
Maltose	0.7–3.0
Maltotriose	0.4–3.4

[a] Higher levels in primed beers.

Source: Baxter and Hughes (2001).

than 1 μg/l. This aldehyde is considered responsible for the cardboard flavor in stale beer. However, most of these compounds are eliminated during the brewing process in different ways, by the spent grain and hot *trub* after the whirlpool and by the filtration at final beer clarification. The concentration of free fatty acids, very low at the beginning of the process, decreases further on during the brewing process. Particularly during fermentation it has been observed that there is an increase in C8 to C10 and a considerable decrease in C12 to C18:3 as consequence of yeast metabolism. The concentration of total fatty acids in finished beers is about 15–30 mg/l and the most abundant are C4–C10 (Bamforth, 2002).

Carbohydrates: Carbohydrates present in beer are showed in Table 20.3.

Obviously most of the sugar in wort is fermented to ethanol by yeast but some carbohydrates are still present at the end of the process and their content is estimated for a range of beer values between about 1.0% and 6.0%. The sugars found in beer range from the simple unit, such as glucose, to molecules having more than 250 glucose units (M_r~45 kDa). In fact the carbohydrates surviving into beer from wort are the non-fermentable dextrins or α-glucans (90%), remnants of enzymatic starch hydrolysis and some polysaccharides compounds (10%) coming from cell walls, in starchy endosperm of barley kernel. In general beers will contain only low levels of fermentable sugars other than those added to sweeten the final product (primings). The dextrins are formed by many glucose units and their number is expressed by the degree of polymerization (DP); the 72.4% of dextrins range from a DP 4 to DP 34 while higher dextrins (DP > 35) are 15.2%. The surviving β-glucans in beer can have a positive influence on beer smoothness and foam retention, however it is important that the concentration of β-glucans in the final beer is not too high because it can cause a "soupy" effect and mouth filling flavor will linger in the mouth and the beer is no longer sharp and fresh.

Carbohydrates are the major components of the residual unfermented solids present in beer which is named "real extract"; it is a measure of the total dissolved solids in beer and consists approximately of 75–80% carbohydrates, mainly dextrins, 6–9% nitrogenous compounds, 4–5% glycerol and

Table 20.4 Vitamin B compounds in beer

Vitamin B compounds	Concentration (mg/l)
Aminobenzoic acid	0.01–0.15
Biotin (B$_8$)	<0.015
Ethyl nicotinoate	<1.5
Folic acid (B$_9$)	0.04–0.6
Methylbutylnicotinoate	<0.01
Methyl nicotinoate	<0.01
Nicotinic acid, niacin (B$_3$)	0.3–5
Phenylethylnicotinoate	<0.01
Pyridoxine (B$_6$)	0.07–1.7
Riboflavin (B$_2$)	0.02–0.1
Pantothenic acid (B$_5$)	0.04–2
Thiamin (B$_1$)	0.08
Cyanocobalamin (B$_{12}$)	<0.03

Source: Modified from Hardwick (1995).

β-glucans, inorganic compounds, phenolic compounds and bitter substances and other compounds which, despite their low concentration, can have an important effect on the sensorial properties and quality of final beer.

Vitamins: Barley and malt are rich sources of several vitamins that, being present in the embryo and aleurone layer, are solubilized into wort during the brewing process. Their importance to the brewing process depends on their content in wort, more than sufficient to ensure a regular yeast performance during fermentation. In particular the B-group vitamins are crucial as growth factor for yeast, especially biotin, inositol and panthotenic acid. This is why beer contains considerably lower levels of these vitamins than does wort.

Some vitamins are present in the malt in bound forms and released during mashing by enzymes. Riboflavin, panthotenic acid and pyridoxine increase during malting, as it happens to ascorbic acid, which is later on completely destroyed by high temperature during kilning. Beer contains (see Table 20.4) small amounts of vitamins of the B-group and for this reason are considered as a valuable source of many of the water-soluble vitamins (particularly folate, riboflavin, panthotenic acid, pyridoxine and niacin). The fat-soluble vitamins do not survive into beer and are lost during the brewing process with insoluble compounds (spent grain, *trub* and yeast). Some beers may contain ascorbic acid (Vitamin C) because it can be added as antioxidant.

- **Yeast is responsible for the fermentation process and has a fundamental impact on the quality of beer. Most breweries use carefully selected strain which are stored and grown to be used within the brewery.**

Yeast (unicellular *fungi*) is the most important microorganism responsible of fermented beverages production. The yeast is used by the brewer several times (usually four to six times) and taken from one fermentation to start the next.

The pitching rates most often used are between 10 and 25 million cells/ml. As a rule of thumb the pitching rate is 1 million viable cells per Plato degree per ml of wort. For example, a 13°P wort would require 13×10^6 cells/ml.

1 Plato degree equates to 1 g sucrose per 100 g water. So, if wort has a specific gravity of 12° Plato, it has the same specific gravity as a 12% solution of sucrose.

Many large and small breweries use several strains of *S. cerevisiae* and/or *S. carlsbergensis* (*S. uvarum*) to produce different beers. The brewer knows very well that the properties of the beer produced depend very much on yeast used. It plays a fundamental role in the synthesis and formation of several compounds found in beers. As yeast grows and metabolizes during fermentation almost all carbohydrates (hexoses, disaccharides and trisaccharides) are converted to ethanol and carbon dioxide. Yeast cell uses some organic carbon skeletons from glycolysis to form new cell substances; there is a combination of these fragments with amino groups from degraded malt proteins to form new amino acids, proteins and nucleic acids. Many other compounds are modified and a lot of yeast-produced compounds in beer are metabolic by-products which are eliminated by the yeast cell. Moreover the yeast enzymes may modify other compounds through reduction, oxidation and esterification reactions forming organic acids, esters and alcohols. The total amount of these compounds expressed as percentage is quite low, less than 1% (not considering ethanol production) but nevertheless they number in the hundreds and they play an important role on the flavor, aroma and final quality of the beer.

- **The properties of the beer depend very much on the yeast used. It produces not only ethanol and carbon dioxide but even other compounds (higher alcohols, organic acids, esters, aldehydes, ketones, sulfur compounds) which play a key role on the sensorial profile of beer.**

Ethyl alcohol (*ethanol*): It is the most important alcohol in beer and its concentration range on average from 30 to 50 g/l (3–5% w/v). However many different beer styles can contain much less (e.g. free alcohol beers and light beers) or much more alcohol (e.g. stronger beers such as Belgian Trappists or Barley wine or German Doppelbocks). It seems that the strongest beer in the world is the American Utopias MM II, brewed in Boston, and with an alcohol content of 25.6% alcohol by volume (ABV). The strength of beer and other alcoholic drinks is expressed in United States as alcohol by weight and in EU as ABV. Since alcohol has a lower specific gravity than beer its concentration expressed "by volume" gives a larger number. The specific gravity of alcohol and beer are respectively and approximately 0.8 and 1 and this means 4% alcohol by weight (w/w) is equal to 5% ABV (v/v). In other words, the percentage of alcohol by weight figure is approximately 20% lower than the ABV figure because alcohol weighs less than its

equivalent volume of water (alcohol by weight/0.8 = ABV; ABV × 0.8 = alcohol by weight). Aqueous solutions of ethanol cause a warming sensation in the mouth and, after swallowing, it continues in the throat and into the stomach. Ethanol is a flavor enhancer and also increases sweetness in beer.

Other alcohols: Besides ethanol beer contains several alcohols which are derived mainly from yeast metabolism and from hops and malts (see Table 20.5). Alcohols which are derived by yeast metabolism are formed during fermentation. These compounds, so-called higher alcohols as they have a larger molecular weight, are referred to as fusel oils and in large quantities can cause headaches, hangovers and general discomfort that follow excessive beer consumption. Higher alcohol content is about 60–100 mg/l but concentrations above 100 mg/l can negatively affect the flavor of beer (Lewis and Young, 1995).

Larger amounts of these alcohols are correlated to high alcohol content in the product, whereas beers with low alcohol content contain less higher alcohols and may be considered more agreeable with a better drinkability. These alcohols are produced by the yeast removing amino groups from the amino acids and replacing them with the —OH group of the alcohols; the concentration of amino acids content is therefore very important and plays a fundamental role in fusel oils synthesis. The main higher alcohols present in beer are 3-methylbutanol (isoamylalcohol), 2-methylbutanol (active-amyl alcohol), 2-methylpropanol (isobutyl alcohol), propanol (propyl alcohol) and β-phenylethanol (phenetyl alcohol). Smaller number of primarily phenolic alcohols is derived from the breakdown of malt and hops polyphenols and can contribute to beer texture in the mouth (mouthfeel) and to harshness. Many hop-derived alcohols give a positive flavor. Floral aromas from some of these contribute to the pleasing aroma of beer.

Glycerol is an important compound, classified as alcohol, and originated during fermentation as a product of yeast carbohydrate metabolism. The interest for this compound comes from the relationship between carbohydrate level, yields of glycerol and ethanol: the latter decrease in proportion to the amount of carbohydrate used to produce glycerol and other fermentation by-products. Its content in beers is 1.5–3.5 g/l, glycerol plays an important role on the beer taste enhancing smoothness and mouthfeel.

Carbon dioxide: During the fermentation, chemical conversion of fermentable sugars in the wort, approximately equal parts of ethanol and carbon dioxide gas, are formed through the action of yeast. The final product contains 3.5–4.5 g/l (0.35–0.45%) of carbon dioxide but oversaturated beers and bottle conditioned beers may contain as much as 6 g/l but gas will be lost as soon as the container is open and the pressure released. The sensory threshold of carbon dioxide is about 1 g/l so the amount present will have an effect on the flavor of beer. The carbon dioxide is responsible of the extent of foam formation and influences the delivery of volatiles into the headspace of beers.

Organic acids: Most beers range on average in pH from about 4 to 5, so beer is a beverage slightly acidic. Other beers (e.g. Lambic) have a pH much lower, around 3.0. Organic acids and carbonic acid (dissolved CO_2 in beer) are responsible for this acidity. These acids are basically all metabolic by-products or intermediates excreted by yeast cells. The total amount is very low and range from 0.2 to 0.5 g/l (see Table 20.6).

These acids, in concert with carbonic acid which also provides the "tingle" in beer, are responsible for the pleasurable sensation of tartness. The most abundant is the acetic (ethanoic) acid (~30–200 mg/l) followed by lactic and succinic acids (respectively about 60–120 and 20–140 mg/l). In some Belgian "acid" beers (such as lambic and gueuze), however, the amount of lactic and acetic acids can be much higher, even more than 1 g/l for acetic acid and 3 g/l for lactic acid. Most of the acids are of yeast origin or, more precisely, they are yeast waste products. The organic acids are formed mainly from the amino acids present in wort: yeast uses the amino group —NH_2, removed from the amino acid, because it needs to synthesize its own proteins releasing the corresponding organic acid formed by this deamination into the beer.

The aliphatic acids with short to middle carbon chain length have distinctive and familiar odors; caprylic and capric acids can be responsible for aromas in beer described as "cheesy" or "goaty" but generally are not at concentrations high enough to negatively affect the beer flavor.

Most of the phenolic acids present in beer are extracted from malt but small amounts can come from hops and adjuncts. Phenolic acids contribute to astringency which is essential to characteristic beer flavor and probably the different chemical structure of these phenolic acids gives variety to this astringency in beer; however when it is too high is not pleasant.

Table 20.5 Some alcohols commonly present in beer

Alcohols	Concentration (mg/l)	Flavor descriptors
Ethanol	20,000–80,000	Alcoholic, strong
Methanol	0.5–3.0	Alcoholic, solvent
1-Propanol	3–16	Alcoholic
2-Propanol	3–6	Alcoholic
2-Methylbutanol	8–30	Alcoholic, vinous, banana
3-Methylbutanol	30–70	Alcoholic, vinous, banana
2-Phenylethanol	8–35	Roses, bitter, perfumed
1-Octen-3-ol	0.03	Fresh-cut grass, perfume
2-Decanol	0.005	Coconut, aniseed
Glycerol	1,200–2,000	Sweetish, viscous
Tyrosol	3–40	Bitter, chemical

Source: Baxter and Hughes (2001).

Table 20.6   Important organic acids in beer

Acids	Concentration (mg/l)	Flavor descriptors
Acetic	30–200	Acid, vinegar
Propanoic	1–5	Acid, vinegar
Butanoic	0.5–1.5	Butter, cheese, sweat
2-Methylpropanoic	0.1–2	Sweet, bitter, sour
Pentanoic	0.03–0.1	Sweat, body odor
2-Methylbutanoic	0.1–0.5	Cheese, old hops, sweat
3-Methylbutanoic	0.1–2	–
Octanoic	2–12	Caprylic, goaty
Lactic	20–80	Acid
Pyruvic	15–150	Acid, salt, forage
Succinic	16–140	–
Phenolic acids		
Caffeic	1–10	Bitter, harsh, sour, diacetyl
Chlorogenic	1–10	Bitter, harsh, bitter–sweet, astringent
Cinnamic	0.5	
p-Courmaric	0.1–0.2	Sour, dry, bitter, astringent, medicinal
Ellagic	1–10	
Ferulic	1.1–6	Bitter–sweet, sour, vanilla, malty
Gallic	1–5	Bitter, harsh, astringent, dry, sour, sweet
Hydroxybenzoic	0.13	Bitter, harsh, astringent, acidic, vinegar
Isochlorogenic	1–10	
Salicylic	0.02–5	
Sinapic	1–10	Bitter, astringent, harsh, sour, dry
Syringic	1–10	Bitter, harsh, astringent, winey, malty
Vanillic	1–10	Harsh, bitter–sweet, sour, astringent, peppery, medicinal

Table 20.7   The most important esters in beer

Esters	Concentration (mg/l)	Flavor descriptors
Ethyl acetate	10–60	Solvent-like, sweet
Isoamyl aceta te	0.5–5.0	Banana, ester, solvent
Ethyl hexanoate	0.1–0.5	Apple, fruity, sweet
Ethyl octanoate	0.1–1.5	Apple, tropical fruit, sweet
2-Phenylethyl acetate	0.05–2.0	Roses, honey, apple, sweet
Ethyl nicotinate	1.0–1.5	Grainy, perfume

Source: Baxter and Hughes (2001).

Esters: All alcohols and acids present in beer are theoretically capable of esterification reaction, potentially forming almost 4,000 esters. In beers many esters have been detected (60–80 mg/l) but since the main alcohol is ethanol, ethyl acetate is by far the most common ester found; its concentration is larger than expected from the equilibrium constant of the reaction between acetic acid and ethanol (see Table 20.7).

This shows the important role played by the yeast in the biosynthesis of esters. Ethyl esters are the most abundant in beer but the acetates (ethanoate) of the higher alcohols are also important (e.g. isoamylacetate, the so-called "banana" ester) and common as are ethyl esters of long-chain fatty acid (caproic and caprylic). The esters in beer contribute several pleasing fruit-like and floral aromas, however wild yeast such as *Hansenula* and *Pichia* produce high quantities of ethyl acetate that may be considered as off-flavors. Yeast strain can influence both the quantity and type of ester produced in beer and an abnormal increase in ethyl acetate is caused by worts with a high sugar concentration. Although some increase in the concentration of ethyl esters takes place also during the beer shelf life (Fix, 2000).

Aldehydes: Aldehydes are derived from alcohols through dehydrogenation (oxidation) (Rabin and Forget, 1998). They contain the radical —CHO and their content in beer is around 10–20 mg/l (see Table 20.8).

Several of the aldehydes are of the yeast origin and others are the result of Strecker degradation of amino acids during kettle boil and still others appear to be the result of a random decarboxylation of organic acids. Acetaldehyde (ethanal) is the most common aldehyde in beer and is

Table 20.8   Important aldehydes in beer

Aldehydes	Concentration (mg/l)	Flavor descriptors
Acetaldehyde	2–20	Green, paint
Propanal	0.01–0.3	Green, fruity
Butanal	0.03–0.02	Melon, varnish
trans-2-Butenal	0.003–0.02	Apple, almond
2-Methylpropanal	0.02–0.5	Banana, melon
C_5 Aldehydes	0.01–0.3	Grass, apple, cheese
Hexanal	0.003–0.07	Bitter, vinous
trans-2-Hexenal	0.005–0.01	Bitter, astringent
Heptanal	0.002	Aldehyde, bitter
Octanal	0.001–0.02	Orange peel, bitter
Nonanal	0.001–0.011	Astringent, bitter
trans-2-Nonenal	0.00001–0.002	Cardboard
cis-3-Nonenal	–	Soy-bean oil
trans-2-*cis*-6-Nonadienal	–	Cucumber, green
Decanal	0.0–0.003	Bitter, orange peel
Decadienal	–	Oily, deep fried
Furfural	0.01–1.0	Papery, husky
5-Methylfurfural	<0.01	Spicy
5-Hydroxymethylfurfural	0.1–20	Aldehyde, stale

Source: Baxter and Hughes (2001).

excreted into the green beer by yeast during the first 3 days of fermentation and it is responsible for the "green" young beer flavor. In the young beer phase the acetaldehyde content is about 20–40 mg/l and it decreases to 5–15 mg/l in the final product. During fermentation, after the first 3 days when its formation is faster than its reduction, acetaldehyde is reduced to ethanol but it can be oxidized to acetic acid, which is, as mentioned above, the most abundant organic acid in beer.

As beer ages in commercial package, aldehydes may be produced through oxidation of higher alcohols by melanoidins. These aldehydes have a much lower threshold values than the origin alcohols and may be responsible for off-flavors. As mentioned above the cardboard flavor typical of stale beer is probably due to *trans*-2-nonenal. Other aldehydes found in beer are 5-hydroxymethylfurfural, 5-methylfurfural and furfural, compounds formed during wort boiling. The furfural content can increase also during pasteurization and storage at 40°C. Usually its concentration is very low (<15 µg/l) but a level of more than 1,843 µg/l was reported by Bernstein and Laufer (1977).

Ketones: Ketones belong, as aldehydes, to the group of carbonyl compounds. A carbonyl is a radical made up of one atom of carbon and one atom of oxygen connected by a double bond ($=C=O$). The most important ketones in beer are the diacetyl (butane-2,3-dione) and the related compound pentane-2,3-dione, which are produced from yeast metabolites secreted into beer.

Both diketones are highly aromatic and considered undesirable in lighter-flavored beer. Diacetyl is the most important beer aroma. Its taste threshold is very low (0.15 mg/l) and above this value it imparts to beer an unclean, sweetish, butterscotch taste, which in high concentration is responsible for the aroma of butter. Since pentane-2,3-dione has a similar effect but with a higher taste threshold (0.9 mg/l) these compounds are often considered together and referred to as VDK because both compounds have adjacent carbonyl group (see Table 20.10). The breakdown of these VDK occurs at the same time to other maturation reactions during the beer conditioning process and for this reason considered as the fundamental criterion to evaluate the state of maturation of a beer. The guideline for the total diacetyl content (expressed as VDK) for a fully matured beer is not more than 0.1 mg/l (see Tables 20.9 and 20.10).

Sulfur compounds: Sulfur compounds may be present in the raw material, primarily in malt but they may also result from the metabolism or from infecting microorganisms (see Table 20.11).

Occasionally hops can have sulfur present as residue from crop treatment. The most common volatile sulfur compounds found in beer are sulfur dioxide (SO_2) and hydrogen sulfide (H_2S) plus a number of organic sulfur mercaptans (thiols) and organic sulfides. The raw materials used in brewing may contain different amounts of sulfur dioxide but most of it disappears during wort boiling and the

Table 20.9 Vicinal diketones in beer

Vicinal diketones	Concentration (mg/l)	Flavor descriptors
2,3-Butanedione (Diacetyl)	0.01–0.4	Butterscotch
3-Hydroxy-2-Butanone	1–10	Fruity, mouldy, woody
2,3-Butanediol	50–150	Rubber, sweet, warming
2,3-Pentanedione	0.01–0.15	Butterscotch, fruity
3-Hydroxy-2-pentanedione	0.05–0.07	–

Source: Baxter and Hughes (2001).

Table 20.10 Summary of ketones in beer

Ketones	Concentration (mg/l)	Flavor descriptors
3-Methylbutan-2-one	<0.05	Ketone, sweet
3-Methylpentan-2-one	0.06	–
4-Methylpentan-2-one	<0.013	–
3,3-Dimethylbutan-2-one	–	–
6-Methyl-5-hepten-2-one	0.05	–
Heptan-2-one	0.04–0.11	Varnish, hops
Octan-2-one	0.01	Varnish, walnut
Nonan-2-one	0.03	Ketone, varnish
Decan-2-one	–	Ketone, flowery
Undecan-2-one	–	Ketone, green plant
Oct-1-en-3-one	–	Metallic, mushroom
Octa-1-*cis*,5-dien-3-one	–	Metallic, geraniums

Table 20.11 Sulfur compounds in beer

Sulfur compounds	Concentration (µg/l)	Flavor descriptors
Hydrogen sulfide (H_2S)	1–20	Sulfidic, rotten eggs
Sulfur dioxide (SO_2)	200–20,000	Sulfidic, burnt match
Carbon disulfide	0.01–0.3	–
Methanethiol	0.2–15	Putrefaction, drains
Ethylene sulfide	0.3–2	–
Ethanethiol	0–20	Putrefaction
Propanethiol	0.1–0.2	Putrefaction, rubber
Dimethyl sulfide (DMS)	10–100	Sweetcorn, tin tomatoes
Diethyl sulfide	0.1–1	Cooked vegetables
Dimethyl disulfide	0.1–3	Rotten vegetables
Diethyl disulfide	0–0.01	Garlic, burnt rubber
Dimethyl trisulfide	0.01–0.8	Rotten vegetables, onion
Methyl thioacetate	5–20	Cabbage
Ethyl thioacetate	0–2	Cabbage
Methionol	50–1,300	Raw potatoes
Methional	20–50	Mash potatoes
3-methyl-2-butene-1-thiol (MBT)	0.001–0.1	Skunk

Source: Baxter and Hughes (2001).

sulfur dioxide in beer is mainly formed during fermentation by yeast. The main factors influencing the sulfur dioxide content in beer are the original gravity of worts (sugar concentration) and the type of fermentation and to a lesser extent the yeast strain. Usually top fermented beers have significantly lower sulfur dioxide levels than bottom fermented beers.

Sulfur-containing amino acids taken up by yeast may be further broken down and the excess sulfur is cast off as hydrogen sulfide which may be responsible for the rotten egg off-flavor. Normal beers, when not contaminated and free from infection, contain little, if any, free hydrogen sulfide. The production of this compound is influenced by the yeast strain and its formation runs parallel with the intensity of fermentation process. However hydrogen sulfide is very volatile and it is swept out during fermentation and maturation by the evolving carbon dioxide.

Dimethyl sulfide (DMS) is a by-product of *S*-methyl methionine (SMM) degradation in the brew kettle and has the odor of fresh corn and is not compatible with beer flavor. In general, however the level of DMS in beer is low and present under taste threshold of 50–60 μg/l but according to Bamforth its threshold is around 30 μg/l. Usually DMS concentration in lager beers seems to be considerably higher than in ales because their malts are highly modified at very high temperatures that partly destroy the SMM, the DMS precursor. The lower DMS values in ales could also be explained by the higher enzymatic activity during the infusion mashing (typical in ales production) or may be due to the higher temperatures used in top fermentation, which may give a more efficient carbon dioxide wash out of volatiles during fermentation. Yeast itself cannot remove the DMS but in some cases more may be produced through reduction of dimethyl-sulfoxide (DMSO) by yeast cell.

Mercaptans are thioalcohols, compounds in which the —OH of the alcohol has been replaced by the thiol group —SH. The most important is the 3-methyl-2-butene-1-thiol (MBT) which imparts to beer an unpleasant, skunk-like flavor (described also as sun-struck or light-struck flavor) by exposure to light. This causes the photolysis of the 4-methyl-pentenyl side chain of iso-α-acids (bitter substances of beer) to release an isopentenyl radical which reacts with a thiol radical to form MBT. The threshold of this compound is extraordinary low, in fact it can be detected at level as low as 0.4 parts per trillion (ng/l). The formation and presence of this compound explains why beer is usually packaged in brown or dark green glass bottles which usefully absorb visible light below about 550 nm providing some protection of the product from the photolysis. To prevent this reaction, in beer packaged into ordinary clear glass bottle (e.g. Ice beers), hop extracts are used that have been chemically reduced; the carbonyl group (=C=O) in the side chain of iso-α-acid is reduced by sodium borohydride to a secondary alcohol group.

- **The main reason for using hops is to provide bitterness and characteristic hoppy flavors in beer. Moreover they provide some protection against bacterial spoilage and they are fundamental for good foam formation.**

Hops are a climbing herbaceous perennial vine (*H. lupulus*) member of the *Cannabiniceae* family. The Romans called it *L. salictarius* (*lupus* meaning wolf) because the plant grew wild among the willows like a wolf among sheep (Bamforth, 2003). The female plant yields flowers of soft-leaved pine-like cones (called strobile) which are used for flavoring beer. In brewing process about 200–600 g are required for every hectoliter of beer. Although all hop varieties provide both bitterness and aromas, some are mainly used for their ability to provide bitterness and others specifically to provide hop aromas. Hops contain a range of chemical species but only two of these constituents are fundamental for the brewer: the resins and the essential oils. However hops also contain several phenols which may be important for the flavor of the finished beer.

Resins: Resins may be separated into what are called soft resins (soluble in hexane) and hard resins (not soluble in hexane). The hard resins are mostly oxidized and polymerized form of the substances present in soft resins. The soft resin fraction contains two groups of compounds known as humulones (α-acids) and lupulones (β-acids); they are acidic because they contain a phenolic group able to release a hydrogen ion (H^+). The α-acids are solubilized and extracted during wort boiling when they are oxidatively isomerized to iso-α-acids (iso-humulones), which are the most important bitter compounds in beer. In fact, using fresh, not deteriorated hops, about 70% of the bitterness in beer is obtained as a consequence of this isomerization reaction. The iso-humulones content in beer is about 20–60 mg/l but a number of other substances, including oxidized β-acids, provide the rest of bitterness. The amount of iso-α-acids is measured by the International Bitterness Units (IBU) which are approximately equal to the concentration expressed as mg/l.

Essential oils: Hops may contain 0.5% to as much as 3.0% essential oils and much of the flavor of a beer depends on the aroma compounds added by the hops. Essential oils of hops are a complex mixture of several hundred components and comprise two major fractions: the first belong to the group of hydrocarbons of which terpene hydrocarbons account for about 70% (Wainwright, 1998). The remaining 30% are compounds containing oxygen (oxygenated fraction which is generally more aromatic and less volatile) such as esters, aldehydes, ketones, acids and alcohols (see Table 20.12). The hydrocarbon fraction of most hops contains the monoterpene myrcene and the sesquiterpenes caryophillene and humulene as the most significant component plus a plethora of other chemically related monoterpenes and sesquiterpenes. The hydrocarbons are very volatile and are

present only in dry-hopped beers. The pleasant aroma in beer originated from kettle-hoping (the so-called late hop aroma) which probably depends on substances derived from the oxygenated fraction.

The essential oil has influence on both the flavor and aroma of beer although most of the oil added to boiling wort is lost by steam distillation. Some of this loss is desiderable because some of the hop oil components have an unpleasant smell and would make beer undrinkable. In general, however, most of the hops used to impart aroma are added near the end of wort boiling to minimize losses. A process known as "dry hopping" is used when producing

Table 20.12 Some hop oil-derived compounds found in beers

Compound	Concentration ($\mu g/l$)[a]
Linalool	1–470
Linalool oxides	Nd–49
Citronellol	1–90
Geraniol	1–90
Geranyl acetate	35
α-Terpineol	1–75
Humulene epoxide I	Nd–125
Humulene epoxide II	1.9–270
α-Eudesmol	1–100
T-Cadinol	Nd–200
Humulenol	1–1,150
Humuladienone	Nd–43
Humulol	Nd–220
Clovanediol	51–677

[a] Nd: not detectable.

Source: Baxter and Hughes (2001).

cask ales; in this case hops are added to the fermented beer and the oils extracted are retained in the beer.

Phenolic compounds: Beers contain several and different polyphenols which are derived from malt (two-thirds) and hops (one-third). The nomenclature of all these compounds is confusing and terms such as tannins, flavonoids, polyphenols are used, often in a very generic way, to describe a group of compounds chemically complex and different. A schematic classification is given in Table 20.13

The proanthocyanidin are very similar in their chemical structure to the anthocyanidins which are the colored pigments (red and blue) presents in many plants and in the red wine, tea, some fruits and vegetables (e.g. tomatoes). In beer an important percentage of phenolic compounds are present in the monomeric form such as hydroxycinnamic acids (e.g. p-coumaric, ferulic, chlorogenic and caffeic acids) and phenolic acids (e.g. gallic). The most important hydroxycinnamic acid found in beer (0.52–2.36 mg/l) is ferulic acid originated mainly from endosperm cell wall of barley (Pollock, 1981; Baxter and Hughes, 2001):

- **Considering the caloric value of beer generally about two-thirds are originated from alcohol and one-third from the residual carbohydrates and proteins. However beers can differ enormously in their composition, depending on their strength and how they were made.**

Before calculating the calorific value of beers it may be useful to keep in mind that beers produced worldwide can greatly differ in their composition, depending on their alcohol content and how they are brewed. In fact the alcohol content may range from less than 0.05% ABV like in

Table 20.13 Classification of phenolic compounds in beer.

Class	Group	Congeners	Concentration
Monophenols	Phenolic alcohols	Tyrosol	3–40 mg/l
	Phenolic acids	p-coumaric acid, ferulic, vanillic, gallic, caffeic, syringic, sinapic acids, etc.	10–30 mg/l including esters and glycosides, e.g. chlorogenic acid, neochlorogenic acid
	Phenolic amines and amino acids	hordenine, tyramine, *N*-methyltyramine, tyrosamine, tyrosine	10–20 mg/l (3–8 mg/l as tyrosine)
Monomeric polyphenols	Flavonoids catechines (flavan-3-ols)	(+) catechin (+) epicatechin, possibly other isomers	0.5–13 mg/l 1–10 mg/l
	Anthocyanogens (leucoanthocyanins, flavan-3,4-diols)	Leucocyanidin	4–80 mg/l
		Leucopelargonidin	0–5 mg/l
		Leucodelphinidin	1–10 mg/l
	Flavonols	Quercetin, kaempferol, myricetin (occur as glycosides) iso-quercitin, astragalin, rutin	Less than 10 mg/l
Condensed polyphenols		Dimeric catechins	5–8 mg/l
		Trimers	1 mg/l
		Polymers of catechins and anthocyanogens	Uncertain

Source: Modified from Pollock (1981).

no-alcohol beers to more than 10% ABV in some Trappist Belgian beers or may even be exceptionally up to 25.6% ABV like in Utopias MM II, an American top fermented beer. However most beers produced in the world have an alcohol content of 3–6% ABV. The energy values of ethanol (7 kcal/g), protein (4 kcal/g), carbohydrates (3.75 kcal/g) and lipids (9 kcal/g) must be considered to evaluate the calorific value of foodstuffs. Obviously, the beer being a fat-free food, the latter class of compounds will not be considered. There are different formulas to calculate this value, Martin in 1982 suggested one which takes quite precisely into consideration the major beer components and their contribution.

$$\text{Energy value (kcal/100 ml)} = (a \times 7) + (b \times 7) + (c \times 3.75)$$

where a = ethanol as g/100 ml [% (w/v)]
   b = protein as g/100 ml [% (w/v)]
   c = carbohydrates (as glucose) as g/100 ml [% (w/v)]

The calorific value of most beers is between 20 and 40 kcal/100 ml (80–180 kJ/100 ml). About two-thirds of this energy is originated from alcohol and one-third from the residual carbohydrates and proteins. The light beers generally contain very low amounts of carbohydrates, however they can still have a high energy value if the alcohol content is significant. This may generate some confusion because the term "light" is used to describe beers with low carbohydrate (as in United States) or low alcohol (as in Europe). In the United Kingdom the energy value is calculated according to a formula defined by Food Labelling Regulations:

$$\text{Energy value (kJ/100 ml)} = (\text{ethanol} \times 29) + (\text{carbohydrate} \times 17) + (\text{protein} \times 17)$$

where ethanol, carbohydrate and protein is expressed as above in g/100 ml [% (w/v)] (Baxter and Hughes, 2001).

Identification of Taste- and Aroma-Active Components of Beer

Paul Hughes International Centre for Brewing and Distilling, Heriot-Watt University, Riccarton, Edinburgh, UK

Abstract

The flavor of beer is a holistic perception, derived from a complicated interplay between well-defined volatile and non-volatile components. Additionally, the presence of oligo- and polymeric components in beer contributes to flavor attributes, such as body, mouthfeel and fullness. It is assumed here that the challenges for the identification of flavors are driven by research and trouble-shooting needs. Thus, the emphasis for identification of taste- and aroma-active compounds is focused on identification of those species that either have not been observed (at the level seen) before in a given beer or because there is an outstanding requirement to understand the sensory properties of a novel component. Two approaches to the identification of taste- and aroma-active compounds in beer are outlined here. The first approach is based on an initial observation of analytical anomalies in a beer, which are subsequently shown to have unusual flavor properties. The ensuing steps focus on understanding whether the observed analytical observations have a cause-and-effect relationship with the sensory observations. The second approach is based on an initial observation of sensory anomalies and how analysis can be used to try and identify the cause of the flavor.

In this chapter, the analytical techniques used to identify potentially flavor-active materials are described. The possible difficulties that arise in trying to compare sensory and analytical data are indicated, particularly in relation to the experimentation that is normally applied in analytical and sensory sciences.

List of Abbreviations

AED	Atomic emission detector
AEDA	Aroma extract dilution analysis
ECD	Electron capture detector
ELSD	Evaporative light scattering detector
FID	Flame ionization detector
FPD	Flame photometric detector
GC	Gas chromatography
GC–O	Gas chromatography–olfactometry
GC × GC	Two-dimensional gas chromatography
HPLC	High performance liquid chromatography
LC	Liquid chromatography
MIPs	Molecular imprint resins
MS	Mass spectrometry
PCA	Principal component analysis
PFBOA	O-(2,3,4,5,6-Pentafluorobenzyl)hydroxylamine
QDA	Quantitative descriptive analysis
SCD	Sievers' chemiluminescence detector
SPE	Solid phase extraction
SPME	Solid phase microextraction
ToF	Time-of-flight
UV	Ultraviolet

Introduction

The term beer is a generic one, encapsulating any beverage, the creation of which requires the fermentation of a sugar source that is ultimately derived from plant material, and flavored with aromatic plants. More specifically, the sugar source is most often malted barley, which can be partially replaced with other sugar sources such as maize, rice and fermentable syrups. The flavoring components are almost always derived, at least in part, from hops or products derived from hops. In 2005, global production volumes of beer exceeded 1,500 million hl (1 hl = 100 l) or around 23 l per capita per year.

It is recognized that the composition of beer is complex, consisting of a mixture of well-defined volatiles, well-defined non-volatiles, and oligo- and polymeric materials, all present in true solution or in a colloidal state in a carbonated, alcoholic matrix. In this chapter, the sources of flavors will be reviewed, which sets the scene for the approaches that are required for the identification of taste- and aroma-active materials in beer. For the purposes of this chapter, flavor-active is considered to be the overarching term for a substance that elicits some form of sensorial response from human subjects, whilst taste-active is restricted to components that elicit a response by direct interaction with the buccal cavity, either in the classical sense (i.e. sweet, salt, sour, bitter, umami) or in terms of body and mouthfeel. Aroma-active

substances are those that are perceived by the olfactory epithelium, whether nasally or retro-nasally.

Sources of Beer Flavor

The flavor of beer can be considered to be derived from four sources: raw materials, the impact of the process, in-pack flavor changes and the ingress of taint materials (Table 21.1). The major raw materials are cereals, in particular malted barley, and hops or hop products (see, for instance, Hughes, 2003). Typically, barley is subject to hydration, partial germination, then kilning, which arrests germination but ensures that specific enzyme activities of the grain survive. This process starts to release simple sugars and free amino acids that, under the influence of heat, combine to yield a complex portfolio of Maillard reaction products. The exact nature of these products will depend on the severity of the kilning regime and the water activity in the grain. Thus low-color, so-called lager malts, will tend to yield low levels of color and flavor, whilst specialty malts can make a substantially larger contribution to beer color and flavor. Malted barley replacements tend to make less of a flavor impact, although when cereals such as sorghum are used, the final beer has a quite distinct flavor, due to different flavor-active compounds being developed from the parent grain. Hops and hop products contribute both the characteristic bitterness and hoppy aroma to beer. Whilst the bitter compounds are well-defined (Verzele and De Keukeleire, 1991), the major impact compounds for the expression of hoppy aroma are poorly understood. Some workers, though, have attempted to define the expression of hop aroma in beer, based purely on the analytical levels of specific beer components (Nickerson and van Engel, 1992).

The process of beer production can in itself influence the final flavor of beer. The most important of these process considerations is the fermentation – where yeast is added to the boiled cereal extract or "wort," primarily to affect the biosynthesis of ethanol. Other components are also generated, particularly a series of esters, longer chain alcohols and free fatty acids, the exact concentrations of which are dependent on factors such as the design of the fermenter, the yeast strain used and its state of health, the temperature of fermentation, the spectrum of sugars in the fermentation and the concentration of the sugars themselves (MacDonald et al., 1984). Other processes, such as the time of maturation (principally to reduce the concentration of the highly flavor-active compound diacetyl), the duration and intensity of the wort boil, which precedes fermentation, and the severity of pasteurization all impact on the final flavor of beer. It is clear then that only by close control of beer production throughout the whole process can a brewer reasonably expect to produce beers with consistent flavor quality.

An additional complication is that beer is not a completely stable product in pack. It is prone to oxidative, non-oxidative and light-induced flavor changes. There are two potentially deleterious flavor changes that can occur to a beer in-pack. Firstly, the formation of the highly flavor-active 3-methyl-2-butene-1-thiol (MBT) in beer when exposed to light in green or clear glass can occur in seconds. Reminiscent of the aroma emitted by skunks, it is also described as a key attribute for certain beers that are unprotected from light. Secondly, a range of flavor-active aldehydes, formed either by lipid oxidation or the Strecker degradation of residual amino acids in the beer, can confer flavors described as cardboard, cooked potato and generally an "oxidized" flavor to an aging beer. However, it is considered that flavor deterioration during beer aging extends beyond the portfolio of aldehydes formed and, indeed is, on the basis of the recent publication record, an active area of research (see, for instance, Sanchez et al., 2003).

The final source of flavors in beer, those derived from tainting materials, are generally undesired and can cause substantial difficulty in a production context. Often these compounds have flavor activities below the level of $1\,\mu g/l$ so that they can be highly elusive in any analytical evaluation. Viable bacteria or wild yeast in the final packaged beer can also cause significant flavor problems during storage. Off-flavors from bacteria generally include diacetyl, short-chain fatty acids, volatile sulfur compounds and acetaldehyde. Fungi, especially wild (i.e. non-brewing) yeast strains, often have the ability to decarboxylate ferulic acid to the highly flavor-active 4-vinylguaiacol, which confers a smoky flavor to beer.

Table 21.1 Sources of flavors in typical beers, with an indication of their flavor descriptors

Flavor source	Major flavor contributions
Raw materials	
– Malted barley	– Maillard reaction products, dextrins
– Wheat	– Fullness, mouthfeel
– Hops/hop products	– Bitterness, hoppy aroma
Process-derived	
– Wort boiling	– Evaporation of volatiles (e.g. hoppy, sulfury)
– Fermentation	– Ethanol, CO_2, esters, higher alcohols
– Maturation	– Reduction of diacetyl
Changes in-pack	
– Ageing	– Various esters, dioxolanes
– Oxidation	– Aldehydes
– Light-induced	– 3-Methyl-2-butene-1-thiol, H_2S
– Microbiological	– Various, including sulfurs, fatty acids, 4-vinylguiaicol
Taints	
– Chlorophenols	– Confer a "medicinal" taint
– Chloroanisoles	– Musty, "corked" flavours
– Others (e.g. geosmin, isoborneol)	– Include earthy, musty

Note: Desired flavors are derived by the impact of the beer production process on selected raw materials. Generally, flavor changes during ageing and taints/off-flavors are undesirable.

Approaches to the Detection of Taste- and Aroma-Active Compounds in Beer

The composition of beer has been systematically investigated over the past few decades, particularly since the advent of gas chromatography (GC) and high performance liquid chromatography (HPLC). However, there is still a need to identify flavor activities in beer, either to understand the contributors to product quality or to troubleshoot potential flavor defects. Another reason for attempting to elucidate the chemical composition of beer is to ensure that there are no compounds that pose a health and safety risk to the consumer. (These will not be considered explicitly here, although the approaches outlined below can be applied in this area.) The flavor goals can be addressed in one of two ways, depending on whether a flavor has been flagged up by instrumental analysis (analysis-led) or by a sensory evaluation (sensory-led; Figure 21.1).

It is important to appreciate that whether initial discovery is analysis- or sensory-led, there is still a need to link the two observations together so that a sensory-led discovery is
Figure 21.1 Interrelationship between sensory- and flavor-led identification of flavors in beer. The identification of flavor-active components in beer can be driven either by sensory detection, triggering a need to investigate the chemical cause, or by the chemical detection of a compound that requires sensory evaluation.

demonstrated to show a cause-and-effect relationship with one or more analytes. Conversely, an analysis-led discovery must be similarly confirmed by sensory evaluation.

There are specific issues with regard to the instrumental analysis and sensory evaluation of beer that need to be considered. A typical beer can be described as an aqueous ethanolic solution (typically 0.5–1.0 M ethanol), containing around 0.1 M carbon dioxide. The liquid medium is acidic (pH 3.8–4.8), and contains dissolved and colloidal, non-volatile components (typically around 40 g/l) and about 0.5 g/l volatiles. Additionally, glycerol may be present at around 1 g/l. The heterogeneity of beer and its propensity both to develop insoluble precipitates and to foam, often make sample handling difficult and can compromise the reliability of certain flavor compound determinations. Perhaps the best example of this is the loss of the bitter iso-α-acids into foam if it is allowed to form, resulting in systematically low bitterness analysis results. Thus, the compositional attributes of beer can provide sampling and analytical challenges. In addition, the quantity of beer consumed in a tasting session should not, of course, unduly overburden tasters.

Analysis-led identification of flavor-active components in beer

The most effective approach for an analysis-led identification of a flavor-active component in beer requires some form of chromatographic technique and the appropriate detection systems (Table 21.2).

Here only HPLC- and GC-based approaches will be considered, although it is recognized that complementary techniques such as capillary electrophoresis and planar chromatography can be useful. The approach for an analysis-led

Table 21.2 Chromatographic detection systems commonly used for the identification of flavor-active components in beer

Chromatography	Detector	Application
HPLC	UV-visible	Compounds with absorption from 190 to 800 nm
	Fluorescence	Selective for compounds with defined excitation and emission wavelengths
	Refractive index	Universal detector, relying only on the ubiquitous property of refractive index
	Evaporative light scattering	Universal detector: useful for compounds with few analytical "handles," such as sugars
	Mass spectrometry	Almost universal detector; often complex fragmentation patterns with few rules for spectral interpretation
	Electrochemical	Can be used in oxidation or reduction modes as a selective detector
	Chemiluminescence	Highly selective for chemiluminescent compounds
GC	Flame ionization	General purpose: detects carbon
	Electron capture	Sensitive to specific compounds such as halogen- and nitro-containing species and 1,2-diketones
	Atomic emission	Can be set to detect a wide range of elements
	(Pulsed) flame photometric	Used mainly for sulfur-containing compounds
	Sievers' chemiluminescence	Used mainly for sulfur-containing compounds
	Nitrogen phosphorus	Specific for nitrogen- or phosphorus-containing species
	Mass spectrometry	Very common, general-purpose detector
	Olfactometry	Used extensively for flavor volatile research and troubleshooting

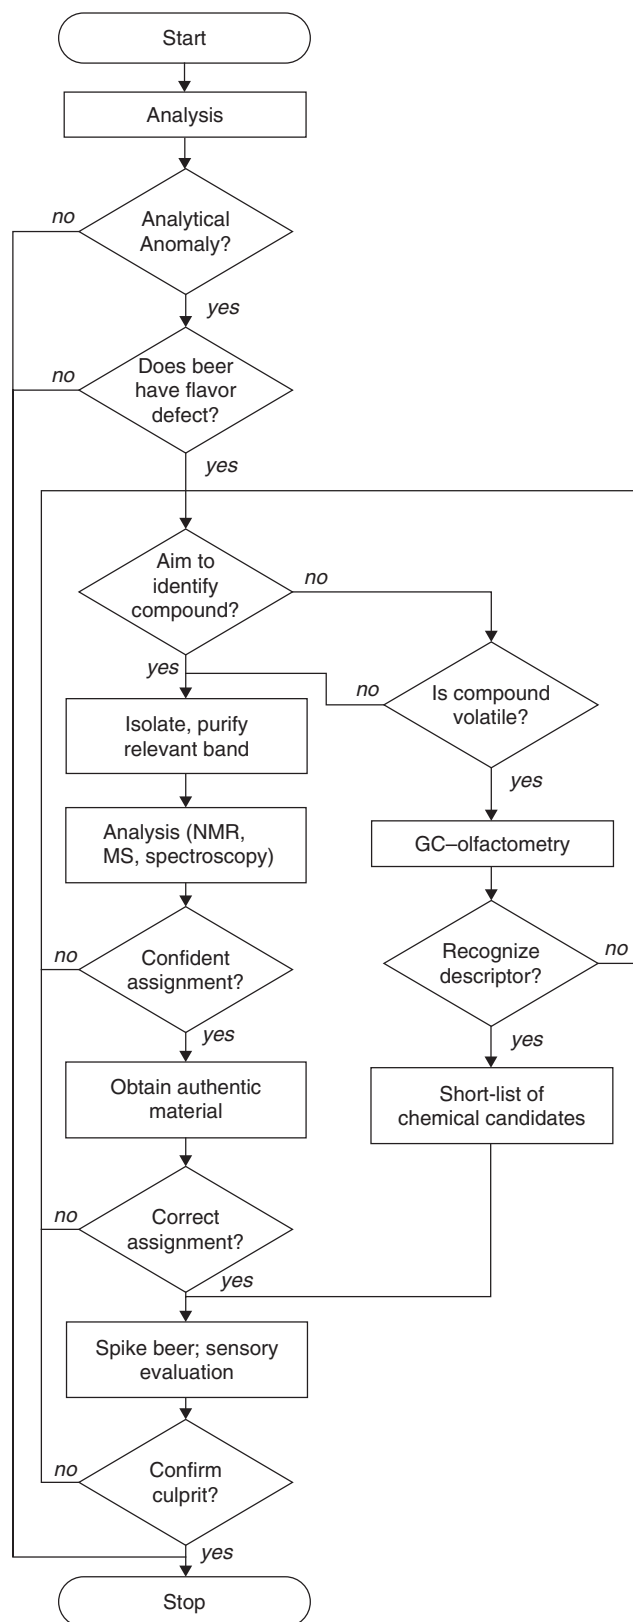
Note: Detector selection depends on the specific sensitivities of the analytes of interest and the degree of selectivity required to eliminate or suppress responses from unwanted, interfering, components.


Figure 21.2 Flowchart illustrating the steps and decision-making points for identification of flavor-active compounds in beer, driven by initial analytical observations. Executed processes (represented by rectangular boxes) require decisions to be made (diamond boxes).

identification of a flavor-active compound (Figure 21.2) often presents itself either as an analytical anomaly (i.e. a chromatographic band at unusually elevated levels or, unexpectedly, present at all) or as a result of analytical screening. In both cases, the implication is that the analysis-led approach relies initially on some form of comparison, either between samples or the "expert eye" perceiving an observation outside expectations. Such an approach can, in its simplest form, be a visual comparison of the appropriate chromatograms. The approach can also be more sophisticated, by applying tools such as principal component analysis (PCA) to identify outlying samples from chromatographic data and probing the variables that make up specific principal components.

So, once the analytical anomaly has been observed and confirmed, the next step is to understand whether the subject beer is also presenting with an unexpected or unusual flavor. As mentioned earlier, sensory evaluation is an essential part of beer quality control, so there is a need to check the sensory records. If these records are deemed to be reliable (i.e. trained panelists, possible track-record that proves sensory evaluation credentials) then we reach a point where the subject beer not only shows analytical anomaly, but also has a specific sensory characteristic flagged up during a routine tasting session.

This correlation does not mean that there is a cause-and-effect relationship, so there is now a need to demonstrate this. There are two approaches to understanding whether or not the anomaly is flavor-active or not. Firstly, the analyst can focus on identification of the chemical entity and use existing knowledge to understand its flavor impact. This can be subsequently confirmed by adding back the authentic material into a beer with a more typical analytical profile, and subsequent sensory evaluation. This is often straightforward when there are high-quality mass spectrometric library hits, although this is only likely to be useful for gas chromatography–mass spectrometry (GC–MS), as identification of unknown compounds by liquid chromatography–mass spectrometry (LC–MS) remains problematic.

However, it is not essential that the chemical identity is known. Here there is a requirement to evaluate the flavor attributes *in situ*, by applying techniques such as GC–olfactometry (GC–O), or by isolation, purification and adding this material back into a "clean" beer. (Currently, there is no non-volatile alternative to GC–O, although there have been some advances made in this area (Frank *et al.*, 2003).) It is asserted here that, in most cases, it is highly desirable to know the chemical identity of a potentially flavor-active compound as:

- It provides a clue as to its origin and will often suggest approaches for elimination or control.
- In most cases, it obviates the need to go through a laborious process of isolation and purification, as chemical

compound, once its identity is known, can be acquired either by purchase from existing catalogs or by custom synthesis.

There are, however, several potential problems associated with this approach. Firstly, the suspect compound may not be considered to be suitable for human consumption. Even if it is, isolation techniques may well involve hazardous materials (e.g. preparative HPLC often requires methanol- or acetonitrile-based mobile phases), and chemical synthesis can suffer from the same limitations. It is clear then that rigorous purity appraisal is essential before submitting "spiked" beers for sensory evaluation. A further complication is the possible chemical lability of the suspect compound. Oxidation-, heat- and light-instability can make isolation and purification difficult, and also encourage the wrong conclusions to be made. Again, knowledge of the chemical structure of the suspect compound can help the flavor chemist appraise any potential difficulties here.

Sensory-led identification of flavor-active components in beer

Most if not all beers produced globally are evaluated by some form of sensory experiment prior to release on to the market. The rationale is straightforward here: the chemical complexity of beer precludes complete analysis, so that whilst the costs associated with reliable sensory evaluation are high, sensory testing allows beer to be evaluated in a fashion similar to that performed by the consumer. Most beer sensory testing relies on some form of flavor profiling, where the beer is assessed on aroma and taste and the assessor is asked to score each of a number of flavor descriptors. Often most of these descriptors are negative terms, so that scoring such terms not only indicates a flavor problem, but also suggests where the flavor problem might lie. Indeed, many flavor-negative terms on a flavor profile are chemically oriented, examples including butyric, metallic, diacetyl and sulfury.

The approach that can be applied for instance to the chemical characterization of an off-flavor (Figure 21.3) requires the problem product to be submitted for analysis. The descriptors scored by the flavor assessors can provide some clue as to where the problem might lie and facilitate analytical detection. For instance, if a product is scoring high on sulfury, initial analysis should logically focus on sulfur volatile determination, which in turn requires specific detection systems (Table 21.2) to enable detection of the potential problem. Again, it is highly desirable to have a typical example of the same brand available for comparison, particularly if the analyses required are not routinely performed and there is little experience in the interpretation of these data. Comparative brands should be of a similar age to the problem beer, to help prevent changes in flavor during aging confounding the flavor evaluation.

Experimental Techniques

Till now, the discussion has in the main used terms such as "instrumental analysis" and "sensory evaluation" as catch-all categories, with some reference to specific techniques. However, both disciplines require rigor and expertise in their application if they are to yield reliable data. The steps taken to derive data from instrumental analysis of unknown compounds in a beer matrix indicate three distinct stages: sample preparation, analysis and data interpretation.

Sample preparation

As mentioned earlier, the composition of beer presents several challenges for the flavor chemist, not least of which is the presence of carbon dioxide and, in some cases, nitrogen gas. The analysis of volatile compounds has been successfully carried out on beers by first applying a wide range of techniques (Table 21.3). For volatile compounds the simplest approach, in principle, is by direct injection of beer. However, this is undesirable due to the solid content of beer, which will have a rapid and deleterious effect on column performance. For non-volatile components, though, direct injection onto an HPLC can often prove straightforward and reliable. Thus the hop-derived iso-α-acids and sugars can be analyzed by initial direct injection. However, it is essential to ensure that the beer is sufficiently degassed to ensure that gas bubbles are not introduced into the HPLC pump. Typically degassing achieved by careful pouring of the beer onto glass beads and leaving for a period of hours.

A commonly used analytical technique for the quantification of higher esters and higher alcohols is to perform direct headspace injection onto the GC, with subsequent flame ionization detector (FID) detection (Strating, 1988). The concentration ranges of these components ranges from less than 1 mg/l for heavier esters such as ethyl octanoate to 80 mg/l for 2- and 3-methylbutanol. The active purging of beer to sweep volatiles onto the GC has been a common approach for the evaluation of the highly flavor-active sulfur volatiles. Whilst detection systems for sulfur analysis tend to be highly selective due to their low concentration (quantification is required from around 0.2 μg/l for methanethiol to 30 μg/l for ethyl thioacetate), this purge-and-trap approach successfully suppresses matrix effects. This is critical for optimal performance of all sulfur detectors with two, the AED and the SCD, being particularly sensitive.

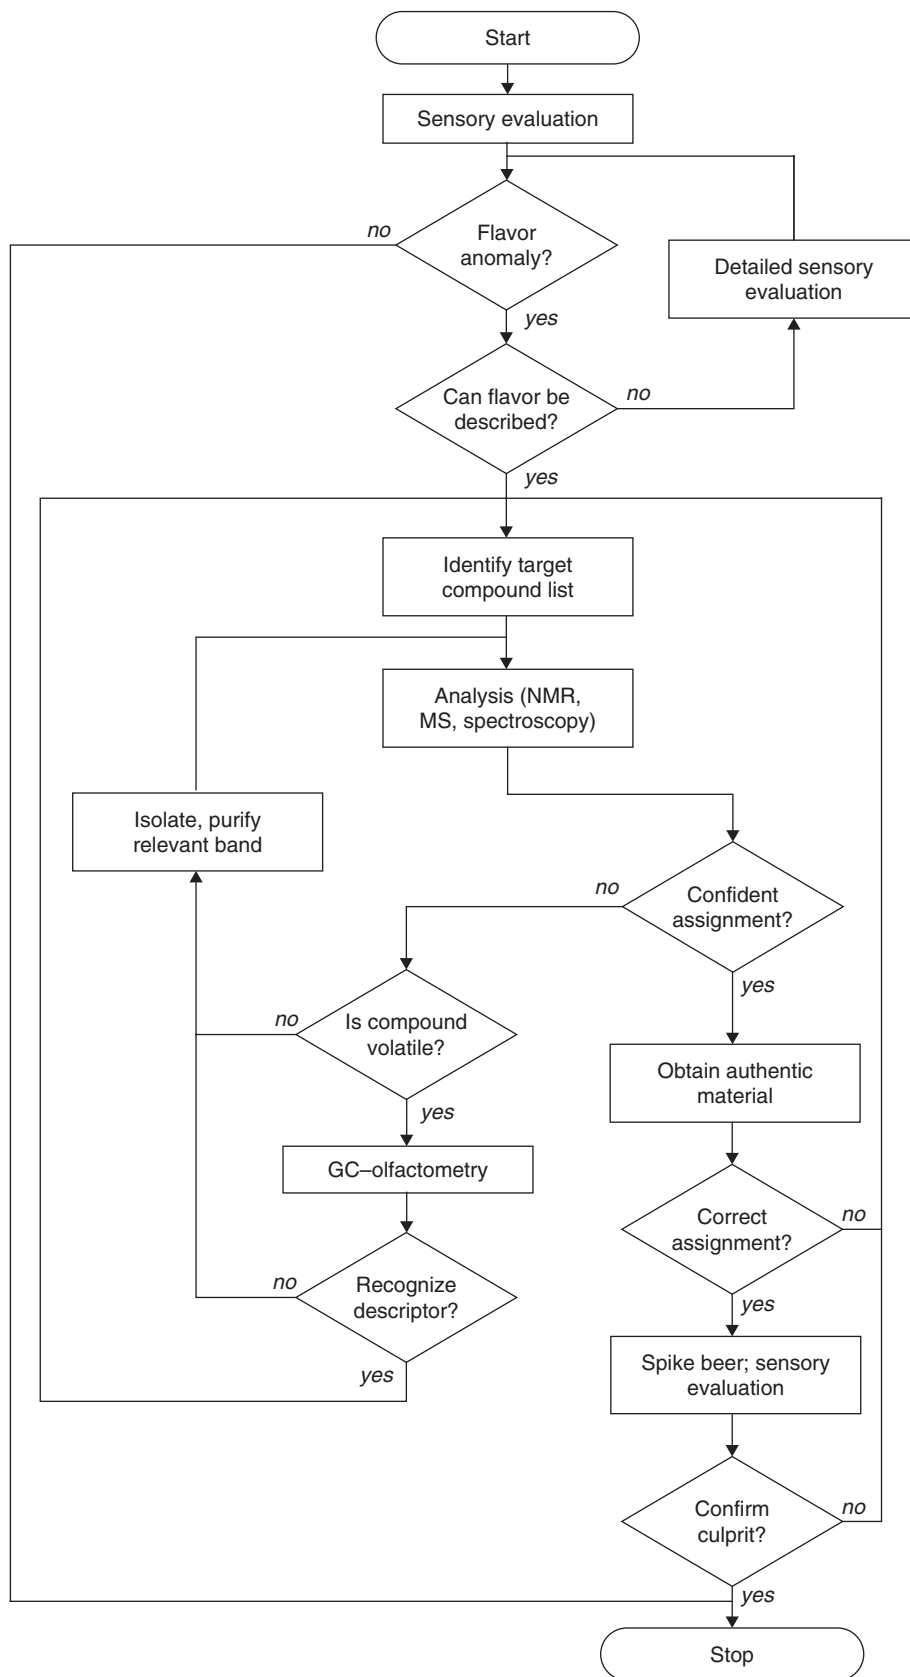
Extraction techniques are perhaps the most traditional of sample preparation methods. Liquid–liquid extraction is rarely used today, although extraction of acidified beer with 2,2,4-trimethylpentane (isooctane) can be used for preparation of an iso-α-acid sample for HPLC analysis. More commonly, solid phase extraction (SPE) can be used both for polyphenol (Lee, 2000) and iso-α-acid analysis (Donley, 1992). The application of SPE can extend to the use of immunoaffinity SPE cartridges. These are most often


Figure 21.3 Flowchart illustrating the steps and decision-making points for identification of flavor-active compounds in beer, driven by initial sensory observations. Executed processes (represented by rectangular boxes) require decisions to be made (diamond boxes).

Table 21.3 Sample preparation methodologies for beer flavor analysis

Sample preparation method	GC?	HPLC?	Examples	References
Direct injection	✕	✓	Sugars	Analytica-EBC (1998)

SPME*	✓	✕	Sulfur volatiles	Hill and Apostolescu, (1999)
On fiber-derivatization SPME	✓	✕	Aldehydes	Vesely *et al.* (2003)

*Solid phase microextraction. The aim of any sample preparation is to prepare the analytes of interest in a compatible format for the analysis of choice. Additionally, there may be a requirement to concentrate analytes and/or suppress background interferents.

used for environmental contaminants, such as mycotoxins, rather than flavor components. Recently, Sellergren *et al.* (2004) indicated that molecular imprint resins (MIPs) could be usefully prepared to selectively scavenge specific analytes from beer. However, to date, there do not appear to be any commercial applications of either immunoaffinity cartridges or MIPs for beer flavor analysis.

Since the 1990s there has been a surge of interest in the application of solid phase microextraction (SPME). Here, a fiber, coated internally with one of a range of phases, is introduced to the beer sample, either in its headspace or by immersion into the beer liquid. The volatile analytes partition into the fiber coating, which are then subsequently desorbed in the hot injector of the GC. Automation of this adsorption–desorption cycle has done much to improve the reproducibility of this technique. This technique has been further modified, by pre-adsorption of a derivatizing agent onto the fiber prior to its introduction to the beer sample. The best example of this is the adsorption of the aldehyde derivatizing agent *O*-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine (PFBOA) onto the fiber (Vesely *et al.*, 2003). Aldehydes, when subsequently adsorbed, react with the derivatizing agent and, as the derivatives themselves are appreciably volatile, they can be desorbed and measured by GC analysis.

Separation systems

Detailed consideration of chromatographic separation systems is beyond the scope of this chapter (for additional information, see, for instance, Nollet, 2000). However, the understanding of whether or not a compound has sufficient volatility and thermal stability is essential if some form of gas chromatographic analysis is to be performed. For GC analysis, the thermal program and choice of column chemistry are the key decisions to be made, although for particularly difficult separations, some advantages can be gained by judicious selection of carrier gas (either hydrogen, helium or nitrogen) and optimization of linear gas velocities.

Similarly, HPLC columns can, to a first approximation, be categorized into normal- and reverse-phase. The former is a highly polar silica-based stationary phase, and is used in conjunction with organic solvents. In contrast, reverse phase consists of an organic substance grafted onto silica (usually C_{18} alkyl groups), effectively reversing the polarity of silica. Mobile phases often consist of water in conjunction with polar organic solvents (most commonly methanol, acetonitrile, tetrahydrofuran and ethanol). Additionally, buffers can be used to adjust the pH of the aqueous phase, and ion-pairing agents can be used to mask any molecular charges on the analytes. This is important as such charges often cause tailing of peaks and a loss of resolving power of the analysis.

In some circumstances, it is important to achieve separation of optically active substances. This is most often addressed by using chiral stationary phases, which are available for both HPLC and GC separations. These phases are commonly based on cyclodextrins, and have been used, for instance, in the HPLC analysis of hop-derived bitter compounds (Ting and Goldstein, 1996).

Recently, there has been increasing application of the so-called GC × GC separation approach. Here, specific bands from a GC column are transferred on to a second column (see Bertsch, 1999, 2000; Phillips and Beens, 1999). This second column provides further opportunity for band resolution. This technique has shown that certain mixtures are exceedingly complex. This has been used successfully for the identification of off-flavors in beer (Sakuma *et al.*, 2000).

Detection systems

Chromatographic detection systems can be conveniently classified according to whether they are "universal," selective or based on mass detection. The term universal indicates that the analyte in question merely needs to exist above its detection limit to enable detection. For GC analysis, the best-known universal detector is the FID, which is universal

in the sense that it detects molecules based on their ability to burn to give carbon. It is clear then that there is little selectivity here, apart from the exclusion of a rare few volatile molecules that lack carbon atoms (for beer, this includes sulfur dioxide, hydrogen sulfide and carbonyl sulfide). The detector that best epitomizes universal detection in the HPLC domain is the so-called ELSD (evaporative light scattering detector). Detection relies on the substances of interest possessing an ability to scatter light after the mobile phase has been evaporated, a property common to all sufficiently non-volatile components.

There is a range of selective detection systems available for both HPLC and GC. Selective implies that the molecules of interest possess physicochemical properties that are not universal. For HPLC, the most common is the UV-visible detector, either in a single wavelength or diode array configuration. The latter can collect complete spectra of chromatographic bands. The analytes of interest must, of course, exhibit absorption bands between around 190 and 800 nm, with a sufficiently high molar absorption coefficient so that it can be detected at the concentrations at which it is likely to be present. The higher the absorption wavelength, the more selective the detection is likely to be. Thus, at 254 nm, a common single wavelength detection setting, many compounds absorb. In beer, this includes a whole array of proteins, polyphenols, aromatic amino acids and the iso-α-acids. At longer wavelengths, the absorbing chromophore needs to be longer. Thus at 500 nm, riboflavin can be detected, although its concentration in beer (typically 0.2–0.3 mg/l) is too low for reliable quantification.

An alternative selective HPLC detection can be based on fluorescence. Here, both the excitation and detection wavelengths can be set, enhancing selectivity. Certain polyphenols, and beer flavin derivatives, can be observed readily by fluorescence detection. In some instances, electrochemical detection can be applied with good effect. In particular, in oxidative mode, it can be used to detect polyphenols and phenolic acids. Whilst electrochemical detection can also be used in reductive mode, in practice, it is highly challenging to exclude atmospheric oxygen sufficiently to allow sensitive detection in this mode. The ESA CoulArray, which can use up to 16 electrodes in series, has found application, again predominantly for polyphenols and phenolic acids (Rehova et al., 2004).

There is a range of selective GC detectors available. One of the most common is the electron capture detector (ECD). It can detect species that are able to accept electrons, which in practice is most commonly nitrated or halogenated derivatizing agents, which are used to assign an analytical handle of sufficient sensitivity to molecules of interest. An example of this, the use of PFBOA to derivatize aldehydes, is mentioned above. The ECD can also detect diacetyl, and is the method of choice for many brewing laboratories. Selective detection is an essential prerequisite for sensitive and reliable sulfur volatile analysis. Traditionally,

the flame photometric detector (FPD) had been used to good effect here, allowing quantification of short-chain thiols, di- and trisulfides, and thioesters. One disadvantage of the FPD is its non-linear response curve, which is close to quadratic. This was effectively solved with the advent of the pulsed FPD (Hill and Apostolescu, 1999), which has typical calibration plots that are more linear. More recently, the Sievers chemiluminescence detector (SCD) has become more commonplace in the brewing laboratories of several of the larger companies. This is highly sensitive detector, although it can be challenging to run consistently. The atomic emission detector (AED) can, in principle, be set up to detect a wide range of chemical elements, including sulfur. However, there are few applications of this detector in the context of beer flavor. For certain heterocycles, the nitrogen phosphorus detector (NPD) has been used, its selectivity being derived from its high level of discrimination for nitrogen and phosphorus atoms (Herent et al., 1997).

Without doubt, the development of cost-effective mass spectrometric detectors has enabled the flavor chemist to derive mass data from individual chromatographic bands (for a review, see Fay et al., 2001). This is far more developed in the GC arena, with substantial collections of library mass spectra and sophisticated software routines available for comparing unknown spectra with known compounds. This, together with catalogs of retention indices, substantially simplifies the flavor chemist's job. Most commonly, the mass detection for the GC is based on ion trap or quadrupole technology. Both determine unit masses, so that no definitive molecular formula information can be derived directly from such mass spectra. Recently, the wider availability of time-of-flight (ToF) mass spectrometric detectors has given the flavor chemist the opportunity to obtain accurate mass data. This is extremely useful, for instance, when attempting to identify unknown compounds, as, with careful calibration, the resolving power of the ToF detector is sufficient to generate a short list of molecular formula possibilities.

Mass spectrometric HPLC detectors are also available in various configurations. However, unlike the situation for GC, there are no substantial libraries of liquid chromatography–mass spectrometry (LC–MS) spectra and, indeed, the rules for interpretation of LC–MS spectra are, as yet, poorly defined. Thus identification of unknown compounds is often far more problematic. The quadrupole and triple quadrupole detectors are useful alternatives for selective HPLC detectors and can be used to determine a wide range of analytes in one chromatographic run. The ToF and quadrupole-ToF (QToF) detectors again allow for accurate mass determination, which is invaluable in any attempt to identify unknown compounds.

GC–olfactometry

The application of GC–O deserves special mention here as it arguably spans the instrumental and sensory interface.

This is intuitively appealing; after all, it focuses detection closely on the property of interest – its olfactory behavior. The use of the human nose as a GC detection system, often in parallel with more conventional detectors, has been increasingly employed with examples of applications including: the identification of aroma-active taints from plastics (Bravo *et al.*, 1992; Marin *et al.*, 1992), aroma thresholds of enantiomeric forms of octalactone derivatives (Abbott *et al.*, 1995), the assessment of lobster meat extracts for their aroma properties (Cadwallader *et al.*, 1995), assessment of virgin olive oil aroma (Morales *et al.*, 1995) and the aroma properties of wines (Ferreira *et al.*, 1995).

GC–O has also been applied to the aroma properties of hops. In two papers, Sanchez *et al.* (1992a, b) describe the sensory properties of hop oil oxygenated compounds and beers brewed with the three different hop varieties compared with unhopped beer. In each case the data was collected using a method called Osme (da Silva *et al.*, 1994). This is based on a time-intensity (TI) device connected to a PC and allows the evaluation of the odor activity of compounds eluting from a GC both qualitatively (by use of descriptors) and quantitatively (by use of intensity ratings). Alternative methods are CharmAnalysis™ and a similar method known as aroma extraction and dilution analysis (AEDA). Both methods are based on the GC–O analysis of serial dilutions of a sample. In CharmAnalysis™, volatiles are extracted from the sample with solvents and separated by GC. The presence or absence of odor in the effluent as a function of time is recorded by the subject using a PC. The data has a value of "zero" (i.e. cannot be detected) or "one" (can be perceived) at every time during the run. A serial dilution of the sample is continued until no odor is detected at all. Combining these results produces a chromatogram-like response called a charm chromatogram (Acree *et al.*, 1984).

Abbott *et al.* (1993) compared AEDA and Charm Analysis for the characterization of beer extracts isolated by SPE. Whilst the authors could not advocate one method over the other, they advised caution if only one approach is employed. Indeed, Marin *et al.* (1988) pointed out that there were significant differences between assessors carrying out CharmAnalysis. When applying GC–O, it is important to relate band elution times to standard retention indices. In this way, small changes in GC parameters (temperature, gas flow rates, *etc.*) can be compensated for. Such indices are generally only dependent on the nature of the stationary phase (Farkas *et al.*, 1994).

It is apparent that these techniques measure different aspects of aroma detection. It can be argued that the use of Osme is more subjective, relying on real-time intensity evaluations. This is known to be problematic (Dijksterhuis and van den Broek, 1995). However, CharmAnalysis is more time consuming, requiring the determination of several "sniffograms" (one for each sniffer employed) to enable a charm chromatogram to be evaluated. In this case, sensory

fatigue becomes a pertinent issue. In addition, sniff ports are invariably located near a heat source. Although they are now designed to produce humidified air to the sniffer, care is required with the ergonomic design of sniff-ports to minimize heat drying the assessor's eyes. Nevertheless, it is undeniable that GC–O offers a route to the evaluation of the sensory characteristics of complex mixtures of volatile compounds, allowing the derivation of both descriptive and intensity parameters.

Whilst there is a need for this type of analytic approach, it should be remembered that work with extracts must be substantiated in whole beer. It is now recognized that a number of macromolecules, whilst not necessarily being flavor-active in themselves, influence the release of aroma compounds from complex matrices (Harrison and Hills, 1997). An extension of this complexity is to consider the dynamics of aroma release in the buccal cavity. This latter approach, though, is challenging (Taylor and Linforth, 1994).

Sensory evaluation

The options available for the sensory evaluation of beers depend on the question posed by the experimentalist. The circumstances in which sensory data will be required are diverse and include the following:

- Ensuring acceptability of an established product prior to its release to the market.
- Ensuring that any (minor) process change, such as new season malt or modification of stabilization treatments, do not affect the flavor attributes of a brand.
- To define the sensory attributes of unfamiliar brands (e.g. new own brands, competitor brands).
- Troubleshooting possible flavor defects.
- Comparison of brand performance, either within the company or at a consumer level.

Each of the above circumstances requires different skills of the taster and different questionnaires to be posed by the sensory analyst. Whilst it is outside the scope of this chapter to review sensory analysis methods in detail (for more information see Meilgaard *et al.*, 1999), it is worthwhile to consider the types of methods that can be applied.

Perhaps the simplest test is to ask the taster to compare two or more products. Typically, three glasses of beer are presented, one of which is different from the other two (a so-called triangle taste test). The taster is simply asked to identify the odd one out. Typically, 24 or more tasters are required to perform such a test, but testing for statistical significance is straightforward and unambiguous. If one of the beers is a control (e.g. a product known to be acceptable for the market), such a test can be used to pass a beer for sale. Alternatively, it can be used to confirm that minor changes in production have not had a significant impact on the flavor qualities of the brand.

For more major process changes, such as brewing an existing brand in a different brewery, it is likely that a period of flavor-matching will be required due to differences in brewery design and operation. A triangle test, at least at the outset, will often show significant differences, and there is a clear need to understand how the beer is performing differently from the flavor benchmark. One approach is to invoke some form of magnitude estimation for a range of flavor descriptors. Here a trained panel of tasters is asked to judge the intensity of a range of taste and aroma descriptors. Depending on the methods of training, tasters will score the various descriptors, either numerically or by marking off on a line scale. The descriptors will often be of both positive attributes (e.g. estery, fruity, bitter, malty) and negative attributes (e.g. diacetyl, butyric, sour), although it is important to remember that some negatives for one brand are acceptable at controlled levels in another. The outcome is a flavor profile, and often around 8–10 tasters will make their judgments independently, and the resulting data processed in an attempt to establish whether the test has identified possible flavor attributes that affect the overall flavor quality. These in turn can give hints as to how the process can be adjusted to bring it in line with the existing flavor benchmark.

Flavor profiling finds other applications too, such as developing flavor benchmarks for new brands, trouble-shooting off-flavors, and comparison between brands to develop a product map. There are occasions though when the scope of a flavor profile is not sufficiently broad to capture the attributes of all the brands being studied. In this case, there may be a requirement to generate new descriptors. Here, procedures such as quantitative descriptive analysis (QDA) can be useful. Here, a group of experienced tasters evaluate a range of beers and record their own flavor impressions and descriptions. After several sessions of this vocabulary generation, the tasters, under the leadership of the sensory analyst, agree a subset of descriptors. Often tasters then train to use these in scaling exercises before the modified profile is applied. QDA finds application in areas such as defining new products and concepts and for capturing brand data for a broad range of products.

Consumer sensory data is often important to brewing companies. Unlike trained sensory panels, consumers require more commonly known flavor descriptors, which can be defined, for instance, in a QDA environment. Tools such as preference mapping (MacFie and Hedderley, 1993; Greenhoff and MacFie, 1994) can be helpful in mapping analytical data and expert sensory data onto consumer sensory data. This can often highlight consumer segments and also indicate what it is about specific products that drives this segmentation.

The management and control of sensory panels and deriving relevant and reliable information from them represents a significant challenge. In particular, as discussed below, the structure of sensory panel data is such that common approaches to data analysis can be flawed.

The Challenges of Relating Sensory and Analytical Data

Earlier, it was indicated that, to identify flavor-active substances in beer, there is a necessity to relate some flavor property with a chemical identification. There are several challenges here that need to be overcome if this relationship is to be firmly established (Table 21.4). Firstly, analysis, as the term implies, requires some form of resolution of a complex composition into simpler parts. Here, analysis is used to resolve chemical mixtures into a number of bands. The ultimate aim is to have an unambiguous chemical identification of the band or bands of interest. This suggests a promise of being able to recreate the flavor effects of identified bands by adding authentic material back to the beer. However, this is often a difficult task. At its simplest, it requires rigorously pure authentic materials to be used for additions, as there are several examples of apparent flavor compounds actually containing low levels of a much more potently flavor-active substance.

One such example is that of oct-1-en-3-ol, endowed with flavor descriptors such as mushroom and metallic. In fact, these flavor characteristics are actually due to the presence of small quantities of its oxidation product, oct-1-en-3-one. Here we encounter the sheer scale of the sensory dynamic range, in comparison with that for analysis. Estimates of the flavor thresholds of oct-1-en-3-ol and oct-1-en-3-one are 1,000 ng/l (Buttery *et al.*, 1988) and 5 ng/l (Buttery *et al.*, 1990), respectively, different by more than three orders of magnitude. Thus the flavor characteristics of oct-1-en-3-ol at 99.5% pure, containing 0.5% oct-1-en-3-one, will be dominated by the trace of the latter compound. However, analytical scrutiny of the former would not necessarily reveal this impurity, as it may be present in too low a relative concentration to be routinely detected if the oct-1-en-3-ol is submitted for chromatographic analysis.

An additional difficulty is that flavor descriptions can often be concentration dependent. This is a particular problem with off-flavors, as they can be present over a vast range

Table 21.4 A comparison of sensory and analytical data attributes

Instrumental analysis	Sensory evaluation
Simplify: eliminate matrix	Holistic: full matrix
Sequential measurements	Virtually instantaneous assessment
All components considered singly	All components can interact
Aim is to measure concentration	Aim is to determine sensory activity
Instrumentation can be calibrated	Time-consuming to "calibrate" tasters
Output: hard numbers	Output: subjective values

Note: Chemical components do not map singly or exclusively on to specific flavor descriptors, although for certain flavors and off-flavors, there is an approximate one-to-one mapping.

of concentrations. Furthermore, the dose–response relationship between flavor component and human judgment of intensity is well-known to be non-linear, so that the application of conventional statistics (which often rely on assumptions of normality) is flawed. However, applying linearized scales for sensory magnitude estimation, such as the Linear Magnitude Scale developed by Green *et al.* (1993, 1996), can improve the chances of success in relating sensory judgments with analytical concentrations or activities.

In short, relating sensory evaluation to analytical data is often challenging. It requires high-quality data from both perspectives and a consideration of the structure of both data sets to ensure that subsequent data analyses do not fatally contravene the assumptions of the data analysis methods employed.

Future Perspectives: Detection of Non-sensory Components of Physiological Significance

The presence of compounds in beer with potential physiological effects has been discussed elsewhere in this book. The approaches described here can, in principle, be used to assess whether specific components are physiologically active (analysis-led) or whether some form of biological activity can be traced to specific beer components (assay-led). Thus, the observation of some form of biological activity can be probed using the analytical approach outlined above. Similarly, the observation in beer of compounds with known or purported biological activity can be evaluated in the appropriate biological assay. Some of the deficiencies mentioned above in relation to the inclusion compared with the control of the matrix may also be important here; biological activity could be a synergistic expression of more than one compound, so that isolation of single components may mean that the most exhaustive search is doomed to failure.

Conclusions

The identification of taste- and aroma-active components in beer has occupied brewing scientists for more than a century. The major chemical contributors to beer flavor have been mapped on to flavor descriptors. Thus the most substantial contributors to bitterness, estery, sulfury, and a myriad of off-flavors are known. The challenge today is to complete this mapping exercise, in the knowledge that flavors, even of quite disparate origin, can interact both synergistically and antagonistically so that flavor expression is specific to a given beer. The role of the relatively abundant non-volatile fraction, particularly in terms of how they impact on the flavor release and flavor intensity of volatile beer components, has been studied in other systems, and also from a theoretical

standpoint. The fact that dextrins have been shown to affect the partitioning behavior of volatiles into the headspace of solutions indicates that this could be a possible expression of the impact of the beer matrix on flavor perception.

Summary Points

- Beer is a complicated mixture of well-defined volatile and non-volatile components, together with a range of oligo- and polymeric substances. These are either truly solvated or in the colloidal state, in a carbonated, acidic matrix (pH 3.8–4.8) of aqueous ethanol (typically 0.5–1.0 M).
- The flavor components of beer can be considered to originate from its raw materials (most commonly malted barley and hops/hop products), the impact of the process (particularly boiling and fermentation) and changes to the beer during its shelf-life. Additionally, unwanted taints can be found in clearly defective beers.
- The motivation for identification of taste- and aroma-active compounds in beer is either to troubleshoot problems or to understand specific flavor expression. In the case of the former and the need is to eliminate the problem, in the case of the latter the need is to apply the appropriate control to ensure product quality and consistency.
- Analysis-led identification of flavor-active components relies on applying chromatographic techniques to spot analytical anomalies, either by comparison with data from other beers, or the experience of the flavor chemist.
- Sensory-led identification of flavor-active components relies on sensory evaluation reliably flagging up flavor issues, which the flavor chemist attempts to identify cause-and-effect relationships with beer components.
- The rigorous proof of the flavor impact of a specific compound requires obtaining authentic material, either by isolation and purification from source, or by (custom) synthesis. Before using any such materials in a sensory evaluation experiment, all efforts must be made to ensure its purity and its safety.
- Instrumental analysis often requires some form of sample preparation to eliminate or control the matrix of the analyte, such that subsequent analytical methodology, almost always based on chromatography, can be applied to reliably detect, identify and/or measure target components.
- Relating sensory and analytical data can be problematic for several reasons, so that attempting to map one or more compounds to a specific flavor attribute can often meet with failure in all but the simplest cases.
- This correlation problem can be addressed, at least in part, by simple mathematical transformation of magnitude estimation data or by applying techniques such as the Labeled Magnitude Scale (LMS) which improves the linearity of sensory data.
- Ultimately, the ability of the flavor chemist to allow for the matrix effects in any sensory evaluation, which are

controlled or eliminated in the analytical experiment, will enhance his/her chances of success.

- The approaches indicated here can in principle be used to relate analytical data to other functional detection systems beyond sensory evaluation. One example is the appraisal of biological activities through specific functional assays.

Hop Essential Oil: Analysis, Chemical Composition and Odor Characteristics

Graham Eyres and Jean-Pierre Dufour Department of Food Science, University of Otago, Dunedin, New Zealand

Abstract

The essential oil of hops (*Humulus lupulus* L.) imparts odor and aroma characteristics to beer. Hops can influence beer aroma in terms of floral, spicy, herbal, woody and fruity characters. There are a large number of hop varieties commercially available with distinct odor characteristics, which can be attributed to the different composition of their essential oils. This composition is complex, potentially containing up to 1,000 compounds from a wide range of chemical classes. Fresh essential oil is dominated by terpene hydrocarbons, predominantly myrcene, α-humulene and β-caryophyllene. The composition varies depending on: intrinsic and extrinsic factors during growth, processing conditions, and the extraction method used to isolate the essential oil. In addition, oxidation and hydrolysis reactions occurring during storage alter the composition and further increase the chemical complexity.

Despite more than 50 years of research, not all character-impact odorants in hop essential oil have been identified. Due to its abundance, myrcene is important for the odor of fresh hop essential oil. Linalool and geraniol have been determined to be important odorants contributing to the floral character of hop essential oil and beer. Other compounds such as β-ionone, β-damascenone, geranial, neral, *trans*-4,5-epoxy-(*E*)-2-decenal, 1,3(*E*),5(*Z*)-undecatriene, 1,3(*E*),5(*Z*), 9-undecatetrene, ethyl 2-methylpropanoate, methyl 2-methylbutanoate, propyl 2-methylbutanoate, (*Z*)-1,5-octadien-3-one, nonanal and isovaleric acid have been implicated as potent odorants in hop essential oil.

Hoppy aroma in beer is still not completely understood due to the physical, biochemical and chemical changes that occur during brewing and fermentation. Hop-derived odorants identified in beer but not present in hop essential oil include citronellol, γ-nonalactone, humuladienone, geranyl acetate and ethyl cinnamate. Oxidation and hydrolysis products of sesquiterpenes (e.g. humulene epoxides) have commonly been associated with "noble" hop characters in beer; however, the importance of these compounds remains controversial.

The complexity of hop aroma in beer has led to increasing trends to add fractionated hop oils with specific odor characteristics to beer post-fermentation.

List of Abbreviations

AU	Aroma Units
^{1}D	First column
^{2}D	Second column
DMS	Dimethyl sulfide
DMTS	Dimethyl trisulfide
FID	Flame ionization detector
GC × GC	Comprehensive two-dimensional gas chromatography
GC–O	Gas chromatography–olfactometry
HACP	Hop aroma component profile
HPLC	High performance liquid chromatography
MDGC	Multidimensional gas chromatography
MS	Mass spectrometry
SDE	Simultaneous distillation extraction
SPE	Solid-phase extraction
Syn.	Synonym
TOFMS	Time-of-flight mass spectrometry

Introduction

Hops (*Humulus lupulus* L.) are added to beer to impart bitterness, odor and aroma. Both hop resins and essential oil are found in the lupulin glands of the female flower cone. The essential oil is comprised of the components that are volatile in steam, usually isolated by distillation (Lawrence, 2002). The iso-α-acids originating from hop resins are predominantly responsible for bitterness, whereas a number of compounds in the essential oil are responsible for imparting hoppy odor and aroma to beer. Essential oil makes up between 0.5% and 3% of the gross composition of the

dried hop cone, varying between varieties (Benitez *et al.*, 1997; Briggs *et al.*, 2004).

Hops are typically added to wort during the boil (kettle hopping) to extract the bitterness and allow the chemical isomerization of the α-acids to the more bitter iso-α-acids. To minimize evaporation of essential oil and retain aroma compounds, premium aroma hops are added at the end of boiling (late hopping) or even to the whirlpool (Benitez *et al.*, 1997; Fritsch and Schieberle, 2003).

There are a large number of hop varieties commercially available with varying α-acids contents, essential oil levels and odor profiles (Benitez *et al.*, 1997; Briggs *et al.*, 2004). It is well known that different hop varieties produce beers with distinct aroma characteristics. Differences in the odor profiles between hop varieties can be attributed to the composition of their essential oil (Gardner, 1994). Brewers often use several varieties in a single beer to achieve the desired balance of bitterness, odor and aroma. This is usually based on α-acids content (which does not directly contribute to aroma), past experience, and trial and error. Varieties of hops are typically classified into bitter varieties with high α-acids, aroma varieties with desirable odor characteristics and dual purpose varieties that meet both criteria.

The terms odor, aroma and flavor are often used synonymously, but in this chapter a distinction will be made between them. Odor and aroma both result from a perception of volatile compounds at the olfactory epithelium in the nose. *Odor* can be defined as an orthonasal perception, where volatiles are breathed in directly through the nose. In comparison, *aroma* is a retronasal perception, where volatiles reach the olfactory epithelium via the mouth during consumption (Acree, 1993; Blank, 2002). Finally, *flavor* is a complex and integrated perception consisting of odor, aroma, taste, texture or mouthfeel, and any other trigeminal sensations such as irritation, cooling or heat (Lawless and Heymann, 1998).

This chapter discusses the chemical composition of hop essential oil and the factors that influence its composition. Methods of extraction, methods of analysis and the fractionation of essential oil are also considered. The odor characteristics of hop essential oil and the current understanding of the compounds responsible are presented with an inference to hop aroma in beer.

Variation and Changes in Composition

Much like other plant essential oils, the composition of hop oil depends on a number of intrinsic and extrinsic factors during growth. The most important of these are genetic differences where the composition varies markedly between hops of different varieties. Minor genetic variation may also occur between hops of the same variety from different growing regions. Hops are typically grown without

male plants to reduce the amount of seeds, but this may reduce yields (kg/ha) (Benitez *et al.*, 1997). However, seedless hops typically produce more essential oil (Briggs *et al.*, 2004). An alternative method is the production of seedless triploid varieties, which have three sets of chromosomes instead of the normal two (diploid), and produce normal harvest yields (Beatson *et al.*, 2003).

Geographical location, climate and agronomical factors also affect the oil composition, potentially creating different profiles for hop samples with the same genetic material. Good yields depend on adequate soil nutrients and nitrogen levels, thus fertilizer is typically applied (Benitez *et al.*, 1997). Variation also occurs between harvest years due to different climatic conditions such as rainfall, temperature and sunshine. Irrigation is also required in arid conditions to ensure a good yield of hops and α-acids." As the flower cone develops, not only does the amount of essential oil increase but the proportions of compounds change. For example, oxygenated compounds are synthesized first, followed by sesquiterpenes (predominantly α-humulene (**1**) (Figure 22.1) and β-caryophyllene (**2**)), and the monoterpenes (primarily myrcene (**3**)) are produced last as the flowers ripen (Briggs *et al.*, 2004). Therefore, the harvest time will impact upon the composition of the essential oil and myrcene concentration can be used as a measure of hop ripeness. However, the humulene:caryophyllene ratio remains constant and is a varietal characteristic.

Infection from viruses and diseases, such as downy mildew, powdery mildew and verticillium wilt, and attack from pests, such as the damson hop aphid, the red spider mite and the two-spotted spider mite, can also change the composition and yield of essential oil as the plant becomes stressed (Benitez *et al.*, 1997; Hysert *et al.*, 1998). This has implications on the quality of the hops and the consistency of the oil composition. These pests and diseases are controlled by selective breeding for natural resistance, application of pesticides and fungicides (Briggs *et al.*, 2004), or alternatively via biological control using predatory mites (Barber *et al.*, 2003).

The composition of the essential oil changes during post-harvest processing, storage and transport. Compounds are partially lost through evaporation to varying degrees depending on their volatility. Furthermore, the composition of the essential oil continues to change due to oxidative degradation. The degree of change during storage depends on: the extent of physical damage to the lupulin glands withstood during harvesting, baling and kiln drying; the processing and packaging method; and the subsequent storage temperature. Larger bale sizes and density increase the damage to the lupulin glands (Forster, 2001). Baled hop cones waiting processing are often stored at ambient temperature, which allows significant changes to occur. It is recommended that temperatures during kiln drying do not exceed 60°C to prevent major losses of essential oil and oxidative degradation (Forster, 2001).

Figure 22.1 Chemical structures of major compounds and potential odorants in hop essential oil and beer.

Whole hops are the most susceptible to oxidation during storage, with significant losses of resins and essential oil occurring. Between 50% and 70% of the essential oil can be lost during 6 months storage at 20°C, mainly due to loss of myrcene (Beatson *et al.*, 2003). Therefore, hop bales should ideally be stored at refrigeration temperatures (0–5°C) (Forster, 2001).

During pelletization, hops are exposed to temperatures up to 65°C due to friction in the pelleting die, which causes the resins and essential oil that are released from the crushed lupulin glands to be susceptible to rapid oxidation. The EBC Manual of Good Practice for Hops and Hop Products (Benitez *et al.*, 1997) advocates a maximum pelleting temperature of 55°C followed by immediate cooling and vacuum packaging under an inert atmosphere (CO_2 or N_2). Packaged pellets should ideally be stored at refrigeration temperatures, but where this is impractical, keeping the temperature below 15°C should be sufficient to maintain freshness and quality (Benitez *et al.*, 1997; Forster, 2001). Extracts of resins and essential oil (see section "Methods of Extraction") are considerably more stable than pellets or whole hops, and therefore a maximum storage temperature of 20°C is acceptable (Forster, 2001).

Essential oil composition also depends on the method of isolation, as different techniques vary in their selectivity for different compound classes. This will be discussed further below (see section "Methods of Extraction").

Analysis and Characterization of Hop Essential Oil

The first characteristic of interest for a hop variety is the percentage yield of essential oil from the dried hop cones. This is determined by measuring the volume of oil recovered from steam distillation of dried hop cones and expressed in ml/g (Analytica-EBC, 2005; ASBC Methods of Analysis, 2006). The ratio of oil to α-acids is also important as brewers will primarily add hops to the kettle based on the content of α-acids to achieve a desired bitterness. Subsequently, the variable volume of essential oil added concurrently with the resins will impact upon the consistency of hop aroma in beer.

Routine analysis to determine the composition of hop essential oil is performed by gas chromatography with either flame ionization detection (GC–FID) or mass spectrometry (GC–MS). The hop essential oil is usually isolated prior to analysis (see section "Methods of Extraction"), although headspace analysis of hop cones or pellets is also performed. Headspace analysis can be achieved by either static or dynamic sampling, and the volatiles may also be concentrated by trapping on adsorbents. A convenient and popular technique for rapid characterization of hop volatiles is solid-phase microextraction (Kenny *et al.*, 2000; Steinhaus *et al.*, 2003).

Common criteria used to characterize a hop variety are the ratios of various sesquiterpene hydrocarbons, the most important being the humulene:caryophyllene ratio. A high humulene:caryophyllene ratio is typically associated with European aroma hops (Deinzer and Yang, 1994). The ratio of these sesquiterpenes is characteristic of a variety, independent of ripeness or storage, and have therefore been used to discriminate between varieties (Kralj *et al.*, 1991; Moir, 1994). However, while these ratios may be useful markers, they cannot be used to predict or explain differences in odor characteristics between varieties.

Consistent bitterness is achieved in beer by hop addition based on α-acids content. However, controlling hop aroma is more difficult as there is no single compound to measure to determine hopping rate. Addition based on total essential oil is not satisfactory due to variable composition, varietal differences and changes during storage. To address this, Foster and Nickerson (1985) proposed the "hoppiness potential" concept to control hopping rates based on the quantitative analysis of 24 compounds per gram of α-acids. This concept was further developed by Nickerson and Van Engel (1992) who refined the list of compounds and renamed it the "hop aroma component profile" (HACP) (Table 22.1). The compounds were classified into three categories: humulene and caryophyllene oxidation products; floral–estery compounds and citrus–piney compounds. These authors defined Aroma Units (AU) as the quantitative sum of the 22 HACP compounds per gram of hops (nl/g). HACP has subsequently been commonly used as a criterion for characterizing the essential oil of different hop varieties. It was envisaged that the compounds comprising HACP would evolve as new odorants were identified and their impact on beer aroma

Table 22.1 Classification of compounds comprising the hop aroma component profile[a]

Oxidation products[b]	Floral–estery compounds	Citrus–piney compounds
Humulene epoxide I (**18**)	Geraniol (**14**)	δ-Cadinene (**5**)
Humulene epoxide II (**19**)	Linalool (**15**)	γ-Cadinene (**6**)

elucidated. This has not really eventuated and an updated review of HACP is required for its potential to be realized.

The problem with analysis of hop essential oil using conventional GC is that the maximum number of compounds that can be resolved on a single 50 m column is limited to only 260 peaks (Bartle, 2002). In addition, peaks are neither evenly nor randomly distributed in a chromatogram because compounds demonstrate related chemical properties (Marriott, 2002). Because the number of compounds present in hop oil exceeds this peak capacity, severe co-elution occurs in conventional GC. This makes identification and quantification of compounds challenging, particularly for trace odorants co-eluting with larger odor inactive peaks. A solution is to use GC–MS in single ion monitoring (SIM) mode to quantify known compounds by a unique mass. This may be performed in conjunction with stable isotope dilution assay, which uses the deuterated target compound as an internal standard (Blank *et al.*, 1999; Steinhaus *et al.*, 2003). However, identification of unknown compounds remains difficult, particularly for trace odorants.

A potential solution to improve resolution is multidimensional gas chromatography (MDGC), which uses two columns with different stationary phases to create two independent separations. Compounds that co-elute on a first column may be resolved on a second column. For example, two compounds with similar boiling points that co-elute on a non-polar column may be resolved on a polar second column if they differ in their polarity. Traditional MDGC (Figure 22.2a) uses either a mechanical or pneumatic valve (V) to selectively transfer discrete regions, known as "heart-cuts," from the first column (^{1}D) to a second column (^{2}D) (Marriott, 2002). Regions that are not heart-cut to the ^{2}D column are diverted to FID 1, which monitors the separation on the ^{1}D column. The second detector is often another FID, but a mass selective detector may also be used to identify the compounds eluting from the ^{2}D column. The limitation of the heart-cut technique is that there must be sufficient time between sequential heart-cuts to prevent compounds from the two separate cuts overlapping on the ^{2}D column. Therefore, only a certain number of regions can be transferred and only a portion of the sample can be separated in two dimensions.

Another technique known as comprehensive two-dimensional gas chromatography (GC × GC) separates the *entire* sample in two dimensions in a single analysis. This is achieved using two columns connected in series with a cryogenic modulator (M) at the interface (Figure 22.2b). The modulator sequentially traps and pulses zones from the first column to the second column (e.g. every 5 s) creating two independent separation dimensions based on different compound properties. A short (0.5–2 m), narrow diameter (0.1 mm) and thin-film (0.1 μm) ^{2}D column is typically used to create a fast, efficient separation in the second dimension so that peaks from sequential pulses do not overlap (wraparound). GC × GC results are typically converted to a matrix and plotted as a contour plot analogous to a topographical map (Figure 22.3b). Retention time on the ^{2}D column is plotted against retention time on the ^{1}D column with detector signal plotted on the *z*-axis with shaded or colored contour levels used to denote peak height and compound abundance.

The greater peak capacity, resolution and sensitivity of GC × GC provide superior analyses compared with conventional GC analysis. Figure 22.3a presents a section of a single column separation of a sample of Cascade hop essential oil and exhibits considerable co-elution in the complex region of oxygenated sesquiterpenoid compounds. Figure 22.3b demonstrates the superior resolution obtained using GC × GC and illustrates the complexity of the region.
Figure 22.2 Schematic diagrams of (a) a traditional heart-cut MDGC system and (b) a comprehensive GC × GC system. ^{1}D, first column; ^{2}D, second column; V, valve; TL, transfer line to FID 1; M, cryogenic modulator. Detector 2 in the MDGC system could either be a FID or a mass selective detector. The detector in the GC × GC system could either be a FID or a TOFMS.

At present, these multidimensional techniques are generally used for research purposes rather than routine analysis, but their potential for the discovery of new compounds is immense. For more information on the development and operation of GC × GC and TOFMS the reader is directed toward two comprehensive reviews (Phillips and Beens, 1999; Marriott, 2002).

Composition of Hop Essential Oil

The composition of hop essential oil is complex. Nijssen *et al.* (1996) compiled a comprehensive list of 425 compounds reported in hop essential from 75 references. During the last decade, a further 60 compounds have been identified and reported bringing the total to 485 (Roberts *et al.*, 2004). However, recent research suggests that up to 1,000 compounds may actually be present (Roberts *et al.*, 2004). This leaves great scope for further identification and discovery of important odor active compounds. Hop essential oil contains a wide range of aliphatic, aromatic and terpenoid compound classes. Figure 22.4 presents a GC × GC separation of a sample of Target hop essential oil demonstrating the complexity of the chemical composition.

Terpenoid compounds

Figure 22.4 shows the main classes of terpenoid compounds present in hop essential oil, namely monoterpene hydrocarbons, monoterpene alcohols, sesquiterpene hydrocarbons, sesquiterpene epoxides and sesquiterpene alcohols. The composition of fresh hop essential oil is dominated by terpene hydrocarbons, primarily the monoterpene

Combining GC × GC to time-of-flight mass spectrometry (TOFMS) results in a very powerful identification tool (Roberts *et al.*, 2004).

Another advantage of GC × GC is that it generates a structured chromatogram which aids peak identification. Different compound classes elute in specific regions and clusters of the chromatogram depending on their interaction with the two stationary phases. For example, using a polar ^{2}D column, early eluting hydrocarbons are at the bottom of the GC × GC plot whereas alcohols are at the top (Figure 22.4). In addition, homologous series of compounds form linear or logarithmic relationships in the separation plane which helps to discriminate between isomeric compounds (Roberts *et al.*, 2004; Eyres *et al.*, 2005) (Figure 22.5).

Figure 22.5 Homologous series of compounds identified in a GC × GC separation of Target hop essential oil. The apex of each peak is plotted with ^{2}D retention time (y-axis) plotted against ^{1}D retention time (x-axis). The trendline for the alkane series was fitted using a linear function. Ester and ketone series were fitted with a logarithmic function. Trendlines could not be fitted to the alcohol series. The numbers in parentheses in the key refer to the range of total number of carbons in each series.

myrcene (**3**) and sesquiterpenes α-humulene (**1**), β-caryophyllene (**2**) and β-farnesene (**4**). Other monoterpenes include α- and β-pinene, sabinene, δ-3-carene, camphene, *p*-cymene, (*Z*)- and (*E*)-β-ocimene, α- and γ-terpinene, α-terpinolene and limonene (**9**). There is a bewildering array of over 40 acyclic, monocyclic, bicyclic and tricyclic sesquiterpene hydrocarbons including (*Z*)- and (*E*)-α-bergomotene, cadinenes (e.g. **5**, **6**), muurolenes (e.g. **7**), selinenes (e.g. **8**), ylangenes, copaenes, germacrenes, selinadienes and many others (Moir, 2000). Sesquiterpenoids are notoriously difficult to resolve and identify because they have the same molecular formulae and therefore interact with column stationary phases in the same manner and exhibit very similar mass spectra.

Autoxidation and subsequent hydrolysis and rearrangement of sesquiterpene hydrocarbons lead to a large number of reaction products that increase during storage of hops (Deinzer and Yang, 1994). These include the epoxides, with the most abundant being humulene epoxide II (**19**) and caryophyllene oxide (**28**). Humulene epoxides I (**18**) and III (**20**) are typically present at lower levels. However, humulene epoxide I is more resistant to hydrolysis than humulene epoxide II and III, and therefore persists during storage and is found at greater concentrations in beer (Deinzer and Yang, 1994). Further oxidation results in the formation of five humulene diepoxide isomers (A–E) (**21–24**), although humulene diepoxide A (**21**) predominates in hop oil and beer (Deinzer and Yang, 1994). Sesquiterpene epoxides and diepoxides undergo further

hydrolysis and rearrangements to form various ketones and alcohols (see below).

Monoterpene alcohols are generally biosynthetic products related to the biosynthesis of myrcene. These include geraniol (**14**) and linalool (**15**), which are particularly important as floral odorants in hop essential oil. Other monoterpene alcohols present are nerol (**13**), α-terpineol, borneol, fenchol, myrtenol and limonene-10-ol (**10**). Sesquiterpene alcohols are typically oxidation degradation products and among many others include humulenol II (**25**), humulol (**26**), caryophyllene alcohol (syn. caryolan-1-ol) (**29**), caryophyllenol, nerolidol, farnesol isomers, cadinol isomers and eudesmol isomers. Biosynthetic alcohols tend to decrease during storage, whereas oxidation-derived alcohols tend to increase (Moir, 1994).

The monoterpene aldehydes neral (**11**) and geranial (**12**) have been identified in freshly distilled hop essential oil but these compounds will be rapidly reduced to their corresponding alcohols during storage or fermentation (Sanchez *et al.*, 1992a). The terpenoid ketones β-ionone (**32**) and β-damascenone (**33**) are found at trace levels in hop essential oil resulting from the degradation of β-carotene (Sell, 2003). The ketones humulenone and humuladienone (**27**) result from the oxidation reactions of humulene.

A number of esters of the terpene alcohols are also present including methyl geranate, methyl nerolate, geranyl propanoate, neryl propanoate, geranyl isobutanoate (**17**), neryl isobutanoate, geranyl acetate (**16**), neryl acetate and linalyl acetate.

Oxygen heterocyclic compounds in hop essential oil include (*Z*)- and (*E*)-linalool oxide (**30**, **31**), rose oxide and cyclic ethers such as hop ether and karahana ether (Moir, 1994).

Non-terpenoid compounds

The composition of hop essential oil includes many homologous series of aliphatic compounds (Figure 22.5). Aliphatic hydrocarbons are present at low levels and are represented by a series of linear alkanes, a number of branched alkanes and several trace alkenes. Hop essential oil contains a number of isomeric series of straight chain and branched ketones. The foremost series is the methyl ketones with the most abundant compound being 2-undecanone (syn. methyl nonyl ketone). Levels of aldehydes are generally low in hop essential oil and are mainly lost during kiln drying. Aldehydes identified include linear alkanals (e.g. nonanal), *E*-2-hexenal, *Z*-3-hexenal, *E*-2-nonenal, benzaldehyde and phenylacetaldehyde (Nijssen *et al.*, 1996).

Hop essential oil is rich in a large variety of aliphatic esters. Many exist as homologous series including: linear methyl alkanoates (e.g. methyl decanoate); branched methyl alkanoates such as methyl 2-methyl-alkanoates

and the methyl isoalkanoates (e.g. methyl 6-methyl-heptanoate); unsaturated methyl alkenoates (e.g. methyl E-2-decenoate); alkyl propanoates (e.g. pentyl propanoate); alkyl isobutanoates (e.g. hexyl 2-methyl-propanoate) and unsaturated alkenyl acetates with unconfirmed stereochemistry (e.g. octenyl acetate). Important esters that do not exist in homologous series include methyl Z-4-decenoate, 2-methylpropyl 2-methyl-propanoate (syn. 2-methylpropyl isobutanoate), 2-methylbutyl 2-methyl-propanoate (syn. 2-methylbutyl isobutanoate), 3-methylbutyl 3-methyl-butanoate (syn. isoamyl isovalerate) and 2-methylbutyl 3-methyl-butanoate (syn. 2-methylbutyl isovalerate). The homologous series of straight chain methyl esters most likely originate from fatty acid biosynthesis, whereas the branched chain esters (e.g. 2-methylbutyl isobutanoate) are derived from amino acid biosynthesis (Briggs et al., 2004).

Alcohols are represented by straight chain alcohols, such as 1- and 2-alkanols, and branched chain alcohols, such as 2-methyl-3-buten-2-ol, which is formed by cleavage of the isoprenyl side chains of the α- and β-acids (Briggs et al., 2004). Acids are also present in hop essential oil and are usually associated with aged hops as degradation products of the α- and β-acids. Cleavage of the acyl side chains yields 3-methylbutanoic acid (syn. isovaleric acid) from humulone and lupulone, 2-methylbutanoic acid from adhumulone and adlupulone, and 2-methylpropanoic acid (syn. isobutyric acid) from cohumulone and colupulone. These acids are responsible for the cheesy aroma of aged hops (Benitez et al., 1997; Briggs et al., 2004). Photo-oxidation of the ring structure of the α- and β-acids also produces 4-methyl-3-pentenoic acid. Other acids include decanoic acid and Z-4-decenoic acid. The degree of acids found in essential oil also varies depending on the sample preparation and extraction or distillation method used to isolate the oil.

Sulfur compounds

Lermusieau and Collin (2003) recently reviewed the occurrence and origins of sulfur compounds in hops and beer. Sulfur compounds are present at trace levels but can have very low odor thresholds and so impact upon the odor of essential oil and beer (Lermusieau et al., 2001). Methyl thioesters have been commonly identified in hop essential oil and Lermusieau and Collin (2003) assert that these are not artifacts of steam distillation because they are also present in cold solvent extracts. The authors suggested a possible biosynthetic pathway from methionine degradation. The concentration of thioesters depends on variety and local growing conditions, and increase considerably upon kiln drying, independent of sulfur dioxide (SO_2) application.

Other sulfur containing compounds include thiophenes, sulfur adducts of myrcene and humulene, and episulfides of sesquiterpenes. These compounds result from reactions with elemental sulfur either applied in the field to control powdery mildew (Briggs et al., 2004) or from burning sulfur during kilning (Benitez et al., 1997). In the presence of light or heat, sesquiterpenes react with the residual elemental sulfur to generate episulfides. These compounds have the same structure as the corresponding epoxides except oxygen is substituted by sulfur. A number of sulfur adducts of myrcene and humulene also form due to reaction with elemental sulfur. These compounds are also formed during steam distillation as a result of the high temperature applied, and can be thought of as artifacts of sample preparation. In contrast, vacuum distillation and CO_2 extracts have much lower levels of sulfur compounds (Briggs et al., 2004). However, these compounds could also form in the kettle during boiling and be introduced into the beer, particularly upon late hopping where limited evaporation occurs (Lermusieau and Collin, 2003).

Dimethyl sulfide (DMS) is also generated during steam distillation and wort boiling by thermal degradation of S-methylcysteine sulfoxide. The levels of DMS and polysulfides (e.g. dimethyl trisulfide, DMTS) also increase with levels of elemental sulfur and when kilning is performed without SO_2. These sulfide compounds have characteristic cooked vegetable, onion, rubbery and sulfury odors that may impact on beer aroma. The compound responsible for the skunky aroma of lightstruck beer, 3-methyl-2-butene-1-thiol (**34**), has also been found in hop pellets being derived from the isoprenyl side chains of α- and β-acids (Lermusieau et al., 2001).

Odor Characteristics of Hop Essential Oil

Although there maybe several hundred compounds present in hop essential oil, only a certain number will be present at a concentration above their detection threshold and contribute to the odor of the oil (Guadagni et al., 1966; Buttery, 1999). Compounds that are responsible for, or significantly contribute to, a sample's distinctive odor profile are known as *character-impact odorants*.

Instrumental analysis of character-impact odorants

The characterization of essential oils is usually based on chemical composition determined by GC–MS or GC–FID. However, odor detection thresholds of volatile compounds can differ by many orders of magnitude (e.g. parts per trillion up to odorless compounds) (Buttery, 1999). The relationship between concentration and odor intensity may also vary considerably between compounds. Therefore, the response of a chemical detector is not representative of odor activity. For example, the most abundant compound in a chromatogram may not be the most important odorant (Eyres et al., 2005). Consequently, the impact of

1
Figure 22.6 Comparison of (a) the GC–O "aromagram" with (b) the FID chromatogram for Saaz hop essential oil. Retention index (x-axis) is plotted against (a) dilution value for GC–O and (b) FID signal. Peak areas in the GC–O aromagram are proportional to odor potency.

a compound on the odor of a sample must be evaluated using human assessors. A valuable tool for identifying character-impact odorants is gas chromatography–olfactometry (GC–O), where human "sniffers" are used to detect and evaluate the odor of compounds as they elute from a GC separation (Delahunty et al., 2006). Figure 22.6 demonstrates that the odor profile generated by GC–O is rather different than the FID chromatogram for a hop essential oil sample. Several odor peaks correspond to major FID peaks but conversely, other important odorants do not correspond to any noteworthy FID peaks, only being present at trace concentrations. The advantage of GC–O is that it specifically measures odor activity and can therefore be used to locate character-impact odorants. Once odorants have been identified and their odor activity confirmed, their concentrations can be routinely measured using a conventional detector.

There are a number of issues that should be taken into account when interpreting GC–O data. Various GC–O methodologies use different properties to rate odorant importance, including odor potency by dilution analysis (concentration/threshold; synonymous to odor activity values or odor units), detection frequency of a panel and direct odor intensity (Delahunty et al., 2006). Two methods may produce different results because the relationship between concentration and odor intensity differs considerably between compounds (Petersen et al., 2003). The objective of GC–O is to assess the odor activity of compounds individually without co-elution. This allows identification of the odorants that are potentially important but does not take into account possible interactions that

occur in the mixture such as synergistic, antagonistic (suppression) or additive effects (Delahunty et al., 2006). For these reasons, assessment of hops using sensory evaluation is indispensable.

Sensory evaluation of odor characteristics

There have been relatively few sensory evaluations of raw hop cones or essential oils. Sanchez et al. (1992b) used a descriptive sensory panel and GC–O to evaluate oxygenated fractions of three hop varieties. Stucky and McDaniel (1997) used free-choice profiling to discriminate 15 varieties, and correlated the sensory results with the concentration of 21 compounds. Myrcene and linalool demonstrated a strong association with the combined sensory characters of fruity, floral, pine and sage in principal components analysis (PCA).

Odorants identified in hop essential oil

The odor characteristics of compounds that are potential odorants in hop essential oil and beer are summarized in Table 22.2. At harvest, the most potent odorant in green hops is Z-3-hexenal (green, cut grass), but this is mostly lost during kiln drying (Steinhaus and Schieberle, 2000). This odorant is common in plants and herbs as a secondary metabolite of linoleic acid. Myrcene is typically the most abundant compound in fresh hop essential oil. Its odor threshold in water has been determined to range between 13 and 36 ppb (Guadagni et al., 1966; Ahmed et al., 1978; Masanetz and Grosch, 1998), and so is expected to exert a large impact on the odor profile of the essential oil. This has been supported in studies using GC–O (Steinhaus and Schieberle, 2000). It has odor descriptors of resinous, herbaceous, balsamic and geranium-like (Masanetz and Grosch, 1998; Steinhaus and Schieberle, 2000).

Odorants that contribute to floral characteristics of hop essential oil include linalool (floral – citrusy), geraniol (floral – rose, geranium) and β-ionone (floral – violet). The importance of linalool in hop essential oil has been confirmed by various authors using GC–O (Sanchez et al., 1992b; Steinhaus and Schieberle, 2000; Lermusieau et al., 2001). Geraniol has been determined to be a potent odorant in hop essential oil (Peacock and Deinzer, 1981; Lam et al., 1986; Eyres et al., 2006) but was not deemed important by Sanchez et al. (1992b) because only one of four assessors detected it during GC–O. It was also not detected by Steinhaus and Schieberle (2000). These results could be influenced by varietal differences (Peacock et al., 1981) or the age of the hops, as geraniol concentration increases during storage. The monoterpene aldehydes geranial and neral have also been implicated for the floral odor of essential oil (Nickerson and Van Engel, 1992). Sanchez et al. (1992b) reported that neral contributed a citrus-spicy odor during GC–O analysis. However, these compounds

Geranyl acetate (**16**)	Floral – lavender, perfumed pine	2, 5
Geranyl isobutanoate (**17**)	Floral – rose	2
Humulene epoxide I (**18**)	Hay-like	6
Humulene epoxide II (**19**)	Moldy, cedar	6, 7
Humulene epoxide III (**20**)	Cedar	7
Humulene epoxides I, II, III	Musty, floral, spicy	3
Humulene diepoxide A, B (**21**, **22**)	No odor	3
Humulenol II (**25**)	Sage-brush, pineapple	6, 7
Humulol (**26**)	Hay-like	6
Humuladienone[c] (**27**)	Flowery, fresh	5
Caryophyllene oxide (**28**)	Musty, floral, spicy, cedar	3, 7
β-Ionone (**32**)	Floral – violet	2, 4
β-Damascenone (**33**)	Cooked apple, tobacco, prunes	3, 4
3-Methyl-2-butene-1-thiol (**34**)	Sulfurous, skunky, mercaptan	2
Dimethyl disulfide	Cheesy, glue	5
Dimethyl trisulfide	Onion, soup	2, 5
trans-4,5-epoxy-(E)-2-decenal (**35**)	Metallic	1
γ-Nonalactone[c] (**36**)	Coconut, fruity, sweet	2, 5
Ethyl cinnamate[c] (**37**)	Cinnamon-like, honey-like strawberry, sweet	2, 5
Citronellol[c] (**38**)	Floral – rose, fruity, apple, citrus	2, 8
Isovaleric acid	Rancid, sweaty, cheesy	2, 4
Ethyl 2-methylpropanoate	Sweet, fruity	1, 2
Methyl 2-methylbutanoate	Sweet, fruity, apple-like	1, 2
Propyl 2-methylbutanoate	Sweet, fruity	1
1,3(E),5(Z)-undecatriene	Fresh, balsamic	1
1,3(E),5(Z),9-undecatetrene	Fresh, balsamic	1
(Z)-1,5-octadien-3-one	Geranium-like	1
Nonanal	Citrus, soapy, fatty	1, 2

[a] Numbers in parentheses refer to the chemical structure depicted in Figure 22.1.

[c] Hop-derived compounds in beer not found in hop essential oil.

will be rapidly reduced to their corresponding alcohols during storage (Briggs *et al.*, 2004).

β-ionone and β-damascenone (cooked apple) have previously been suggested to be important odorants due to their low odor thresholds (Tressl *et al.*, 1978), which range between 0.008–0.17 ppb and 0.002–0.009 ppb in water, respectively (Plotto *et al.*, 2006). Their importance as odorants has also been supported by various GC–O investigations for β-ionone (Eyres *et al.*, 2006) and β-damascenone (Sanchez *et al.*, 1992b; Lermusieau *et al.*, 2001; Murakami *et al.*, 2003), respectively. However, it is estimated that approximately 1/3 of the population have a specific anosmia for β-ionone and therefore cannot detect it (Brenna *et al.*, 2002; Plotto *et al.*, 2006). Recent research indicates that β-damascenone may also be partially affected by anosmia

(Plotto *et al.*, 2006) and that it has low odor intensity even at high concentrations above threshold (Petersen *et al.*, 2003). Therefore, the overall impact of these two compounds is still unconfirmed.

Steinhaus and Schieberle (2000) found *trans*-4,5-epoxy-(E)-2-decenal (**35**), a fatty acid oxidation product with a metallic odor, to be the most potent odorant in an extract of dried hop cones using GC–O. However, it was not present in a headspace sample and has not been reported in hops since, so its importance is still unverified. The same study also identified 1,3(E),5(Z)-undecatriene and 1,3(E),5(Z), 9-undecatetrene as important odorants in both the extract and headspace samples contributing a fresh, balsamic odor. Other potent odorants identified were ethyl 2-methylpropanoate (sweet, fruity), methyl 2-methylbutanoate (sweet,

fruity), propyl 2-methylbutanoate (sweet, fruity), (Z)-1,5-octadien-3-one (geranium-like), nonanal (citrus, soapy), and 2- and 3-methylbutanoic (isovaleric) acid (cheesy).

A panel of four assessors used the terms musty, floral and spicy to describe the odors perceived during GC–O for humulene epoxide I, II and III and caryophyllene oxide in oxygenated fractions of hop oil (Sanchez *et al.*, 1992b). This was confirmed using a synthesized mixture of the three humulene epoxides. In contrast, no odors were detected for humulene diepoxide A or B, even for a synthesized sample at high concentration. Steinhaus and Schieberle (2000) did not detect any humulene oxidation products by GC–O, but the oil may have been too fresh for oxidation to have occurred. Deinzer and Yang (1994) reported that almost all humulene and caryophyllene oxidation products exhibited cedar-like aromas during sensory evaluations. Fukuoka and Kowaka (1983) evaluated the aroma of several synthesized oxidation products. Humulene epoxide I and humulol had a hay-like odor, humulene epoxide II had a moldy odor and humulenol II had a sage-brush odor. The authors concluded that these compounds were not responsible for the odor of a concentrated high performance liquid chromatography (HPLC) fraction exhibiting a strong herbal, spicy character. The two herbal odorants actually responsible were not identified, but were reported to have an oxygenated sesquiterpenoid structure ($C_{15}H_{24}O$ and $C_{15}H_{26}O$). One of these compounds was also found in a sample of commercial Japanese beer.

Guadagni *et al.* (1966) and Tressl *et al.* (1978) suggested that hop ether, karahana ether, methyl-4-decenoate and methyl thiohexanoate were important odorants based on their odor activity values (concentration/threshold). The detection threshold and the odor impact of the two ethers in beer were re-evaluated by Lam and Deinzer (1986) who determined that neither compound was a major contributor to hop aroma.

Hop Aroma in Beer

Because all of the compounds responsible for hop aroma in beer have not been completely identified, sensory evaluation is still the method of choice for product development and quality control of beer. It is well established that the hoppy aroma in beer is due to the perception of complex mixtures of volatiles rather than single compounds. Hop aroma in beer is usually complex, and accurately describing the specific characteristics can be challenging. In addition, it is often difficult to differentiate hop-derived aroma from aroma compounds produced during fermentation. Hops can impact on beer aroma in terms of floral, spicy, herbal, woody and fruity (particularly citrus and tropical fruit) characters. However, the official beer flavor wheel does not adequately reflect this complexity of hop aroma, only using "hoppy" as a specific first-tier term (Meilgaard

et al., 1979). This is subdivided into three second-tier terms which are "kettle hop," "dry hop" and "hop oil." Use of the term "noble hop aroma" is common in the literature and is usually associated with traditional aroma hop varieties from Europe such as Hallertauer mittelfrüh, Hallertauer Hersbrucker, Saaz, Spalter and Tettnanger (Sanchez *et al.*, 1992b; Deinzer and Yang, 1994). However, the actual aroma description of this character is poorly defined, but is often described as herbal or spicy (Sanchez *et al.*, 1992b).

Physical, chemical and biochemical changes that occur during wort production and fermentation complicate the analysis of hop-derived compounds in beer. Thereby, not all compounds present in hop essential oil are found in kettle-hopped beer, and conversely not all hop-derived compounds in beer are found in hop essential oil itself. Hydrocarbons are not typically detected in beer except when dry hopping is used. Conversely, oxygenated compounds are much more likely to dissolve into wort and survive the boiling and fermentation processes.

Correlating sensory characteristics of hopped beer with instrumental composition may elucidate associations to aid understanding of hop aroma in beer. For example, Peppard *et al.* (1989) used multivariate statistics to correlate sensory characteristics for beer brewed with 8 different hop varieties with the concentration of 36 hop-derived compounds. Linalool oxide, and to a lesser extent caryophyllene alcohol and humulol, were correlated with "European hop aroma." A large number of compounds were associated with the spicy character including spiroacetal, dihydrospiroacetal, humulene epoxide I, humulenol II and humulene diepoxides. However, a good correlation does not prove a cause and effect relationship, so the impact of the compounds reported must still be directly confirmed (Peppard *et al.*, 1989).

Peacock *et al.* (1981) concluded that geraniol and linalool were responsible for most of the floral aroma in a beer brewed with Cascade hops. Geranyl isobutanoate was present below threshold, but could be hydrolyzed by yeast to yield free geraniol and contribute to the aroma. Linalool in particular has been implicated as being important in overall hoppy aroma and the noble hop aroma in beer (Steinhaus and Schieberle, 2000; Steinhaus *et al.*, 2003; Fritsch *et al.*, 2005). These compounds would be expected to produce a floral hop aroma in beer when added post-fermentation but are also expected to survive fermentation (Irwin, 1989).

There is also a difference in sensory threshold and odor character between linalool enantiomers. In hop essential oil, 92–95% of linalool is present as the more active (R)-enantiomer, which has an odor threshold approximately 80 times lower than (S)-linalool (Kaltner *et al.*, 2003; Steinhaus *et al.*, 2003). It has been shown that interconversion between the enantiomers occurs during wort boiling so that (S)-linalool may actually constitute 30% in beer, potentially decreasing the overall odor impact of linalool

(Fritsch and Schieberle, 2003). The extent of this conversion appears to be dependent on the wort pH (Marriott *et al.*, 2006).

Lermusieau *et al.* (2001) assessed amberlite resin (XAD-2) extracts of beer using GC–O. The authors compared the odorants present in unhopped beer with those in two beers late-hopped with Saaz and Challenger, respectively. Potent hop odorants were linalool, β-damascenone, dimethyl disulfide (cheesy, glue), DMTS (onion, soup) and an unidentified spicy, hoppy odorant eluting with a retention index of 810 on an apolar stationary phase. Hop-derived odorants that were detected in hopped beer but not in steam distilled hop essential oil were γ-nonalactone (fruity, sweet) (**36**), humuladienone (flowery, fresh), geranyl acetate (perfumed pine) and ethyl cinnamate (strawberry, sweet) (**37**). Sanchez *et al.* (1992a, 1992b) reported 9-methyl-2-decanone (musty, vinyl, rancid) as a possible odorant in hop oil and beer extracts.

Citronellol (floral – citrus, fruity, apple) (**38**) has also been identified as a hop-derived compound in beer by GC–MS and GC–O and is implicated in contributing to hop aroma (Lam *et al.*, 1986; Sanchez *et al.*, 1992a). It has been shown that citronellol can be transformed from geraniol by yeast during fermentation (King and Dickinson, 2000, 2003). It has also been suggested that it is formed by reduction of geranial and neral by yeast (Lam *et al.*, 1986; Sanchez *et al.*, 1992a).

β-damascenone has been identified as a potent odorant in beer by various authors (Schieberle, 1991; Sanchez *et al.*, 1992a; Lermusieau *et al.*, 2001; Chevance *et al.*, 2002; Fritsch *et al.*, 2005). Its concentration has been shown to increase during wort boiling (Kishimoto *et al.*, 2005), decrease during fermentation due to reduction or adsorption by yeast, and then increase again upon storage (Chevance *et al.*, 2002). β-damascenone is likely to contribute to the odor of beer because of its low threshold. However, its sensory impact on overall beer flavor still needs to be confirmed using sensory evaluation to assess its odor intensity and interaction with other aroma compounds. It should also be noted that β-damascenone only partially originates from hops, also being present in unhopped wort and beer (Lermusieau *et al.*, 2001; Chevance *et al.*, 2002; Fritsch and Schieberle, 2003).

Oxidation and hydrolysis products of sesquiterpenes have been associated with the noble and spicy hop characters in beer (Peacock and Deinzer, 1981; Lam *et al.*, 1986; Deinzer and Yang, 1994; Goiris *et al.*, 2002). Good correlations between increasing concentrations of humulene epoxides and these hop characters have been demonstrated (Kowaka *et al.*, 1983; Peppard *et al.*, 1989). As a result, so-called noble hop varieties are often purposefully stored prior to brewing to increase the levels of oxygenated compounds (Deinzer and Yang, 1994; Briggs *et al.*, 2004). However, a good correlation does not prove a cause and effect relationship (Peppard *et al.*, 1989), and the importance of these oxidation compounds for imparting hoppy aroma remains controversial (Fukuoka and Kowaka, 1983; Irwin, 1989; Goiris *et al.*, 2002). The compounds so far identified have exhibited concentrations below their detection thresholds and their aroma characteristics do not correspond to the desired spicy or noble hop aroma (Deinzer and Yang, 1994).

Yang *et al.* (1993) found that a hydrolysis reaction mixture from humulene epoxide I and II contributed a cedar, lime, spicy character to beer, but with a relatively high sensory threshold of 2.3 ppm. This concentration was exceeded in pilot beers, but not in any commercial brands tested. In the study by Sanchez *et al.* (1992a), only one out of four assessors detected the odors associated with humulene oxidation products in beer extracts using GC–O, despite being detected in hop oil and identified in the beer extracts by GC–MS. It was concluded that the compounds were not present at high enough concentration. This may indicate that humulene epoxides may contribute to hop aroma but are not essential to it (Deinzer and Yang, 1994).

Goiris *et al.* (2002) found that adding 20 ppb of an oxygenated sesquiterpene fraction isolated by supercritical CO_2 extraction and solid-phase extraction (SPE) to a bland pilot beer produced a desirable spicy or herbal aroma reminiscent of noble hop aroma. The authors concluded that this was due to unidentified compounds present in this fraction, associated with humulene oxidation products.

There is growing evidence for the release of glycosidically bound hop aroma compounds during wort boiling, fermentation or ageing (Goldstein *et al.*, 1999; Chevance *et al.*, 2002; Fritsch *et al.*, 2005; Kishimoto *et al.*, 2005). Examples that are implicated in hop aroma are geraniol, linalool and β-damascenone. These glycosidically bound compounds are not isolated with the essential oil but may affect hop aroma in kettle-hopped beer as they are released by acid catalyzed hydrolysis during boiling (Chevance *et al.*, 2002).

Methods of Extraction

One should distinguish between methods used to isolate hop essential oils for analysis or for the manufacture of commercial products. The simplest method for isolation of essential oil is either steam distillation or hydro-distillation. A method solely used for analytical sample preparation are many adaptations of the Likens–Nickerson simultaneous steam distillation-solvent extraction (SDE) (Likens and Nickerson, 1964). Distillation methods involve the application of heat and therefore there is the possibility to produce artifacts by thermal degradation. Composition will differ depending on whether the distillation is performed at atmospheric or reduced pressure due to the temperature that is applied (Briggs *et al.*, 2004). Steam distillation at atmospheric pressure is known to cause a number of degradative changes so that the odor of the resultant oil

is not representative of the original sample (Moyler, 1993; Gardner, 1994). As a result, early attempts at using these oils for dry hopping were unsuccessful (Gardner, 1994).

Solvent extraction is another method of obtaining hop volatiles, although according to Lawrence (2002) these extracts cannot strictly be called essential oils and are more accurately described as "volatile concentrates." However, for all intents and purposes the final result is very similar – an isolated volatile oil. Various solvents have been used commercially including hexane, ethanol, methanol, trichloroethylene and methylene chloride (Gardner, 1993). However, only hexane and ethanol are still in use and even these are in decline (Briggs *et al.*, 2004). These solvent extracts are known to decrease the yield and alter the composition and odor characteristics of hop essential oil due to the loss of volatile compounds during evaporation of the solvent (Gardner, 1993; Benitez *et al.*, 1997). The most volatile compounds, which are responsible for top notes in the odor profile, are most severely affected. There are also safety and regulation concerns regarding solvent residues remaining in the extracts.

Currently the method of choice to extract hop essential oil is extraction using liquid or supercritical CO_2. Liquid CO_2 extraction is typically carried out at 5–15°C and 60–65 bar whereas supercritical CO_2 requires greater temperature (40–60°C) and pressure (200–250 bar) (Benitez *et al.*, 1997). Composition of the two extracts is likely to be extremely similar, except that supercritical CO_2 extracts contain more hard resins, polar bitter substances and pigments (e.g. chlorophyll), the latter giving a dark green color to supercritical extracts (Gardner, 1993; Benitez *et al.*, 1997). The extraction efficiency and flexibility of supercritical CO_2 are greater, because the solvent properties can be altered by varying the temperature and pressure. In comparison, the properties of liquid CO_2 can only be altered by small changes in temperature (Gardner, 1993; Benitez *et al.*, 1997). The impact on trace odor compounds has not been thoroughly investigated, with liquid CO_2 extraction theoretically giving a milder extraction and a more representative extract (Moyler, 1993). In practice, liquid CO_2 is used when the extract is further processed for essential oil and aroma products due to its greater selectivity and lower temperature (Gardner, 1993).

Oil enriched extracts (~26 ml oil per 100 g extract) may be produced using either partial extraction with liquid CO_2 or by two-step fractionation using supercritical CO_2, where the resins are initially precipitated by reducing the pressure to 100–120 bar before recovering the essential oil in an evaporator (Benitez *et al.*, 1997). However, it is more practical to make a total extract comprising both hop resins and essential oils and isolate the essential oil using molecular distillation under high vacuum (1.33×10^{-6} bar) (Gardner, 1994; Benitez *et al.*, 1997; Briggs *et al.*, 2004). For essential oils, the great advantage of CO_2 extraction is that the aroma compounds are obtained quantitatively without the creation

of artifacts. Therefore, the odor profile is much more representative of the original sample than steam distillation or other solvent extraction methods (Moyler, 1993; Gardner, 1994). Separating the essential oil from the resins allows hop aroma and bitterness to be controlled independently in the brewing process (Gardner, 1993).

Essential Oil Fractionation

Hop essential oils are often fractionated by physical and chemical properties in an attempt to improve the resolution of compounds for the chemical analysis of hop essential oils. Historically, hop essential oils were separated into a hydrocarbon fraction and an oxygenated fraction by elution from a silica gel column with light petroleum and ether, respectively. More recently, pre-analytical fractionation has been achieved by HPLC (Fukuoka and Kowaka, 1983; Deinzer and Yang, 1994) and SPE (Irwin, 1989; Goiris *et al.*, 2002).

A great deal of research has been invested into developing commercially fractionated hop oil products with specific aroma qualities that may be added either pre- or post-fermentation (Haley and Peppard, 1983; Westwood and Daoud, 1985; Westwood, 1987; Gardner, 1994; Marriott, 2001; Goiris *et al.*, 2002). Isolated hop oil was originally dosed into wort and beer as aqueous emulsions or entrained in a liquid CO_2 stream (Westwood, 1987). However, post-fermentation products must be soluble in beer to prevent problems with haze. A soluble Dry Hop Essence was subsequently developed by removing the insoluble monoterpene and sesquiterpene hydrocarbons by liquid–liquid extraction (Westwood and Daoud, 1985; Marriott, 2001).

Further fractionation by functional groups using a combination of fractional distillation and column chromatography gave rise to four Late Hop Essences with specific aroma characteristics (Westwood and Daoud, 1985; Gardner, 1994; Marriott, 2001). These fractions became known as: the Spicy fraction, rich in monoterpene and sesquiterpene alcohols; the Floral fraction, containing ketones, epoxides and esters; the Ester fraction, predominantly made up of branched and straight chain fatty acid methyl esters; and the Citrusy fraction, composed of a mixture of terpene alcohols, short chain aliphatic alcohols and ketones (Marriott, 2001). Post-fermentation products are currently sold as Pure Hop Aroma and also now include Herbal (herbaceous, green, vetivert odor) and Sylvan (woody, earthy, resinous, pine odor) fractions (Marriott and Parker, 2004). They are supplied dissolved in food grade ethanol and are used at typical dose rates of 50–100 ppb (Marriott, 2001). The impact on hop aroma in beer will greatly depend on interactions with the aroma compounds present in the base beer and must therefore be evaluated in each case (Gardner, 1994; Marriott and Parker, 2004). Hop fractions obtained from different hop varieties also retain distinct aroma profiles due to differences in their chemical composition (Gardner,

1994; Marriott, 2001). Post-fermentation products allow great flexibility in new product development and allow the introduction of specific hop aroma without the changes that occur during wort boiling and fermentation (Marriott, 2001).

Concluding Remarks

Despite more than 50 years of research, the compounds responsible for important odorants in hop essential oil and hop aroma in beer are still not completely understood (Moir, 2000). More research is required to identify character-impact odorants in hop essential oil, determine their sensory impact on beer aroma and ascertain their fate during the brewing process. Identification of important odorants will allow hop breeders to select for varieties containing these compounds. In addition, knowledge of the important odorants for "hoppy" aroma in beer will allow for better quality control and development of new products. The authors contend that MDGC techniques in combination with GC–O are essential to improve our understanding of hop aroma in beer. The impact of identified character-impact odorants must then be confirmed using sensory evaluation.

Summary Points

- Hop essential oil is a complex mixture of volatile compounds from a wide range of compound classes.
- Differences in odor characteristics of hop varieties can be attributed to differences in the composition of the essential oil.
- The composition of the essential oil varies considerably with genetics, geographical location, growth conditions, infection from diseases and attack from pests. The composition alters during storage increasing the complexity due to oxidation, hydrolysis and rearrangements.
- Composition also depends on how the essential oil is isolated prior to analysis.
- Routine analysis of composition is performed by conventional GC but multidimensional techniques using two columns are often required to resolve and identify co-eluting compounds.
- The odor of hop essential oil and hop aroma in beer is due to a complex mixture of contributing volatile compounds.
- Not all character-impact odorants in hops have been identified and hoppy aroma in beer is still not completely understood.
- Hop aroma in beer is complex and complicated by physical, biochemical and chemical changes occurring during brewing and fermentation. This has led to increasing trends to add fractionated hop oils with specific odor characteristics to beer post-fermentation.

Ethanol Content of Beer Sold in the United States: Variation Over Time, Across States and by Individual Drinks

William C. Kerr Alcohol Research Group, Emeryville, CA, USA

Abstract

Research studies estimating the average alcohol content of beer sold in the United States indicate that beer strength has generally declined over time from around 5% alcohol by volume (% ABV) in the 1950s to a low of 4.5% ABV in 2005. This decline is mainly attributed to the growth in popularity of light beer, with a market share of over 50% in 2005, and to growth in lower alcohol content brands in other categories, particularly Mexican beers among the imported beers. Differences in the popularity of beer types by state also result in varying estimates of average % ABV by state. Some states in recent years have a market share for light beer of over 60%, while others are below 40% and consume more imported and super premium beers. The particularly strong beer types, malt liquor and ice beer, also show substantial variation in market share across states. Individual beer drinks in the United States have been found to be more consistent and to have less alcohol on average than wine or spirits drinks but also to vary by size and alcohol content, especially when served in bars and restaurants. For example, a 16 oz. beer with a strength 7.3% ABV contains nearly two US standard drinks of alcohol. The research presented highlights the importance of obtaining information on drink size and brand or alcohol content in understanding survey response to questions regarding the number of beer drinks consumed and of taking estimates of mean beer % ABV into account when evaluating trends in alcohol consumption or modeling relationships between alcohol consumption from beer and health or other outcomes.

List of Abbreviations

% ABV	Percentage alcohol by volume
AEDS	Alcohol Epidemiologic Data System

NIAAA	National Institute on Alcohol Abuse and Alcoholism
USA	The United States of America

Introduction

Individual's beer drinks

The alcohol content of individual drinks of beer and the mean alcohol content of beer sold in the United States in a given year are important factors in the accuracy and interpretation of epidemiologic research regarding the effects of beer on health and other outcomes. Beer is the most popular alcoholic beverage in the United States, comprising 59.4% of the ethanol consumed in 2002 (Kerr *et al.*, 2006a). In their respective analyses and consumption decisions, researchers and, in many cases, consumers typically assume that all beer drinks contain roughly the same amount of ethanol. However, the detailed description of the US beer market presented here indicates considerable variation in the ethanol content of the beer drinks available at any given time. This variation has important implications for both consumer decision-making and survey assessment of consumer behavior. The essential dimensions of beer drink ethanol content variation are straightforward: the liquid volume of beer in the container or glass and the alcohol (ethanol) content by volume (% ABV) of that beer. Yet it is difficult for consumers to gauge the size and strength of the beer they drink and even harder for them to translate these into the often vaguely described "standard drink" in terms of which they are expected to report for many surveys. In the United States a standard drink of beer is most often defined as 12 oz. at 5% ABV, containing 0.6 oz. (14 g) of alcohol. This difficulty may be reflected in the inability of general population surveys to account for all of the beer (and similarly wine and spirits) sold (Rogers and Greenfield, 2000). Further, systematic differences in the ethanol content of beer drinks across individuals could lead to differential under- and over-estimates of their consumption, confounding the modeling of the determinants of and outcomes related to beer consumption.

Aggregate beer sales

Similarly, aggregate analyses of trends and cross-state differences in per capita consumption of beer, wine, spirits and total alcohol, and the estimation of population-level relationships between alcohol consumption measures and outcome measures require accurate estimates of the mean % ABV for each beverage, year and geographic unit. Only recently have empirically based estimates of mean % ABV become available for the United States and for specific states (Kerr *et al.*, 2006a). For beer, as suggested in guidelines published by the World Health Organization (2000), these estimates are based on information on producer-reported brand % ABV, national brand-level sales, national and state beer type sales and measures of malt and other ingredients per barrel for earlier years. Estimates for wine and spirits mean % ABV are based on similar types of information and also utilize different types of information for some years (Kerr *et al.*, 2006a, b). These estimates were found to differ from the *ad hoc* estimates, which were originally developed by the Rutgers Center for Alcohol Studies (Efron *et al.*, 1974) and are currently used by the Alcohol Epidemiologic Data System (AEDS) (Lakins *et al.*, 2004). The empirically based estimates described in Kerr *et al.* (2006a) indicate that beer had more alcohol in all years and wine and spirits less alcohol in most years than the AEDS estimates had assumed. Mean % ABV estimates for beer, wine and spirits were also found

to vary across states (Kerr *et al.*, 2004; 2006a, b), a factor not considered in any previous analyses of US state-level relationships between alcohol measures and outcomes.

This chapter presents a variety of information on the alcohol content of the beer sold in the United States and beer drinks consumed by US drinkers. This information has been collected and organized as part of two ongoing research programs at the Alcohol Research Group in Emeryville, California. One focused on estimating per capita consumption of alcohol for use in modeling relationships between alcohol intake and potentially alcohol-related mortality outcomes in the US states and a second focused on estimates of the amount of alcohol contained in individual drinks of beer, wine and spirits consumed in the United States and the key sources of variation in these amounts to better understand and estimate self-reported alcohol intake in surveys. Both of the projects are supported by grants from the National Institute on Alcohol Abuse and Alcoholism (NIAAA).

US Beer Types and Brand % ABV

Beer sold in the United States is generally divided into seven types by sources that monitor and track beer industry statistics: premium, popular, light, super premium (including craft, microbrew and flavored malt beverages), imported, ice and malt liquor (Adams Beverage Group, 2006). The popularity of these types varies by state (as discussed below) and has changed considerably over time as seen in Figure 23.1.
Figure 23.1 US market shares of industry beer types as a percentage of beer sold. Each line represents the percentage of overall beer sales accounted for by each type of beer in each year from 1988 to 2005.

Statistics on the market share of beer types presented here come from all issues of the Beer Handbook (Jobson Publishing Corporation, 1994, 1995; Adams/Jobson Publishing Corporation, 1996; Adams Business Media, 1997, 1998, 1999, 2000; Adams Business Research, 2001; Adams Beverage Group, 2002, 2003, 2004, 2005, 2006).

Light beer

Light beer has by far the largest market share of any category comprising over 50% of the beer sold in 2005. Light beer is generally defined as beer with at least 20% fewer calories than the regular version of the same brand. In practice this also means less alcohol since most beer calories come from the alcohol so the major light beers have 4.2% ABV. The market share of light beer in the United States has risen annually since its invention in the late 1960s. Its market share has doubled since 1988 (see Figure 23.1).

Premium beer

Much of the rise in market share for light beer has been at the expense of the premium beer category, which declined from 40% of the market in 1988 to only 15.7% in 2005. Premium beer is considered to be the regular US beer and includes brands from the largest US breweries such as Budweiser, Coors and Miller Genuine Draft. These beers are generally 5% ABV although they have all changed over time. Most recently Miller Genuine Draft reduced its % ABV to 4.7%, returning to its pre-1995 level. In 1995 Coors was 4.6% ABV and Budweiser was 4.8% ABV. These shifts by major brands over time highlight the difficulty of tracking the alcohol content of beer for both researchers and consumers as these changes are not usually announced and, in some cases, do not appear on the label.

Popular beer

Popular beer has also lost popularity over time and now makes up less than 10% of the market. This category consists of lower priced brands from major breweries and some historically regional brands. Many of these brands have been consolidated by Pabst Brewing. These include Old Milwaukee, Schlitz, Rainer and Pabst Blue Ribbon. The alcohol content of popular beers varies widely with some as low as 4.3% such as Milwaukee's Best, others around 4.6% such as Busch or 4.7% like Miller High Life, while others are as high as 5% ABV including Pabst Blue Ribbon. The % ABV of popular beer brands has changed over time as well, for example Busch was 4.9% ABV in the late 1990s and is now 4.6% ABV (Table 23.1).

Imported beer

Imported beer has grown substantially in recent years and now constitutes 12.5% of the beer market. Much of this growth is due to the popularity of Mexican beers which now make up 5 of the top 10 imported brands. As with domestic beers, the lighter brands have grown most in popularity resulting in a lower mean % ABV for this category over time. While a few 5% ABV brands such as Heineken and Labatt Blue are still among the most popular, most have lower % ABVs. The leading imported brand is Corona Extra (4.6%) and other Mexican brands are 4.4% ABV. In addition some imported light brands like Corona Light (4.1%) and Amstel Light (3.5% ABV) have become popular. Guiness Stout at 4.2% ABV has always had an alcohol content similar to light beers.

Super premium beer

The super premium category, which includes craft beers, microbreweries and in recent years flavored malt beverages,

Table 23.1 2005 alcohol content and market share of top beer brands

Brand	% ABV	Market share (%)	Cumulative market share (%)
Bud Light	4.2	19	19
Budweiser	5.0	13	32
Miller Lite	4.2	9	40
Coors Light	4.2	8	48
Natural Light	4.2	4	53
Corona Extra	4.6	4	56
Busch	4.6	3	59
Busch Light	4.1	3	62
Miller High Life	4.7	2	65
Heineken	5.0	2	67
Miller Genuine Draft	4.7	2	69
Michelob Ultra	4.2	2	70
Keystone Light	4.2	1	72
Natural Ice	5.9	1	73
Budweiser Select	4.3	1	74
Milwaukee's Best	4.3	1	75
Milwaukee's Best Light	4.2	1	76
Michelob Light	4.3	1	77
Icehouse	5.5	1	78
Yuengling Traditional Lager	4.4	1	78
Milwaukee's Best Ice	5.9	1	79
Pabst Blue Ribbon	5.0	1	80
Coors	5.0	1	80
Old Milwaukee	4.6	1	81
Tecate	4.4	1	81
Modelo Especial	4.4	1	82
Labatt Blue	5.0	0	82
Smirnoff Twisted V	5.0	0	83
Colt 45	6.1	0	83
King Cobra	6.0	0	84
Mean % ABV of top brands	4.5	84	84

Note: Producer reported % ABV and estimated market share from the Adams Beer Handbook 2006 for leading brands in 2005.
Figure 23.2   Beer ethanol content distribution for 2000. Bars represent the percentage of beer sold among major brands that had the labeled percentage ethanol content by volume in the year 2000.

has also grown over time and is now over 7% of the beer market. While the Michelob brand led this category for many years, the top brand is now Yuengling Lager, which is lower in alcohol than most beers in this category at 4.4% ABV. Many beers in this category have higher alcohol contents such as Sierra Nevada Pale Ale (5.6%) and some are as high as 7% or 8% ABV. The category includes a very large number of low production beers and is thus difficult to form a complete picture of it in terms of the % ABV distribution.

Ice beer

Ice beer is a type of beer that has been clarified by forming small ice crystals and then removing them. This process also removes some of the water, increasing the alcohol content such that these beers are typically 5.5–5.9% ABV. As seen in Figure 23.1, this category was introduced in 1994 and has maintained a small share of the market since. This category is a mix of low cost high alcohol beers with 5.9% ABV such as Natural Ice, Milwaukee's Best Ice and Keystone Ice that compete with malt liquors in offering the most alcohol for the dollar among beers and 5.5% ABV brands including Icehouse and Bud Ice that are priced like premium beers. The stronger, lower priced brands have gained a larger share of this category in recent years, possibly through some consumers switching from the declining malt liquor category.

Malt liquor beer

Malt liquor is generally lower priced, higher alcohol content beer that is often sold in larger containers such as 16 or 40 oz.

Malt liquor consumption peaked in the mid-1990s at nearly 5% of the beer market and has since declined to only 2.1% in 2005. This category covers a range of % ABVs from Mickey's at 5.6% ABV to King Cobra and Colt 45 at 5.9% to Olde English 800 or St. Ides at 7.3% ABV or more. Malt liquor % ABV appears to be more complicated than other beers because versions with very different strengths have been sold in different parts of the country. Some brands have sold 5.9% ABV versions in the Eastern United States due to certain states that do not allow higher % ABVs while selling much stronger versions in the Western states. Brand % ABVs also change over time as with other beer types.

Distribution of beer alcohol contents

The beer ethanol content distribution for major beer brands in 2000 is shown in Figure 23.2. This illustrates the concentration of % ABVs at 4.2%, 5% and between these in that year with much smaller market shares for beers with higher or lower % ABVs. By 2005 there has been a further shift toward lower % ABV beer as can be seen in Table 23.1. These beers represent 84% of the beer market and have an average % ABV of 4.5. While this estimate is based on less detail than those presented in Kerr *et al.* (2004), it indicates that the average % ABV of beer has likely fallen since 2001 due to the increasing market share of light beers and lower % ABV imports like Corona and reduced % ABVs for major brands such as Busch and Miller beers. Considering the strong trend in this direction it can be expected that even further declines in the mean % ABV of beers in the United States will occur in the future.
Figure 23.3   Estimated mean % ABV of beer in the United States. The line shows the estimated mean % ABV for all beer sold in the United States in each year from 1950 through 2005.

Time Trends in % ABV and Beer Consumption

Estimates of the mean % ABV of beer sold in the United States (Figure 23.3) indicate a generally declining trend over the past 50 years from about 5% ABV in the early 1950s to 4.5% ABV in 2005. One exception to this was a rise in the late 1990s, which was mainly due to the increase % ABV of certain brands (Kerr *et al.*, 2004). As noted above, the major factor in this shift has been the relentless rise in the popularity of light beer.

The importance of the changing alcohol content of beer can bee seen in Figure 23.4 where trends in the liters of beer sold and the ethanol contained in that beer are charted. While both are seen to peak around 1980, at the same time as overall alcohol consumption, the ethanol consumed in the form of beer has declined proportionally more than beer sales. For purposes of estimating the relationship between alcohol consumption from beer and health outcomes, it is the ethanol, rather than the beer, that would be relevant. This has increased from a low of about 4l per capita aged 15 years and older in the late 1950s and early 1960s to a high of about 5.5l per capita around 1980 and has subsequently fallen to below 5l from the early 1990s.

In comparison to wine and spirits, beer has been the largest source of alcohol for the US population since the end of prohibition. As seen in Figure 23.5, the proportion of US alcohol intake from beer declined from over 55% in the early 1950s to below 50% around 1970. During that time spirits rose in popularity from 35% of the alcohol sold to nearly 42%. With the decline of spirits popularity since the mid-1970s, beer's share of US alcohol intake has risen to over 60% by the mid-1990s. Wine has never comprised more than 15% of the alcohol sold in the United States but has risen from about 10% through 1970 to nearly 15%. Spirits have also seen a small increase in recent years resulting in a small decline in beer's share of US alcohol intake. However, beer remains by far the main source of alcohol for the US population.

State Differences in % ABV and Type Shares

The mean % ABV of beer sold has been found to vary across states in the United States in addition to changing over time as discussed above (Kerr *et al.*, 2004). Estimates of state mean % ABV utilize each state's market shares of the seven beer types along with estimates of the mean % ABV by beer type calculated using national sales of major brands. These estimates are presented in Table 23.2 for selected years for states sorted by the 2001 % ABV estimate. While it would be preferable to utilize brand-level sales by state to calculate these means, this information has not yet been found, although producers or wholesalers are likely to have these data due to the separate licensing and
Figure 23.4　Per capita (15+) liters of beer and ethanol from beer for the United States Line with circles shows the amount of beer sold in liters on the left axis and the line with diamonds show the amount of ethanol sold as beer in liters on the right axis for each year.
Figure 23.5　Proportion of total ethanol from beer, wine and spirits in the United States over time. Each line represents the percentage of total ethanol consumed in the United States from each beverage type with circles for beer, diamonds for spirits and squares for wine.

tax requirements of each state. State means are found to differ by about 0.25% ABV from the highest to lowest in later years with somewhat less variation seen in earlier years. The main source of this variation is in the share of light beer relative to the share of imported and super premium beer

across states. The states with higher mean % ABV such as New York and New Jersey have particularly high shares of imported beer in 2005 at over 20% and super premium beer, about 9%, as well as ice beer and malt liquor, over 8% combined in New York compared to 5.4% nationally

Table 23.2 Estimated mean % ABV of beer in selected years by state (sorted by 2001 estimate)

State	1993 (%)	1995 (%)	1997 (%)	1999 (%)	2001 (%)

(Adams Beverage Group, 2006). Conversely these states have low share of light beer at around 40% of the market while states like Texas and especially Iowa have very high shares of light beer. In 2005, nearly 70% of the beer sold in Iowa was light beer and a number of other states including Texas, Louisiana, Kansas, Oklahoma and South Dakota had around a 60% share of light beer (Adams Beverage Group, 2006). As both light beer and the imported and super premium categories show increasing trends in market share, the differences in mean % ABV across states may

also be expanding over time highlighting the importance of considering these differences in research studies utilizing cross-state variation in beer consumption.

Alcohol Content of Beer Drinks

Containers

In 2000, 51% of beer sold in the United States was packaged in cans, 40% was in bottles and 9% was on draft (Beer Institute, 2001). States differ in these percentages with 15% of sales or more in the form of draft beer in Iowa, Minnesota, New Jersey, Oregon, Pennsylvania, Washington and Wisconsin, while 5% or less of sales were in the form of draft beer in Alabama, Arkansas, Georgia, Louisiana, Mississippi, New Mexico, North Carolina, Oklahoma, South Carolina, Tennessee and Texas (Beer Institute, 2001). Including sales of both draft and cans and bottles, 24.9% of beer in 2000 was sold for on-premise consumption while 75.1% was sold for off-premise consumption (Adams Beverage Group, 2002). Less information is available on the size of the cans and bottles sold but figures are available from 1992. In that year about 90% of the volume of beer sold in both bottles and cans of beer were 12 oz., not including malt liquor (about 5% of the packaged market), which typically is sold in larger containers. About 6.4% of beer sold was in 16 oz. cans and about 1.4% was sold in 32 oz. bottles with the small remainder being of unknown size (Beer Institute, 1998). While it is clear that 12 oz. containers make up a large majority of total beer sales, roughly 82%, other sizes and draft beer could account for significant drink size differences if larger-sized containers, or various-sized glasses of draft, are reported as a single drink.

Brand % ABV

As shown in Table 23.1 and discussed in the section about beer types, the % ABV of different brands varies widely. Figure 23.2 shows that while most of the beer sold is between 4.2% and 5% ABV, a wide variety of strengths are available. The importance of a beer's % ABV and container size in determining the number of 0.6 ethanol ounce (14 g) standard drinks consumed for a given number of beer drinks is shown in Figure 23.3. When beer is 3.6% ABV even six 12 oz. drinks do not add up to five drinks, the typical threshold used to determine heavy drinking occasions. For 4.2% or 4.6% beers, six 12 oz. drinks must be consumed to reach five standard drinks. For stronger beer or larger sizes, fewer drinks will be required. For beer above 7% ABV only four 12 oz. drinks and only three 16 oz. drinks are needed to reach five standard drinks. These conversions to standard drinks clearly illustrate the importance of considering size and % ABV in determining an individual's alcohol intake (Table 23.3).

Table 23.3 The effect of beer drink size and % ABV on the number of standard (0.6 oz. of ethanol) drinks consumed when drinking one to six drinks

| % ABV | Number of drinks | | | | | |
	1	2	3	4	5	6
12 oz.						
3.6	0.72	1.44	2.16	2.88	3.6	4.32
4.2	0.84	1.68	2.52	3.36	4.2	5.04
4.6	0.92	1.84	2.76	3.68	4.6	5.52

7.7	2.05	4.11	6.16	8.21	10.27	12.32

Note: Each cell represents the number of US standard drinks (14 g of ethanol) that would be consumed for a given number of actual drinks and a given % ABV for two common drink sizes 12 and 16 oz.

Measured drinks

More detailed information on the size and strength of beer drinks consumed in the United States is available for individuals surveyed in the 2000 National Alcohol Survey (NAS) Methodological Follow-up Study, a national sample of 323 individuals conducted in the winter of 2003–2004 (Kerr *et al.*, 2005) and the 2003 San Francisco Bay Area Pilot Study of drink ethanol content measurement where 24 individuals reported on beer drink size and brand in consumed in bars or restaurants. Variation in both glass and container size and in brand ethanol content were found to influence drink ethanol content. Figure 23.6 shows the distribution of beer drink ethanol content for home drinks from the 2000 NAS Follow-up Study. Home beer drinks were found to average 0.56 oz. of ethanol with large numbers reporting either 0.5 oz., the amount in 12 oz. of light beer, or 0.6 oz., the amount in 12 oz. of regular 5% ABV beer. The ethanol content of beers served in restaurants and bars reported in the 2003 Bay Area Pilot Study are more varied and are, on average, larger than those of beer consumed at home in that study or in the 2000 NAS Follow-up Study. Beer served at bars and restaurants averaged 0.69 oz. of ethanol with a substantial proportion of drinks being larger than 0.7 oz. of ethanol, as seen in Figure 23.7. In this sample, the beer drinks served at restaurants and bars tended to be larger, 21.5% larger on average, than those served at
Figure 23.6 Distribution of beer ethanol content in measured home drinks from the 2000 NAS Methodological Follow-up Study. Histogram shows the number of respondents in the 2000 NAS Methodological Follow-up Study reporting home drink ethanol content in 0.1 oz. groupings between 0.05 and 1.55 oz. of ethanol per drink.
Figure 23.7 Ethanol content of beer drinks at restaurants and bars in Pilot Study. Histogram shows the number of respondents in the 2003 Bay Area Pilot Study reporting drink ethanol content in 0.1 oz. groupings between 0.4 and 0.9 oz. of ethanol per drink.

home. Most (38 of 43) home drinks were reported to be consumed from 12 oz. cans, bottles or glasses while bar and restaurant drinks included thirteen 16 oz., two 14 oz. and three 24 oz. glasses compared to only six 12 oz. drinks. The results of this pilot study clearly indicate the importance of both size and ethanol concentration in determining the amount of alcohol in one drink of beer. The home drinks measured in the larger study indicate that for these drinks the brand % ABV is the main varying factor in this context and both studies together indicate that context of drinking may be an important determinant of beer drink alcohol content.

Limitations and Measurement Issues

The results reported here do not represent the final word on the alcohol content of beer sold or the alcohol content of beer drinks in the United States. Considerable extrapolation from available data was required to achieve the mean beer % ABV estimates. This is especially true for years prior to 1988 and for state-level estimates. More detailed information could certainly alter these estimates if it was to become available. These estimates also utilize producer provided brand % ABV in most cases and the accuracy in these is not known. Further studies where samples are directly measured may indicate that there is a degree of error or even systematic bias in these reports. Also, as mentioned above, the use of type averages rather than state-specific brand sales reduces the accuracy of the estimates presented.

Research on the alcohol content of beer drinks by US consumers is at a very early stage. Our national estimates of home beer drinks have shown that these drinks are less varied and contain, on average, less alcohol than wine or spirits drinks but larger samples are need to confirm these results and explore potential sources of variation. The pilot study results also indicate that beer drinks in bars, at least in one part of the United States, tend to be larger and to contain more alcohol than drinks consumed at home. Future research to directly measure the alcohol content of drinks consumed in bars and restaurants across the United States is needed to fully understand the dimensions of this important issue.

Concluding Remarks

Considering the wide range of beer choices available to American beer drinkers and the changes over time in the brand % ABV and market share, it is particularly important for both survey and aggregate-level analyses to consider the details of beer size and strength to the extent possible. Unlike some countries where almost complete brand-level sales information is available, for example Sweden, Norway and some Canadian provinces, in most countries, including the United States, this information is more difficult and time consuming to obtain. Often, as in the figures presented in this chapter, a variety of information sources that are less than perfect can be used to generate the best possible estimates while still leaving considerable room for improvement. The assessment of individual's beer drink ethanol content is important for surveys and other types of individual-level research. It is now clear that not all drinks contain the same amount of alcohol, particularly across beverage types but also within them. Therefore, beer drinks should be assessed separately from wine and spirits drinks and information on the size and brand or type of beer should be collected where possible.

The importance of accurate ethanol measurement is probably most keen in studies of health and medical outcomes.

In these studies an individual's self-reported number of drinks, often from relatively simplistic question formats, is converted into a number of grams per day variable that gives the appearance of precision. These variables are then used to estimate relationships and risk thresholds in terms of grams of alcohol, which are then extrapolated to populations and used to form drinking guidelines and recommendations. In fact, almost none of the literature regarding alcohol's relationship with health outcomes is based on detailed measures of drink alcohol content and very little of it includes assessment of drinking patterns (Rehm *et al.*, 2006), another dimension likely to be essential in most of these relationships. Hopefully this overview of the US beer market and individual beer drinks will encourage researchers and consumers of research finding to consider these important dimensions in the conduct and interpretation of future studies.

Summary Points

- The mean % ABV of beer sold in the United States has generally declined since 1950 from around 5% to a low of 4.5% in 2005.
- The popularity of beer types, as represented by US market share, has changed over time with light beer increasing to over 50% of the market in 2005 and popular and premium beer types declining. Imported beer has also grown substantially since the early 1990s.
- The alcohol content of major beer brands sold in the United States ranges from 3.5 to over 8% ABV. However, most beers are between 4.2% ABV, the typical strength of light beer, and 5% ABV, the typical strength of regular beer.
- Beer is the most commonly consumed form of alcohol in the United States, representing around 60% of all alcohol since 1990.
- The estimated mean alcohol content of beer differs by US state with the lowest % ABVs found in states with large market shares for light beer and the highest % ABVs seen in states with the highest shares of imported and super premium beers and lower shares of light beer.
- Individual's drinks of beer in the United States are more consistent and lower on average in terms of alcohol content than wine or spirits drinks since most beer is consumed from 12 oz. bottles or cans.

Soluble Proteins of Beer

Marion Didier and Bakan Bénédicte   INRA Unité Biopolymères, Interactions, Assemblages, Nantes cedex, France

Abstract

Soluble beer proteins are heat-stable proteins from malted barley. These proteins are mainly composed of proteins that would be involved in the defense of barley against microbial pathogens as a serpin-like cysteine protease inhibitor (protein Z) and lipid transfer proteins (LTPs). These proteins are essential for the formation of beer foam. To become surface active these barley proteins undergo a structural maturation including glycation through Maillard reaction on malting and unfolding on heating during the brewing process. In the case of LTP1, another modification involves an acylation by a product of the activity of two enzymes from barley embryo (i.e. lipoxygenase and allene oxide synthase) on polyunsaturated fatty acids. These structural modifications increase the amphiphilic character of the proteins and their spreading behavior at the gas–liquid interfaces. Finally, minor beer proteins, weakly soluble in water, barley storage proteins (i.e. hordeins) are responsible for the haze formation of freshly fermented beer.

List of Abbreviations

9-LOX	9-Lipoxygenase
AOS	Allene oxide synthase
FFA	Free fatty acids
RCL	Reactive center loop
LTP	Lipid transfer protein

Introduction

Beer contains 0.5–1 g/l proteins with molecular mass from 5 to 100 kDa (Sorensen and Ottesen, 1978). The major beer proteins are involved in haze formation and foam stability, two significant criteria that define the quality of a beer for the consumer. Actually, other plant raw products such as maize grits or wheat malt can be added in the brewing process, but most of the data available on beer proteins have been obtained starting from barley malt, the major plant source of beer.

Beer Concentrate Heat-Stable Barley Albumins

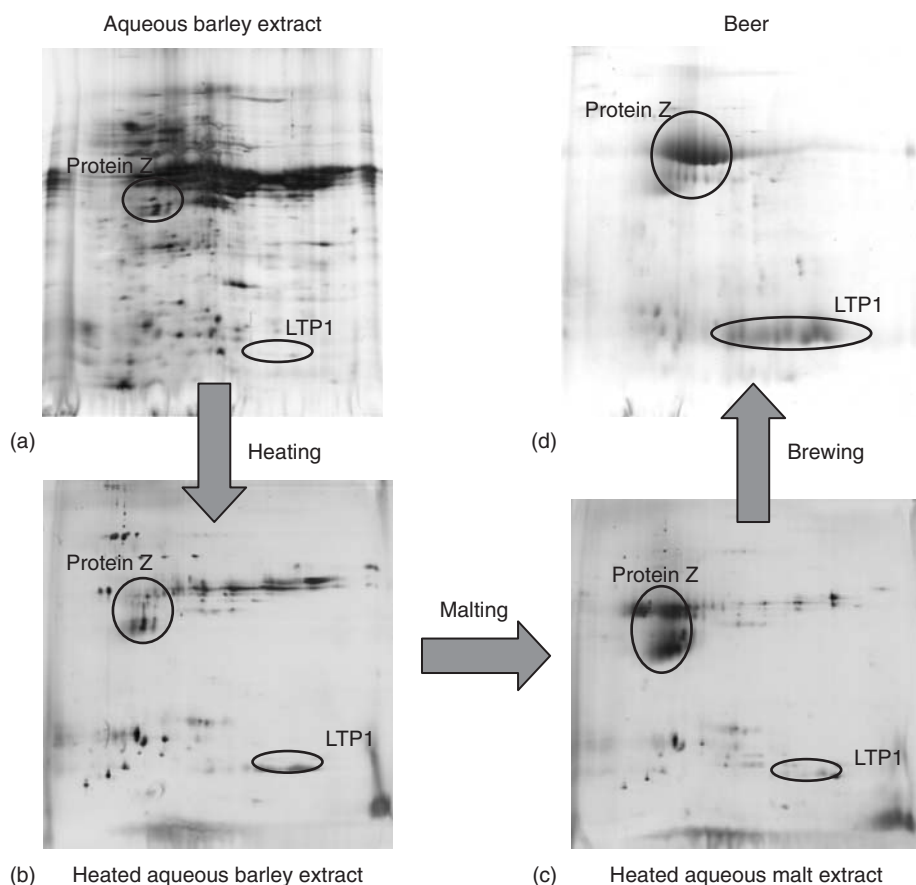
Beer proteins have been characterized after fractionation using different chromatographic procedure including ion exchange, size exclusion and hydrophobic interaction chromatographies. Recently, using the current strategy of proteomic, two-dimensional electrophoresis coupled with mass spectrometry, an overall view of beer proteins was provided (Figure 24.1). Most data converge with the presence of two main proteins in beer: protein Z and lipid transfer proteins (LTPs). Protein Z is a protein with a molecular mass of 45 kDa protein. The second major beer protein, LTP, is composed by two proteins, LTP1 (about 9 kDa) and LTP2
Figure 24.1   Two-dimensional electrophoresis of beer proteins (pH 3–10). The protein spots were identified by mass spectrometry after trypsin cleavage. *Source*: Perrocheau *et al.* (2005).


Figure 24.2 Two-dimensional electrophoresis of soluble proteins from barley, before (a) and after (b) boiling, malt after boiling (c) and beer (d).

(about 7 kDa). LTP1 is the most abundant protein of this family. Other minor proteins have been highlighted as protease and amylase–protease inhibitors, barwin and storage proteins (i.e. hordeins). Yeast proteins were also identified in beer such as enolase and triose phosphate isomerase, enzymes that play a major role in the metabolism of yeast cells (Perrocheau *et al.*, 2005). Except hordeins, most of the identified proteins are soluble proteins (i.e. albumins) as expected from the aqueous extraction of malted barley. However, not all soluble proteins of barley are recovered in beer. Actually, it was shown that only heat-stable soluble proteins were present in agreement with the boiling procedure of the brewing process (Figure 24.2). Comparing heated malt extract and beer more hordeins are extracted from malt. Most of these proteins precipitate during the maturation of beer in part by forming large aggregates with phenolic compounds from hop and malt. These complexes are responsible for the haze formation in beer (see below).

Protein Z belongs to the serpin superfamily of serine protease inhibitors and are composed by protein Z4 and protein Z7 that share about 75% sequence identity (Østergaard *et al.*, 2000) and are encoded by chromosomes 4 and 7 (Hejgaard and Kaersgaard, 1983). These soluble and lysine-rich proteins (>5% lysine) are abundant in the

starchy endosperm of monocots where they account for about 5% of barley albumins. Although there are different consensus glycosylation sites in protein Z, no glycosylation was observed on the proteins purified from barley seeds. However, this protein is glycated in beer (Curioni *et al.*, 1995). Glycation of protein Z is due to Maillard reaction that occurs on malting. The Maillard reaction is a reaction between the amine group of lysine and reducing sugar (glucose and maltose) (Figure 24.3) that occurs on during the kilning step of the malting process (Jégou *et al.*, 2001). Protein Z irreversibly inhibits chymotrypsin and other non-plant proteases but are not inhibitory for endogenous protease, including cysteine proteinase that degrades storage protein on germination. It was suggested that protein Z, by inhibiting exogenous protease, could play a role in the defense of plant against their predators (fungi, insects, etc.) (Østergaard *et al.*, 2000). Recently, it was shown in *Arabidopsis thaliana* that serpin is a suicide inhibitor of a cysteine protease, metacaspase9 (Vercammen *et al.*, 2006). Plant metacaspases are involved in signaling of cell death. The normal development of barley endosperm, that is, as in other cereals, lead in fine to its death. Cereal serpin could play a role in the control of endosperm cell death in preventing premature apoptosis of this storage compartment of
Figure 24.3 Schematic glycation of proteins in the Maillard reaction.
Figure 24.4 Structure of the main beer proteins. (a) Protein Z (the structure of the prototypical serpin α1-antitrypsin is presented with the RCL, up, pdb code 1QLP; Elliott *et al.*, 2000). (b) Barley LTP1 complexed with a fatty acid (1BE2; Lerche and Poulsen, 1998). (c) Wheat LTP2 complexed with lysophosphatidylglycerol (1TUK; Pons *et al.*, 2003).

the grain. This protein could participate in the mechanisms determining the final protein content of the grain, a key factor that determines the quality of malt for the brewers. The structure of plant serpins has not yet been determined but by analogy with animal serpins, it can be suggested that they are composed of nine helices and three β-sheets (Figure 24.4a). They are composed by a loop of about 20 amino acid residue, that is, the reactive center loop (RCL) that is flexible and contains a sequence complementary to the active site of its target protease (Huntington, 2006). Serpins display high metastability especially with respect to the RCL. This loop, exposed in the native protein, is fully incorporated in a β-sheet for the irreversible high-energy state. The serpin with the RCL incorporated in the β-sheet denatures at temperature above 100°C while the native protein denatures at about 60°C (Kaslik *et al.*, 1997). This unique behavior of serpins could explain the concentration

of protein Z in beer. However, no data are available on the folded state of protein Z in beer.

LTPs (i.e. LTP1 and LTP2) are ubiquitous plant lipid binding proteins. They form a multigenic family where the expression of the different proteins is spatially and temporally regulated. This is well illustrated for wheat seeds where the nine LTPs are expressed at the different stages of the developing grain. The major LTP1 and LTP2 of barley and wheat seeds are expressed in the aleurone cells at the last stage of grain development (Boutrot *et al.*, 2005). These helical proteins are stabilized by four disulfide bonds. Within the protein, there is a large hydrophobic cavity or a tunnel that is the lipid binding site (Figure 24.4b and c). These proteins are capable of binding all sorts of lipids and hydrophobic molecules. Lipid binding generally involved non-covalent bonds between lipids and the protein (Douliez *et al.*, 2000). However, it has been recently shown that the barley LTP1 is also capable to bind covalently oxygenated fatty acid derivatives (i.e. oxidation products of polyunsaturated fatty acids) also called oxylipins (Bakan *et al.*, 2006; Perrocheau *et al.*, 2006). A specific site has been highlighted for these oxylipins (see below). The biological role of LTPs is still unknown but most data converge for a role of these proteins in the defense signaling of plants against microbial pathogens (Douliez *et al.*, 2000). Some LTPs are capable to inhibit fungal growth by permeabilizing the membranes of the pathogens (Blein *et al.*, 2002). These proteins could also inhibit protease and especially barley endoproteases (Jones, 2005). LTPs are also ubiquitous plant food allergens and the corresponding beer proteins have been described in rare patients as a major allergen (Asero *et al.*, 2001; Marion *et al.*, 2004). These proteins are highly stable to heat treatments and only long boiling procedure or heating in presence of reducing agent allow their denaturation (Van Nierop *et al.*, 2004; Perrocheau *et al.*, 2006). As for protein Z these proteins are not glycosylated in barley seeds but are glycated in beer. The glycation of LTPs occurs on the last step of kilning through Maillard reaction when the hydration of the green malt decreases and kilning temperature increases (Jégou *et al.*, 2001). In beer, most of the LTP1 is unfolded and some to all disulfide bonds are broken (Jégou *et al.*, 2000). Interestingly, some rearrangement of disulfide bonds can occur and a chimeric protein associating LTP1 and LTP2 have been observed in beer (Jégou *et al.*, 2000).

Structural Maturation of Proteins and Development of Beer Foam

Formation and stability of head foam strongly determine the perception of the quality of beer by the consumer (Bamforth, 1985; Evans and Sheehan, 2002). Proteins are essential in the foaming properties of a beer in forming a visco-elastic film around gas bubbles (Maeda *et al.*, 1991;
Figure 24.5 Biochemical mechanism of the adduction of barley LTP1 with 9-hydroxy-10-oxo-12(Z)-octadecenoic acid (alpha-ketol).

Sorensen *et al.*, 1993; Wilde *et al.*, 2003). Other components can influence the formation and stability of beer foam. For example, ethanol improves foam formation but decreases its stability (Brierley *et al.*, 1996; Evans and Sheehan, 2002). Hop acids increase foam stability in forming complexes with protein at the gas–liquid interface (Smith *et al.*, 1998; Evans and Sheehan, 2002). Lipids are the main foam-negative substance of beer. These hydrophobic and/or amphiphilic molecules adsorb rapidly at the interface and destabilize the protein film by displacing protein and decreasing protein–protein interactions. This leads to the rupture and coalescence of foam bubbles (Wilde *et al.*, 2003).

The malting and brewing process transforms the barley albumins into foaming proteins. The mechanism involved in these structural maturation has been recently delineated, especially for one of the major beer proteins, LTP1. Actually, the barley LTP1 does not form any foam while the corresponding beer protein display good foaming properties (Bech *et al.*, 1995; Marion *et al.*, 2001). In beer, LTP1 is a mixture of glycated proteins displaying different unfolding state (Jégou *et al.*, 2000). Glycation occurs on kilning during the malting process while unfolding occurs on brewing (Jégou *et al.*, 2001; Van Nierop *et al.*, 2004). Heat-induced unfolding of LTP1 is strengthened by the reduction of disulfide bonds of the protein

during the extraction of malt (Perrocheau *et al.*, 2006). The disulfide bond reducing mechanism of malt has not been identified yet, but it should involve the thioredoxin and/or glutathione oxido-reducing pathways (Marx *et al.*, 2003). The other important modification is the acylation of LTP1. This acylation is catalyzed by two enzymes from the embryo, a 9-lipoxygenase (9-LOX) and an allene oxide synthase (AOS). 9-LOX generates a 9-hydroperoxide from linoleic acid, the major polyunsaturated free fatty acids (FFAs) from cereal seeds while the AOS transforms the hydroperoxide in the corresponding allene oxide. The electrophilic attack of the unstable allene oxide by an acidic side chain of the protein (Asp7) leads to the covalent binding of an alpha-ketol to LTP1 (Figure 24.5). This acylation has been observed in beer for the glycated LTP1 (Jégou *et al.*, 2000). Up to two alpha-ketol can be covalently bound to the barley LTP1 (Jégou *et al.*, 2001; Perrocheau *et al.*, 2006). Finally, glycation and acylation increase the amphiphilic character of the protein while unfolding improves spreading of the protein at the air–water interface allowing a better anchoring in the interface through the acyl adducts and formation of protein–protein interaction in the film surrounding gas bubbles (Figure 24.6). Lipids and especially FFAs are detrimental to the formation and stability of beer foam (Wilde *et al.*, 2003). Trapping of the major barley FFA (i.e. linoleic acid) by LTP1 through
Figure 24.6 Structural maturation of LTP1 from a non-foaming protein to a foaming protein during the malting and brewing processes. During germination of barley, amylase secreted by the aleurone cells into the starchy albumen provides glucose and maltose (starch hydrolysis) necessary for glycation of the LTP1 during the kilning step of malting. During germination of barley or extraction of malt, LTP1 or glycated LTP1 from the aleurone cells is acylated by the enzyme complex from the embryo (i.e LOX and AOS). On mashing the non-reduced LTP^{S-S} is reduced to LTP^{SH} by a redox system from malt. The disulfide bond reduction and boiling promote protein unfolding during brewing. The glycated, acylated and unfolded beer LTP1 displays higher foaming properties than the corresponding non-modified protein from barley.

the combined activity of LOX and AOS should limit the accumulation of the foam-destabilizing FFAs. This mechanism could act synergistically with the non-covalent lipid binding (Cooper *et al.*, 2002) to protect beer against lipid-induced foam destabilization. Finally, it should be emphasized that the quality of beer foam is not due to a unique protein but to complex associations between the different beer proteins and between proteins and other components (phenolic compounds, hop acids, minerals, etc.) as well as to the technological process (i.e. malting and brewing) that induce different structural modifications essential to generate pro-foaming entities.

Over-foaming can produce on opening packages. This phenomenon called gushing is one of the major source of economical losses for the brewers. Primary gushing is caused by factors from malt or other cereal raw material entering in the brewing process. Secondary gushing is due to the presence of aggregates and particles related to technological impurities or to haze. Primary gushing is closely

related to *Fusarium* contamination of malt and is assumed to be due to surface active proteins that form a highly stable film around gas bubbles. Most studies converge for a role of small proteins of fungi (i.e. hydrophobins). These fungal proteins with four disulfide bonds are highly stable. They can survive to heating on brewing and only small quantities of these proteins can induce gushing (Linder *et al.*, 2005). These proteins display an amphiphilic character that allow rapid adsorption at the gas–water interface to form stable and ordered aggregated protein films with unique elasticity (Szilvay *et al.*, 2007). As suggested by Hippeli and Elsner (2002), the modified forms of LTPs (i.e. glycated and acylated proteins) could also be involved in gushing. These proteins share structural characteristics with the gushing factor isolated from wort (Kitabatake, 1978). Although these proteins are essential to the foaming properties of beer, they could induce gushing above a threshold concentration. Since synthesis of most LTPs is induced on pathogen attack (Douliez *et al.*, 2000; Blein *et al.*, 2002), higher level of

LTPs could be produced in response to the fungal infection of barley. The role of LTPs in gushing, alone or in interaction with fungal hydrophobins, has not been highlighted yet, but has to be investigated in the perspective of improving the quality of beer foam by increasing LTP content either through barley breeding or by genetic modifications.

Proteins and Beer Haze

Brilliance or brightness (i.e. absence of a haze or sediment) is considered as a significant parameter for the acceptance of beer by most consumers. Haze is generally formed on cold conditioning of freshly fermented beer and can be due to multiple materials as yeast cells and colloidal particles of organic or mineral origin (Bamforth, 1999). Much research has been conducted to characterize the haze-forming materials in beer as well as in other beverages by analyzing the chemical composition of the sediment (Siebert, 1999). Significantly, haze-forming molecules are mainly composed of polypeptides derived from the storage proline-rich proteins of barley endosperm (i.e. hordeins) and polyphenols from malted barley and hops. Another protein, the barley trypsin inhibitor, that is not a proline-rich proteins in regard to hordeins, also seems to play a role in the formation of beer haze (Robinson *et al.*, 2007). Although carbohydrates are present in high amount in the sediment, it was shown that they are not involved in haze formation but co-aggregate with haze particles (Siebert, 1999). Haze is mainly due to the formation of protein and polyphenol aggregates on cold conditioning. The polyphenol–protein complex grows to sufficient size to result in turbidity and finally can form large particles that can sediment.

Conclusion

As illustrated here for two important factors of the quality of beers (i.e. foams and haze) proteins are essential components. Until now, individual protein components have been identified as the major actor of these properties. Their technological role involves structural maturation that is under the control of both physiological and technological processes. Today, there is also evidence that the role of proteins on the quality of beer involves molecular and macromolecular interactions. These interactions have been poorly studied and it will be essential in the future to devise a beer interactome strategy to delineate the precise role of these interactions on the foaming and haze-forming properties of beer. These studies will allow to improve the quality of beer through barley breeding and technological processes. Finally, it is worthy to note that beer concentrates on plant allergens and especially the ubiquitous plant LTP allergen. The low prevalence of allergy to beer can be related to the structural modification that occurs on malting and brewing.

Actually, chemical modifications and unfolding should improve the sensitivity of this putative beer allergen to proteases of the digestive tract (Marion *et al.*, 2004).

Amino Acids in Beer

Marta Fontana Department of Agriculture and Environmental Sciences, University of Udine, Udine, Italy
Stefano Buiatti Department of Food Science, University of Udine, Udine, Italy

Abstract

Nitrogenous compounds are considered very important in beer playing a key role in determining the quality and stability of the finished product. They include amino acids, peptides, polypeptides, proteins, nucleic acids and their degradation products. These compounds affect flavor, foam stability, haze formation, color, yeast nutrition and biological stability. The nitrogenous compounds in beer are derived mainly from barley malt and its adjuncts. Moreover the brewing process may have an important role in determining complex profile of nitrogenous compounds present in the final beer. The content of nitrogen compounds in barley depends on variety and on environmental condition in cultivation. During malting the storage proteins are degraded to amino acids and other peptides. These amino acids are important in wort to promote a good fermentation and the yeast budding. During fermentation amino acids are used in different ways by yeasts and may have many effects on the final quality of beer: in particular the amino nitrogen content influences the flavor profile of beer. The amino acids present in final beer could influence negatively the stability of product promoting haze formation. Nitrogen compounds may also play an important role influencing the foam quality and stability.

Introduction

Quality and stability are the most important qualities of alcoholic beverages, particularly in beer. Different and complex compounds are responsible for these properties. About 800 constituents have been characterized in beer and very important are macromolecules such as proteins, nucleic acids, polysaccharides and lipids (Briggs *et al.*, 2004). Several authors considered that the most important substances present in beer are alcohol and proteins. These proteins in beer are present at 0.3–1.0 g/l of total nitrogen, equivalent to 0.11–0.63% of protein (Hough *et al.*, 1982). If there is general agreement on the fact that hydrolysis of proteins produces polypeptides, peptides and amino acids, there is discordance about the classification of the same proteins. Some authors classify proteins by their function, others by molecular size. Only few proteins survive into beer and most of the nitrogen is present as polypeptides. The simpler nitrogen constituents of beer comprise mainly α-amino acids and the estimation of the latter has been the subject of several researches (Charalambous, 1981), therefore, the study of amino acids is frequently associated to the study of proteins. Proteins and their derivatives play a key role in determining beer quality and stability; they are in fact responsible for yeast nutrition and performance, influence malt color, foam formation, permanent haze and may affect the flavor. Amino acids in beer are originated mostly from malt and in particular, content and composition of proteins and amino acids depend on raw materials and on technological process of brewing.

Nitrogenous Compounds

The content of nitrogenous compounds is often reported as the protein content. The factor 6.25 is used to convert total nitrogen to total protein because, on average, proteins contain 16% nitrogen. But not many proteic substances contain nitrogen and the protein value obtained in this way could be too high. Thus, it is sometimes utilized the factor 5.7. Amino acids are the principal building blocks of proteins. They are incorporated into proteins by transfer
Figure 25.1 Basic structure of an amino acid.

Table 25.1 The amino acids are grouped according to the characteristics of the side chains

Side chains	Amino acids
Aliphatic	Alanine, glycine, isoleucine, leucine, proline, valine
Aromatic	Phenylalanine, tryptophan, tyrosine
Acidic	Aspartic acid, glutamic acid
Basic	Arginine, histidine, lysine
Hydroxylic	Serine, threonine
Sulfur-containing	Cysteine, methionine
Amidic (containing amide group)	Asparagines, glutamine

RNA according to the genetic code while messenger RNA is being decoded by ribosomes. During and after the final assembly of a protein, the amino acid content dictates the spatial and biochemical properties of the protein. The amino acids in peptides and proteins (excluding proline) consist of a carboxylic acid (—COOH) and an amino (—NH$_2$) functional group attached to the same tetrahedral carbon atom. This carbon is the α-carbon (Figure 25.1).

All amino acids found in proteins have this basic structure, differing only in the structure of the R-group or the side chain. The amino acids are grouped according to the characteristics of the side chains (Table 25.1).

Amino Acids in Barley

Production of high-quality malt depends on a number of factors. One of the most important parameters is the nitrogen content in malting barley. The nitrogenous components in barley change with the variety, the growing season, the soil and the amount of fertilizer and topography of the field (Bertholdsson, 1999; Agu and Palmer, 2003). In particular, variation in quality is caused by a complex set of interacting factors during the growth of the crop (De Ruiter and Haslemore, 1996). For example, high availability of nitrogen and stress situation (drought or heat in association with drought) may increase the protein level above the limit for malting barley. In fact, it is very important that barley used to produce malt has a grain protein concentration (GPC) lower than 11.5% (Bertholdsson, 1999); higher protein in barley is undesirable because of reduced potential fermentable extract which decreases the amount of beer that can be made from barley's malt. Nevertheless higher nitrogen barleys are likely to produce extracts that are rich in soluble nitrogen, free amino nitrogen (FAN) and peptide nitrogen. In contrast, lower nitrogen barleys are likely to produce extracts that are rich in carbohydrates. While some researchers and maltsters believe that barleys containing higher nitrogen levels would produce higher enzyme levels, other authors seem to disagree with this concept (Agu, 2003). Many studies have evaluated the content of proteins and their fractions in barley and beer but only few works have considered the evaluation of amino acids content. Table 25.2 shows the content of amino acids (%) in grain protein of barley.

Instead, it is usually accepted to classify barley proteins, and generally cereal proteins, with their solubility characteristics in different solvents. By classifying barley proteins with solvents, four different fractions can be obtained. Proteins soluble in salt solution are albumins and globulins which include enzymes. The protein material, which is insoluble in salt solution but soluble in warm alcohol, is prolamine (called hordein in barley). Finally, protein material insoluble in warm alcohol is glutelin (Hough, 1994). In Table 25.3 the protein composition of barley is reported.

Hordein is the major storage protein in the endosperm. It is a complex mixture of proteins that can be separated using sodium dodecyl sulfate and polyacrylamide gel electrophoresis (SDS-PAGE) into four groups with different molecular weight: A (<25 kDa), B (35–46 kDa), C (59–72 kDa) and D (90–105 kDa) (Palmer, 1989). Fraction A has low molecular weight, with bands frequently indistinct and variable for distinguishing barley varieties (Baxter and Wainright, 1979). Shewry (1992) has reported a fractioning of hordein using SDS-PAGE and two-dimensional analyses (isoelectrofocusing IEF/SDS-PAGE): these polypeptides are classified into two main sub-fractions: B and C and at least two minor sub-fractions: D and γ. These groups are also called, on the basis of their amino acid content, sulfur poor (C hordein), sulfur rich (B and γ hordein) and high molecular weight prolamins (D hordein). The amino acids composition of B, C, D and γ fractions have been reported in Table 25.4.

Hordeins are characterized by having high levels of amino acids proline and glutamine. The levels of tryptophan and threonine are low and level of lysine is reported to be limited (Bewley and Black, 1994). The B and D hordeins fractions are reported to contain sulfur (cystine) bridges (Field et al., 1983). Howard et al. (1996) have suggested that the amount of fraction D hordein in grain should be an accurate guide to malting quality than the use of total protein alone. The amino acid composition of the total protein fraction present in grains is strongly influenced by hordein (Bewley and Black, 1994) but the proportion of the different hordein

Table 25.2 Amino acids present in barley proteins

Amino acid	(%)

Valine	5.6	1.0	4.5	3.7
Methionine	0.6	0.2	0.2	1.2
Isoleucine	4.1	2.6	0.7	2.9
Leucine	7.0	3.6	3.3	8.6
Tyrosine	2.5	2.3	3.9	1.7
Phenylalanine	4.8	8.8	1.4	4.7
Histidine	2.1	1.1	3.4	2.0
Lysine	0.5	0.2	1.1	1.6
Arginine	2.4	0.8	1.5	2.0

Note: Hordein is a complex mixture of protein that can be classified and separated into two major groups (B and C hordeins) and into two minor groups (D and γ hordeins) which vary in their molecular weight, isoelectric point and amino acid composition.

Source: Shewry (1992).

fractions present in mature grain are affected by growth conditions, particularly nitrogen nutrition. Glutelin is a storage protein present in the aleurone layer and globulin is the storage protein of embryo but it represents only a small proportion of the total reserve protein of the whole grain. Albumins and globulins, which include many enzymes, are not seriously deficient in specific amino acids. They contain a higher level in lysine and methionine than hordein (Briggs, 1998). However, Kunze (1999) has reported that globulin does not completely precipitate during boiling of wort and can promote haze in beer, whereas albumins precipitate completely when wort is boiled. Unmalted adjuncts such as rice or corn for all practical purposes do not contain proteins that are soluble in wort. Thus, their use will directly dilute the protein content of wort (Fix, 2000).

Amino Acids in Brewing Process

During malting, the storage proteins of barley, mainly in the endosperm, are hydrolyzed by proteases into polypeptides, peptides and amino acids. During this step there is some utilization of amino acids (other loss of protein will occur during mashing due to precipitation), but for the most part, the protein content of malt is similar to that of the barley from which the malt was made. There is some continuation of protein breakdown in the mash, but the extent is greatly influenced by the mashing program used (Fix, 2000). The amino acids present in wort are necessary to promote yeast multiplication and a good fermentation. The presence of FAN, peptides and polypeptides also influences yeast growth, the foam and haze properties of derived beer (Agu and Palmer, 1999). The value of 150–175 mg/l of α-amino nitrogen is optimal to maintain a healthy yeast and maximum fermentation.

- **During fermentation amino acids are used in different ways by yeasts.**

Wort amino acids represent the major source of assimilable nitrogen for brewing yeast. Yeast metabolizes each one of them in a different way largely independent of the conditions of fermentation. On the basis of yeast assimilation, amino acids have been categorized into four groups. In Table 25.5 the order of absorption of amino acids from brewer's wort by yeast is illustrated.

Group A amino acids are absorbed rapidly, in the first step of fermentation (about 20 h). Amino acids of group B are utilized more slowly, and group C amino acids are taken up only after the complete removal of group A amino acids

in wort. Group D consists only in proline, in fact yeast uses proline more slowly under anaerobic condition. Proline has no free amino group and therefore cannot take part directly in transamination reactions that often cause the formation of flavor-producing beer compounds. If proline is present in final beer it supports the instability of product. The order of amino acid assimilation is not affected by the concentration of specific amino acids but appears to involve the nature and specificities of amino acids permeases. The process of uptake of amino acids by yeast appears very complex. It is often convenient to consider individual aspects of metabolism in terms of biochemical pathways. In fermentation, amino acids present in wort are preferentially taken up and utilized to supply nitrogen to the cell and yeasts are considered to incorporate up to 50% of wort amino acids directly into protein. Of these, approximately one-third are excreted back into wort, but this proportion can be higher in adverse conditions. Under normal conditions, 33.5% of the wort amino acids are consumed during the fermentation, while 16.5% of the wort amino acids are assimilated, only to be excreted back into the fermenting wort (Fix, 2000). As seen before, yeasts take up amino acids in a definite order. The amino nitrogen is used as a nutrient, while the carbon skeleton is sent to the oxo-acid pool in the yeast cell for further processing. As a general rule, amino acids are not treated separately, but rather in pairs. The Strickland reaction is a major mechanism whereby one amino acid donates hydrogen atoms and the second acid acts as an acceptor.

Table 25.5 Classification of wort amino acids according to their consumption rate by yeast

Group A	Group B	Group C	Group D
Fast absorption	Intermediate absorption	Slow absorption	Little or no absorption
Glutamic acid	Valine	Glycine	Proline
Aspartic acid	Methionine	Phenylalanine	
Asparagine	Leucine	Tyrosine	
Glutamine	Isoleucine	Tryptophan	
Serine	Histidine	Alanine	
Threonine			
Lysine			
Arginine			

In Figure 25.2, amino nitrogen and carbon skeletons (oxo-acids) are shown.

When amino acids enter the cell their amino groups are removed by a transaminase system and their carbon skeletons assimilated. Transaminase catalyze readily reversible reactions dependent on the presence of cofactors. The oxo-acids, derived from the carbon skeleton of the amino acid present in wort or from carbohydrate metabolism, enter the cell's metabolic pools. The synthesis of amino acids by the yeast cell then proceeds and, in the latter instance, *ex novo* synthesis of amino acids is said to occur and the penultimate reaction is usually transamination (Hough *et al.*, 1982). Yeast-synthesized amino acids, including lysine, histidine, arginine and leucine, are extremely critical because their carbon skeletons are derived entirely from exogenous wort amino acids with no carbon contribution from sugar catabolism. Low levels of lysine, histidine, arginine and leucine can cause important changes in yeast-induced metabolism of nitrogen, lowering the final quality of beer (Meilgaard, 1976). Amino acids such as proline, threonine and methionine are essential because they are generally produced by yeast until late in the fermentation and valine, glycine and tyrosine are critical because late they serve as the major sources of yeast carbon skeletons. Jones and Pierce (1969) have reported that concentration in wort of amino acids isoleucine, valine, phenylalanine, glycine, alanine, tyrosine, lysine, histidine, arginine and leucine are considered important and changes in the concentration of amino acids in wort will influence nitrogen metabolism.

- **Free amino acids are very important on influencing flavor development in beer.**

Many factors may influence the beer flavor but, in general, aromatic profile of beer is determinated by yeast and by their ability to grow and to metabolize the nitrogenous constituents of wort. The amino nitrogen content influences the flavor profile of beer mainly via higher alcohol and ester formation. In this metabolism, the amino group of amino acids may be transferred to an enzyme (transaminase) and the remaining carbon skeleton excreted or used to regenerate adenine dinucleotide phosphate (NAD^+). The oxo-acid produced by transamination is decarboxylated to give carbon dioxide and an aldehyde. The aldehyde
Figure 25.2 Formation of higher alcohols, aldehydes and oxo-acids from amino acids. (generalized pathway: R any amino acid chain) a = amino acid; b = oxo-acid; c = aldehyde; d = alcohol [NH₂] indicates group transferred to transaminase enzyme CO₂ = carbon dioxide Enzyme involved: 1 = transaminase; 2 = decarboxylase; 3 = dehydrogenase.

is then reduced to an alcohol, called higher alcohol. These substances have higher boiling points than ethanol and are potently aromatic. A variety of alcohols are produced during yeast metabolism and in Table 25.6 the amino acids level present in wort and flavors compound obtained during their catabolism are reported.

A similar correlation was found between the wort amino acid content and the formation of higher alcohols, ester and carbonyl compounds in the resulting beer by Äyräpää (1971). In their work, Vesely *et al.* (2004) have reported the use of single amino acids by yeast during two different fermentation temperatures: 10°C and 15°C. The effect of the fermentation temperature on the yeast causes different use of single amino acids with different aromatic profiles in beer. The higher the temperature, the more significant the amino acid level decrease during fermentation, and the higher rate of yeast growth. At the end of a fermentation carried out at 15°C, 90% of amino acids are metabolized, except for glycine and proline. It is well known that glycine is one of the last amino acids utilized by yeast and proline is not a substrate of yeast metabolism. At 10°C fermentation, utilization of amino acids by the yeast was slightly lower, particularly for alanine, glycine, histidine and tyrosine. Limited nitrogen concentration may alter the time course of flavor precursor production and therefore change the flavor of the final beer (Dufour and Devreux, 1986). The compounds responsible are mainly butane-2,3-dione (diacetyl) and pentane-2,3-dione, by-products of valine, leucine and isoleucine amino acids (Almeida *et al.*, 2004). If valine is deficient in wort, yeast synthesizes it by a pathway involving α-acetolactate as an intermediate. Accumulation and oxidation of acetolactate produce diacetyl that causes flavor defects (Pollock, 1988). Sulfur compounds also influence the flavor and aroma of beer. They can derive from organic sulfur compounds in wort, such as the amino acids methionine and cysteine and peptides and proteins that contain sulfur. Wainwright (1971) has reported that the wort's content of the sulfur-containing amino acid methionine greatly influences the production of volatile sulfur compounds by yeast: a methionine-poor wort leads to higher sulfur dioxide and hydrogen sulfide levels in beer.

- **The color of final beer depends on malt used and products of Maillard reaction originated from amino acids and sugar.**

During kilning, malting and boiling of wort various complex compounds are generated, mainly melanoidines. These compounds are the products of Maillard reaction, partly responsible of the color of beer, and obtained through a reaction between amino acids and sugar. Charalambous (1981) has reported that the most important browning reaction is believed to take place between the amino acid proline and maltose to 3-hydroxy-2-metyl-4-pyrone (maltol). The level of proline in wort can thus affect color development in beer.

Amino Acids in Final Beer

Only about 30% of nitrogen compounds in barley are present in the final beer. As previously reported, beers contain only low levels of amino acids, since during fermentation amino acids are assimilated for yeast growth (Briggs *et al.*, 2004); in particular the content of proline is quantitatively higher if compared to other amino acids. In beer, nitrogenous compounds comprise denatured proteins, denatured nucleic acid, amino acids, amides, amines and heterocyclic compounds. Beers from all malt wort contain 32.6–44.7 mg/l α-amino nitrogen equivalent to 8.2% of the total nitrogen and beers brewed from a grist containing 22.8% of wheat flour contained 21.3–26.7 mg/l α-amino nitrogen, 5.8% of the total nitrogen (Hough *et al.*, 1982). Table 25.7 has reported the content of amino acids found in different beers.

Table 25.6   Compounds originated by amino acid catabolism in anaerobic environment

Amino acid	α-Keto acid	Aldehydes	Alcohols	Carboxylic acids	Others
Asparagine	Oxaloacetate	–	–	Malate	Diacetyl, acetoine

Source: Modified from [a] Bamforth (2004), [b] Charalambous (1981), [c] Briggs et al. (2004).

The level of protein in beer is low but it has very important effect on the quality of beer. Many studies on the characterization of proteins in beer are associated to studies of the quality aspect, often associated to foam and haze stability. In fact, these two aspects, foam and haze stability, are of critical importance to brewers (Evans *et al.*, 2003).

- **Nitrogenous compounds can combine with polyphenols to form complex responsible of haze in beer.**

One of the most common quality defects found by the consumers in beer is cloudiness or haze, which can negatively effect the shelf-life of the product and its acceptability. Many consumers think that it is caused by a microbial contamination, but beers are biologically safe after the pasteurization treatment which destroys microbial contamination. In fact it is important to distinguish the two different kinds of haze in beer: biological haze and non-biological (or colloidal) haze. Microbiological haze is caused by infections that involve bacterial or yeast and can be avoided with a sterile filtration and pasteurization. The presence of colloidal or non-biological haze can appear in bright beer and it can be caused by several types of substances. The most important non-biological haze is chill (or permanent) haze. Chill haze starts to develop at low temperature (0–4°C) with particle size between 0.1 and 1.0 μm, but it disappears when the beer is returned to 20°C. On the contrary, permanent haze is present in beer even at 20°C with particle between 1 and 10 μm (Bamforth, 1999). Chill haze

is an important problem with lager beers which are served at lower temperatures than ales. The appearance of haze is a visual clue of the reduced flavor stability of beer since the haze and flavor stability is both directly influenced by oxidation processes during storage (Robinson *et al.*, 2004). Several chemical species can enter into such insoluble complexes. However the most common chill hazes found in beer are originated by interactions between proteins and polyphenols. These compounds form weak, temperature-sensitive hydrogen bonds that are broken as the beer's temperature increases. The other form of haze is permanent and is characterized by strong bonds of covalent type in which constituent atoms share the available electrons to achieve a more stable energy state. Typical protein–polyphenol haze consisted of about 50% protein, 25% polyphenol and the remaining 25% from polysaccharides and metals. The 0.1% of the total nitrogen in beer is sufficient to produce protein–polyphenol haze (McMurrough *et al.*, 1999). A quantity as 2 mg/l of protein can produce a haze of 1 EBC (Chapman, 1993), equivalent to 69 FTU (formazin turbidity units). Haze-active proteins isolated from beer have been found to be derived primarily from residues of the barley proteins group, the hordeins. These protein fragments consist of several different molecular weights and are relatively rich in proline. This description matches the characteristics of the nitrogen-terminal sequence repeats of the hordeins that are rich in glutamine (which comprise 30 mol% of hordein) and proline (20 mol%), which are produced by proteolytic modification during malting and

Note: Four fractions responsible for haze are isolated in beer and they are called haze-forming proteins I, II, III and IV. Their molecular weights were estimated to be 1–10 kDa (fraction I); 19 kDa (fraction II); 16 kDa (fraction III); 40 kDa (fraction IV).

Source: Modified from Asano et al. (1982)

mashing (Robinson *et al.*, 2004). Properties and compositions of haze-forming proteins have been studied by Asano *et al.* (1982). They used a procedure to isolate and fractionate four different fractions of haze-forming proteins in beer. The amino acids composition of these four fractions and hordein, albumin, globulin present in malt is shown in Table 25.8.

They concluded that haze-forming proteins derived from hordein were rich in proline, and derived from polypeptides albumin and that globulin may also react with polyphenols to form haze. Proline is the amino acid that has a specific affinity for polyphenols. The force of attraction between polyphenols and proteins is mainly described as hydrogen and hydrophobic bonding involving hydrophobic amino acids such as proline but also tryptophan, phenylalanine, tyrosine, isoleucine and valine. Hough *et al.* (1982) have reported that the main amino acids present in haze are proline, glutamic acid, arginine and aspartic acid. It is extensively accepted that protein with high levels of amino acid proline and polyphenols with higher degree of polymerization are most likely to form haze (Siebert *et al.*, 1996). Many researchers have studied influences of proline amino acid in beer stability. This imino acid, not metabolized during fermentation, is the principal amino acid present in the finished product. Gorinstein *et al.* (1999) have studied protein, proline and lysine contents of beer during brewing process. They emphasized that maximum proline content corresponds to the fermentation and storage stages while in the final product the content of proline decreases remaining significantly higher than in wort. In all cases, final filtration decreases the level of amino acids. Polypeptides which contain low level or no proline produce little or no haze (Briggs *et al.*, 2004). Protein and polyphenol complexes cross-link together by weak interactions such as hydrogen bonds and hydrophobic interactions; alcohol, pH, free amino acids, and metal content may influence protein–polyphenol haze formation as well. The amount of alcohol in the beer will change the hydrophobic bonding between the proteins and the polyphenols due to the lesser polarity of ethanol than water. Siebert *et al.* (1996), in a model system, have studied the effect of pH on haze formation and concluded that there was decreased haze formation at a lower pH value with a maximum haze formation at pH 4.2. Asano *et al.* (1982) have described the chemical combination between protein and polyphenols. The pyrrolidine rings of proline forming proteins have unfolded molecular structures that facilitate the entry of polyphenols into them. Furthermore, the pyrrolidine ring of proline cannot form intramolecular and intermolecular hydrogen bonds with oxygen atoms of peptide bonds and, consequently, these free oxygen atoms readily form hydrogen bonds with hydroxyl groups of polyphenols. Moreover proline also participates in hydrophobic bonding between the haze-forming proteins and polyphenols. These two mechanisms of combination between the haze-forming proteins and polyphenols
Figure 25.3 Model for protein–polyphenol interaction causing haze. *Source*: Modified from Siebert and Lynn (1998).

were probably responsible for chill haze formation of beer. Siebert *et al.* (1996) have investigated the mechanism of protein–polyphenol interaction and they proposed a model where only a fixed number of sites in the protein (primarily proline containing proteins) serve as attachment point for polyphenols. In protein–polyphenol complexes, the polyphenolic compounds act as a bridge between adjacent protein molecules. A diagram of a model for protein–polyphenol interactions is shown in Figure 25.3.

The model assumes that polyphenol has a fixed number of binding ends (two or more) and each protein also has a fixed number of polyphenol binding sites (two or more). If the number of polyphenol ends is equal to the number of protein binding sites, the largest network of protein and polyphenols should be produced thereby creating the largest amount of haze. If the amount of protein is in excess relatively to the polyphenols, as it usually happens in beer, then each polyphenol molecule can bridge two protein molecules, making it unlikely that an extended network of bridges would be formed between the protein and polyphenol molecules. If the number of polyphenol molecules significantly exceeds the number of haze-active protein molecules, all of the haze-active protein binding sites would likely be bound to polyphenols making it unlikely that an extended network of bridges between haze-active protein and polyphenol molecules would be created (Siebert *et al.*, 1996). The fixed number of binding sites on haze-active protein is considered to be accessible prolines, which are attachment sites for the polyphenols (Siebert and Lynn, 1998). More haze results from the same amount of protein and polyphenol when their ratio is more nearly even; later on use of compounds that reduce some haze-active protein could result in an initial increase in haze (Siebert and Lynn, 1997). Stabilization treatments are necessary to improve the colloidal stability and to extend the shelf-life of beer. Bamforth (1999) reported three different strategies: protein removal, polyphenol removal or remove a proportion of each. Many different substances can be used to improve the stability of beer and to remove polyphenols polyvinylpolypyrrolidone (PVPP) is commonly

used. Its chemical structure, in comparison with polyproline structure, is reported in Figure 25.4.

Siebert and Lynn (1998) have showed that the structure of PVPP strongly resembles the structure of polyproline and that it binds polyphenols in the same way proteins rich in proline bind with polyphenols. Both substances have five-membered, saturated, nitrogen-containing rings and amide bond with no other functional groups. Proteins have not to be eliminated completely because they are associated with important characteristics of beer such as the head-forming properties and the development of a full palatability (Hough *et al.*, 1982). It is not clearly established if the haze-forming and foam-forming proteins are different. Hough *et al.* (1982) have reported that two proteins, which reacted with barley antibodies, were present in both foam and haze. It is important to use coadjuvants that are able to remove constituents of haze without reducing foam stability, flavor and taste. Papain was one of the first stabilizers used in brewing. It is a proteolytic enzyme; it hydrolyzes peptides but it reduces the foam quality (Bamforth, 1999). Also tannic acid and bentonite, used as a specific precipitant of haze-active proteins, can damage foam in beer. It is most common to use silica gels that bind to proline residue in the protein with minimal negative effects on the protein fraction involved in beer foam-active quality (Siebert and Lynn, 1998). Lopez and Edens (2005) have proposed alternatives to the traditional stabilization compounds. A proline-specific protease in wort that can hydrolyze proteins rich in proline has been used, yielding a peptide fraction that is unable to form a haze without negative effect on foam stability. Evans *et al.* (2003) have proposed a different approach; since haze activity is dependent on the distribution of proline in the hordein, they have studied immunological methods that can predict the potential of malt samples to produce beer with superior foam and haze stability.

- **The quality and stability of foam are influenced by proteins in beer and by their complex with other substances.**

According to Omrod (1994) volume and quality of beer foam are generally considered by consumers as a major factor in beer quality. Foams are colloids composed of gas bubbles dispersed through a liquid. The stability of the beer foam is related to the stability of the bubbles and anything that disrupts the bubbles will result in unstable foam. Compounds that influence foam stability and quality include proteins, bittering substances of hops, metal ions, polysaccharides and melanoidins. The foam is richer than the beer in such substances as specific proteins and hop components, particularly iso-α-acids. Beer proteins are considered the major foaming agents and variations in foaming behavior are due to interaction of the protein with other substances (Hough *et al.*, 1982). Other components foam-negatives, such as lipids, are also important in determining the overall head-forming characteristics of
Figure 25.4 Comparison of partial structures of polyproline and PVPP. *Source*: Modified from Siebert and Lynn (1998).

a particular beer. Beer proteins form complex with iso-α-acids and metal ions. These strongly hydrophobic complexes are known to enhance foam stability and adhesion. During foam formation, amphipathic proteins surrounding the bubbles interact with hydrophobic region, forming a stable "bridge" between the hydrophobic gas bubbles and the aqueous beer; these are then cross-linked by hop bitter acids and metal ions, forming a semirigid structure (Dickie *et al.*, 2001). Ryder *et al.* (1991) have reported the chemical interaction and colloidal aspect present in beer foam. Formation of foam requires the presence of surfactants in solution and one property of proteins, or polypeptides, and iso-α-acids present in beer, is to be surfactants. In fact only few proteins are surface active to some degree and tend to form foams: the incorporation of both hydrophilic and hydrophobic amino acid gives proteins their amphipathic properties. The principal components of beer that stabilizes foam are proteins derived from barley (Bamforth, 1985) but they undergo considerable modification during malting, mashing and brewing. Several researchers have reported that proteins present in beer foam are greater than 10 kDa (Siebert and Knudson, 1989). Other studies have considered that beer proteins with a molecular weight between 5–10 and 100 kDa (termed as high molecular weight fraction – HMW) have a positive effect on beer foam quality and compounds with a molecular weight below 10 kDa (termed as low molecular weight fraction – LMW) have a negative effect on foam and the ratio of these two fractions, rather than their absolute amounts, is very important (Sharpe *et al.*, 1981; Omrod, 1994). Protein associated with beer foam formation and stability are protein Z, lipid transfer protein 1 (LPT1), hordein and glutelin fragments (Siebert and Knudson, 1989). Protein Z and LPT1 are considered the predominant proteins in beer (Leisegang and Stahl, 2005). Protein Z is a 40 kDa protein derived from barley albumin which has been related to beer foam stability (Bamforth *et al.*, 1993). Protein Z with 50–200 mg/l (Leisegang and Stahl, 2005) is partially homologous to serine protease inhibitors and these inhibitory properties might be the reason why protein Z is not degraded by proteolytic enzymes during malting and mashing. Protein Z can be resolved into two isoforms: Z4 (80%) and Z7 (20%) (Briggs *et al.*, 2004). Protein LPT1 has a rate of 50–90 mg/l and is concentrated in beer foam

(Leisegang and Stahl, 2005). LPT1 is a 9.6 kDa protein and it has been suggested that it is important in beer foam formation. It is made up of 91 amino acid residues including eight cysteines that are probably present in the beer protein in the oxidized form as four cystines (Lusk *et al.*, 1995). Leisegang and Stahl (2005) have evaluated the degradation of LTP1 by protease A. This is an enzyme primarily released by autolysis from dead yeast cell and the degradation of LPT1 may have a negative influence on beer foam stability. Kapp and Bamforth (2002) have established that albumin and hordein fractions from barley are capable of foaming and that the foam stability of the albumin fraction is greater than that of the hordein fraction. Evans *et al.* (2003) have described that malt derived, foam positive proteins, including protein Z4, LPT1 and some members of the hordein storage protein family, interact principally with isomerized hop acids to stabilize foam. Several research groups have studied the influence of polymeric amino acids on beer foam. Amino acids and their concentrations in the main beer protein may vary from beer to beer depending on the type of malt and adjuncts used in brewing. Wheat contain more foam stability proteins than the equivalent proteins from barley; adjuncts based on corn, rice and sugars provide no foaming material and their use, therefore, dilutes foam potential (Lewis and Bamforth, 2006). Asano and Hashimoto (1980) have studied amino acids composition of foaming proteins. They isolated three different molecular weight fractions of foaming proteins: higher, medium and lower with molecular weights from 90 to 100 kDa, 40 kDa and 15 kDa. The result of analysis is reported in Table 25.9.

The amino acid composition of these three fractions were similar to that of barley albumin or globulin. Lysine occurred more frequently in higher and medium molecular weight fractions than in lower fraction; cysteine and methionine were not present in the third fraction. ε-Amino groups of lysine residue in foaming proteins combine electrostatically with acidic groups of iso-α-acids molecules derived from hops (Asano and Hashimoto, 1976). Because higher and medium molecular weight fractions have the higher content of lysine, these fractions must combine preferentially with iso-α-acids and this complex increases the foaming of beer. Asano *et al.* (1982) also provided data for malt hordein and malt albumin plus globulin; amino acid composition shows that beer haze-forming protein is derived from malt hordein and the beer foam-active protein originates from the malt albumins and globulins. Siebert and Knudson (1989) have proposed a Coomassie blue dye binding assay to determine high molecular weight protein (over 5 kDa) in beer. The dye-binding procedure responds strongly to basic and aromatic amino acids, mainly present in foam-active proteins. Yokoi *et al.* (1994) have studied the hydrophobic beer proteins and their function in beer foam; they have fractioned beer proteins and analyzed the

amino acid composition of these fractions. They reported that proteins in beer have a different hydrophobicity; proteins rich of hydrophobic amino acids form strongly complex with iso-α-acids and are concentrated in beer foam and play an important role in foam stability.

- **Amino acids are precursors of formation of biogenic amines.**

Biogenic amines can be found in beer, in fact brewing process fulfills the three factors that govern the formation of amines. Free precursors of amino acid are available; microorganisms with amino acid decarboxylating activity can occur and favorable conditions for the growth of microorganisms can be found. Biogenic amines formation is attributed to thermal amino acid decarboxylation and possibly to enzymatic activity in malt. Only few studies are available on the relationship between precursor of amino acids and formation of their corresponding amines. Ardö (2006) has reported a research about amino acid catabolism and Table 25.10 shows the amines produced from decarboxylation of amino acids.

Izquierdo-Pulido *et al.* (2000) have investigated the influence of a precursors amino acid on tyramine formation during beer fermentation. They concluded that it is difficult to establish a direct relation between tyramine and tyrosine. Probably more attention should be paid to keep under control the bacteria contamination than the amount of free tyrosine present in wort.

Table 25.10 Biogenic amines originated from corresponding amino acids

Amino acid	Biogenic amine
Tyrosine	Tyramine
Histidine	Histamine
Ornithine	Putrescine
Lysine	Cadaverine
Tryptophane	Tryptamine
Phenylalanine	Phenylethylamine

Source: Modified from Ardö (2006).

- **Amino acids can influence the sensory quality of beer.**

Aroma profile in beer is depending on many different compounds, responsible of different sensations. According to Hough (1994) some amino acids are involved in taste perception; it has been reported that L-alanine and L-tryptophan are respectively associated to sweet and bitter sensation.

- **Amino acids in excess are responsible of biological stability in beer.**

Above all, the beer's biological stability is related to resistance to *Lactobacillus* infection. When present in excess, the amino acids in beer can promote infections by acting as nitrogen sources for spoilage microorganism (Bamforth, 2004).

Purines in Beer

Tetsuya Yamamoto and Yuji Moriwaki Division of Endocrinology and Metabolism, Department of Internal Medicine, Hyogo College of Medicine, Hyogo, Japan

Abstract

As compared with other alcoholic beverages, beer contains considerable amounts of purines, which high-performance liquid chromatography has shown to consist of purine nucleosides and bases. According to that analysis, the nucleoside guanosine was most abundant, as compared with other types of purines. Purine ingestion causes an increased production of uric acid, leading to an increase in the serum concentration of urate. According to the results of a study on nucleic acid ingestion, the serum concentration of urate was increased to a greater degree in patients with hyperuricemia or gout than in normal subjects. In addition, the serum concentration of urate was increased by ingestion of nucleotides (adenosine monophosphate (AMP), guanosine monophosphate, and inosine monophosphate (IMP)) and purine bases (adenine, hypoxanthine, xanthine) in all three subject groups, while it was shown that hypoxanthine, AMP, and IMP had greater hyperuricemic effects on patients with gout than those with hyperuricemia and the normal subjects. The effects of guanosine (the most plentiful purine in beer) on the serum urate levels were not examined in previous human studies. However, since it was found that guanosine was more readily absorbed than other nucleosides, nucleotides, or bases and rapidly converted to uric acid via guanine and xanthine in animals, it is suggested that its ingestion may increase the serum concentration of urate. Since purines in beer have a clinical effect on serum urate and augment hyperuricemic effect in patients with gout, it is important for those patients to refrain from consuming large amounts of beer that contains considerable amounts of purines.

List of Abbreviations

ADP	Adenosine diphosphate
AMP	Adenosine monophosphate
ATP	Adenosine triphosphate
GMP	Guanosine monophosphate
HPLC	High-performance liquid chromatography
IMP	Inosine monophosphate
S-AMP	Adenylosuccinic acid
SDS	Sodium dodecyl sulfate
XMP	Xanthosine monophosphate

Introduction

A purine is a heterocyclic aromatic organic compound that consists of a pyrimidine ring fused to an imidazole ring (Figure 26.1), and the term purines refers to substituted purines and their tautomers. Many purine bases including hypoxanthine, xanthine, adenine, guanine, and uric acid are present in the body. Deoxynucleic acid contains two of the bases, adenine, and guanine. Therefore, purines are known to play an important role in animals, bacteria, fungi, viruses, and plants, as well as in other organisms. Beer is produced from malt by fermentation with yeast fungus, and since malt contains considerable amounts of purines, beer also contains high levels of purines. In the human body, most ingested purines are metabolized to the end-product uric acid (Figure 26.2) (Clifford *et al.*, 1976). Therefore, ingestion of large amounts of purines causes an increased production of uric acid, leading to hyperuricemia. Continued hyperuricemia causes gouty attack, tophus, and
Figure 26.1 Purine ($C_5H_4N_4$). A purine is a heterocyclic aromatic organic compound that consists of a pyrimidine ring fused to an imidazole ring.

gouty kidneys; therefore, it is important for individuals at risk to restrict the intake of large amounts of purines as well as reduce other factors that contribute to hyperuricemia, such as obesity and vigorous exercise (Yamashita *et al.*, 1986; Takahashi *et al.*, 1997; Yamamoto *et al.*, 1997). Beer contains greater amounts of purines than other alcoholic beverages as shown in Table 51.2 of this book in the article entitled "Relationship between exercise and beer ingestion in regard to metabolism" (Chapter 51 of this book) and may contribute to hyperuricemia to a greater degree than other alcoholic beverages. Therefore, it is important to obtain data regarding the contents and effects of purines in beer and other beverages.

Analysis of Purines in Beer

Purines in beer consist of nucleosides and bases, the majority of which are derived from the malt contained in beer, and it is important to use a reliable method to measure these nucleosides and bases in beer easily and accurately. In several studies (Yamamoto *et al.*, 2002, 2004a; Cortacero-Ramirez *et al.*, 2004a, b), purines in beer were analyzed using a high-performance liquid chromatography (HPLC) technique, which is known to be rapid and easy, and able to determine the amounts of purines in aqueous solution accurately. In our previous study (Yamamoto *et al.*, 2002, 2004b), the concentrations of hypoxanthine, xanthine, inosine, adenosine, guanosine, deoxyinosine, deoxyguanosine, and deoxyadenosine in beer were determined by reversed-phase HPLC, with the mobile phase of 20 mM/l phosphate buffer (pH 2.2), the flow rate of 1 ml/min, and the detection wavelength of 254 nm, using a Wakosil 5C18-200 (Wako Pure Chemicals Industries, Osaka, Japan). In addition, the concentrations of adenine, guanine, and deoxyuridine in beer were determined by another HPLC method. In brief, the chromatograph consisted of two CCPM pumps (Tosoh, Tokyo, Japan), a SC-8020 system controller (Tosoh, Tokyo, Japan), two spectrophotometric detectors (UV-8010 and UV-8020) (Tosoh, Tokyo, Japan), and a VC-8020 column switching valve (Tosoh, Tokyo, Japan). The chromatographic columns were a Wakosil 5C18-200 (4.6 × 250 mm) (Wako Pure Chemicals Industries, Osaka, Japan) as the first column and a NAVI C18-5 (4.6 × 250 mm) (Wako Pure Chemicals Industries, Osaka, Japan) as the second column. In the first column, the mobile phase was 20 mM KH_2PO_4 (pH 4.70) and in the second column, the mobile phase was 20 mM KH_2PO_4 (pH 2.20). The flow rate was 1 ml/min and the detection wavelength was 254 nm. Using two methods, the purine nucleosides and bases in Japanese regular beer (Kirin Brewery, Yokohama, Japan) were determined, with the results shown in Table 26.1.

Another method termed the capillary electrophoretic method, which uses micellar electrophoretic capillary chromatography, has also been reported (Cortacero-Ramirez, 2004a) and shown to have high resolving power, high separation efficiency, high sensitivity, and unique selectiv-

Table 26.1 Concentrations of purine nucleosides and bases, and uridine and its metabolites in Japanese beer (μmol/l)

Hypoxanthine	17.5 ± 1.5
Xanthine	58.5 ± 3.6
Guanine	42.4 ± 3.6
Adenine	17.2 ± 2.3

Uracil	17.6 ± 1.5
Inosine	20.3 ± 2.5
Guanosine	174 ± 16.1
Adenosine	42.1 ± 7.9
Uridine	210.6 ± 27.2
2'-Deoxyguanosine	ND
2'-Deoxyadenosine	19.4 ± 3.7
2'-Deoxyinosine	ND
2'-Deoxyuridine	7.9 ± 2.1

Note: Values are expressed as mean ± SD. Beer contains various purines.

ity. The advantages of this method include a low consumption of solvents and less rigorous requirements for sample cleanup, as compared with traditional HPLC. The system comprises a 0–30 kV high-voltage built-in power supply and is equipped with a diode array detector. In their study, the mobile phase was 25 mM $Na_2B_4O_7$ adjusted to pH 10.5 and 110 mM sodium dodecyl sulfate, with detection wavelengths of 210 and 270 mM while the separation voltage was 14 kV at a constant temperature of 25°C. All of the capillaries had an inner diameter of 75 mm, a total length of 50 cm, and an effective separation length of 50 cm. The concentrations of purines in each of seven different kinds of beer determined by this method are shown in Table 26.2. Further, in another study (Cortacero-Ramirez, 2004b), using the same method, the concentrations of purines in different kinds of beers were determined (Table 26.3). However, the methods are not sufficient to determine the quantities of purines in beer, as only guanosine, adenosine, adenine, and xanthine were detected in contrast to the large variety present in beer.

Purines in Beer and Other Beverages

British beer, home-brewed beer, and lager beer each contain many different types of purines, such as adenine, hypoxanthine, adenosine, and guanosine (Table 26.4) (Gibson *et al.*, 1984). Japanese beer contains greater amounts of purines than other types of beer, including purine nucleosides (inosine, guanosine, adenosine, and deoxyadenosine) and purine bases (hypoxanthine, xanthine, guanine, and adenine), with guanosine being the most abundant (Table 26.1). Guanosine is more quickly absorbed and rapidly converted to uric acid via guanine and xanthine in animals (Figure 26.3), and thus it may increase the serum concentration of uric acid (Potter *et al.*, 1980). In Japan, low malt liquor (happo-shu) and purine-free happo-shu have been developed (Yamamoto *et al.*, 2004), and have a taste that is similar to beer. Happo-shu contains 249.4 μmol/l

Table 26.2   Analysis of different types of beer samples

	Concentration (mg/l)						
Analytes	Extra	Classic I	Classic II	Special	Special black	Light	Non-alcoholic
Adenosine	n.q.	n.q.	8.3 ± 1.0	7.1 ± 0.9	n.q.	21.3 ± 1.9	12.3 ± 1.4

Xanthine	94.0 ± 5.1	95.9 ± 3.6	116.6 ± 5.5	77.6 ± 6.0	99.0 ± 6.7	34.7 ± 1.1	35.3 ± 5.9

Note: n.d. not detected; n.q. not quantified. Values are expressed as mean ± SD. Different types of beer contain considerable amounts of purines including guanosine and xanthine.

Table 26.4   Purine bases and nucleosides in different types of beer

	Adenine	Hypoxanthine	Xanthine	Adenosine	Guanosine	Total purines
British beer	1.2	0.6	3.3	3.5	13.6	22.2
(Range)	(0.4–3.0)	(0–2.5)	(2.6–3.8)	(0–6.0)	(10–17.3)	(20.3–27.5)
Home-brewed beer	0.7	1.2	0.2	0	1.8	3.9
Guinness	0	0	5.5	7.7	10.6	23.8
Lager beer	4.3	3.0	3.5	0	6.9	17.7

Note: Values are expressed in mg purine nitrogen/l. British beer, Guinness, and Lager beer contain considerable amounts of purines.

of purines, indicating that it contains lower amounts of malt and purine (Table 26.5) as compared with Japanese regular beer that contains 391.4 μmol/l of purines (Table 26.1). However, happo-shu still contains a considerable amount of purines, especially guanosine (Table 26.5). On the other hand, purine-free happo-shu contains the same amounts of malt and very low levels of purines (13.2 μmol/l), as compared with regular happo-shu (249.4 μmol/l). Purine-free happo-shu was recently developed for individuals who were concerned about increases in urate serum concentration. However, ingestion of large amounts of purine-free happo-shu causes an ethanol-induced increase in that concentration.

Figure 26.3   Guanosine degradation. Words in white indicate pathway of guanosine degradation.

Comparison of Purines Between Beer and Other Beverages

Wine contains 1.6 mg/l of purines and sake contains 4.6 mg/l of purines expressed contains mg purine nitrogen/l, while whisky, brandy, and shouchu (a traditional Japanese distilled sprits, which has a high ethanol concentration at about 20–40% spirit), each a type of distilled liquor, contain 0.5, 1.6, and 0.1 mg/l (Table 51.2 in the article entitled "Relationship between exercise and beer ingestion in regard to metabolism", Chapter 51 of this book). As compared with beer and happo-shu, these alcoholic beverages contain lower amounts of purines, suggesting that the serum concentration of urate may not be increased if they are not ingested in large amounts.

Table 26.5 Concentrations of purine and pyrimidine nucleosides and bases in regular and purine-free happo-shu (μmol/l)

	Regular happo-shu	Purine-free happo-shu
Adenosine	30.9 ± 1.0	0.3 ± 0.1
Deoxyadenosine	5.5 ± 0.5	Nd
Guanosine	162.6 ± 4.1	12.1 ± 1.8
Deoxyguanosine	Nd	Nd
Inosine	9.6 ± 1.5	Nd
Deoxyinosine	Nd	Nd
Xanthine	32.5 ± 1.1	0.8 ± 0.1
Hypoxanthine	1.4 ± 0.1	Nd
Adenine	4.4 ± 0.1	Nd
Guanine	2.5 ± 0.2	Nd
Uric acid	Nd	Nd
Uridine	113.2 ± 5.7	20.8 ± 1.3
Deoxyuridine	3.8 ± 0.2	Nd
Thymidine	42.8 ± 1.7	4.6 ± 0.1
Cytidine	80.4 ± 4.3	7.6 ± 0.3
Deoxycytidine	Nd	Nd
Uracil	17.0 ± 0.9	1.2 ± 0.1
Thymine	Nd	Nd
Cytosine	Nd	Nd

Note: Nd denotes not detected. Values are shown as the mean ± SE. Happo-shu is a low malt liquor, which has a taste that is similar to beer and it contains lower amounts of purine.

Effects of Purines on the Serum Concentration and Urinary Excretion of Uric Acid

Since beer contains many kinds of purines, it is important to investigate the hyperuricemic effects of each. Previous studies (Griebsch and Zollner, 1974; Clifford *et al.*, 1976) have demonstrated that intake of nucleic acid increased the serum concentration and urinary excretion of uric acid. Further, those studies also showed relationships among nucleic acid (RNA) and serum and urinary uric acid levels (Table 26.6) (Clifford *et al.*, 1976). According to those findings, nucleic acid intake was positively correlated to serum concentration and urinary excretion of uric acid, and the increase in the serum concentration of urate following the same amounts of RNA intake was greater in patients with hyperuricemia than in normal control subjects, while the increase in urinary excretion of uric acid was not different between the two groups. In addition, it was reported that the intake of 2 g of RNA per day increased the serum concentration of uric acid by 1.13–1.80 mg/100 ml and the urinary excretion of uric acid by 226–328 mg in 24 h in normal subjects. In patients with gout or hyperuricemia who ingested 2 g of RNA per day, the serum concentration of urate was 1.5-fold greater than that in normal subjects. Although the mechanism by which RNA increased the serum concentration of uric acid to greater levels in the patients was not elucidated, it may have been ascribable to various unknown deficiencies of purine metabolism in individuals with gout. In addition to nucleic acid, the effects of adenine, guanine,

hypoxanthine, xanthine, adenosine monophosphate (AMP), guanosine monophosphate (GMP), and inosine monophosphate (IMP) on the serum concentration and urinary excretion of uric acid were investigated in normal subjects, patients with hyperuricemia, and patients with gout (Tables 26.7 and 26.8) (Clifford *et al.*, 1976). Each of those purines (0.1 mmol/kg body weight), except guanine, increased the serum concentration of urate, while each, except for guanine and xanthine, also increased the urinary excretion of uric acid. These findings indicate that many types of purines have hyperuricemic effects. In that study, hypoxanthine, GMP, AMP, and IMP had greater hyperuricemic effects than xanthine and guanine in the control subjects. In the hyper-uricemic patients, hypoxanthine, GMP, AMP, IMP, and adenine had greater hyperuricemic effects than guanine, while AMP, hypoxanthine, GMP, IMP, and adenine had greater hyperuricemic effects than xanthine and guanine in the patients with gout. In addition, hypoxanthine, AMP, and IMP had greater hyperuricemic effect in the patients with gout than in those with hyperuricemia and the control subjects. Each of the examined purines, except for xanthine, guanine, and adenine, increased the urinary uric acid/creatinine ratio in all of the groups. On the other hand, adenine increased the urinary uric acid/creatinine ratio in the control subjects and patients with hyperuricemia, but not in the patients with gout, while neither xanthine nor guanine had effects on the urinary uric acid/creatinine ratio in any of the groups. The differences in effects of the hypoxanthine, AMP, IMP, xanthine, and guanine on the serum concentration and urinary excretion of uric acid may be ascribable to differences in absorption, utilization, and degradation of each purine, as well as differences among the three groups. Nevertheless, these findings suggest that most purines in beer contribute to hyperuricemia in normal subjects and gouty attack in patients. On the other hand, the influence of guanosine toward the increase in the serum concentration of urate in humans has not been studied, even though it is the most abundant purine in beer. However, since guanosine is more readily absorbed than other nucleosides, nucleotides, or bases and rapidly converted to uric acid via guanine and xanthine in animals (Potter *et al.*, 1980), it is suggested that its ingestion may increase the serum concentration of uric acid.

Effects of Purines in Beer and Happo-shu, on Plasma Concentration of Urate

The ingestion of beer is known to increase the plasma concentration of urate. In a previous study (Gibson *et al.*, 1984), 41% of the subjects with gout consumed more than 60 g of ethanol daily and the intake of purine nitrogen, half of which was derived from beer, was higher in those with gout who consumed more than 60 g of ethanol daily. Those results suggested that purines in beer have a clinical effect on serum urate and augment the hyperuricemic effect following its

Table 26.6 Regression equations describing the relationship among dietary RNA intake and serum and urinary uric acid levels in human adults

| Type of subjects | Regression equation of diet RNA g/day (X) on | |
	Serum urate mg/100ml (Y)	Urinary uric acid mg/day (Y)
Normal	Y = 4.84 + (0.65)(g RNA)	Y = 367.8 + (147.2)(g RNA)
Normal	Y = 5.05 + (0.56)(g RNA)	Y = 645.0 + (163.6)(g RNA)
Normal	Y = 3.25 + (0.9)(g RNA)	Y = 377.0 + (113)(g RNA)
Hyperuricemic	Y = 4.4 + (1.46)(g RNA)	Y = 286.0 + (120)(g RNA)

Note: Dietary RNA intake increases serum and urinary uric acid levels.

Table 26.7 Effects of ingestion of oral purines (0.1 mmol/kg body weight) on serum urate concentrations in normal, hyperuricemic, and gouty subjects

| | Subjects | | |
	Normal	Hyperuricemic	Gouty
Fasting serum urate (mg/dl)	63 ± 0.5	8.5 ± 0.2	8.3 ± 0.7
Changes in serum			
Urate due to			
Adenine	+1.8 ± 0.3	1.6 ± 0.1	2.0 ± 0.2
Guanine	−0.2 ± 0.1	+0.1 ± 0.2	+0.2 ± 0.3
Hypoxanthine	+2.4 ± 0.2	+2.8 ± 0.2	+4.1 ± 0.4
Xanthine	+0.7 ± 0.1	–	+0.7 ± 0.1
AMP	+2.2 ± 0.3	+1.9 ± 0.1	+4.2 ± 0.4
GMP	+2.3 ± 0.6	+2.2 ± 0.2	+3.3 ± 0.2
IMP	+1.5 ± 0.1	+1.7 ± 0.2	+3.2 ± 0.3

Note: Values are shown as mean + SE. – denotes "not determined." Changes in serum uric acid were determined by subtracting the fasting value from the highest subsequent value after purine intake and are expressed as mg/100ml. All purines except guanine significantly elevated serum urate levels above fasting values ($p < 0.05$).

Table 26.8 Effects of ingestion of oral purines (0.1 mmol/kg body weight) on urine uric acid/creatinine ratio

| | Subjects | | |
	Normal[a]	Hyperuricemic[b]	Gouty[a]
Before test purines	0.39 ± 0.03	0.40 ± 0.04	0.34 ± 0.04
After administering			
Adenine	0.46 ± 0.02[c]	0.53 ± 0.02[c]	0.40 ± 0.02

Note: Values are shown as mean ± SE.

[a] Based on complete 24-h urine collections.
[b] Based on spot urine samples.
[c] Greater than the ratio before loading ($p < 0.05$). All purines except guanine and xanthine increased urine uric acid/creatinine ratio.

ingestion in gout patients. In our recent study (Yamamoto *et al.*, 2002), we found that regular beer (10 ml/kg body weight) increased the plasma concentration of urate by 30 μmol/l, while freeze-dried beer (0.34 g/kg body weight) also increased that by 20 μmol/l. Since 10 ml of regular beer contains 0.34 g

of content when freeze-dried, the amount of purines in freeze-dried beer are the same as those in regular beer. These results indicate that the contents of beer contribute to an increase in urate in blood (Figure 51.7). Accordingly, beer may cause a greater increase in the plasma concentration of urate than
Figure 26.4 Effects of regular and purine-free happo-shu on plasma concentration of urate. *denotes p < 0.05, as compared with the reference value before ingestion. Happo-shu is a low malt liquor, which has a taste that is similar to beer and it contains lower amounts of purine. Purine-free happo-shu contains the same amounts of malt and very low levels of purines.

other alcoholic beverages. This result strongly suggested that the purines in beer are the cause of an increase in plasma concentration of urate. In another study (Yamamoto *et al.*, 2004), ingestion of purine-free happo-shu (10 ml/kg body weight) did not increase the plasma concentration of urate, whereas regular happo-shu (10 ml/kg body weight) did, which confirmed our earlier speculation that purines in beer cause an increase in the plasma concentration of urate (Figure 26.4).

Effects of Beer and Other Alcoholic Beverages on Serum Urate Levels

Recently, a prospective study related to nutrition found that subjects who drank 40 ml of distilled liquor (whisky and brandy) had their serum concentration of urate increased by 0.29 mg/dl (Choi *et al.*, 2004). Since distilled liquor rarely contains purines, this finding indicates that the ethanol content increased the level of serum urate. However, the increase in urate caused by distilled liquor is less than that caused by beer ingestion, even when the ingested ethanol volume is not different. Thus, it is considered important for individuals at risk to refrain from drinking large amounts of beer to prevent the development of gout. That prospective study also found that ingestion of 4 oz. of wine per day decreased the serum concentration of uric acid by 0.04 mg/dl, while another study showed that drinking not more than 236 ml (less than 22.0 g ethanol) of wine per day did not increase the risk of gout. Therefore, it was speculated that the components present in wine which were not related to alcohol, such as polyphenol, may prevent ethanol from increasing serum urate, as well as cause a decrease in uric acid production and/or increase urinary uric acid excretion. On the other hand, another report (Abu-Amsha *et al.*, 2001) indicated that ingestion of red wine

(5 ml/kg body weight) rapidly increased the serum concentration of urate, while four glasses of red wine each day for 12 weeks increased the serum concentration of urate by 9%, as compared with an 8% increase caused by ingestion of regular spirits containing the same volume of ethanol. Together, these findings suggest that the effect of red wine on serum urate is not significantly different from that of regular spirits.

Summary points

- Beer contains greater amounts of purines than other alcoholic beverages.
- Beer purines consist of purine nucleosides and purine bases, with guanosine being the most abundant.
- Purines in beer augment the hyperuricemic effect following its ingestion.
- It is considered important for individuals at risk to refrain from drinking large amounts of beer to prevent the development of gout.

Beer Carbohydrates

Isabel M.P.L.V.O. Ferreira REQUIMTE, Serviço de Bromatologia, Faculdade de Farmácia, Universidade do Porto, Porto, Portugal

Abstract

Cereals provide the carbohydrates for beer production. Barley that has been malted is the most usual cereal used. However, other cereals, including wheat, rice, maize, oats, sorghum and sugar syrups, may also be used. During malting all enzymes necessary for total degradation of starch are synthesized and/or activated, together with enzymes that contribute to the hydrolysis of β-glucans and in less extension arabinoxylans. Important transformations occur during mashing, namely, starch is converted into maltose and dextrins. Carbohydrates form 90% of the wort extract, 64–77% of which is usually fermentable by yeast to produce ethanol and carbon dioxide.

Carbohydrate levels in beer range from 3 to 61 g/l. Specific data concerning the beer carbohydrate contents reported by different authors are presented. Different contents of total and fermentable sugars are reported according to beer type. Lagers are in general more fully fermented than ales. Total carbohydrate content of lager and ale beers range between 10–30 and 15–60 g/l, respectively. Lagers also contain less residual carbohydrates than ales, 1–7 g/l and 5–10 g/l, respectively. New brewing styles include fully attenuated low carbohydrate beers that contain less carbohydrate amounts (4–9 g/l) because dextrins have been more or less completely digested and fermented. In general, non-alcohol beers produced by short fermentation present higher level of fermentable sugars (about 55 g/l).

List of Abbreviations

α-L-Ara	α-L-Arabinofuranosyl units
β-D-Glc	β-D-Glucopyranosyl units
β-D-Xyl	β-D-Xylopyranosil units
HPLC	High performance liquid chromatography
TCA	Tricarboxylic acid cycle
t_R	Retention time

Introduction

Beer is a fermented beverage made from malted grains (usually barley), hops, yeast and water. It has a complex composition, containing a vast number of compounds widely ranging in nature and in concentration level. In addition to water and ethanol, major beer components are carbohydrates comprising fermentable sugars as well as glucose oligosaccharides and arabinoxylans (Brandolini *et al.*, 1995; De Keukeleire, 2000; Duarte *et al.*, 2003).

The source of carbohydrates in beer is starch-rich cereals, mainly malted barley, but other cereals including wheat, rice, maize, oats, sorghum and sugar syrups may also be used. The brewing process converts the malt starch to soluble sugars and then uses yeast to ferment these to alcohol. Fermentation takes place at 7–13°C for lagers (using bottom-fermenting yeast, *Saccharomyces carsbergensis*) or 16–18°C for ales (using top-fermenting yeast *Saccharomyces cerevisiae*) (Fix, 1989; Bamforth, 1998; Hughes and Baxter, 2001; Pelter and MaQuade, 2005).

Beers of the lager type include different styles, namely, Bock, Dortmunder, Munchner, Pilsener and Vienna (Marzen). All too often the term lager is used synonymously with Pilsener, the classic style originated in mid-nineteenth century, in the Pilsen city brewhouse. Beers of ale type include a variety of styles such as, Porter, Stout, Salsons, Alt, Light ale, Pale ale, Bitters and Barley wines (Caballero *et al.*, 2003). New brewing styles are introduced, such as those involved in the production of light, dry and low alcohol beers. Here, aspects related to beer carbohydrates, origin and concentration in lager and ale beers will be described. For clarity, brewing specific vocabulary is introduced in Table 27.1.

Origin of Beer Carbohydrates

Beer preparation involves incubating and extracting malt and sometimes other starchy materials and/or enzymes with warm water. After filtration the solution is boiled with hops or hop preparation and the cooled liquid is fermented by added yeast. Cereals provide the carbohydrates and amino acids for the yeast to grow, generate ethanol and carbon dioxide, and produce key flavors in the final beer. Thus, three polysaccharides, starch, pentosan (arabinoxylan) and β-glucan together with saccharose, are the primary source of carbohydrates in beer.

Table 27.1   Definitions of common malting and brewing terms

Term	Definition
Adjunct	Any source of fermentable extract other than malted barley used in the mash tun, for example, cereal grits or sugar syrup
Aleurone	Layer of living cells in the mature barley kernels, which surround the starchy endosperm
Boiling	Operation that follow lautering. Wort sterilization. Hop is added. Yeast is added to the cooled product to begin fermentation
Fermentation	Metabolization of wort constituents into ethanol and other fermentation products to produce beer
Germination	The sprouting of the barley seed to form new roots and shoots
Lautering	Filtration of mash assisted by insoluble husk material that creates a filter bed
Malt milling	Process carried out in the brewery to reduce the size of the malt particles
Malting	Partial germination to convert barley into malt, followed by quickly drying before the plant develops. Technologically, it is divided into three stages, steeping, germination and kilning
Mashing	Process in which milled malt is mixed with water to form the "mash," which is heated under controlled conditions between 40 and 70 K°C (1–2 h). Important transformations are carried out, namely, proteins are hydrolyzed and amino acids are released, starch is converted into maltose and dextrins
Primings	Sugar added after the primary fermentation to provide additional fermentable extract for secondary fermentation
Sorghum	A small-grained cereal grown in Africa and southern United States
Wort	The liquid obtained after lautering. Sweet wort contains high level of fermentable sugars. Bitter wort or hopped wort is obtained after addition of hop
Yeast	A single-celled microorganism which, in the absence of oxygen, can use glucose as a respiratory substrate and convert it to ethanol.

Table 27.2   Summary of the enzymes necessary for degradation of malt carbohydrates synthesized and/or activated during malting

Type	Enzyme	Substract	Function
Amylases	α-Amylase	Starch	Breakdown of α(1,4) glucosyllinkages
	β-Amylase	Starch and malto-oligosaccharides	Cleave the penultimate α(1,4) glucosyllinkages from non-reducing end
	Limit dextrinase	Amylopectin and branched dextrins	Cleave α(1,6) glucosyllinkages
	α-Glucosidases	Oligosaccharides and maltose	An exoenzyme that releases glucose
Carbohydrases	Endo-β-glucanases	β-Glucan	Releases β-D-glucopyrano-syl oligosaccharides
	Exo-β-glucanases	Oligosaccharides released by endo-β-glucanases	Produce glucose from β-glucan oligosshacarides
	Endo-β-xylanases	Arabinoxylans	Cleave β-1,4 xylan linkages
	β-Xylopyranosidases	Arabinoxylans	Breakdown xylan polymers
	α-L-Arabinofuranosidase	Arabinoxylans	Release α-L-arabinofura-nosyl units from pentosans
Carboxipeptidases	β-Glucan solubilase	β-Glucan	Degrades ester linkages between proteins and β-glucan, releases β-glucan

Malt

Barley that has been malted is the most usual cereal used in beer production. It has an appropriate level of protein (8–12% dry weight), low level of lipids, develops high levels of amylolytic enzymes during germination and it has a husk (the outer case of the barley grain) that creates a filter bed and assists in the separation of insoluble material from the extract.

Barley grain germination is initiated by the uptake of water. The grain is hydrated or steeped by immersion in water. Germination occurs in a cool, moist atmosphere with occasional turning, and involves partial development of the embrion, activating several endogenous enzymatic systems. Hydrolytic enzymes are secreted from the aleurone and the scutellar epithelium and migrate into the starchy endosperm. Thus, during malting all enzymes necessary for total degradation of starch are synthesized and/or activated (Table 27.2). Some enzymes also contribute to the hydrolysis of β-glucans and hordeins (water insoluble proteins), which would otherwise restrict access of enzymes to the starch granules.

…4) − β-D-Glc (1,3) − β-D-Glc (1,4) − β-D-Glc (1,4) − β-D-Glc (1,4) − β-D-Glc (1,4) − β-D-Glc (1,3) −

↑   ↑

Germination is allowed to proceed over around 5 days to obtain green malt, which is stopped during the kilning phase by forced flow of hot air. Hydrolases produced during malting are partially inactivated during this process and the malt is suitable for the milling process, which precedes brewing.

During mashing the crushed malt, named grist, is mixed with hot water in the mash tun and the whole mash is held at around 65°C for about 1 h. This temperature is chosen as it is the temperature at which malt (i.e. barley) starch will gelatinize – making it more susceptible to enzyme attack.

Adjuncts

Other cereals, both malted and unmalted, including wheat, rice, maize, oats and sorghum, are used as adjuncts for certain beers. Adjuncts come in a variety of forms, for example grits that are fragments of starchy endosperm from cereal grains. If they are used directly in the brewery they must be cooked or flaked (the grain is heated at 85°C and passed through feed rolls to flaking rolls).

To use in the brewery, all grits must be cooked to disrupt them and gelatinize the starch. Because the starch is already gelatinized the flakes do not need cooking and can be added directly to the mash. Like barley starch, wheat starch also gelatizes at 65°C. Rice and maize starches gelatinize at higher temperatures, so if either of these cereals is used as an adjunct, it must be pre-cooked in a separate vessel (known as a cereal cooker) before being added to the mash (Hughes and Baxter, 2001; Briggs *et al.*, 2004; Urias-Lugo and Saldivar, 2005).

Syrups of sucrose and its hydrolysis product, inverted sugar, are used by some brewers during beer production, produced either from sugar cane or from sugar beet, the range of products is large.

Adjuncts are used to reduce the quantity of malt used, since malt is more expensive than these products, and so the use of adjuncts in relatively large amounts (20–30%) significantly reduces the cost of brewing process. Good quality malt presents amylolytic activity surplus to requirements. Thus, an adjunct's starch is hydrolyzed during mashing by enzymes from the malt, not only to provide a less expensive source of sugars, but also to change the character of the wort. For example, small quantities of wheat are often used in ales to enhance the beer foam, while unmalted rice and maize grits may be used to improve the flavor stability of light-flavored lagers. In a few countries the use of adjuncts is forbidden. In Germany, the *Reinheitsgebot* stipulates that

beer may be made only with water, malt, hops and yeast (Hughes and Baxter, 2001; Caballero *et al.*, 2003; Urias-Lugo and Saldivar, 2005).

Degradation of cell-wall polymers

The major component of the endosperm of barley cell walls are β-glucans, which are linear polymers composed of β-D-glucopyranosyl residues linked with a mixture of β-1,3 (about 30%) and β-1,4 (about 70%) linkages (Figure 27.1). About 90% of the 4-linked residues occur in groups of two or three residues, separated by (1,3) linkages. Breakdown of the endosperm cell walls initiates from the scutellum and advances more or less uniformly through the grain. The extent to which β-glucans are degraded during malting depends on the moisture content of the steeped grain, on the amount of cell-wall-degrading enzymes, and on the structure of the cell walls. Endo-β-glucanases are enzymes that hydrolyze high molecular weight β-glucans and produce tri and tetrasaccharides. Exo-β-glucanases produce glucose from β-glucan or oligosacchacarides. β-Glucan solubilase are carboxipeptidases that degrade ester linkages between proteins and β-glucan (see Table 27.2) (Eliasson, 2006).

Incomplete breakdown of the β-glucan linkage can cause several problems during brewing, namely, decrease rates of wort separation and beer filtration, formation of hazes and precipitates in the final beer.

Arabinoxylans consist of a linear xylan backbone of β-1,4 linked to D-xylopyranosil residues to which α-L-arabinofuranosyl units are attached mostly as single substitutes. These pentosans are side-chain branched heteroglycans built from pentose sugars, arabinose and xylose (Figure 27.2). Several enzymes are involved in the hydrolytic breakdown of barley arabinoxylans, namely, endo-β-xylanases, β-xylopyranosidases, α-L-arabinofuranosidase (see Table 27.2). However, whereas β-glucans are degraded extensively during malting, pentosans are not and remain in malt (Beldman *et al.*, 1988).

Starch Degradation

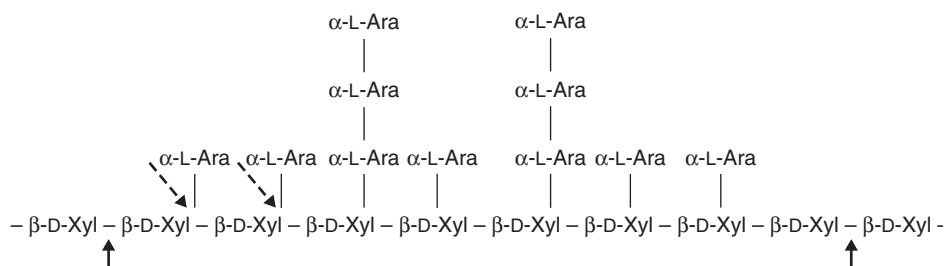
Cereal starch consists of approximately 75% amylopectin and 25% amylase. Although built up from the same glucopyranose units, they differ in the type of glycosidic linkages and require different enzymes for their degradation. Amylopectin is a very large, branched molecule (the molecular weight has been estimated at several million,


Figure 27.2   Structure of barley arabinoxylans. α-L-Ara, α-L-arabinofuranosyl units; β-D-Xyl, β-D-xylopyranosil units. ↑ Examples of sites of hydrolysis by endo-β-xilanases. ↘ Examples of sites of hydrolysis by α-L-arabinofuranosidase.
Figure 27.3   Structure of amylose and amylopectine. (a) Amylose and (b) amylopectine. α-D-Glc: α-D-glucopyranosyl units; (1,4), α-1,4 linkages; (1,6), α-1,6 linkages. ↑ Examples of sites of hydrolysis by α-amylases. ↑ Examples of sites of hydrolysis by β-amylases. ◄⋯ Examples of sites of hydrolysis by limit dextrinase.

10^6–10^8 Da) made up of glucose units linked by α-1,4 bonds (which give linear chains) and α-1,6 bonds (which give branch points). On average, each branch is made up of around 25 glucose units. Amylose, on the other hand, is a linear molecule made up of up to 2,000–5,000 glucose units linked by α-1,4 bonds only (Figure 27.3(a) and (b)).

During malting starch is only partially degraded (15–18%). It is during mashing that the malt amylolytic enzymes break down the starch into fermentable sugars. Both α- and β-amylase can hydrolyze α-1,4 bonds. α-Amylase hydrolyze intact starch granule, degrade amylose to oligosaccharides, maltose and glucose. It also attacks lengths of α-1,4 chains between branch points of amylopectin, releasing smaller, branched dextrins with long straight side-chains. These provide more substances for β-amylase action. β-Amylase attacks from the outer reducing ends of the amylopectin and amylase molecules, releasing free maltose (two glucose units), but stopping when it reaches an α-1,6 bond. α- and β-Amylases acting together reduce amylose to maltose, maltotriose and glucose, however, amylopectin gives rise to small branched dextrins which cannot be further broken down during mashing.

Limit dextrinase hydrolyzes α-1,6 linkages in amylopectin or in branched dextrins. It requires at least one α-1,4-glicosidic linkage on either side of the α-1,6 linkage. However, this enzyme is inhibited by a heat-stable protein present in barley. α-Glucosidase converts maltose and other small dextrins to glucose (Hughes and Baxter, 2001; Caballero et al., 2003; Pelter and MaQuade, 2005).

Wort Carbohydrates

Carbohydrates form 90% of the wort extract, 64–77% of which is usually fermentable by yeast. Its composition will depend on the make-up grist and the mashing conditions. However, the most important sugars and dextrins in wort are made of glucose, which also occurs free and d-glicopyranosyl units joined by α(1,4) linkages or α(1,6) linkages for dextrins. Maltose and maltotriose are the major sugars in brewer's wort, but other carbohydrates are present, some of them detected in tiny amounts (Table 27.3). Maltose usually accounts for 50–60% of the fermentable sugar in wort (Briggs et al., 2004). Carbohydrate

Table 27.3 Major and minor wort saccharides

Major wort saccharides	Content (g/l)	Minor wort saccharides	Content (mg/l)
Fructose + glucose	9–12	Xilose	15
Maltose	56–59	Arabinose	14
Saccharose	4–5	Ribose	2
Maltotriose	14–17	Isomaltose	Traces

	Maltulose	Melizitose	

Source: Adapted from Gey *et al*. (1996), Vinogradov and Bock (1998), Floridi *et al*. (2001), Duarte *et al*. (2003), Briggs *et al*. (2004), Bamforth (2005), Ramirez *et al*. (2005), Bruggink *et al*. (2005).

fermentability of the wort is determined by the evaluation of "fermentable sugars" and "dextrins" and the results are presented as fermentable carbohydrates as a percentage of the total carbohydrates.

The carbohydrates undergo some changes during wort boiling which include browning reactions that take place between reducing sugars and the primary amines. These reactions consist of condensation reactions between simple sugars, such as glucose with primary amines to give aldosylamines. These unstable compounds can undergo Amadori rearrangement to form ketosamines, which condense with another aldose molecule to form diketosamines that can undergo further condensation reactions with additional amines (Hughes and Baxter, 2001). All these reactions are complex and not completely understood, however, they occur in very low extension. Whole hops and pellets only contribute to 0.15% of the total carbohydrates in hopped wort, thus, the carbohydrate composition of hopped wort is very similar to that of sweet wort.

Beer Carbohydrates

Brewing yeast strains (ale and lager strains) are capable of utilizing saccharose, glucose, fructose, maltose and maltotriose in this order, whereas the higher oligomers remain in solution. Consequently, the total carbohydrates in beer include residual fermentable sugars and a variable amount of higher dextrins, most of which contain two or more branches (Uchida *et al.*, 1991; Shanta-Kumara *et al.*, 1995; Clement *et al.*, 1992; Castellari *et al.*, 2001). Nevertheless, trace amounts of other carbohydrates have been detected in beer including the monosaccharides; D-ribose, L-arabinose, D-xilose, D-mannose and D-galactose, the positional isomers of α and β-glucobioses and the trisaccharides panose and isopanose and β-linked materials are derived from the β-glucan and arabinoxylan present in barley (Vinogradov and Bock, 1998; Duarte *et al.*, 2003; Briggs *et al.*, 2004; Bamforth, 2005). Table 27.4 summarizes monosaccharides, disaccharides, trisaccharides and oligosaccharides identified in several types of beers. The total carbohydrates remaining

in beer can be estimated spectrophotometrically with anthrone in 85% sulfuric acid (Analytica-EBC, 1998) for a range of beers values between 2.8–61 g/l as glucose were found. However, in general, carbohydrate levels range from 20 to 30 g/l. Table 27.5 presents more specific data concerning the beer carbohydrate contents reported by different authors.

Beer fermentable sugars

Alcoholic fermentation of wort sugars to ethanol and carbon dioxide is conducted by yeasts predominantly under anaerobic conditions, however, oxygen is required by brewing yeasts in the initial stages of wort fermentation for the biosynthesis of membrane sterols and fatty acids. Thus, yeast, when under anaerobic conditions (which means that air exposure is to be kept to a minimum), converts glucose to pyruvic acid via the glycolysis pathways, then go one step farther, converting pyruvic acid into ethanol,

a C-2 compound (see Figure 27.4). Once most of the available sugars are fermented, metabolism slows down. The freshly produced or "green" beer is held for a period of maturation or secondary fermentation. During this process the flavor of the mature beer is improved. Sometimes "priming" sugar or a small amount of wort is added to boost yeast metabolism and the "maturation," "conditioning" or "lagering" process (Briggs *et al.*, 2004).

Fermentable sugars directly contribute to the sweetness of beer. These can arise either from the malt if they have survived fermentation/or else they have been added as "primings" to stimulate secondary fermentation to bring the beer up to specified carbon dioxide levels. The carbohydrates with more than four glycosyl units possess little sweetness. However, they can be beneficial to the perception of beer in that they contribute to body or mouthfeel (Corradini *et al.*, 1997; Ferreira *et al.*, 2005).

Different contents of fermentable sugars are reported according to beer type (Tables 27.6 and 27.7). Lagers are in general more fully fermented (attenuated) than ales and contain less residual carbohydrates. During fermentation the yeast absorbs and ferments first all the glucose and then maltose. Some lager yeasts can also utilize maltotriose (Thomas *et al.*, 2000).

Fructose, glucose, maltose and maltotriose contents of beers from 10 different countries, including Belgium, Brazil, Czech Republic, Denmark, Germany, Holland, Ireland, Portugal, Spain and UK, were evaluated by high performance liquid chromatography (HPLC)/light scattering (Ferreira *et al.*, 2005; Nogueira *et al.*, 2005). The results obtained in this work (Table 27.8) are in good agreement with others from literature that were reported previously.

Figure 27.4 Conversion of glucose to ethanol in yeast. *Glycolysis* – the sequence of reactions that converts glucose into pyruvate with the concomitant production of a relatively small amount of adenosine triphosphate (ATP). *Anerobic* (in the absence of oxygen) – pathway for organisms that can ferment sugars and produce the alcohol found in beer. *Aerobic* (in the presence of oxygen) – pathway for pyruvate degradation by the tricarboxylic acid cycle (TCA) or cycle Krebs to produce larger amounts of ATP.

Dextrins, pentosans and β-glucan

Dextrins, derived from partial degradation of starch, are not fermentable, thus, when branched dextrins are present in brewer's wort, they will be found in the final beer (Jodelet *et al.*, 1998). Beer dextrins impart body and contribute to calorific value because dextrins are readily hydrolyzed by pancreatic amylase. The branched dextrins are broken down slowly by the oligo-1,6-glucosidase which is found in the mucosal cells lining the intestine.

Pentosan and β-glucan depolymerized to some degree remain partially in beer, where they can cause undesired precipitation and filtration problems.

Carbohydrate Contents in New Brewing Styles

Brewers intent on marketing new brewing styles to answer specific demands of consumers, namely, low carbohydrates beers and low alcohol beers. The enormous incidence of excess body weight in several countries stimulates the interest in these new products, together with the presence of

Figure 27.5 Typical chromatogram for separation of five carbohydrates in an alcohol free beer sample. Fructose (t_R = 7.245 min), glucose (t_R = 7.942 min), maltose (t_R = 12.900 min), maltotriose (t_R = 19.722 min), maltotetraose (t_R = 27.268 min). Analyses performed by HPLC with an amine-bonded silica column, acetonitrile–water as eluent, and a light scattering detector.

Table 27.9 Fructose, glucose, maltose, maltotriose and maltotetraose composition of non-alcohol beers.

Sugar	According to Nogueira et al. (2005)	Evaluated in seven brands using the methodology validated by Nogueira et al. (2005)
Fructose	2.57	2.46 ± 0.13
Glucose	4.56	5.60 ± 1.53
Maltose	38.5	44.13 ± 12.14
Maltotriose	8.14	10.89 ± 2.89
Maltotetraose	1.39	2.39 ± 1.03

Source: Values collected from literature, together with results from seven brands from Brazil, Portugal and Spain.

healthy carbohydrates, such as, soluble fiber and prebiotic molecules that it contains and which are derived from the β-glucan and arabinoxylans.

Low carbohydrate beers

Fully attenuated low carbohydrate beers with carbohydrate contents of 4–9 g/l were originally brewed for diabetic patiens, but are now generally available (Briggs *et al.*, 2004; Bamforth, 2005). The low carbohydrate beers contain less carbohydrate because dextrins have been more or less completely digested and fermented by a combination of techniques. For example, special yeasts, known as "highly attenuating yeasts," may be used enabling digestion of a wide range of dextrins. Another possibility is the use of lightly kilned malts, which contain higher levels of debranching enzyme (Hughes and Baxter, 2001).

Non-alcohol beers

Non-alcohol beers can be produced by restricting the ability of yeasts to ferment wort. Figure 27.5 shows the typical chromatographic profile for fructose, glucose, maltose, maltotriose and maltotetraose of a free alcohol beer sample obtained by this process. These samples suffered short fermentation, thus, great part of fructose, maltose, maltotriose and maltotetraose remained in beer (Table 27.9).

Fructose, glucose, maltose and maltotriose contents of beers from three different countries, including Brazil, Portugal and Spain, were evaluated by HPLC/light scattering (Nogueira *et al.*, 2005; Ferreira *et al.*, 2005). The results obtained in this work are also presented in Table 27.8. Low alcohol beers were poorly fermented and contained higher amounts of fermentable carbohydrate. However, another process to obtain non-alcohol beer is removing the alcohol from a full-strength brew by techniques such as vacuum distillation or reverse osmosis. These techniques are more expensive.

Summary Points

- Major beer components are water, ethanol and carbohydrates comprising fermentable sugars (i.e. fructose, glucose, maltose and maltotriose) as well as glucose oligosaccharides and arabinoxylans.
- Barley that has been malted is the most usual cereal used in brewing. However, other cereals, including wheat, rice, maize, oats, sorghum and sugar syrups may also be used.
- During malting all enzymes necessary for total degradation of starch are synthesized and/or activated, together with enzymes that contribute to the hydrolysis of β-glucans and in less extension arabinoxylans.
- Important transformations occur during mashing, namely, starch is converted into maltose and dextrins. Carbohydrates form 90% of the wort extract, 64–77% of

which is usually fermentable by yeast to produce ethanol and carbon dioxide.

- Total carbohydrates in beer include residual fermentable sugars and a variable amount of higher dextrins, most of which contain two or more branches.
- Different contents of fermentable sugars are reported according to beer type. Lagers are in general more fully fermented than ales and contain less residual carbohydrates.
- Brewers intent on marketing new brewing styles to answer specific demands of consumers, namely, low carbohydrates beers and low alcohol beers.

Dietary Fiber in Beer: Content, Composition, Colonic Fermentability, and Contribution to the Diet

I. Goñi Unidad Asociada Nutrición y Salud Gastrointestinal (UCM-CSIC),
Dpt. Nutrición I, Facultad de Farmacia, Ciudad Universitaria, Madrid, Spain

Ciudad Universitaria, Madrid, Spain

Abstract

Most reports on carbohydrates in beer deal with sensory and technological properties, but a nutritional approach indicates that dietary fiber (DF) is a quantitatively important beer constituent, composed mainly of indigestible carbohydrates. DF is usually determined exclusively in plant foods probably because the official methods of analysis are not applicable to beverages. Consequently, international food composition tables report zero DF content in beer and other beverages. A specific method to determine DF in beer is reported. DF content in beer is around 2 g/l, the largest constituents being arabinoxylans and β-glucans. Beer DF is highly fermented by colonic bacteria, similarly to healthy soluble DF-like psyllium and β-glucans.

The consumption of beer (150 ml person/day) in Spain accounts for 1.6% and 5% of the total DF and soluble DF intake of the diet, respectively.

DF occurs in beer as a complex with appreciable amounts of indigestible carbohydrates (88–91%), polyphenolic compounds (4.2–2.9%) and indigestible protein (7.7–5.9%).

Further research on the physicochemical structure and biological properties of beer DF is needed to elucidate its nutritional significance.

List of Abbreviations

DF	Dietary Fiber
SDF	Soluble Dietary Fiber
SCFAs	Short Chain Fatty Acids
IDF	Insoluble Dietary Fiber
PP	Polyphenols
WHO/FAO	World Health Organization/Food and Agriculture Organization

Introduction

Nowadays, the importance of dietary fiber (DF) in nutrition and health is well defined. Numerous clinical and epidemiological studies have addressed the role of DF in intestinal health, prevention of cardiovascular disease, colon cancer, obesity and diabetes.

The knowledge of the consumption of DF in the diet is important for a proper nutritional evaluation. DF is determined exclusively in plant foods, and it is generally assumed that drinks, including beer, do not contain DF. Consequently, the presence of DF in common dietary beverages is ignored in nutritional studies and in reports of DF intakes in diets. However, drinks are quantitatively important items in any diet and they may contain measurable amounts of soluble dietary fiber (SDF). Here we focus on DF in beer, the most widely consumed drink in many western countries.

This chapter deals with the content, composition and colonic fermentability of DF in beer, and the analytical methodology used to determine this beer constituent. The contribution of beer to DF intake in the diet is also addressed.

First, the concept and main properties of DF are briefly described for readers who are not familiar with this topic. In this respect, there is comprehensive information available on the carbohydrate composition of beer, which is associated with its sensory and technological properties. The second point adopts a nutritional approach, dividing these beer constituents into two groups: indigestible and digestible. Non-digestible polysaccharides are the major constituents of DF.

Official methods for analysis of DF were developed for plant foods and cannot be applied to beverages, and hence the third point of this chapter presents a specific procedure to determine DF in beer. The DF content and composition in different types of beer, which were determined using a specific procedure to determine DF in beer, is presented in the third point.

Fermentation in the large intestine is an essential property of DF. The degree of colonic fermentation of beer DF is described in point four, including the extent of fermentation and the production of short chain fatty acids (SCFAs).

The dietary significance of DF in a specific food or beverage depends on its contribution in the context of a whole

diet. This aspect is addressed in point five, where intake and sources of DF in the Spanish diet, including beverages, are presented.

The traditional concept of DF based on indigestible non-starch polysaccharides and lignin is changing. There is agreement among nutritionists to extend the concept of DF to include other non-digestible plant food constituents. Following this line, the last point of the chapter reports the presence of significant amounts of polyphenolic compounds and protein associated with DF in beer.

Dietary Fiber

Plant foods and beverages contain a wide variety of carbohydrates that supply a large part of the energy in human diet and have different metabolic functions relating to fat synthesis, protein sparing, connective tissue, detoxification, cell recognition and others.

Classification of carbohydrates can be based on chemical composition and/or nutritional properties. From a nutritional point of view, there are two main groups of carbohydrates: digestible ones in the small intestine, or glycemic carbohydrates, and non-digestible ones which are partially fermentable in the large intestine (WHO/FAO, 1999).

Digestible carbohydrates are hydrolyzed by digestive enzymes and metabolized after enzymatic hydrolysis. monosaccharides such as glucose and fructose, low-molecular-weight saccharides like sucrose, lactose and maltose, and polysaccharides with α bonds like starch are the main dietary digestible carbohydrates. Indigestible polysaccharides are neither hydrolyzed nor absorbed in the small intestine and become available in the large intestine as fermentable substrates for the colonic microflora. Cellulose, β-glucans, pentosans, arabinoxylans, galactomannans and other β-polysaccharides are the major constituents of DF. Table 28.1 summarizes the definition and main constituents of DF.

DF is one of the most talked-about food constituents in connection with health promotion and disease prevention.

Table 28.1 Definition and main constituents of DF

	Insoluble dietary fiber: Non-water soluble at 100°C and pH = 6–7	Main constituents: Cellulose, lignin, insoluble hemicelluloses
Dietary fiber: Plant food and drinks constituents resistant to digestion and absorption in the small intestine	Soluble dietary fiber: Water soluble at 100°C and pH = 6–7	β-Glucans, arabinoxylans, gums, pectins, oligosaccharides, soluble hemicelluloses

Note: DF improves gastrointestinal health. DF constituents are fermented in the large intestine providing energy to maintain the intestinal bacteria.

The definition of DF, besides specifying the constituents, describes their physiological and metabolic significance (Cho and Dreher, 2001; McCleary and Prosky, 2001). DF consists of the indigestible parts of plants that are resistant to digestion and absorption in the human small intestine. DF includes non-starch polysaccharides, lignin and other non-digestible carbohydrates. These DF components are neither degraded nor absorbed during their passage through the upper part of the gastrointestinal tract, and they can exert nutritionally important effects by slowing down gastric emptying and affecting nutrient assimilation in the small intestine. When non-digestible compounds pass into the large intestine, they can be degraded by bacterial enzymes and their degradation products can be fermented to produce SCFAs as well as gases and water.

Also, DF includes many components that are categorized by whether or not they are soluble in the human digestive system. Insoluble dietary fiber (IDF) includes cellulose and other polysaccharides along with non-carbohydrate compounds such as lignin and cutin and other cell wall constituents. SDF includes pectins, β-glucans, arabinoxylans, galactomannans and other indigestible polysaccharides and saccharides.

Both SDF and IDF are present in all plant foods, with varying degrees of each depending on a plant's characteristics. Insolubility refers to lack of solubility in water, but it also implies passive water-attracting properties that help to increase bulk soften stools and shorten transit time through the intestinal tract. Solubility indicates a fiber source that will readily dissolve in water and form viscous solutions. Soluble fibers delay gastric emptying, slow glucose absorption, enhance immune functions and lower serum cholesterol levels. These terms proved very useful in the initial understanding of the physiological properties of DF, allowing a simple division into those which principally affected glucose and lipid absorption from the small intestine, SDF, and those which were slowly and incompletely fermented and had more pronounced effects on bowel habit, IDF.

The soluble fraction is mainly contained in fruits, vegetables and legumes and is associated with colonic degradation and high fermentability, while insoluble fiber is thought to affect primarily the function of the large bowel and is predominant in cereals and legumes. Insoluble fiber consists mainly of cell wall components such as cellulose, lignin and hemicellulose.

DF is an essential nutrient in human nutrition. Dietary guidelines from the WHO and many national government health bodies recommend an increase in the daily intake of DF, which is especially low in the current diets of western countries. One important aspect of epidemiological and nutritional studies is estimation of the intake of DF in populations and specific diets.

All solid plant foods contain both IDF and SDF, while only beverages can be expected to contain SDF. Nevertheless, international food composition tables report zero DF content in most drinks, including beer.

The literature contains little information on DF in beer because studies on non-digestible carbohydrates in beer have mainly dealt with organoleptic and technological aspects but not with nutrition and health. A second reason for the absence of values of fiber in beer may be the fact that the official methods for determining DF in foodstuffs are not applicable to beverages.

However, measurable amounts of non-digestible polysaccharides may be solubilized during processes for the making of beer – a drink derived from fiber-rich plant foods – and so we may expect DF to be a common constituent of it.

Carbohydrates and DF in Beer

The composition of beer includes 3.3–4.4 g of carbohydrates per 100 ml, consisting of dextrins as the major constituent along with monosaccharides, oligosaccharides and pentosans. Table 28.2 lists the carbohydrates reported in beer.

Dextrins are saccharide polymers linked primarily by α-(1–4)-D-glucose units and can have different properties and molecular compositions depending on starch and how it is digested. Properties include hygroscopicity, fermentability, viscosity, stability, gelation, solubility and bioavailability. Barley starch contains both linear α-(1 → 4) amylose and branched α-(1 → 6) amylopectin, which are released from starch gelatinized by heating in mashing process. Enzyme hydrolysis with α-amylase efficiently hydrolyzes the α-(1 → 4) linkages but not the α-(1 → 6) linkages, leaving behind a small amount of high-molecular-mass residues. On the other hand, hydrolysis with a α-(1 → 6) specific enzyme (pullulanase) will render a higher proportion of linear α-(1 → 4) oligosaccharides, which are more susceptible to retrogradation and gelling.

The saccharides containing fewer than four glucose units that remain in beer after fermentation include glucose, fructose, maltose, sucrose and maltotriose. Glucose and fructose are the main monosaccharides. The main disaccharides are maltose and sucrose; much of the sucrose emanates from malt itself, while the maltose present is produced in the mash tun (Cortacero-Ramírez et al., 2003).

Table 28.2 Carbohydrates in beer

Digestible carbohydrates	Non-digestible carbohydrates
Dextrins	β-Glucans
Maltotriose	Arabinoxylans
Sucrose, maltose	Cellobiose
Fructose, glucose	Laminaribiose

Minor Carbohydrates: Arabinose, galactose, ribose, xylose, isomaltose, panose, isopanose, kojibiose, nigerose, maltulose, maltotetraose

Note: Major (digestible and non-digestible) and minor carbohydrates reported in beer. Major digestible carbohydrates provide caloric value; non-digestible carbohydrates are the beer DF constituents.

Arabinoxylans and β-glucans are the main non-starch polysaccharides. Arabinoxylans are composed of a complex backbone of D-xylopyranosyl residues linked by β-(1–4) glycosidic bonds and have been reported to constitute 3–11% of the barley kernel. β-Glucans are linear homopolysaccharides. They are the major components of the barley cell walls (Holtekjolen et al., 2006) and are partially degraded by endogenous enzymes during germination of barley, but a part remains in the beer.

Fermentable sugars directly contribute to the sweetness of beer, whereas carbohydrates with more than four glycosyl units contribute to body or mouthfeel. β-Glucans and arabinoxylans are responsible for viscosity (Jian Lu and Yin Li, 2006; Yin Li et al., 2005), rate of filtration or haze formation in beer. β-Glucan and arabinoxylans form viscous solutions and can contribute to extraction problems in the brewing industry (Voragen et al., 1987; Viëtor and Voragen, 1993; Schwarz and Han, 1995). Paul et al.'s (2002) research and Sadosky et al. (2002) reported that the effects of arabinoxylans on viscosity and filterability were at least as important as the effects of β-glucan. Stewart et al. (1998) found that pilot-brewed beer viscosity and membrane filter ability were correlated with arabinoxylan content, whereas β-glucan was correlated only with viscosity. β-glucan may increase the viscosity of beer by forming gels, consisting primarily of high-molecular-weight β-glucan molecules.

It is clear, as it is summarized above, that carbohydrates in beer are usually studied in relation to sensory or technological properties, but a nutritional approach is also appropriate for these compounds.

A major part of beer carbohydrates, as Table 28.2 indicates, are digestible and are responsible for the caloric value of beer. However, an appreciable amount passes to the large intestine, where it may be fermented by the colonic microflora to produce a variety of substances which are metabolized. These indigestible carbohydrates – β-glucan and arabinoxylans – are the largest constituents of DF in beer; there may also be amounts of other compounds such as cellobiose, laminaribiose and some indigestible chains derived from starch.

The concept of beer non-digestible carbohydrates as DF is a relatively new one and there is a shortage of physicochemical or biological data on this fraction. We need to know more about the composition and physiological and nutritional properties of beer DF.

Content and Composition of DF in Beer

A specific method developed to determine DF in beverages was used. This procedure includes four steps: concentration, enzymatic treatments, dialysis and determination of DF (Saura-Calixto et al., 2002; Diaz-Rubio and Saura-Calixto, 2006).

SDF contents of the lager and dark beers most widely consumed in Spain are shown in Table 28.3.

Table 28.3 SDF content in beer

Beer		Alcohol (%v/v)	Soluble dietary fiber (g/l)[a]
Águila Amstel®	Lager	5	1.98 ± 0.11
Mahou Clásica®	Lager	4.8	1.87 ± 0.07
Bock Damm®	Dark	5.4	1.91 ± 0.09
Voll Damm®	Lager	7.2	2.02 ± 0.01
Buckler®	Lager	<1	1.12 ± 0.05
San Miguel 0.0®	Lager	0	1.64 ± 0.05

Notes: SDF in most common beer in Spain (trade mark, alcohol content).

[a] Each value is the mean ± standard deviation (*n* = 3).
Figure 28.1 SDF in drinks. SDF content in common dietary drinks, determined by enzymatic-dialysis procedure. Data are mean ± standard deviation of three determinations.

Table 28.4 DF content in foods

	Dietary fiber[a] (g/100 g edible portion)		
	Soluble	Insoluble	Total
Oatmeal, medium ground	3.7	2.9	6.6
Rice, white	–	0.5	0.5
Bananas	0.7	0.4	1.1
Apples	0.6	1.0	1.6
Oranges	1.4	0.7	2.1
Corn Meal	0.3	1.4	1.7
Wheat bran	3.8	32.2	36.0
Brussels sprouts	3.0	2.6	5.6

Walnuts	1.5	2.0	3.5
Tomatoes	0.4	0.7	1.1
Carrots	1.4	1.0	2.4
Beer[b,c]	0.20	0	0.20
Orange juice[b,c]	0.19	0	0.19
Red wine[b,c]	0.16	0	0.16

Notes: Soluble, insoluble and total DF content in beer and other beverages and foods. Total dietary fiber = SDF + IDF.

[a] Solid foods values from Food Standards Agency (2002).
[b] DF in beverages expressed as g/100 ml.
[c] Values from Saura-Calixto *et al.* (2002).

Table 28.5 Monomers forming soluble DF in beer[a, b]

	Dark	Lager	Alcohol-free
Xylose	40.1 ± 0.6	34.0 ± 0.7	30.6 ± 0.6
Arabinose	30.1 ± 0.4	24.5 ± 0.4	21.8 ± 0.4
Glucose	17.7 ± 0.5	30.5 ± 0.5	38.7 ± 0.7
Manose	6.9 ± 0.1	6.6 ± 0.1	4.8 ± 0.1
Galactose	5.2 ± 0.1	4.4 ± 0.1	4.1 ± 0.2

Notes: Monomers (monosaccharides) percentage composition of SDF (polymer). Beer soluble DF is a macromolecule make up of different monosaccharides.

[a] Expressed as percentage in neutral sugars.
[b] Each value is the mean ± standard deviation (*n* = 3).

Lager and dark beers contain similar amounts of SDF (1.87–2.02 g/l), while the content is lower in low alcohol or alcohol-free beer (1.12–1.64 g/l), presumably due to differences in the brewing procedure (mashing, malting and dealcoholizing). These may be considered reference values for beer, although higher DF contents may be found in other types of beer, depending on the cereals used and the brewing procedure.

SDF is a quantitatively important constituent of beer and is present in larger quantities than vitamins, minerals, PP and others. Probably only water, alcohol and dextrins are present in larger quantities than DF.

Note that in comparison with other common beverages (Figure 28.1) the amount of SDF in beer is higher than in wine and similar to orange juice.

The DF contents of beverages and vegetable foods differ quantitatively and qualitatively. There is naturally less DF in beverages than in solid vegetable foods – DF is expressed in g/l in beverages and in g/100 g in plant foods. On the other hand, vegetables contain both insoluble and soluble fiber, while only soluble fiber is found in beverages. Table 28.4 shows the DF contents of various different items.

The contribution of beer to the SDF intake in a common diet may be significant; a moderate daily consumption of 250 ml of beer contributes to 0.5 g of SDF, which is equivalent to eating 125 g of tomatoes, 166 g of Brussels sprouts or 83 g of apples.

Table 28.5 shows the monomers forming SDF polysaccharides in beers. Xylose (30.6–40.1%), arabinose (21.8–30.1%) and glucose (17.7–38.8%) were the major constituents in all the different beers, indicating that arabinoxylans and β-glucans are the main polysaccharides in SDF (Figure 28.2).

The high glucose content is mainly derived from β-glucans, but the presence of minor amounts of resistant starch
Figure 28.2 β-Glucans and arabinoxylans (arabinose + xylose) in beer. Major polysaccharides constituents of DF in beer. β-Glucans are formed by glucose units and arabinoxylans are formed by arabinose and xylose. Glucose, arabinose and xylose were determined by gas–liquid chromatography. Data are mean ± standard deviation of three determinations.

chains (amylose and amylopectin) cannot be ruled out. The low proportion of galactose and mannose suggests that galactomannans are minor fiber constituents.

In malting and brewing, sizeable proportions of the β-glucan and pentosan survive as oligosaccharides or di-saccharides such as cellobiose and laminaribiose. These saccharides are not detected by the DF analytical method and they cannot therefore be ruled out as minor constituents of the indigestible carbohydrate fraction. In any case, the contribution of these oligosaccharides to the potential pre-biotic properties of beer is surely nutritionally irrelevant given their negligible concentrations.

Fermentability of Beer DF

DF reaches the colon intact, where it may be totally fermented, partially fermented, or remain unfermented. Colonic fermentation consists in the interaction between the non-digestible dietary components and the intestinal ecosystem, involving the metabolism of non-digestible compounds by the bacteria and the effects of DF on the composition, ecology and metabolic activity of the microbiota. The extent to which these processes occur depends on the chemical structure and physical properties of the fiber components, and they can have positive effects on health and well-being (Edwards, 1995).

When the indigestible compounds are fermented, they are metabolized to hydrogen, methane, carbon dioxide and SCFAs, principally acetic, propionic and butyric acids. These SCFAs are absorbed and further metabolized in the colonocytes, the liver cells, or the peripheral tissues

(Cummings and Macfarlane, 1991; Macfarlane and Macfarlane, 1993). Fibers also contribute to fecal bulking in a number of ways. They can do so directly via their own mass and/or via the mass of the water they attract. They can also influence fecal bulking indirectly in that they are fermented by colonic microflora; this stimulates their growth and results in increased microbial biomass.

The major end-products of fermentation are the SCFAs which acidify the proximal colon and bulk the stool. Acidity is one of the major factors determining the composition of bacterial population. Water is removed from the colon by osmotic equilibration with the mucosal blood.

The major SCFA metabolites are absorbed from the colon and contribute to the energy balance of the host. Butyrate from the colonic lumen has been shown to be the major source of energy supply to the colonic mucosal cells and is known to be a potent trophic agent. It may therefore be implicated in the prevention of colorectal cancer and in the maintenance of epithelial mucosa. Propionate is cleared by the liver and may modulate hepatic carbohydrate and lipid metabolism. Acetate largely escapes colonic and hepatic metabolism and serves primarily as fuel for peripheral tissues. Acetate and propionate have been associated with hypocholesterolemic effects (Mathers and Sakata, 2003).

Fermentation products can favor colonization resistance by increasing the numbers and variety of bacteria. SCFA fermentation end-products are likely to be major factors in increasing colonization resistance and aiding recovery.

The increase of certain types of bacteria (Lactobacillus, Bifidobacterium) or the decrease of others (Clostridium, Bacteroids, etc.) by DF or specific DF constituents is known as the pre-biotic effect.

Soluble fibers are usually more extensively fermented than insolubles, and hence beverage DF can be expected to be highly fermentable. In fact, beer DF is extensively degraded by colonic bacteria. Ninety-nine percent of DF components are fermented, the bulk of them being converted to SCFAs.

The fermentability (Table 28.6) and high propionic acid production of beer DF (molar ratio: acetic, 61: propionic, 30: butyric, 9) is consistent with the high fermentability of β-glucans (Berggren et al., 1993).

Fermentability and propionic production are comparable to that of psyllium (38%) but significantly higher than other soluble fibers such as citric pectins (7%) or inulin (19%). Psyllium and β-glucan are both recognized as healthy fibers, for which health claims have been accepted by Food and Drug Administration (FDA).

Contribution of Beer to DF Intake in the Diet

The intake of DF should range between 30–35 g/day or 10–13 g/1,000 kcal according to dietary guidelines from international health organizations. A balanced DF composition is also recommended (SDF/total DF ratio: 1/3).

Table 28.6 Fermentability and SCFAs production in beer and some DF

| | Fermentability[a] | Molar proportions | | |
		Acetic	Propionic	Butyric

However, the usual intake in developed countries is only about half of that level.

The European nutrition and health report (Elmadfa and Weichselbaum, 2005) indicates DF intakes ranging from 16 to 21 g/person/day in the European Union. Note that beverages are not included in the reports on DF intake.

There are significant differences in DF quality due to considerable regional differences in food sources. Northern European countries obtain 58% of DF (range: 54–64) from cereals, while Mediterranean countries such as France, Italy and Spain obtain only 42% (range: 36–49). Intake of vegetables, fruits and legumes varies reciprocally, with low intakes in Northern Europe and much higher intakes around the Mediterranean. Some of the postulated benefits of diets rich in fruits and vegetables might then be attributable to the intake of fiber. This suggests differences in composition and properties of DF. Fruits, vegetables and legumes possess a higher proportion of SDF than cereals. The fiber intake in the Spanish diet was recently determined (Table 28.7), including an estimation of the contribution of beverages.

The Spanish population consumes around 19 g/day of DF in which 33% is soluble fiber (Saura-Calixto and Goñi, 2004). The contribution of plant foods to the total DF intake is shown in Figure 28.3. Fruits, vegetables and legumes account for 53%, cereals for 43% and beverages for around 3%. The average beer consumption in Spain is 150 g per capita per day, which would contain 0.3 g of SDF.

The contribution of beverages is estimated at 11% of SDF intake, the largest part of that (5%) coming from beer (Figure 28.4). The average per capita beer consumption in the European Union is around 202 g/day, accounting for some 0.4 g of SDF. A moderate consumption of 500 ml of beer per day could imply an intake of 1 g of SDF.

Table 28.7 DF intake in the Spanish diet

| | Daily consumption[a] (g/p/d) | Dietary fiber[a] (g/p/d) | |
		Soluble	Insoluble
Cereals	231.2	1.95	5.33
Vegetables	311.2	1.90	2.79

Are Polysaccharides the Only Constituent of DF in Beer?

DF was first defined as non-starch polysaccharides and lignin which are resistant to hydrolysis by the digestive enzymes of man (Trowell *et al.*, 1976). On the basis of this definition, an analytical methodology was developed to determine DF in foods and a large number of clinical and epidemiological studies established were performed.

However, our knowledge has grown since DF was first defined, and the general tendency among nutritionists nowadays is to extend the concept of DF to include other compounds of proven resistance to the action of digestive
Figure 28.3 Contribution of plant foods to the total DF intake in the Spanish diet (year 2000). Contribution of beverages and vegetable foods to the total DF intake in the Spanish diet (year 2000) (Saura-Calixto and Goñi, 2004). Major items in each group: cereals (white bread, rice), vegetables (potatoes, tomatoes), legumes (beans, chickpeas, lentils), fruits (oranges, bananas) and nuts (peanuts, almonds). Beverages include beer, wine and orange juice.
Figure 28.4 DF complex in lager beer DF in beer is made up of non-digestible polysaccharides (β-glucans and arabinoxylans) along with PP compounds and indigestible protein.

enzymes, such as resistant starch, indigestible saccharides or oligosaccharides, indigestible protein and certain PP (Saura-Calixto et al., 2000; Nelson, 2002). These compounds may also be constituents of beer DF.

Resistant starch is a part of dietary starch that is not digested in the human gut and is largely fermented by the colonic bacteria (Asp et al., 1996). Resistant starch is a major component of DF in solid starchy foods such as cereals and legumes, but we may only expect to find minor or negligible amounts in beer DF, made up of indigestible amylose and amylopectin chains. Insoluble saccharides like cellobiose and laminaribiose have also been reported in beer, but at very low concentrations. The presence of resistant starch and indigestible saccharides is therefore nutritionally irrelevant, and only β-glucans and arabinoxylans can be considered significant beer DF constituents.

Proteins from meat and fish are fully digestible, but part of the protein in plant foods remain indigestible after the action of digestive enzymes. Indigestible or resistant protein is a typical constituent of DF in vegetable foods (Goñi et al., 2002).

In the analytical procedure used to determine DF in beer, digestible protein is hydrolyzed to amino acids or peptides by pepsin treatment, but part remains in the dialysis retentate as indigestible protein.

PP and protein content were determined in both beer and the retentates (just after dialysis) which contain the non-digestible polysaccharides solution (Table 28.8). The protein content determined in lager beer (with-alcohol and alcohol-free) was 1.7–1.5%, while a significant amount around 1.3–0.9% of beer protein was found in the SDF solution of the dialysis retentate. Hence, about 76–60% of the beer protein appears to be resistant protein (Table 28.8).

The presence of polyphenolic compounds associated with DF is a characteristic feature of PP-rich plant foods. The presence of PP in both insoluble and soluble DF of grapes and other vegetable materials has been reported by the authors elsewhere (Bravo et al., 1994; Saura-Calixto and Bravo, 2001). Beer contains appreciable amounts of PP. Beer PP are single molecules or oligomers with a molecular weight (MW) considerably below the cut-off (12 kDa) of the dialysis membrane used in our experiment, and they therefore had to be dialyzed. However, appreciable

Table 28.8 Protein and phenolic compounds associated with non-digestible polysaccharides in beer

	Lager[a]		Free-alcohol[a]	
	Polyphenols[b] (mg/l)	Protein (mg/l)	Polyphenols[b] (mg/l)	Protein (mg/l)
Original beer	312.15 ± 2.8	172 ± 3	299 ± 1.4	147 ± 2
Dialysis retentants	66.02 ± 2.2	134 ± 1	52.12 ± 1.34	95 ± 3

Notes: Polyphenols and protein found in original beer (before any treatment) and in dialysis retentants obtained after enzyme treatment and dialysis. Dialysis retentants contain DF and associated compounds.

[a] Each value is the mean ± standard deviation (n = 3).
[b] Expressed as gallic acid.

amounts of total PP remained in the dialysis retentates after enzymatic treatment (Table 28.8). This suggests that the phenolics quantified in the retentates are associated with macromolecules of molecular weights greater than 12 kDa.

Indigestible polysaccharides or DF and protein are the chief beer macromolecules that can bind PP. Polysaccharides and protein undegraded by the enzymes used in the analytical procedure, which constituted the DF, remained in the dialysis retentate and emerged as the chief target for PP bonding.

It has been shown that proteins with high proline content have a high affinity for binding PP. The proteins in beer that are able to bind PP have been shown to originate in barley hordein. Hordein is a prolamin and prolamin is a proline-rich protein (containing approximately 20 mol% proline). Gliadin, or wheat prolamin, is also rich in proline (15 mol%) and exhibits an affinity for binding PP (Siebert, 2006).

Our experiment showed the presence of significant amounts of PP and protein along with DF in the dialysis retentates. We conclude that beer contains a DF complex (DF plus indigestible protein and associated PP) at concentrations of about 1.2–2.3 g/l. We would note particularly that this complex contained from 17% to 21% of the total phenolics in beer and about 75–65% of the protein.

DF complex will not be bioavailable in the human upper intestine and are therefore not susceptible of absorption through the intestinal mucose. Complex may be expected to reach the colon, where the polysaccharides will be extensively fermented as described above, and this could favor fermentation of the associated PP. These PP, and the products of their degradation, may contribute to an antioxidant environment in the colon and may also be absorbed and metabolized.

To sum up, beer contains a considerable amount of DF complex made up of polysaccharides, protein and PP. The objective of this study was simply to show that beer contains DF. The presence of DF in beer should be neither overestimated nor underestimated for purposes of nutrition and health. Further studies on the composition, physicochemical and biological properties of this complex are needed to elucidate its nutritional significance.

Summary Points

- International food composition tables report no DF in beer. However, DF is a quantitatively important constituent of beer.
- Lager and dark beer contain around 2 g of DF/l. Arabinoxylans and β-glucans are the major constituents of beer DF.
- Beer DF presents high colonic fermentability, similar to β-glucans and psyllium, two recognized healthy fibers.
- The contribution of beer (150 ml person/day) to the intake of DF in the Spanish diet is estimated at 1.5% and 5% of total DF and SDF, respectively. A higher contribution may be expected in other European countries where beer consumption is greater.

- DF occurs in beer as a complex (2.3 g/l) made up of indigestible carbohydrates, polyphenolic compounds and indigestible protein.
- The biological and nutritional significance of DF in beer remains to be elucidated.

Beer and Arabinoxylan
Glen P. Fox Plant Science – Wheat, Barley & Oats, Toowoomba, Qld, Australia

Abstract

Arabinoxylans are non-starch polysaccharides (NSP) and are found in a number of tissues, primarily in the cell wall of the aleurone layers and the endosperm. Arabinoxylans are comprised of a mixed linkage between arabinose and xylose. The arabinoxylan structure is degraded, in conjunction with β-glucan, by enzymes during the malting process to facilitate a trouble-free breakdown of the main endosperm contents (protein and starch). Low temperature mashing (<50°C) continues the breakdown of these NSP. However, arabinoxylans have been attributed to contribute to filtration problem during brewing and haze formation in beer. There is variation with a grain type as well as between grain types used for brewing, with barley having a high arabinoxylan content compared to sorghum with a low content. Further research is required to gain a more detailed understanding of the genetic control of arabinoxylan as well as the enzyme systems that degrade this NSP to ensure trouble-free brewing and consistent beer quality. Improvements in filtration technology could increase pressure on barley breeders and maltsters breeders to produce low level arabinoxylan barley and malt which could impact on other quality parameters.

Arabinoxylans are polysaccharides that exist in the cell walls of tissues of grains. These polymers have been reported to be a major positive component of dietary fiber. However, intact arabinoxylans can have a negative impact of malt and beer quality. Arabinoxylans are one of many chemical and biochemical components from grains that are enzymically degraded and solubilized during malting, mashing and boiling to produce beer. To produce trouble-free brewing, a number of grain and malt attributes must meet tight specifications. While the levels of hot water extract, free amino nitrogen and wort β-glucan (BG) can be prescribed to make brewing as trouble free as possible and produce a consistent quality and flavor, one particular group of carbohydrates is generally ignored. This group of carbohydrates is called non-starch polysaccharides (NSP).

These important NSPs consist of two main polysaccharides that include β-glucan and arabinoxylan. If these are not degraded during malting and mashing then significant brewing problems can arise.

Arabinoxylans are found in the cell walls of a number of tissues in cereals, including husk (Höije *et al.*, 2006), aleurone (Bacic and Stone, 1981; Rhodes and Stone, 2002) and endosperm cell walls (Henry, 1986). However, there has been more interest in the endosperm cell walls composition in barley (*Hordeum vulgare*), wheat (*Triticum aestivum*) and sorghum (*Sorghum bicolor*) which are the most common cereals used for producing beer. Arabinoxylan also is found in other cereals used as brewing adjuncts such as maize (*Zea mays*) and rice which can also impact on beer production. In addition, arabinoxylan also exits in the minor grains such as buckwheat (*Fagopyrum esculentum*), finger millet (*Eleusine coracana*) (Rao and Muralikrishna, 2004) and pearled millet (*Pennisetum typhoideum*) which are used in producing gluten-free beer.

Arabinoxylan is located in the cell walls of the outer layers of the grains as well as in the endosperm cell wall. There is considerable variation in arabinoxylan content as well as the levels of arabinose and xylose between species. There are differences between cereal species as well as within a species and the portion of arabinoxylan in the endosperm compared to the whole grain (Henry, 1986). Most of the arabinoxylan in grain is in the outlet layers of the grain with a 70/20% arabinoxylan/β-glucan mixture. However, in the endosperm cell walls the reverse proportions exist with only around 20% arabinoxylan (Fincher, 1992).

The Structure of Arabinoxylan

Arabinoxylan has a linear backbone structure of β-D-xylopyranosyl residues linked by β-(1→4)-glycosidic bonds, other monosaccharides such as L-arabinofuranose attached as branches by β-(1→2) or β-(1→3)-linkages

(Luchsinger, 1967; Bacic and Stone, 1981; Henry, 1988a; Vietor *et al.*, 1991). Typically, L-arabinofuranose or other side chains are carried on the main chain as non-reducing end groups. Ferulic acid is esterified to some arabinofuranosyl chains. However, there is variation in the esterification of ferulic acid depending on the species and tissue.

Bamforth and Kanauchi (2001) reported a stylized structural model for barley cell wall (Figure 29.1). It was hypothesized that there was a layer of xylose, partially covering the β-glucan. The xylose had arabinose linked in addition to ferulic and acetic acid. This structure provides a rigid backbone to the cell wall but it was not impenetrable to enzymic attack which is critical to allow the movement of protein and starch degrading enzymes and the resultant products during germination (Figure 29.2)

Arabinoxylan can be extracted in either water or alkali solutions (Medcalf *et al.*, 1968; Izydorczyk *et al.*, 1998a, b), with water extractable arabinoxylan able to form viscous solutions (Medcalf *et al.*, 1968). Ferulic acid dimers play a major role in crosslinking in gel formations (Dervilly-Pinel *et al.*, 2001). The negative aspects of gel formation on beer quality will be described later. Cyran *et al.* (2002) concluded that there was more water soluble arabinoxylan present in a barley malt as well as a greater portion of high molecular weight arabinoxylan.
Figure 29.1   Structure of arabinoxylan. *Source*: Fincher and Stone (1986).
Figure 29.2   Theoretical model of the structure of arabinoxylan in endosperm cell walls. *Source*: Bamforth and Kanauchi (2001).

Arabinoxylan in the Endosperm Cell Wall

As mentioned above arabinoxylan has been detected at around 20% in the endosperm cell walls (Fincher, 1992). There is variation in the level of endosperm arabinoxylan between species as well as within a species (Henry, 1986, 1987). A hypothetical structure for barley is shown in Figure 29.1. While arabinoxylan is the minor partner to β-glucan, like β-glucan, the level can seriously effect the processing of wort in the beer production. The degradation of the cell wall is critical to the efficiency of the malting process. Enzymic attack on the arabinoxylan substrate releases smaller oligosaccharides and simple sugars. In addition, ferulic acid is hydrolyzed from the arabinofuranose side chain. For the degradation of arabinoxylan, a number of enzymes are involved. In recent years, numerous studies have provided more detail on the chromosomal location, gene expression, enzyme functionality and substrate specificity (details provided below).

Arabinoxylan in the Husk and Aleurone Layers

As mentioned previously, a significant amount of the total arabinoxylan is present in the husk and outer layers of barley and other grains where there is approximately 70% arabinoxylan and only 20% β-glucan. Not only is the content of arabinoxylan different but also the structure and the ratio of arabinose to xylose. In barley, the husk and aleurone, the ratio of arabinose:xylose is lower in barley than in wheat. The difference between the arabinose to xylose ratio is also dependant on the genotype, growing environments and extraction solution (Henry, 1988b). These differences can also be measured in the malt (Han and Schwarz, 1996), wort (Debyser *et al.*, 1997) and beer samples (Han, 2000).

Genetic and Environmental Variation

Like most endosperm structures, the cell walls and components within the cell walls are influenced by the growing environment. Arabinoxylan has been detected in the developing endosperm tissue as early as 7 day after anthesis (Wilson *et al.*, 2006). The final arabinoxylan content has been shown by many researchers to be influenced by genotype and environment. In addition, there are differences between species used in brewing. For the purpose of this chapter, the results will describe arabinoxylan from endosperm cell walls only, which is a critical phase in malting and brewing performance.

The variation is quite considerable between species which is influenced partly whether the grain has a husk. The dominant grain used in brewing is barley and the range has been shown to be between 3% and greater than 10%. Henry

(1986) reported significant genetic and environmental effects on a range of malting and non-malting commercial varieties. This study was comprehensive in the number of genotypes and environments used. However, more expansive studies by Lehtonen and Aikasalo (1987), Mikyska *et al.* (2002) and Holtekjølen *et al.* (2006) also showed similar genetic and environmental effects. Lehtonen and Aikasalo (1987) reported differences in pentosan content between barley types (two- vs. six-rowed), varieties and sites with over one hundred varieties tested over three locations.

However, the most difference was between two- and six-rowed barleys. Six-rowed barleys generally have a higher husk content and reduced endosperm. Mikyska *et al.* (2002) reported on the arabinoxylan content in eight varieties grown at four locations in Czechoslovakia. There was significant variation between genotypes as well as locations. In addition, there were correlations between arabinoxylan and malt traits such as hot water extract, friability and viscosity. While Holtekjølen *et al.* (2006) tested 39 barley varieties from a number of countries of origin (Europe and Canada) and found statistically significant variation between cultivars with a hulless variety having the lowest amount, although similar in levels to that reported by Trogh *et al.* (2004). Han (2000) tested two varieties, with one sourced from different locations showed non-significant differences in arabinoxylan content. This was also in the resultant malt and beer samples with around 40–60% loss in arabinoxylan from barley to malt and almost greater than 90% loss from barley to beer.

Variation was identified in water soluble, insoluble and total arabinoxylan between three European hulless barley cultivars (Trogh *et al.*, 2004) with one variety grown at two locations. There were differences between the three varieties and slight difference between the varieties grown at two locations. While Debyser *et al.* (1997) tested the malts of six barley varieties with only slight differences between them.

In regards to wheat, Finnie *et al.* (2006) described the genetic and environmental variation in arabinoxylan in a wide range of wheat varieties. These varieties were not used in brewing but the results highlighted the differences that can be obtained in wheat which can be used as a primary raw ingredient or as an adjunct.

Sorghum has been extensively around the world for brewing either as a raw material or as an adjunct. While detailed analysis has been carried out on most quality attributes usually measured in assessing the suitability for malting and brewing (i.e. protein, amylases, etc.). There has been little reported on the variation of arabinoxylans between varieties of sorghum. Single varieties of sorghum, wheat and pearled millet were assessed for hemicellulose content, with variation between the three species in the arabinose, xylose and arabinose/xylose ratios (Nandini and Salimath, 2001a). Nandini and Salimath (2001b) assessed the structural features of a single sorghum variety.

A less common ingredient used in brewing has been triticale. Triticale is a hybrid species derived from a genetic fusion of wheat and rye. Glatthar *et al.* (2005) found variation in the water soluble and insoluble arabinoxylan content between triticale and wheat varieties grown over multiple years. The triticales were much higher in total, soluble and insoluble arabinoxylan than the wheats tested but had values similar to a commercial barley malt.

Two other grains used in brewing a speciality beer, that is gluten free, are pearled millet and buckwheat. Both of these cereals contain arabinoxylan although there is very limited data on variation between varieties.

Effects in Malting

Many thousand of years ago, the people living in Mesopotamia were the first to "brew" beer, although the process was a little dissimilar to modern brewing practices. These ancient brewers did germinate barley but they had no knowledge of the complex biochemical reactions that convert the endosperm components into food for the growing germ as well important factors having a positive influence on the quality of beer.

The process of malting has had volumes written about it. In simple terms, malting is a four stage process where firstly, grain is steeping in water, which triggers germination. The second stage is germination where the sprouted grain is allowed to germinate, with controlled air flow, temperature and turning of the grain. During this phase, a significant number of the biochemical systems start to work on the insoluble endosperm structures. The third stage is where the grain is dried, again under controlled conditions, where temperature and air flow ensure the malt is finished in the best possible quality. The final stage is malt storage where it is critical for the malt to be maintained in optimal quality. Also, this is where malt is blended to meet brewers' specifications. It is absolutely critical to maintain ideal storage conditions once blending is completed.

The steeping, germinating and kilning processes all impact on the expression and optimal functionality of enzymes that will work to produce the products to be utilized, initially for the growing embryo, but also for the yeast during fermentation. Key enzymes including (1→4)-β-endoxylanases, β-D-xylosidases, α-L-arabinofuranosidases and esterases, involved in degrading the arabinoxylan structure are synthesized during steeping and germination. These enzymes are synthesized in the aleurone layer, stimulated by the presence of gibberellic acid (Taiz and Honigman, 1976; Dashek and Chrispeels, 1977), and move into the endosperm to commence working on the arabinoxylan substrate. Although it is shown that the major (1→4)–β-endoxylanase was synthesized only after day 4 of germination and increased until 15 days in one barley variety (Casper *et al.*, 2001). This supports previous data that

suggested the endoxylanase is bound in the aleurone layer cell walls until complete breakdown before it migrates to the endosperm (Fincher, 1989; Slade *et al.*, 1989)

The breakdown of the endosperm cell walls is critical for the successful modification on the two other key endosperm components, the protein matrix and the starch granules. Chandra *et al.* (1999) have shown the effect on the rate of breakdown of β-glucan has an impact on modification regardless of whether a lager or ale malt was produced from three barley varieties. Incomplete breakdown of the cell walls leaves residual β-glucan and arabinoxylan which impacts on brewing efficiency and beer quality (see below). Sungurtas *et al.* (2004) identified differences between four varieties in the expression of three important enzymes, namely (1→4)-β-endoxylanases, β-D-xylosidases and α-L-arabinofuranosidases. There were differences in the rate of expression and total amount of enzymes. The varieties that had the higher levels of the main enzyme (1→4)-β-endoxylanase did not show the highest levels of arabinoxylan content in a hot water extract.

During germination, the cell wall degrading enzymes act on the appropriate substrates, producing smaller, more soluble molecules. While there is a decrease in total arabinoxylan content, there is little change in the amount of the two sugars, namely arabinose and xylose. Kilning effectively suspends the action of the enzymes. However, the high temperature (>60°C up to 85°C) during the later stages of kilning reduces the activity of the enzymes.

These enzymes are temperature sensitive and while they could continue to act on the arabinoxylan substrates, high temperature (infusion) mashing will render the enzymes inactive almost immediately. Li *et al.* (2004) demonstrated the effect of different mashing temperatures and mash stand times on xylanase activity and arabinoxylan content. They developed a model to predict the xylanase activity, arabinoxylan content in wort using laboratory and commercial mashes. For those breweries that mash-in using a lower temperature (<50°C), the breakdown of the arabinoxylan will continue until the temperature increases thereby denaturing the enzymes. Hence, it is important that all the arabinoxylan (and β-glucan) is degraded during the malting process. Although complete degradation of both NSPs is always possible, Cyran *et al.* (2002) showed that there was an increased level of arabinoxylan than β-glucan in malt and there was also a high portion of molecular weight arabinoxylan residues.

Impacts on Brewing

The final quality of beer is influenced by a number of inputs and processes during production. These inputs and processes would include:

• the quality of the primary cereal ingredient (barley, wheat or sorghum);

• the malting quality (ale or lager malts);
• the mashing process (decoction vs. high temperature infusion);
• the adjunct and processing of the adjunct.

The effect of the primary cereal ingredient is twofold, with the level of arabinoxylan as well as the expression of enzymes that degrade it. As mentioned previously, there were genetic and environmental effects on the level of arabinoxylan in barley, wheat, sorghum and a range of other grains (Henry, 1986; Lehtonen and Aikasalo, 1987; Han, 2000; Nandini and Salimath, 2001a, b; Mikyska *et al.*, 2002; Trogh *et al.*, 2004; Glatthar *et al.*, 2005; Holtekjølen *et al.*, 2006; Finnie *et al.*, 2006). Also the malting process impacts on the breakdown of the endosperm cell walls and the degradation of the β-glucan and arabinoxylan.

The differences in malt styles, that is ale or lager malts, and hence, level of endosperm modification, is controlled by the malting process. While the quality of the raw material could impact on the malting performance, the process itself will control the final malt quality. Although the difference in beer style (ale vs. lager) is controlled by the brewing process, the malt itself plays a role. Brewers will set malt specifications for the maltster to produce a malt style that complements the brewing process. Lager malts generally have a lower Kolbach Index (KI) which could therefore have slightly high levels of cell wall material intact, including arabinoxylan. A number of studies have shown significant correlations between arabinoxylan and the KI, suggesting that if there was reduced protein modification there was a higher level of arabinoxylan. A high level of arabinoxylan indicates incomplete endosperm cell wall breakdown (Stewart *et al.*, 1998; Evans *et al.*, 1999). Conversely, ale malts with a higher KI would have greater degradation of the cell walls.

While lager malts may be lower in KI compared to ale malts, the malt could still produce excellent beer with no processing problems. Also, ale malts, with a high level of protein breakdown, could still have a high level of intact cell wall material but produce beer within specifications and causing no brewhouse problems. However, where malts were under-modified, and there are high levels of arabinoxylans then there may be processing problems with low rates of wort separation, high wort viscosity (Li *et al.*, 2004, 2005), beer viscosity, decrease of beer microfiltration rate (Stewart *et al.*, 1998; Stewart *et al.*, 1999), haze formation in the brewery (Coote and Kirsop, 1976) and foam instability (Evans *et al.*, 1999). Furthermore, incomplete degradation of endosperm cell walls reduces the yield of extract which can be derived during mashing.

A number of these studies have identified two important but different effects of arabinoxylan. Firstly, the level of arabinoxylan impacted on wort separation, viscosity (Li *et al.*, 2004, 2005) and haze formation (Coote and Kirsop,

1976). Secondly, the molecular weight of the arabinoxylan residues was shown to affect beer viscosity, filtration rate (Stewart *et al.*, 1998, 2000) and foam stability (Evans *et al.*, 1999). Although there were a small number of samples used in the studies the results clearly indicated that negative effects of undegraded arabinoxylan on beer quality and processing efficiency.

These studies used combinations of commercial malts, pilot scale brewing as well as commercial brewing samples of barley malt. However, similar problem have been shown in wheat malts and beer with high molecular arabinoxylan effect quality and processing (Cleemput *et al.*, 1993; Schwarz and Han, 1995). However, there are few reports of solubilization of arabinoxylans in mashing with grist containing wheat and wheat malt (Lu and Li, 2006). Historically, reduced beer filtration efficiency has been mainly attributed to β-glucan. Sadosky *et al.* (2002) reported that the concentration and molecular weight of arabinoxylan had a negative effect on beer viscosity and filterability. These effects were at least as important as the effects of β-glucan.

There are a number of quality attributes that contribute to the production of beer and well as the visual acceptability of the beer, these include viscosity, haze, filterability and foam retention. Arabinoxylan has been shown to impact on all of these four traits and importantly, it is both the concentration as well as the molecular size of the arabinoxylan residues that influence the quality.

Adjuncts

Most brewers around the world use adjuncts to impact particular characteristics to the final beer quality. Liquid adjunct brewers would use products such as corn syrup or cane sugar (sucrose from sugar cane). The function of liquid adjuncts would be to contribute additional fermentable sugars for fermentation. There would be little non-fermentable sugar present, that is oligo- or polysaccharides from either starch or NSP.

Solid adjunct brewers on the other hand would use either unprocessed or processed (malted or steamed flaked) grains. These grains would include rice, corn, barley or sorghum depending on the flavor target of the brewer. The use of an adjunct cooker would assist in the gelatinization of the starch prior to the addition into the mash. However, the presence of NSP in the form of β-glucan and arabinoxylans could impact on beer processing and quality.

Enzymic Degradation During Malting

As mentioned previously, the action of enzymes on the cell walls and in particular arabinoxylan is critical to producing malt that will cause minimal to no problems during brewing. A number of enzymes are involved in this process (Preece and MacDougall, 1958). These particular enzymes are required to degrade arabinoxylan during germination, which, in conjunction with the breakdown of the major endosperm cell wall component, β-glucan, will allow a more efficient modification of the endosperm.

The endo- and exo-enzymes work synergistically to:

- remove the arabinose side chains;
- attack the xylan backbone;
- cleave individual xyloses and arabinoses from the backbone and side chains;
- cleave ferulic acid.

The natural process of germination induces the development of enzymes. This process is common for all grains. The function and activity of the cell wall degrading enzymes are of particular importance to those grains used in brewing.

Over the years many reports have documented the various enzymes and the roles in degrading the arabinoxylan component as well as describing effects of germination with and between species. It would appear that (1→4)-β-endoxylanase is the main enzyme that cleaves internal bonds of the xylan backbone. There are a number of isoforms of the enzyme and there is variation due to variety (Slade *et al.*, 1989; Debyser *et al.*, 1997; Autio *et al.*, 2001) and species (Autio *et al.*, 2001; Simpson *et al.*, 2003; Grant *et al.*, 2003). (1→4)-β-endoxylanase is synthesized during germination (Preece and MacDougall, 1958) and stimulated by the action of gibberellic acid (Taiz and Honigman, 1976; Dashek and Chrispeels, 1977).

Another critical enzyme is arabinofuranohydrolase and is suggested to act first to remove the arabinosyl side chains. Several reports also describe the differences between barley varieties, species and the effect of germination (Taiz and Honigman, 1976; Autio *et al.*, 2001; Grant *et al.*, 2003). Further Ferré *et al.* (2000) identified an arabinoxylan arabinofuranohydrolase from germinated barley and suggested that this enzyme hydrolyzed arabinose from singly or doubly substituted xylose.

Two other enzymes that play a minor but still important role in breaking down the arabinoxylan structure have been described in recent research. These enzymes are xylanopyranosidase and esterase. The xylanopyranosidase is an exo-enzyme cleaving xylose from the xylan backbone. Grant and Briggs (2002) identified the presence of this enzyme in various wheat tissues. Further, Grant *et al.* (2003) showed the development of two isoforms of β-xylopyranosidase in germinating wheat. Both isoforms increased in total activity during in 7 days of germination.

Finally, esterases hydrolyze the esterified bonds between the non-reducing end arabinose and ferulic acid. Sancho *et al.* (1999) identified the presence of an esterase in barley and followed the activity during germination. The level of the enzyme decreased from the level in barley significantly from day 2 to day 6 of germination. Ward and Bamforth

(2002) also identified esterases in two varieties of barley and malt with a difference between the varieties. Also there were differences in the thermostability between the enzymes suggesting that some of the enzymes could survive malting and mashing. Further, the distribution of the enzymes between the husk/aleurone layer and endosperm indicated that some of the esterases where tissue specific and synthesized during germination. Finally, one particular esterase was involved in cell wall breakdown. Sancho *et al.* (2001) esterases cleaved ferulic acid bound to arabinose in spent brewers grain.

Conclusions

The research carried over the last 20 years has improved understanding of structure of arabinoxylan and its location in tissues. Also there is better understanding of enzymes involved in the breakdown of arabinoxylan, the aleurone and endosperm cell wall, both functionally as well as structurally. Arabinoxylan plays a positive role in dietary fiber when it is in its native state. However, when undegraded arabinoxylan has serious negative impact on malt and brewing quality and it has been suggested that arabinoxylan may impact more on brewing than β-glucan. Like most of the grain endosperm components arabinoxylan must undergo enzymic breakdown so as to ensure trouble-free brewing and beer quality.

For many years, there have been national and international discussions on the relevance of some of the malt specifications in relation to brewhouse performance and beer quality. One of the traits that should be routinely measured in arabinoxylan content and like its cell wall counterpart, the molecular weight of the final arabinoxylan residues is equally as important.

Future research into the genetic variability in the expression of arabinoxylan, the genes and translated proteins responsible for its breakdown during malting and brewing, and changes in brewing practices will herald arabinoxylan to be an equal partner to β-glucan and its importance in brewing.

Summary Points

- Arabinoxylans are NSP.
- They are found in the cell wall of the aleurone layers (75%) and the endosperm (25%).
- Arabinoxylans are degraded by enzymes during the malting process to facilitate continued breakdown of the endosperm contents (protein and starch).
- Low temperature mashing (<50°C) continues the breakdown of these NSP.
- Arabinoxylans contribute to filtration and haze problems in beer.
- Further research is required to gain a more detailed understanding of the genetic control of arabinoxylan

as well as the enzyme systems that degrade this NSP to ensure trouble-free brewing and beer production.
- Improvements in filtration technology could increase pressure on barley breeders and maltsters breeders to produce low level arabinoxylan barley and malt which could impact on other quality parameters.

Histamine in Beer

Susanne Diel, Maria Herwald, Hannelore Borck and Friedhelm Diel
Institut für Umwelt und Gesundheit (IUG) and University of Applied Sciences,
FB:Oe, Biochemistry, Fulda, Germany

Abstract

Histamine is the major mediator in inflammation and allergy. Furthermore, histamine is a product of microbial metabolism especially during fermentation and spoiling of food. In this paper histamine is determined in beverages like beer before and after mechanical and chemical cleaning of tap installation in selected German bars and restaurants. After a couple of weeks without cleaning storage devices, tubes and taps, histamine increases up to 35 mg/l in a beer sample on-draft. However, this contamination can be significantly reduced after mechanical (35%) and after combined mechanical/chemical cleaning (93%), respectively. Beside histamine other biogenic amines, especially tyramine, are produced and must also be taken into account in the health risk assessment. Brewing, brewery location and hygienicity are most important factors for the *Enterobacteriaceae*, *Lactobacillae*, *Pediococcus* and *Staphylococcus* spp. derived biogenic contaminations. The specific mammalian histamine responses are also discussed. Special focus is laid on histamine-activated G protein coupled receptors (GPCR), the signal transduction induced by the gastro/intestinal (H2R) and the "new" lymphocyte (H4R) histamine receptor. It can be suggested that beer consumption is better than wine related to the prevalence of allergic reactions. Specific "beer allergies" are very rare, and only a few articles are published on this matter in the international literature.

List of Abbreviations

AC	Adenylyl cyclase
ALDH	Aldehyde dehydrogenase
AVE	Allergie-Verein in Europa
cAMP	Cyclic AMP
CREB	cAMP-response element-binding protein
DAG	Diacylglycerol
DAO	Diamino-oxidase
ELISA	Enzyme-linked immuno sorbent assay
GPCR	G protein coupled receptor
Gut	Intestinum
HDC	L-histidine decarboxylase
HIS	Histamine
HPLC	High performance liquid chromatography
HR	Histamine receptor
IgE	Immunoglobulin E
InsP3	Inositol triphosphate
JAK	Janus kinase
LTP	Lipid transfer protein
MAO	Monoamino-oxidase
MAPK	Mitogen-activated protein kinase
MC	Mast cells
MMC	Mucosal mast cells
NFkB	Nuclear factor kappa B
OPD	Ortho-phthaldialdehyde
PIP2	Phospho-inositol-diphosphate
PKA	Protein kinase A
PKC	Protein kinase C
PLA2	Phospholipase A2
PLC	Phospholipase C
p.o.	Oral
PTX	Pertussis toxin
RIA	Radioimmunoassay
STAT	Signal transducer and activator of transcription

Introduction

Beer is one of the most popular beverages all over the world. It mainly contains substances derived from malt, hops and brewer's yeast. For the production of special beers, other cereals (e.g. wheat, rice or corn) and enzymes may be added. Malt is obtained from germinated and heated or roasted barley. Hops (*Humulus lupulus*) belong to the cannabinaceae family. It provides the characteristic bitterness and aroma of beer and prevents bacterial contamination. For the fermentation process, the yeast-species *Saccharomyces cerevisiae* and *S. carlsbergensis* are used.

Furthermore, the consumption of beer can provide histamine and other biogenic amines and aids in the release

of histamine in the gastric intestinal tissue (gut). As histamine shares the same aldehyde dehydrogenase (ALDH) for its metabolism, increased alcohol from beer can also prevent the breakdown of histamine. This leads to allergy-like reactions including most notable hay fever symptoms like, for example, nasal disorders and flushing of the skin. Combined neuronal responses of alcohol and biogenic amines like migraine and headache are concentration dependent and are related to the individual precondition.

The main responses of histamine can be defined to cause vasodilatation with specific effects to the neuro-immune system. Toxicity thresholds in human subjects are assumed to be in the range 10–100 mg p.o. and are closely related to the individual histamine sensitivity (Beutling, 1996a).

As we could show in recent work histamine obtains only poor sensory characteristics, and the average threshold value of "taste" is difficult to specify even in normal tap water (Rohn *et al.*, 2005). However, as histamine is an important mediator in inflammation and influences the exocrine and paracrine processes in the gastric mucosa, cell regulation in the gut and circulating blood is of special interest (Diel and Szabo, 1986; Wackes *et al.*, 2006).

The aim of the present study is to assess whether histamine can be tasted and measured in commercially available beer. Furthermore, it shall be elucidated in how far hygienic handling can suppress histamine concentration in beer on draft. For a better understanding the biosynthesis of histamine and the mechanistic understanding in health responses shall give the frame of this contribution.

Metabolism of Histamine

As it is shown in Figure 30.1 histamine is synthesized by decarboxylation of histidine. Pyridoxal-5-phosphate-dependent l-histidine decarboxylase (HDC EC **4**.1.1.22) is a widespread ubiquitous enzyme and this is the main pathway for the production of histamine. However, degradation can occur in different pathways: amino-oxidases (unspecific monoamino-oxidase – MAO EC **1**.4.3.4, diamino-oxidase – DAO EC **1**.4.3.6), *O*- and *N*-methylation – methyl-transferases (EC **2**.1.1.8), histidase (L-histidine/-ammonialyase EC **4**.3.1.3) and more or less specific *N*-acetyltransferases as well as hydrolases may participate at the histamine degradation.

The cleavage of L-amino acids (histidine in case of histamine) from proteins is precondition for the production of histamine and other biogenic amines. Furthermore, the amino acid–COOH group must be activated and may not be bound to salt or may not be associated or "deactivated" by other molecular-binding sites. Interestingly, the coenzyme for decarboxylases is ATP-dependent and the lack of Vitamine B6 inhibits the carboxylases in *Enterococcus faecalis* (Beutling, 1996b).

The decarboxylation of other amino acids for the biosynthesis of biogenic amines is analog to the histamine

synthesis: lysine is the progenitor for cadaverine, arginine for agmatine, tyrosine for tyramine, ornithine for putrescine, respectively. All these biogenic amines can be toxic for mammals in a concentration-related manner. Biogenic amines are produced by symbiotic bacteria, after resorption through the colon mucosal tissue, entering the blood vessels. Beside histamine, tyramine is reported to be the most important biogenic factor in beer (for review Beutling, 1996b).

Analyses of Histamine in Beer

Determination of histamine in biological samples is not so easy and values in the literature are contradictionary. The most sensitive way to measure histamine is fluorimetry or mass spectrography after high performance liquid chromatography (HPLC). Immunological tests like radioimmunoassay (RIA) and enzyme-linked immuno sorbent assay (ELISA) are not sufficiently specific related to the relative small molecular weight and poor epitopal character of the molecular structure. Best efficacy can be elucidated using the post-column derivatization with ortho-phthalaldehyde (OPD) (Diel, 2001).

Ten test samples were purchased from supermarkets and beer on draft from typical German bars.

Types of beer and alcohol concentration were documented from the label. Sugar was estimated refractometrically.
Figure 30.1   The main histamine metabolism. Histamine is synthesized by histidine-decarboxylase (HDC) and degraded by amino-oxidases (MAO and DAO). Methylation and acetylation of histamine are not shown here.

Immediately after opening the bottles, freshly drawn beer was tested using standardized sensitivity assessment methods by 10 instructed assessors – trained according to German DIN 10961/ISO 6658. Triangle test was performed according to DIN ISO 4120 as a double blind method (Bodmer *et al.*, 1999). The reference test samples were diluted in normal tap water (0–5 μM Histamine-HCl; Janssen, Belgium). Specific sensory statistic software FIZZ was used (Rohn *et al.*, 2005). Histamine and other biogenic amines in beer samples like tyramine, cadaverine and putrescine were measured fluorimetrically after HPLC and thin-layer chromatography (data not shown here) (Shore *et al.*, 1959; Busch-Stockfisch, 2002).

Sensory Thresholds

Ten instructed assessors indicated a mean sensory threshold for reference histamine 2.5 ± 1.5 μM (SDM, *n* = 10) in normal tap water. However, the triangle test resulted that only one of the test persons recognized the histamine reference as the right one.

Sensitivity criteria such as pharyngeal irritation, tingling tongue and swelling of mucosal tissues in the mouth were defined to be characteristic for the "specific taste" of the biogenic amines. No positive correlation was found between histamine/biogenic amine concentration in beer and the sensory sensation ($R = 0.6$; ranking of intensity of biogenic amines in seven lager beer samples – data not shown here).

Histamine Concentrations

Histamine concentrations in the international literature

Main methods for the determination of histamine in beverages are RIA, ELISA and fluorimetry after HPLC. Best specificity and validity can be revealed using the OPD-coupled fluorimetric post-column detection as it is mentioned above (Diel *et al.*, 1981).

Related to the method which is used the variety of published histamine concentrations in beer differ depending on origin, brewery and type of beer. Microbial contamination and the hygienic control must also be taken into consideration.

Since six decades histamine is determined in beer. The most important biogenic amines producing bacteria are *Enterobacteriaceae*, *Lactobacillus casei*, *Lactobacillus lindneri*, *Lactobacillus coryniformis*, *Pediococcus inopinatus*, *Lactobacillus brevis* and *Pediococcus cerevisiae* (Koch, 1986).

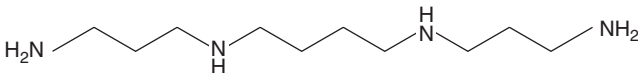
Histamine concentrations in beer are published in, for example, Scandinavia 2.6–15 mg/l (Granerus *et al.*, 1969), France 0.3–20 mg/l (Zappavigna *et al.*, 1974; Vidal-Carou *et al.*, 1989) and Germany 0.44–35.2 mg/l (Wackes *et al.*, 2006), respectively.

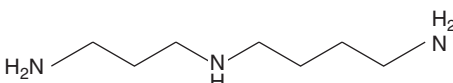
In a review of Beutling (1996b) it is shown that histamine in alcohol-free beer is relatively low (0.04–0.18 mg/l), whereas beer with high contents of basic wort contain relatively high values (approx. 10 mg/l).

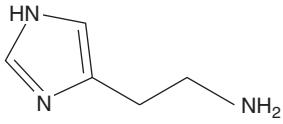
It is suggested that the influences of brewing processes and fermentation are crucial on the distinct formation of histamine and other biogenic amines in beer (Romero *et al.*, 2003).

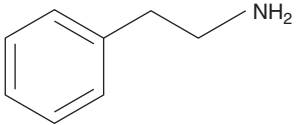
Histamine measured in the Fulda lab

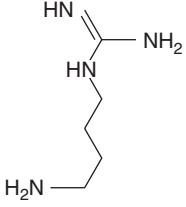
The mean histamine concentration in beer from 10 typical German restaurants, as it is determined in the Fulda lab, ranges 0.49 mg/l (0.44–0.55 mg/l) in the bottled and 10.3 mg/l (range 0.5–35.2 mg/l) in the drawn lager beer, respectively (Table 30.1; Figure 30.1). Although black beer "Schwarzer Hahn" shows a particularly soft taste, the histamine level is pretty high (35.2 mg/l). It must be considered that in this case histamine measurements are performed 2 hours after drawing (Table 30.1).

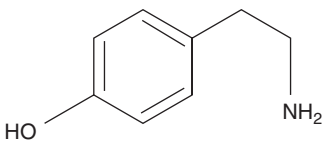
Table 30.1   Histamine and other compounds in eight selected beer bottled samples


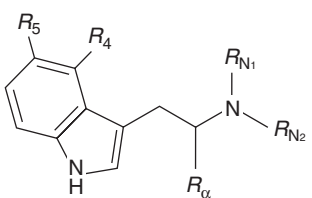












Type of beer	HIS[a] (HPLC) (mg/l)	Sugar[b] (%)	Protein[b] (%)	Alcohol[c] (Vol. %)	Remarks
Schwarzbier (K.)	0.41	5.2	0.41	4.8	
Kristallweizen 5.3%	0.45	5.2	0.29	5.3	
Ur-Weisse dunkel 5.3%	0.48	5.5	0.34	5.3

Cadaverine	102.2	
Agmatine	130	
Group 3		*Exclusively processing*
Tyramine	137	
Tryptamine		

Source: Modified from Beutling (1996b).

In a 15-year-old beer sample the histamine peak is suppressed, however the other biogenic amines seem to dominate the HPLC profile (data not shown).

It can be concluded that only the beer on draft reveals high histamine values (up to 33 mg/l). The sensory characteristics do not correlate to the measured histamine concentrations, using the standardized sensitivity assessment.

Other Biogenic Amines

Biogenic amines are produced predominantly by *Lactobacillae* and *Staphylococcae*. Yeast and other additives are contaminated during the breeding process. Furthermore, storekeeping and drawing lead to additional microbial activity. Tyramine is the most important biogenic factor beside histamine as it is stated already in the introduction. It can be produced rapidly (4 mg/l/day), up to maximal concentrations approx. 45 mg/l (Izquierdo-Pulido *et al.*, 1994). Other biogenic amines are specifically associated to ingredients like malt (spermidine, putrescine, spermine, agmatine, tyramine, tryptamine, cadaverine, phenylalanine …) and hop (spermidine, spermine, phenylalanine, tyramine, putrescine, agmatine …). Related to its origin, biogenic amines in beer can be selected into three groups (Table 30.2).

Hygienic Aspects

In recent work beer on draft samples from distinct city restaurants in central Germany have been examined. Hygienic criteria like organoleptic assessment as well as pH, carbohydrate and protein are measured and compared to the histamine concentrations. The examinations take place before and after mechanical and/or chemical cleaning.

In Figure 30.2a, a typical HPLC graph is shown before cleaning the tap and the beer storage devices. In Figure 30.2b the beer "peak" is significantly suppressed after mechanical cleaning, and in Figure 30.2c it can be demonstrated that after mechanical and additionally chemical cleaning no more histamine contamination can be detected in the drawn beer samples. The results – including also other similar studies – are summarized in Table 30.3.

From the presented results it can be suggested that color and smell of the drawn samples are not varying after the cleaning of the bar equipment. However, there are significant differences of the histamine content before and after cleaning. And it is also of certain importance how the cleaning was performed.

In the present work beer on draft samples from six different Fulda city restaurants are examined. A correlation is found between the histamine contents relevant for health and the present hygienic conditions which depend on several factors as it is shown in Figure 30.3.

From the data of this study it can be concluded that:

1. The hygienic criteria – organoleptic, pH, sugar and protein values do not show significant differences.

(a)

(b)

(c)
Figure 30.2 Typical ion-exchange HPLC fluorimetry profile of one selected beer sample "Schwarzer Hahn" on draught: (a) before cleaning (last cleaning was 4 weeks ago), (b) after mechanically cleaning, (c) mechanically and chemically cleaning of the tubes and tap devices. For analyses beer samples were treated with perchloric acid and were separated in oxalate/tartrate elutant (0.75/0.5 g/l): 1 ml/min; post-column OPD-derivatization, fluorescence (340/455 nm). The histamine peak is indicated by the arrow.

2. Before and after the cleaning of the tap installation weak sensory differences in taste are ascertained. However, after HPLC the fluorimetric determination of histamine (detection limit 3.8 ng/ml) shows before mechanical cleaning 4.84–31.94 ng/ml, 3.94–6.13 ng/ml after mechanical cleaning, in case of the combined chemical and mechanical cleaning before 2.63–5.5 ng/ml and after 4.06–4.46 ng/ml, respectively.

3. In spite of few data and the fact that the ascertained histamine is concentrated in the allowed range it can be suggested – and this is in particular true for people with elevated histamine sensitivity – that consumption of "unhygienic" beer can induce an increase of health risk.

Histamine Responses and Histamine Receptors

Histamine is a small molecular messenger that regulates a wide variety of physiological responses. Signal transduction is induced via G protein coupled receptors (GPCR)

Table 30.3 Histamine in selected German beer samples before and after mechanical and combined mechanical–chemical cleaning of the tap installations

Selected beer No	Type of cleaning	Histamine before cleaning* (ng/ml)	Histamine after cleaning* (ng/ml)	Histamine reduction (%)
1	Mechanical	31,943	6,129	81
2	Mechanical	6,560	5,537	16
3	Mechanical	4,843	3,940	18
4	Chemical–mechanical	5,499	406	93

(Bakker and Leurs, 2005). It acts as a neurotransmitter in the central nervous system (CNS) and also as a major inflammatory factor with certain immune-regulatory potency (Hill *et al.*, 1997). Histamine exerts distinct effects by binding to histamine receptors which is classified on the basis of pharmacological studies influencing gene expression of four histamine subtypes all of which belonging to the superfamily of GPCR.

After the first description of histamine receptors the observation that not all "anti-histamines" can modulate the effects of histamine led Ash and Schild (1966) hypothesize the existence of at least two distinct receptor subtypes antagonizing the responses of histamine on heart and stomach.

Specific H2-receptor (H2R) antagonists are developed in the sixteenths and those are proved to be very useful in gastric ulcer therapy.

Identification of the presynaptic H3R by Arrang *et al.* (1983) gives rise to a new field of interest. For example, sleep/wakefulness, cardiovascular control, nutrition habits like appetite and hormonal secretion are strongly associated to the responses of histamine in mammalian cerebral areas and brain functions.

The identification of a new histamine receptor H4R has possibly been related to genomic database studies. H4R is

the target in the regulation of immune function and can be the gate for histamine induced signal transduction of the janus kinase/signal transduction and activation of transcription (JAK/STAT) downstream in human lymphocytes (Oda *et al.*, 2000; Horr *et al.*, 2006).

The four histamine receptors shall be characterized in the following brief summaries. This is for the better theoretical understanding of possible histamine responses derived from exogenous histamine – from beverages like beer. In this context it must be considered that the mammalian mediator cells like mast cells (MC), mucosal mast cells (MMC) and circulating basophilic granulocytes can secrete histamine which can be pathogenic in case of allergy diseases. (*Note*: histamine sensitivity of mammals has nothing to do with constitutively increased precondition for receiving an allergic disease = atopy. This issue – with special focus on "beer allergy" – is discussed in the last chapter.) The H4R is of special interest, because that can be the main histamine receptor of lymphocytes in the human immune system (Schneider *et al.*, 2002). Nevertheless exogenous histamine from beverages must reach those receptor targets once incorporated after drinking beer and penetrating through the intestinal tissues.

H1R

As H1R is involved in many of the allergic symptoms, anti-histaminica against this receptor are developed and widely spread in the western hemisphere (Woosley, 1996). Contractions in airway smooth muscle are histamine induced via H1R mediated Gq/11 stimulation of the inositol phospholipid signaling system. Production of inositol-1,4,5-triphosphate (IP3) and 1,2-diacylglycerol (DAG) as well as activation of protein kinase C (PKC) take place and modulate Ca^{2+} connected to the activation of phospholipase D by monomeric GTP-binding. This can also stimulate phospholipase A2 (PLA2) resulting in arachidonic acid release. Involving immune functions H1R can induce the mitogen-activated protein kinases (MAPK/K) pathway and the transcription factor NFκB.

H2R

H2R is especially known for its role in the gastric regulation and must be considered to be also a first target for histamine and ingredients in beer. An important key for the understanding of ulcer and gastroesophageal reflux diseases can be addressed to this receptor (Bakker and Leurs, 2005).

Activation of H2R transduces Gi-modulated adenylyl cyclase (AC) activity and subsequent regulation of cyclic AMP (cAMP) in the cell (Diel *et al.*, 2006). Downstream activation of protein kinase A and the cAMP-responsive element-binding transcription factor (CREB) modulate the gene transcription. Other signal transduction mechanisms including Ca^{2+} transport are induced by H2R ligand interaction.

H3R

This receptor is located at the CNS and can be associated to a manifold brain derived disorders, including diabetes and obesity, attention deficit hyperactivity disorder (ADHD), Alzheimer's disease, epilepsy, Parkinson and Schizophrenia (Bakker and Leurs, 2005).

Furthermore myocardial ischemia, gastric acid-related and inflammatory diseases are associated centrally via regulatory responses of H3R.

Signal transduction by Gi-subunit predominantly results in an inhibition of AC. Na^+/K^+ exchange is inhibited and activation of efflux (ATPase-activity) decreases the intracellular Ca^{2+} concentration, and in a complex neuronal signal transduction via H3R, for example, glycogen synthase activity 3β (GSK3β) is inhibited (for review Bakker and Leurs, 2005).

H4R

The fourth histamine receptor H4R shares a big part with the H3R derived protein subunits, nevertheless obtains a relatively high affinity for histamine. The expression profile is most abundant in leukocytes including eosinophils, dendritic cells and tonsil B-cells, as well as cells from the bone marrow and spleen (Liu *et al.*, 2001). This receptor may also be relevant in the signal transduction of STAT1 downstream phosphorylation- and histamine-modulated STAT1/STAT6 interaction at the DNA in human lymphocytes (Horr *et al.*, 2006). Furthermore leukotriene B4 production and neutrophil recruitment, chemotaxis and cytoskeletal changes of eosinophils are activated by histamine via H4R (Ling *et al.*, 2004). MC activation (autocrine histamine release!) and B-lymphocyte interleukin-16 (IL-16) secretion are also described. H4R is also expressed in parts of the brain and lung and can indirectly be relevant for the assessment of histamine in beverages with focus on the immune system (for review Bakker and Leurs, 2005).

As it is shown in Figure 30.4 similarly to the H3R, the H4R couples to members of the Gi-family thus inhibiting
Figure 30.4 Histamine receptor H4R major signaling pathways. *Source*: Modified from Bakker, and Leurs (2005). H4R activates G proteins which inhibit the adenylyl cyclase (AC) resulting in turn a reduced cAMP, protein kinase A (PKA) and CREB-modulated transcription. Ca^{2+} is activated through phospholipase C (PLC) by Gβγ via inositol triphosphate (InsP3) and diacylglycerol (DAG). The janus kinase/signal transduction and activator of transcription (JAK/STAT) pathway provides crosstalk upon the histamine induced STAT6/STAT1 balance. This is constitutively upregulated in atopy (gray).

the AC – CREB pathway. The H4R-mediated Ca^{2+} signaling is induced through a PTX-sensitive (PTX = pertussis toxin) activation of phospholipase C (PLC). Furthermore, the JAK/STAT-downstream activation can induce an intracellular crosstalk to the MAPK/K as well as G protein signal transduction system/pathways in human T-lymphocytes (Michel *et al.*, 2008).

In conclusion the four described histamine receptors have quite different physiological roles and it is still unclear in how far exogenous histamine – particular from beverages like alcohols and beers – succeeds in interacting with H1R–H4R targets. It appears that the constitutive activity of H2R and H3R is more relevant than H1R and H4R, respectively. Nevertheless, H4R shows more constitutive selectivity and specificity concerning the immune responses.

Beer and Allergy

Alcoholic beverages – like beer – obtain a dual effect resulting histamine induced allergic symptoms: a direct one from histamine as a natural ingredient (exogenous), and an indirect one derived from the histamine release after, for example, beer allergenic MC degranulation ("anaphylaxis" – endogenous). As it is shown in Figure 30.5 exogenous and endogenous histamine affect the "immuno-/allergological cycle" in mammals.

In general, alcoholic drinks are capable of triggering a wide range of allergic and allergy-like responses, including rhinitis, itching, facial swelling, headache, cough and asthma. Wine is clearly the most frequent reported elicitor for adverse responses. Despite the worldwide and abundant consumption of beer, allergic reactions following beer ingestion are uncommon. One of the first reports was in 1980 (Van Ketel, 1980). Van Ketel described two patients with acute reactions after drinking beer. In scratch tests both persons exhibited positive results to malt. In 1986, Jover *et al.* studied 12 patients with immediate hypersensitivity to beer. They had positive scratch tests to beer, malt, brewer's yeast and rice. Nine of them were also positive to hops. As oral challenge tests with raw rice and yeast powder yielded negative results in these patients, malt was considered the main causative antigen of beer allergy. Fernández-Anaya *et al.* (1999) examined three patients who suffered anaphylactic reactions after consuming beer. The patients experienced a range of symptoms including a tingling sensation in the face, lip or tongue angioedema, chest tightness, coughing, fainting and generalized urticaria. The research team prepared an extract from barley-made beer and performed skin prick testing. The 3 patients had positive skin prick test results, while 20 control patients had negative test responses. Anaphylaxis – with the consequence of immunoglobulin E (IgE)-mediated histamine release – is a severe allergic reaction that affects multiple systems in the body. Symptoms can include severe headache, nausea and vomiting, sneezing and coughing, abdominal cramps, diarrhea, hives, swelling of the lips, tongue and throat, itching all over the body, and anxiety. The most dangerous symptoms include breathing difficulties, a drop in blood pressure and shock. This study indicates that barley-made beer is a potential culprit of severe anaphylaxis and barley-sensitive patients should be questioned about beer tolerance.

As well as the just described data, the majority of studies concerning allergic reactions to beer basically implicate malt to precipitate the observed symptoms. (Gutgesell and Fuchs, 1995; Vidal and González-Quintela, 1995; Santucci *et al.*, 1996; Bonadonna *et al.*, 1999; Curioni *et al.*, 1999) The first identification of allergens in malt and barley was achieved by Figueredo and co-workers in clinical and immunological studies carried out in a patient in whom anaphylaxis developed after drinking beer (Figueredo *et al.*, 1999). Via immunoblotting assays they demonstrated a 38-kDa IgE-binding component in precipitated beer proteins. Interestingly, more and stronger IgE-binding bands were identified in malt than in barley itself. The authors suggest the enzymes that are needed during the germination process to turn starches into brewing sugar as a possible explanation for the enhanced allergenicity of the malted grain. In an ensuing work based on immunoblotting assays and skin prick tests two main barley proteins, that could survive the malting and brewing process, were isolated and characterized as beer allergens (García-Casado *et al.*, 2001). With apparent molecular weights of 9 kDa (lipid transfer protein 1, LTP1) and 45 kDa (barley protein Z_4) these two allergens had in fact previously been identified as the major components of the proteinaceous material present in beer (Curioni *et al.*, 1995).

Besides the barley malt, beer contains other ingredients, including wheat, hops or yeast, which may cause an allergic reaction. They also have been investigated as elicitors of observed allergic symptoms.

Wheat

In 2004, the unusual case of severe anaphylaxis following the ingestion of wheat beer was reported (Herzinger *et al.*, 2004). The patient tolerated lager beer well, but experienced angioedema, generalized urticaria and unconsciousness after ingesting wheat beer. Skin prick tests were positive for wheat flour, but negative for baker's yeast, hops and a brand of lager beer. Specific IgE antibodies to wheat were found in blood serum of the patient. Immunoblot analysis revealed that patient's IgE was bound to a protein of approximately 35 kDa in wheat extract.

Hops

Pradalier *et al.* (2002) reported on a patient who presented four times with systemic urticaria, arthralgias and fever treated successfully with corticosteroids. Wild hop was finally proved to be the causal factor. Hop dermatitis in hop workers population is the most widely described clinical manifestation. Rhinitis, conjunctivitis and asthma are rare as well as contact urticaria.

Yeast

All alcoholic drinks depend on specific yeast metabolism to produce alcohol – obtaining the well-known health risk.

However, in contrast to popular believing, yeast in alcoholic beverages causing allergy is very rare. No allergenic difference has been observed between baker's yeast and brewer's yeast.

Ethanol

As little as 1 ml of pure alcohol (equivalent to 10 ml of wine or a mouthful of beer) is enough to provoke severe rashes, difficulty breathing, stomach cramps or collapse, a condition known as anaphylaxis. Given that the body constantly produces small amounts of alcohol itself, the reason that such reactions occur is poorly understood, but closely associated to gastric histamine release (Diel *et al.*, 1981). Allergy examinations using alcohol are usually negative, but sometimes positive to breakdown products of ethanol such as acetaldehyde or acetic acid. For example, a comprehensive allergological approach in a patient exhibiting hypersensitivity reactions toward beverages and medication containing alcohol led to the observation that the ethanol metabolite acetic acid yielded positive prick test results in concentrations not eliciting reactions in healthy and atopic controls (Boehncke and Gall, 1996). Finally, alcohol can sometimes act as a "co-factor," increasing the likelihood of anaphylaxis from other causes as stated initially.

In a summarizing conclusion it can be stated that different to the declaration of food additives, there is no legal requirement for beer makers to list the ingredients of their product on the can or bottle. However, beer can contain a number of ingredients other than the basic malted grain, hops, water and yeast, as, for example, health risk relevant histamine and biogenic amines.

Organic beers (bio-beer) have a growing consumer base as breweries must conform to stringent standards, anecdotally there appears to be lessened allergic reactions to this type of beer.

Summary Points

- Histamine in beer is a product of microbial metabolism. It is synthesized by decarboxylation of histidine and is mainly be metabolized by amino-oxidases and methyltransferases.
- Histamine concentration is measured fluorimetrically after HPLC separation and ranges 0.4 mg/ml in bottled beer up to 35 mg/l in beer on-draft from typical German bars.
- The sensory threshold of histamine in tap water: $2.5 \pm 1.5 \,\mu\text{M}$ (SDM, $n = 10$).
- Other biogenic amines are also relevant and specifically associated to ingredients like malt (spermidine, putrescine, spermine, agmatine, tyramine …) and hop (spermidine, spermine, phenylalanine, tyramine, putrescine …).

- In a pilot study it could be shown that mechanically cleaning of the tap and the storage devices reduces histamine concentrations up to 35% and combined mechanical and chemical hygienic prevention even 93%, respectively.
- Brewing and brewery location are most important factors for the *Enterobacteriaceae*, *Lactobacillae*, *Pediococcus* and *Staphylococcus* spp. derived biogenic contaminations.
- Specific mammalian histamine responses are discussed and special focus is laid on histamine-activated GPCR, the signal transduction induced by the gastro/intestinal (H2R) and the "new" lymphocyte (H4R) histamine receptor.
- It can be suggested that beer consumption is better than wine related to the prevalence of allergic reactions. Specific "beer allergies" are very rare and only a few articles are published on this matter in the international literature.

Terpenoids in Beer

J. Richard Dickinson Cardiff School of Biosciences, Cardiff University, Cardiff, UK

Abstract

Terpenoids are all derived from the intermediary metabolite isopentyl pyrophosphate. Terpenoids in beer derive mainly from hops. They impart important organoleptic properties to beer. Some are metabolized by yeast during fermentation to other terpenoid compounds. Yeast's ergosterol biosynthetic pathway also comprises intermediates that can potentially serve as precursors to important terpenoids such as farnesol, geraniol and linalool. Attempts to manipulate this pathway for enhanced terpenoid production are now proving successful. One terpenoid in particular (farnesol) has attracted particular attention since it has been demonstrated to have a wide spectrum of desirable properties including: anti-tumour, antioxidative, antifungal and antibacterial effects. Farnesol has been shown to act synergistically at low levels with other compounds/cellular components in some experimental systems. For prevention of oxidative stress or carcinogenesis and tumor development, the required doses of farnesol or geraniol could never be provided by the consumption of beer. However, the farnesol obtained by beer drinking could play a very useful part in antibacterial and some antifungal therapies. A possible role for farnesol in prevention of Parkinsonism warrants further investigation.

Introduction

Terpenoids are all derived from isopentyl pyrophosphate (Figure 31.1). They occur widely in nature and include monoterpenoids (C_{10} comprised of two isopentyl units), sesquiterpenoids (C_{15} comprised of three isopentyl units), diterpenoids (C_{20} four isopentyl units), triterpenoids (C_{30} six isopentyl units), carotenoids, sterols, phytols and quinones. Monoterpenoids and sesquiterpenoids have strong sensory qualities and are highly valued for their flavors and fragrances. They are found in the essential oils of plants (Bauer *et al.*, 1990). Those terpenoids which are important in beers are shown in Figure 31.2 along with their aromas. From perusing Figure 31.2 it is clear that different isomers of a particular terpenoid can have varying
Figure 31.1 *Isopentyl pyrophosphate: the basic building block of terpenoids.* For simplicity the molecule has been drawn as a line structure in which individual carbon atoms are omitted.
Figure 31.2 *The structures of terpenoids present in beers and their aromas.* 1: geraniol (floral, rose-like, citrus); 2: linalool (floral, fresh, coriander); 3: citronellol (sweet, rose-like, citrus); 4: nerol (floral, fresh, green); 5: α-terpineol (lilac); 6: terpinen-4-ol (spicy, medicinal); 7: linalool oxide (herbaceous, medicinal); 8: nerolidol (floral); 9: farnesol (floral); 10: β-myrcene (medicinal); 11: α-pinene (pine); 12: β-pinene (pine); 13: limonene (sweet, spicy, citrus); 14: α-humulene (medicinal); 15: β-caryophyllene (herbaceous); 16: β-caryophyllene oxide (spicy). The aromas assigned to each compound are as described by Bauer *et al.* (1990). This figure was re-drawn from King and Dickinson (2003) with permission.

aromas. For example, geraniol (structure "1" in Figure 31.2) is ascribed a rose-like "citrus" odor, whereas the *cis* isomer, nerol (structure "4"), has a fresh, "green" odor (Bauer *et al.*, 1990). The use of hops (*Humulus lupulus*) in beer making is detailed elsewhere in this volume. Suffice to say, that the essential oil of hops is extremely complex comprising over 200 constituents including terpenoids (Sharpe and Laws, 1981). It is well-known, especially among beer drinkers, that hops impart bitterness and aroma. In past times, hops were also used as preservatives of fermenting worts and finished beers. This notion is disputed by some but it should be recalled that until the advent of municipal water treatment and chlorination, beer was drunk daily by the whole population because it was safer than the water that was available. Undoubtedly, the fact that the water used in beer making was heated (in the wort-boiling step) played a part in its increased potability. However, until relatively recently in terms of the history of brewing, beers were generally brewed to a much lower alcohol content. Hence, a preservative effect is credible. It is appropriate that a twenty-first century appreciation of the health benefits of beers should appraise the contribution of terpenoids.

Terpenoids in Beers

Analysis of the levels of hop-derived terpenoids in beers is not entirely straightforward. Usually, extraction into a solvent (Cocito *et al.*, 1995) is followed by concentration and then detection and quantitation by gas chromatography – mass spectrometry (GCMS). Recently, a new extraction method known as "stir bar-sorptive extraction" (SBSE) has been developed. This is based on the partition coefficient between poly(dimethylsiloxane) and water. A magnetic stirrer bar is coated with poly(dimethylsiloxane) and immersed in the beverage for about 2 h after which it is washed, dried and thermally desorbed into a GCMS. It has been shown to be very suitable for analysis of beers with low-intensity hop aromas such as those from Japan (Kishimoto *et al.*, 2005). One fact is agreed by all: the majority of hop oil is lost during wort boiling. Consequently, (as pointed out by Sharpe and Laws, 1981) brewers have devised a number of strategies to ensure that their products have an appropriate hoppy character. These include late addition of hops to the wort-boiling kettle; restricted evaporation during wort boiling; addition of hops, hop pellets, powdered hops or hop oil at later stages (e.g. during conditioning or prior to final filtration).

The concentrations of the different terpenoids present in finished beer is not the same as in fresh wort. Several different processes occur during fermentation and maturation. The more volatile components simply evaporate. Some adsorb to the various external and internal components of yeast cells and others are metabolized by the yeast. Despite the great differences in beer types, tastes and aromas, the concentrations of many of the terpenoids in beer when actually consumed are surprisingly similar. (The reader is

Table 31.1 The range of concentrations of some terpenoids found in beers

Compound	Concentration range (µg/l)
β-Caryophyllene	0.0–0.2
Citronellol	3.0–22.1
Farnesol	0.0–0.1
Geraniol	2.2–6.1
α-Humulene	0.0–0.2
Linalool	0.0–21.9
β-Myrcene	0.0–0.5
α-Terpineol	0.0–45.0

Note: The table shows the lowest and highest concentration of each compound reported in beers from around the world over the last 40 years.

reminded that terpinoids are not the sole flavor and aroma compounds present.) Typical ranges are shown in Table 31.1. From the literature, linalool and α-terpineol display the greatest concentration ranges between beers. The farnesol concentration is frequently below the limit of detection.

King and Dickinson (2003) showed that ale and lager yeasts transform the monoterpene alcohols geraniol and linalool during fermentation. In both cases, citronellol was the most abundant product from geraniol. Smaller amounts of linalool, nerol and α-terpineol were also formed. In addition, lager yeast also produced acetate esters of geraniol and citronellol. Linalool was metabolized into α-terpineol, geraniol and nerol. We have little knowledge of the enzymes involved in these transformations (and the genes which encode them). Such a lack of knowledge has not prevented the exploitation of yeast for regio-selective biotransformations in other areas, but the biochemical mind is left unsatisfied. However, one such enzyme activity has been identified. This is an activity which is capable of de-phosphorylating farnesyl pyrophosphate to farnesol, geranyl pyrophosphate to geraniol and geranylgeranyl pyrophosphate to geranylgeraniol (Song, 2006). The activity was assigned to yeast's Pho8p. Geranyl pyrophosphate, farnesyl pyrophosphate and geranylgeranyl pyrophosphate are all intermediates in yeast's sterol biosynthetic pathway which culminates in the end product ergosterol (Figure 31.3) and where the gene products are all well characterized.

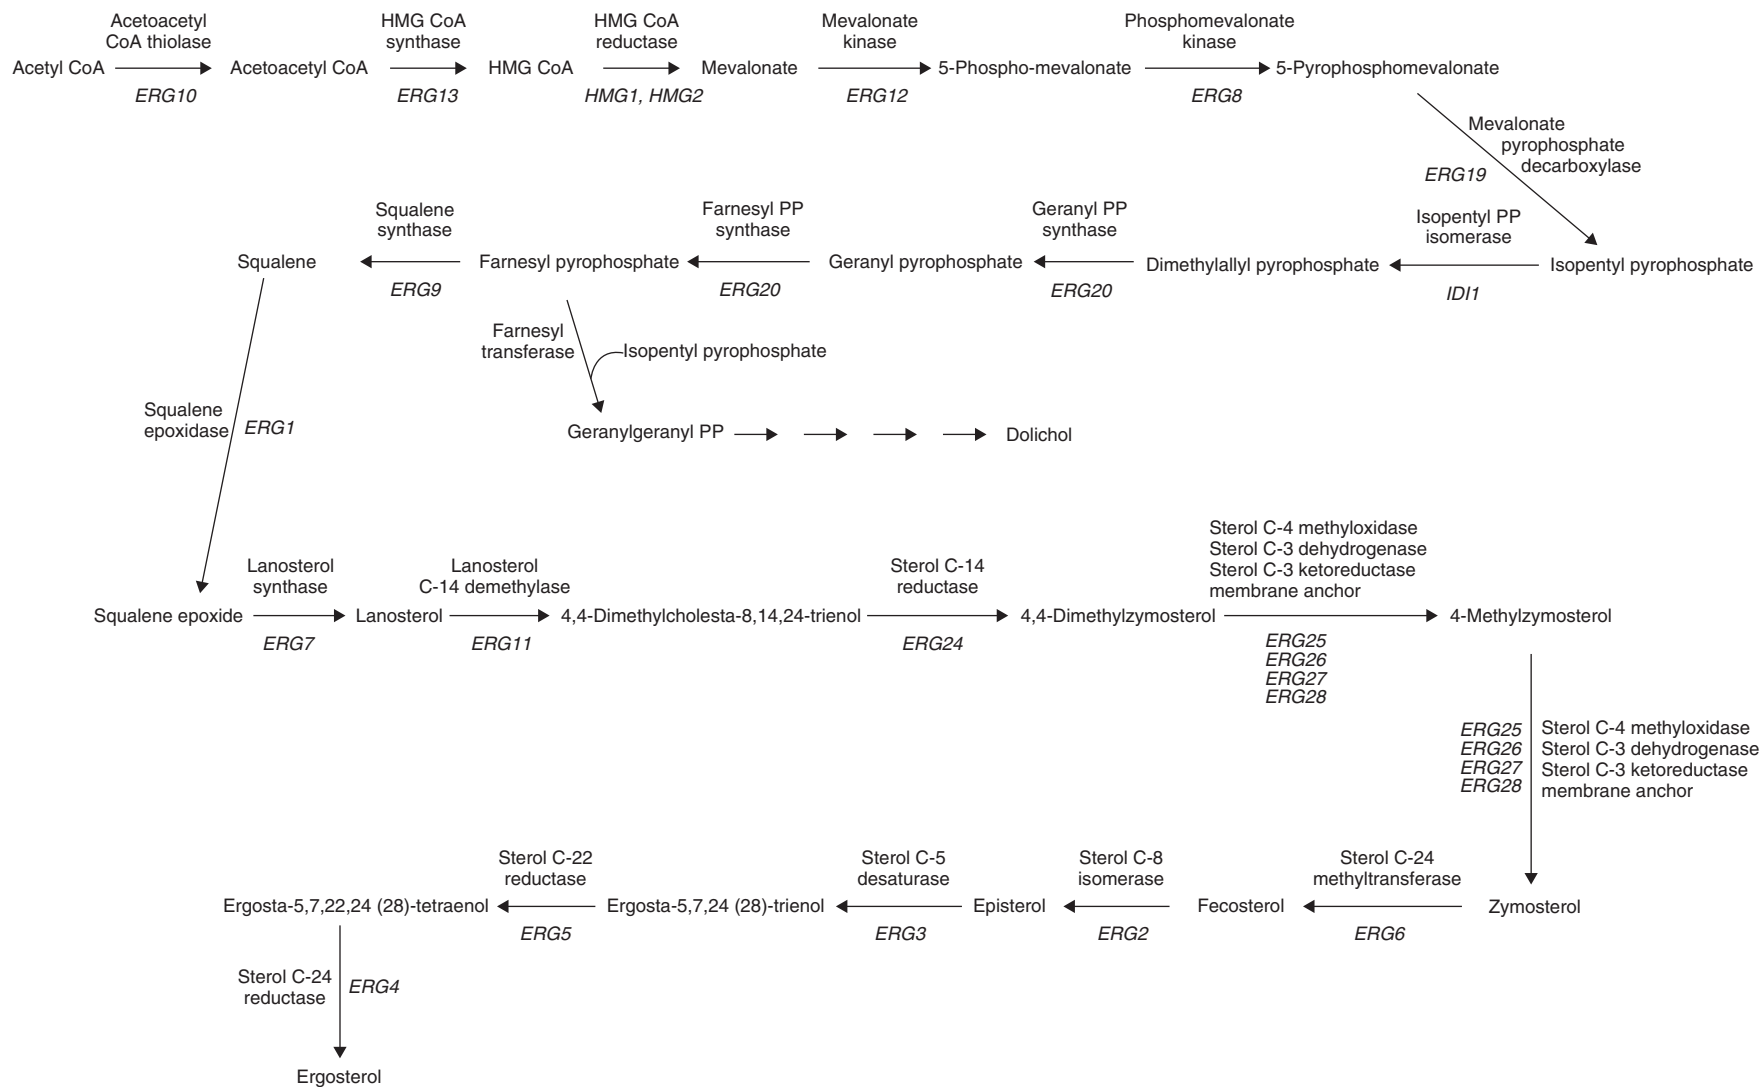
Ergosterol is an essential membrane component in yeast and the ergosterol biosynthetic pathway has received considerable attention over the years from researchers eager to modify the pathway to allow enhanced production of specific terpenoids. The reason for wanting to do this is that most terpenoids are currently produced by chemical and/or physical extraction from plant materials or by chemical modification of another terpenoid. Using a yeast culture (with appropriately modified metabolism) to synthesize high levels of a specific terpenoid is an attractive commercial proposition. "Spent" Brewer's yeast which is available in huge quantities worldwide (which commands at best a low


Figure 31.3 *The ergosterol biosynthetic pathway in yeast.* The diagram shows the complete biosynthetic pathway from acetyl CoA to ergosterol. The name of the third intermediate in the pathway (3-hydroxy-3-methyl-glutaryl-CoA) has been shortened to its usual abbreviation "HMG-CoA". Also shown in abbreviated form is the important branch point from farnesyl pyrophosphate via geranylgeranyl pyrophosphate to dolichol. Enzyme names are given (mainly above arrows). The genes which encode each enzyme are denoted by the approved acronym in italics (mainly below arrows).

price for use in products such as "Marmite" or animal feed, and at worst costs the brewer money for disposal) could enjoy a very profitable "second life" in terpenoid production. At present, however, given brewers' apparent universal refusal to use genetically modified strains, this seems an unlikely prospect. Nevertheless, yeast-produced terpenoids, using strains designed solely for this purpose, must arrive in the near future.

Manipulation of Metabolism

Mutants affected in the ergosterol synthesis pathway provided the first step toward the goal of yeast-produced terpenoids. For example, a mutation in the *ERG20* gene which encodes farnesyl pyrophosphate synthase results in excretion of geraniol and linalool but not farnesol (Chambon *et al.*, 1990, 1991). Some attempts to use mutants affected in the ergosterol pathway have been thwarted by its in-built regulation. The early stages are particularly tightly regulated. For example, the first enzyme, acetoacetyl CoA thiolase is subject to feedback regulation by ergosterol acting through translation (Dimster-Denk and Rine, 1996). The two isoenzymes of HMG CoA reductase (encoded by *HMG1* and *HMG2*) are differentially regulated. HMG1p is most abundant during aerobiosis whilst HMG2p is the abundant form under anaerobiosis (Bard and Downing, 1981). Hence, attempts to manipulate the pathway by either genetic or physiological conditions must take account of this situation. Both isoenzymes, but especially HMG1p, are subject to feedback inhibition by ergosterol (Kawaguchi, 1970; Casey *et al.*, 1991). HMG CoA reductase activity is also affected by fatty acid levels. In particular, palmitoleic acid positively regulates HMG1p, whilst oleic acid inhibits HMG2p (Casey *et al.*, 1992). The stabilities of these two crucial enzymes also vary: HMG1p is very stable but HMG2p is prone to rapid degradation during anaerobiosis (Hampton and Rine, 1994). It has been postulated that the two isoenzymes of HMG CoA reductase evolved to allow yeast to control metabolic flux under anaerobic conditions (Hampton *et al.*, 1996). Under aerobic growth, the majority of mevalonate will be converted to ergosterol (and its esters.) These molecules can all be accommodated safely within the yeast cell. During anaerobiosis, sterol production is not possible (because the squalene epoxidase step requires molecular oxygen). Hence ergosterol levels cannot be used to regulate the pathway. However, the yeast cell still requires several compounds that are derived from mevalonate (albeit at reduced rates). These are toxic if allowed to accumulate significantly. Thus, the ability to degrade HMG2p during anaerobiosis is important if these mevalonate-derived materials start to accumulate. It should also be noted that the activity of mevalonate kinase is inhibited by high levels of farnesyl pyrophosphate (Chambon *et al.*, 1991). All this might lead the faint-hearted to conclude that manipulation of the pathway to yield substantially greater metabolic flux into, for example, farnesol or geraniol is bound to fail because of the array of compensatory regulatory mechanisms.

The expression of heterologous (i.e. deriving from sources other than yeast) activities in yeast may be one way around the problem of complex and tight regulation of its own ergosterol pathway. A very recent study (Oswald *et al.*, 2007) described the expression of "geraniol synthase" (an enzyme converting geranyl pyrophosphate to geraniol) from *Ocimum basilicum* (sweet basil) in laboratory strains of *Saccharomyces cerevisiae* which resulted in the excretion of significant quantities (approximately 500 µg/l) of geraniol and linalool into the growth medium. These authors concluded that this shows that wild-type yeast strains contain sufficient levels of available geranyl pyrophosphate for conversion by appropriate enzymes. They contend that it is the absence (non expression?) of the enzymes, not a lack of geranyl pyrophosphate, that explains the normal lack of monoterpenoid alcohols. Oswald *et al.* (2007) also reported a further increase in geraniol synthesis when expressing the plant enzyme in yeast mutants defective in farnesyl pyrophosphate synthase. Not surprisingly, expression of the plant protein also affected yeast's ergosterol pathway. In one strain the level of ergosterol fell about 30% but in another strain (with a different genetic background) there was little change. This clearly shows that we have much more to learn about the metabolic consequences of different genetic backgrounds but it also shows there is considerable scope for further work. This could include the use of other heterologous enzymes, different genetic backgrounds and eventually, fine tuning of industrial production strains and operating processes all of which can be reasonably expected to yield further significant improvements upon the initial "proof of principle."

The Biological Effects of Terpenoids

Besides their involvement in flavors and fragrances, a huge variety of effects have been ascribed to individual terpenoids and to essential oils which contain mixtures of terpenoids and other bioactive chemicals. These include antibacterial, antifungal, insecticidal, medicinal and wound-healing effects. Much of this knowledge pre-dates modern science and medicine and forms the basis of folklore remedies and cures. Nevertheless, many modern enquiries focussing on a single pure terpenoid serve to substantiate the old knowledge. In these modern enquiries one compound is pre-eminent: farnesol. The following subsections of this chapter detail a few of the effects which have recently been ascribed to this remarkable molecule.

Antibacterial effects

The position of *Staphylococcus aureus* as a major pathogen is well-known. The general public has become aware of

"MRSA," even if unable to specify that the acronym stands for "methicillin resistant *S. aureus.*" The organism causes infections of the bloodstream and forms biofilms on host tissues and indwelling medical devices (catheters, pacemakers, etc.). Its resistance to antibiotics is almost always greater when growing as a biofilm than in planktonic (freely suspended) form. Thus, it was interesting to read that farnesol has been shown to inhibit biofilm formation in both methicillin resistant and susceptible strains (Jabra-Rizk *et al.*, 2006). Although high concentrations of farnesol (150 nM) were required to reverse resistance to antimicrobial compounds, it was found to enhance the effectiveness of all of the antibiotics to which both types of organism were partly susceptible. Furthermore, farnesol acted synergistically with gentamicin and at 100 nM (22 ng/ml) reduced bacterial growth by 2 log units. These results indicate that farnesol could be used as an adjuvant (i.e. to increase the efficacy) to current antibiotics.

Antifungal effects

Candida albicans is a fungus which can exist in yeast, pseudohyphal and hyphal forms. It is a normal part of the human microflora and in most individuals causes no problem throughout life. However, there are a variety of situations in which infections by this organism can become at least troublesome and at worst deadly. These include the after-effects of antibacterial treatment in which *C. albicans* flourishes in the absence of bacterial competitors, hormonal fluctuations in women, immune suppression (e.g. as a result of HIV infection or treatment with immune suppressing drugs following a transplant) or post-operative systemic infection. It is the third most common cause of nosocomial (hospital acquired) infections. Systemic infection carries a 50% risk of death. The yeast to hyphal transition is widely believed to form a key part of the virulence of *Candida*. The yeast form facilitates dispersal and the hyphal form facilitates penetration of cells and tissues. *C. albicans* produces farnesol to regulate the yeast to hyphal transition (Ramage *et al.*, 2002) and the formation of biofilm (Hornby *et al.*, 2003). Candidiasis is currently treated with antifungal agents such as polyene antibiotics, flucocytosine and azoles. The range of antifungal drugs is clearly limited, some have undesirable side effects and/or counter-indications and resistances are emerging. *In vitro* studies have shown that farnesol not only reduced the growth of *C. albicans*, but also exerted synergistic effects with human gingival tissue (i.e. when *C. albicans*, farnesol and gingival cells were present together, there was much greater inhibition of the yeast to hyphal transition than when farnesol was applied to *Candida* alone) (Saidi *et al.*, 2006.) Farnesol concentrations as low as 10 μM were effective. The approach was not without problems, because farnesol caused some damage to gingival cells. However, as no drug treatment is without side effects, further study of the use of farnesol (possibly as an adjuvant at lower dose) is warranted.

Prevention of carcinogenesis and tumor progression

Rats fed farnesol in their diets for eight consecutive weeks subsequently showed fewer hepatocyte nodules in their livers than geraniol-fed animals compared to controls which received only corn (maize) oil. Compared to the control animals, those consuming either farnesol or geraniol also showed reduced preneoplastic lesion cell proliferation and DNA damage (Ong *et al.*, 2006). Consequently, Ong *et al.* (2006) conclude that both farnesol and geraniol are promising chemopreventative agents against hepatocarcinogenesis. The rats were fed the terpenoids at 25 mg/100 g body weight. If the same dosage were required in a human weighing 75 kg, this would require a terpenoid intake of 18.75 g. Using an upper range for the geraniol concentration in beer of 5 μg/l (see Table 31.1), this would require the consumption of 3,750,000 l of beer! Whilst the health benefits of farnesol and/or geraniol may be undeniable, it is quite obvious that intake at these levels will not come from beer (even if its terpenoid concentrations were to be raised 1,000-fold as seems feasible from the work of Oswald *et al.* (2007)).

Prevention of oxidative stress

Excess iron brings about organ dysfunction in mammals. A principle cause of this is oxidative damage to cells. When rats were given farnesol for 7 days before intoxication with iron, they were able to reverse a wide range of the biochemical processes in their kidneys (markers of oxidative damage) which usually occur. Markers of tumor progression were also reduced in a dose-dependent fashion (Jahangir *et al.*, 2006). Once again, the doses were impossibly huge if one were to attempt to supply the farnesol as beer.

Selective inhibition of monoamine oxidase B in the brain

Inhibition of monoamine oxidase B in the brain protects against the induction of Parkinsonism by a range of chemicals. Farnesol has been demonstrated to selectively inhibit monoamine oxidase B of rat brain (Khalil *et al.*, 2006). Farnesol did not inhibit human placental monoamine oxidase A nor beef liver monoamine oxidase B. Assuming that farnesol can cross the blood–brain barrier, this would indicate that low levels of farnesol may have a beneficial effect in prevention of onset of this debilitating neurological disorder.

Are the Terpenoids in Beers Good for Us?

The recent experiments detailed all point to farnesol and geraniol having beneficial effects for human health and disease prevention. However, as noted above, it is clear that for

prevention of oxidative stress or carcinogenesis and tumor development, the doses required are at pharmaceutical levels and could never be provided by the daily consumption of a few glasses of beer. However, it seems reasonable to conclude that farnesol obtained by beer drinking could play a very useful part in antibacterial and some antifungal therapies because the synergism demonstrated (with other antibiotics or even tissues) requires much lower amounts of this terpenoid. The work by Saidi *et al.* (2006) found that regular doses of farnesol every 2 h was particularly effective against oral candidiasis. This would fit well with the regular taking of an antibiotic. Of course, since the medical profession's routine advice is that alcoholic drinks must not be consumed whilst on a course of antibiotics, either the advice must change when farnesol is an adjuvant or the patient must drink alcohol-free beer! With regard to farnesol's selective inhibition of rat brain monoamine oxidase B, it would be very interesting to know if this finding can be replicated in human brain. If as seems likely, it is, then a detailed evaluation of the rates of Parkinsonism amongst beer drinkers and non-beer drinkers could prove illuminating.

In the United Kingdom and elsewhere, a number of food items are required by law to contain supplements. Well-known examples include lysine in flours and vitamins A, B_6, B_{12}, D, E and folic acid in margarines and vegetable oil-based spreads. One is tempted to wonder if we ever see the time when beers are required to contain statutory levels of selected terpenoids. If this ever happens the flavor and aroma of many beers would suffer some extreme changes.

Summary Points

- Terpenoids in beer derive mainly from hops.
- They impart important organoleptic properties to beer.
- Some are metabolized by yeast during fermentation to other terpenoid compounds.
- Yeast's ergosterol biosynthetic pathway comprises intermediates that can potentially serve as precursors to important terpenoids such as farnesol, geraniol and linalool.
- One terpenoid in particular (farnesol) has attracted particular attention since it has been demonstrated to have a wide spectrum of desirable properties including: anti-tumor, anti-oxidative, antifungal and antibacterial effects.
- Farnesol has been shown to act synergistically at low levels with other compounds/cellular components in some systems.

- For prevention of oxidative stress or carcinogenesis and tumor development, the required doses of farnesol or geraniol could never be provided by the consumption of beer.
- The farnesol obtained by beer drinking could play a very useful part in antibacterial and some antifungal therapies.
- A possible role for farnesol in prevention of Parkinsonism requires further investigation.

Proanthocyanidins in Hops

Hui-Jing Li and Max L. Deinzer Department of Chemistry, Oregon State University, Corvallis, OR, USA

Abstract

Liquid chromatography–tandem mass spectrometry (LC/MS^n) coupled with various two-dimensional NMR methods are among the most practical approaches for analyzing proanthocyanidins from hops. Using these and other analytical approaches, it has been shown that hops contain a preponderance of polymeric material, including proanthocyanidins which are dominant, but small quantities of prodelphinidins and propelargonidins are also present. The flavanoids (+) catechin and proanthocyanidin B3 are the most representative followed by B1, B4 and C2. The relative proportions of the various proanthocyanidins vary greatly depending on the variety and climatic conditions as shown by differences in the proanthocyanidins in the same cultivar from different geographic regions. Proanthocyanidins have received a considerable amount of attention in the brewing industry because of their tendency to complex with proteins and contribute to non-biological haze formation, but they stabilize the organoleptic properties and color, and contribute to the astringency and bitterness, which are desirable attributes. Recent studies also show that these compounds, which are classic antioxidants, may also have significant beneficial health effects. Numerous proanthocyanidins including catechin, prodelphinidin B3, procyanidin B3 and epicatechin are present in beer.

List of Abbreviations

APCI	Atmospheric pressure chemical ionization
BFF	Benzofuran-forming fission
C	Catechin
DP	Degree of polymerization
EC	Epicatechin
(E)C	(epi)catechin
(E)GC	(epi)gallocatechin
GC	Gallocatechin
GPC	Gel permeation chromatography
HPLC	High-performance liquid chromatography
HRF	Heterocyclic ring fission
LC/ESI-MS^n	Liquid chromatography/electrospray ionization multistage tandem mass spectrometry
mDP	Mean degree of polymerization
MS	Mass spectrometry
NMR	Nuclear magnetic resonance
PAs	Proanthocyanidins
PC	Procyanidins
PD	Prodelphinidins
PP	Propelargonidins
PVPP	Polyvinylpolypyrrolidone
QM	Quinone methide fission
RDA	Retro-Diels–Alder fission
TLC	Thin layer chromatography

Introduction

Beer is the most widely consumed beverage in the world. Of all the herbs that have been used in beer, only the hop (*Humulus lupulus* L., Cannabinaceae) plant has gained widespread acceptance and is regarded as an essential raw material in the brewing industry (Moir, 2000). Hops are perennial plants grown on trellises, and different varieties are derived from breeding programs. The hop plant is dioecious and cultivated in most temperate zones of the world for its female inflorescences, which are commonly referred to as hop cones or simply hops. The female flower clusters are partly covered with lupulin glands, while male flowers have only a few glands in the crease of their anthers and on their sepals. The resin secreted by these glands contains bitter acids, essential oils and flavonoids (flavonol glycosides, prenylflavonoids and proanthocyanidins) (Stevens *et al.*, 2000). Hops or hop products account for the bitter taste and the flavor of beer. In addition, hops have a favorable influence on the stability of beer foam and contribute to the microbiological stability of beer. Different hop cultivars are traditionally classified into three groups, that is, aroma (noble) hops (e.g. cv. Saaz, Hallertau, Hersbruck, Cascade, Mt Hood), high α-bitter hops (e.g. cv. Northern Brewer, Wye Target, Nugget) and intermediate α-bitter hops (e.g. cv. Kent, Cluster, Brewers Gold). Modern brewing technology allows for the post-fermentation introduction of a variety of hops or hop preparations to adjust bitterness levels and to control formability. Brews may benefit from proper selection of particular hop

varieties that add subtle tastes and flavors. Therefore, it is important to know the nature of the hop constituents in different varieties. Among various hop constituents, hop proanthocyanidins have attracted increasing attention, and have been considered as the most reactive of hop polyphenols.

Proanthocyanidins, better known as condensed tannins, are flavan-3-ol oligomers and polymers that give anthocyanidins upon acid-mediated oxidative depolymerization reactions. Proanthocyanidins are widely distributed throughout the plant kingdom, and are present as the second most abundant class of natural phenolic compounds after lignin. There is a growing body of evidence linking these compounds with plant defense mechanisms, organoleptic characteristics and stabilizing effects of pigments in plants (Stevens *et al.*, 2002; Merghem *et al.*, 2004; Callemien *et al.*, 2005; Jerkovic *et al.*, 2005; Maatta-Riihinen *et al.*, 2005; Zhou *et al.*, 2005). Proanthocyanidins exhibit general toxicity toward fungi, yeast and bacteria. They account for astringent properties of many commonly consumed fruits and their beverage products presumably because of interactions with salivary proteins that might contribute to astringency. They also exhibit a wide range of biological activities through their action as antioxidants that lead to protection against cardiovascular disease, immune disorders and neurodegenerative diseases.

Proanthocyanidins or oligomeric proanthocyanidins, names that are often used interchangeably, consist of sequences of phenolic compounds built from single monomer units called afzelechin, epiafzelechin, catechin, epicatechin, gallocatechin and epigallocatechin (Figure 32.1). Although usage of the word "oligomeric" varies somewhat, dimers, trimers and up to heptamers are generally referred to as oligomeric ($n = 2–7$, Figure 32.1), while larger chains are referred to as polymeric or as tannins ($n = 8–24$, Figure 32.1). These flavan-3-ol monomer units are sometimes esterified with gallic acid to form 3-*O*-gallates. Proanthocyanidins can be divided into A-type and B-type proanthocyanidins. The latter are flavan-3-ol oligomers and polymers linked mainly through C4→C8 and sometimes C4→C6 bonds. When an additional ether linkage is formed between C2→O→C7, the compounds are called (C4→C8 or C4→C6) A-type proanthocyanidins. These compounds are also classified as procyanidins, propelargonidins and prodelphinidins. The proanthocyanidins consisting exclusively of (epi)catechin are designated procyanidins. Those containing (epi)afzelechin or (epi)gallocatechin subunits are named propelargonidins or prodelphinidins, respectively. These compounds are mostly heterogeneous in their constituent units and co-exist with procyanidins. Proanthocyanidin structures (Figure 32.1) vary depending on their stereochemistry and the hydroxylation pattern of the flavan-3-ol starter and extension units, the position and stereochemistry of the linkage to the lower unit, the degree of oligomerization, and the presence or absence of modifications such as esterification of the 3-hydroxyl group. The building blocks of most proanthocyanidins are the flavan-3-ols of (+)-catechin and (−)-epicatechin with 2,3-*cis*-stereochemistry of (−)-epicatechin and the 2,3-*trans*-stereochemistry of (+)-catechin.

Up to 30% of the proanthocyanidins present in beer are derived from hops; the rest are derived from the malt.
Figure 32.1 Flavanol units of proanthocyanidins (PAs) in hop cones; n: degree of polymerization; A–F: ring labels.

The estimated amount of total hop proanthocyanidins ranges from 0.5% to 5% on a dry weight basis, depending on the variety, geographic origin, freshness and harvesting procedure (Stevens *et al.*, 2002; Callemien *et al.*, 2005). The effects of hop proanthocyanidins in beer depend on their affinity for the proteins that is largely determined by their chemical structures. Therefore, knowing something about the composition and distribution of proanthocyanidins in different hops has become increasingly important. The discussion in this chapter concerns proanthocyanidin composition and their distribution in different hop varieties.

Proanthocyanidin Composition in Hops

Proanthocyanidin compounds in hop samples can be resolved at the preparative scale by a number of chromatographic procedures including such stationary phases as Sephadex G25, Sephadex LH-20 and Toyopearl TSK HW 40 (Ricardo Da Silva *et al.*, 1991; Stevens *et al.*, 2002). A reliable and efficient strategy for the isolation and purification of hop proanthocyanidins involves extraction of the hops with aqueous acetone followed by the removal of the solvent. The resulting extracts are washed with hexane to remove nonpolar material, then with dichloromethane to remove pigments, flavonoids and lipids followed by column chromatography to separate and collect proanthocyanidins and monomeric flavan-3-ols (Taylor *et al.*, 2003).

Previous investigators elucidated the structures of hop proanthocyanidins by combinations of gel permeation chromatography (GPC), high-performance liquid chromatography (HPLC), nuclear magnetic resonance (NMR), acid-catalyzed degradation and mass spectrometry (MS). The mean degree of polymerization (mDP) of crude Willamette hops (Oregon, 2000) proanthocyanidins was shown to be 7.8, with heptamers being the largest oligomers visible in the mass spectra. Seven proanthocyanidins from Saazer hops were elucidated by MS, NMR and chemical degradation, and another 10 were isolated and identified by liquid chromatography–atmospheric pressure chemical ionization tandem MS (HPLC/APCI-MS/MS), and acid-catalyzed degradation in the presence of phloroglucinol, or by partial or complete acid-catalyzed degradation and reaction with benzyl mercaptan followed by desulfurization. Finally, a systematic study was performed on Oregon-Willamette female hop varieties by electrospray ionization multistage tandem MS (ESI-MS^n) through which a total of 25 proanthocyanidins were identified. A new protocol to reliably sequence proanthocyanidin oligomers as described below emerged from these studies.

Molecular weight distribution of proanthocyanidin mixtures

Proanthocyanidins can differ in degree of polymerization (DP), subunit composition and type of linkage between subunits (Porter, 1988). As oligomer size increases, the possible number of isomers increases as well, making chromatographic resolution into pure compounds increasingly difficult. Hop proanthocyanidin mixtures were characterized by acid catalysis, GPC and by MS to give a profile of the molecular weight distribution. Although the individual fractions still were mixtures, a better picture of size distribution is revealed than could be gained from analysis of the whole hop cones.

The mass spectra are usually dominated by the monomers and lower-molecular-weight oligomers, even though chemical methods indicate that large proanthocyanidins are present in appreciable quantities. As demonstrated by Taylor *et al.* (2003), MS methods may not reflect the DP of proanthocyanidins but only the relative ease of ionization or transmission of the ions. A series of solvent mixtures (Table 32.1) was used to rinse the crude proanthocyanidin extracts, which were pooled into eight fractions. The sub-unit composition and DP of the "total" sample and the eight pooled samples were analyzed by acid catalysis in the presence of excess phloroglucinol (Table 32.2).

The proanthocyanidins in Willamette hops are a complex mixture with a large molecular weight range. Catechin is the main terminal unit, and epicatechin is the major extension unit. Prodelphinidin epigallocatechin comprises 25% of the extension unit. In chromatograms of the acid cleaved products, a minor peak ($\sim$5 mol%) was observed that is believed to be a prodelphinidin extension unit, and is likely a gallocatechin–phloroglucinol.

The average sample retention times correlate with the molecular weights of the samples. Proanthocyanidins elute later from Sephadex LH-20 because of their greater hydrodynamic volumes. In fact, a comparison of the average molecular weights of the samples determined by compositional and mDP information from acid catalysis (Table 32.2) with their respective chromatographic retention times indicates that these properties are strongly correlated ($R^2 = 0.996$).

Structure identification of individual proanthocyanidins in different hops

The major hop proanthocyanidins, catechin (Stevens *et al.*, 2002), epicatechin (Stevens *et al.*, 2002),

Figure 32.2   HPLC chromatogram of Oregon-Willamette hop proanthocyanidins. HPLC separations were performed on a 250 mm × 4.6 mm Synergi 4 μm Hydro-RP-80A column with a linear gradient of 5–50% methanol in 1% aqueous formic acid over a 50 min period at 0.8 ml/min. Eluting peaks were monitored at 280 nm (Li and Deinzer, 2006).

epicatechin-(4β→8)-catechin (procyanidin B1) (McMurrough, 1981), epicatechin-(4β→8)-epicatechin (procyanidin B2) (McMurrough, 1981; Moll *et al.*, 1984), catechin-(4α→8)-catechin (procyanidin B3) (McMurrough, 1981; Moll *et al.*, 1984), catechin-(4α→8)-epicatechin (procyanidin B4) (McMurrough, 1981; Moll *et al.*, 1984) and epicatechin-(4β→8)-catechin-(4α→8)-catechin (Stevens *et al.*, 2002), were identified early on by several research groups using NMR, HPLC, MS and chemical degradation. But it was difficult to elucidate the structures of minor hop proanthocyanidins by NMR because of both the low amounts available and the multiplicity and broadening associated with rotational and conformational isomerism that often complicates the interpretation of the spectra. Systematic chemical degradation coupled with HPLC and MS technologies was a strategy that helped in the identification of some minor amounts of proanthocyanidins in hops.

Structural Identification of Isolated Hop Proanthocyanidins   A liquid chromatogram of a hop extract containing proanthocyanidins (Figure 32.2) shows the large difference in relative amounts of the individual constituents, but some are sufficiently resolved so that, compounds **8**, **9**, **3**, **10**, **11** and **13** could be isolated in pure form by preparative HPLC and identified by systematic chemical degradation, and analysis by HPLC/APCI-MS/MS and HPLC/ESI-MS/MS. Flavan-3-ol monomers were identified by comparison of the LC–MS spectra with authentic samples. Thus compounds **1** ([M + H]$^+$, *m/z* 291), **2** ([M + H]$^+$, *m/z* 291) and **3** ([M + H]$^+$, *m/z* 307) were identified as catechin, epicatechin and gallocatechin, respectively (Figures 32.1 and 32.2). The other 14 proanthocyanidins shown in the chromatogram could be partially characterized by their retention times, molecular ions and molecular fragments, but the confirmation of their identities was achieved by acid-catalyzed
Figure 32.3 Degradation of proanthocyanidins in the presence of phloroglucinol.

degradation in the presence of phloroglucinol, or benzyl mercaptan, through which adducts with known structures were produced.

Acid-Catalyzed Degradation of Proanthocyanidins in the Presence of Phloroglucinol Interflavonoid C—C linkage bonds of hop proanthocyanidins are easy to cleave in mild acidic solution, which makes it relatively straightforward to determine the subunit compositions. Acid-catalyzed degradation with phloroglucinol present reacts to form an adduct (Kennedy et al., 2001) whose identities have been established. Hop proanthocyanidin dimers (dimer 1), for example, can be degraded (Figure 32.3) to release the terminal subunits (i.e. the flavan-3-ol monomers (monomer 1) and in turn the extension subunits. The mechanism involves intermediate C4 carbocations that are trapped by phloroglucinol to generate the analyzable adducts (adduct 1). The authentic samples epicatechin-($4\beta\rightarrow2$)-phloroglucinol and epigallocatechin-($4\beta\rightarrow2$)-phloroglucinol can be obtained from grape seeds and the authentic sample of gallocatechin-($4\alpha\rightarrow2$)-phloroglucinol from blackcurrant leaves (Ribes nigrum "Raven") (Foo and Porter, 1981). The authentic sample of catechin-($4\alpha\rightarrow2$)-phloroglucinol can be prepared from commercial (+)-Taxifolin (Kennedy and Jones, 2001). The flavan-3-ol monomers (monomer 1) and phloroglucinol adducts (adduct 1) when compared to authentic samples by HPLC–APCI-MS/MS or HPLC–ESI-MS/MS served to identify the precursors. Phloroglucinol is a popular trapping

nucleophile, but benzyl mercaptan can also be used to trap the intermediate carbocations.

To illustrate compound **8** showed a molecular ion with m/z 595 $[M + H]^+$, indicating that it was a proanthocyanidin dimer. After acid-catalyzed degradation and reaction with phloroglucinol, gallocatechin-($4\alpha\rightarrow2$)-phloroglucinol and catechin were obtained, which confirmed that **8** was gallocatechin–catechin. The identity could of course be further confirmed as gallocatechin-($4\alpha\rightarrow8$)-catechin by comparing the data with the authentic sample (Sun et al., 1987; Goupy et al., 1999). Using this procedure hop proanthocyanidin dimer structural identifications were made for **4** (epicatechin-($4\beta\rightarrow8$)-catechin, procyanidin B1), **5** (epicatechin-($4\beta\rightarrow8$)-epicatechin, procyanidin B2), **6** (catechin-($4\alpha\rightarrow8$)-catechin, procyanidin B3), **7** (catechin-($4\alpha\rightarrow8$)-epicatechin, procyanidin B4), **8** (gallocatechin-($4\alpha\rightarrow8$)-catechin), **9** (gallocatechin-($4\alpha\rightarrow6$)-catechin), **10** (catechin-($4\alpha\rightarrow8$)-gallocatechin), **11** (catechin-($4\alpha\rightarrow6$)-gallocatechin) and **12** (afzelechin-($4\alpha\rightarrow8$)-catechin) (Figure 32.4).

Acid-Catalyzed Degradation of Hop Proanthocyanidins in the Presence of Benzyl Mercaptan Since no authentic samples of afzelechin-($4\alpha\rightarrow2$)-phloroglucinol and epiafzelechin-($4\beta\rightarrow2$)-phloroglucinol were available, these prodelphinidin dimers could not be identified by acid-catalyzed adduct formation with phloroglucinol. Instead benzyl mercaptan (Kennedy et al., 2000) was used to trap the acid generated carbocation. Benzyl mercaptan adducts of afzelechin-($4\alpha\rightarrow2$)-benzyl sulfide adduct and epiafzelechin-($4\beta\rightarrow2$)-benzyl sulfide adduct are desulfurized by hydrogen with Raney nickel to give afzelechin and epiafzelechin, respectively, and their authentic samples can be prepared according to published procedures. Although benzyl mercaptan has an obnoxious odor, the chemical degradation with it can be an efficient method for structural elucidation of proanthocyanidins. For example, compound **12** (Figure 32.5) showed a molecular ion with m/z 563 $[M + H]^+$, indicating that it was a prodelphinidin dimer. After acid-catalyzed degradation and reaction with benzyl mercaptan, compound **12** released catechin and the benzyl mercaptan sulfide adduct of (epi)afzelechin that was desulfurized by hydrogen with Raney nickel catalyst to give afzelechin. Compound **12** was characterized as afzelechin–catechin, and was tentatively identified as afzelechin-($4\alpha\rightarrow8$)-catechin by comparing the data with the authentic sample.

Partial Acid-Catalyzed Degradation of Proanthocyanidins in the Presence of Benzyl Mercaptan Proanthocyanidin trimers are best elucidated by acid-catalyzed degradation in the presence of benzyl mercaptan, which finally releases the terminal subunits, and the benzyl mercaptan adducts of the upper and central subunits (Ricardo Da Silva, 1991; Hsu, 1985; Foo, 1989). The benzyl mercaptan (sulfide) adducts can then be desulfurized by hydrogen and Raney nickel catalyst to give the upper and central subunits as monomers. Partial
Figure 32.4 Structures of proanthocyanidin dimers isolated from hops.
Figure 32.5 Degradation of proanthocyanidins in the presence of benzyl mercaptan followed by reduction of sulfide linkage.

acid-catalyzed degradation in the presence of benzyl mercaptan (Figure 32.6) combined with desulfurization allows for controlled chemical reactions yielding a mixture of the central-terminal subunits (dimer 1), terminal subunits

(monomer 1) and the benzyl mercaptan adducts of the upper-central and upper subunits which are then analyzed. The benzyl sulfide adducts can be desulfurized to give the upper-central subunits (dimer 2) and upper subunits (monomer 2) that are analyzed. Thus, the structures of the proanthocyanidin trimers (trimer 1, Figure 32.6) are determined from the structures of the upper-central subunits (dimer 2) and central-terminal subunits (dimer 1).

The trimers in the hop extract were identified using this general procedure. Compound **13** (Figures 32.2 and 32.7) showed a molecular ion with m/z 867 [M + H]$^+$, indicat-ing that it was a proanthocyanidin trimer. After partial acid-catalyzed degradation and adduction with benzyl mercaptan, compound **13** yielded its central-terminal subunit ([M + H]$^+$, m/z 579) which identified it as catechin-(4α→8)-catechin and the benzyl mercaptan adduct of the upper-central subunit ([M + H]$^+$, m/z 701) that was desulfurized to give the corresponding upper-central subunit catechin-(4α→8)-catechin. Catechin-(4α→8)-catechin can be confirmed by co-chromatography with the authentic sample, that is, dimer **6**. Thus compound **13** was identified as catechin-(4α→8)-catechin-(4α→8)-catechin. Using the same method (Figure 32.7), the structures of **14** (epicatechin-(4β→8)-catechin-(4α→8)-catechin), **15** (epicatechin-(4β→8)-epicatechin-(4β→8)-catechin), **16** (catechin-(4α→8)-gallocatechin-(4α→8)-catechin) and **17** (gallocatechin-(4α→8)-gallocatechin-(4α→8)-catechin) were established.
Figure 32.6 Partial degradation of proanthocyanidins in the presence of benzyl mercaptan followed by reduction of sulfide linkage.

Sequencing of Hop Proanthocyanidins by Tandem MS

A general method for establishing the presence of proanthocyanidins in malt, hops and potential beer utilized liquid chromatography-mass spectrometry (LC/MS) (Whittle et al., 1999). The approach is particularly important for hop proanthocyanidins where as noted above the amounts of the individual constituents vary over a very broad range and require the capacity for rapid analysis of small amounts of sample that can be accomplished only by MS. Thus, Li and Deinzer have successfully used ESI-MS^n to reliably identify and sequence hop proanthocyanidins via a systematic analysis of their retro-Diels–Alder (RDA) fission, heterocyclic ring (HRF) fission, benzofuran-forming (BFF) fission, and (QM) fission (Li and Deinzer, 2007). Twenty-five* proanthocyanidins isolated from hops ranging

---

*Since the preparation of this chapter, a total of forty-four A- and B-type proanthocyanidins have been identified in hops.

from monomers to hexamers have been sequenced and identified by this approach. All of the fragmentation mechanisms were proposed based on data obtained by ESI-MS^n. These indirect analytical protocols have expanded the possible analytical approaches for sequencing proanthocyanidins in hops and other plants that contain only trace levels of these compounds.

Catechin was used as a representative compound for the off-line HPLC and ESI-MS^n studies to establish the fundamentals of the mass spectral fragmentation pathways for flavan-3-ol monomers, proanthocyanidin oligomers and polymers (Figures 32.2 and 32.8 and Scheme 32.1). Through an examination of complementary fragmentation patterns, the following five general fission rules were postulated: (Rule 1) Fragmentation of the single C-ring by HRF fission cannot undergo further RDA fission and vice versa, fragmentation of this C-ring by RDA fission cannot undergo additional HRF fission. (Rule 2) A ring fragmented by BFF fission cannot undergo HRF fission, and vice versa the product produced by HRF fission cannot fragment further by BFF fission. (Rule 3) A neutral loss of 126 Da always occurs through HRF$_C$ fission (Rule 4) Neutral losses through RDA fissions from (epi)afzelechin, (epi)catechin and (epi)gallocatechin units are 136, 152 and 168 Da, respectively. (Rule 5) Neutral losses through BFF fission of these three compounds respectively are 106, 122 and 138 Da, and neutral losses of H_2O/BFF fission are respectively 124, 140 and 156 Da. Rules 1–5 can be applied to provide an efficient and reliable sequencing protocol for proanthocyanidin dimers, timers and oligomers.

The five rules were applied to analyze proanthocyanidin oligomers. To illustrate the process Compound **4** (Figure 32.2), a dimer, that showed a molecular ion with m/z 563 $[M + H]^+$, is used to illustrate the interpretation of the fragmentation processes. The simplest fragmentation (Figure 32.9a–c) involves a well-known QM fission. Fragment ions with m/z 273 and 291 are formed, thereby identifying the upper and terminal units (Scheme 32.2), and the compound is (epi)afzelechin–(epi)catechin. The abundance of the two characteristic ions were somewhat lower than for the other product ions. The identity, however, can be confirmed by the other general fission rules. Fission of **4** cannot proceed via RDA$_C$ fission and then HRF$_C$ fission (Rule 1), nor can HRF$_C$ fission take place after RDA$_C$ fission (Rule 1), but RDA$_F$/HRF$_C$ fission can proceed. Neutral loss of a 126 Da fragment by HRF$_C$ fission (Rule 3) following RDA$_F$ fragmentation (Rule 4) yields the ion with m/z 285 (411 – 126 Da). The formation of this ion indicates that the one with m/z 411 (563 – 152 Da) was formed via RDA$_F$ fission (Rule 4), from which it follows that the terminal unit of compound **4** was (epi)catechin (Rule 4). This is confirmed by further H_2O/BFF$_C$ fission (Rule 5) and the upper unit was, therefore, (epi)afzelechin (Figure 32.9b and Scheme 32.2). The ions formed by HRF$_C$/RDA$_F$ fission give the same result.

Neutral loss of 126 Da (ion with *m/z* 437, Figure 32.9a and Scheme 32.2) indicating that HRF fission of the C-ring had taken place (Rule 3), hence the ion with 285 (437 – 152) was formed by RDA$_F$ fission (Figure 32.9c), indicating that the terminal unit of compound **4** was (epi)catechin (Rule 4). In addition, a single ring fragmentation by HRF (in this case HRF$_C$) cannot undergo further BFF$_C$ fission (Rule 2), but HRF$_C$/BFF$_F$/H_2O fission (Figure 32.9c and Scheme 32.2)
Figure 32.7   Structures of proanthocyanidin trimers isolated from hops.

Scheme 32.1   Fragmentation pathways of the monomer catechin: **RDA**, **HRF**, **BFF** and loss of water (H_2O).
Figure 32.9 Positive ion ESI tandem mass spectra of B-type dimer **4** (a) MS^2 of (M + H)$^+$ (*m/z* 563), (b) MS^3 of *m/z* 411 ion and (c) MS^3 of *m/z* 437 ion (Li and Deinzer, 2007).

can take place to yield the ion with *m/z* 297 (437 – 140 Da) which further confirms the identity of the terminal unit of compound **4** as (epi)catechin (Rule 5). The upper unit also had to be (epi)afzelechin. Finally, the fragment ion with *m/z* 165 ([M + H – HRF$_F$ (398 Da)]$^+$) was formed from HRF$_F$ fission and further serves to confirm that the upper unit of 4 was (epi)afzelechin.

The sequences of 7 B-type dimers (compounds **4–10**) were deduced from the product ions formed via QM fission, RDA$_F$/HRF$_C$, HRF$_C$/H$_2$O/BFF$_F$ fission and HRF$_C$/RDA$_F$ fission (Table 32.3). Since the signals of the characteristic ions (low mass) of dimers **4–10** formed by QM fission generally were quite weak or not even present (Table 32.3), HRF, BFF and RDA fragmentation pathways by the indirect MS protocols played a key role in determining their sequences.

The rules for structural elucidation of flavan-3-ol monomers and proanthocyanidin dimers by ESI tandem mass spectral analysis are straightforward and logical as the dimers are generally simple and well-known structures. But the larger the oligomers the more complicated the interpretation becomes and having several different fragmentation routes available makes sequencing these compounds more secure. The rules combined with the general QM fission were used to sequence the B-type trimers **13–17**. All of the above proanthocyanidin monomers and oligomers were successfully sequenced in the mixtures from 13 different hops extracts (Li and Deinzer, 2006). In addition, eight larger proanthocyanidin tetramers, pentamers and hexamers in the extracts present

25	(E)C-(E)C-(E)C-(E)C-(E)C-(E)C	1731	1441, 1143, 1155, 867, 579

Note: *m/z* was omitted. (E)C and (E)GC are abbreviations for (epi)catechin and (epi)gallocatechin. The symbol (E) indicates there are two possibilities: "catechin or epicatechin, gallocatechin or epigallocatechin" (Li and Deinzer, 2007).

in very small amounts were also sequenced by a systematic analysis starting with QM fission (Table 32.4). Generally however, other diagnostic ions were required either for confirmatory evidence or because QM fission products were not observable in the spectra. The diagnostic ions arising from the other fragmentation pathways always yielded sufficient information to allow sequencing and structural elucidation of the oligomers.

A survey of 13 samples of German and US hop varieties was conducted by isolating individual proanthocyanidins via HPLC, followed by acid degradation and analysis of the acid hydrolysates by ESI-MS (Li and Deinzer, 2006). The chromatograms for the varieties analyzed were qualitatively very similar, that is, peaks were seen at similar

retention times for the largest peaks thereby allowing the identification of the largest peaks by comparison with authentic samples. Furthermore, 25 proanthocyanidins were present in all 13 hops, which included Willamette hop cones (Oregon, Idaho, and Washington, USA), Vanguard pellet (USA), Palisade pellet (USA), Tettnang-Hallertauer pellet (Germany), Hallertauer-Hallertauer pellet (Germany), North American Hallertauer pellet (USA), Zeus pellet (USA), Cascade pellet (USA), Saaz 36 pellet (USA), Saaz 72 pellet (USA) and Glacier pellet (USA).

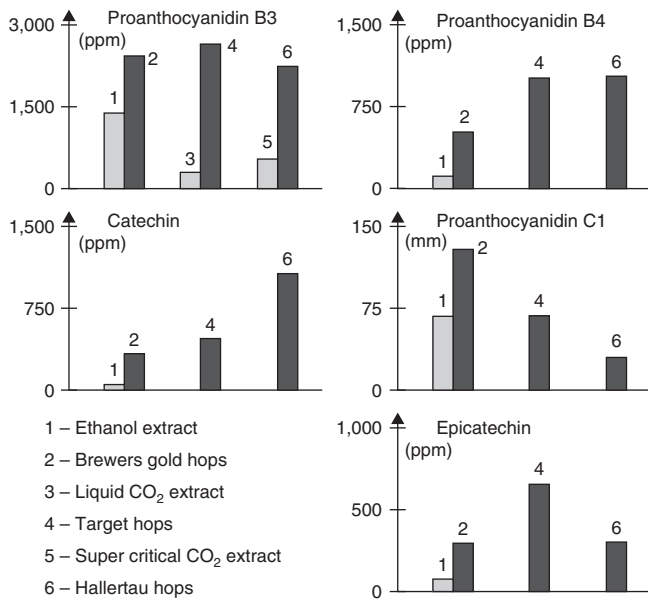
In summary, the structures of hop proanthocyanidins can be elucidated by combinations of GPC, HPLC, NMR, acid-catalyzed degradation and MS. Gas chromatographic analysis generally gives a better representation of the size distribution but for elucidating proanthocyanidins, individual fractions are best analyzed by LC-MS. NMR resonance can be useful for structure analysis, but signal multiplicities, broadening associated with rotational and conformational isomerism and low sample amounts often complicate the interpretations. Acid-catalyzed degradation in the presence of a nuclophile with which the intermediate can react can be very useful for identifying proanthocyanidins provided a sufficient amount of sample is available. Tandem mass spectrometry coupled with liquid chromatography (LC/MS^2) is a new and very powerful method for sequencing proanthocyanidin oligomers because of its capacity for reliably analyzing small sample amounts. Once the sequences are known, NMR spectroscopy can be used to determine the relative stereochemistry of the 2,3-positions (2,3-*cis* vs. 2,3-*trans*) and 3,4-positions (3,4-*cis* vs. 3,4-*trans*) on the C-ring, F-ring and I-ring, as well as to establish the proanthocyanidin interflavan linkages (4→6 vs. 4→8). Thus, LC/MS^2 coupled with various two-dimensional NMR methods are among the most practical approaches for analyzing proanthocyanidins not only from hops, but from any natural product.


Figure 32.10 Concentrations of polyphenols in hops and hop products (Mollet *et al.*, 1984).

Table 32.5 Flavanoids in hops (mg/g)

Varieties	(+)-Catechin (mg/g)	Procyanidin B3 (mg/g)	Procyanidin C2 (mg/g)
Alsace record	0.8	0.4	0.3
Hallertau	1.1	0.6	0.4
Saaz	2.8	1.5	0.9
Tettnang	1.5	0.8	0.5

Note: mg/g stand for individual proanthocyanidin per gram of hop cone weight (Jerumanis, 1985).

Proanthocyanidin Content of Hops and Beer

The composition of low molecular proanthocyanidins in different hop varieties

McMurrough (1981) reported that hops contained a preponderance of polymeric material. In Challenger hops the relative amounts of the dimers B1, B2, B3 and B4 present were 3:0.5:10:5. Cyanidin and delphinidin were also detected in whole hops with ratios that varied widely, as, for example, 1.2 in Northern Brewer and 6.2 in Talisman. Five flavanols, tentatively identified as trimers, were resolved by HPLC and measured but collectively they amounted to only 0.07 mg/g in hops. The B-series procyanidin dimers amounted to 0.17 mg/g in hops. Whereas the contents of (−)-epicatechin and (+)-catechin were 0.19 and 0.26 mg/g, respectively, in Challenger hops.

Moll *et al.* (1984) reported the identification and concentrations of certain phenolic substances including prodelphinidin, proanthocyanidins B3 and B4, catechin and epicatechin in hops, hop extracts, pellets and finished beer (Figure 32.10). These studies showed that (i) extracts of hops made using liquid or supercritical carbon dioxide contain only proanthocyanidin B3 in low concentration; (ii) hop extracts made with ethanol contain all the known polyphenols, but in view of the small amounts of extracts used when hopping, the quantity of polyphenols introduced into the beer is negligible; (iii) cone hops and pellets contain higher concentrations of proanthocyanidin B3, B4, catechin, epicatechin and the trimer C1; (iv) The relative proportions of the various proanthocyanidins vary greatly depending on the hop variety.

Jerumanis (1985) described an HPLC method for the quantitative analysis of flavanoids in hops. The flavanoids (+) catechin and proanthocyanidin B3 were the most representative followed by procyanidin C2 (Table 32.5). The values found for these three major components in Saaz hops totaled about 5 mg/g.

Forster *et al.* (2002) have undertaken a comparison study of 11 hop varieties harvested in 1997 and 1998 in an effort to determine whether the relative amounts of certain components can be used to identify the hop variety. Some clear differences were evident, but it appears not to be possible to make a variety of identification by means of any single indicator substance such as the level of proanthocyanidin. The relative amounts of several constituents have to be considered. Low-molecular-weight polyphenols may help to differentiate hop varieties. Additionally, the influence of the growing region has been investigated by studying two hop samples of a single variety from the United States and the Hallertau region in Germany. Clear differences were found in the composition of proanthocyanidins between the two growing regions. Generally, the Hallertauer hops showed higher contents of catechin, and procyanidins, B1, B2 and B3 in both Perle and Nugget hops (Table 32.6). The considerable climatic differences between the two regions apparently have a significant influence on proanthocyanidin content in hops.

Li and Deinzer (2006) also studied the relative amounts of individual proanthocyanidins discussed above in 13 different hop varieties to determine whether the composition of proanthocyanidin oligomers had any value in hop variety identification. The mole percent (mol%) composition of proanthocyanidins was based on a comparison of peak integrations at 280 nm. The detector response of proanthocyanidin dimers and trimers was estimated using molar absorption coefficients relative to the monomers. Molar absorptivities of three representative compounds were: monomer (catechin, ε_{280}: 3975); dimer (procyanidin B1, ε_{280}: 6725) and trimer (epicatechin-(4β→8)-epicatechin-(4β→8)-catechin, ε_{280}: 11,360), giving a relative molar response ratio of monomers:dimers:trimers of 1:1.69:2.86. The same 17 hop proanthocyanidin oligomers (Table 32.7) were found in all varieties consisting mostly of three flavan-3-ol monomers, nine proanthocyanidin dimers and five proanthocyanidin

Table 32.6 Proanthocyanidins in Nugget and Perle hops (mg/g)

| Compound | Variety | 1996 | | 1997 | | 1998 | |
		Hallertau	USA	Hallertau	USA	Hallertau	USA

Note: Abundance (mol%) of the total hops proanthocyanidins determined by HPLC (Procedure 1) at 280 nm, mol% is based on oligomeric proanthocyanidin mixtures. **1[#]** (Willamette) [**1a[#]** (Oregon-Willamette), **1b[#]** (Idaho-Willamette) and **1c[#]** (Washington-Willamette)], **2[#]** (Vanguard), **3[#]** (Palisade), **4[#]** (Tettnang-Hallertauer), **5[#]** (Hallertauer-Hallertauer), **6[#]** (Zeus), **7[#]** (Idaho-Hallertauer), **8[#]** (Cascade), **9[#]** (Saaz 36), **10[#]** (Saaz 72) and **11[#]** (Glacier) (Li and Deinzer, 2006).

trimers, but the concentrations of these individual compounds were significantly different (Figure 32.2).

On average the flavan-3-ol monomers, catechin (**1**, 17.6%), epicatechin (**2**, 14.7%), procyanidin B1 (**4**, 14.8%), procyanidin B2 (**5**, 7.2%), procyanidin B3 (**6**, 15.2%) and procyanidin B4 (**7**, 12.3%) together with the newly identified procyanidin trimer epicatechin-(4β→8)-epicatechin-(4β→8)-catechin (**15**, 3.2%) were the major proanthocyanidins present, with the other 10 proanthocyanidin oligomers amounting to a total of 15.0% (Table 32.7). On the whole, proanthocyanidins (87.5%) were dominant in all samples, but small quantities of prodelphinidins (9.8%) and propelargonidin (2.7%) were also present (Table 32.7).

Saaz 36 and Tettnang-Hallertauer hops had the highest content of catechin, that is, 32.1% and 29.5%, respectively, but the Washington-Willamette and Glacier hop proanthocyanidin oligomers showed exactly the opposite, as the levels

were 7.7% and 9.8%, respectively (Table 32.7). With regard to proanthocyanidin dimers, procyanidin B3 (**6**, 15.2%) and procyanidin B1 (**4**, 14.8%) were dominant, followed by procyanidin B4 (**7**, 12.3%) and procyanidin B2 (**5**, 7.2%). The procyanidin B3 content in Vanguard, Hallertauer-Hallertauer and Glacier hop proanthocyanidin oligomers was 24.7%, 22.7% and 20.2%, respectively, but Saaz 72 hop proanthocyanidin oligomers contained only 4.7% procyanidin B3 (Table 32.7). Prodelphinidin dimers (compounds **8–11**) and the propelargonidin dimer (afzelechin-(4α→8)-catechin, **12**) were generally present in hop proanthocyanidin oligomers. Tettnanger-Hallertauer and Saaz 36 hop proanthocyanidin oligomers contained gallocatechin-(4α→8)-catechin (**8**) at 4.4% and 4.5%, respectively. Saaz 72 hop proanthocyanidin oligomers contained 7.5% catechin-(4α→6)-gallocatechin (**11**), and the compound **12** content in Idaho-Willamette and Washington-Willamette hop proanthocyanidin oligomers

Table 32.8 Determination of proanthocyanidin content of a number of hop cultivars

Cultivar	Proanthocyanidins (mg/g)
Yeoman	12
Target	39
Northern brewer	31
Fuggle	29
Saaz	51

Note: mg/g stand for the whole proanthocyanidins per gram of hop cone weight (Neve, 1992).

was 4.4% and 4.3%, respectively (Table 32.7). Proanthocyanidin trimers included epicatechin-(4β→8)-epicatechin-(4β→8)-catechin (**15**, 3.2%), C2 (**13**, 1.4%) and epicatechin-(4β→8)-catechin-(4α→8)-catechin (**14**, 1.6%). Idaho-Hallertauer and Cascade hop proanthocyanidin oligomers contained compound **15** at 5.9% and 4.8% levels, respectively, but Zeus hop proanthocyanidin oligomers contained only 1.0%. Catechin-(4α→8)-gallocatechin-(4α→8)-catechin (**16**, 0.2%) and gallocatechin-(4α→8)-gallocatechin-(4α→8)-catechin (**17**, 0.2%) were very limited in hop proanthocyanidin oligomers (Table 32.7).

Differences in relative amounts of compounds **1**, **5** and **7** in Saaz 36 and Saaz 72 hop proanthocyanidin oligomers (Table 32.7) were also observed. The two hops were supposedly genetically identical, and they were grown in the same location in Idaho. These clones were established many years apart, and it had been observed that clone selections from varieties established long ago in a given locality might be different. Anecdotally, they were reported to have different brewing characteristics as well. Willamette hops (Oregon, Idaho and Washington) and Hallertauer hops (Germany-Tettnang, Germany-Hallertauer and Idaho) were selected to study the effect of geographic origin on their proanthocyanidin profiles (Table 32.7). Most hop constituents were found to be affected by geographic origin. For example, the relative percentage of compound **1** in Willamette hop proanthocyanidin oligomers, from Oregon, Idaho and Washington, was 21.7%, 16.5%, and 7.7%, respectively (Table 32.7). The relative percentages of compound **6** in Hallertauer hop proanthocyanidin oligomers from Tettnang (Germany, 2004), Hallertauer (Germany, 2004) and Idaho (2004) were 6.5%, 22.7% and 15.2%, respectively (Table 32.7). As in the previous studies by Forester *et al.* (2002), these results indicate that the proanthocyanidin profiles of hops are affected by geographic origin.

Recent barley breeding work by Carlsberg has resulted in the development of cultivars that are free of proanthocyanidins. Brewing with malt from these barleys produces beers with a considerably longer shelf life and if this type of malt were used exclusively, the proanthocyanidin content and hop variety used would likely have a significant impact on beer flavor and overall quality. Determinations of the amounts proanthocyanidins in various hop cultivars made

by the Carlsberg brewery (Neve, 1992) showed significant differences (Table 32.8).

In conclusion hops contained a preponderance of polymeric material. The relative proportions of the various proanthocyanidins vary greatly depending on the hop variety. Climatic differences between the different regions apparently have a significant impact on proanthocyanidin content. On the whole, proanthocyanidins were dominant in hops, but small quantities of prodelphinidins and propelargonidin were also present. The flavanoids (+) catechin and proanthocyanidin B3 were the most representative followed B1, B4 and C2.

Proanthocyanidins in beer

Beers are known to contain a wide variety of polyphenols, which originate from the brewing raw materials, that is, barley and hops (Madigan *et al.*, 1994). Polyphenols can protect food such as fats from being spoiled by oxygen which otherwise would affect the taste. They are also active in trapping free radicals in the human body thus exerting an anticarcinogenic effect. Beers contain complex mixtures of polyphenols ranging from 150 to 330 mg/L. The most reactive of the polyphenols are the proanthocyanidins. It is estimated that about 70–80% of the proanthocyanidins in beer are derived from barley, and about 20–30% originate from the hops. The proanthocyanidins from hops are structurally very similar to those found in barley, the main difference being the higher proportion of gallocatechin units in the oligomers derived from barley.

It is generally agreed that polyphenols and more particularly proanthocyanidins are major contributors to the formation of non-biological haze in beer. The haze formed on storage of beer has been shown to consist of polyphenols and proteinaceous material. The protein–polyphenol complexes that are formed are insoluble in beer thus causing beer to appear cloudy. The formation of non-biological hazes in beer can be reduced by the addition of silica gel to reduce the protein content, or polyvinylpolypyrrolidone (PVPP) to reduce the polyphenols during filtration. The use of specially cultivated varieties of barley free of proanthocyanidins such as Caminant or pure-resin hop extracts that are free of polyphenols reduces or eliminates haze formation, but the reduction of proanthocyanidins can affect the final flavor of beer.

Numerous studies have shown that proanthocyanidins are present in beer. Thus, Eastmond (1974) found catechin and procyanidin B3 (catechin-(4α→8)-catechin) in beer by chromatographic methods. Dadic and Belleau (1976) reported procyanidin B3 and procyanidin B4 (catechin-(4α→8)-epicatechin) in beer and confirmed their presence by ^{1}H NMR experiments. Vancraenenbroeck *et al.* (1977) found procyanidin B1 (epicatechin-(4β→8)-catechin), procyanidin B2 (epicatechin-(4β→8)-epicatechin), procyanidin B3 and procyanidin B4, and Jerumanis (1979) found procyanidin B2 and procyanidin B4 in beer by chromatographic means. Kirby and Wheeler (1980) found certain

beers contain procyanidin B3 and prodelphinidin B3 (gallocatechin-(4α→8)-catechin) by chromatographic means. Jan and Geert (1984) found procyanidin B3, prodelphinidin B3 and prodelphinidin B9 (epigallocatechin-(4β→8)-catechin) in Pilsner beers by ^{1}H NMR, MS and circular dichroism of their methyl ether diacetates.

Using direct-injection HPLC with electrochemical detection, McMurrough et al. (1992) found that lager beers contain catechin, procyanidin B3 and prodelphinidin B3. McMurrough and Baert (1994) developed a method for the measurement of simple flavanols in beer by direct-injection HPLC using dual-electrode electrochemical detection. These investigators used this method successfully to measure small amounts of monomeric and dimeric flavanols in commercial beer. The method offered greatly improved sensitivity and selectivity

compared to the ultraviolet detection method used previously. In addition to catechin, epicatechin, prodelphinidin B3 and procyanidin B3, small amounts of three trimer proanthocyanidins T1, T2, T3 and T4 (B4) were also tentatively identified in a typical lager beer. Treatment with PVPP markedly decreased the amounts of total polyphenols and individual PAs in lagered beer, but no decrease in epicatechin was evident (Table 32.9).

Madigan et al. (1994) developed an HPLC method using dual-channel electrochemical detection for the determination of proanthocyanidins, and found catechin, epicatechin, prodelphinidin B3 and procyanidin B3 in lager beers. The beer that was taken from the storage vessel (unstabilized) and from cans (stabilized) showed marked differences in flavanol content (Table 32.10). The treatment of beer with PVPP results in a near total reduction in the amount of dimers present, and a significant reduction in monomer content.

Using HPLC/ESI-MS and HPLC/EI-MS to analyze proanthocyanidins in beer, Nigel et al. (1999) found proanthocyanidins including catechin, epicatechin, (epi)gallocatechin, (epi)catechin-(epi)catechin, (epi)catechin-(epi)gallocatechin, (epi)gallocatechin-(epi)catechin, (epi)

Table 32.9 Polyphenol composition of commercial lager storage beer and stabilized beer[a]

Analysis	Storage beer (mg/l)	Stabilized beer (mg/l)

Food	Monomers	Dimers	Trimers	4–6 mers	7–10 mers	>10 mers	Total proanthocyanidins	Type
				mg/l (beverages)				
Beer	4 ± 0	11 ± 1	3 ± 0	4 ± 0	ND	ND	23 ± 2	PC, PD

[a] Values are means S ± D, n = 4–8.
[b] Monomers, dimers and trimers are listed separately. Tetramers through hexamers are pooled as 4–6 mers. Polymers with DP > 10 are quantified collectively and listed as >10 mers. Abbreviations and symbols: ND, not detected. The PP, PC and PD are propelargonidins, procyanidins and prodelphinidins, respectively (Gu et al., 2004).

gallocatechin-(epi)gallocatechin,(epi)catechin-(epi)catechin-(epi)catechin,(epi)catechin-(epi)gallocatechin-(epi)catechin, (epi)gallocatechin-(epi)catechin-(epi)catechin,(epi)gallocatechin-(epi)gallocatechin-(epi)catechin and (epi)gallocatechin-(epi)gallocatechin-(epi)gallocatechin in beer.

An optimized normal-phase HPLC–MS fluorescent detection method (Gu, 2004) was used to estimate the concentrations of proanthocyanidins in common foods and beverages (Table 32.11). With this technique, tetramers through hexamers were first found in beer with concentrations of 4 mg/l. Significant reduction in proanthocyanidins in beer is effected by treatment with 50 g/hl PVPP (Table 32.12).

In summary, numerous studies have shown proanthocyanidins present in hops and malt (barley) are easily extracted from these raw materials into the beer during brewing because of their high solubility. Proanthocyanidin monomers, dimers and trimers have been reported to be present in beer with total amounts generally present around 20 mg/l. Catechin and prodelphinidin B3 are the most representative proanthocyanidins followed by procyanidin B3 and epicatechin. In view of their high aqueous solubilities, it remains to be seen whether larger oligomers may also be present in beers. Proanthocyanidins have received a considerable amount of attention in the brewing industry because they stabilize the organoleptic properties and color, and contribute to the astringency and bitterness, all of which are desirable attributes. Non-biological haze is produced as a result of the protein–polyphenol complexes that are formed on storage of beer. Although the potential for haze formation can be reduced by removing protein or proanthocyanidins or both, marked changes in the balance of these components can negatively affect the quality and flavor of beer as well as the possible health benefits that are associated with the presence of these antioxidants. Future research may show how the beneficial properties of proanthocyanidins may be retained through judicious selection of certain polyphenol components and/or grains with soluble proteins that exhibit a lower tendency for complexation or aggregation.

Summary Points

- Tandem mass spectrometry coupled with liquid chromatography (LC/MS[2]) is a new and powerful method for sequencing proanthocyanidin oligomers because of its capacity for reliably analyzing small sample amounts. Once the sequences are known, NMR spectroscopy can be used to determine the relative stereochemistry and the proanthocyanidin interflavan linkages.
- Twenty-five* proanthocyanidins have been structurally identified in hops, and the relative proportions of the various proanthocyanidins have been found to vary greatly depending on the hop variety and climatic differences. Proanthocyanidins were dominant in hops, but small quantities of prodelphinidins and one propelargonidin were also present. The flavanoids (+) catechin and proanthocyanidin B3 were most representative followed B1, B4 and C2.
- Proanthocyanidin monomers, dimers and trimers have been reported to be present in beer with total amounts generally present around 20 mg/l. Catechin and prodelphinidin B3 are the most representative proanthocyanidins followed by procyanidin B3 and epicatechin.
- Proanthocyanidins have received a considerable amount of attention in the brewing industry because they stabilize the organoleptic properties and color, and contribute to the astringency and bitterness of beer, all of which are desirable attributes.
- Although the potential for haze formation can be reduced by removing protein or proanthocyanidins or both, marked changes in the balance of these components can negatively affect the quality and flavor of beer as well as the possible health benefits that are associated with the presence of these antioxidants.

Metals in Beer

Pawel Pohl Division of Analytical Chemistry, Faculty of Chemistry, Wroclaw University of Technology, Wroclaw, Poland

Abstract

Major, minor and trace metals are important in the fermentation processes since they supply the appropriate growth environment for yeasts and have the influence on their metabolism due to the co-factoring of different enzymes. The presence of the transition metals like copper and iron in their non-complexed forms is a real concern since these metals affect the conditioning and aging of beer by catalyzing the reactions in which the reactive oxygen species are formed. The resulted reactive oxygen species, especially free radicals, are likely to oxidize variety of the organic compounds present in beer which substantially contributes to the foaming quality and the flavor stability of beer. In view of the brewing technology and beer processing, the knowledge regarding the functions of metals and their different speciation forms in brewing liquors and beer is of special significance to the brewers. In the products of final quality, the metals can have a certain nutritional importance to the consumers, however, the effect on the human organism depends on the type of the metal species present in beer since many low and high molecular mass organic species likely bind the metal ions and form the complexes of different stability and availability. This chapter reviews the role of the metals in beer and the processes involved in beer production. The attention is paid to the endogenous and exogenous sources of metals in beer, the nutritional aspects of metals, their bioavailability and partitioning in beer, as well as the roles in brewing and the fermentation performance, and the effect on final quality and taste.

Introduction

Sources of metals in beer

Beer is the product of yeast alcoholic fermentation of the extracts of malted cereals, usually barley malts, with or without the starchy material, and to which hops are added. All these natural components used for brewing, that is water, cereals, barleys and yeasts, are the main endogenous sources of metals in beer. Apparently, the mineral composition of

beer usually reflects the composition of the ingredients and refers to the brewing processes carried out. In consequence, the content of the metals is rather variable and depends on the quality of the substrates taken, the type of beer brewed and the country of origin of beer (Hardwick, 1995; Moll, 1995; Goldammer, 1999; Baxter and Hughes, 2001; Briggs *et al.*, 2004).

Metals found in beer may originate also from many other adjunctive substances added during the brewing to control the fermentation and the maturation processes taken place in beer. Another exogenous source of metals in beer can be the contamination from different components of the brewery equipment, for example pipes, fluid lines, vessels and tanks, in which beer is fermented, conditioned, filtrated, carbonated and packed, as well as the containers, for example kegs, casks, cans, in which the product of the final quality achieved is kept during the storage and transport. In this case, moderately acidic brewing liquors and beer (pH 4.2 on average) can contribute to a large extent to the ingestion of the metal ions, especially in aluminum cans, kegs and casks (Sharpe and Williams, 1995; Vela *et al.*, 1998; Wyrzykowska *et al.*, 2001). The deterioration of beer can liners and the interaction of the beverage with the containers usually lead to the increase in the concentrations of metals such as Al, Co, Cr, Cu, Fe or Ni, which migrate to the beer components. In the case of Al, it can be presumed that the longer the length of beer storage, the higher concentrations of the metals are found in beer. Moreover, the higher the temperature of storage, the more rapid the rate of can corrosion takes place, regardless of its coating, and the higher the accumulation of the metals in beer occurs (Vela *et al.*, 1998).

Metals in Beer

Total metal content

The major metals of beer are calcium (4–140 mg/l), potassium (20–1,100 mg/l), sodium (1–230 mg/l) and magnesium (20–270 mg/l). At level of minor and trace metals in beer are aluminum (0.005–2.2 mg/l), barium (0.01–0.07 mg/l), cadmium (up to 0.7 mg/l), cobalt (up to 0.0008 mg/l), chromium (up to 0.02 mg/l), copper (0.008–0.8 mg/l), iron (0.02–1.6 mg/l), manganese (0.03–0.8 mg/l), nickel (up to 0.3 mg/l), lead (0.0008–0.03 mg/l), strontium (0.1–0.7 mg/l) and zinc (0.001–1.5 mg/l). Ranges of the concentrations of major, minor and trace metals determined in beers of different country of origin are given respectively in Table 33.1 (Ca, K, Na, Mg), Table 33.2 (Al, Cd, Cu, Fe, Mn, Ni, Sr, Zn) and Table 33.3 (Ba, Co, Cr, Hg, Pb).

With respect to the nutritional value of metals to human and according to relatively high contents of some of them in beer, it is accepted that moderate and reasonable consumption of beer can be to some extent a valuable source of recommended daily dietary intakes of metals. However, it should be noted as well that although the information on the total metal content is advantageous in the estimation of the metal nutrient uptake source, the bioavailability of metals from beer to humans and its absorbability crucially depends on the speciation forms in which they are present in beer (Sharpe and Williams, 1995; Svendsen and Lund, 2000; Pohl and Prusisz, 2007). For example, it has been indicated that aluminum, whose excessive intake is linked with Alzheimer's disease, is predominantly present in beer in the form of citrate and phosphate complexes and that only a small portion

of the total Al found in beer is transported through the wall of the gut. Therefore, beer plays a minor part in the bioavailable uptake of Al from the diet (Sharpe and Williams, 1995).

The assessment of the total metal composition of beer, including the determination of major, minor and trace metals, is of particular interest and notice to the brewers and the consumers since, in dependence of the concentration and type, they might be essential or toxic in the human body and they can also have an influence on the brewing process and the quality of beer in view of the flavor stability or the formation of haze (Bellido-Milla *et al.*, 2000; Svendsen and Lund, 2000; Wyrzykowska *et al.*, 2001; Alcazar *et al.*, 2002; Vinas *et al.*, 2002; Bellido-Milla *et al.*, 2004; Pohl and Prusisz, 2004; Asfaw and Wibetoe, 2005; Nascentes *et al.*, 2005; Llobat-Estelles *et al.*, 2006; Onate-Jaen *et al.*, 2006; Pohl and Prusisz, 2007). For example, some metals may be harmful above a certain concentration (Al, Cd, Hg, Pb), some of them are regarded to affect the quality of foam and

flavor (Cu, Fe, Mn), others are essential and have advantageous effect on human health (Fe, Zn).

With regard to different health and/or disease implications of metals, their nutritional value as well as the impact on the quality and sensory properties of beer, the total allowed content claims of the metals in beer are precisely regulated (Baxter and Hughes, 2001; Briggs *et al.*, 2004).

Chemometric differentiation and classification of beer

The information regarding the total contents of metals in beer, typically originated from the natural raw products used for its manufacturing, that is water, cereals, hops and yeasts, the brew processing, further treatment, storage and finally aging in the containers, is documented to be a valuable parameter used for the differentiation and the classification of beer (Bellido-Milla *et al.*, 2000; Wyrzykowska *et al.*, 2001; Alcazar *et al.*, 2002).

For the purpose of the chemometric classification of beer, different pattern recognition techniques are applied to the data matrix referred to the mineral contents found through the analysis of relatively high number of different beer brands. Hence, the principal component analysis (PCA) is used as a result of visualization technique, while the linear discriminant analysis (LDA) and the artificial neural networks (ANN) are the supervised learning methods applied to find adequate classification rules.

This chemometric approach along with the complete information on the mineral composition including the total concentrations of number of metals (Ag, Al, Ba, Ca, Cd, Co, Cr, Cu, Fe, Ga, Hg, K, Mg, Mn, Na, Ni, Pb, Rb, Sr, V, Zn) has been shown to be a very suitable tool for the differentiation and the classification of beer samples in relation to the type, origin and container of beer or the kind of raw material from which beer was brewed. Among others, the concentrations of metals such as Mn, Mg and K have appeared to be the most important variables for such kind of beer classification (Alcazar *et al.*, 2002).

Furthermore, the PCA indicates that a certain degree of association exists between some metals as they tend to group together, that is Cs and Hg, Cd and Co; Cr and Cs; Fe and Zn; or Mn and V (Wyrzykowska *et al.*, 2001). These metal cluster correlations established can be explained bearing in mind two main sources of metal intake in beer, that is the endogenous source associated with raw materials used for the brewing and the exogenous source originated from the contamination taking place during the production and storage of beer.

In addition, the analysis of variance (ANOVA) between the groups is also recognized as a valuable statistical method which can be used for the characterization of beers of different type, country of origin and container as well as for the control of the quality of the final product achieved with respect to its taste and flavor stability (Bellido-Milla *et al.*, 2000). For example, on the basis of the analysis of 25 different beer samples and the determination of seven metals (Al, Ca, Cu, Fe, Mg, Mn, Zn), it has been found that the concentrations of Cu and Fe in canned beers are commonly higher than those found in bottled beers. The notable differences in the contents of Ca, Cu, Fe, Mg, Mn and Na are observed as well among lager, stout, wheat and ale beers which demonstrates that the metals intake is differentiated according to the type of beer and the distinctive technology of its production.

Metal–Organic Matter Associations in Beer

Although the studies devoted to the characterization, the quality control and the estimation of the nutritional value of beers in relation to their total mineral composition are obviously valuable, it should be accentuated that the effect of metals present in beers on their stability and wholesomeness does not depend on their concentrations but foremost on the type of metal species resulted from binding the metals by different low and high molecular organic compounds present in beer and the equilibrium existing between the complexed and the non-complexed metal ions (Pohl and Prusisz, 2007).

Beer contains various classes of natural compounds, including polyphenolics, proteins, amino acids or other organic species, that have a capacity of binding the metals through the donor nitrogen, oxygen and sulfur atoms. Therefore, the metals can be present in beer as non-complexed cations as well as in the form of complexes of different stability and, in a consequence, of different bioavailability and toxicity to the human organisms (Montanari *et al.*, 1999; Gorinstein *et al.*, 2000; Cortacero-Ramirez *et al.*, 2003; Nardini and Ghiselli, 2004; Khatib *et al.*, 2006).

Due to the crucial role of Cu^+ and Fe^{2+} ions in the activation of molecular oxygen and further oxidation of the organic compounds responsible for stability and flavor of beer, the investigations of possible associations of these metals with different endogenous ligands existing in beer are of special interest and significance in terms of the brewing technology and processing (Irwin *et al.*, 1991; Mochaba *et al.*, 1996; Andersen and Skibsted, 1998; Montanari *et al.*, 1999; Blanco *et al.*, 2003; Morales *et al.*, 2005). Apparently, iron and copper are bound by amino acids, polyphenols and melanoids being the products of the last stage of the Maillard reaction and form their very stable complexes. Emphasized complexing reactions are recognized to take place mainly during the storage of beer. Hence, they strictly determine the type of the aging characteristics of beer and its final aroma and taste, as the capture of metal ions and the associations with chelating organic compounds is one of the important anti-oxidative approaches decreasing the formation and the activity of the reactive oxygen species (Bamforth, 1999a; Blanco *et al.*, 2003; Vanderhaegen *et al.*, 2006).

Conversely, the non-complexed copper and iron ions may have a negative effect on beer quality considering their contribution to the deterioration and the changes in stability occurred with aging.

The partitioning of other metals such as manganese or zinc is less explored. The ability of Mn^{2+} ions to form complexes with organic compounds is considered to be rather low (Onate-Jaen *et al.*, 2006). Although the involvement of the divalent cations of that metal in the radical generation and the oxidative staling reactions has not been reported, the chemical properties of manganese tend to the conclusion that its effect on beer colloidal and flavor instability may be possible. The non-complexed manganese ions may enhance the action of copper and iron in catalyzing the staling reactions, however, relatively low concentration of Mn in beer compared to those determined for Cu and Fe may mask this effect (Mochaba *et al.*, 1996).

For the reasons mentioned above, for better elucidation and understanding of the functions of metals in the processes related to the flavor stability, changes during the maturation, taste and odor of beers as well as their health implications and nutritional value referred to the consumption of that alcoholic beverage, it is essential to study the speciation or fractionation of metals in beer.

Metal fractionation pattern in beer

Very few research works have been dedicated so far to the partitioning of metals in beer and the assessment of the pattern of possible metal groupings in terms of the bioavailability of different metal forms.

The charge of Cu, Fe and Mn species in bottled beer (Ringnes Pilsner, Norway) has been established by means of the cation and anion exchange cartridges and off-line measurements by means of the electrothermal atomic absorption spectrometry (Svendsen and Lund, 2000). Analyzing the effluents obtained after separate passing of the aliquots of the untreated beer through the ion exchange cartridges, it has been found that Mn is present in the studied beer in the form of positively charged species (over 94% of the total content) presumably being simple Mn^{2+} cations. On the contrary, Fe has been determined to be entirely present as negatively charged species which indicates the presence of the species of Fe bound to different organic compounds. Finally, in case of Cu, both positively and negatively charged species (34% and 72%, respectively) have been found supposing the existence of different complexes of this metal.

The spiking of the beer sample with free metal cations (Cu^{2+}, Fe^{3+}, Mn^{2+}), followed then by the ion exchange experiments and the evaluation of the metal recoveries, has indicated that beer contains free ligands that readily bind Cu and Fe forming their negatively charged complexes. In contrast to that, added Mn^{2+} has been completely recovered as positive ions.

In addition, in the cited work by Svendsen and Lund (2000), the size exclusion chromatography was subjected to the untreated beer sample for the assessment of possible metal associations with ligands of different molecular weight ranges. The chromatograms, constructed on the basis of the metal quantities found in the column effluents, point out that Mn is present entirely in beer in the non-complexed forms, presumably as Mn^{2+}. In case of the remaining metals under consideration, that is Cu and Fe, the retention volumes of the eluted species (peaks) lead to the conclusion that these metals are likely to be present in beer as negatively charged species bound to organic molecules of the molecular weight of 4–12 and 4–9 kDa, respectively in case of Cu and Fe, and relating to different polyphenolics compounds.

A strong cation exchanger Dowex 50Wx4 has been applied by Pohl and Prusisz (2004) to evaluate the amount of broadly meant cationic fraction of Cd, Co, Cu, Ni and Zn in canned beer (Warka Full Light, Poland). The content of the metals under discussion in that operationally defined fraction was determined by passing the untreated beer sample through the column, followed by their recovery carried out by the acid digestion of the resin beads with adsorbed analytes. It was presumed that this fraction is of the highest bioavailability to the human organisms *via* gastrointestinal system and comprises free cations, stable cationic complexes with small molecular mass, non-volatile acids, including pyruvic acid, malic acid, lactic acid, citric acid, oxalic acid and labile metal species which dissociate the resin badly giving a donation to the cations. In case of Al, Co, Cr and Cu, the quantity of the cationic fraction in relation to the total metal contents was varied from 6% for Cu to 11% for Co. For Mn, Ni and Zn it was ranged from 23% to 28%.

Recently, a tandem column protocol, based on the retention of distinct metals species on a hydrophobic Amberlite XAD7

adsorbent, followed by a strong cation exchanger Dowex 50Wx4, has been developed for the operational fractionation of Mn and Zn, in various Polish canned and bottled beers (Pohl and Prusisz, 2007). The scheme of this fractionation manifold using two different sorption mechanisms to the metal species classification is given in Figure 33.1.

The distinct compounds of Mn and Zn, that is the fraction of the hydrophobic metal species and the fraction of the cationic metal species, were sorbed respectively on solid phase of the Amberlite XAD7 adsorbing resin and the strong cation exchanger Dowex 50Wx4 connected in a series. The metal contents in the respective metal species fractions were measured by means of the flame atomic absorption spectrometry method in the eluates obtained by the subsequent solvent elution. The residual metal fraction was determined on the basis of the metal amount found in the effluents resulted from passing the beer aliquots through the column system.

The procedure proposed by Pohl and Prusisz (2007) has enabled the assessment of the distribution of Mn and Zn among defined chemical species classes, that is the hydrophobic, high molecular weight species of the metal complexes with the polyphenolic and flavonoid compounds, the sum of the free metal cations and the stable cationic metal complexes with the low molecular weight species (mostly amino acids, organic acids being of primary origin (citric,

malic) or the secondary products of alcoholic fermentation (pyruvic, lactic, ketoglutaric, succinic, citramalic, fumaric)) and finally the residual metal species, possibly being the anionic and neutral metal associations either with low molecular mass ligands. The distribution of both metals among the fractions distinguished in some Polish bottled and canned beers is exemplified in Figure 33.2.

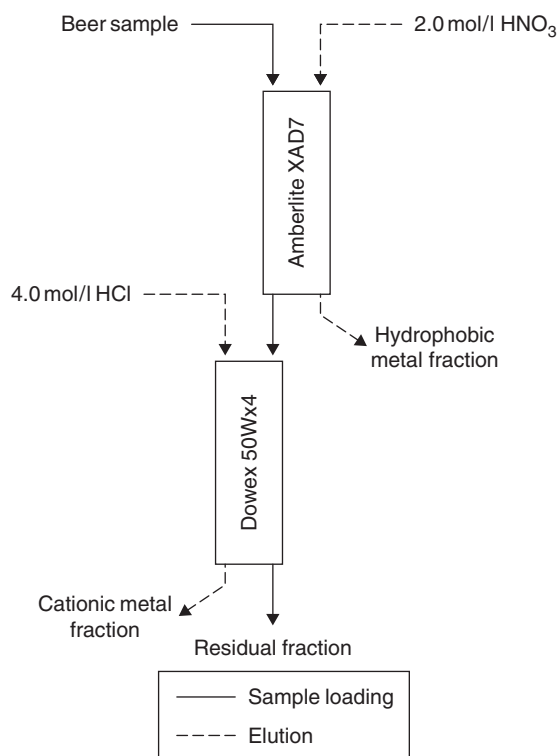
The case of Mn is of special significance. In comparison to the previous results devoted to the speciation of Mn and reported by Svendsen and Lund (2000), it has been established that possible chemical forms and associations of that metal are more differentiated as it was expected before. In conformity to the former findings, it appears that the predominant class of Mn species is the cationic fraction; the concentrations of Mn in that class of the species vary from less than 60 to over 100% of the total metal concentration. In addition, it was found that there is a considerable donation of the residual metal fraction (from 22% to 42%) to the total content of manganese in the analyzed beers. Manganese has also been determined to be present in the form of the complexes with polyphenolic substances (up to 8% of the total metal concentration).


Figure 33.1 Tandem column fractionation protocol used for the classification of Mn and Zn groupings in beer. *Source*: Adapted from Pohl and Prusisz (2007).
Figure 33.2 The fractionation patterns of Mn and Zn in beer. The distribution of the hydrophobic, the cationic and the residual metal fractions in Polish canned (A, Piast; B, Tyskie; C, Ksiaz; D, Zywiec; E, Karpackie; F, Perla) and bottled beers (G, Mocne dobre; H, Zywe; I, Ksiazece). *Source*: Adapted from Pohl and Prusisz (2007).

It should be noted that, the metal groupings distinguished through the fractionation protocol devised by Pohl and Prusisz (2007) are operationally defined and relate to the sorption behavior of Mn and Zn species toward the adsorbent and the cation exchanger applied; however, with respect to the total content analysis, the information retrieved on the abundance of different metal fractions in analyzed beers yields useful knowledge about metal bioavailability, beverage safety, authenticity and nutrition. Bearing in mind the possible associations of metals with natural organic substances present in beer (Montanari *et al.*, 1999; Cortacero-Ramirez *et al.*, 2003; Khatib *et al.*, 2006), the hydrophobic fraction can be regarded as hardly bioavailable to the humans while the sum of the cationic and the residual metal fractions, accounting respectively for over 92% and 85% of the total manganese and zinc in beers analyzed, can be assumed to be highly absorbable.

Metals in Brewing

Besides the nutrition value of metals of beer in response to their potential relationship and contribution to the daily diary nutrition requirements in diet, they are very important and influential in the brewing processes, especially in terms of proper growth and metabolism of yeasts. In case these last, they are essential co-factors for numerous fermentative enzymes, necessary components of transport systems fulfilling a charge-balancing or structural roles. Typically, the concentrations of metals, for example Ca^{2+}, Co^{2+}, Cu^{2+}, Fe^{3+}, K^+, Mo^{2+}, Mn^{2+}, Mg^{2+}, Ni^{2+} and Zn^{2+}, required for the appropriate growth of yeasts are relatively small. At high concentrations, the mentioned metals are usually toxic or exert a salt stress on the yeasts (e.g. Na^+) (Briggs *et al.*, 2004).

For that purpose, the metal metabolism of yeast is of special interest to brewers considering the improvement of yields, the enhancement of the fermentative capacity, and finally, the preservation of the consistency of the product quality (Walker *et al.*, 1996; Chandrasena *et al.*, 1997). Usually, the metal ion composition of brewing liquors changes significantly depending on the raw materials used and the conditions of brewing process applied and hence, it should be controlled. However, it should be emphasized that the uptake of the metal ions required by the yeast cells relies on the concentration of the particular ions in the growth environment and on to a great degree to their bioavailability. The latter one depends on both the solubility and the properties of different ion-complexing ligands originated from raw materials used. The most bioavailable are the free metal ions, but the chelating and adsorbing constituents present in wort and other brewing liquors regulate their availability by formation of the complexes of different stability. This reduction of free metal ions' bioavailability (e.g. Ca^{2+}, Mg^{2+}, Zn^{2+}) has a detrimental effect on the yeast growth kinetics and the fermentation performance (Walker *et al.*, 1996; Chandrasena *et al.*, 1997).

The detailed account to the role of particular major, minor and trace metals in the yeast metabolism and the fermentative and sensory performance of beer is given below (Hardwick, 1995; Moll, 1995; Walker *et al.*, 1996; Chandrasena *et al.*, 1997; Goldammer, 1999; Baxter and Hughes, 2001; Briggs *et al.*, 2004).

Role of major metals

Calcium Calcium ions (Ca^{2+}) are regarded as the most significant metal ions in brewing processes; they have several important functions in the metabolism of yeasts and their fermentation action. By the reaction with phosphate, phytate, peptides, proteins and other mash and wort components, the calcium ions involve the release of the hydrogen ions. It results in useful reduction of the mash and wort pH, which is critical for the stabilization of the fermentation enzymes, including α-amylase, β-amylase and other proteolytic enzymes. Their sufficiency is also important in the oxalate precipitation and in the governing of the yeast cells flocculation. Accordingly, the content of the Ca^{2+} ions in the brewing liquors should not exceed a certain concentration (100 mg/l on average) since it would lead to the substantial removal of the phosphate from the wort. In consequence, under conditions of serious deficiency of the phosphate ions, the yeasts would have an inadequate nutrition supply required for their adequate growth.

The effect of the calcium concentration on flavor of beer is rather minor, however, the content of that metal is recommended to be in the range from 20 to 150 mg/l.

Magnesium Magnesium ions (Mg^{2+}) behave similarly as calcium ions but since magnesium salts are more soluble, their effect on the lowering of the mash and wort pH is rather less pronounced. The presence of the magnesium ions is very important and beneficial to the yeast growth and the fermentative metabolism through the stimulation of cell division cycle progression and the co-factoring of more than 300 enzymes, including hexokinases, phosphofructokinase, phosphoglycerate kinase, pyruvate kinase and enolase in glycolysis. The growth demand for the Mg^{2+} ions by yeast cells is very high and cannot be replaced by the other metal ions. In fact, the Ca^{2+} ions may act antagonistically toward Mg^{2+} ions in many biochemical and physiological functions of the yeasts. The magnesium ions may also exert a protective effect on yeast cells from disadvantageous effects caused by ethanol, high temperature and osmotic pressure.

The upper limit of magnesium in beer is proposed to be of 30 mg/l. Much greater concentrations than that usually contribute to a sour or bitter flavor of beer.

Sodium Sodium ions (Na^+) have rather no special chemical influence. It is recognized that at higher concentrations, that is above 150 mg/l, which is proposed to be the maximum

Na concentration limit in beer, sodium ions are responsible for sour and salty flavors of beer. Usually, the levels of sodium changing in the range from 75 to 150 mg/l contribute to a round smoothness and accentuate a proper sweetness of beer.

Potassium   Like sodium ions, potassium ions (K^+) present at concentrations above 10 mg/l can have different laxative effects and impart a salty taste of beer. They are required for yeast growth since their transport through membrane cells maintains the charge homeostasis. It is also involved in the osmoregulation and in the regulation of divalent cation and phosphate uptake into the yeast cells.

Role of minor metals

Iron   Iron can occur in brewing liquors and beer as simple ions (Fe^{2+}, Fe^{3+}) or in the form of complexes with different organic compounds. Being present in too much amounts (above 1 mg/l), iron ions can convey metallic and harsh tastes to beer, as well as dark colors due to associations with phenolic substances from the malt and hops. Negative action of high concentrations of iron ions results also in the hampering of yeast activity, the prevention of complete saccharification and finally the production of haze in beer.

Hence, the concentration of Fe in wort and beer is usually recommended to be lower than 0.1 mg/l. Iron ions also exert a catalytic action in the oxidation processes occurring in beer and are responsible for aerobic aging and flavor stability during storage.

Copper   Copper ions (Cu^{2+}), similarly as iron ions, (Fe^{2+}/Fe^{3+}) contribute to the quality of beer and the flavor enhancement due to their oxidation/reduction catalysis action. At too high concentrations, they are toxic and mutagenic to yeasts that accumulate them as well as cause the irreversible beer haze. Usually, brewing liquors should contain less than 0.1 mg/l of Cu.

Manganese   Manganese ions (Mn^{2+}, Mn^{4+}) present at trace levels (0.05–0.2 mg/l) in brewing liquors are needed for proper growth of yeasts. Their other role is to attribute the solubilization of proteins and the support of proper enzymatic action. Like copper and iron, manganese ions are supposed to be oxidation/reduction catalysts and have adverse effect on flavor and beer colloidal stability owing to the role in the formation of the reactive oxygen containing species. In appreciable amounts, manganese ions can impart an unpleasant beer taste.

Zinc   Zinc ions (Zn^{2+}) are essential micronutrient to the growth and metabolism of yeasts and protein synthesis. They are directly involved in ethanol production as co-factors of the essential enzymes such as alcohol and aldehyde dehydrogenases. At too much high concentration they cause damage to yeasts and affect fermentation. On the other hand, its

deficiency leads to impaired fermentation progress. The recommended range of zinc amount in brewing liquors is from 0.15 to 0.5 mg/l.

Beer aging and haze formation

It has been evidenced that in the presence of Fe^{2+} and Cu^+ ions, stable molecules of oxygen dissolved in beer capture the electrons and form the superoxide anions (O_2^-). The resulted metal cations (Fe^{3+}, Cu^{2+}) can be reduced again to the respective lower oxidation state forms (Fe^{2+}, Cu^+ cations) by pro-oxidant molecules, for example some polyphenols. (Bamforth *et al.*, 1993; Uchida and Ono, 1996; Andersen and Skibsted, 1998; Kaneda *et al.*, 1999; Vanderhaegen *et al.*, 2006). By further protonation, the superoxide anions form the perhydroxyl radicals (OOH$^\bullet$) that have much higher oxidative activity. Other reaction is the reduction of O_2^- anions by Fe^{2+} and/or Cu^{2+} cations to peroxide anions (O_2^{2-}), which can be easily protonated in beer to hydrogen peroxide (H_2O_2). Hydroxyl radicals (OH$^\bullet$) that are intensely reactive can be then produced from the resulted H_2O_2 or O_2^- by metal ions induced Fenton and Haber–Weiss reactions, which are given in Figure 33.3.

The resulted reactive oxygen species (O_2^-, OOH$^\bullet$, H_2O_2, OH$^\bullet$) are crucial to beer staling as they react with all classes of organic compounds in beer, that is polyphenols, isohumulones, alcohols, amino acids, fatty acids, iso-α-acids, α-acids and β-acids, leading to permanent changes in the sensory profile of beer and determining the flavor stability of beer. The rate and level of the reactive oxygen species formation is related to the concentration of iron and copper ions (Fe^{2+}/Fe^{3+}, Cu^+/Cu^{2+}), therefore its concentration is of special significance, should be minimized and controlled during the brewing process.

It is established as well that the polyphenols contribute to these beer aging reactions. Some of them are pro-oxidants that are capable of transferring the electrons to metal ions and reducing Fe^{3+} and Cu^{2+}, respectively, to Fe^{2+} and Cu^+ what indirectly stimulates the activation of oxygen in beer. In this process, they may itself become the radicals that react further with other constituents of beer or decompose producing various off-flavors. On the other hand, polyphenols act as anti-oxidants by capture of the iron ions and formation of their stable complexes. Apart from the polyphenols, such components of brewing liquors and beer as amino acids, phytic acid and melanoidins have the ability to sequestrate the metal ions to promote the formation of active oxygen radical species (Vanderhaegen *et al.*, 2006).

It has been also found that the free metal ions can be responsible for the protein–polyphenol haze (chill haze) formed by cross-linkage of proteins by low molecular weight polyphenols (Siebert *et al.*, 1996; McMorrough *et al.*, 1999). In this case, metal effect on the protein–polyphenol haze formation can be presumably attributed to their catalytic action on the polymerization of the polyphenols.

Organic compounds – pro-oxidants

$$Fe^{2+} + H_2O_2 = Fe^{3+} + OH^\bullet + OH^-$$

$$Fe^{3+} + H_2O_2 = Fe^{2+} + O_2^- + 2H^+$$

Fenton reactions

Haber–Weiss reactions

$$Fe^{3+} + O_2^- = Fe^{2+} + O_2$$

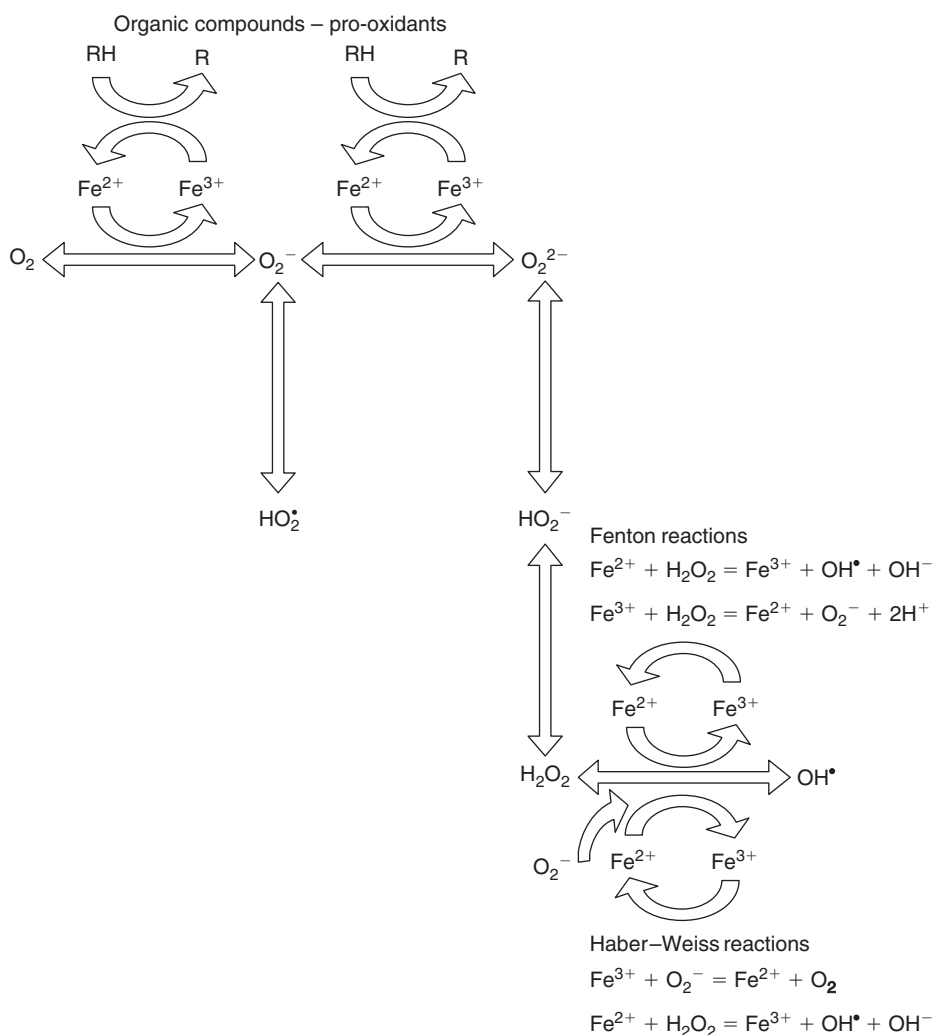
$$Fe^{2+} + H_2O_2 = Fe^{3+} + OH^\bullet + OH^-$$


Figure 33.3   The reactions leading to the formation of the reactive oxygen species in stored beer. *Source*: Adapted from Kaneda *et al.* (1999).

The polyphenols, however, are likely to undergo polymerization. When they interact with proteins after this process, they form a "permanent haze" of particle size between 1 and 10 μm. It should also be that the polymerization of the polyphenols is promoted by their oxidation. Therefore, the reactive oxygen species formed in the reactions activated and catalyzed by iron and copper ions (Fenton and Haber–Weiss metal-catalyzed reactions) are responsible for haze formation owing to the efficiency with which they oxidize the polyphenols in beer (Kaneda *et al.*, 1990; Kaneda *et al.* 1992; Bamforth, 1999b).

Summary Points

- The knowledge regarding the content and type of metals in beer is imperative to the beer brewers and the consumers since metal ions determine the quality of beer in terms of the course of the processes involved in brewing,

conditioning and storage of beer as well as imply the profound effect on the human health and well-being.
- There is a worldwide awareness of the importance of the controlling of metal composition at various steps of brewing to ensure the excellent quality of beer.
- On account of the nutritious value and critical role of metals in beer performance and final quality, the analysis of beer composition in reference to the total contents of major, minor and trace metals is of particular interest and significance.
- Along with the chemometric methods of data analysis and interpretation, the determination of metals in beer enables its characterization and authentication according to type, origin or packaging what is very useful in beer labeling and fraud tracing.
- It should be expected that the development of new analytical tools and methods linking chromatographic and electrophoretic separation techniques with sensitive

spectrometric method of detection in terms of speciation and fractionation analysis would help in the systematic elucidation of the mechanistic roles of these metals for which metabolic functions in beer processing and implications on beer quality, flavor and taste stability are not yet clearly established.

- On the other hand, the identification and the quantification of ultimate physicochemical forms of major, minor and trace found metals in beer would be determinative in the evaluation of their actual bioavailability or toxicity to human organisms.

Minerals in Beer

Luigi Montanari, Heidi Mayer, Ombretta Marconi and Paolo Fantozzi Italian Brewing Research Centre (CERB), University of Perugia, Via San Costanzo, Perugia, Italy

Abstract

The principal ions in beer are the cations – calcium, magnesium, sodium, and potassium – and the anions – sulfate, nitrate, phosphate, chlorides, and silicate. The minor ions are iron, copper, zinc and manganese. Cereals, water, hops and adjuncts are the main sources of the minerals present in beer, while in yeast, industrial processing and the containers contribute to a lesser extent. The mineral content of the brewing water is particularly important for the brewing process and hence for the quality and flavor of the final beer. In beer most of the minerals originate from the barley. About 75% derives from the malt, while the remaining 25% originates from the water. The mineral composition of the malt depends on the variety, place where it was grown, atmospheric condition, growing techniques, harvesting, storage, and malting system. Hops contribute a negligible amount of the minerals in beer because of the small quantities used (200 g to produce 100 l beer). However hops make a notable contribution of nitrate to the beer wort. In many countries a part of the malt can be substituted with other cereals like maize grits and rice. These cereal matrices normally contain fewer minerals than malt and so the metal level is less than an all-malt wort. The large amount of minerals from the raw materials decreases during the brewing process due to some minerals being removed through precipitations.

List of Abbreviations

°dH	German degree
ATP	Adenosine triphosphate
Ca	Calcium
Cl	Chloride
Cu	Copper
Fe	Iron
K	Potassium
Mg	Magnesium
Mn	Manganese
Na	Sodium
ppm	Parts per million
Zn	Zinc

Introduction

There is a well-balanced amount of minerals contained in beer. Being relatively high in potassium and low in sodium it is an ideal drink to include in diets for hypertensive patients (De Stefano and Montanari, 1996). It is low in calcium and rich in magnesium which may help protect against gall stone and kidney stone formation. These minerals have nutritional importance and also contribute to the flavor of the beer as non-volatile taste-active compounds. Schoenberger *et al.* (2002) showed that all taste qualities (sweet, salty, bitter, and sour) come from the minerals of the beer. Their concentration varies with the raw materials used and with the production process (Table 34.1).

The principal ions are the cations – calcium, magnesium, sodium, and potassium – and the anions – sulfate, nitrate, phosphate, chlorides, and silicate. The minor ions are iron, copper, zinc, and manganese. The level of toxic metals is limited by law. Cereals, water, hops, and adjuncts are the main sources of the minerals present in beer, while in yeast, industrial processing and the containers contribute to a lesser extent.

Calcium

Ca^{2+} ions that derive principally from the brewing water react with malt constituents such as phosphates and proteins during mashing to lower the pH. Most processes in beer production proceed better or faster the more acidic the pH (Kunze, 2004). Wort produced from liquor containing no calcium has a pH on the order of 5.8–6.0, compared to values in the range of 5.3–5.5 for worts produced from treated brewing liquor. For example the Ca^{2+} of neutral calcium sulfate reacts in the mash with the alkaline dipotassium hydrogen phosphate from the malt, forming insoluble

Table 34.1 Mineral composition of beer

Inorganic substances	Amount in beer (mg/l)	Recommended daily intake (mg/day)	Physiological effects in humans
Phosphates	300–400	1,250–1,500	Important constituent of bones and teeth; responsible for energy storage and transmission
Sulfate	150–200	–	No important effect
Nitrate	10–80		Nitrate can be converted to nitrite which is harmful to health. The amount of nitrate in beer is usually below the legal limit of 50 mg/l for drinking water and is harmless
Chloride	150–200	2,500	–
Potassium	500–600	2,500	Good for prophylaxis against heart attack; a high potassium content is diuretic
Sodium	30–32	550	Low sodium content desirable
Calcium	35–40	800–1,000	Can prevent heart diseases
Magnesium	100–110	300–350	Lowers the cholesterol level, beneficial effect on cardiac activity

Note: The type and the quantity of the main inorganic substances in the beer and their physiological effects in humans.

Source: Kunze, 2004.

calcium phosphate. Potassium dihydrogen phosphate is acidic and consequently the pH of the solution is lowered.

$$3CaSO_4 + 4K_2HPO_4 \rightarrow$$

Calcium sulfate   Dipotassium hydrogen phosphate

$$Ca_3(PO_4)_2\downarrow + 2KH_2PO_4 + 3K_2SO_4$$

Calcium phosphate   Potassium dihydrogen phosphate   Potassium sulfate
It thus has a positive effect on the activity of β-amylase and thus of wort fermentability and extract because the optimum pH for β-amylase activity is about 5.2–5.6. Furthermore, it has a beneficial effect on the precipitation of wort proteins, during both mashing and boiling.

$$Protein + Ca^{2+} \rightarrow Ca\ proteinate\downarrow + 2\ H_3O^+$$
The hydrogen ions released further reduce the pH which encourages further precipitation of proteins, increasing the colloidal stability of the beer. Calcium ions protect the enzyme α-amylase from inhibition by heat. Moreover they eliminate excess oxalate. Calcium oxalate normally separates from beer during fermentation and storage and is the major constituent (50–65%) of the beer stone which forms on the inner surface of fermentation and storage tanks. For this reason various authors recommend having 250 ppm calcium sulfate in the wort (Moll, 1987, 1995). A method commonly used by brewers to have a sufficient amount of calcium, and consequently to decrease the oxalate content in beer, is to add gypsum (calcium sulfate dihydrate) during brewing either to the brewing water at the mashing stage or during wort boiling. The dissolved calcium ions can combine with anionic oxalate to produce an almost totally insoluble calcium oxalate precipitate, which may be removed by settling, centrifugation, or filtration before packaging the product (Madigan and McMurrough, 1994). Thus during ageing, clarification, stability and flavor of the finished beer are improved. Calcium ions are also important for the flocculation of yeast because they activate the protein component essential for floc-forming ability (Nishihara *et al.*, 1994). Flocculation requires at least two types of molecules on the yeast surface: mannan (a type of carbohydrate) and flocculins (sugar-binding proteins). The flocculins bind the mannans on the surface of the neighboring cells in the presence of calcium ions (Dengis *et al.*, 1995; Touhami *et al.*, 2003). Calcium also extracts fine bittering principles of the hops and reduces wort color.

Magnesium

Magnesium ions react like calcium ions, but since magnesium salts are much more soluble, the effect on wort pH is not as great. Magnesium is most important for its benefit to yeast metabolism during fermentation. It is an essential element of the brewing liquor because it is required by yeast as a co-factor for the production of enzymes that are indispensable for the fermentation process. Yeast cells have a very high demand for magnesium that cannot be met by other metal ions. In fact, calcium ions act antagonistically toward magnesium in many biochemical and physiological functions of yeast through inhibitory competitive binding mechanisms. Yeast cells actively take up Mg^{2+}, but exclude Ca^{2+} and so Mg^{2+} functions intracellularly, while Ca^{2+} acts mainly extracellularly influencing yeast flocculation. Mg^{2+} also stabilizes biological membranes and is known to protect yeast cells from stress caused by ethanol, temperature, and osmotic pressure (Walker *et al.*, 1996).

Sodium

Normally, sodium comes from the water supply and brewing ingredients. The level of sodium in malt depends on the

levels in the processing water at the malt house (Rehberger and Luther, 1995). Sodium ions are not involved in chemical reactions with other components but pass unchanged into the beer (Kunze, 2004); they contribute to the perceived flavor of the beer by enhancing its sweetness. Sodium levels from 75 to 150 ppm give a round smoothness and accentuated sweetness, which is more pleasant when paired with chloride ions than when associated with sulfate ions. In the presence of sulfate, sodium creates an unpleasant harshness, so the more sulfate there is in the water, the less sodium there should be (and vice versa) (Goldammer, 2000). If the sodium levels exceed 150 ppm, it could indicate contamination by a cleaning solution.

Potassium

Like sodium, potassium can create a "salty" flavor effect. Potassium is required for yeast growth, and like magnesium, is a yeast co-factor that is required at trace levels for satisfactory fermentation. Potassium is particularly necessary for the metabolism of carbohydrates and supports all enzymatic reactions which proceed with ATP. It is more acceptable than sodium from a flavor point of view, giving a salty taste without sour notes. A large amount of potassium (500–600 mg/l) is particularly interesting for the nutritional importance of beer. Due to an osmotic effect, a high potassium content promotes the elimination of sodium and chlorides and therefore helps body dehydration and demineralization (De Stefano and Montanari, 1996). It remains in the final product and accounts for 30% of the recommended daily amount, considering 1l of medium alcoholic beer as an acceptable daily intake.

Silicon

Beer is a rich source of dietary silicon which is readily absorbed by the body. This silicon comes from two natural sources – water and barley (The Brewer of Europe, 2004). In the form of silicate, it is soluble as a colloid and can be detected in all beer hazes (Kunze, 2004).

Phosphate

Phosphates occur in the structures of many compounds in barley grains (e.g. in phytin, nucleic acids, coenzymes, proteins, etc.). They are released from these compounds in reactions occurring during malting and brewing. Most of the phosphates are bound in phytin that is salts of the organic acid myoinositol hexakis – (dihydrogen phosphate). Phytin is hydrolyzed in the mash tun releasing inorganic phosphate and the B vitamin, myoinositol (deLange, 2004). The amount of phosphate in malt is as much as 1% of its weight (as P_2O_3) according to Briggs et al. (1981). The term phosphate refers to compounds that involve the

ions of phosphoric acid. Phosphates react with calcium and magnesium as reported earlier. The presence of phosphate is extremely important for fermentation. Phosphorus is required for the formation of ATP, the formation of the phospholipid double membrane around the yeast cell and buffering against pH shift. A deficiency of phosphates causes fermentation problems and reduction in cell growth (Kunze, 2004).

Sulfate

Sulfates positively affect protein and starch degradation, which favors mash filtration and trub sedimentation. However, if the levels are too high, it may result in poor hop utilization (bitterness will not easily be extracted). Sulfates can lend a dry, crisp palate to the finished beer, but if used in excess, the finished beer will have a harsh, salty, and laxative character. The composition of the beer type or beer brand plays an important role in the taste threshold value (TTV). The TTV of $CaSO_4$ in a German lager is 430.5 mg/l, while in wheat beer it is 114.04 mg/l (Schoenberger et al., 2002). Sulfate is absorbed by yeast cells during fermentation (Kunze, 2004).

Chloride

Chloride gives a mellow and full palate. It limits yeast flocculation and improves clarification and colloidal stability.

Nitrate

Nitrate has no effect on beer flavor. It can be reduced to nitrite during the brewing process. Nitrite is a yeast toxin that causes poor multiplication and weak fermentation. Levels as low as 20 mg nitrate/l are dangerous for the yeast (Kunze, 2004).

Zinc

Zinc is found in trace amounts in wort. It is of great physiological importance for protein synthesis and yeast cell growth and thus for fermentation. If zinc is deficient, yeast growth is retarded, fermentation proceeds slowly and there is incomplete reduction of diacetyl. During the brewing process a higher zinc content can be favored by low pH, low mashing temperature, and a grist:liquor ratio of 1:2.5 (Kunze, 2004). However, only about 20% of the zinc in the malt goes into solution on mashing and the zinc content decreases further during mashing. If zinc levels of 0.10–0.15 mg/l are not maintained, the above-mentioned fermentation difficulties may occur because zinc is bound by a number of enzymes, like alcohol, dehydrogenase, and regulatory proteins (Bromber et al., 1997; Kunze, 2004). To compensate for zinc deficiency, zinc chloride, or zinc

Table 34.2   Classic beer styles and the mineral profile of the water of the city where they were developed

Water composition	Munich beer	Pilsner beer	Dortmund beer	Vienna beer
Total dissolved solids (mg/l)	284.0	51.2	1,110.0	947.8
Calcium (Ca^{2+}) (mg/l)	75.7	7.0	262.0	162.5
Magnesium (Mg^{2+}) (mg/l)	18.1	0.7	23.0	68.0
SO_4^{2-} (mg/l)	9.0	5.2	289.5	216.5
NO_3^- (mg/l)	Traces	Traces	Traces	Traces
Cl^- (mg/l)	2.0	5.0	107.0	39.0
Total hardness (°dH)[a]	14.8	1.6	41.3	38.5
Non-carbonate hardness (°dH)[a]	0.6	0.3	24.5	7.6
Carbonate hardness (°dH)[a]	14.2	1.3	16.8	30.9

Notes: The mineral content of the brewing water is particularly important for the brewing process. Brewing cities with a characteristic water composition have developed their own style of beer.

[a]dH = German degree.

Source: Schormüller (1968).

Sources of Minerals

Most of the minerals in beer derive from the raw materials: brewing water, malt, hops, and adjuncts.

Brewing water

The mineral content of the brewing water is particularly important for the brewing process, and hence for the quality and flavor of the final beer. In the course of time, brewing cities with a characteristic water composition have developed their own styles of beer which are now produced throughout the world, associating the name of the original city with a certain style of beer. For this reason modern brewers add minerals and other natural elements to water or eliminate them by boiling or filtration so that the water used in the brewing process always produces beer with the same flavor and enables brewers to produce identical-tasting beer at different brewing locations throughout the world (Table 34.2).

For example, the Pilsen region of the Czech Republic was the birthplace of the Pilsner style beer which is a crisp, clear golden beer with a very clean hoppy taste. The water of Pilsen is very soft, free of most minerals, and very low in bicarbonates, which allows the proper mash pH to be reached with only base malts. The lack of sulfate provides a mellow hop bitterness. Dortmund Export, a pale lager beer, derives its name from Dortmund, a city in Germany. It has less hop character than a Pilsner, with a more assertive malt character due to higher levels of all minerals. The water of Vienna in Austria is similar to that of Dortmund, but lacks the level of calcium to balance the carbonates, and also lacks sodium and chloride for flavor. So, Vienna malt is used to balance the mash to produce Vienna lager (Frank,

1969; Goldammer, 2000). It is cured at slightly higher temperatures than Pilsner malt. Consequently Vienna malt gives a golden colored beer with increased body. Dark beers require brewing waters rich in carbonate and bicarbonate ions. These ions have a pH-increasing effect which opposes the pH-lowering effect of the dark malts and the other calcium and magnesium ions, present in calcium chloride, calcium sulfate, magnesium chloride, and magnesium sulfate. The calcium, magnesium, and sodium bicarbonates of the brewing water decrease the acidity of the wort in the following order: Ca > Mg > Na. An example of increasing the pH during mashing is the reaction of the acidic potassium dihydrogen phosphate with calcium bicarbonate:

$$2KH_2PO_4 + Ca(HCO_3)_2 \rightarrow$$

Potassium dihydrogen phosphate   Calcium bicarbonate

$$CaHPO_4 + K_2HPO_4 + 2H_2O + 2CO_2$$

Calcium hydrogen phosphate   Dipotassium hydrogen phosphate   Water   Carbon dioxide
Alkaline dipotassium hydrogen phosphate is formed from acidic potassium dihydrogen phosphate (Kunze, 2004).

Malt

In beer most of the minerals originate from the barley. About 75% derives from the malt, while the remaining 25% originates from the water. The minerals include about 35% phosphates (expressed as phosphorous (5)-oxide P_2O_3), about 25% silicates (expressed as silicon dioxide, SiO_2), and about 20% potassium salts (expressed as potassium oxide, K_2O) (Table 34.3).

The mineral composition of the malt depends on the variety, place where it was grown, atmospheric conditions, growing techniques and harvest, storage and malting systems. The malting technique is particularly important.

Table 34.3 Minerals in malt (mg/kg dry matter)

Minerals	Reference 1[a]	Reference 2[b]	Reference 3[c]
K^+		3,530	3,618
PO_4^{3-}	6,329		
Mg^{2+}	1,155	1,370	1,421
Ca^{2+}	479	730	824
Na^+		28.2	25.0
Cl^-	830		
SO_4^{2-}	300		
SiO_2	5,260		

Notes: The quantity of different minerals in malt from different authors.

[a] Kolbach and Rinke (1963).
[b] Holzmann (1975).
[c] Mändl *et al.* (1972).

A short-germinated and undermodified malt has a different grist composition in husks, grits, and flour than a longer-germinated and overmodified malt. In a cereal grain, mineral elements are transferred from the storage tissues to the developing seedling. Minerals are more concentrated in the germ than in the central section, whereas the distal section has an intermediate amount. Rootlets and shoots contain substantially more potassium, phosphorus, iron, zinc, manganese, and copper than kilned malt. Calcium is transported to rootlets but not to shoots, and is more uniformly distributed throughout the kernel than magnesium. High-protein fractions are substantially richer in minerals than low-protein fractions. In differently modified malts, the development of rootlets and acrospires and the extent of metal transport from the central and distal section to the germ end are variable. It can thus be expected that the mineral concentrations in worts derived from such malts will vary. The metal distribution is also highly dependent on protein modification. Consequently, the brewer must carefully plan both malt modification and mashing conditions to achieve a desired mineral level in the wort (Holzman and Piendl, 1976).

Hops

Hops contribute a negligible amount of most minerals in beer because of the small quantities used (200 g to produce 100 l beer). However hops make a notable contribution of nitrate to the beer wort. Approximately 5–30 mg of nitrate/l of wort comes from raw hops or type-90 pellets, depending on beer bitterness and hop variety. A reduction of some 60% can be achieved by using type-45 pellets, the reduction is about 90–95% when using pure ethanol resin extracts, and complete elimination is possible, by using a CO_2 extract (Forster, 1989). New hop products, like potassium salts of the dehydro iso-alpha-acids, are now available that can be added at the end of fermentation to produce a light resistant beer in clear glass bottles, which contribute to the potassium content of the beer. Similarly, the potassium

Table 34.4 Minerals in adjuncts

Minerals	Maize grits (mg/kg)	Rice (mg/kg)
Ca^{2+}	24 ± 8	460 ± 26
K^+	894 ± 93	940 ± 79
Mg^{2+}	270 ± 22	494 ± 25
Na^+	16 ± 7	97 ± 20
PO_4^{2-}	605 ± 15	1,360 ± 25
SiO_2	7.5 ± 1	13.3 ± 8
Zn^{2+}	5.7 ± 0.5	15 ± 1.5

Note: The concentration of the minerals in substitutes of malt.
Source: Moll and Moll (1993).

salts of iso-alpha-acids are used to replace bittering hops for utilization or economic reasons and to adjust bitterness in beers that were underhopped in the kettle.

Adjuncts

In many countries a part of the malt can be substituted with other cereals like maize grits or rice. These cereal matrices normally contain fewer minerals than malt and so the metal level is less than of all-malt wort. Adjunct worts are less buffered, so there is a lower pH during fermentation (Holzman and Piendl, 1976) (Table 34.4).

Influence of the Brewing Process on the Mineral Content of the Beer

The large amount of minerals from the raw materials decreases during mashing due to the formation of insoluble phosphates (e.g. with calcium and magnesium), the formation of salts with the acidic groups of proteins, and the mechanical adsorption on spent grains and trub. The insoluble material precipitates out and thus does not get into the wort. The brewhouse yield of minerals is about 100% for potassium and sodium, 95% for chloride, 84% for sulfuric acid, and 63% for phosphoric acid. More than 50% of the other minerals are lost, and the loss of trace elements is particularly high. The precipitation of nitrogenous compounds at high temperatures removes sequestering agents from the wort leading to a significant loss of minerals. An important parameter that influences the mineral content is the mash concentration. Dilution of the mash concentration leads to a higher solubility of potassium, sodium, calcium, magnesium, manganese, and zinc. Increasing mashing time increases potassium, magnesium, and copper levels and decreases sodium, calcium, iron, manganese, and zinc levels. Wort boiling diminishes the mineral concentration due to metals binding to the precipitated material. With the addition of hops, minerals are also added (Holzman and Piendl, 1976) (Table 34.5).

During fermentation yeast requires minerals, particularly phosphorous and sulfur, as well as a number of metal ions

Table 34.5 Mineral contribution of raw material to the wort (mg/l)

	K^+	Na^+	Ca^{2+}	Mg^{2+}	Cu^{2+}	Fe^{2+}	Mn^{2+}	Zn^{2+}
Malt	556	6	100	184	1.1	6.1	2.1	3.7
Brewing water	3	17	75	21	Traces	0.4	0.04	Traces
Hop	66	Traces	25	9	1.2	0.6	0.3	0.3
Total	627	23	200	214	2.3	7.1	2.4	4.0
Wort 12% *P*	630	24	33	100	0.11	0.05	0.14	0.10
Loss	0	0	83	53	95	99	94	97

Note: The contribution of the different raw materials to the wort minerals and the loss in percent of them after wort boiling during the brewing process due to the formation of insoluble phosphates (e.g. with calcium and magnesium), the formation of salts with the acidic groups of proteins, and the mechanical adsorption on spent grains and trub.

Source: Moll and Moll (1993).

in small amounts. This and other subsequent production steps, like filtration or centrifugation of the final beer, further decrease the mineral content of the beer, bringing it to its desired balanced value.

Summary Points

- There is a well-balanced amount of minerals contained in beer. The principal ions are the cations – calcium, magnesium, sodium, and potassium – with the anions – sulfate, nitrate, phosphate, chlorides, and silicate. The minor ions are iron, copper, zinc, and manganese.
- Ca^{2+} ions derive principally from the brewing water. During mashing they react with malt constituents like phosphates and proteins lowering the pH.
- Magnesium is most important for yeast metabolism during fermentation because it is required by yeast as a co-factor for the production of enzymes that are indispensable for the fermentation process.
- Sodium has its origins in the water supply and brewing ingredients. The level of sodium in malt depends on the levels in the process water at the malt house.
- Potassium is a yeast co-factor and is required at trace levels for satisfactory fermentation and for the metabolism of carbohydrates.
- Phosphates occur in the structures of many compounds in the barley corns (e.g. in phytin, nucleic acids, coenzymes, proteins, etc.). They are released from these compounds in reactions that occur during malting and in the brewery.
- Sulfates positively affect protein and starch degradation, which favors mash filtration and trub sedimentation.
- Zinc is found in trace amounts in wort. It is of great physiological importance for protein synthesis and for yeast cell growth and thus for fermentation.
- The mineral content of the brewing water is particularly important for the brewing process and hence for the quality and flavor of the final beer.
- About 75% of the mineral content derives from the malt, while the remaining 25% originates from the water. The minerals include about 35% phosphates (expressed

as phosphorous (5)-oxide P_2O_3), about 25% silicates (expressed as silicon dioxide, SiO_2), and about 20% potassium salts (expressed as potassium oxide, K_2O).
- The mineral composition of the malt depends on the variety, place where it was grown, the atmospheric conditions, growing techniques and harvest, storage and malting systems.
- Hops contribute a negligible amount of the minerals in beer because of the small quantities used (200 g to produce 100 l beer).
- The large amount of minerals from the raw materials decreases during the brewing process due to some minerals being removed through precipitation.
- The brewhouse yield of minerals is about 100% for potassium and sodium, 95% for chloride, 84% for sulfuric acid, and 63% for phosphoric acid. More than 50% of the other minerals are lost, and the loss of trace elements is particularly high.

Abstract

There is increasing support for an important biological role of the trace element, silicon, in the optimal health of connective tissue, especially bone. Beer contains high levels of dietary silicon, in the well absorbed and biologically active form of orthosilicic acid $[Si(OH)_4]$. It is widely accepted that barley, especially following malting and maceration, provides the major source of silicon within beer. However, how the different aspects of the brewing process then influence the final beer–silicon concentration is not known. Here we describe the findings of two previously unreported studies. First, we confirm that beer contains a high level (typically around 20 mg/l) of silicon. Secondly, from a pilot brewing trial, we show that barley is the major source of silicon in beer. Two different malts (malted barley) had distinctly different silicon concentrations, presumably because silicon levels of barley vary genetically. Silicon levels of the final product also depended on mashing and rinsing (sparging) conditions during the brewing process while filtration was also shown to affect (reduce) silicon levels of the beer, probably due to adsorption of orthosilicic acid onto material that is trapped by or that comprises the filter. Silicon levels of the water used for brewing are likely to have a small additional influence on the final beer–silicon levels, but in this particular work were negligible.

Introduction

Silicon is an ubiquitous environmental element that is second only to oxygen in terms of elemental makeup of the earth's crust. Nonetheless, the role of silicon in human biology and health remains enigmatic although there is increasing support for an important biological role of this trace element, when delivered in its orthosilicic acid form $[Si(OH)_4]$, in the optimal health of connective tissue, especially bone, skin and blood vessels. Interested readers are referred to a recent review by Sripanyakorn *et al.* (2005) as well as to the Chapter 80 in this book. Indeed, this latter chapter is relevant because of the realization that beer is a potentially rich dietary source of silicon in a form that can be well absorbed by humans into the bloodstream (Sripanyakorn *et al.*, 2004).

Although the source water in the brewing process is likely to contribute to the final beer–silicon content, it is widely accepted that barley, especially following malting and maceration, provides the major source of silicon within beer. However, how the different aspects of the brewing process influence the final beer–silicon concentration is not known. This chapter briefly presents the typical levels of silicon that are found within beers and then reports on an investigation into the unit operations within the brewing process by sampling the process streams at appropriate points for silicon analysis. Thus information has been gained on the inputs, losses and fractionation of silicon in the process. This work was undertaken by two of the authors (Walker and Freeman) at the pilot brewery of BRI and samples then analyzed as previously reported (Sripanyakorn *et al.*, 2004) by Jugdaohsingh and Powell at St. Thomas' Hospital. For solid or slurry samples, prior acid-assisted microwave digestion was undertaken.

The Silicon Content of Alcoholic Beverages

We previously reported a mean ($\pm$SD) concentration of 19.2 ± 6.6 mg Si/l beer from the analysis of 76 different beers (range: 9–39.4 mg/l; Sripanyakorn *et al.*, 2004). Silicon concentration was not dependent on geographic origin, type of beer, alcohol content or the type of storage and packaging (Sripanyakorn *et al.*, 2004). In contrast, levels of silicon in wines are more varied and although they can be as high as some beers in a recent small analysis (Powell *et al.*, 2005), actual intakes of silicon in terms of servings are at least fivefold lower: 0.62–2.89 mg Si/serving wine (one glass or 125 ml) compared with 3.8–16.3 mg Si/serving for beers (300–574 ml) (Powell *et al.*, 2005). Moreover, it is not clear what the chemical form of silicon is in wine as it may be added as a colloidal, insoluble form during fining (post-vinification). Such an addition is less common in beer, and therefore the silicon is usually only present as soluble orthosilicic acid (Sripanyakorn *et al.*, 2004). Silicon levels in liquors/spirits are much lower being 1.3 ± 0.04 mg/l (Jugdaohsingh *et al.*, 2004) and intake from these beverages are completely unimportant in terms of dietary silicon exposure. Table 35.1 shows analytical results for a small series of previously unreported beer, wine and spirit samples that were analyzed in a single batch with individual sample-based standards. These data emphasize the dominant role of beer in its potential to provide dietary silicon amongst the alcoholic beverages, especially given the likelihood that it is drunk in larger volumetric quantities.

Changes in Silicon Content Through the Brewing Process

A pilot study was undertaken to investigate how the different aspects of the brewing process influences the final beer–silicon concentration. The process employed in the pilot brew (Figure 35.1) was typical of commercial brewing processes. Brewing water was tap water that had been through the process of reverse osmosis (RO). The malted barley was milled (ground). Barley varieties were "Pearl" as the standard brewing malt (87.5% by mass of the grist) and crystal malt, which is highly flavored (12.5%). This was then mixed with the hot brewing water (3 kg water to 1 kg malt) and maintained at 64°C for 60 min in a process known as mashing. The separation of liquid from spent grains, or "run-off," involved raising the temperature to 78°C and draining the liquid (sweet wort). The spent grains were then rinsed with water at 78°C (sparging), until the bulked sweet wort volume was 86 l. Yeast (351 wet grams of *Saccharomyces cerevisiae strain NCYC 1681*) was then added and wort fermented for 6 days at 18°C. A 3-day maturation period at 13°C was employed, followed by cold maturation at 3°C for 1 day. Subsequently the settled yeast was

Spirits	1.26	0.56–2.06	12
Ports/sherry		14.15–19.59	2

Note: Silicon concentrations of different beers available in London (UK) in shops and/or pubs and, for comparison, silicon levels in spirits and wines are also shown. Silicon concentrations were determined by inductively coupled plasma optical emission spectrometry, from sample-based standards. N = number of samples analyzed.

removed, followed by cold storage for a minimum of 7 days at 0°C. The beer sample was divided into two, and one sample was filtered through XE5/XE200 filter sheets and bottled. The other sample was filtered through kieselguhr at a dosage rate of 1 g/l. Samples of the bottled beer were processed separately through stabilizers, silica hydrogel (0.8 g/l) and polyvinylpolypyrollidone (PVPP) (0.5 g/l).

Samples collected at the different stages of the brewing process were analyzed by inductively coupled plasma optical emission spectrometry as previously described (Sripanyakorn *et al.*, 2004). Solid or slurry samples were prior digested by acid-assisted microwave digestion.

The brewing process, and the points at which samples were taken for analysis, are shown in Figure 35.1 while the analytical results, and any specific observations (comment) on the sample at the time of analysis, are given in Table 35.2.

Silicon ingress to the process from treated brewing water (liquor) was insignificant in these trials (Table 35.1). However, it should be noted that some water supplies have significant silicon content and the possibility should be considered that this passes *pro rata* through to the finished product. Regardless of the starting liquor silicon content, barley malt is an obvious major source of silicon in beer. Greater than 80% of silicon is in the cereal husks and absolute silicon levels vary between different varieties of barley, which appears to be at least partly genetically determined (Ma *et al.*, 2003). This would translate into different silicon contents of the chosen malts (i.e. malted barley) used for brewing. For example, in this work (Table 35.2), standard ale malt contained 0.28 mg Si/g malt while crystal malt (a darker, toffee-tasting malt) contained 0.45 mg Si/g malt.

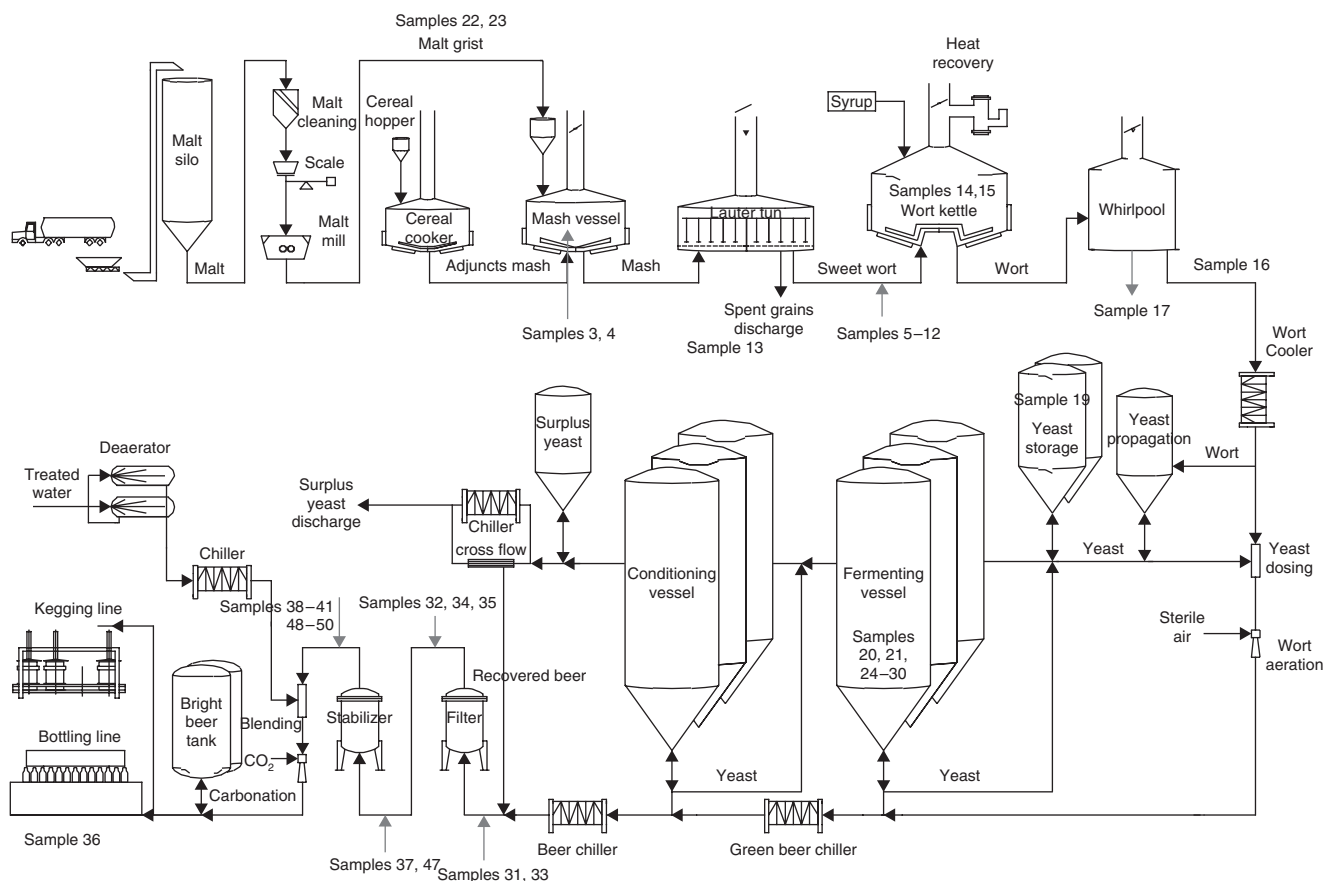
Next we considered how silicon from the malted barley passed into solution and into the final product itself (beer). While the initial stirring of the malt in hot water, released


Figure 35.1 The brewing process and samples taken for analysis. Schematic of the brewing process used and the identification of the points at which sampling were undertaken (i.e. sample numbers) for silicon analysis as reported in Table 35.2.

approximately 10 mg Si/l, the first few rinses with very hot water released a further 10–60%, which, with continued rinsing, rapidly fell away as the washed husks were exhausted in terms of dissolvable sugar and silicon (Figure 35.2).

Thus, it is clear that not only does the brewing process release silicon from the malted barley into solution but the rinsing process, that brewers use to recover sugar from the leftover husks, also results in increasing the silicon content of the beer.

Nonetheless, in this work only 19% of the silicon in the malted barley was recovered into the beer. Fermentation had no effect on the silicon content of the beer (Figure 35.3), so the remaining silicon was left in the husks. It would be interesting to see how brewing techniques that grind the husks more finely could further affect how much silicon is released into the final product (presumably increased due to an increase in surface area of the husks). Interestingly, filtration reduced the beer–silicon content by one-third (Figure 35.3), in spite of the fact that orthosilicic acid $(Si(OH)_4)$, which is the form of silicon almost exclusively present in beer, is too small to be retained directly as a consequence of filtration. However, there is a possibility of the adsorption of silicon directly onto the filtration mat or indirectly onto material (e.g. yeast cells) trapped by the filtration mat. It should be

noted that some brewers also use silicon-containing filters but we found no loss of silicon from these into the beer.

Many brands of beer are treated with process aids (materials that are employed in the brewing process that come into contact with the product, but have no function in the final product). These include kieselguhr (filtration aid, samples 33–35 in Table 35.2) and colloidal stabilizers such as silica hydrogel (samples 37–41) and PVPP (samples 47–50). The effect of these materials was measured on a laboratory pressure filter (a "Walton" filter). There was some evidence of adsorptive loss onto the PVPP but not the kieselguhr or silica hydrogel.

In summary, the silicon content of the beer in this work was at the low end of that found in commercial samples, and this was only a single pilot study, but certain conclusions can still be drawn with confidence. The data clearly show that macerated barley is the predominant source of silicon in beer and that aspects of the brewing process including choice of malt, extent of grinding, maceration and rinsing, as well as filtration could impact upon silicon levels of the final product. These factors will vary between breweries causing the wide range of silicon content seen in commercial beers and explaining why geographical variation and the style/type of beer are not significant factors in determining beer–silicon content.

Table 35.2　Silicon content of samples at the different points of the pilot brewing process

Sample	Description	Comments	Si concentration (mg/l)	µg Si/g of sample

Note: Silicon concentration of samples taken at different points of the pilot brewing process (see Figure 35.1 for a schematic representation of the brewing process and points where the samples were collected). Collected samples were analyzed by inductively coupled plasma optical emission spectrometry as previously described (Sripanyakorn *et al.*, 2004). Solid or slurry samples were prior digested by acid-assisted microwave digestion. Specific observations or measurements made on the sample during the brewing process are tabulated under comments. FV: fermenter vessel. KG: Kieselguhr, a filtration aid. PG: present gravity, measured in saccharin, equivalent to density (at 20°C, kg/m^3) × 1,000. PVPP: polyvinylpolypyrollidone, a colloidal stabilization agent. XE5, XE200: filtration sheets employed consecutively in filtration operation.
Figure 35.2 Release of silicon and sugars from the malt during rinsing. Silicon (Si) levels (mg/l) in solution as malted barley is stirred and rinsed with separate volumes of hot water. Sugar levels are also shown based on present gravity (PG; equivalent to density (at 20°C, kg/m³) × 1,000). The individual rinses are combined with the liquor (sweet wort) collected prior to rinsing and the pooled sample then fermented.
Figure 35.3 The effects of fermentation and filtration on silicon content of the beer. Silicon content (mg/l) of beer before fermentation, after fermentation and following filtration through XE5/XE200 filter sheets where a loss in soluble silicon is observed.

Summary Points

- Beer contains a high level (typically around 20 mg/l) of soluble and absorbable dietary silicon.
- Barley is the major source of silicon in beer.
- Silicon levels of barley vary genetically and thus different malts (malted barley) have varying silicon contents.

- Silicon levels of the final product also depend on mashing and rinsing conditions during the brewing process.
- Filtration may also affect (reduce) silicon levels of the beer due to adsorption onto material that is trapped by or comprises the filter.
- The process aid PVPP, which is employed as a colloidal stabilizer in some brands of beers, may remove some silicon by adsorption but further confirmatory trials should be performed.
- Silicon levels of the water used for brewing are likely to have a small additional influence on the final beer–silicon levels.

The Chemistry of Aging Beer

D.P. De Schutter, D. Saison, F. Delvaux, G. Derdelinckx and F.R. Delvaux Department of Microbial and Molecular Systems, Centre for Malting and Brewing Science, Catholic University of Leuven, Belgium

Abstract

Packaged beer is a closed system that continuously will be submitted to alterations by chemical reactions. These alterations will lead to perceivable changes in flavor, foam and colloidal stabilities. In this chapter, the underlying mechanisms of the reactions leading to aging of beer are discussed. Radical reactions, often initiated by reactive oxygen species, have an important contribution to beer staling and form a continuous thread to the stability of beer. Oxidation of unsaturated fatty acids and Maillard reactions leads to hundreds of different compounds. Furthermore degradation of hop bitter acids and carotenoids, oxidation of polyphenols, hydrolysis of glycosides and esters or synthesis of esters, acetalization of aldehydes will all contribute to the aging of beer. When using antioxidants, attention has to be paid to the slower reacting oxygen species such as H_2O_2, rather than the most reactive species as the hydroxyl radical.

Introduction

Every living creature alters its environment due to the continuous exchange of metabolites. A closed system will be highly influenced by this metabolism and will evolve to a state of thermodynamic non-equilibrium, far from the minimal Gibbs free energy. When this living entity is removed, a myriad of chemical reactions will slowly lead toward the chemical equilibrium of the system. This principle also counts for beer fermentation. Yeast in concentrations of 60 up to 120 million cells/ml will convert wort sugars into alcohol and CO_2, while producing secondary metabolites and converting components already present in the fermenting wort. Some of these compounds are present above their flavor threshold, while others are precursors of potent compounds arising during beer aging, altering the quality of the beer. When yeast is removed from beer before packaging, exogenous enzymes will still be present, influencing the chemical composition of the beer by enzymatic reactions. When finally the beer is pasteurized, the reactions will have a pure chemical origin, ultimately leading to the minimal enthalpy and maximal entropy. Some of these alterations will remain unnoticed, but others will lead to significant changes in beer flavor, haze and foam stability. While microbiological and colloidal stabilities are largely under control, flavor stability still remains a major concern to the brewer in the twenty-first century. More precisely it is the flavor instability or flavor deterioration that upsets a brewer. If the consumer cannot identify the flavor perception of the tasted beer with the expectation of that particular fresh brand, the beer will be called aged. However, the consumer will not necessarily have less appreciation for the aged beer, as flavor perception is a very personal sensation. Nevertheless flavor stability remains the engine of beer-aging research. At first, with the discovery of (E)-2-nonenal (Palamand and Hardwick, 1969; Jamieson and Van Gheluwe, 1970), the primary focus was set on the oxidation of lipids. At present, it is clear that not only lipid oxidation is responsible for beer deterioration, as other reactions such as radical chain reactions, Maillard reactions, degradation reactions of polyphenols and hop bitter acids also play an important role. This chapter intends to obtain insight in the extreme complexity of beer-aging reactions, focussing on the reaction mechanisms and the chemical nature of compounds, rather than the flavor appreciation that is crucial to brewers.

Chemical Changes During Beer Aging

Pure chemically, beer has to be considered as a water–ethanol solution (ethanol content 3–12 vol.%) with a pH between 4 and 4.5 and several hundreds, or thousands of

different compounds. The nature of these compounds can vary from very small volatiles as methanethiol to high-molecular, non-volatile proteins, polyphenols and melanoidins. As these compounds are not in chemical equilibrium, formation and degradation processes will take place during beer storage. Each reaction rate is determined by its reaction rate constant, its activation energy and the initial concentration of substrates, and largely depends on the storage temperature (the storage temperature has to be kept as low as possible) and the initial concentration of the reagents. Therefore, every different kind of beer will age in a typical way, determined by the raw materials, production parameters, packaging techniques and storage conditions. An important staling agent is oxygen, which is present in low levels in beer bottles. Although modern equipment allows not more than 20–50 ppb (μg/l) oxygen in the bottled beer, it is impossible to have the headspace entirely oxygen-free. In this section, first the role of oxygen on radical formation will be discussed, followed by two main chemical reaction pathways: lipid oxidation and Maillard reactions. Then individual beer staling reactions will be considered and finally some antioxidants and pro-oxidants will be highlighted.

Formation of reactive oxygen species

Oxygen in its ground state ($^3O_2$) is relatively non-reactive; it seems thus unlikely that oxygen immediately attacks beer constituents after beer is bottled. However, by energy, light or catalytic activity, activated forms of oxygen can be generated (reactive oxygen species), like singlet oxygen ($^1O_2$), superoxide ($O_2^{\bullet-}$), hydroperoxyl radical ($^{\bullet}OOH$), hydroxyl radical ($^{\bullet}OH$) and hydrogen peroxide (H_2O_2). Reactive oxygen species, as the name indicates, have a strong activity which allows them to react with different kinds of components (Halliwell and Gutteridge, 1984; Bamforth and Parsons, 1985). Recently a general generation pathway (Figure 36.1) of reactive oxygen species in beer has been proposed (Kaneda et al., 1999). First, $O_2^{\bullet-}$ will be produced from O_2 during storage of beer. This reaction will be catalyzed by the oxidation of Fe^{2+} ions or Cu^+ ions to Fe^{3+} and Cu^{2+}, both present in beer in trace amounts. The pKa value of $O_2^{\bullet-}/^{\bullet}OOH$ is 4.7–4.9, the $^{\bullet}OOH$ radical being the most reactive species. Thus the low pH value of beer slightly favors the formation of $^{\bullet}OOH$, unless $O_2^{\bullet-}$ is further reduced to O_2^{2-}. Due to the high pKa values of O_2^{2-}/HO_2^- and HO_2^-/H_2O_2, predominantly H_2O_2 will be formed in beer. It is believed that the formation of hydrogen peroxide is a consequence of mixed function oxidation systems, which involve oxygen in its ground state, Fe^{3+} and Cu^{2+}, but also require electron donors, like ethanol (Chapon and Chapon, 1979), ascorbic acid (Brezova et al., 2002), polyphenols, isohumulones and melanoidins (Irwin et al., 1991; Morales, 2005). Next, $^{\bullet}OH$ is produced by metal-catalyzed reactions such as the Fenton reaction and the Haber–Weiss reaction.

There seems to occur a so-called lag-time in beer before the $^{\bullet}OH$ radical is formed during storage. In that period endogenous antioxidants in beer consume the $O_2^{\bullet-}$, O_2^{2-} and H_2O_2 produced during the coupled oxidation reactions, before the $^{\bullet}OH$ radical can be formed (Uchida et al., 1996). It was reported that an antagonistic action of pro-oxidants,
Figure 36.1 Creation of reactive oxygen species (Reprinted from Vanderhaegen et al., 2006, Copyright (2006), with permission from Elsevier). Stable $^3O_2$ will be converted to O_2- and O_2^{2-} by mixed function oxidation systems. Hydrogen peroxide in combination with Fe^{21} or Cu^1 will generate the $OH^{\bullet}$ via the Fenton reaction or the Haber–Weiss reaction.

like iron and Maillard reaction products, shortens the lag-time (Uchida and Ono, 2000). Pro-oxidants are defined as compounds that are known to be able to produce H_2O_2 (like cysteine or sulfhydryl group containing proteins), or are known to be able to reduce metal ions to the oxidation states that are active for the Fenton reactions with peroxides as mentioned before (Brezova et al., 2002).

Antioxidants are defined as compounds able to quench peroxides (like sulfite), or able to inactivate trace amounts of metals that otherwise may generate hydroxyl or alkoxyl radicals from the peroxides (Andersen et al., 2000). After depletion of these antioxidants, $^{\bullet}OH$ radicals will accumulate and can cause damage to beer components. The $^{\bullet}OH$ radical displays a high reactivity toward several beer compounds such as ethanol, sugars, isohumulones, polyphenols, alcohols, fatty acids, etc. This can initiate a series of reactions responsible for the production of carbonyl and phenolic radicals and ultimately lead to staling compounds in beer. This lack of specificity of the $^{\bullet}OH$ radical makes it almost impossible to quench this radical intermediate in beer by adding antioxidants that would react specifically with this radical. Hydrogen peroxide and organic hydroperoxides are the only reactive oxygen species that are stable enough to be trapped efficiently by antioxidants which are normally present in micro-molecular concentrations (Andersen et al., 2000). Because of the high reactivity of ethanol, being the most abundant compound in beer, this compound will be the primary reactant of $^{\bullet}OH$ radical, resulting in the $EtO^{\bullet}$ radical. This radical will bind oxygen, resulting in acetaldehyde and the hydroperoxyl radical (Figure 36.2). The latter can be reduced to hydrogen peroxide, which can react again with metal ions to continue the radical chain reactions (Andersen and Skibsted, 1998). As it is impossible to know all of the variables necessary to prevent oxidative deterioration by reactive oxygen species, minimization of radical formation will be the best strategy. This can be accomplished by keeping the level of O_2 as low as possible, by lowering the temperature, and by introducing chain breakers or quenchers, generally referred to as antioxidants (Bamforth, 2001).

Oxidation of unsaturated fatty acids

Since the identification of (E)-2-nonenal as the volatile which is presumed to be responsible for the cardboard flavor of aged beer (Jamieson and Van Gheluwe, 1970, Palamand and Hardwick, 1969), this powerful odorant was embraced by all beer researchers as the principal cause of beer deterioration. These findings directed the beer-staling research toward the formation of (E)-2-nonenal by the oxidation of unsaturated fatty acids (Drost et al., 1971; Stenroos et al., 1976; Dale et al., 1977; Tressl et al., 1979).

There are two pathways to the oxidation of unsaturated fatty acids: enzymatic oxidation (Drost et al., 1971) and autoxidation (Lindsay, 1973). Enzymatic oxidation occurs during mashing. Due to the activity of both lipase and lipoxygenase, present in malt, linoleic and linolenic acid hydroperoxides are formed (Kobayashi et al., 1993). The limitation of oxygen ingress and a mashing-in temperature at 65°C can decrease the production of hydroxy fatty acids during mashing (Kobayashi et al., 2000b). Nevertheless, the levels of dihydroxyoctadecenoic acid and trihydroxyoctadecenoic acid in commercial beer vary between 0.6–1.6 ppm and 6–15 ppm, respectively (Kobayashi et al., 2000a).

During the boiling process, the enzymes are inactivated due to the high temperature in the wort kettle. As the presence of oxygen cannot completely be excluded, reactive oxygen species are formed due to heat addition to wort. These reactive oxygen species attack susceptible double bonds of oleic, linoleic and linolenic acid, resulting in predominantly 9- and 13-hydroperoxides. Further breakdown of these hydroperoxides leads to the formation of (E)-2-nonenal and other aldehydes. As reduction of these compounds by yeast occurs during fermentation and maturation, it seems evident that yeast exerts a high influence on the overall flavor stability of beer (Wackerbauer et al., 2003).

Despite all the beer-aging models, actual lipid oxidation neither does not seem to occur in bottled beer at normal storage temperatures, nor can nonenol oxidation account for the presence of (E)-2-nonenal (Lermusieau et al., 1999). The total amount of (E)-2-nonenal in aged beer originates from autoxidation during wort boiling (Noël et al., 1999), and enzymatic action during mashing (Liegeois et al., 2002). During mashing and wort boiling, (E)-2-nonenal
Figure 36.2 Radical reaction of OH with ethanol (Reprinted from Andersen and Skibsted, 1998, with permission from the American Chemical Society). Ethanol is the most abundant molecule in beer and the non-selective $^{\bullet}OH$-radical will quickly react predominantly with ethanol. Preferentially, this will lead to acetaldehyde and the perhydroxyl radical, which after reduction to H_2O_2 can regenerate $^{\bullet}OH$ via the Fenton or Haber–Weiss oxidation pathway.

can form an imine adduct with amino acids and proteins through the formation of Schiff's base. Hence the compound is protected from reduction to nonenol by yeast (Noël and Collin, 1995). During beer aging, (E)-2-nonenal can again gradually be released by acid hydrolysis of (E)-2-nonenal-adducts at beer pH (Lermusieau *et al.*, 1999).

Measures were taken to prevent or to limit oxygen ingress in the brewhouse, which will lead to a decreased oxidation of unsaturated fatty acids, but oxygen cannot completely be excluded during wort production and wort treatment in practical brewing (Drost *et al.*, 1990).

The Maillard reaction

The Maillard reaction predominantly occurs during wort production due to the high temperatures, but some of the reactions will continue during beer storage, even at low temperature.

Initial Reaction   Initiated by the reaction of a reducing sugar and an amino-compound, the Maillard reactions develop as a highly complex labyrinth of pathways, which are at present not yet fully elucidated. The complexity of the Maillard reactions was first visualized 40 years after its discovery in a complex scheme of reactions and products (Hodge, 1953). The non-enzymatic browning reactions are ubiquitous in all processed food products; hence they will occur during the production of wort (Tressl, 1979) and continue during beer storage (Bravo *et al.*, 2002).

After mashing, the fermentable sugar content of wort consists of 10% glucose, 60–70% maltose (2 glucose-units linked together in an α-1,4 glycosidic linkage) and 20–30% maltotriose (3 units). Due to the high sugar level and the presence of amino compounds, the Maillard reaction will easily and rapidly occur during wort boiling. An overview of the Maillard reaction involving monomer formation is depicted in Figure 36.3.
Figure 36.3   The Maillard reaction (Bravo *et al.*, 2002). The reaction of a reducing sugar and an amino acid leads to the formation of the Amadori product. After enolization, 1- and 3-deoxy dicarbonyl compounds can be formed, leading to the synthesis of furanones and furan compounds, respectively. Retro-aldolic cleavage of the dicarbonyl compounds or Strecker degradation give rise to other dicarbonyl compounds or Strecker aldehydes, respectively.

Quantitatively, 5-hydroxymethylfurfural (HMF, originating from hexose sugars) and furfural (from pentose sugars) are the most important Maillard monomers in wort. The reaction is initiated with the formation of a Schiff's base between the carbonyl group of the reducing sugar and an amino-compound (which acts as a nucleophile), resulting in an imine. This undergoes an Amadori-rearrangement to 1-amino-1-deoxyketose (Yaylayan and Huyghues-Despointes, 1994). This Amadori product is subjected to enolization and subsequent release of the amino group; 2,3-enolization resulting in the formation of 1-deoxy-2,3-hexodiulose (1-DH) or 1,2-enolization in the formation of 3-deoxy-2-hexosulose (3-DH) (Hirsch et al., 1995). At wort and beer pH, the latter reaction is favored, so quantitatively more 3-DH is formed. After subsequent dehydrations, finally HMF or furfural can be formed, while 1-DH predominantly generates furanones like furaneol.

The monomeric compounds are not the end products of the Maillard reaction. After further reactions (condensation, cyclization, dehydration, isomerization, . . .), highly colored melanoidins are produced. Notwithstanding several models of melanoidin structures have been proposed so far, the majority of melanoidins is still lying in mysterious obscurity (Tressl et al., 1998; Cammerer et al., 2002; Adams et al., 2003). Although melanoidins are known to act as antioxidants, some reports also indicate a prooxidant activity (Hashimoto, 1972). There are various mechanisms by which Maillard reaction products may act as antioxidants (Ames, 2001): oxygen scavengers, reactive oxygen scavengers (Morales, 2005), reducing agents and metal chelating agents (Wijewickreme et al., 1997). A strong correlation between malt color (and therefore beer color) and antioxidative activity is established. According to Coghe et al. (2003), at least two types of Maillard reaction related antioxidants are present in wort: redox-reducing antioxidants and radical scavenging antioxidants. Redox-reducing antioxidants develop linearly with malt color (accounting for the observed correlation between malt color and antioxidative activity). Fast-acting antiradical antioxidants however, seem to be associated with low-colored malts. No correlation has been found between browning intensity and efficiency for scavenging oxygen radicals in solution (Morales, 2005).

Glucose accounts for only 10% of the reducing sugars available in wort, while the concentration of maltose is about 60–70% of the fermentable sugars. Maltose, maltotriose and other malto-oligosaccharides are reducing sugars as well and can also react with amino compounds, yielding α-dicarbonyl compounds via a peeling-off mechanism, proposed by Hollnagel and Kroh (2000). In the case of maltose (Figure 36.4), a β-elimination of D-glucose occurs, resulting in 1-amino-1,4-dideoxysone. The addition of a water molecule and subsequent retro-Claisen condensation yields formic acid and 3-deoxypentosulose, the latter being a precursor of furfuryl alcohol (Vanderhaegen et al., 2004). Furfural, after reduction by yeast, and furfuryl alcohol are precursors of 2-furfuryl ethyl ether, a well-known beer

staling compound with a solvent-like flavor and harsh taste (Harayama et al., 1995; Vanderhaegen et al., 2004).

In the following sections, the importance of α-dicarbonyl compounds, the Strecker degradation and aldol condensation will be discussed.

Alpha-Dicarbonyl Compounds   Although the Maillard reaction is significantly accelerated at elevated temperatures like wort boiling, the reaction still occurs during beer storage at room temperature. The formation of 10 different α-dicarbonyl compounds was observed during beer storage: glyoxal, methylglyoxal (formed by a retro-aldolic cleavage of 1-DH or 3-DH) according to Weenen (1998), 2,3-butanedione, pyruvate, pentanedione, 1,4-dideoxypentosulose (Strecker degradation product of 1-deoxy-2,3-pentodiulose), 1,4-dideoxyhexosulose (Strecker degradation product of 1-DH), 1-DH and 3-DH (Bravo et al., 2002). The accumulation of these compounds indicates that the Strecker degradation, retro-aldolic cleavage and the degradation of Amadori-compounds still take place during beer aging at moderate temperatures. Due to the central role of α-dicarbonyl compounds in the proceeding of the Maillard reactions, blocking these intermediates could prevent typical aging compounds to develop. The use of α-dicarbonyl trapping reagents like aminoguanidine, also used in diabetes research (Edelstein and Brownlee, 1992), can block these intermediates and inhibit the dicarbonyl-mediated beer aging. When adding aminoguanidine to dicarbonyl compounds, it reacts irreversibly and rapidly to a permanent 3-aminotriazine, as depicted in Figure 36.5 (Hirsch et al., 1992), which prevents any further reaction with the dicarbonyl moiety (Bravo et al., 2001; Rangel-Aldao et al., 2001a). It has been observed that the addition of 2 mM aminoguanidine to fresh beer retards the formation of HMF during storage and moreover, it has a positive effect on the flavor stability during natural aging (Rangel-Aldao et al., 2001b).

Strecker Reaction   In the 1970s it was found that an increased formation of 2-methylpropanal and 3-methylbutanal occurred in beer when valine and leucine were added, respectively (Blockmans et al., 1975). This was explained by the Strecker reaction between amino acids and α-dicarbonyl compounds. The reaction of phenylalanine with methylglyoxal is shown in Figure 36.6 as an example. The Strecker degradation involves a transamination, followed by a decarboxylation and hydrolysis, resulting in an aldehyde with one carbon atom less than the amino acid, and an α-aminoketone (Hofmann et al., 2000). Although the Strecker aldehydes (acetaldehyde (Ala), 2-methylpropanal (Val), 2-methylbutanal (Ile), 3-methylbutanal (Leu), methional (Met), phenylacetaldehyde (Phe) and benzaldehyde (Phe)) increase significantly during beer aging, the individual compounds rarely exceed their flavor threshold (Thum et al., 1995). However, they are frequently monitored to get insight in overall quality parameters, brewing
Figure 36.4   Formation of 3-deoxypentosulose from maltose (Reprinted from Hollnagel and Kroh, 2002, with permission of the American Chemical Society). After β-elimination of glucose, a 1-amino-1,4-didesoxyosone is produced, that after water addition and a retro-Claisen reaction leads to formic acid and a C-5 dicarbonyl compound.

technology and storage conditions (Methner *et al.*, 2003). Beside Strecker aldehydes, also α-aminoketones are formed in this reaction, which can further react with other aminoketones to alkylpyrazines, after subsequent cyclization and dehydration (Tressl, 1979). These alkylpyrazines are often characterized by a nutty, roasted flavor.

Recently a Strecker-type degradation of amino acids by oxidation products of unsaturated fatty acids, the 4,5-epoxy-2-alkenals, was observed by Hidalgo and Zamora (2004). Later, the proposed reaction mechanism was extended to hydroxyalkenals as well (Hidalgo *et al.*, 2005). The authors suggested a reaction mechanism, shown in Figure 36.7, where in the first step an imine is formed, followed by a decarboxylation and hydrolysis, yielding a Strecker aldehyde and an alkyl-pyridine. As the reaction proceeds evenly at 37°C and 60°C, the results suggest that heating is not required for this reaction to occur. Moreover, these Strecker-like reactions lead to pyrrole compounds, able to

polymerize to brown pigmented melanoidin-like structures (Zamora *et al.*, 2000; Hidalgo *et al.*, 2003). Based on these observations, a merged reaction pathway between the Maillard reaction and lipid oxidation was proposed (Zamora and Hidalgo, 2005).

Aldol Condensation   Hashimoto and Kuroiwa (1975) suggested that an aldol condensation in beer is possible under mild conditions during storage. They observed an aldol condensation between acetaldehyde and heptanal, after 20 days of incubation at 50°C, in the presence of proline (which is always present in beer, as it is not metabolized by yeast under normal fermentation conditions). In this reaction amino acids can act as catalysts by the formation of an imine intermediate. This pathway can convert compounds with a medium flavor threshold into compounds with a very low flavor threshold. The proposed reaction mechanism is shown in Figure 36.8.
Figure 36.5 Formation of aminotriazine adducts after reaction of aminoguanidine with 1-DH and 3-DH (Reprinted from Hirsch *et al.*, 1995, with permission of Elsevier). Amadori compounds will react to either 1-DH or 3-DH. These dicarbonyl intermediates can be trapped by the reactive guanyl-group of aminoguanidine, which leads to the irreversible formation of triazines.
Figure 36.6 Strecker degradation of phenylalanine by methylglyoxal (Reprinted from Hofmann *et al.*, 2000, with permission from the American Chemical Society). After condensation of the α-dicarbonyl compound and the amino acid to an imine intermediate, decarboxylation occurs. Water addition to the intermediate releases the aminoketone and phenylacetaldehyde.

Degradation of Hop Bitter Acids Hop bitter acids (α-acids, β-acids and iso-α-acids) also undergo oxidative degradation during beer storage, resulting in alkanones, alkenals and alkadienals of varying lengths and structures (Hashimoto and Eshima, 1977). Particularly isohumulones are very susceptible to oxidative degradation due to the double bond and the carbonyl group of the isohexenoyl side chain. This oxidation of bitter acids is accompanied by a decrease in beer bitterness (Hashimoto and Eshima, 1979). More recently, it was demonstrated that the gradual decrease of beer bitterness intensity is largely due to the instability of *trans*-iso-α-acids. It was suggested that the ratio of *trans/cis*-iso-α-acids offers a reliable criterion

to evaluate bitterness deterioration as a function of time (De Cooman *et al.*, 2000). The difference between *cis*- and *trans*-iso-α-acids is depicted in Figure 36.9. Oxidation of α-acids and iso-α-acids leads to complex polycyclic structures by intramolecular reactions, mostly dehydrations. Presumably, as long as functional groups remain in the oxidized bitter substances, oxidation will continue to proceed. Hop β-acids are highly unstable due to the highly susceptible unsaturated side chains and undergo autoxidation which starts already during hop storage. During the brewing process, β-acids will be oxidized almost completely (De Keukeleire, 1981a, b). To overcome the oxidative deterioration of hop bitter compounds, reduced isomerized
Figure 36.7 Strecker-type degradation of phenylalanine by a 4,5-epoxy-2-alkenal (Reprinted from Hidalgo and Zamora, 2004, with permission of the American Chemical Society). After the condensation of a 4,5-epoxy-2-alkenal and an amino acid to an imine, decarboxylation occurs. Subsequent hydrolysis of the imine compound releases the Strecker aldehyde and the unsaturated amine, which can further react to an alkylpyridine.
Figure 36.8 Aldol condensation of heptanal and acetaldehyde (Hashimoto and Kuroiwa, 1975). Aldehydes can react via an aldol condensation to unsaturated aldehydes. Amino acids function as catalysts by the formation of an imine intermediate to accelerate the reaction. After hydrolysis of the imine intermediate, the amino acid is recovered and the unsaturated aldehyde is released.

hop extracts are frequently used. Tetrahydroiso-α-acids are extremely resistant to oxidative deterioration and promote foam stability and bitterness consistency, while the light-stable dihydroiso-α-acids do not appear to be stable at all during storage (De Cooman et al., 2001).

A well-known isohumulone degradation compound is 3-methyl-2-butene-1-thiol (MBT), responsible for the light-struck or skunky flavor in beer exposed to visible light. The light-struck flavor compound is characterized by an extreme low flavor threshold, 7 ng/l (Irwin et al., 1993). As isohumulones do not absorb light in the visible region, MBT production has to be triggered by a photo-sensitizer, like riboflavin. There exists a correlation between MBT formation and the riboflavin concentration in beer (Sakuma et al., 1991). Riboflavin, present in beer in concentrations of 0.2–1.3 mg/l, absorbs visible light and can be excited to its triplet state ($^3RF^\bullet$), followed by an electron transfer from iso-α-acids to $^3RF^\bullet$ (Goldsmith et al., 2005). This leads to the formation of the 2-methyl-2-butene radical, which reacts to MBT with H_2S (Huvaere et al., 2005). The initiation of the radical reaction is depicted in Figure 36.10. As this reaction can occur in the absence of oxygen, it can have a major impact on beer quality. Therefore, it is better to store beer in darkness and the use of brown beer bottles is preferred over green or white bottles.

Oxidation of Polyphenols Degradation of polyphenols may affect not only the bitter quality and astringency of beer, but also the beer color (Dadic, 1974). Upon oxidation or acid catalysis, polymerization reactions lead to complex polyphenols of high molecular weight. Possibly, the
Figure 36.9 Reduced and non-reduced *cis*- and *trans*-iso-α-acids (De Cooman *et al.*, 2001). After reduction to dihydro- or tetrahydro-iso-α-acids, the susceptible carbonyl function and unsaturated bonds of the iso-α-acids are transformed in a hydroxyl function and saturated bonds, respectively. The distinction between cohumulone, humulone and adhumulone is made by the composition of the side chain (R).

initiation of the polymerization reactions starts with the oxidation to quinone or semi-quinone radicals, which then further interact with other phenolic compounds (Gardner and McGuinness, 1977). During beer storage, the complex phenolic polymers, called tannoids, as well as oxidized monomeric phenols interact with proteins to form insoluble complexes and hazes, finally leading to colloidal instability.

Treatment of beer with recommended dosages of polyvinylpolypyrrolidone (PVPP) extends effectively the colloidal stability of beer without compromising flavor stability. Although partial removal of flavanoid polyphenols reduces the endogenous-reducing capacity, the resulting beers do not seem to be more susceptible to oxidative flavor damage (McMurrough *et al.*, 1996).

Carotenoid Degradation or Hydrolysis of Glycosides   The most important member of the norisoprenoids in beer, β-damascenone, can be found in malt extract (Farley and Nursten, 1980), hops (Tressl *et al.*, 1978a, b), beer (Lermusieau *et al.*, 2001) and wine (Genovese *et al.*, 2005). This compound is characterized by a very low flavor threshold in water (20–90 ng/l) and can be found in naturally aged beer in a concentration up to 210 μg/l. Concerning the mechanism of formation of β-damascenone, acid hydrolysis might explain the increase of β-damascenone during beer aging (Chevance *et al.*, 2002). The hypothesis of acid hydrolysis is supported by the observed increase in β-damascenone concentration when lowering the beer pH (Gijs *et al.*, 2002). Potential precursors include the allene triols and acetylene diols arising from the degradation of neoxanthin (shown in Figure 36.11). Degradation of neoxanthin leads first to the Grasshopper ketone. Reduction of the Grasshopper ketone, followed by acid hydrolysis, ultimately leads to β-damascenone.

It was also found that β-glucosidase treatment of beer leads to an increase in the β-damascenone concentration, due to the hydrolysis of glycosylated β-damascenone precursors (Chevance *et al.*, 2002). Through degradation of
Figure 36.10 Reaction of triplet riboflavin with isohumulones (Reprinted from Huvaere *et al.*, 2005, with permission from the American Chemical Society). Excited riboflavin will extract an electron from bitter acids. This initiates intramolecular reactions, ultimately leading to the formation of the 2-methyl-2-butene radical. After reaction with H_2S, MBT is formed.

carotenoids or hydrolysis of glycosides, other important compounds, contributing to beer aging, might also be released.

Acetalization of Aldehydes A condensation reaction between 2,3-butanediol (concentration up to 280 mg/l in beer) and an aldehyde like acetaldehyde, isobutanal, 3-methylbutanal and 2-methylbutanal, leads to cyclic acetals as 2,4,5-trimethyl-1,3-dioxolane, 2-isopropyl-4,5-dimethyl-1,3-dioxolane, 2-isobutyl-4,5-dimethyl-1,3-dioxolane and 2-secondary butyl-4,5-dimethyl-1,3-dioxolane, respectively (Peppard and Halsey, 1982). The equilibrium between 2,4,5-trimethyl-1,3-dioxolane, acetaldehyde and 2,3-butanediol is reached rapidly in beer. Consequently, during beer aging, the concentration of 2,4,5-trimethyl-1,3-dioxolane will increase similarly to the increase of acetaldehyde (Vanderhaegen *et al.*, 2003).

Synthesis and Hydrolysis of Esters During beer aging, esters formed above their chemical equilibrium will

hydrolyze at a characteristic rate. Acetate esters of higher alcohols will hydrolyze more rapidly than the corresponding ethyl esters, independent of the alcohol content of the beverage (Ramey and Ough, 1980). Isoamyl acetate is found to be hydrolyzed both chemically and enzymatically. The enzymatic hydrolysis depends greatly on pH, storage temperature and fermentation/maturation conditions and is performed by esterases released after cell-lysis during fermentation/maturation and bottle conditioning (for beers refermented in the bottle, a typical habit for Belgian specialty beers). The greatest decrease in positive fruity esters is observed in beers refermented in the bottle and in non-pasteurized beers. After pasteurization, the enzymatic hydrolysis is eliminated during beer aging (Neven *et al.*, 1997).

In contrast to hydrolysis, the esterification of ethanol with organic acids also occurs during beer aging. In fresh beer, the concentration of these ethyl esters is relatively low and well under the equilibrium concentration. It is therefore most likely that they were almost not formed by yeast during fermentation (Vanderhaegen *et al.*, 2003).
Figure 36.11 Formation of β-damascenone from neoxanthin (Reprinted from Chevance *et al.*, 2002, with permission from the American Chemical Society). Degradation of neoxanthin leads to the formation of the Grasshopper ketone, which after reduction and subsequent acid hydrolysis, gives rise to β-damascenone.

The precursor acids are found to be originating partly from hop, by oxidation of hop bitter acids to, for example, isovalerate and 2-methylbutyrate. After the conversion with ethanol to ethyl esters, these compounds impart a winey, brandy-like flavor to beer (Williams and Wagner, 1978, 1979). Precursors of ethyl ester formation can also be delivered by the Strecker degradation, which can also give rise to organic acids (Hofmann *et al.*, 2000). In addition to the hop acids and the Strecker acids, acids originating from yeast metabolism are present in beer, which may explain the increased concentration of diethyl succinate, ethyl pyruvate, ethyl lactate, ethyl nicotinate and ethyl phenylacetate in aged beer (Vanderhaegen *et al.*, 2003).

Antioxidants and Reducing Agents vs. Pro-oxidants A broad definition of an antioxidant is: a substance that, when present at low concentrations compared with those of an oxidizable substrate, significantly delays or prevents oxidation of that substrate (Halliwell and Gutteridge, 1989). However, the way antioxidants can exert their antioxidant activity differs among compounds. Moreover, most of the presumed antioxidants can have pro-oxidant capabilities as well, for example, ascorbic acid (Brezova *et al.*, 2002), sulfhydryl compounds, chelating agents, polyphenols, Maillard-reaction products (Bamforth, 2001). Maillard-reaction products as melanoidins are known to scavenge free and active oxygen, act as reducing agents and chelate metals (Ames, 2001). However, there have been reports of pro-oxidant activity as well (Hashimoto, 1972).

Phenolic compounds, like (+)-catechin, quercetin, 4-vinylguaiacol and rutin are known to quench superoxide radicals and to inhibit lipid peroxidation. Recently however, it was stated that at beer pH, the scavenging activity of the polyphenols and phenolic acids is very low comparing to sulfite (Nakamura *et al.*, 2003). Other phenolic compounds, as ferulic acid, often demonstrate poor quenching abilities but good peroxidation inhibition. However, some antioxidants can have pro-oxidant properties as well, like (+)-catechin in low concentrations (Walters *et al.*, 1997a). In beer (+)-catechin and ferulic acid also seem to specifically decrease the rate of the *cis*-isohumulone degradation, but they can exert a negative influence on beer colloidal (catechin) or flavor (ferulic acid, after conversion to 4-vinylguaiacol) properties (Walters *et al.*, 1997b).

Sulfite is a very potent inhibitor of flavor deterioration. It is naturally formed by yeast and is frequently used in the food industry. Sulfite stabilizes the flavor in two ways, as antioxidant and as carbonyl scavenger in aldehyde-bisulfite adducts.

Concerning the formation of reactive oxygen species, sulfite is found to be the only compound that is able to effectively retard the formation of radicals in beer during storage. Hydrogen peroxide and organic hydroperoxides are the only reactive oxygen species that are stable enough to be trapped efficiently by antioxidants which normally only are present in micromolecular concentrations (Andersen *et al.*, 2000). Moreover, sulfite reacts with H_2O_2 in an acid-base catalyzed reaction that does not involve radical intermediates. This action prevents the radicals to be produced via the Fenton and Haber–Weiss reactions (Hoffmann and Edwards, 1975).

Sulfite is known to form adducts to staling aldehydes. The strength of the aldehyde bisulfite complexes decreases with increasing chain length and the presence of double bonds. Based on these observations, a staling mechanism was proposed. When the concentration of acetaldehyde rises during beer storage, sulfite will be transferred from staling aldehydes to acetaldehyde, thereby releasing the staling aldehydes (Nyborg *et al.*, 1999).

Kaneda *et al.* (1996) observed the bisulfite adduct of acetaldehyde and other aldehydes, and concluded that the interaction between nonenal and bisulfite was too weak to form stable adducts during beer fermentation. Dufour *et al.* (1999) on the other hand, observed a permanent irreversible sulfite adduct to the double bond of unsaturated aldehydes. The stability of such adducts makes the mechanism of release of unsaturated aldehydes during beer aging relatively improbable. In Figure 36.12 different possible bisulfite adducts are shown. The sulfite addition to the carbonyl group is reversible, but the addition to the carbonyl double bond is irreversible and highly stable.
Figure 36.12 Proposed mechanism of bisulfite addition to (E)-2-nonenal (Dufour *et al.*, 1999). The addition of sulfite to the carbonyl group of (E)-2-nonenal is reversible. This is in contrast with the definitive addition of sulfite to the double bond of (E)-2-nonenal.

It is also believed that sulfite stabilizes intermediates of the Maillard reaction by forming adducts. For example, glyceraldehyde forms a stable hydroxysulfonate adduct, which renders this aldehyde non-reactive in processed food (Keller *et al.*, 1999). In conclusion, it can be stated that sulfite stabilizes the flavor as an antioxidant because of the good radical scavenging characteristics rather than its capacity to bind carbonyls (Kaneda *et al.*, 1994). Concerning the formation of reactive oxygen species, sulfite is found to be the only compound that is able to effectively retard the formation of radicals in beer during storage. Moreover, sulfite reacts with H_2O_2 in an acid-base catalyzed reaction that does not involve radical intermediates. This action prevents the radicals to be produced via the Fenton and Haber–Weiss reactions (Hoffmann and Edwards, 1975).

Yeast itself is also a very potent antioxidative creature. *Saccharomyces cerevisiae* is able to reduce a variety of carbonyls and seems to play a very important role in the reduction of beer staling compounds and their precursors (Shimizu *et al.*, 2002).

Conclusion

It is obvious that the knowledge of beer aging is far from complete, given the myriad of reactions that exert an influence on the composition and freshness of beer. Most of the reactions cannot be avoided, but they can at least be minimized. Therefore, excessive heat addition during wort production should be avoided, beer should be bottled with a minimum of oxygen and it should be stored at low temperatures and in the dark.

Summary Points

- Beer changes continuously toward its chemical equilibrium.
- Beer aging will lead to flavor deterioration and colloidal instability.
- Activated forms of oxygen play an important role in beer aging, initiating radical reactions.
- Trace metals function as catalysts during radical formation.
- Lipid oxidation leads to the formation of aldehydes.
- The Maillard reaction pathway is highly complicated and exerts a major influence on beer staling by dicarbonyl compounds and Strecker reactions.
- Degradation of hop bitter acids decreases bitterness but also creates flavor compounds.
- Oxidized polyphenols will form complexes with proteins and cause colloidal haze.
- Certain esters, present above their equilibrium and responsible for the fresh flavor will be hydrolyzed, while other esters will be synthesized chemically.
- Carotenoid degradation and hydrolysis of glycosides lead to the release of potent flavor compounds.
- Most of the used antioxidants are also known to exhibit pro-oxidant behavior in certain circumstances.
- Antioxidants should trap hydrogen peroxide or organic peroxides to efficiently protect beer from aging reactions.

Trans-2-nonenal During Model Mashing

José da Cruz Francisco and Estera Szwajcer Dey Pure and Applied Biochemistry, Lund University, Lund, Sweden

Abstract

A study on *trans*-2-nonenal (T2N) production during laboratory mashing of barley malt reveals that during the mashing-in step of kilned malt, an elevated amount of T2N (up to 14 ppb) is produced, and at the mashing-off step, a rapid decrease takes place. The decrease of T2N level observed is independent of the presence of spent grains. At moderate temperature, spent grains have a stabilizing effect on T2N levels. The decreased amount of T2N during mashing-off can be quantitatively determined in a potential test. Reduced levels of T2N have also been observed when the mashing-in liquor was acidified to pH 5.3, or by using coarse ground malt or by making a thicker mash. Increased amounts of T2N have been found in the extracts carried out at 5°C. No correlation between lipoxygenase activity in kilned malt and the corresponding soluble T2N during wort production was found in the study.

List of Abbreviations

GC–MS	Gas chromatography–mass spectrometry
HCB	Hexachlorobenzene
LOX	Lipoxygenase
NICI	Negative ion chemical ionization
PFBHA	*O*-(2,3,4,5,6-pentafluorobenzyl)amine
ppb	Parts per billion
RSD	Relative standard deviation
T2N	*Trans*-2-nonenal

Introduction

Beer off-flavor depends on the production of volatile aldehydes from lipid oxidation during malting, kilning, mashing and wort boiling processes. During beer production, stepwise enzymatic degradation of lipids and fatty acids continues and can lead to the formation of stale flavor substances such as *trans*-2-nonenal (T2N) (Drost *et al.*, 1990). Plants degrade linoleic acid through the action of lipoxygenases (LOX)

pathway enzymes, generating T2N and other derivatives of which some are involved in plant defence, gene regulation and plant to plant signaling (Feussner and Waternack, 2002; Hambraeus and Nyberg, 2005).

By enzymatic oxidation of linoleic acid or trilinolein, 9-hydroperoxylinoleic acid is formed by the enzyme LOX-1. T2N is then produced from 9-hydroperoxylinoleic acid by the secondary plant enzyme hydroperoxide lyase (Van Aarle, 1993). It is asserted that flavor stability of beer is inversely related to LOX activity during the early stages of mashing (Martel *et al.*, 1991). The formation of T2N may also occur both during malting and during wort production. Tressl *et al.* (1979) has reported an amount of T2N as high as 200–400 ppb in the final malt. During mashing-in, enhanced amounts of 9-hydroperoxylinoleic acid are produced (Walker *et al.*, 1996); however, it is not elucidated to which degree this compound is converted to T2N by hydroperoxide lyase, or trihydroxy octadecanoic acid by LOX or to ketols produced by dehydrase. Baur *et al.* (1977) have found elevated amounts of trihydroxy fatty acids in beer and after isolation it was established that trihydroxy fatty acids have a bitter taste. T2N is also generated during wort boiling in non-enzymatic process (Noeel *et al.*, 1999). Keeping beer at 38°C for only a few days suffices to increase the concentration of T2N above the threshold (Drost *et al.*, 1990) but exactly how this is formed in the beer remains elusive.

This chapter presents a case study of the changes occurring in soluble T2N and corresponding variations in LOX activity during model laboratory mashing. The experimental design used is described in detail. The methods used for the identification of T2N, its potential determination, the LOX extraction and its activity are simply mentioned to guide the reader for possible repetition.

Experimental Design

For the case studies presented in this chapter, malt is milled to particle size of 1 mm (fine milling). Fifty grams of malt flour is mashed-in with 450 ml of distilled water at 37°C.
Figure 37.1 Temperature profile and sampling points under standard mashing conditions. Samples are collected at the points marked with arrows and capital letters.

The standard mashing program has three steps (Figure 37.1) with mashing-in at 37°C for 20 min, saccharification at 68°C for 30 min and mashing-off at 77°C for 10 min. Between each step the temperature is raised at 1°C/min.

Samples are collected after mashing-in (point A), at the start of saccharification (point B) and at the end of mashing-off (point C). The entire contents of one mashing beaker is used for each sampling. The sample from each mashing steps is filtered immediately on a folded filter paper. The filtrate is collected in a measuring glass immersed in an ice bath. Collection of filtrate is stopped when 150 ml has been collected. To prevent enzymatic lipid oxidation, pH must be decreased from 6.0 to about 4.0 by the addition of 0.55 ml 8.5% phosphoric acid. The wort (filtrate) is analyzed for T2N after acidification. One part of the wort is analyzed directly and another part is kept at −20°C for the determination of T2N potential.

Monitoring the Mashing Process

Prior to analysis for T2N and T2N potential determination, cleaning up of wort (filtrate) is necessary. For this purpose a solid phase extraction C_{18} column (1 g/6 ml, EC) conditioned with 6 ml of methanol and washed with 6 ml of Milli Q water is recommended. Five milliliters of filtrate is supplemented with 0.8 ml methanol and 4.8 ml of Milli Q water and mixed well. The mixture is then passed through the column. For the described case the column was washed with 6 ml of 30% methanol followed by 3 ml of 70% methanol. T2N was eluted with 6 ml of 90% methanol. T2N present in the eluate from the cleaning is derivatized with 0.5 ml O-(2,3,4,5,6-pentafluorobenzyl)amine (PFBHA) solution (0.2 g PFBHA in 50 ml Milli Q water) for 2 h, at room temperature. Fifty microliters sulfuric acid 9 M are added to terminate the reaction. Then T2N is extracted with 2 ml n-hexane using a whirl-mixer (minimum 30 s). The n-hexane phase is dried with sodium sulfate and quantitatively

transferred to a clean test tube and concentrated to less than 0.5 ml under a gentle stream of nitrogen at no more than 40°C. Internal standard hexachlorobenzene for instance is added to the sample and made up to a volume 0.5 ml with hexane and transferred for analysis with gas chromatography–mass spectrometry (GC–MS).

For GC, the interface temperature, the ion source temperature at and the injection temperature are usually kept at 260°C, 190°C and 230°C, respectively. The GC oven temperature is kept at 40°C for 2 min and run at the following temperature gradients: 40–120°C at 25°C/min, 120–240°C at 10°C/min, 240–260°C at 30°C/min held for 15 min.

The mass spectrometer is operated in full scan mode: m/z 282–317. The acquisition time is 18 min scanning in negative ion chemical ionization mode; m/z 315 and 285 were used as characteristic ions for T2N. For the case study, m/z 285 was the quantification ion, m/z 284 and 286 were used as characteristic ions for the internal standard, and the sum of both ions were used for quantification. For T2N potentialdetermination, the acidified extract/wort (pH 4.0) is boiled for 2 h before measurements as described by Drost *et al.* (1990).

Procedure

The analysis for LOX activity is preceded by the enzyme extraction.

Five grams of malt are milled for 2 min in a water cooled analytical mill. One gram of flour is stirred for 30 min at 5°C with 10 ml of 0.1 M phosphoric buffer, pH 6.0. The suspension is centrifuged for 10 min at 5,500 rpm, and the supernatant used as an enzyme extract. When LOX activity is assayed in filtrates from mashes, the filtrate is used directly as an enzyme extract.

The enzyme assay is then performed by adding 25 μl of freshly prepared enzyme extract to a mixture of 50 μl linoleic acid (25 mM in 1% Tween 20) and 925 μl phosphate buffer (0.1 M, pH 6.0). Afterwards, LOX activity is determined spectrophotometrically by measuring the initial increase at Ab 234 nm indicating the formation of conjugated diene of linoleic acid hydroperoxide with extinction coefficient = 25,000/$M^{-1} cm^{-1}$ at room temperature in a 1 ml quartz cuvette against a blank. One unit of LOX activity is defined as the amount of activity that produces 1 μmol of conjugated diene of linoleic acid hydroperoxide in 1 min at room temperature.

Laboratory Model Mashing Study

During beer production, stepwise enzymatic degradation of lipids and fatty acids continues and can lead to the formation of stale flavor substances such as T2N (Drost *et al.*, 1990). T2N is also generated during wort boiling in a non-enzymatic

Table 37.1   *Trans*-2-nonenal in samples collected at points A, B and C during laboratory mashing

Sampling point/time	Trans-2-nonenal in wort (ppb)						
	1 day	2 days	3 days	4 days	Mean	SD	RSD (%)
A	15.1	13.8	13.7	13.2	13.8	±0.6	4.35
	14.3	13.3	13.9	13.3			
B	4.8	4.4	5.1	4.9	4.7	±0.4	8.51
	4.8	3.9	4.7	5.0			
C	3.7	3.7	3.9	3.9	3.6	±0.4	11.1
	3.1	2.9	3.9	3.9			

SD = standard deviation; RSD = relative standard deviation.

Table 37.2   *Trans*-2-nonenal found at points A, B and C in spiked and unspiked filtrates incubated according to the normal mashing program

Sampling point	Trans-2-nonenal (ppb)		
	Un-spiked sample	Spiked sample	Difference (ppb)

B	3	5	2
C	2	3	1

process (Noeel *et al.*, 1999). One of the crucial steps in generation of T2N during brewing is the mashing process.

Following the design and the analytical procedures described above, the reproducibility of the T2N analysis (including mashing and sampling) was investigated. Duplicates of Alexis malt mashing were performed on four different days. Samples were collected at points A, B and C; see Figure 37.1.

As displayed in Table 37.1, the T2N values from different batches of wort were reproducible. At all sampling points, the standard deviation was (±)4–6%. However, the coefficient of variations (RSD) for sampling points A, B and C showed increasing values: 4.35%, 8.51% and 11.1%, respectively. The dispersion of the variations increased while the absolute values decreased.

The role of spent grains in reduction of soluble T2N during mashing

A relatively large amount of soluble T2N, approximately 14 ppb, was found after mashing-in (point A). A rapid drop in T2N was observed as the temperature was increased to 68°C (point B). At this point, almost 65% of the T2N found at point A had disappeared. A further decrease was observed after saccharification and mashing-off (point C). The reduction of soluble T2N may be due to a chemical or an enzymatic reaction. Alternatively, T2N may adsorb to the insoluble spent grain particles and thus be removed during filtration. To investigate the role of spent grains, an extract free of spent grains and with a relatively high level of T2N was made by mashing Alexis malt and filtering the

mash after mashing-in (point A). A part of this filtrate was spiked with 11 ppb T2N. The two filtrates, spiked and unspiked, were then re-incubated according to the mashing program shown in Figure 37.1. Samples were collected at points A, B and C, and the results are shown in Table 37.2.

Fifteen parts per billion (15 ppb) of T2N was found in the original filtrate free of spent grains made after mashing-in (point A). When this filtrate was re-incubated at 37°C for 20 min, the level of soluble T2N decreased by about 50% to 7 ppb. In the samples collected at points B and C, the level of soluble T2N decreased further to 3 and 2 ppb, respectively, levels somewhat lower than those found in mashing with spent grains present (Table 37.1). In the extracts spiked with 11 ppb, the exogenous T2N disappears just like the endogenous T2N. At points A, B and C, the levels of soluble T2N are only slightly higher in the spiked extract than in the original one. These observations suggest that the reduction in T2N observed during normal mashing was not due to adsorption of spent grain particles. One of the theories is that T2N-adducts are created between the aldehyde and the amino groups of peptides and protein present in wort (Liegeois *et al.*, 1999). Laboratory made adducts between T2N and myoglobin, at pH 7 and 37°C, are water-soluble, non-volatile and flavorless substances (Dey *et al.*, 2005).

T2N potential during mashing

The level of free T2N in fresh beer is below 0.05 ppb, however, during storage the level of free T2N increases. This is explained by the release of the so-called imine-protected T2N

at a lower pH during aging (Collin *et al.*, 1999). Drost *et al.* (1990) have introduced the "T2N potential" concept in final pitching wort. This potential is believed to reflect the flavor stability of the resulting beer and is determined by measuring T2N in wort acidified to pH 4.0 (beer pH) and boiled for 2 h. The "T2N potential" during mashing was investigated by analyzing samples from a standard mashing (one of the mashings performed on day 3 in the reproducible experiments, Table 37.1). The results are shown in Table 37.3.

In boiled samples, the concentration of T2N reaches approximately the same level as found after mashing-in in fresh un-boiled samples. These results (Table 37.3) indicate that the reduction of T2N during mashing may be due to a chemical "masking" occurring at elevated temperatures and pH 6.0.

Effect of pH during mashing-in

It has been claimed that the T2N potential in wort is correlated to LOX activity in malt (Drost *et al.*, 1990; De Buck *et al.*, 1997). The activity of LOX-1 was optimal at about pH 6.3 and was markedly reduced at lower pH (Doderer *et al.*, 1992). Earlier, it has been reported that mashing at a lower pH reduces the T2N potential in final wort due to reduced LOX activity during mashing-in.

To see the effect of pH on T2N levels after mashing-in, the mashing-in liquor was acidified with phosphoric acid prior to addition of malt flour. Samples are taken after mashing-in (point A) and pH, T2N and T2N potential are measured in the filtrates. The results are shown in Table 37.4.

The level of free T2N and the T2N potential decrease when pH decreases during mashing-in. When pH was reduced from 6.0 to 4.8, 70% less of T2N was found. This supports the hypothesis that a reduced LOX activity due to

low pH during mashing-in leads to reduced levels of T2N in wort.

Effect of temperature

Apart from low pH, LOX activity may also be low due to a low reaction temperature. Thus, at 5°C, LOX activity was expected to be very low, however, the available soluble oxygen at this temperature was higher than at 37°C. The enzyme may also be inactivated by high temperature, and it is known that LOX gets inactivated immediately at temperatures above 60°C. To investigate the effect of temperature, experiments with "mashing-in" at temperatures of 5°C, 37°C and 60°C were carried out. T2N and dissolved LOX activity were followed in filtrates made at fixed time intervals up to 1 h of incubation. The results from this experiment are shown in Table 37.5.

After 5 min incubation at 5°C, 6 ppb T2N was found in the extract, and after 30 min it increased to a steady level of 17 ppb. At 37°C the level of T2N was almost constant at 12 ppb, while at 60°C the level of T2N decreased from 5 ppb after 5 min to 2 ppb after 60 min. T2N potential was measured after 20 min of mashing-in on samples that were at 5°C, 37°C and 60°C, and it was found to be 15, 11 and 20 ppb, respectively. At 5°C, the level of LOX activity was practically constant throughout the extraction period (0.22–0.25 U/ml), at 37°C (after 20 min) it was 0.66 U/ml and at 60°C, no activity was detected. The stability of the LOX already present at temperature higher than 37°C decreases the activity of these enzymes. LOX-1, which survives kilning, is the key enzyme in the pathway leading to T2N in plants

Table 37.3 *Trans*-2-nonenal and *trans*-2-nonenal potential in filtrates from a laboratory mashing

Sampling point	Trans-2-nonenal (T2N) in filtrates (ppb)	
	Free (T2N)	Potential (T2N)
A	14	11
B	5	18
C	4	16

Table 37.4 *Trans*-2-nonenal and *trans*-2-nonenal potential in filtered samples after incubation at 37°C for 20 min. Mashing-in liquor was acidified with addition of phosphoric acid before addition of malt

Added ml 8.5% phosphoric acid	pH	Trans-2-nonenal (ppb)	
		Free	Potential
0	6.0	13	11
0.45	5.7	13	5
0.9	5.3	9	4
1.2	5.1	7	4
1.6	4.9	5	3
1.8	4.8	4	3

Table 37.5 *Trans*-2-nonenal in filtrates made after mashing-in at 5°C, 37°C and 60°C

	Time of mashing-in (min)					
	5	10	20	30	40	60
Free trans-2-nonenal in filtrate (ppb)						
Incubation at 5°C	6	9	13	17	17	17
Incubation at 37°C	11	13	12	12	12	13
Incubation at 60°C	5	3	3	3	2	2

(Drost *et al.*, 1990; Van Aarle, 1993; De Buck *et al.*, 1997). LOX-1 has a pH optimum at about 6.3, and at lower pH the activity is markedly reduced (Drost *et al.*, 1990; Yang *et al.*, 1993). It is puzzling that in the "T2N potential test", mashing-in made at 60°C generates as high a level of T2N as the mashing-in at ambient temperature, in spite of the fact that no LOX activity was present.

Effect of malt-to-water ratio and malt particle size

The level of T2N in wort may not only be a result of enzymatic production during mashing. It may also depend on the level of T2N already present in kilned malt. During malting and kilning, T2N may be produced by the same type of reaction as during mashing. It was not clear to which extent T2N was produced during malting, and there was no knowledge about the solubility of T2N from malt during mashing. To investigate a possible effect of solubility of T2N from malt, experiments were performed with different malt-to-water ratios and with different malt particle sizes. The effect of malt-to-water ratio was investigated by incubating 10–50 g of Alexis malt in 450 ml of 37°C water for 20 min. T2N and LOX activity was measured in the filtrates. The results are shown in Table 37.6. The amount of soluble T2N after mashing-in was almost independent of the ratio between malt and water.

Five times more malt results in only 1.6 times more T2N. In contrast, LOX activity increases almost proportionally to the amount of malt.

Table 37.6 *Trans*-2-nonenal in filtrates made after mashing-in (37°C) with different ratios between malt and water

Amount of malt (g)	Ratio (malt:water)	Trans-2-nonenal (ppb)	LOX activity (U/ml)
10	1:45	9	0.026
20	1:23	10	0.044
30	1:15	13	0.066
40	1:11	14	0.080
50	1:9	14	0.077

Note: In all extractions, 450 ml water was used.

Table 37.7 *Trans*-2-nonenal and *trans*-2-nonenal potential after mashing-in and after mashing-off with fine, middle or coarse ground malt

	Trans-2-nonenal (ppb)			
	Mashing-in		Mashing-off	
Grinding	Free	Potential	Free	Potential
Fine	11	11	3	13
Middle	10	8	2	8
Coarse	4	5	1	5

The role of malt particle size was investigated using Alexis malt milled on a mill, with settings of 0.1, 0.7 and 1.3 mm between the disks giving fine, middle or coarse grindings. T2N and T2N potential are measured after mashing-in (point A) and at mashing-off (point C). Results are shown in Table 37.7.

The amount of T2N in filtrates decreased with increasing malt particle size, both after mashing-in and after mashing-off. There was almost no difference between the level of T2N and T2N potential in filtrates made after mashing-in with malt of the same grinding. The level of T2N at mashing-off was much lower than after mashing-in, but the T2N potential after mashing-off corresponds well to the levels found after mashing-in.

Comparison of LOX activity and T2N in kilned malt

It has been claimed that kilned malt with a high level of LOX(s) produces an enhanced level of T2N potential in wort (Drost *et al.*, 1990; De Buck *et al.*, 1997). To investigate this claim, extracts of seven different kilned malts were assayed for LOX activity. T2N was determined in filtrates made from the same malts after mashing-in. The results are shown in Table 37.8.

No correlation was found between LOX in malt extracts and T2N found after mashing-in in this set of malts. On the other hand, the non-correlation between LOX activity of malt and T2N produced has been previously observed by Kuroda *et al.* (2002), a fact that was considered to depend on peroxidase-like activity (Kuroda *et al.*, 2003).

As shown in this study, it was difficult to clarify whether the level of T2N in wort depends mainly on LOX activity during mashing or on solubility of T2N already present in kilned malt. Most of the research in this area has focused on the role of LOX during mashing, whereas there was very limited knowledge of the impact of the T2N accumulated during the malting process. According to our findings, this part of the process from barley to wort may be just as important as the mashing process for flavor stability in beer.

Table 37.8 LOX activity in seven malts and corresponding T2N found after mashing-in

Malt	LOX* (U/g of malt)	T2N after mashing-in (ppb)
1	3.6	14
2	6.5	2
3	2.4	26
4	8.4	16
5	3.6	27
6	3.6	19
7	3.8	43

* Extracted at 5°C as described in Procedure.

Summary Points

- At 5°C T2N could already be released and present as free T2N.
- T2N potential correlates with the free T2N extracted at 5°C, after 30 min of incubation.
- Spent grains are not arresting the T2N.
- Endogenous and spiked T2N is arrested by components present in the wort during temperature increases.
- LOX activity was not correlating with the free T2N.
- The ratio between malt and water has no effect on the amount of free T2N, it correlates with the extracted LOX activity.

E-2-nonenal and β-Damascenone in Beer

José Rodrigues and Paulo Almeida Department of Chemistry,
Faculty of Science, University of Porto, Porto, Portugal

Abstract

One of the main concerns among brewers is to maintain the
organoleptic stability of stored beer. This objective has
prompted a series of scientific studies, which have given a bet-
ter knowledge of all the brewing procedures. Nowadays, the
brewers have a better comprehension of the beer-ageing phe-
nomenon and the know-how to increase the organoleptic sta-
bility of packaged beers.

E-2-nonenal (also called *trans*-2-nonenal), a compound with
an extremely low taste threshold (0.1 μg/l), is widely recognized
as the major cause for the development of the typical unpleas-
ant cardboard flavor in aged beers. Recently, an increase of
β-damascenone concentration during beer ageing was dis-
covered. These two compounds were proposed as analyti-
cal markers for beer-ageing characterization. However, at the
levels found in beer, there is no evidence that *E*-2-nonenal and
β-damascenone could have effects, adverse or beneficial, on
human health. In this chapter, the formation and the determi-
nation of these two carbonyl compounds in beer are reviewed.

GC/MS	Gas chromatography/mass spectrometry
HPLC/UV	High-performance liquid chromatography/ultraviolet detection
LC/MS	Liquid chromatography/mass spectrometry
NMR	Nuclear magnetic resonance
ppb	Parts per billion
SBSE	Stir bar sorptive extraction
SPME	Solid-phase microextraction
UV	Ultraviolet

Introduction

Chemically, the changes in flavor that develop in packaged
beers are very hard to define since they occur progressively
during storage and are due to a combination of the effects
of many flavor components (Vanderhaegen *et al.*, 2006).

Lustig (1996) lists 10 substances as the principal deter-
minants of staling: 2-methylbutanal, 2-furaldehyde,
5-methyl-2-furaldehyde, benzaldehyde, 2-phenylethanal,
diethylsuccinate, ethylphenylacetate, 2-acetyl furan,
2-propionyl furan and γ-nonalactone. Compounds such
as 2-furaldehyde are generally held to be good markers of
oxidation in beer without themselves being present in suf-
ficient quantity to be detectable. Others in this category
include acetaldehyde, 5-hydroxymethylfurfural, γ-hexalac-
tone, 3-methylbutanal and the ethyl ester of nicotinic acid
and 2-furfurylethyl ether and furfuryl acetate (Bamforth,
1999). It has long been known that the excellent rela-
tionship between furanic aldehydes (2-furaldehyde and
5-hydroxymethylfurfural) and the degree of organoleptic
deterioration of beer is induced by heat. The impact of
oxygen on the development of furanic aldehydes in aged
beer is disputable (Madigan *et al.*, 1998), but agreement
exists regarding the importance of acetaldehyde, which is
the main carbonyl component of beer, as a good indicator
of the oxygen levels in the bottle.

The disappearance of the stale off-flavor after addition
of carbonyl scavengers to beer, such as aminoguanidine
(Bravo *et al.*, 2002), confirms the volatile carbonyl com-
pounds as ones mainly responsible for the beer taste insta-
bility. However, the myriad of flavor notes changing during
staling are due to a much broader range of chemical enti-
ties. Organoleptic-active volatile aldehydes, especially those
having 7–10 carbon atoms and very low thresholds, are
considered to be the most important. In Table 38.1, some
saturated and unsaturated aldehydes that have been detected
in beer along with their flavor and threshold level in beer are
indicated. Only three of the substances listed – *E*-2-nonenal
(also called trans-2-nonenal), (2*E*,6*E*)-nonadienal and (2*E*,4*E*)-
decadienal – are present in aged beer in concentrations higher
than their flavor thresholds. However, it is known that mix-
tures of carbonyls can cumulatively cause a perceived flavor.

Of all these aldehydes, *E*-2-nonenal is most frequently
cited as the cause of an unpleasant cardboard flavor in beer.
A concentration increase of this compound during beer

Table 38.1 Typical flavor notes, sensory threshold value and typical concentration of aldehydes in aged beer

Aldehydes	Typical flavor notes	Threshold value (ppb)	Concentration in aged beer (ppb)
Alkanals			
Pentanal	Grassy	500	6
Hexanal	Vinous, bitter	300	4

(2*E*, 4*E*)-decadienal	Oily, rancid	0.3	0.8

Source: Data from Huige (1993).

ageing has been reported, eventually exceeding its flavor threshold (Jamieson and van Gheluwe, 1970; Wang and Siebert, 1974; Drost *et al.*, 1990).

Recently, an increase of the concentration of another carbonyl compound, β-damascenone, has been found in aged beer. As with *E*-2-nonenal, β-damascenone has also attracted particular attention in the overall context of flavor instability due to its potential use for the characterization of beer ageing (Gijs *et al.*, 2002).

E-2-Nonenal

Since the first manifestation of the term "cardboard flavor" in 1954, by Burger *et al.* (1954), the search to understand the reasons for its development and to identify the compounds responsible for this off-flavor is a main topic in brewing research. Twelve years later, Hashimoto (1966) found a relationship between the development of an oxidized flavor in beer and the level of volatile carbonyl compounds. Jamieson and van Gheluwe in 1970, using GC/MS, were the first to identify *E*-2-nonenal as the compound responsible for the cardboard off-flavor produced in beer when submitted to artificial ageing at elevated temperature and low pH values. Wang and Siebert (1974) demonstrated, 4 years later, that the rise in concentration of *E*-2-nonenal induced by artificial ageing (6 days at 38 °C) causes a perceptible change in beer flavor, from fresh to stale, large enough to account for the papery/cardboard taste sensation, without requiring the synergistic participation of other compounds. The flavor threshold of *E*-2-nonenal, which was reported to be between 0.1 μg/l (Meilgaard, 1975) and 0.03 μg/l in beer (Meilgaard, 1993), is unusually low compared with other aldehydes found in beer.

Drost *et al.* (1990) submitted a packaged beer to natural ageing over 6 months and found, at the end of that time, a *E*-2-nonenal concentration between 0.1 and 0.22 μg/l (Figure 38.1). They suggested that the main mechanism contributing to the generation of *E*-2-nonenal in beer is both the enzymatic and nonenzymatic oxidation of lipids and oxidized free fatty acids.

Recently a study regarding the cytotoxicity of *E*-2-nonenal has been published (Dey *et al.*, 2005). The authors studied the cytotoxicity of unbonded and bonded *E*-2-nonenal and concluded that both forms are cytotoxic at concentration of 95–125 and 200 μg/ml, respectively. However, these levels of *E*-2-nonenal are absolutely impossible to attain only by the ingestion of beer.

The strong dependency with the analytical methodology used should be taken into consideration when comparing the values reported in the literature. Because of the unusual trace level of *E*-2-nonenal in beer, measurement of this compound requires a rather sensitive analytical method. Additionally, since a significant fraction of *E*-2-nonenal in wort and beer is linked to amino acids (Noël and Collin, 1995; Lermusieau *et al.*, 1999) and sulfite (Nyborg *et al.*, 1999; Dufour *et al.*, 1999), a rigorous control of the pH during the sample preparation is required. Most analytical procedures involve a preliminary concentration step followed by a derivatization step. Carbonyl compounds have been isolated from beer by liquid–liquid extraction (Wang and Siebert, 1974), vacuum distillation (Currie *et al.*, 1990), steam distillation (Santos *et al.*, 2003), low-pressure distillation followed by purge and trap (P&T) with Tenax TA (Harayama *et al.*, 1994), and solid-phase extraction (Verhagen *et al.*, 1987; Santos *et al.*, 2003). Solid-phase microextraction (SPME) and stir bar sorptive extraction (SBSE) followed by thermal desorption GC–MS analysis
Figure 38.1 Increase of *E*-2-nonenal concentration over 6 months in beers from four different breweries (after Drost *et al.*, 1990).

The Nonenal Potential Concept

Drost *et al.* (1990) developed a fast and easy method to predict beer flavor stability, assuming the formation of *E*-2-nonenal as one of the main causes of beer staling. The method allows the determination of the so-called nonenal potential of wort. It is defined as the potential of wort to release *E*-2-nonenal under beer conditions and by using a forced ageing procedure. To establish these beerlike conditions, the pH of the wort is adjusted to 4.0 (approximately the beer pH). This solution is then heated at 100°C in a closed tube under an argon atmosphere for 120 min, and the released *E*-2-nonenal is determined. The described heating procedure should simulate a staling process in a closed, almost oxygen-free, beer bottle.

The interactions of *E*-2-nonenal with other groups of substances, such as sulfite (Dufour *et al.*, 1999; Nyborg

are methods recently developed for the determination of *E*-2-nonenal in beer (Ochiai *et al.*, 2003; Vesely *et al.*, 2003). In high-performance liquid chromatography (HPLC) with ultraviolet (UV) detection, it is possible to directly determine *E*-2-nonenal (Currie *et al.*, 1990; Santos *et al.*, 2003); however, for a more general determination of aldehydes, a derivatizing procedure can be used. 2,4-Dinitrophenylhydrazine is the most widely used derivatizing agent for aldehydes (Currie *et al.*, 1990), but dansylhydrazine (Verhagen *et al.*, 1987) and dabsylhydrazine (Wu and Lin, 1995) have also been used because of their high sensitivity. These aldehydes derivatives are then separated and estimated by HPLC/UV. Determination of derivatized *E*-2-nonenal by GC/MS was recently reported (Ochiai *et al.*, 2003; Vesely *et al.*, 2003).

et al., 1999) and amino acids (Noël and Collin, 1995; Lermusieau *et al.*, 1999), account for the essential control of the pH during this experiment. Furthermore, Wang and Siebert (1974) discovered a strong dependence of the formation of this aldehyde on the pH level: a 400-fold increase in the *E*-2-nonenal concentration in a superacid environment compared to the usual pH of beer conditions was found.

According to some authors (Drost *et al.*, 1990; Lermusieau *et al.*, 1999; Ueda *et al.*, 2001), there is a good correlation between the measured nonenal potential in wort and the results of an overall quality rating of the beer produced. Using this assay, very successful malt selections and malting methods for improving flavor stability of beer have been developed (Fournier *et al.*, 2001). However, the biochemical background of the formation of *E*-2-nonenal during mashing is not completely understood (Kuroda *et al.*, 2005). Some authors argued that the nonenal potential in wort is not a good indicator for the later flavor stability of the produced beers (van Waesberghe, 2002; Wackerbauer and Meyna, 2002).

Formation and Chemical Equilibrium of *E*-2-Nonenal

The earlier theories for aldehydes formation in staled beer only consider their *de novo* synthesis in beer. Although it cannot be disputed that aldehydes are produced by reactions taking place in beer, the extensive research involving *E*-2-nonenal over the past few years reveals that 2-alkenals participate in various chemical equilibria. Consequently, flavor staling could be the result of equilibrium shifting in favor of free aldehydes from compounds that are formed during the malting and mashing processes (Geois *et al.*, 2002). The first evidence for the existence of 3-hydroxy alkanals in malt and wort was provided by Barker *et al.* (1983), who detected 3-hydroxybutanal and 3-hydroxynonanal, formed from aldol condensation of shorter chain aldehydes or by hydration of unsaturated aldehydes. It has been suggested that hydration plays an integral role in the key equilibrium that determines the stability of the α,β-unsaturated aldehyde (Barker *et al.*, 1983).

Isolation and identification of *Z*-3-hexenal and *Z*-3-nonenal in beer extracts led Barker *et al.* (1989) to suggest that these *Z*-3-alkenals, directly derived from the oxidative degradation of linoleic and linolenic acids, would be direct sources of the corresponding *E*-2-alkenals via isomerization induced by heat and under acidic conditions. Results of this investigation suggested that some of the *Z*-3-nonenal, produced by linoleic acid oxidation of barley lipids during malt kilning and wort production, survived from wort into beer, where its ultimate isomerization was likely to be retarded by not only low storage temperatures but also by the formation of sulfite complexes. The flavor imparted by *Z*-3-nonenal is not

a cardboard flavor but a soybean-oil-like flavor, and its flavor threshold in beer was determined to be $0.5\,\mu g/l$ (Sakuma and Kowaka, 1994). The isomerization ratio from Z-3-nonenal to E-2-nonenal was shown, by Sakuma and Kowaka (1994), to be approximately 20% after 1 day of storage of beer at 5 °C. Sulfite, produced by yeast during fermentation or added before bottling, readily forms adducts with carbonyl compounds, rendering them non-volatile and flavor-inactive (Nyborg *et al.*, 1999). In addition, the interaction of sulfite with carbonyl compounds was recently demonstrated by voltammetry (Guido *et al.*, 2003). Development of the cardboard flavor in aged beer is strongly retarded when such beers are supplemented with sulfite. Nordlöv and Winell (1983) found that most of the E-2-nonenal is bound as a taste-inactive sulfite adduct as long as the level of total SO_2 in aged beer exceeds 2 mg/l, although they do not verify the existence of such adducts. Nyborg *et al.* (1999) demonstrated that flavor-active E-2-nonenal disappeared from beer on addition of sulfite species, suggesting the formation of flavor-inactive adducts. They confirmed the adduct formation between E-2-nonenal and sulfite, in aqueous solution at beer pH, indirectly by ^{1}H NMR spectroscopy and directly by LC/MS. The mechanism of the addition reaction proceeds in a two-step process, to initially give a carbonyl adduct and ultimately yield a disulfonate as the thermodynamic product (Dufour *et al.*, 1999).

Another kind of complex was suggested to be the major degradation product of E-2-nonenal during mashing and boiling. Approximately 90% of E-2-nonenal was retained by an amino acid mixture after 15 min at 36 °C, by forming Schiff bases (Noël and Collin, 1995). The resulting imine, created during mashing and boiling, would protect E-2-nonenal from the reducing activity of yeast releasing it at lower pH during beer storage (Lermusieau *et al.*, 1999). Addition of amino acids to beers should therefore delay alkenal release.

The equilibrium proposed above shows various alternative routes for the fate of E-2-nonenal and other α,β-unsaturated aldehydes throughout the malting and the brewing process (Figure 38.2). It has been postulated that these reactions equilibriums are interconnected and that volatile carbonyls may be slowly released from their nonvolatile complexes through equilibrium shifts. These shifts may be caused by some perturbation, such as the oxidative loss of sulfite, the decrease in pH or the increase in storage temperature.

Recently, a detailed discussion of reaction mechanisms leading to the formation of aldehydes, particularly of E-2-nonenal, in beer was published (Vanderhaegen *et al.*, 2006).

β-Damascenone

β-Damascenone, a terpenic ketone (8E-megastigma-3,5,8-trien-7-one, Figure 38.3) first identified in Bulgarian rose
Figure 38.2 Potential equilibrium of α,β-unsaturated aldehydes in beer (after Dufour *et al.*, 1999).
Figure 38.3 Hypothetical pathways for the formation of β-damascenone from neoxanthin (adapted from Puglisi *et al.*, 2001).

oil (Demole *et al.*, 1970) and later found in the essential oils of other natural materials, is a highly odoriferous compound important in the creation of modern fragrances (Lee *et al.*, 1991). As it is characterized by a very low odor threshold in water (0.02–0.09 ng/g) (Buttery *et al.*, 1990), β-damascenone was considered to be a significant flavor in many alcoholic beverages such as whiskey, brandy, rum, wine and beer (Masuda and Nishimura, 1980). β-Damascenone has been identified as a key odor in a variety of fruits, vegetables and derived products, including

wine where it imparts a pleasant "stewed apple," "fruity" and honeylike character.

Additionally, β-damascenone has been included among the five most important flavor-active compounds in young red wines (Ferreira *et al.*, 2000) and has been identified as the compound with the highest odor activity in Bavarian pale lager beer (Fritsch and Schieberle, 2005).

Fickert and Schieberle (1998) had already identified β-damascenone as an odor-active volatile compound in an extract from barley malt, but only recently an increase in the use of β-damascenone concentration during an artificial ageing of a variety of commercial Belgian beers (Chevance *et al.*, 2002) and top-fermented beers (Vanderhaegen *et al.*, 2003) has been reported. Moreover, β-damascenone was identified as the cause for the most intense aroma in a 6-month-old beer sample (Murakami *et al.*, 2000).

The origin of β-damascenone in beer and its relationship with beer ageing are two topics of great importance that have not yet been clarified. Kotseridis *et al.* (1999) showed that the levels of β-damascenone of wine almost double by heat treatment. Recent studies have indicated that β-damascenone in wine results from the hydrolytic breakdown of complex grape-derived secondary metabolites formed from carotenoids such as neoxanthin (Skouroumounis and Sefton, 2000).

Although the investigation of the mechanisms for the formation of β-damascenone in beer is just beginning, it is believed that it can be formed by acid-catalyzed conversion of the glycoconjugated forms of the allenic triol and derived from enzymatic transformations of the carotenoid neoxanthin (Figure 38.3) present in the basic ingredients of beer (Puglisi *et al.*, 2001). Chevance *et al.* (2002) suggest that the increase in β-damascenone during beer ageing could also be partially explained by acid-catalyzed hydrolysis of glycosides present in fresh beer. A remarkable amount of β-damascenone was formed after acidic hydrolysis of the hop glycoside of 3-hydroxy-β-damascone (Figure 38.4). This glycoside was also found in unhopped beer, suggesting that hop is not the only source for β-damascenone (Biendl *et al.*, 2003).

β-Damascenone is already present at a high level in the initial wort, but it is extensively removed after 7 days of fermentation at 20 °C, after reduction and/or adsorption by yeast (Chevance *et al.*, 2002). Beer pH seems to have a crucial role on the β-damascenone level, with higher concentrations of this compound observed for aged beers having lower pH (Gijs *et al.*, 2002). Air in the headspace of the bottles seems to have no influence on the β-damascenone content of a 6-month-old beer stored at 40 °C (Vanderhaegen *et al.*, 2003).

Clear evidences exist nowadays regarding the relevance of β-damascenone as one of the most important carbonyl compounds contributing to the odor variation observed during beer ageing. It has been recognized by some authors that β-damascenone seems at least as important as *E*-2-nonenal in the flavor of aged beer (Gijs *et al.*, 2002).

Determination of *E*-2-Nonenal and β-Damascenone in Beer

Most of the methods for the assessment of *E*-2-nonenal in beer are laborious and time-consuming, requiring strong acidic conditions to obtain derivatives, which may change the carbonyl compounds of interest or induce equilibrium shifts. Recently a new analytical method for the simultaneous determination of *E*-2-nonenal and β-damascenone in beer by reversed-phase liquid chromatography with UV detection was developed by Santos *et al.* (2003). The proposed method is fast and easy to implement with no need for derivatization. The method is believed to be more sensitive than the gas chromatographic-mass spectrometric method, provided that potential interferences were effectively removed. The experimental procedure used for the extraction, separation and determination is described in detail elsewhere (Santos *et al.*, 2003). The major advantages of the proposed methodology, when compared to other existing methods, are fastness and simplicity whereas the major drawback is the possibility of some conversion of precursors into *E*-2-nonenal during the steam distillation step used in the extraction of the volatile compounds.

Effect of storage on the concentration of *E*-2-nonenal and β-damascenone found in beer

Using the afore-mentioned methodology, Santos *et al.* (2003) monitored *E*-2-nonenal and β-damascenone in beer during an extended storage time at different conditions. They used two different lots of beer that were stored in the following conditions: 4 weeks at 4 °C, 4 and 12 weeks at 20 °C in the dark (naturally aged beers) and 7 days at 37 °C in the dark (artificially aged beers). As it can be deduced by observing data in Table 38.2, a strong correlation between the storage conditions and the concentrations of *E*-2-nonenal and β-damascenone was verified. No variation was found in the concentrations of *E*-2-nonenal and β-damascenone for beers stored at 4 °C, although the concentration of both compounds increases for beers stored at higher temperatures. It is noteworthy that the concentration of *E*-2-nonenal after 12 weeks of natural ageing exceeds its flavor threshold in beer (roughly 0.1 μg/l). High storage temperatures led to the formation/liberation of β-damascenone, resulting

Table 38.2   Concentration of *E*-2-nonenal and β-damascenone (confidence limits for four determinations) found in beer (Lot A and B) after different storage conditions

Lot	Fresh beer	4°C 12 weeks	20°C 4 weeks	20°C 12 weeks	37°C 1 week

Figure 38.6   Relationship between sensory evaluation and β-damascenone concentration found in beers.

in an increase of the concentration of this compound during beer ageing. Although the mechanisms responsible for this behavior have not been completely elucidated yet, the acidic hydrolysis of glycosides has been described in the literature as the most likely hypothesis (Skouroumounis and Sefton, 2000; Chevance *et al.*, 2002).

Santos *et al.* (2003) have also studied the effect of beer pH, after a pH adjustment, on the concentration of *E*-2-nonenal and β-damascenone, showing that both compounds have a comparable behavior regarding the influence of pH. The results obtained confirm that the formation/liberation of β-damascenone from its precursors is much higher at lower pH values (Figure 38.5), thus supporting the hypothesis that an acidic hydrolysis is responsible for the development of β-damascenone in beer. These results are in agreement with those obtained by Gijs *et al.* (2002).

β-Damascenone as an analytical marker of organoleptic deterioration of beer

Guido *et al.* (2003) have made a specific study to evaluate the possible correlation between the β-damascenone content in beer and the development of off-flavors during beer ageing, with the aid of a sensory panel. β-Damascenone was

determined in several beers stored for a long period of time under different conditions and, simultaneously, the sensory changes were followed regularly by an expert evaluation panel. This panel consisted of eight trained tasters who were asked to comment on general quality (discrimination test) as well as to describe the flavor profile according to a special form (description test). All beers were tested at 4°C and evaluated for the degree of staling on a 5-point scale defined as: (+1) no sign of oxidation, (0) very slight oxidation symptoms (−1) slight oxidation symptoms, (−2) enough level of oxidation to reject the beer and (−3) very strong level of deterioration by oxidation. The sensory classification of each beer consisted in the mean value of the scores provided by all the tasters, with an adopted sensory rejection limit of −1.5. The organoleptic state of a beer with a sensory rating lower than −1.5 is considered not satisfactory, implying the rejection of the product by the panel.

As it can be seen in Figure 38.6, a good correlation was found between the concentration of β-damascenone in beer and the sensory evaluation, with higher concentrations of β-damascenone corresponding to lower values of the sensory evaluation. A more detailed inspection of Figure 38.6 allows the identification of three different regions. Region 1 includes beers analyzed immediately

after bottling and stored at 4°C for 4 and 12 weeks; these beers obtained the highest score in the sensory evaluation tests and contained the lower concentrations of β-damascenone. Region 2 is formed by beers stored at 20°C; beers stored during 12 weeks (subregion 2b) were given a slightly worse sensory evaluation than beers stored during 4 weeks only (subregion 2a), approaching the sensory rejection line; this decrease in the sensory evaluation was accompanied by an increase in the concentrations of β-damascenone. Finally, all the beers of region 3 (stored at 37°C for 1 week) were considered not satisfactory by the sensory panel, and this worse evaluation was correlated with higher contents of β-damascenone.

The observed correlation between the β-damascenone content and the storage temperature of beers shows that this can be used as a good analytical marker of beer ageing induced by heat. Additionally, the obtained results suggest that β-damascenone can also be used as an analytical marker of the organoleptic state of beer. Obviously, this does not imply that β-damascenone has a direct impact on the organoleptic degradation that beer suffers during ageing, or that the off-flavors perceived by the sensory panel are a direct consequence of the increase in concentration of β-damascenone.

Summary Points

- The knowledge of the mechanisms of beer ageing could help to develop strategies to improve brewing technology and to produce beer with increased flavor stability.
- *E*-2-nonenal has been recognized as the compound responsible for the characteristic cardboard off-flavor, an organoleptic problem that arises during beer storage. Therefore, the study of *E*-2-nonenal and its formation mechanisms is a main topic of research on beer ageing.
- There is strong evidence that the mechanism for development of *E*-2-nonenal in beer begin with the formation of precursors from enzymatic and non-enzymatic lipid oxidation, mainly from linoleic acid, during malting and mashing. These precursors (recognized as nonenal potential) are incorporated into the beer and slowly converted to *E*-2-nonenal during beer storage.
- β-Damascenone, a carotenoid-derived compound, can directly affect beer flavor during ageing, generating a pleasant "stewed apple," "fruity" and honey-like character.
- Both *E*-2-nonenal and β-damascenone have a similar increasing behavior through extended storage of beer. β-Damascenone can advantageously be used as a chemical indicator of beer ageing instead of *E*-2-nonenal, because its analytical determination is easier. The evolution of β-damascenone and *E*-2-nonenal concentrations in beer during storage correlates well with expert sensory panel taste scores.
- There is no evidence that *E*-2-nonenal and β-damascenone could have effects, adverse or beneficial, on human health, at the levels found in beer.

Pathogens in Beer

Garry Menz, Peter Aldred and Frank Vriesekoop School of Science and Engineering, Institute of Food and Crop Science, University of Ballarat, Ballarat, Australia

Abstract

Pathogenic (disease-causing) microorganisms cannot survive in beer due to the presence of various inhibitory factors/hurdles. The major intrinsic hurdles that a pathogen must overcome to survive in a beer are the presence of ethanol produced by yeasts during fermentation (up to 10% (v/v), typically 3.5–5.0% (v/v)), hop (*Humulus lupulus*) bittering compounds (approx. 17–55 parts per million *iso*-α-acids), low pH (approx. 3.9–4.4), carbon dioxide (approx. 0.5% (w/w)), low oxygen (<0.1 ppm), and the lack of nutritive substances. Ethanol and hops interfere with essential cell membrane functions, the low pH hinders enzyme activity, the lack of nutrients and oxygen starves many potential pathogens, whilst elevated dissolved carbon dioxide lowers the pH, inhibits enzymes, affects cell membranes, and creates an anaerobic environment. In addition to these intrinsic factors, many stages of the brewing process reduce the potential for contamination, such as mashing, wort boiling, pasteurization, filtration, aseptic packaging and cold storage. Various studies have shown that the survivability of pathogens such as *Escherichia coli*, *Salmonella* Typhimurium, and *Vibrio cholerae* in most beers is very poor. However, beers without, or with, reduced levels of one or more of these antimicrobial "hurdles" are more prone to the survival and/or growth of pathogenic organisms. Examples are low-alcohol and unpasteurized beer, for which special attention must be paid to ensure their safety.

Introduction

Beer is considered to be an intrinsically safe beverage, resistant to microbial contamination. This is mainly due to a number of inhibitory factors (hurdles), which when combined inhibit the growth and survival of pathogenic (disease-causing) microorganisms. The presence of ethanol (up to 10% (v/v), typically 3.5–5.0% (v/v)), hop (*Humulus lupulus*) bittering compounds (approx. 17–55 ppm *iso*-α-acids), low pH (approx. 3.9–4.4), elevated dissolved carbon dioxide (approx. 0.5% (w/w)), low oxygen (<0.1 ppm), and the lack of nutritive substances protect beer from many potential pathogens. In addition to these intrinsic factors, many stages of the brewing process reduce the potential for contamination, such as mashing, wort boiling, pasteurization, filtration, aseptic packaging, and cold storage. This chapter reviews the occurrence and survivability of pathogens in beer, and discusses the antimicrobial hurdles that ensure the microbial safety of beer.

Pathogens in Beer

Reports of pathogens in beer and associated products

It is widely recognized that pathogens cannot grow or survive in beer, due to the presence of various intrinsic and extrinsic antimicrobial hurdles. However, there have been several reports of pathogens occurring in beer-like products (Table 39.1). These beer-like products differ from traditional European-style beers, as they either lack one or more of the antimicrobial hurdles typical of beer, or the hurdles are present at a reduced level.

Pseudomonas spp. and *Escherichia* spp. were reported as beer spoilers during World War I and II in "weak" beers, such as those with a pH above 5.0 or with short lagering time (Chevalier, 1946, as cited in Rainbow, 1981). The pathogens *Bacillus cereus*, *Escherichia coli*, *Proteus vulgaris*, *Salmonella* Typhimurium, *Shigella sonnei*, and *Staphylococcus aureus* were detected in boza (a traditional Belgian ale-type product made from millet, with an alcohol content of approx. 1%) (Enikova *et al.*, 1985). This product lacked many of the antimicrobial hurdles that usually protect beer, as boza typically has a low ethanol content (<1%) and is not hopped. However, an investigation into brewing equipment hygiene has yielded coliforms and *Aeromonas* spp. (Nishikawa *et al.*, 1979), although *Aeromonas* spp. is yet to be reported in beer.

Traditional African beers have the potential to support the growth of pathogens, as they typically lack or have lower levels of some of the antimicrobial hurdles that usually offer protection to beer. For example, high levels of coliforms (indicative of the presence of potential pathogens such as *E. coli*, *Salmonella* spp., and *Shigella* spp.) have been detected in Orubisi (Table 39.1), a traditional Tanzanian banana and sorghum beer with a low alcohol content (2.2% ethanol (v/v)) (Shayo *et al.*, 2000). Further, *Bacillus* spp.

have been reported in a South African sorghum beer with a lowered ethanol content (<3% ethanol (v/v)) (Pattison *et al.*, 1998).

Although pathogens may not have been detected in beer itself, beer dispensing equipment may be a potential reservoir for pathogenic microorganisms. Schindler and Metz (1990) detected coliforms on beer mugs and tankards, which were suspected to be due to unsatisfactory cleaning. In a later study Taschan (1996) collected 62 samples of beer from German inns, finding that 5% contained *E. coli*, 45% were positive for coliforms, and 70% contained spoilage microorganisms. Comparative studies of bottled beer suggested that the source of contamination was the inn's dispensing equipment. In addition to beer dispensing systems, Storgårds (2000) proposed cross-contamination with food as a potential source of coliforms in beer.

The survival of pathogens in beer

Bacteria Although no pathogenic bacteria have been isolated from beer, several researchers have investigated the survivability of selected pathogenic bacteria in beer. Beer without or with lower levels of one or more of the antimicrobial hurdles will be more susceptible to the growth of bacteria. For example, the potential foodborne pathogens *E. coli*, *Salm.* Typhimurium, *Pseudomonas aeruginosa*, *Shigella flexneri*, *Klebsiella pneumoniae*, *Yersinia enterocolitica*, and *Enterococcus faecium* were capable of growing in an alcohol-free beer (0.5% (v/v) ethanol), although they were destroyed by pasteurization and could not grow in a full strength beer (5% (v/v) ethanol) (L'Anthoën and Ingledew, 1996). Unlike most beers, this alcohol-free beer was nutrient-rich, containing elevated levels of maltose, maltotriose, glucose, and fructose, which supported the bacteria. According to Schmidt (1990), most reduced alcohol beers have a higher pH, are weakly hopped, and contain residual

Table 39.1 Reports of pathogens in beer-like products

Product	Brief description	Major inhibitory factors	Pathogen survival	References
Boza	Fermented low-alcohol millet ale	<1% ethanol (v/v), lactic acid	Pathogens detected: *Bacillus cereus*, *Escherichia coli*, *Proteus vulgaris*, *Salmonella* Typhimurium, *Shigella sonnei*, *Staphylococcus aureus*	Enikova *et al.* (1985)
"*Weak beer*"	Weak beer produced during WWI and WWII with high pH (>5.0) and/or short lagering time	As for beer, although an increased pH	*Escherichia*, *Pseudomonas*	Chevalier, as cited in Rainbow (1981)
Orubisi	Traditional Tanzanian banana and sorghum beer, spontaneous alcoholic and lactic fermentation	2.2% ethanol (v/v), pH 3.7, lactic acid	High levels of coliforms indicate presence of the pathogens: *Escherichia coli*, *Salmonella*, *Shigella*	Shayo *et al.* (2000)
Sorghum beer	Lactic and alcoholic fermentation South African	<3% ethanol (v/v), pH 3.1, lactic acid	*Bacillus* spp. detected, pathogenicity unreported	Pattison *et al.* (1998)

nutrients, leaving them susceptible to undesirable microbial growth. In these beers, several of the protective hurdles are at reduced levels, thus a secondary treatment such as pasteurization is necessary to ensure their safety.

The survival of the enteric pathogens *E. coli*, *Salm.* Typhimurium, and *Sh. sonnei* in beer was briefly studied by Sheth *et al.* (1988). A single beer was inoculated with 2×10^6 colony forming units (CFU) per ml, and incubated at 36°C. Survival of the pathogens was poor, although small numbers (approx. 5 CFU/ml) could be detected after 48 h. Similar results have been obtained by other workers, such as Zikes (1903) who reported that *Salm.* Typhimurium survived for less than 15 min in beer. Furthermore, Bendová and Kurzová (1968) reported that *Sh. flexneri* and *Salm.* Typhimurium were capable of limited survival in wort and beer maintained at 4°C for 7 days, although no growth was observed. In this study, survival was higher in wort than in beer, highlighting the importance of ethanol and the lack of available nutrients on the antimicrobial properties of beer.

Using various inoculum levels (100–800 CFU/ml), Bunker (1955) investigated the survival of several pathogens in four different beers. The greatest resistance was shown by *E. coli*, which survived up to 3 days, whilst *Salm.* Typhimurium, *Sh. sonnei*, and *Staph. aureus* survived 24 h, and *Corynebacterium diphtheriae* and *Streptococcus haemolyticus* remained viable for up to 1 and 3 h, respectively.

Early work by Lentz (1903) and Sachs-Müke (1908) investigated the survivability of *Salmonella* Typhi in beer. Lentz (1903) showed that the bacterium causing typhoid fever had low viability in beer, and could not be detected after 48 h, whereas Sachs-Müke (1908) reported that *Salm.* Typhi and *Salmonella* Paratyphi remained culturable for 2–5 days. Additional studies by Hompesch (1949) found that *Salm.* Typhi and *Salm.* Paratyphi could survive in beer for up to 5 and 10 days, respectively. Using an unrealistic inoculation level (two million CFU/ml), *Salm.* Typhi remained viable for 55 days, and *Salm.* Paratyphi survived for 63 days (Hompesch, 1949). The viability of *Salm.* Typhi on the rubber seals of swing-top bottles was also studied by Sachs-Müke (1908), who found that the bacteria survived on the rubber seals after 10 days, but could not be isolated out of beer from the same bottles. The author suggested that the bad habit of the working class drinking beer from the bottle (rather than from a glass) could lead to the transmission of typhoid fever.

The survival of the waterborne bacteria *Vibrio cholerae* in beer has been investigated by several authors. Pick (1893, as cited in Zikes, 1903) and Zikes (1903) reported that this pathogen survived for less than 10 min in beer. Other studies have shown that *V. cholerae* could survive for 24 h in a Thai beer (Felsenfeld, 1965), and remained viable for more than 1 h but less than 24 h in another study by Weyl (1892, as cited in Zikes, 1903). Zikes (1903) investigated the factors that influence the survival of *V. cholerae* in beer,

by inoculating the bacteria into both fresh and sterilized beer (the sterilization process removed the majority of CO_2 and ethanol). It was concluded that the low survivability of *V. cholerae* in beer is primarily due to the CO_2 and ethanol content (rather than the pH and hops), with the low storage temperature having only a limited influence on survivability.

In a study by Dogel' *et al.* (1984), pathogenic *Yersinia* spp. were found to be resistant to alcohol, surviving for more than 30 min in 3% ethanol. Based on this alcohol tolerance, the authors suggested that beer and other low-alcohol beverages may be involved in the transmission of yersiniosis and pseudotuberculosis. However, the combined effect of the other antimicrobial hurdles in beer (such as hops, low pH and CO_2) was not evaluated.

Protozoa   By volume, the major component of beer is water, which is known to be a vehicle for the transmission of various diseases. The majority of brewing water (liquor) is treated and then boiled for at least 45 min during the kettle boil, eliminating the potential for contamination. However, high gravity dilution liquor and water added during filtration are potential sources of pathogenic waterborne protozoa, such as *Cryptosporidium* and *Giardia* (Kuhn and Owades, 1985; Baxter, 1999). Survival of these protozoa was studied by Friedman *et al.* (1997) and Kuhn and Owades (1985). Beer (5% (v/v) ethanol, pH 4.3) was unable to be a host for *Giardia* (Kuhn and Owades, 1985), and Friedman *et al.* (1997) reported that after 24 h in beer at 4°C and 22°C, less than 20% of *Cryptosporidium parvum* oocysts were viable. The reduction in viability was predominantly due to the carbonation and the low pH of the beer.

Opportunistic pathogens

Opportunistic pathogens affect only high-risk subgroups of the population, such as the immunocompromised, and are usually related to an underlying disease (Tauxe, 2002). There have been various reports of species previously associated with the brewing process acting as opportunistic pathogens (Table 39.2). However, these brewery microorganisms generally do not survive into finished beer, and pathogenic strains are yet to be isolated from beer (van Vuuren and Priest, 2003).

Toxins

Despite pathogens being unable to survive in most beers, fungal toxins from contaminated raw materials (such as malt) can prevail and be detected in packaged beer (Scott, 1996). Selected studies reporting on the occurrence of fungal toxins (aflatoxins, deoxynivalenol, ochratoxin A, and zearalenone) in beer are summarized in Table 39.3. Despite aflatoxin levels in beer generally being low (Odhav and Naicker, 2002; Mably *et al.*, 2005), their presence in the food chain must be

Zearalenone	Africa	Traditional	Nkwe et al. (2005)

minimized as they are considered to be hepatotoxic, carcinogenic, immunosuppressive, and antinutritional (Williams *et al.*, 2004). Other toxins can exhibit similar effects, as deoxynivalenol is immunosuppressive, ochratoxin A is nephrotoxic, teratogenic, immunotoxic, and possibly carcinogenic, fumonisins cause equine leukoencephalomalacia, pulmonary edema in swine, hepatotoxicity, nephrotoxicity, and are carcinogenic, whereas zearalenone has been reported to be genotoxic and a cause of infertility in livestock (Murphy *et al.*, 2006).

In addition to the heat treatments applied during beer production, the presence of brewing yeast minimizes the prevalence of toxins. A significant proportion of the aflatoxins can be mopped up by the yeast during the fermentation (Chu *et al.*, 1975; Scott *et al.*, 1995). The attenuation of the toxicity potentially caused by the aflatoxins is facilitated by yeast cell wall material (Huwig *et al.*, 2001; Ringot *et al.*, 2005), and more specifically due to manno-oligosaccharides associated with the yeast cell wall (Stanley *et al.*, 1993; Baptista *et al.*, 2004). However, while the cell wall mannans are actively involved in the biosorption of aflatoxins, active yeast cells have a greater effect in reducing toxicity symptoms compared to manno-oligosaccharides alone (Baptista *et al.*, 2004). This might be due to the fact that active yeast cells have a greater nutritional value by providing vitamins that could aid in the body's ability to rectify the damage done by aflatoxins.

The other class of microbial toxins that may be of concern is the Gram-negative bacterial endotoxins. However, these were undetectable in packaged beer, albeit in a limited study, by di Luzio and Friedmann (1973).

The Antimicrobial Hurdles of Beer

The microbial safety and stability, the sensory and nutritional quality, and the economic potential of many foods are maintained using a combination of preservative factors (hurdles), termed hurdle technology (Leistner, 2000). By employing numerous hurdles at reduced levels, rather than a single hurdle at an intense level, a product can be produced with more desirable organoleptic properties. A good example of the applied use of hurdle technology in beers is the India Pale Ales (IPAs). During the late 1700s, ales bound for British troops in India spoiled very quickly during the long sea journey (Edgerton, 2005). British brewers needed to increase the stability of their beers, and by the early 1800s this was achieved by brewing beer with higher levels of hops and ethanol (Edgerton, 2005).

Beer contains an array of antimicrobial hurdles that, under most circumstances, prevent the growth of pathogenic microorganisms. Figure 39.1 depicts many of the typical hurdles that ensure the safety of beer, namely boiling in the kettle, the presence of hops, ethanol, carbon dioxide (CO_2), the low pH, and the lack of available nutrients and oxygen (O_2).

Beer is more susceptible to undesirable microbial growth when one or more of these hurdles are absent or at a reduced level. For example, Vaughan *et al.* (2005) noted that beers with elevated pH levels, low ethanol, low CO_2, and those with added sugar (increased nutrients) are more prone to spoilage. According to the work of Fernandez and Simpson (1995), levels of nitrogen (free amino and total soluble), amino acids, maltotriose, beer pH and color significantly
Figure 39.1 Pathogens cannot survive in beer due to the antimicrobial "hurdles," including the kettle boil, hop bitter acids, low pH, ethanol, carbon dioxide (CO_2), and the lack of nutrients and oxygen (depicted by the wasteland). Artwork by Ms. Peggy Hsu.

Table 39.4 Primary targets and mode of inhibition of both the intrinsic and extrinsic (processing) antipathogenic hurdles of beer

Antipathogenic hurdles	Primary targets	Mode of inhibition
Intrinsic hurdles		
Ethanol	All pathogens	Inhibits cell membrane functions
Low pH	All pathogens	Affects enzymes and permeases (nutrient utilization), enhances inhibitory effects of hops
Hops	Gram-positive bacteria	Inhibits cell membrane functions
Carbon dioxide	Aerobic pathogens	Creates anaerobic conditions, lowers pH, inhibits enzymes, effects cell membrane
Low oxygen levels	Aerobic pathogens, Gram-negative bacteria	Creates anaerobic conditions
Lack of nutrients	All pathogens	Starves cells
Sulphur dioxide*	Gram-negative bacteria	Affects various metabolic systems
Processing hurdles		
Mashing	Gram-negative bacteria	Causes thermal destruction of cells
Kettle boil	All pathogens	Causes thermal destruction of cells
Pasteurization*	All pathogens	Causes thermal destruction of cells
Filtration*	All pathogens	Removes cells by physical size exclusion
Bottle conditioning*	Aerobic pathogens	Creates anaerobic conditions

*Not applicable to all beers.

affected the resistance of beers to spoilage by lactic acid bacteria (non-pathogenic). Unlike the similar study by Dolezil and Kirsop (1980), the cultures were adapted to grow in beer prior to inoculation, providing more reliable results.

Table 39.4 summarizes the primary targets and mode of inhibition of many of the antipathogenic hurdles of beer, which are discussed in more detail below. Although these hurdles are considered in reference to preventing the survival and growth of pathogens, it is important to note that these principles can also be applied to reducing the incidence of beer spoilage bacteria.

Ethanol

The conversion of carbohydrates to ethanol (0.5–10% (v/v), typically 3.5–5.0%) by yeasts during the fermentation of beer provides one of the major hurdles to the growth of pathogens. The antimicrobial properties of ethanol in beer

have been recognized for some time, with the prominent brewing microbiologist Shimwell (1935) noting that beers with a higher ethanol content were more resistant to spoilage by *Saccharobacillus pastorianus* (now *Lactobacillus brevis*) than those of lower ethanol content. It can be assumed that the same applies for pathogens.

Mode of Inhibition   Ethanol inhibits cell membrane functions (Casey and Ingledew, 1986), and inactivates bacteria by inducing cell membrane leakage (Eaton *et al.*, 1982). At concentrations typical of beer (3.0–4.9% (v/v)), ethanol has been shown to effect the peptidoglycan assembly of some strains of *E. coli* (Ingram and Vreeland, 1980). Like penicillin, ethanol inhibits the transpeptidase reaction, resulting in the production of uncrosslinked peptidoglycan, leading to lysis of the weakened cell wall after 3–4 h (Ingram and Vreeland, 1980). As a result of damage to the cell membrane by ethanol, morphology and a range of cell functions may be affected. These include cell division (filament formation), glycolytic enzymes, membrane permeability, solute uptake/ion pumping systems, and the synthesis of peptidoglycan, DNA, RNA, protein, fatty acids, and phospholipids (Kalathenos and Russel, 2003). Interference with cell division and elongation due to ethanol have also been observed, for example in *E. coli* (Fried and Novick, 1973) and *Clostridium botulinum* (Daifas *et al.*, 2003). Exposure to 5% (v/v) ethanol increased the permeability of the cell membrane of the pathogen *Listeria monocytogenes*, which heightened the sensitivity of the cell to low pH by allowing an increased passage of protons into the cytoplasm, leaving the cell unable to maintain pH homeostasis (Barker and Park, 2001).

At concentrations typical of beer, ethanol exerts only a limited effect on enzyme activity. Few of the glycolytic enzymes studied by Scopes (1989) showed any substantial changes in activity at ethanol concentrations up to 5.8% (v/v), and membrane-bound enzymes in *E. coli* were reported to be relatively insensitive to inhibition by ethanol (NADH oxidase, d-lactate oxidase, and ATPase were inhibited by less than 10% by the presence of 3.9% (v/v) ethanol) (Eaton *et al.*, 1982). A dose-dependent inhibition of lactose permease by ethanol was reported by Ingram *et al.* (1980).

Effect on Pathogens   The growth of pathogenic bacteria is mitigated by the presence of ethanol at levels typical of beer, as the growth of *L. monocytogenes* was almost completely inhibited by 6.3% (v/v) ethanol in tryptic soy broth supplemented with yeast extract, whilst only slight growth inhibition was observed at lower concentrations (3.2% (v/v)) (Oh and Marshall, 1993). The maximum ethanol concentrations (v/v) at which growth could occur was determined to be 2.8% for *Salmonella* Enteritidis, 4.9% for *Staph. aureus*, and 4.1% for *B. cereus* (Lanciotti *et al.*, 2001). The effect of ethanol on the survival of four foodborne pathogens (*L. monocytogenes, Salm.* Typhimurium*, Staph. aureus*, and *E. coli* O157:H7) in tryptic soy broth after 24 h was

determined by Ahn and Shin (1999). Complete inhibition was obtained with 7% (v/v) ethanol (only present in strong beers), however typical ethanol levels of beer would also provide strong protection against these pathogens, as the inhibition rate was greater than 75% for 5% (v/v) ethanol, and more than 40% for 3% (v/v) ethanol. All ethanol levels (>0% (v/v)) increased the lag phase for the growth of *Cl. botulinum*, whilst 6.9% (v/v) would completely inhibit the growth of this pathogen in trypticase peptone glucose yeast extract broth (Daifas *et al.*, 2003).

The consumption of alcoholic beverages has been reported to enhance a person's resistance to infection by pathogens. Intake of alcohol during or after consumption of contaminated food may protect against *Salmonella* spp. (Bellido-Blasco *et al.*, 2002), and consumption of beverages with >10% alcohol provided a protective effect against Hepatitis A from oysters (Desenclos *et al.*, 1992). Furthermore, moderate alcohol consumption suppresses *Helicobacter pylori* infection (Brenner *et al.*, 1997; Brenner *et al.*, 2001; Murray *et al.*, 2002).

Low pH

A second hurdle common to all beers which prevents the growth of pathogens is a low pH (pH range 3.4–4.8). The importance of a low pH on the stability of beer has been recognized for some time by researchers such as Shimwell (1935), who noted that beer with a lower pH showed increased resistance to spoilage by *Saccharobacillus pastorianus* (now *Lact. brevis*). In addition to its direct action, the low pH of beer exhibits a synergistic effect with the antimicrobial properties of hop compounds, as hops exhibit increased antibacterial activity at lower pH values (Fernbach and Stoleru, 1924; Shimwell, 1937). Simpson and Hammond (1991) reported that a decrease in the pH of 0.2 can increase hop antibacterial activity by up to 50%.

Mode of Inhibition   Low pH values disrupt the plasma membrane, cause the destruction of enzyme systems, and reduce nutrient uptake, leading to metabolic exhaustion. For example, Neal (1965) reported that low pH values (4.0) impacted on alcohol dehydrogenase, aldolase, and pyruvate decarboxylase. Microorganisms attempt to maintain a steady, close to neutral intracellular pH, in spite of the pH of the external environment (Beales, 2004). The ability of a cell to maintain a desired internal pH is limited and varies between strains, being primarily driven by the controlled movement of cations across the membrane (Beales, 2004). When the mechanisms of passive and active pH homeostasis are overwhelmed, starvation ensues, leading to cell death.

Effect on Pathogens   Figure 39.2 plots the minimum growth pH for many foodborne bacterial pathogens against the typical pH range of beer. The pH values are for growth, not survival, as sufficient comparable data is not available in the literature. The cited minimum pH values are under
Figure 39.2 Minimum growth pH of pathogens under optimal conditions, compared to the typical pH range of beer. [a] Labbe and Duncan (1974); [b] Fehlhaber (1981); [c] International Commission on Microbiological Specifications for Foods (ICMSF) (1996a); [d] ICMSF (1996b); [e] Doyle and Roman (1981); [f] Fehlhaber (1981); [g] Beuchat (1973); [h] Lanciotti *et al*. (2001); [i] Palumbo *et al*. (1985); [j] ICMSF (1996c); [k] Farber *et al*. (1989); [l] Brocklehurst and Lund (1990); [m] Genigeorgis *et al*. (1971); [n] Wong *et al*. (1988); [o] Růžičková (1996); [p] Range excluding outliers, from analysis of 444 beers of various styles (van Leeuwen, 2006).

optimal conditions for each organism, which is not the case for beer, as it contains other inhibitory factors.

Many pathogens are unable to grow at typical beer pH levels, and only *Y. enterocolitica*, *Staph. aureus*, *Cl. botulinum*, and *Salmonella* spp. have been reported to grow at the pH levels of the majority of beers (Figure 39.1). Even though these pathogens can grow at these low pH values, other hurdles in beer (such as ethanol, hops, and CO_2) provide extra barriers to growth.

Hops

Hops are primarily added to beer to impart a characteristic bitterness and aroma, although their antimicrobial properties have long been recognized. For example, during the late 1700s IPAs were developed with increased levels of hops and alcohols to resist the growth of undesirable microorganisms during extended seaborne transportation (Edgerton, 2005).

Hop compounds can be divided into two fractions; the total resins, and the essential oils. Of most significance are the total resins, which include the α-acids (humulone and its congeners) and β-acids (lupulone and its congeners). The α-acids are isomerized during wort boiling to the more soluble iso-α-acids, which impart bitterness and antimicrobial properties to the beer. Early reports of these chemical changes were documented by Hayduck (1888). Although

the β-acids show increased antimicrobial action (Walker and Parker, 1937), they have low solubility in wort (Sakamoto and Konings, 2003), and are therefore of little significance in the resistance of beer to pathogens. Hop aroma is provided to the beer from the essential oils.

Mode of Inhibition The undissociated forms of hop and hop-derived compounds are antimicrobial, whereas their ionized forms have negligible activity (Simpson, 1993b). Hop compounds (lupulone, humulone, isohumulone, and humulinic acid) have been shown to induce leakage of the cell membrane of *Bacillus subtilis* (Teuber and Schmalreck, 1973). This breakdown of the cell membrane led to inhibition of the active transport of sugars and amino acids across the membrane, thus respiration and the synthesis of protein, DNA, and RNA were interrupted. Further studies determined that hop bitter acids act as mobile-carrier ionophores and cause complete dissipation of the transmembrane pH gradient of sensitive cells (Simpson, 1993b). The reduction in intracellular pH leads to inhibition of nutrient transport, and ultimately starvation of the cell (Simpson, 1993a).

Effect on Pathogens With the exception of some resistant strains of lactic acid bacteria, hop compounds exhibit antibacterial activity against Gram-positive bacteria, but not against Gram-negatives (Shimwell, 1937). Hop compounds

have been shown to inhibit the growth of the Gram-positive pathogens *L. monocytogenes* (Larson *et al.*, 1996) and *Staph. aureus* (Schmalreck *et al.*, 1975; Haas and Barsoumian, 1994; Sağdiç *et al.*, 2003). For example, *L. monocytogenes* was inhibited by more than 60% in the presence of typical hop levels (30 ppm α-acids) in tryptic soy broth (Larson *et al.*, 1996). In contrast, Gram-negative bacteria are resistant or only affected at higher concentrations, such as the pathogens *E. coli* (Sağdiç *et al.*, 2003), *Salm.* Typhimurium (Schmalreck *et al.*, 1975), *Serratia marcescens* (Schmalreck *et al.*, 1975), and *Y. enterocolitica* (Sağdiç *et al.*, 2003). Gram-negative bacteria are resistant to hop compounds due to the presence of phospholipids in their outer membrane, as lupulone and humulone are inactivated by serum phosphatides (Sacks and Humphreys, 1951). Like the hop acids, hop essential oils exhibited antimicrobial activity against the Gram-positive pathogen *Staph. aureus*, and had only negligible effects on the Gram-negative bacterium (*E. coli*) (Langezaal *et al.*, 1992).

Dissolved gasses

The presence of carbon dioxide (CO_2) and the lack of oxygen (O_2) enhance the microbial resistance of beer. CO_2 is produced during the primary fermentation of beer, and the beer is further carbonated by the direct addition of CO_2 or via secondary fermentation, to give final dissolved CO_2 concentrations of approximately 0.5%. Carbonation and modern bottling techniques limit the amount of dissolved O_2 available for growth in the bottled product. In addition to improving the chemical stability of the beer, decreased O_2 levels reduce the potential for the growth of many pathogenic microorganisms (Schmidt, 1990).

Mode of Inhibition CO_2 inhibits pathogens by a variety of mechanisms; CO_2 creates an anaerobic environment to exclude the growth of aerobic pathogens, causes a lowering of the pH (see section "Low pH"), influences carboxylation and decarboxylation reactions, and exerts a direct inhibitory effect on growth.

The exact mechanism of CO_2 inhibition is not yet clear (Dixon and Kell, 1989), although it has been shown that the inhibitory effects of CO_2 are not solely due to the lowered pH (Coyne, 1933) or displacement of O_2 with CO_2 (King Jr. and Nagel, 1967; Daniels *et al.*, 1985), but rather there is a direct effect of CO_2 (King Jr. and Nagel, 1967; King and Mabbitt, 1982). CO_2 has been shown to inhibit certain enzymes including isocitrate dehydrogenase, malate dehydrogenase, aconitase, succinate dehydrogenase, succinyl-CoA synthetase, fumarase, and formate dehydrogenase (Swanson and Ogg, 1969; Gill and Tan, 1979), and the antimicrobial activity of CO_2 may also be due to adverse affects on the permeability of the cell membrane, as ion uptake is reduced as CO_2 interacts with the membrane lipids (Sears and Eisenberg, 1961). Complementary to the action of hops, CO_2 shows

greater inhibition of Gram-negative bacteria than of Gram-postitives, although significant increases in lag phases have been observed for both types of bacteria (Martin *et al.*, 2003).

Effect on Pathogens   Hammond *et al.* (1999) reported that beers with low levels of dissolved CO_2 are at a heightened risk of undesirable microbial growth. This study supported the work of Šavel and Prokopová (1980), who documented that a decrease in the dissolved CO_2 level of beer reduced its shelf life (changes in CO_2 levels showed a larger impact than variations in dissolved O_2) (Šavel and Prokopová, 1980). Dissolved CO_2 in raw milk is inhibitory to bacteria (King and Mabbitt, 1982), increasing the lag phase and the generation time of microbes (Daniels *et al.*, 1985). More recent studies have demonstrated the effect of CO_2 on the growth of *B. cereus*, *Enterococcus faecalis*, *E. coli*, *L. monocytogenes*, and *Pseudomonas fluorescens* in milk (Loss and Hotchkiss, 2002; Martin *et al.*, 2003).

Lack of nutrients

The concentrations of nutritive substances available for the growth of pathogenic microorganisms in beer, such as carbohydrates and amino acids, are very low in most beers as the majority of these compounds have been metabolized by the yeast during fermentation (Sakamoto and Konings, 2003). Thus, well-attenuated beers (those with minimal residual nutrients) are the least prone to microbial spoilage (Rainbow, 1971). The effect of a lack of nutrients on the resistance of lager beers to undesirable microbial growth was studied by Fernandez and Simpson (1995). Increased levels of free amino nitrogen, total soluble nitrogen, amino acids, and maltotriose were correlated with an increased incidence of bacterial growth (Fernandez and Simpson, 1995).

Sulfur dioxide

Typically, sulfur dioxide (SO_2) levels in beer range from <1 to 30 mg/l (Ilett, 1995). Sulfur dioxide may be present as a by-product of yeast metabolism, added indirectly through raw materials and processing aids preserved with sulfur dioxide, or added directly (Ilett, 1995). The addition of SO_2 is limited by law to varying amounts in different countries. In beer, sulfur dioxide acts as an antioxidant, reacts with carbonyl compounds to mask stale flavors, and shows antimicrobial action, primarily toward Gram-negative bacteria (Ilett, 1995). However, the antimicrobial action of SO_2 in beers is weak, as most of the SO_2 is bound at typical beer pH levels, therefore it is only a minor hurdle to the growth of pathogens (Hough *et al.*, 1982).

An exact site of action for sulfur dioxide cannot be clearly established, rather it is considered to affect many metabolic systems (Gould and Russel, 2003). These systems include intermediary metabolism (enzymes, cofactors, prosthetic groups), energy production (enzymes, electron carriers,

cofactors), protein biosynthesis (proteins, enzymes, nucleic acids), DNA replication (enzymes, nucleic acids), and membranes (proteins, lipids) (Gould and Russel, 2003).

Additional hurdles

In addition to the chief hurdles detailed above, there are a number of other compounds that may increase the antimicrobial nature of beer. Hammond (1999) demonstrated the antimicrobial effects of phytic and ferulic acid on *Lactobacillus* spp., although at much higher levels than typically found in beer. Various specialty beers are brewed with the addition of known antimicrobial compounds such as honey and various spices, which would slightly reduce the products susceptibility. At levels approximately 100 times higher than those found in beer, diacetyl has been shown to inhibit *Salm.* Typhimurium (Archer *et al.*, 1996).

Processing hurdles

As discussed above, beer contains several antimicrobial hurdles to prevent the growth or survival of pathogens. In addition to these, various processing steps add further barriers. Some of the first physical barriers are the use of treated water and the heat applied during mashing. Gram-negative bacteria, yeasts, and molds are rapidly killed in the mash, however lactic acid bacteria and spore forming bacilli are able to survive the mashing process (O'Sullivan *et al.*, 1999). During the kettle boil, the wort is boiled for at least 45 min, destroying vegetative cells and their spores. The majority of craft and microbreweries carbonate their products by bottle conditioning (secondary fermentation), and there is evidence that bottle conditioning reduces a beer's susceptibility to microbial attack, as the fermenting yeast reduces the O_2 content in the bottle headspace by approximately one-third (Derdelinckx *et al.*, 1992). Dolezil and Kirsop (1980) reported that bottle conditioning appeared to be a factor in the production of resistant beer. Many breweries employ post-fermentation treatments such as filtration (physical exclusion), pasteurization (heat treatment), and cold storage to further protect the microbial stability of their beers. However, many small breweries (such as brewpubs and microbreweries) produce unpasteurized and unfiltered beer, thus extra care should be taken to ensure that the intrinsic hurdles are adequate, and that hygiene and sanitation regimes are well maintained.

Conclusion

Beer is rightly considered to be a microbiologically safe product. Various studies have shown that pathogens exhibit poor survival in beer, thus it is unlikely to be a vehicle for the transmission of pathogens. This fermented beverage is protected by an array of intrinsic hurdles, including the presence of ethanol, carbon dioxide, sulfur dioxide, and hops, and the low pH, oxygen, and nutrient levels. Further, extrinsic processing factors provide enhanced protection, including the kettle boil, filtration, pasteurization, and cold storage. However, those beers with reduced levels of these hurdles are more susceptible, such as low-alcohol and unpasteurized beers. In such instances, special attention should be paid to maintaining adequate levels of the other hurdles (such as the pH and ethanol levels), or new hurdles may need to be implemented, such as pasteurization or filtration.

Summary Points

- Pathogenic (disease-causing) bacteria, such as *E. coli* and *Salmonella*, show poor survival in beer.
- The majority of beers are protected against pathogens by antimicrobial "hurdles" (inhibitory factors), including the:
  - Low pH
  - Ethanol content
  - Presence of hops
  - High carbon dioxide content
  - Low oxygen content
  - Lack of nutrients
- Several processing steps also protect beer
  - Mashing
  - Kettle boil
  - Filtration (only for some beers)
  - Pasteurization (only for some beers)
  - Aseptic packaging (only for some beers)
  - Bottle conditioning (only for some beers)
- Beers without, or with, reduced levels of one or more of these antimicrobial "hurdles" are more prone to the survival and/or growth of pathogenic organisms. Such beers include low-alcohol and unpasteurized beers, thus special care needs to be taken to ensure their safety.

Fate of Pesticide Residues During Brewing

Simón Navarro and Nuria Vela Department of Agricultural Chemistry, Geology and Pedology, School of Chemistry, University of Murcia, Campus Universitario de Espinardo, Murcia, Spain

Abstract

This chapter emphasizes the influence of the different phases of beer-making and the removal of pesticide residues. The effect of their presence on beer quality and health impact is also assessed. With this aim, based on the current data an overview of the behavior and fate of agrochemical residues during the brewing stages (malting, mashing, boiling, fermentation, and stabilization of the beer) is presented. The methodology for analysis of pesticide residues and their metabolites in raw materials, wort, and beer and the main aspects of the food safety and policy in the European Union (EU) are summarized. Depending on the stage involved and the physical–chemical properties (mainly K_{OW} [as $\log P$] value, water solubility, vapor pressure and Henry's law constant) of the residue in the raw materials, differences in the final fate of the residues are observed. As a general rule, the malsters should devote special attention to the residues of hydrophobic pesticides with $K_{OW} > 2$ because they can remain on the malt. On the contrary, brewers should control residues of hydrophilic pesticides with $K_{OW} < 4$ because they can be carried over into beer. Thus, the monitoring and surveillance of pesticide residues with K_{OW} ranging from 2 to 4 (most of them) during the brewing process is essential to get a "healthy drink." Additionally, the influence of pesticide residues on flavor, sugar content, acidity, color or total polyphenol, and flavonoid contents has been pointed out. Therefore, the knowledge of the behavior of pesticide residues must be intended to (i) provide information on the transfers of residues from barley to malt, wort, and beer to calculate concentration or reduction factors during each process; (ii) achieve a realistic estimate of the dietary intake of pesticide residues; (iii) propose maximum residue limits (MRLs) for residues in beer when necessary; and (iv) avoid alterations in the beer quality.

List of Abbreviations

ASE	Accelerated solvent extraction
CAC	Codex Alimentarius Commission
CCP	Control critical point
CEC	Commission of the European Communities
CI	Chemical ionization
CID	Collision-induced dissociation
DMG	Danish Malting Group
EBDC	Ethylene bisdithiocarbamate
ECD	Electron capture detection
EFSA	European Food Safety Authority
ESD	Element-selective detector
ETU	Ethylenethiourea
EU	European Union
FAO	Food and Agriculture Organization
GAP	Good agricultural practices
GC	Gas chromatography
GC/MS	Gas chromatography/mass spectrometry
GLP	Good laboratory practice
HACCP	Hazard analysis critical control point
HPLC	High performance liquid chromatography
IARC	International Agency for Research on Cancer
IPM	Integrated pest management
LC	Liquid chromatography
LC/MS	Liquid chromatography/mass spectrometry
MAE	Microwave-assisted extraction
MRL	Maximum residue limit
MRM	Multiresidue method
MSD	Mass spectrometric detection
MSPD	Matrix solid-phase extraction
NPD	Nitrogen phosphorus detection
OHA	Hydroxy atrazine
OHT	Hydroxy terbuthylazine
OTA	Ochratoxin A
PBDC	Propylene bisdithiocarbamate
PLE	Pressurized liquid extraction
PTU	Propylenethiourea
QA	Quality assurance
QC	Quality control
RAC	Raw agricultural commodity
SBI	Sterol biosynthesis-inhibiting
SFE	Supercritical fluid extraction
SPE	Solid-phase extraction
SPME	Solid-phase microextraction
UNIDO	United Nations Industrial Development Organization
WHO	World Health Organization
WTO	World Trade Organization

Introduction

For years there has been a great deal of publicity highlighting the health benefits of a moderate consumption of beer. The influence of beer on health is related to the absence of negative attributes and the presence of positive attributes. Beer, a wholesome beverage that has been a staple part of our diet for many thousands of years, contains a number of components such as antioxidants, which can be beneficial to health. Furthermore, the nutritive aspects of beer include its low sugar content and significant amount of vitamins and minerals (Sendra and Carbonell, 1998; Baxter and Hughes, 2001). One of the most important factors contributing to the public perception of beer as a "healthy drink" has been the accumulation of studies showing that moderate drinkers have lower death rates from all causes, especially from cardiovascular-related diseases, than either non-drinkers or heavy drinkers (Fagrell *et al.*, 1999). The quality of raw materials (barley, hops, water, and yeasts) has a decisive influence on the quality of the final product (Kunze, 2004). Knowledge of the properties of the raw materials and their effects on the process and the product provides the basis for their handling and processing. Therefore, it is important to assess the pollution load of barley and how pesticide residue evolves during the malting process. The ingredients used for brewing must not be allowed to act as a transmitter of unacceptable pollutants that are a risk for the beer consumer and animals.

Barley pests

Because of their high content of starch and storage proteins, barley grains represent an attractive source of nutrients for insects and microbial pathogens. The vulnerability of the grain to insect and pathogen attack is expected to increase during germination, when amino acids, fermentable carbohydrates, nitrogenous bases, and other degradation products of reserve polymers accumulate in the starchy endosperm (Fincher and Stone, 1993). Good weed control is essential to the crop to make efficient use of moisture and to prevent weed seeds from contaminating the harvest. Furthermore a range of head, root, leaf, and stem diseases may affect barley, depending on climate, environment, and farm history. Some of the more common diseases include crown rot, rust, smut, root rot, net blotch, and nematode infection. Finally, armyworms, cutworms, or mites cause important damage to cereals in some areas (Theaker *et al.*, 1989; Domínguez, 2004). Additionally, barley with a moisture content of about 14% may be attacked by fungi during storage especially by *Aspergillus* and *Penicillium* spp. These genera produce secondary metabolites such as ochratoxin A (OTA); it has been shown to be teratogenic and immunosuppressive. The International Agency for Research on Cancer (IARC) lists OTA as possibly carcinogenic to humans, group 2B (IARC, 1993). Some of these metabolites cause gushing, a very severe quality defect, where the beer spontaneously gushes from a bottle on opening. It is therefore important that malting barley is stored under conditions that prevent fungal growth (DMG, 1999).

Use of pesticides on barley

For the reasons mentioned earlier, pesticides are widely used in different combinations at many stages of cultivation and also during postharvest storage. From the past decades there has been, in the developed countries, an increasing concern over possible dangers to human health and/or the environment resulting from the excessive or inappropriate use of chemical pesticides. At present, good agricultural practices (GAP) are formally recognized in the international regulatory framework for reducing risks associated with the use of pesticides, taking into account public and occupational health, environmental, and safety considerations. The International Code of Conduct on the Distribution and Use of Pesticides (the worldwide guidance document on pesticide management for all public and private entities engaged in, or associated with, the distribution and use of pesticides adopted for the first time in 1985 by the Twenty-fifth Session of the FAO Conference) focuses on risk reduction, protection of human health and the environment, and support for sustainable agricultural development by using pesticides in an effective manner and applying integrated pest management (IPM) strategies (FAO, 2002).

The environmental and health impact of pesticides is being reduced through the implementation of a number of concrete programs on pesticide management, such as residue analysis, product standards setting and methods to analyze them, prevention of accumulation of obsolete stocks of pesticides and means to dispose them, and exchange of information on national actions taken to control pesticides.

Presence of pesticide residues in raw materials

The problem is that traces of these pesticides may remain in the beer produced from the treated ingredients, although the residues may also come from the soil itself and the water used; a problem that affects the brewing industry in several countries. During the first step (malting), some residues of pesticides having $\log K_{OW} > 2$ (as $\log P$) would remain on malt as indicated by some authors (Miyake *et al.*, 2002). After mashing and boiling, the pesticides on the malt can pass into the wort in different proportions, depending on the process used, although it should be noted that the removal of material in the form of trub and spent grains tends to reduce the level of pesticides, which are often relatively insoluble in water (Hack *et al.*, 1997; Miyake *et al.*, 1999; Navarro *et al.*, 2005a, 2006). Finally, if pesticide residues, especially some fungicides, are present in the brewer wort, they may cause organoleptic alterations

to the finished beer and have toxic effects on the consumer (Jones *et al.*, 1988; Navarro *et al.*, 2007a).

Analysis of Pesticide Residues in Raw Materials and Beer

The widespread use of pesticides in cereals and hops had led to the presence of pesticide residues in beer. Public concern over pesticide residues in malt beverages and beers has been increasing such that it has become a significant food safety issue. Routine analyses of the composition of the raw materials used in the malting and brewing processes aim to assist quality control (QC). Validation protocols are essential for the analyst to provide the proper documentation of analytical results required to meet the QA/QC criteria of GLP/GMP and of various regulation agencies such as the Codex Alimentarius Commission (CAC) (Sherma, 1999). Additional analyses are performed to detect trace amounts of undesirable compounds such as pesticides to confirm that they are not present in the raw materials used in production. For this, multiresidue methods (MRMs) are needed to reliably and rapidly detect and quantitate as many pesticides as possible in the most cost-effective manner (Ghosh *et al.*, 2005).

Traditional batch liquid–liquid solvent extraction in a separatory funnel, Soxhlet extraction, or ultrasonic solvent extraction methods have been progressively substituted by more modern sample preparation methods in the past years (Sherma, 1999). These include general solid-phase extraction (SPE), polymeric reversed-phase (RP)SPE, disk format SPE, automated SPE, matrix solid-phase dispersion (MSPD), solid-phase microextraction (SPME), membrane filtration, solvent extraction flow injection, miniaturized liquid–liquid extraction, accelerated solvent extraction (ASE) or pressurized liquid extraction (PLE), microwave-assisted extraction (MAE), and water or supercritical fluid extraction (SFE). Methods and instruments for modern extraction methods have been reviewed (Jordan, 1998).

Residues in extracts are most commonly separated by gas chromatography (GC) or high performance liquid chromatography (HPLC) using ultraviolet (UV) absorbance, nitrogen phosphorus detection (NPD), or electron capture detection (ECD). However, although these element-selective detectors (ESDs) provide low ppb detection limits and are easy to operate, the data do not provide sufficient information to confirm a compound's presence with confidence. Owing to the universal nature of mass spectrometric detection (MSD), a mass spectrometer provides additional information and increases confidence in the assignment of compound identity (Meng, 2001). GC/MS has features to enhance specificity, such as chemical ionization (CI), selective ion monitoring (SIM), or MS/MS. Even with SIM, where multiple ions are monitored (MIM), the matrix may contain similar ions at the same retention time, so more stringent selectivity must be invoked to remove the matrix ions from the mass spectrum, which eliminates false positives and raises

concentration values from matrix interferences. MS/MS does just that by ejecting all except the ion of interest out of the group. Then, a collision-induced dissociation (CID) energy is applied to fragment the ion into a very unique product ion spectrum (Butler and Conoley, 2005). However, although many established MRMs for analysis of food samples have used GC, some water-soluble pesticides that may be very important in beverages such as wine or beer are not suitable for analysis or their recoveries are very low. For these water-soluble pesticides, there are many analytical methods using liquid chromatography (LC). Recently, MS was found to be superior to other LC detectors, in particular, tandem mass spectrometry (MS/MS) was found to be far superior to any other method because of its high selectivity and sensitivity with the advantage of unequivocal analyte identification due to the ion selection of two mass analyzers. Also, as a single analytical procedure is desirable to screen beverage samples, the LC–MS/MS method allows the quantitation of many pesticides in beer without any sample preparation other than centrifugation. Many analytical methods using these techniques have been proposed in recent years for analysis of pesticide residues in cereals, malt, hops, and beer (Williams *et al.*, 1994; Hack *et al.*, 1996; Tadeo *et al.*, 2000; Hengel and Shibamoto, 2002; Wong *et al.*, 2004; Trösken *et al.*, 2005; Omote *et al.*, 2006; Vela *et al.*, 2007).

Food Safety and Policy in the European Union

The agro-food sector is of major importance for the European economy as a whole. The food and drink industry is a leading industrial sector in the European Union (EU), with an annual production worth almost €600 billion, or about 15% of total manufacturing output. An international comparison shows the EU as the world's largest producer of food and drink products. Production of beer worldwide was forecast to increase to an annual growth rate of 2.3% through 2005 to a volume of about 153 billion liters. Concretely, about 34% of the world beer production in 2004 (530 million Hl) was manufactured in Europe – Germany, Great Britain, and Spain being the main producers of the EU (Barth-Haas Group, 2005).

The contamination of food by chemical hazards is a worldwide public health concern and is a leading cause of trade problems internationally. Contamination may occur through environmental pollution, as in the case of toxic metals, polychlorinated biphenyls (PCBs), and dioxins, or through the intentional use of chemicals such as pesticides, animal drugs, and other agrochemicals. Food additives and contaminants resulting from food manufacturing and processing can also adversely affect health. The EU's food policy is based on high food safety standards, which serve to protect and promote the health of the consumer. Regulation (EC) No. 396/2005 on maximum residue levels of pesticides in or on food and feed of plant and animal origin emphasizes the importance of carrying out further work

to develop a methodology to take into account cumulative and synergistic effects of pesticides on human health. The EU food safety policy must be based on a comprehensive, integrated approach. This means throughout the food chain ("farm to table"), across all food sectors, between the Member States, at the EU external frontier and within the EU, in international and EU decision-making fore, and at all stages of the policy-making cycle. The pillars of food safety contained in the White Paper (scientific advice, data collection and analysis, regulatory and control aspects, as well as consumer information) must form a seamless whole to achieve this integrated approach (CEC, 2000).

HACCP system in the food industry

The hazard analysis critical control point (HACCP) system is a relatively new approach to the prevention and control of foodborne diseases. The HACCP system identifies specific hazards and preventative measures for their control to ensure the safety of food. HACCP is a tool to assess hazards and establish control systems that focus on preventative measures rather than relying mainly on end-products testing. Table 40.1 summarizes the seven HACCP principles.

For many years public health and food control authorities worldwide, as well as international organizations such as Food and Agriculture Organization (FAO), World Health Organization (WHO), and United Nations Industrial Development Organization (UNIDO) have promoted the application of the HACCP system. FAO/WHO CAC adopted at its 20th Session (1993), the Guidelines for the Application of the HACCP System (CAC/GL 18-1993). This session emphasized that the work of Codex has increased in importance with the establishment of the World Trade Organization (WTO) and the WTO Agreement on the Application of Sanitary and Phytosanitary Measures coming into force. According to this Agreement; Codex standards;

guidelines and recommendations relating to food additives, veterinary drug and pesticide residues, contaminants; methods of analysis and sampling; and codes and guidelines of hygienic practice have been recognized as the reference for international food safety requirements, and thus as a benchmark for national requirements.

The Food Hygiene Directive (93/43/EEC) obliges food businesses in the EU to implement systems that are based on the principles of HACCP. Although non-EU suppliers of food products do not legally have to comply directly with the EU directive on food hygiene, they are affected by the Euhygiene rules. It was clearly confirmed that food businesses in Europe, implementing systems to ensure that hazards are identified and controls are in place, have become increasingly selective in dealing with their (foreign) suppliers and request a strict application of HACCP in the request countries of origin of imported products. In some cases, they have even set out additional hygienic requirements for their suppliers regarding specific product(s).

Food businesses in Europe and other industrialized countries, applying systems to assure food safety, will not buy any raw material if they think that, even after sorting and processing, it could make food unfit for human consumption. Any raw material or processed food product that is only suspected or known to be infected or contaminated with parasites or foreign substances will not be accepted.

Therefore, it is important to carry out a HACCP plan (a document describing the activities developed in accordance with the principles of HACCP to ensure control of hazards, which are significant for food safety in the product under consideration and its intended use) in order to reveal the weaknesses of the production line of beer and to suggest the critical limits in compliance with legislation and the corresponding preventive and corrective measures (Kourtis and Arvanitoyannis, 2001).

Effects of Brewing on the Pesticide Residues

Depending on the type of process involved and the chemical nature of the residue in the raw agricultural commodity (RAC), differences in the nature of the residue in the processed commodities and the RAC may have to be determined. Once the nature of the residues formed during processing has been clarified and active ingredients and relevant metabolites to be analyzed have been identified, processing studies are conducted with RACs that normally undergo processing in the home or under commercial conditions. The process may be physical or may involve the use of heat or chemicals (Timme and Waltz-Tylla, 2003). These types of processing are intended to (i) provide information on the transfer of residues from RACs to the processed product, in order to calculate reduction/concentration factors; (ii) enable a more realistic estimate to be made of the

Table 40.1 Principles of the hazard analysis critical control point (HACCP) system

1. Conduct a hazard analysis. Steps in the process where significant hazards can occur including preventive measures.
2. Identify the critical control points (CCPs) in the process.
3. Establish critical points for preventive measures associated with each identified CCP.
4. Establish CCP monitoring requirements and procedures for using the results of monitoring to adjust the process and maintain control.
5. Establish corrective actions to be taken when monitoring indicates that there is a deviation from an established critical limit.
6. Establish effective record-keeping procedures that document the HACCP system.
7. Establish procedures for verification that the HACCP system is working correctly.

dietary intake of pesticide residues; and (iii) establish MRLs for residues in processed products when necessary. Figure 40.1 summarizes the principal steps of the brewing process. More detailed descriptions can be found in Eaton (2006).

Dissipation of pesticide residues during storage of barley, malt, and spent grains

When appropriate application methods of agrochemicals are not followed, pesticide residues on barley can be above the maximum residue limits (MRLs) established by the governments of each country, and the time for pesticide dissipation is also high. Desmarchelier *et al.* (1980) reported the losses of several pesticides (bioresmethrin, carbaryl, fenitrothion, *d*-fenothrin, methacrifos, and pirimiphos-methyl) from barley

Figure 40.1 begins here (flow chart):

Barley grains → Malting → Malted barley

Steeping → Steeped grains
Germination → Germinated grains
Kilning → Kilned grains

Malted barley → First wort
Lautering ← Mashing
Lautering → Spent grains
→ Second wort → Sweet wort

Sweet wort → Boiling → Brewer wort → Spent hops
Brewer wort → Primary fermentation → Young beer → Spent yeasts
Young beer → Lagering → Matured beer
Matured beer → Clarification, filtration → Stabilized beer
Stabilized beer → Carbonation, packaging, storage → Finished beer

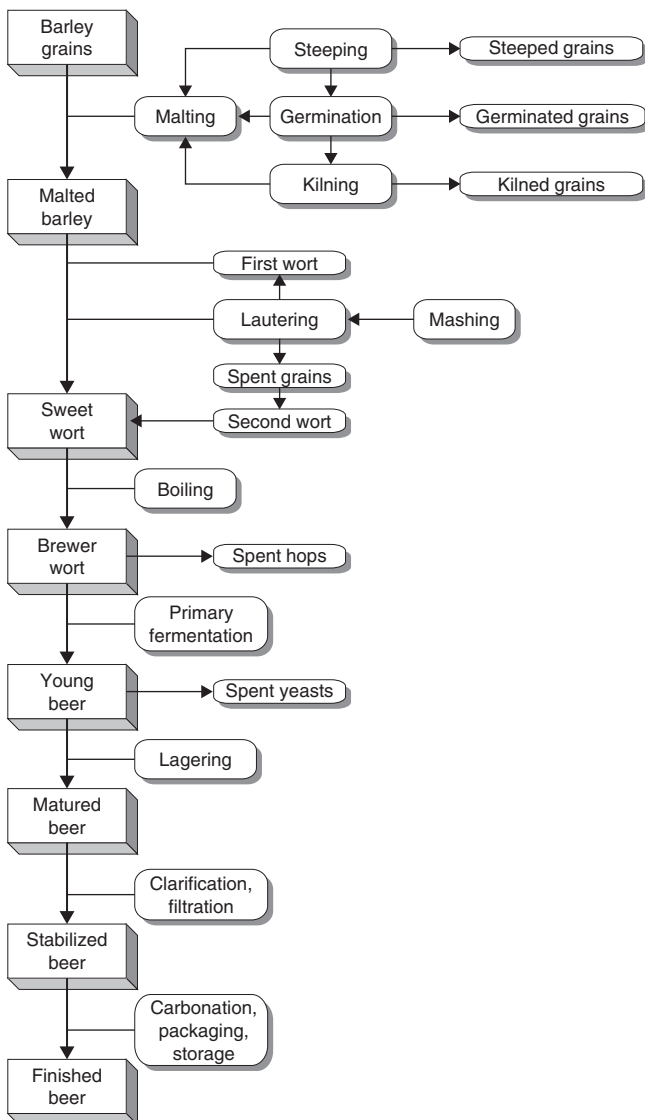
Figure 40.1 Scheme illustrating the principal stages of the brewing process.

after storage and malting finding losses of 58–100%. Other authors show that after pesticide application using some insecticides (phentoate, fenitrothion, and ethiofencarb) and fungicides (triflumizole, mepromil, propiconazole, and triadimefon), common in barley cultivation, more than 80% of residues of phentoate and fenitrothion (organophosphorus insecticides) remained after 2 months of grain storage at room temperature, whereas the loss of other pesticides ranged from 28% to 85%, and metabolites of triadimefon (triadimenol) and triflumizole (TF-6-1) increased slightly (Miyake *et al.*, 2002). Several models (Timme and Frehse, 1980; Timme *et al.*, 1986; Morton *et al.*, 2001) are used to describe the decay of pesticides in different matrices. Probably, the most commonly used model to describe loss of grain protectants is the following equation, where R_t is the residue at time t, R_0 the residue at time zero, and K the rate constant (Desmarchelier, 1977, 1978).

$$\ln R_t = \ln R_0 - Kt$$

Navarro *et al.* (2007b) found a good linear correlation ($r \geq 0.95$) between $\ln R_t$ and time when they studied the dissipation of several pesticides over 3 months of malt storage at $20 \pm 2°C$. Additionally, a perfect correlation ($r > 0.99$) between the analytical and theoretical concentration calculated (R_0) at 0 days was observed, which indicates that the model is valid. According to the calculated values for the rate constant (K), the following dissipation rate was observed: myclobutanil > propiconazole > fenitrothion > trifluralin > pendimethalin > malathion > nuarimol with half-lives ranging from 244 to 1,533 days.

A moist by-product from the brewing industry, made up of spent grains, is widely fed to ruminant animals used as a buffer or as a forage or concentrate replacer. Therefore, although the nutritional potential of the spent grains for animals has been demonstrated, it is important to ascertain the pollution load of the same and how any pesticide residues evolve during storage.

To know the dissipation rate of pesticide residues in the spent grains, Navarro *et al.* (2005a, 2006) studied their disappearance during storage (3 months). In all cases, there was a good linear correlation ($r > 0.96$) between residue level and time. The necessary times to reach their respective MRLs in barley were 408, 515, 958, 711, 719, and 934 days for nuarimol, myclobutanil, propiconazole, fenitrothion, trifluralin, and pendimethalin, respectively, which indicates a high persistence level and minimum degradation for all compounds, especially for propiconazole. In the case of malathion, the initial residue was below its MRL.


Decline of pesticide residues from barley to malt (malting)

Common malting operations involve four basic stages: barley intake, drying and storage, steeping, germination

Table 40.2 Carryover of some pesticide residues after each stage of malting

| Pesticides | Log P_{OW}* | Stage | | | References |
		Steeping	Germination	Kilning	
Ethiofencarb	2.04	3	1	5	Miyake *et al.* (2002)

Trifluralin	3.07	80	65	50	

*Tomlin (2003).

and kilning (Bamforth and Barclay, 1993). The process commences with the steeping of barley in water to achieve a moisture level sufficient to activate metabolism in the embryonic and aleurone tissues, leading in turn to the development of hydrolytic enzymes. Germination is generally targeted to generate the maximum available extractable material by promoting endosperm modification through the development, distribution, and action of enzymes. Finally, after a period of germination sufficient to achieve even modification, the "green malt" is kilned to arrest germination and stabilize the malt by lowering moisture levels, typically to less than 5%.

Table 40.2 shows some bibliographical data relative to pesticide decline during malting. Although in general terms steeping reduces residue levels significantly, the carryovers for dinitroaniline herbicides (pendimethalin and trifluralin) vary from 80% to 85% in steeped grains. Both are hydrophobic pesticides because of their high $\log P_{OW}$ (>5) and low solubility (0.2–0.3 mg/l). In consequence, a low proportion of their residues (10–15%) are removed with the steeping water. Regarding the organophosphorus pesticides, 55% of malathion ($\log P_{OW} = 2.7$) is removed from the barley grains after steeping whereas 48% of fenitrothion residues ($\log P_{OW} = 3.5$) are removed in this stage (Navarro *et al.*, 2007b). Other published data show carryover of 43% for fenitrothion after steeping process whereas other organophosphorus insecticide such as phentoate remains in lower proportion (27%) as indicated by Miyake *et al.* (2002). On the contrary, other insecticide of the same family as pirimiphos-methyl remains in high proportion (90%) after steeping (Collins and Armitage, 2006). Some fungicides such as nuarimol (pyrimidine), myclobutanil, and propiconazole (triazole) are removed from the barley grains (after steeping) in proportions ranging from 30% to
Figure 40.2 Correlation between carryover of some pesticides after steeping and their $\log P_{OW}$ values according to the data shown in Table 40.1 (solid line is 95% confidence interval and dash line 95% prediction interval).

41%, this is expected bearing in mind their respective coefficients between *n*-octanol and water (P_{OW} values). Miyake *et al.* (2002) found higher percentages of elimination for some azole fungicides, specifically 50%, 62%, and 76% for propiconazole, triflumizole, and triadimefon, respectively. These data are supported by the relationship between amounts removed after steeping and $\log P_{OW}$ of the pesticides used in this study, as can be seen in Figure 40.2. The carryover of hydrophilic pesticides (low $\log P_{OW}$) such us malathion is lower, whereas carryovers of hydrophobic pesticides (pendimethalin and trifluralin) are higher. Miyake *et al.* (1999) suggest that brewers should pay attention to

Table 40.3 Carryover of some pesticide residues after mashing and boiling

Pesticide	Log P_{OW}[a]	Sweet wort	Spent grains	Brewer wort	Spent hops	References

[c] Below detection limit.

the residues of hydrophilic pesticides on malt with P_{OW} values <4 because they can be carried over into beer; the steeping stage of the malting process being of special interest. The same authors (Miyake *et al.*, 2002) showed that pesticides with $\log P_{OW} > 2$ can remain on malt. Therefore, the control of pesticides with P_{OW} values ranging from 2 to 4 must be very important for maltster and brewers.

Removal and transference of pesticide residues from malt to sweet wort (mashing)

As a general rule, about 200 g of grains are used to produce 1 litre of wort at 12° Brix, although this amount varies according to whether a higher or lower alcoholic content is desired. Any residues present in the grain, even if completely transferred to the beer, should, therefore, undergo dilution by a factor of 5 although $\log P_{OW}$ values of pesticides should be kept in mind (Miyake *et al.*, 1999). Taking into account the low solubility of most pesticide residues in water and their tendency to be easily adsorbed on the suspended matter, as in wine making, the presence of residues in beer should be very low (Farris *et al.*, 1992).

The carryovers of residues for several pesticides after mashing are shown in Table 40.3. During mashing, the soluble substances (sugars, amino acids, and peptides) produced in malting and mashing are extracted into the liquid fraction (sweet wort), which is then separated from the residual solid particles (spent grains). According to Navarro *et al.* (2005a), at the end of the mashing phase, the remaining percentages are below 10% of the amount recorded in malt; propiconazole showing the greatest decrease (to 4%). On the contrary, the retained amounts on spent grain is relatively high (38%, 42%, and 26% for myclobutanil, propiconazole, and nuarimol, respectively, all the compounds having $K_{OW} > 2$) (Figure 40.3). Similar behavior was observed for atrazine and terbuthylazine during mashing, when 70% and 90%, respectively, were adsorbed on spent grain (Hack *et al.*, 1997). In a general way, adsorption affinity depends on the polarity of the compounds: the more polar the pesticide, the lower the adsorbed amount (Hengel and Shibamoto, 2002). It is necessary to bear in mind that maceration of the malt and adjuncts produces a great quantity of suspended matter, which could adsorb the pesticide residues and, if the recorded levels allow it, the spent grains could be used as animal feeds, implying
Figure 40.3 Correlation between carryover of some pesticides after mashing and their $\log P_{OW}$ values according to the data shown in Table 40.3 (solid line is 95% confidence interval and dash line 95% prediction interval).

a commercial use of this by-product. As shown in Table 40.3, the amounts remaining of dinitroaniline herbicides practically disappear after mashing (<1% of the initial amount in sweet wort), whereas the remaining percentages of fenitrothion and malathion in the sweet wort are greater (4.2% and 6.6%, respectively). On the contrary, the retained amounts on spent grain were relatively high (22%, 17%, 30%, and 40% for pendimethalin, trifluralin, fenitrothion, and malathion, respectively). Other pesticides such as glyphosate (organophosphorus) and pirimicarb (carbamate) were found in sweet wort in proportions higher than 80%. On the contrary, no residues of pyrethroid compounds (fenvalerate, deltamethrin, permethrin, and flucythrinate) were obtained from sweet wort; they were recovered from the spent grains. In the case of oxamyl, dichlorvos, parathion-methyl, chlorpyrifos, dichlofuanid, and captafol, pronounced losses were observed, possibly due to thermal degradation, evaporation, or chemical reactions with some wort components during the mashing process (Miyake *et al.*, 1999).

Removal and transference of pesticide residues from sweet wort to brewer wort (boiling)

Table 40.3 shows the carryovers of several pesticides in brewer wort and spent hops. As can be seen, a very small decrease (<10%) has been observed in the residual content after the wort had been boiled for myclobutanil, nuarimol, and penconazole residues, which points to the stability of the three compounds at temperatures higher than 100°C (Navarro *et al.*, 2005a). The carryovers of pendimethalin and trifluralin recorded from the brewer wort were lower than 30% of their content in sweet wort after wort boiling. With regard to the fall of organophosphorus compounds at this time, the levels of fenitrothion and malathion were 83% and 65%,

respectively, of the content in wort after mashing (Navarro *et al.*, 2006). Other authors (Miyake *et al.*, 1999) show that the percentages of residues for glyphosate, fenobucarb, and pirimicarb into the cold wort were prominently high showing a great stability at temperatures above 100°C, whereas dicofol and pyrethroid insecticides were mainly recorded in the spent hops, and dichlorvos, dichlofuanid, and captafol completely disappear, probably due to the higher temperature of the boiling process in this case. However, the sum of residues for oxamyl, parathion-methyl, and chlorpyrifos in cold wort and spent hops was slightly higher than that of the mashing process. Authors assumed this behavior on the basis that these pesticides can react with some components or proteins in the sweet wort but not in the cold wort.

The fate of pesticide residues from hop to wort during boiling has also been studied. Some researchers have demonstrated that no pesticides added to the hops were detected in the young beer after wort boiling (Miyake *et al.*, 1999). Other work carried out by Navarro *et al.* (2005b) shows that residues of malathion, methidathion, and fenamiphos were below their detection limits in the young beer after addition of spiked hop pellets (2 μg/g) to the boiling wort, whereas 1 μg/l was recorded for fenarimol. In most of the cases, the absence of pesticide residues is due to their losses during boiling and the high dilution of hops. Other studies carried out with field-treated hops with several pesticides show that residues of tebuconazole, Z- and E-dimethomorph were lower than 31% of the amount expected, bearing in mind these were only the diluted residues. Subsequent analysis showed that 84–109% of pesticide residues (chlofenapyr, quinoxyfen, pyridaben tebuconazole, fenarimol, and both Z- and E-dimethomorph) remain on the spent hops (Hengel and Shibamoto, 2002), which is explained by the highly lipophilic components of hops such as waxes and resins. In Europe, processing studies on hops are only required when residues are higher than 5 mg/kg of dried cones because of the high dilution factor – around 250 (Timme and Waltz-Tylla, 2003).

Evolution of pesticide residues during fermentation

With regard to the influence of the fermentative process on the elimination of pesticide residues (Table 40.4), a significant reduction has been observed for propiconazole residues (47% of the content recorded in brewer wort) but much less for other fungicides such as myclobutanil and nuarimol (around 20%) (Navarro *et al.*, 2005a). However, no residues of dinitroaniline herbicides were found in young beer fermented with bottom-yeasts, although there was a significant reduction in the cases of organophosphorus insecticides fenitrothion and malathion (58% and 71% of the content recorded in brewer wort) (Navarro *et al.*, 2006). Other fermentation studies showed that top-fermenting yeasts (*Saccharomyces cerevisiae*) had a much greater ability

Table 40.4 Carryover of some pesticide residues after fermentation

Pesticide	LogP_{OW}[a]	Young beer[b]	Spent yeast	References
Atrazine	2.5	95 (76)	ND[c]	Hack *et al.* (1997)

[d] Below detection limit.

to convert triazine herbicide residues into their hydroxylated products than bottom-fermenting yeasts (*Saccharomyces carlsbergensis*) (Hack *et al.*, 1997). For Miyake *et al.* (1999), no significant reduction was observed during the fermentation process for some group of pesticides. Other pesticides such as chlofenapyr, quinoxyfen, and pyridaben show a dramatic drop after addition to the pitching wort, being below detection limit after fermentation, whereas tebuconazole, fenarimol, and both *Z*- and *E*-dimethomorph had relatively high residue recoveries; their carryover, at the end of the fermentation, ranging from 41% to 75% (Hengel and Shibamoto, 2002). These results suggest that there is a relationship between K_{OW} and the amount of pesticides found in the young beer and the trub as can be seen in Figure 40.4. The losses during fermentation may be attributed to biotic metabolism of the yeast and abiotic degradation from the anaerobic environment created by fermentation

(Cabras *et al.*, 1995). Also, according to the Henry's law constants (the tendency of a compound to volatilize from aqueous solution to air), those pesticides with high vapor pressure and low solubility in water may escape into the atmosphere (Mackay *et al.*, 1979). This process is also favored by the constant evolution of CO_2 during the first few days of the fermentation.

Decrease of pesticide residues during maturation phase (lagering), filtration, and beer storage

No important decrease on the residual levels has been observed in any case after maturation and filtration. Nuarimol decreased its concentration (by 10%) with regard to the young beer. However, fenitrothion and malathion decrease their contents with regard to the young beer by
Figure 40.4 Correlation between carryover of some pesticides after fermentation and their log P_{OW} values according to the data shown in Table 40.4 (solid line is 95% confidence interval and dash line 95% prediction interval).

Figure 40.5 Evolution of specific gravity ($n = 3$) vs. time during fermentation phases (I: initial, II: low krausen, III: high krausen, IV: krausen collapsing, and V: collapsed foam) for blank and treated samples. *Source*: Navarro *et al.* (2007a).

33% and 37%, respectively (Navarro *et al.*, 2005a; Navarro *et al.*, 2006). Hack *et al.* (1997) did not find loss of triazines after filtration. Finally, after the storage period (3 months), the concentrations of myclobutanil and fenitrothion fall sharply (50% and 75%, respectively), whereas the decrease observed for nuarimol and myclobutanil, being lower than 25% of the amount in the finished beer is less pronounced, and malathion residues are below detection limits.

Influence of Pesticide Residues on the Beer Quality

During fermentation, yeast metabolizes sugars into energy, alcohol, carbon dioxide, secondary by-products, and more yeast. Those fermentation by-products have a considerable effect on the taste, aroma, and other characteristics of the beer. Beer flavor is a very complex subject. More than 800 compounds have been identified that contribute to the characteristic flavor of beer. Some pollutants, such as pesticides, can alter the normal fermentative process, being able to cause in certain cases sluggish and even stuck fermentation, although it will depend to a great extent on the initial concentrations in the malted barley, physical–chemical characteristics of each product, and beer-making procedure. In consequence, the organoleptic properties of the beer should be modified as in other fermented beverages such as wine (Cabras *et al.*, 1987; Navarro, 2000).

Flavor assessment is very important in quality control of beer. One of the most important tools is the sensory analysis by a panel of well-trained tasters. In some cases, the harsh astringent flavor observed in some beer samples was found to be due to products (metabolites) derived from pesticides present in the raw materials. Thus, residues of
up to 5 mg/kg of carbaryl were found on treated barley and up to 41 µg/l of carbaryl-derived 1-naphtol were found in beer. Removal of up to 90% of the carbaryl and all of the 1-naphtol occurred during malting. Some tasters were able to consistently identify beer containing 20 µg/l of 1-naphtol (Jones *et al.*, 1988).

According to Navarro *et al.* (2007a), a marked influence of some pesticides in the fermentation rate has been observed (see Figure 40.5 where the evolution of specific gravity with time is shown for blank and treated samples). As can be seen, from the fourth day onward, the fermentation prematurely ceases (stuck fermentation; i.e., the premature termination of fermentation before all fermentable sugars have been metabolized) in the samples with propiconazole residues compared with the blank. No significant differences in the evolution of specific gravity has been found for samples fermented with myclobutanil residues whereas for samples treated with fenarimol and nuarimol residues the fermentative kinetic is quicker, from 2 to 6 days, probably due to the rapid assimilation of nitrogen by the yeasts. The four compounds are sterol biosynthesis-inhibiting (SBIs) fungicides. They inhibit the cytochrome P_{450} monooxygenase, which catalyzes the oxidative C_{14} demethylation of 24-methylenedyhydrolanosterol in the biosynthesis pathway, and are a widely applied class of antifungal agents because of their broad therapeutic window, wide spectrum of activity, and low toxicity (Koller, 1988). Some authors suggest that the complex nitrogen composition of the medium may create conditions resembling those responsible for inducing sluggish/stuck fermentation (Batistote *et al.*, 2006).

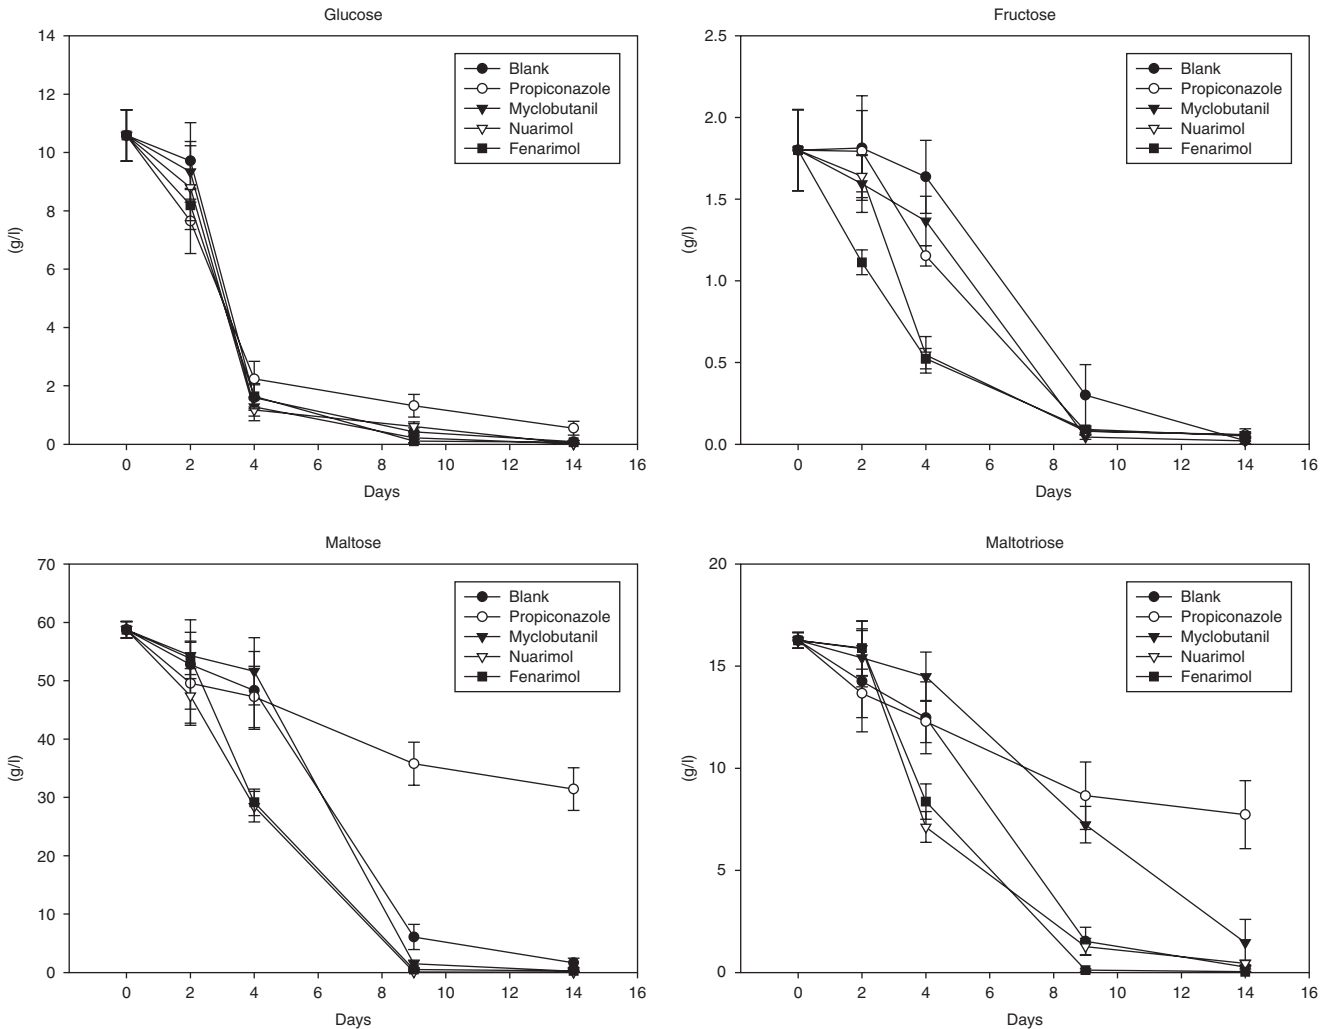
The sugars in wort are not all fermented in the same proportion. Figure 40.6 shows the evolution of fermentable


Figure 40.6   Change in glucose, fructose, maltose, and maltotriose content (*n* = 3) vs. time during fermentation for blank and samples treated with fungicides (error bars are 95% confidence intervals). *Source*: Navarro *et al.* (2007a).

carbohydrates during fermentation according to Navarro *et al.* (2007a). Since yeast has to hydrolyze sugar polymers before it can use them, it always attacks hexoses first. For this reason, the yeasts assimilate a greater proportion of glucose during the first 96 h. No significant differences were observed between the blank sample and those treated with myclobutanil, nuarimol, and fenarimol residues whereas in the case of propiconazole, a delay in the glucose consumption was observed after 4 days. Sucrose was easily fermented by yeast in all cases because the enzyme that decomposes it, invertase, is located in the cell wall and sucrose is therefore treated as a start of fermentation sugar by the yeast. No significant differences were observed between the blank and the other samples although assimilation of this sugar was to some extent slower in the blank sample during the first 48 h. Fructose assimilation follows a different behavior among glucose and sucrose. Samples with nuarimol and fenarimol (pyrimidine fungicides) residues reduced this sugar quicker

than those with propiconazole and myclobutanil (triazole fungicides) residues. The slowest assimilation corresponds to the blank sample. In all cases, the highest reduction occurs from 24 to 216 h. Maltose exhibits similar behavior although the biggest consumption takes place between 96 and 216 h, during the main fermentation. It is important to remark that after the fourth day the consumption of this sugar decreased drastically by the yeasts in the sample with propiconazole residues with logical bearing in mind that fermentation was stopped at this time. Finally, maltotriose is the last sugar assimilated by the yeasts. No significant differences were observed when comparing the behavior of the blank sample and those with residues of nuarimol and fenarimol. However, triazole fungicides, especially propiconazole, have a marked influence on the assimilation of this sugar by the yeasts.

The effect of some pesticide residues on the pH and color of the beer has also been observed (Navarro *et al.*, 2007a).

Thus, the pH values at the end of the fermentation were 4.1 for the blank sample and 3.0, 3.7, 3.8, and 3.9 for those containing residues of propiconazole, myclobutanil, fenarimol, and nuarimol, respectively. In this case also, the presence of propiconazole alters the final quality of the beer. pH values below 4.0 cause an acidic beer taste and must be avoided, in particular, acidification by microbial infections during fermentation. Therefore, maturation should be completely excluded. Regarding color, at the beginning of the process 5.35 EBC units were recorded. Although a slight increase after 2 days of fermentation can be observed in all cases, color of the beer falls about 1–1.5 EBC units during fermentation. This is possibly due to the decoloration of some substances caused by the drop in pH, and absorption of highly colored compounds in the yeast cells or precipitation in the vessel bottom (Kunze, 2004).

As a result of a decrease in pH during fermentation or adsorption on the yeast cells, a number of colloidally dissolved bitter substances and polyphenols can precipitate as surface active compounds on the CO_2 bubbles in the foam head (Kunze, 2004). As a consequence of their low solubility at a pH below 5 and temperatures lower than 10°C, the α-acids are not isomerized during the boiling of the wort precipitate. For this reason, in the study carried out by Navarro *et al.* (2007a), the values of bitterness are below detection limits in all cases. Regarding the total polyphenol and flavonoid contents found after fermentation, significant differences have been observed between the samples containing residues of triazole fungicides and the others, especially in the case of propiconazole due to the stuck fermentation after 4 days of beginning.

In other cases such as carbaryl residues during brewing its metabolization to 1-naphtol confers, above 20 μg/l, a characteristic harsh astringent flavor to the beer (Jones *et al.*, 1988).

Bearing in mind the aforementioned laser, if the pitching wort contains SBIs, especially triazole compounds, it is important to use fining agents such as activated charcoal, bentonite, or polyvinylpolypyrrolidon (PVPP) to eliminate or at least reduce their concentration in the wort since they can alter the quality of the beer. Some results obtained by Pérez *et al.* (2006) confirm that the use of activated charcoal reduce considerably the level of these compounds in the wort. Specifically, more than 80% and 70% of myclobutanil and propiconazole residues, respectively, can be removed.

Toxicological Risk of Pesticide Residues on Beer

In some cases, pesticide metabolites produced during the brewing phases have the same or more toxicity than their parent compounds and they can persist during fermentation. Agrochemical metabolites are generally water-soluble because most of them have hydroxyl or amine groups.

This is the case of triadimenol and TF-6-1, metabolites of triadimefon and triflumizole, respectively. Both have been found in beer (Miyake and Tajima, 2003). Similar behavior has been observed for triazine compounds such as atrazine and terbuthylazine. Hydroxy analogs (OHA and OHT) were mainly detected in top-fermented beers. Monitoring of these herbicides, mainly in the brewing water, is essential because like atrazine these polar degradation products are classified as possible human carcinogens (Hack *et al.*, 1997).

The ethylene bisdithiocarbamate (EBDC) or propylene bisdithiocarbamate (PBDC) fungicides are often used to illustrate the formation of toxicologically relevant metabolites during processing procedures. The conversion of EBDCs and PBDCs into ethylenethiourea (ETU) and propylenethiourea (PTU) is particularly favored by high pH and heat (Timme and Waltz-Tylla, 2003) although the formation of ETU by thermal degradation in aqueous medium can be greatly reduced by the addition of copper sulfate by the formation of a stable cupric EBDC complex (Lesage, 1980). A study carried out with hops treated with radiolabeled EBDCs showed that parent fungicides (maneb/propineb) are mainly changed to ETU/PTU. ETU and PTU are EBDC and PBDC degradation products with carcinogenic effects (Nitz *et al.*, 1984). Therefore, studies to characterize the behavior of pesticide residues during brewing are necessary to perform a more realistic dietary risk assessment.

Summary Points

- Introduction
  - Barley pests
  - Use of pesticides on barley
  - Presence of pesticide residues in raw materials
- Analysis of pesticide residues in raw materials and beer
- Food Safety and Policy in the EU
  - HACCP system in the food industry
- Effects of brewing on the pesticide residues
  - Dissipation of pesticide residues during storage of barley, malt, and spent grains
  - Decline of pesticide residues from barley to malt (malting)
  - Removal and transference of pesticide residues from malt to sweet wort (mashing)
  - Evolution of pesticide residues during fermentation
  - Decrease of pesticide residues during maturation phase (lagering), filtration, and beer storage
- Influence of Pesticide Residues on the beer quality
- Toxicological risk of pesticide residues on beer

Ethanol in Beer: Production, Absorption and Metabolism

Rajkumar Rajendram Nutritional Sciences Research Division, School of Life Sciences, King's College London, London, UK

Victor R. Preedy Nutritional Sciences Research Division, School of Life Sciences, King's College London, London, UK

Abstract

Beer is brewed using malted grain (usually barley), water, hops and yeast. The fermentation of malted barley during the brewing process generates ethanol. After caffeine, ethanol is the most commonly used recreational drug worldwide and drinking beer is a very popular way of ingesting ethanol. Although non-alcoholic beers exist, the ethanol content of beer usually varies between 3% and 9% alcohol by volume. However, the concentration of ethanol in some specialist brews can be significantly higher. When beer is consumed, ethanol is absorbed from the gastrointestinal tract and rapidly distributed around the body in the blood before entering tissues. Some ethanol is metabolized to acetaldehyde in the stomach and liver before reaching the systemic circulation (first-pass metabolism). The average rate of oxidation of ethanol to acetaldehyde is approximately 15 mg/dl blood/hour. Acetaldehyde is highly toxic and binds cellular constituents generating harmful acetaldehyde adducts. Acetaldehyde is further oxidized to acetate. The metabolism of acetate and its significance in the effects of ethanol are less well understood.

In one study, consumption of 5 units of alcohol (40 g ethanol) as 1,000 ml of beer with an evening meal resulted in a mean blood ethanol concentration (BEC) of 6.8 mmol/l after 1 h and just below 2 mmol/l after 3 h. However, the relationship between BEC and the effects of ethanol is complex and varies between individuals and also with drinking habits. Many effects correlate with the peak BEC or peak ethanol concentrations within organs during a drinking session. Other effects are due to products of metabolism and the total dose of ethanol ingested over a period of time. The effects of gender, the ethanol content of the beverage consumed and the coincident consumption of food on the absorption, distribution and metabolism of ethanol are reviewed.

List of Abbreviations

ABV	Percentage content of alcohol by volume
ABW	Percentage content of alcohol by weight
ADH	Alcohol dehydrogenase
ALDH	Aldehyde dehydrogenase
AUC	Area under the blood ethanol concentration curve
AUC_{ip}	Area under the blood ethanol concentration curve after intraperitoneal administration of ethanol
AUC_{iv}	Area under the blood ethanol concentration curve after intravenous administration of ethanol
AUC_{oral}	Area under the blood ethanol concentration curve after oral administration of ethanol
BEC	Blood ethanol concentration
CYP2E1	Cytochrome P4502E1
C_2H_5	Carbonyl group of ethanol
FPM	First-pass metabolism
GABA	Gamma aminobutyric acid
GI	Gastrointestinal
GIT	Gastrointestinal tract
GSH	Glutathione
H_2O_2	Hydrogen peroxide
i.v.	Intravenous
Km	Half-maximal activity
MEOS	Microsomal ethanol oxidizing system
mRNA	Messenger ribonucleic acid
NAD^+	Nicotinamide adenine dinucleotide to NADH
NADH	Reduced form of nicotinamide adenine dinucleotide
NDMA	*N*-methy-d-aspartate
OH	Hydroxyl group
SD	Standard deviation

Introduction

Beer is a fermented alcoholic beverage which is brewed using malted grain (usually barley), water, hops and yeast. Ethanol is one of the most commonly used recreational

Table 41.1 The unit system of ethanol content of alcoholic beverages

Beverage containing ethanol	Units of ethanol
Half-pint of beer (284 ml)	1
Pint of beer (568 ml)	2
One glass of wine (125 ml)	1
Bottle of wine (750 ml)	6
One measure of spirits (e.g. whisky)	1
Bottle of spirits (e.g. whisky; 750 ml)	36

Note: The above table outlines the average amount of ethanol in units in some alcoholic beverages. The unit system is a convenient way of quantifying consumption of ethanol and is a helpful means to give practical advice. However, there are several confounding factors. The ethanol content of various brands of alcoholic beverage varies considerably (Table 41.4) and the alcohol consumed in homes bear little resemblance to standard measures.

Table 41.2 The geographical variation in the amount of ethanol in one unit

Country	One unit of alcohol (g)	ml ethanol
UK	8	10
Australia	10	12.7
Canada	13.5	17.1
USA	14	17.7
Japan	19.75	25

drugs worldwide and drinking beer is one of the most popular ways of ingesting ethanol. Beer has been brewed for thousands of years and gained popularity in Europe during the Middle Ages when clean water was often difficult to find. Where sanitation was poor, beer was often safer to drink than water because of its ethanol content.

In the United Kingdom, a standard alcoholic drink or unit of alcohol (Table 41.1) contains 8 g of ethanol. The UK Department of Health (1995) and Royal College of Physicians, Psychiatrists and General Practitioners (1995) have recommended sensible limits for ethanol intake based on units of alcohol. However, the amount of ethanol in one unit varies around the world (Table 41.2) which causes confusion and prevents international comparisons. Unless otherwise specified all references to units of alcohol in this chapter are based on the UK definitions of standard alcoholic drinks (Table 41.3).

Despite these guidelines, ethanol intake varies significantly between individual drinkers. Many drinkers enjoy the pleasant psycho-pharmacological effects of the ethanol in beer. However, some experience adverse reactions due to genetic variation of enzymes that metabolize ethanol and the consumption of excessive amounts of ethanol undoubtedly affects every organ in the body.

Many of the effects of the ethanol intake correlate with the concentration of ethanol in the blood (blood ethanol

Table 41.3 Guidelines for the consumption of alcohol

	Women (units)		Men (units)	
	Weekly[a]	Daily[b]	Weekly[a]	Daily[b]
Harmful	>35	≥1–2[c]	>50	
Hazardous	15–35	≥3	22–50	≥4
Low risk	0–14	2–3	0–21	3–4

Notes: Guidelines on the consumption of alcohol are designed to reduce harm (Royal College of Physicians, Royal College of Psychiatrists, Royal College of General Practitioners, 1995; Department of Health, 1995). Whilst the Department of Health recommendations are concerned with daily consumption, the Royal Colleges' guidelines are for weekly consumption rates.

[a]Recommendations of the Royal College of Physicians, Royal College of Psychiatrists and Royal College of General Practitioners (UK).
[b]Recommendations of the Department of Health (UK).
[c]When pregnant or about to become pregnant consumption of more than 1–2 units of alcohol, 1–2 times per week is harmful.

concentration (BEC)). It is therefore important to understand those factors that influence the BEC achieved from a dose of ethanol (i.e. drinking beer). However, the concentration of ethanol in each type of beer and therefore the dose of ethanol from a pint varies significantly between brews.

In most countries the concentration of ethanol in beer is expressed as a percentage of alcohol by volume (ABV). However, in the United States the legal standard requires the concentration of ethanol in beer to be expressed as a percentage of alcohol by weight (ABW). To approximate ABW from ABV, one needs to multiply ABV by 0.8. To determine ABV, ABW should be multiplied by 1.25. Thus, a beer which is 5% ABV is approximately 4% ABW. To avoid confusion all further references to strength of alcoholic beverages in this chapter will be in terms of ABV.

The strength of beer as ABV typically ranges from 3% to 8%, although some specialist beers can have higher concentrations (Table 41.4). Although low- and non-alcoholic beers are available, the interest in these is minimal. The factors which affect the ethanol content of a beer are described below.

Brewing Beer

The principles of brewing beer have been described by Goldammer (2000) and elsewhere in this book and are only briefly outlined here. All beers are brewed using a process that requires grain, usually barley, which has been malted (allowed to germinate). Germination generates enzymes such as amylase, which are used to convert the starch in the grain into sugars such as maltose (Goldammer, 2000).

The malt is dried in a kiln before being crushed and mixed with hot water in a vat called a "mash tun" where it is "mashed." During mashing, the enzymes within the

Table 41.4   Ethanol content of selected beers

Brewery	Beer	ABV (%)
Anheuser-Busch	Budweiser Bud Light	4.2

malt break down the starches of the grain into the sugars required for fermentation (Goldammer, 2000). Mashing usually takes 1–2 h, and time spent at different temperatures (mash rests) activates various enzymes depending on the type of malt and the yeast being used (Goldammer, 2000). These enzymes convert starches to shorter chain carbohydrates such as dextrins and maltotriose. These can be further broken down to sugars such as maltose and glucose which are fermentable.

A mash rest at 40°C activates beta-glucanase, which breaks down beta-glucans, which facilitates the production of sugars later in the process (Goldammer, 2000). A mash rest temperature between 65°C and 71°C is used to convert the starches to fermentable sugars (Goldammer, 2000). A mash rest with a temperature at the lower end of the range results in the production of more low-order sugars. These are easier to ferment and this results in beer with higher ethanol content. Higher temperatures result in the production of higher-order sugars which are more difficult to ferment. This results in a sweet tasting beer with less ethanol. The mash temperature may then be raised to deactivate the enzymes (mashout; Goldammer, 2000). Additional water may then be sprinkled on the grain to extract additional sugars (sparging; Goldammer, 2000).

After mashing, the produced liquid is strained from the grains. The liquid (wort) is moved into a large tank where it is boiled with hops and sometimes other ingredients such as herbs or sugars (Goldammer, 2000). This deactivates enzymes, precipitates proteins and concentrates and sterilizes the wort. The hopped wort is then settled and clarified before being cooled.

The wort is moved into fermentation vessels where yeast is added (Goldammer, 2000). Initially, the concentration of

Polar hydroxyl group

sugars is high and sugars such as glucose enter the yeast by simple net diffusion, facilitated (carrier-mediated) diffusion or active transport (Pretorius, 2000). Each glucose molecule is broken down by glycolysis into two pyruvate molecules (three carbon sugars; Pretorius, 2000). The pyruvate molecules are then converted into carbon dioxide and ethanol by the yeast (Pretorius, 2000).

After 1–3 weeks, the fresh beer is run off into conditioning tanks (Goldammer, 2000). Conditioning may take several months, after which the beer may be filtered to remove yeast and any other particles. The beer is then ready for serving or packaging (Goldammer, 2000).

Types of yeast used to brew beer

Many different species of yeast are used to make beer, but there are two main types: ale yeasts and lager yeasts (Goldammer, 2000). Ale yeasts rise near to the surface of the beer during fermentation (top fermenting e.g. *Saccharomyces cerevisiae*), and typically prefer temperatures ranging from 10°C to 25°C (Goldammer, 2000). Lager yeasts sink to the bottom of the beer (bottom fermenting e.g. *Saccharomyces uvarum*) and ferment more slowly, preferring colder temperatures, around 7–15°C (Goldammer, 2000).

There are no significant differences between ale and lager yeasts with respect to ethanol tolerance. Ales are generally around 4–5% ethanol while lagers generally contain 4.5–5.2% ethanol. Beer yeast generally cannot tolerate an environment with greater than about 10–11% ethanol (Wyeast Laboratories, 2006) and as the ethanol concentration in the environment rises the efficiency of fermentation declines. However, some specialist brews have higher concentrations of ethanol and are brewed with specific types of yeast which are able to tolerate these levels of ethanol.

The Physical Properties of Ethanol

Ethanol (Figure 41.1) is highly soluble in water due to its polar hydroxyl (OH) group. The non-polar (C_2H_5) group enables ethanol to dissolve lipids and thereby disrupt

Table 41.5 Approximate ethanol concentrations in the GI tract and in the blood following oral ethanol administration (0.8 g/kg)

Site	Ethanol concentration (g/dl)
Stomach	7–8
Proximal jejunum	1–5
Ileum	0.1–0.2
Blood (15–120 min after dosage)	0.1–0.2

Note: Ethanol appears in the blood as quickly as 5 min after ingestion and is rapidly distributed around the body. A dose of 0.8 g ethanol/kg body weight (56 g ethanol (7 units) consumed by a 70 kg male) should result in a blood ethanol concentration of 100–200 mg/dl between 15 and 120 min after dosage. Highest concentrations occur after 30–90 min.

biological membranes. Ethanol crosses cell membranes easily by passive diffusion as it is a relatively uncharged molecule.

Absorption and Distribution of Ethanol in Beer

The basic principles of ethanol absorption from the gastrointestinal (GI) tract, and subsequent distribution are well understood. Alcoholic beverages such as beer pass down the esophagus, into the stomach. Ethanol continues down the GI tract until absorbed (Halsted, 1973; Rajendram *et al.*, 2005). The ethanol concentration therefore decreases down the GI tract. There is also a concentration gradient of ethanol from the lumen to the blood. The concentration of ethanol in plasma is much lower than that in the lumen of the upper small intestine (Table 41.5; Halsted, 1973; Rajendram *et al.*, 2005). Ethanol diffuses passively across the cell membranes of the mucosal surface into the submucosal space and then the submucosal capillaries (Kalant, 2004).

Although absorption is fastest in the duodenum and jejunum, uptake of ethanol occurs across all of the GI mucosa. The rate of gastric emptying is the main determinant of absorption as most ethanol is absorbed after leaving the stomach through the pylorus (Kalant, 2004).

However, concentrations of ethanol within the ileal lumen are not significantly different from BEC (Bode and Bode, 2003). This suggests that ethanol enters the ileum and colon from the blood and any luminal sequelae of ethanol ingestion occur mainly in the upper small intestine.

Ethanol diffuses into tissues from the blood stream through the walls of capillaries. Ethanol concentration equilibrates between blood and the extracellular fluid within a single pass. The time taken for equilibration between blood water and total tissue water can vary from minutes up to an hour or more, depending on the cross-sectional area of the capillary bed and tissue blood flow (Kalant, 2004). Ethanol enters most tissues but its solubility in bone and fat
is negligible. Therefore, in the post-absorption phase, the volume of distribution of ethanol reflects total body water. Total body water is highly correlated with fat-free mass and lean body mass. Thus, for a given dose of ethanol, BEC will reflect lean body mass.

Metabolism of Ethanol

The average rate of oxidation of ethanol is approximately 15 mg/dl blood/hour (Fisher *et al.*, 1987). However, many factors influence this rate and there is considerable individual variation.

Absorbed ethanol is initially oxidized to acetaldehyde (Figure 41.2) by one of the three pathways (Figure 41.3):

1. Alcohol dehydrogenase (ADH) – cystosol.
2. Microsomal ethanol oxidizing system (MEOS) – endoplasmic reticulum.
3. Catalase – peroxisomes.

Alcohol dehydrogenase

ADH couples oxidation of ethanol to reduction of nicotinamide adenine dinucleotide (NAD^+) to NADH. ADH also has a wide range of other substrates and functions, including dehydrogenation of steroids and oxidation of fatty acids (Kalant, 2004).

ADH isoenzymes

ADH is a zinc metalloprotein with five classes of isoenzymes that arise from the association of eight different subunits into dimers (Table 41.6; Kwo and Crabb, 2002). A genetic model accounts for these five classes of ADH as products of five gene loci (ADH1-5; Bosron *et al.*, 1993). Km is the concentration of substrate that results in half-maximal velocity. Class 1 isoenzymes generally require a low concentration of ethanol to achieve "half-maximal activity" (low Km) whilst Class 2 isoenzymes have a relatively high Km. Class 3 ADH has a low affinity for ethanol and does not participate in the oxidation of ethanol in the liver (Lieber, 2005). Class 4 ADH
Figure 41.3 Pathways of ethanol metabolism. This figure illustrates the metabolism of ethanol to acetaldehyde and then to acetate. *Source*: Adapted from Rajendram *et al*. (2005) with permission from Elsevier.

Table 41.6 Alcohol dehydrogenase (ADH) isoenzymes

Class	Subunit	Location	Km (mmol/l)[a]	Vmax
Class 1

is found in the human stomach (Yin *et al.*, 1990; Moreno and Pares, 1991; Stone *et al.*, 1993) and Class 5 has been reported in liver and stomach (Yasunami *et al.*, 1991). Whilst the majority of ethanol metabolism occurs in the liver, gastric ADH is responsible for some of the oxidation of ethanol.

Catalase

Peroxisomal catalase which requires the presence of hydrogen peroxide (H_2O_2) is of little significance in the metabolism of ethanol (Lieber, 2005). Metabolism of ethanol by ADH inhibits catalase activity as H_2O_2 production is inhibited by the reducing equivalents produced by ADH (Lieber, 2005).

Microsomal ethanol oxidizing system

Chronic administration of ethanol with nutritionally adequate diets increases clearance of ethanol from the blood. This phenomenon could not be adequately explained until 1968 when the MEOS was identified and characterized (Lieber and DeCarli, 1968, 1970). The MEOS has a higher Km for ethanol (8–10 mmol/l) than ADH (0.2–2.0 mmol/l) so at low BEC, ADH is more important. However, unlike

Table 41.7 Aldehyde dehydrogenase (ALDH) isoenzymes

Class	Structure	Location	Km (µmol/l)[a]
Class 1			
ALDH1	α4	*Cytosolic*	
		Several tissues: highest in liver	30
Class 2			
ALDH2	α4	*Mitochondrial*	
		Present in all tissues except red blood cells	1
		Liver > kidney > muscle > heart	

Notes: This table describes the properties of the ALDH isoenzymes. *Km* is the concentration of substrate that leads to half-maximal velocity. Although there are several isoenzymes of ALDH the most important are ALDH1 (cytosolic) and ALDH2 (mitochondrial).

[a]*Km* supplied is for acetaldehyde – ALDH also oxidizes other substrates.

Source: Adapted from Kwo and Crabb (2002) with permission from the Taylor & Francis Group.

the other pathways, MEOS is highly inducible by chronic ethanol consumption. The key enzyme of the MEOS is cytochrome P4502E1 (CYP2E1). Chronic ethanol use is associated with a 4–10-fold increase of CYP2E1 due to increases in mRNA levels and rate of translation.

Acetaldehyde metabolism

Acetaldehyde is highly toxic but is rapidly converted to acetate. This conversion is catalyzed by aldehyde dehydrogenase (ALDH) and is accompanied by reduction of NAD^+ (Figure 41.3). There are several isoenzymes of ALDH (Table 41.7; Kwo and Crabb, 2002). The most important are ALDH1 (cytosolic) and ALDH2 (mitochondrial). The presence of ALDH in tissues may reduce the toxic effects of acetaldehyde and thereby ethanol.

In alcoholics the oxidation of ethanol is increased by induction of MEOS. However, the capacity of mitochondria to oxidize acetaldehyde is reduced. In man, hepatic acetaldehyde therefore increases with chronic ethanol consumption (Di Padova *et al.*, 1987). A significant increase of acetaldehyde in hepatic venous blood reflects the high tissue level.

Metabolism of acetate

Acetaldehyde is converted to acetate by ALDH. However, the ultimate fate of acetate is not well understood. Some important principles of acetate metabolism have been elucidated and reviewed by Cornier (2004). Three important points are summarized here:

1. Most of the ethanol absorbed from the GI tract is metabolized in the liver and results in the production

and release of acetate. Acetate can be metabolized in the brain and readily crosses the blood–brain barrier. Cardiac and skeletal muscles are also important in the metabolism of acetate.
2. The conversion of acetate to acetyl-CoA is catalyzed by acetyl-CoA synthetase. This reaction requires adenosine triphosphate and results in the production of adenosine monophosphate. 5'nucleosidase catalyses the production of adenosine from adenosine monophosphate.
3. The acetyl-CoA generated from acetate may be used to generate adenosine triphosphate via the Kreb's cycle. Acetyl-CoA may be converted to glycerol, glycogen and lipid particularly, in the fed state. However, this only accounts for a small fraction of absorbed ethanol. The neurotransmitter acetylcholine is produced from acetyl-CoA in cholinergic neurons.

In view of these findings, future investigations of acetate metabolism should consider the effects on skeletal and cardiac muscle and the brain.

Blood Ethanol Concentration

In one study, consumption of 5 units of alcohol (40 g ethanol) with an evening meal (500 ml of beer 1 h before eating and 500 ml beer during the meal) generated mean BECs of 6.8 mmol/l (31 mg/dl) 1 h after the meal and 1.95 mmol/l (9 mg/dl) 3 h after the meal (Hendriks *et al.*, 1994). However, the relationship between BEC and the effects of ethanol is complex and varies between individuals and also with drinking habits. In another study, a 73 kg Japanese male heavy drinker consumed 16 ml of beer per kg body weight (1,168 ml) over 20 min at noon without food. The effect of this on his BEC over the next 6 h is shown in Figure 41.4. For comparative purposes urinary ethanol concentration is also shown in Figure 41.4. However, as with BEC, a number of variables affect the urinary-blood partition (Kroke and Dierkes, 2005).

Many effects correlate with the peak BEC or peak ethanol concentrations within organs during a drinking session. Other effects are due to products of metabolism and the total dose of ethanol ingested over a period of time. These factors are linked as the ethanol concentration during a drinking session may determine which pathways of ethanol metabolism predominate.

The factors which increase the probability of higher maximum ethanol concentrations for any given level of consumption are therefore clinically relevant.

Factors affecting BEC

Gender Differences in BEC   When given the same dose of ethanol per kilogram of body weight women achieve higher peak BEC than men (Marshall *et al.*, 1983; Smith *et al.*, 1993). The volume of distribution of ethanol reflects total body water (Marshall *et al.*, 1983). It is therefore not
Figure 41.4 Blood and urinary ethanol concentrations after drinking beer. A 73 kg Japanese male consumed 16 ml of beer per kg body weight (1,168 ml) over 20 min at noon without food. The ethanol content of the beer was not provided. (a) Blood and (b) urine were collected at 30 min, 1, 2, 4 and 6 h after beer consumption. It is important to note that the shape of the BEC curve will depend on several factors, including the amount of ethanol consumed, co-ingestion of food and its type, gender, ethnic origins (e.g. if an ALDH2 polymorphism was present) and previous drinking history. See main text for other variables. The data for this figure was derived from a Japanese man classified as a heavy drinker but was a non-flusher (i.e. he had a functional ALDH2*1 genotype rather than a non-functional ALDH2*2 genotype). For comparative purposes urinary ethanol is displayed (b). In general, the ratio of urine to BEC is reported to be about 1:3 but in this study it is about 1:1. However, as with BEC levels, several variables affect the urinary-blood partition (Kroke and Dierkes, 2005). *Source*: Adapted from Tsukamoto *et al.* (1989) with permission from Oxford University Press and the Medical Council on Alcoholism.

surprising that the BEC is higher in women given that the bodies of women contain a greater proportion of fat. Furthermore, when ethanol dosing is based on total body water (TBW) rather than body weight, these sex differences in BEC disappear (Goist Jr. and Sutker, 1985; Savoie *et al.*, 1988). However, gender differences in the gastric metabolism of ethanol may also be relevant.

Effects of Food on BEC In a two-part crossover study, 10 healthy men drank ethanol (0.80 g/kg; 56 g or 7 units for a 70 kg man) either after an overnight fast or immediately after standardized breakfast (Jones and Jönsson, 1994). The BEC was determined from venous samples taken at various times after drinking. The peak BEC was 67 mg/dl (standard deviation, SD 9.5; 14.4 mmol/l SD 2) after ethanol and breakfast compared with 104 mg/dl (SD 14.5; 23.7 mmol/l SD 3.1) when drinking occurred after an overnight fast ($p < 0.001$). The mean area under the BEC vs. time curve (AUC; 0–6 h) was 398 mg/dl × h (SD 56) in fasting subjects compared with 241 mg/dl × h (SD 34) when ethanol was ingested after breakfast ($p < 0.001$). The time required to metabolize the ethanol was approximately 2 h less if breakfast was eaten before drinking (Jones and Jönsson, 1994).

This study demonstrates that when ethanol is consumed with or after food the peak BEC is reduced. Food delays gastric emptying into the duodenum and reduces the sharp early rise in BEC seen when ethanol is taken on an empty stomach. However, food also increases elimination of ethanol from the blood. The area under the BEC vs. time curve (AUC) is reduced (Figure 41.4). This was confirmed in a separate experiment when a meal was eaten 5 h after drinking, that is, in the post-absorptive phase of ethanol metabolism. The mean rate of clearance of ethanol from blood was increased by up to 50% after eating (Jones, 1993).

The contributions of various nutrients to these effects have been studied, but small often conflicting differences have been found. It appears that the caloric value of the meal is more important than the precise balance of nutrients (Carbonnel *et al.*, 1994). However, food increases splanchnic blood flow which maintains the ethanol diffusion gradient in the small intestine (Kalant, 2004). Food-induced impairment of gastric emptying may be partially offset by faster absorption of ethanol in the duodenum (Kalant, 2004).

In animal studies ethanol is often administered with other nutrients in liquid diets. The AUC is less when ethanol is given in a liquid diet, than with the same dose of ethanol in water (de Fiebre *et al.*, 1994). The different blood ethanol profile in these models could affect the expression of pathology in these models (Kalant, 2004).

First-Pass Metabolism of Ethanol The AUC after oral dosing of ethanol (i.e. AUC_{oral}) is significantly lower than after intravenous administration (i.e. AUC_{iv}) or intraperitoneal administration (i.e. AUC_{ip}). The total dose of intravenously administered ethanol is available to the systemic circulation. The difference between AUC_{oral} and AUC_{iv} represents the fraction of the oral dose that was either not absorbed or metabolized before entering the systemic circulation, that is first-pass metabolism (FPM). The ratio of AUC_{oral} to AUC_{iv} reflects the oral bioavailability of ethanol.

The investigation of ethanol metabolism has primarily focused on the liver and its relationship to liver pathology. The role of the stomach in ethanol metabolism has been controversial. However, the presence of multiple ADH isoenzymes in human gastric mucosa suggests that the stomach metabolizes ethanol and contributes to FPM (Yin *et al.*, 1990; Moreno and Pares, 1991; Yasunami *et al.*, 1991; Lieber, 2005).

Approximately 90% of the rate of all ethanol elimination is performed by the liver (Utne and Winkler, 1980). However, several factors including ethnicity (Dohmen *et al.*, 1996), gender (Frezza *et al.*, 1990) and alcoholism (Di Padova *et al.*, 1987) alter FPM, despite an opposite effect on the total hepatic metabolism of ethanol. The observations that their effects on FPM correlate with those on gastric ADH activity (Di Padova *et al.*, 1987; Frezza *et al.*, 1990; Dohmen *et al.*, 1996) is further evidence for the contribution of the stomach to ethanol metabolism.

When gastric ADH activity is measured with BEC below 100 mM, it is negligible compared to liver ADH activity. The gastric cells, however, are close to the lumen of the stomach and thus exposed not only to the BEC, but also to gastric juices, in which the ethanol concentration is much higher (Lieber, 2005). Increasing the ethanol concentration used to test for ADH activity results in reduction of hepatic ADH activity as a result of saturation and substrate inhibition of Classes 1 and 2 ADH (Lieber, 2005). However in the stomach, activity progressively increases (Lieber, 2005).

Vmax is the maximum enzyme velocity in units of concentration of product per unit of time. σ-ADH has a high activity, with a Vmax considerably higher than that of the other enzymes, and a Km around 40 mM (Kwo and Crabb, 2002). Thus, although, hepatic oxidation of ethanol cannot increase once ADH is saturated, gastric ADH can significantly metabolize ethanol at the high concentrations in the stomach after

initial ingestion. Thus, the function of gastric ADH could be to protect the body from excessive consumption of ethanol. If gastric emptying of ethanol is delayed, prolonged contact with gastric ADH increases FPM. Conversely, increasing the speed of gastric emptying by fasting virtually eliminates gastric FPM (Di Padova *et al.*, 1987).

Contribution of FPM to Overall Ethanol Metabolism
FPM increases with decreasing amounts of alcohol, for example, a dose of 0.15 g ethanol/kg b.w. results in greater FPM than 0.3 or 0.8 g ethanol/kg b.w. When ethanol is given at a high dose, the presystemic contribution to its metabolism is relatively small, as hepatic metabolism dominates. In contrast, when small doses of alcohol are administered, the relative contribution of FPM to overall ethanol metabolism is greater (Gentry *et al.*, 1994; Crabb, 1997).

Beverage Ethanol Content and BEC   The ethanol concentration of the beverage consumed (Table 41.7) affects ethanol absorption and can affect BEC. Absorption is fastest when the concentration is 10–30%. However, the ethanol concentration of most beers is below 6%. After drinking beer, diffusion of ethanol is slow because ethanol concentration in the GI tract is low and the large volume of liquid slows gastric emptying.

The concentration of ethanol in the GI tract also affects FPM. Gastric ADH requires a high ethanol concentration for optimal activity. The ethanol concentration in the beverage consumed affects oxidation of ethanol to acetaldehyde (Roine *et al.*, 1991). After ingestion of equivalent amounts of ethanol less FPM and higher blood levels occur after consumption of beer than whiskey (Roine *et al.*, 1993).

Quantification of Ethanol Absorption and FPM   Many groups have attempted to develop models of ethanol pharmacokinetics to define and quantify the absorption and
Figure 41.5   Predicted BEC profiles after ingestion of beer. The effect of food on BEC after oral dosing of ethanol as beer. (a) Coincident with a standard meal. (b) Without food. The peak BEC and the area under the curve are reduced if ethanol is consumed with food. *Source*: Adapted from Levitt (2002) with permission.

FPM of ethanol (e.g. see Levitt, 2002). However it has been difficult to produce accurate models, perhaps because there are several pathways of ethanol metabolism. Levitt (2002) applied a physiologically based pharmacokinetic computer program to human ethanol data and suggested that the predominant factors which affect ethanol absorption and FPM are the rate of gastric emptying and the dose of ethanol. When ethanol is ingested with food absorption is slow and for a dose of 0.15 g/kg (12 g for an 80 kg man) the predicted fractional FPM was 36%, but only 7% for a dose of 0.3 g/kg (24 g for an 80 kg man; Levitt, 2002). For comparison, in fasting subjects the absorption of oral ethanol is rapid and the predicted FPM was small. Levitt (2002) used this computer program to predict BEC profiles after consumption of one and three cans of beer over 20 min either with or without food. These BEC profiles are illustrated in Figure 41.5.

Summary

Ethanol in the form of beer is one of the most commonly used recreational drugs worldwide. When beer is consumed, ethanol is absorbed from the GI tract by diffusion and is rapidly distributed around the body in the blood before entering tissues by diffusion. Ethanol is metabolized to acetaldehyde mainly in the stomach and liver. Acetaldehyde is highly toxic and binds cellular constituents generating harmful acetaldehyde adducts. Acetaldehyde is further oxidized to acetate. The fate of acetate and its role in the effects of ethanol are much less well understood. Ethanol and the products of its metabolism affect nearly every cellular structure or function and is a significant cause of morbidity and mortality.

Summary Points

- The ethanol in beer is derived from the fermentation of malted grain by yeasts.
- The ethanol content of beer as ABV typically ranges from 3% to 8%.
- After ingestion of beer, ethanol travels along the GI tract until absorbed by diffusion.
- Absorbed ethanol is initially oxidized to acetaldehyde (FPM) by one of the three pathways: ADH, MEOS or catalase. Acetaldehyde is oxidized further to acetate.
- After consumption of beer, factors which affect the absorption, distribution and FPM of ethanol determine BEC. These factors include gender, beverage ethanol content, time over which ethanol is consumed and food.

What Contribution Is Beer to the Intake of Antioxidants in the Diet?

Fulgencio Saura-Calixto, José Serrano and Jara Pérez-Jiménez Department of Metabolism and Nutrition, CSIC, Ciudad Universitaria, Madrid, Spain

Abstract

Beer is a low-alcohol beverage brewed from natural ingredients and may contain appreciable amounts of bioactive compounds, mainly antioxidants, which are associated with health effects. Polyphenols and melanoidins are the major natural antioxidants in beer. Polyphenol and melanoidin contents are largely influenced by genetic and agricultural factors in the raw material and by technological factors in the brewing. Common beer polyphenols include flavonols, phenolic acids, catechins, procyanidins, tannins and chalcones. Beer also contains Maillard reaction products, largely formed during the malting and brewing process. Various assays have shown that beer has greater antioxidant capacity than white wine, but less than red wine. Nevertheless, in several countries the consumption of beer contributes significantly to the total intake of polyphenols and to the antioxidant capacity of the diet. Beer in Spain (150 ml/person/day) provides 7.2% of the daily dietary intake of polyphenols and accounts for around 3% of the total antioxidant capacity of the diet. Further research is needed to elucidate the potential role of beer in the prevention of chronic diseases associated with the intake of antioxidants.

List of Abbreviations

ABTS   2,2′-Azino-bis(3-ethylbenz-thiazoline-6-sulfonic acid)
DPPH   2,2-Diphenyl-1-picrylhydrazyl
FRAP   Ferric reducing/antioxidant power
HDLs   High density lipoproteins
ORAC   Oxygen radical absorbance capacity
ROS   Reactive oxygen species
TEAC   Trolox equivalent antioxidant capacity
TRAP   Total radical-trapping antioxidant parameter

Introduction

Epidemiological evidence from many studies overwhelmingly supports the hypothesis that moderate alcohol consumption is significantly associated with a reduction in cardiovascular disease incidence (Rimm *et al.*, 1991). In this context, alcoholic beverages that were identified as especially beneficial were red wine and beer. At the outset it was suggested that alcohol could be the main component responsible for the observed beneficial effects, since ethanol is able to increase the level of high density lipoproteins (HDL), decrease platelet aggregation and enhance blood fibrinolysis (Rotondo *et al.*, 2001). However, it was later suggested that the protective effects of red wine and beer may be the result of non-alcoholic components such as phenolics and antioxidants (Ghiselli *et al.*, 2000; Vinson *et al.*, 2001).

Nowadays, there is ample reason to believe that antioxidants provide protection from chronic diseases. In the last two decades, numerous biochemical and clinical studies have provided consistent evidence of the healthy properties of foods and beverages rich in antioxidants, such as olive oil, red wine, fish, citrus fruits and legumes (Halliwell, 1997). Dietary antioxidants are able to neutralize free radicals created during the aging process, thus preventing the onset of chronic diseases.

Free radicals may originate endogenously, basically from the respiratory chain, where the reduction of oxygen molecule gives rise to different radical species. They may also be of exogenous origin, from exposure to certain radiations (sunlight, ozone, electromagnetic radiations), some food additives, certain tobacco components, etc. Oxidative stress is involved in the pathology of many diseases, such as atherosclerosis, diabetes, neurodegenerative diseases, aging and cancer. The prevalent situation of an organism will be of health or of disease depending on the equilibrium between oxidants and antioxidants. Antioxidants are a group of compounds of varying chemical nature that can prevent oxidation. They can be natural or synthetic. Plant foods and beverages possess a large number of antioxidant compounds, and in recent years there has been considerable research into natural antioxidants prompted by consumer interest in natural rather than synthetic products.

Recent renewed interest has focused on beer, a common beverage rich in antioxidant compounds with moderate antioxidant activity coupled with low ethanol content. The compounds chiefly responsible for this antioxidant capacity are

polyphenols and Maillard compounds. It is therefore important to determine the antioxidant contents of natural products such as beer, their activity *in vitro* and *in vivo*, and the contribution of a given food item to the total antioxidant capacity of a diet. This chapter deals with the antioxidant capacity of beer, focusing mainly on the contribution of beer to the total antioxidant intake of a whole diet.

Beer Antioxidants: Contents and Antioxidant Power

Beer antioxidants mainly come from the two natural ingredients used in brewing: barley and hops. The antioxidant power of beer therefore presumably depends on the antioxidant contents in these two ingredients and on a number of parameters involved in brewing, namely the variety of barley and the malting process, temperature and pH during mashing, sparing, boiling, the variety of hops added during wort boiling and yeast fermentation.

The main antioxidant compounds in beer are phenolic compounds and Maillard compounds. In addition, some antioxidant additives used in beer (i.e. vitamin C) may also contribute to its antioxidant capacity.

Polyphenols

Polyphenols are a broad group of substances present in plant foods, with more than 8,000 compounds currently known. They are products of secondary metabolism of plants which may be classified, depending on their chemical structure into different groups, such as flavonoids, stilbenes, hydroxybenzoic acids, hydroxycinnamic acids, proanthocyanidins and hydrolysable tannins.

Most of the polyphenols present in beer come from barley. However, it should be noted that hops, although added in a proportion 100 times lower than malt, provide about 30% of the total polyphenols present in beer (Callemien *et al.*, 2005). The polyphenol content may range from 3% to 6% depending on the variety, geographic origin and freshness of the hops, the harvesting procedure and the manner in which hop cone is packaged.

Barley phenolics include phenolic acids derived from tyrosine and tyramine, their esters and glycosides, anthocyanins, proanthocyanidins, lignans and lignin-related substances (Salomonsson *et al.*, 1980; Yu *et al.*, 2001). Phenolics are mainly located in the outer layers (husk, pericarp, aleurone) of the grain (Nordkvist *et al.*, 1984; Hernanz *et al.*, 2001). Ferulic acid is the predominant free phenolic acid in barley seeds (Nordkvist *et al.*, 1984) and barley grains (Madhujith *et al.*, 2006). The proanthocyanidins from barley are implicated in the formation of haze in beer (Siebert *et al.*, 1996). These compounds are located in the testa of the grain and are a mixture of oligomeric prodelphinidins and procyanidins (McMurrough *et al.*, 1996).

Besides the polyphenols present in the different raw materials, it is important to note that the final phenolic compound content of beer may also be influenced by the processing. For example, mashing increases the concentrations of hydroxycinnamic acid derivatives as they are released from previously non-extractable combinations. Also, the extraction of phenolics from malt into the wort is highly dependent on malt to water ratios. And again, polymerization of phenolics and formation of polyphenols can occur during wort boiling, and possibly also during fermentation and storage of beer (Shahidi and Naczk, 2004).

There are many references in the literature to determine the total polyphenols content of beer. The results of some of these are summarized in Table 42.1. Dark beer contains more polyphenols, whereas the polyphenols content of lager beer – the most widely consumed type – is intermediate. And finally, low-alcohol beers contain much less polyphenols than the others.

Some authors have characterized beer polyphenols, identifying 78 different phenolics compounds in beer (Table 42.2), including simple phenolics, aromatic carboxylic and phenol carboxylic acids, hydroxycoumarins, catechins, leucoanthocyanidins, anthocyanidins, flavonols, flavonones, flavones, prenylated flavonoids and phenolic glycosides (Shahidi and Naczk, 2004; Gerhäuser, 2005).

Figure 42.1 shows the percentage of the different groups of polyphenols in lager beer. Proanthocyandins are the group with the highest presence (81%), followed by phenolics acids and flavonoids.

Proanthocyanidins are a particular kind of polyphenols which despite low bioavailability in the gastrointestinal tract can be fermented by the colonic microflora, producing an antioxidant status in the colon.

The most abundant phenolic acids in beer are gallic acid, ferulic acid and syringic acid. Some of these are present in beer mainly in free form, while others are mainly present in conjugated forms (Nardini *et al.*, 2004).

Beer also contains phenolic compounds of the flavonoid group such as catechin, epicatechin and quercetin, which come from the outer layers of malt and from hops. Total flavonoid content has been estimated at between 13.4 and 52.6 for lager beer (Gasowski *et al.*, 2004).

A number of *in vitro* studies have shown that polyphenols possess considerable antioxidant capacity, even more than other well-known natural antioxidants such as vitamin C or vitamin E (Sánchez-Moreno *et al.*, 1998). For example, when antioxidant capacity was measured by the 2,2-diphenyl-1-picrylhydrazyl (DPPH) assay, the EC_{50} (grams of compound needed to neutralize 1 g of the stable free radical DPPH) of these two vitamins was 76 ± 7 and 201 ± 11, respectively, while the EC_{50} of gallic acid, one of the main phenolic acids present in beer, was 26 ± 1; in other words, it was a more potent antioxidant compound. The antioxidant capacity of ferulic acid, another phenolic acid present in beer, was less than that of gallic acid

Table 42.1 Total polyphenols content of beer

Kind of beer	Polyphenols content (mg/100 ml)
Lager beer	31.2–37
Dark beer	47.3–57.2
Alcohol-free beer	18.9–21.8

Source: Gorinstein *et al.* (2000), Saura-Calixto *et al.* (2002), Lugasi and Hóvári (2003), Pulido *et al.* (2003) and Gasowski *et al.* (2004).

Figure 42.1 Distribution of phenolic acids, flavonoids and proanthocyanidins in lager beer.

Table 42.2 Summary of beer polyphenols

Simple phenols	Benzoic acid derivatives	Cinnamic acids
• 4-Vinyl phenol	• 4-Hydroxybenzoic acid	• Cinnamic acid
• 4-Vinyl guaiacol	• Protocatechuic acid	• *p*-Coumaric acid
• 4-Ethyl phenol	• Vanillic acid	• Caffeic acid
• Isoeugenol	• Gallic acid	• Ferulic acid
• Tyrosol	• Syringic acid	• Sinapic acid
• 4-Propyl syringol	• Salicylaldehyde	
• 2,3-Dihydroxy-guiacylpropane-1-one	• *o*-Vanillin	
	• Syringic aldehyde	

Coumarins	Flavan-3-ols	Proanthocyanidins
• Umbelliferon	• (+)-Catechin	• Procyanidin B1
• Scopoletin	• (−)-Epicatechin	• Procyanidin B2
• Daphnetin	• Gallocatechin	• Procyanidin B3
	• Catechin gallate	• Procyanidin B4
	• Epicatechin gallate	• Procyanidin C2
	• 3′-*O*-methylcatechin	• Prodelphinidin B3
	• Catechin-7-*O*-β-(6″-*O*-nicotinoyl)-β-ᴅ-glucopyranosid	• Prodelphinidin B9
		• Prodelphinidin C
		• *ent*-Epigallo-catechin-(4α→8, 2α→*O*→7)catechin
		• *ent*-Epigallo-catechin-(4α→6, 2α→*O*→7)catechin
		• 2,3-*cis*-3,4-*trans*-2-[2,3-*trans*-3,3′,4′,5,7-Pentahydroxyflavan-8-yl]-4-(3,4-dihydroxyphenyl)-3,5,7-trihydroxybenzopyran

Chalcones	Flavanones	Flavones
• Xanthohumol	• Isoxanthohumol	• Apigenin
• Desmethylxanthohumol	• Naringerin	• Chrysoeriol
	• 8-Prenylnaringenin	• Tricin
	• 6-Prenylnaringenin	• Saponaretin
	• 6-Geranylnaringenin	• Saponarin
	• 5-Methyl-6″-dimethyl-4″,5″-dihydropyrano[2″,3″,7,8]naringenin	• Vitexin
	• Taxifolin	

Flavanoles	Alpha-acids	Others
• Kaempferol	• Cohumulone	• Indole-3-carboxylic acid
• Kaempferol-3-rhamnosid	• *n*-Humulone	• Indole-3-ethanol
• Quercetin	• Adhumulone	• 1-Methyl-1,3,4,9-tetrahydropyrano[3,4]indol
• Quercitrin	• *iso*-Cohumulone	• 4-Ketopinoresinol
• Isoquercitrin	• *iso-n*-Humulone	• Syringaresinol
• Rutin	• *iso*-Adhumulone	• 3-Acetoxy-propan-1,2-diol
• Myricetin		
• Myricitrin		

as measured by the 2,2′-azino-bis(3-ethylbenz-thiazoline-6-sulfonic acid) (ABTS) and DPPH methods, but higher as measured by oxygen radical absorbance capacity (ORAC) assay (Villaño *et al.*, 2005). This shows that the same polyphenol may react in a different way with different radicals, and hence the antioxidant capacity of beer will be determined by the activity of all these compounds.

Different assays have shown that flavonoids present in beer, such as catechin, epicatechin and quercetin, also possess significant antioxidant capacity (Villaño *et al.*, 2005). And again, a DPPH assay of the antioxidant capacity of quercetin showed that it was more antioxidant than α-tocopherol and comparable to ascorbic acid (Sánchez-Moreno *et al.*, 1998).

Beer polyphenols seem to be bioavailable, since the ingestion of 500 ml of beer in a human study produced a significant temporary increase in plasma antioxidant activity (Ghiselli *et al.*, 2000). In general, phenolic acids from beer have been found to present maximum absorption peaks at 30 min. The rapidity of phenolic acid absorption indicates that it probably takes places in the proximal part of the intestine. Given the presence of both free and bound forms of phenolic acids in beer, plasma phenolic acids may be the result of direct absorption of the free forms or of enzymatic digestion of the bound forms.

The general consensus has been that many of these bound forms may not be available in the gastrointestinal tract but may be susceptible to fermentation by the colonic microflora, producing an antioxidant status in the colon. Nevertheless, some authors have suggested that some of these bound forms might be absorbed in the colon; for instance, Andreason *et al.* (2001) found that some diferulate esters could be detected in the plasma of rats after oral ingestion. Similarly, Nardini *et al.* (2002) suggested that chlorogenic acid, a bound form of caffeic acid, is absorbed in the colon, having found that after ingestion of coffee there was an increase in the plasmatic caffeic acid concentration despite the fact that coffee lacks free caffeic acid.

Finally, beer ethanol could play an important indirect role in the absorption of phenolic compounds. Phenolics are aromatic compounds which are not readily soluble in water but are readily soluble in ethanol. The increased solubility of these compounds in hydroalcoholic solution may affect the rate and the amount of their absorption (Ghiselli *et al.*, 2000).

Maillard compounds

The Maillard reaction is one of the most common processes in food products. It takes place between the amino groups of peptides and proteins and the aldehyde group of sugars, particularly in the presence of heat, and it is responsible for the characteristic color of many foodstuffs like bread or coffee.

In the case of beer, Maillard compounds are originated initially during the malting process, and later on in the
Figure 42.2   Melanoidins content of beer.

extraction and boiling processes. These compounds, and especially melanoidins, influence the color, aroma and flavor characterizing some special styles of beers, and of course they also influence beer antioxidant capacity.

Rivero *et al.* (2005) quantified the melanoidin content of beer (see Figure 42.2). Dark beer obviously contains more of these compounds than lager or alcohol-free beer, since it is precisely that they are responsible for its characteristic color. There are no significant differences between the melanoidin contents of lager beer and alcohol-free beer.

From a nutritional point of view, various studies have also demonstrated the high antioxidant capacity of melanoidins, which act through a chain breaking, oxygen scavenging, free radical direct scavenging, metal chelating mechanism (Nicoli *et al.*, 1997; Borrelli *et al.*, 2003) without showing cytotoxic effects (Borrelli *et al.*, 2003). Also, Delgado-Andrade *et al.* (2005) recently measured the antioxidant capacity of certain pure melanoidins. The results showed that although melanoidins exhibit antioxidant capacity, this is much lower than the antioxidant capacity exhibited by certain phenolic compounds present in beer, such as catechin or epicatechin (Tsao *et al.*, 2005). Also, no relationship has been found between the antioxidant capacity of different melanoidins and the degree of browning (Morales and Babbel, 2002).

Melanoidins show a very low bioavailability in the upper gastrointestinal tract. However, it has recently been shown that they may be fermented by colonic microflora (Borrelli *et al.*, 2005). This is an aspect that should be widely studied, for a better understanding of the metabolism of these compounds and their relative contribution to the *in vitro* and *in vivo* antioxidant capacity of beer.

Antioxidant additives

The use of antioxidant additives in beers was first proposed by Gray and Stone in the United States, with the incorporation of ascorbic acid. Following its introduction into American breweries, ascorbic acid came to be used in various European countries (Moll and Joly, 1987). Ascorbic acid is a powerful antioxidant in beer, preventing color changes and alterations of aroma and flavor and prolonging

the storage life of bottled beverages. Normally, between 30 and 50 mg of ascorbic acid is added to most beers (Leubolt and Klein, 1993). Nevertheless, several authors have analyzed the residual ascorbic acid content in commercial beers, finding a total amount between 18–33 mg/l (Moll and Joly, 1987; Wagner and McGarrity, 1991; Matos *et al.*, 1998; Luque-Pérez *et al.*, 2000). Ascorbic acid is a hydrophilic compound; it is able to scavenge peroxyl radicals and to inhibit the cytotoxicity induced by oxidants. Also, it can prevent or reduce H_2O_2-induced lipidic peroxidation and OH-deoxyguanosine formation, which occur as a consequence of DNA oxidation (Yen *et al.*, 2002).

Sulfite is another common preservative used in a wide variety of foods to prevent enzyme activity causing browning and to inhibit the growth of microorganisms during storage. Sulfur compounds such as cysteine, and glutathione and disulfide bridges in peptides and proteins occurring naturally in the raw materials used during the brewing process, may be oxidized to sulfite. Reactive oxygen species (ROS) are known to be deactivated by reaction with cellular thiols to form disulfides. The ready oxidation of thiols by ROS serves as an enzyme-based cellular antioxidant defence system. The amount of sulfite in commercial beers may range between 2.35 and 6.6 mg/l (Wagner and McGarrity, 1991; Leubolt and Klein, 1993). However, in recent years, it has been increasingly realized that sulfite can potentially cause an adverse reaction in sulfite-sensitive asthmatic individuals.

Antioxidant Capacity of Beer

The antioxidant capacity of a food is not the same as the sum of the antioxidant capacities of individual bioactive compounds. Antioxidant capacity is derived from synergistic effects between bioactive compounds, trace elements, metals and other food constituents (Liu, 2004). Antioxidants may act through very different mechanisms such as metal chelation, suppression of the first free radicals which initiate oxidative damage, capture of free radicals and formation of complexes or induction of the activity of antioxidant biological systems. They are also present in heterogeneous matrixes, as in the case of food products, and the existence of both factors means that their antioxidant capacity cannot be evaluated by a single method (Frankel and Meyer, 2000; Sánchez-Moreno, 2002; Aruoma, 2003; Prior *et al.*, 2005). Therefore, a number of procedures that take all these aspects into account have been developed to determine antioxidant capacity, and many of them have been applied to beer.

The antioxidant capacity of beer (Table 42.3) measured by two different assays: ferric reducing/antioxidant power (FRAP), which measures the reducing power of the sample, and ABTS or TEAC (Trolox equivalent antioxidant capacity), which is based on the ability of a sample to scavenge organic free radicals. Results are expressed as μmol Trolox/

Table 42.3 Antioxidant capacity of beer

Kind of beer	ABTS (μmol Trolox/100 ml)	FRAP (μmol Trolox/100 ml)
Lager beer	220.0–305.6	139.6–149.5
Dark beer	259.0–536.5	278.8
Alcohol-free beer	155.8–175.3	75.6–91.2

Source: Saura-Calixto *et al.* (2002) and Lugasi and Hóvári (2003).

100 ml, Trolox being a hydrophilic analog of vitamin E that behaves as a potent antioxidant. As explained earlier in connection with polyphenols content, dark beers or higher-alcohol beers present greater antioxidant capacity, whereas low-alcohol or alcohol-free beers present the least antioxidant capacity, as measured by either ABTS or FRAP.

The effect of beer intake on plasma antioxidant capacity has also been studied. Ghiselli *et al.* (2000) found that 1 h after the consumption of 500 ml of beer there was a significant increase in plasma antioxidant capacity (measured by total radical-trapping antioxidant parameter (TRAP), which determines the ability of a sample to scavenge peroxyl radicals), which reverted to its basal value 2 h after ingestion. There was no such effect after intake of an aqueous solution with similar alcohol content, and the effect was not so pronounced after intake of dealcoholized beer. This is consistent with *in vitro* antioxidant capacity assays, in which ethanol presents no antioxidant capacity. The observed increase in plasma antioxidant capacity must therefore be caused by the antioxidant compounds present in beer.

Given that free radicals may also cause oxidative damage to DNA, one way to determine the antioxidant capacity that a sample may possess *in vivo* is to measure the inhibition of DNA damage, and specifically the inhibition of formation of the nucleotide 8-OH-dG, a product of DNA oxidation. Beer has been shown to have a positive effect on the inhibition of DNA oxidative damage, and the inhibiting effect was strongest in the case of dark beer. In this study, an inverse correlation was also observed between the levels of 8-OH-dG and the melanoidin content in beer, indicating how melanoidins may contribute to the overall antioxidant capacity of beer (Rivero *et al.*, 2005).

A possible explanation for these results is that the positive effects of beer intake may be associated not only with the presence of phenolic and other antioxidant compounds, but also with a combined effect of these compounds and ethanol, given that some large population studies have shown that the mortality rate is lower in people reporting moderate alcohol intake than in either non-drinkers or heavier drinkers.

Table 42.4 shows the antioxidant capacity of different beverages as measured by FRAP and ABTS assays (Pulido *et al.*, 2003). Coffee, red wine and tea exhibit the highest values. The antioxidant capacity of beer (Table 42.3) is similar to that of rose wine, higher than white wine, but lower than red

Table 42.4 Antioxidant capacity of beverages (FRAP and ABTS assays)

Beverage	FRAP (µmol Trolox/100 ml)	ABTS (µmol Trolox/100 ml)
Coffee	2,267 ± 18.9	1,328 ± 5.1
Tea	601 ± 5.5	631 ± 8.0
Red wine	1,214 ± 24.5	1,093 ± 54.2
White wine	154 ± 36.8	181 ± 22.2
Rose wine	286 ± 39.2	261 ± 23.7
Orange juice	515 ± 41.5	249 ± 3.4
Cola	20.7 ± 0.7	≤10

wine, which is the most commonly consumed. These results agree with the findings of Lugasi and Hóvári (2003), who also found that the antioxidant capacity of beer and white wines is similar in terms of hydrogen-donating potency as determined by the DPPH assay. Table 42.4 also shows that the antioxidant capacity of beer (Table 42.3) is higher than that of orange juice when measured by ABTS assay.

Contribution of Beer to the Antioxidant Capacity of Diet

Many epidemiological studies have reported an association between diets with a high intake of plant food (which are rich in antioxidants in addition to other bioactive compounds) and a lower risk of certain chronic processes, such as cardiovascular disease (Serafini, 2006). However, intervention studies based on the intake of specific antioxidants have produced conflicting results. For example, in the Alpha-Tocopherol, Beta Carotene Cancer Prevention Trial conducted in Finland, smokers who received β-carotene presented a marked increase in lung cancer incidence compared with subjects who received a placebo (Woodside *et al.*, 2005). This led to an interest in the way that antioxidants are present in foods and diets, that is in complex matrixes where they are released by the action of enzymes and intestinal microbiota and may interact with other compounds; the global effect may then be due to the combined effect of all the bioactive compounds present in the foodstuff. It could also be that several of these compounds work together but have no effect individually, or that other dietary components, such as trace elements, act as effectors of micronutrient action (Woodside *et al.*, 2005).

Moreover, food products should not be considered individually, but globally as part of a diet. In this respect, it is important to know all the bioactive compounds that a whole diet contains and not only the ones supplied by a single food. Indeed, although the Mediterranean diet is considered a good pattern for the prevention of cardiovascular disease, no strong association has been found between any one of its individual dietary components and survival, suggesting that it is the overall pattern that is protective
(Trichopolou *et al.*, 2003). In the light of this, research was recently conducted to determine the total antioxidant capacity of the Spanish Diet as a type of Mediterranean diet (Saura-Calixto and Goñi, 2006). The antioxidant capacity of the whole diet was estimated at 6,014 and 3,549 µmol Trolox/day by FRAP and ABTS procedures, respectively. About 68% of the total dietary antioxidant capacity came from beverages and 20% from fruits and vegetables, with very little from cereals.

The per capita daily beer intake in Spain in 2001 was 150.4 ml, accounting for nearly one-third of the total intake of beverages. Beer contributes 84.2 mg of polyphenols, which is about 7.2% of the total polyphenol intake in the Spanish diet.

The contribution of beer to the total antioxidant capacity of beverages in the Spanish diet has also been evaluated by Pulido *et al.* (2003) (Figure 42.3). Coffee and wine were the principal contributors to antioxidant capacity of the beverage group, while beer accounted for 5% of the total antioxidant capacity intake from beverages, which is more than reported for tea and orange juice.

As regards the antioxidant capacity of the whole diet, following the same procedure it was found that beer provides 3% of the total antioxidant capacity of the Spanish diet as measured by ABTS assay (Figure 42.4). However, this means that as a single food item beer is a major contributor to the antioxidant capacity of the Spanish diet, considering that the entire nuts group supplies only 5% and fruits and vegetables 22% of the total antioxidant capacity of the Spanish diet. Note that this value represents the daily intake of antioxidants; but the biological effects would depend on their bioavailability, which is usually a fraction of the total intake. Comparative studies on bioavailability of antioxidants from different types of food groups are needed to elucidate their actual contribution to antioxidant status in humans.
Figure 42.4 Contribution of beer to the total antioxidant capacity intake of the Spanish Mediterranean diet.

In the United States, daily per capita beer consumption in 1999 was 226.8 ml according to the Beverage Market Index (Beverage World Publications Group (2000), accounting for 19% of the total intake of beverages. This would mean a daily intake of 127.12 mg of polyphenols supplied by beer and an antioxidant capacity of 244 μmol Trolox/day by FRAP assay or 174 μmol Trolox/day by ABTS assay. Some researchers have studied the antioxidant capacity supplied by a large number of food products consumed in the United States (Wu *et al.*, 2004), as well as the daily intake of certain antioxidants such as anthocyanins (Wu *et al.*, 2006), but no exhaustive work has yet been done on the total antioxidant content and antioxidant capacity of the diet in the United States, including the contribution of beverages.

More studies dealing with the total antioxidant capacity of diets are needed, but the findings published so far show that beer is a significant contributor to the total antioxidant capacity of the diet. Whether moderate consumption could play a role in the prevention of several chronic diseases remains to be seen.

Summary Points

- Beer is a natural beverage with low alcohol content and appreciable antioxidant capacity.
- The antioxidant capacity of beer is mainly derived from polyphenols, Maillard compounds and vitamin C.
- Beer polyphenols come from the natural ingredients (barley and hops) employed in brewing. Maillard compounds are formed during malting, extraction and boiling processes. Vitamin C is incorporated exogenously to beer during the brewing process.
- Polyphenols, the main antioxidants in beer, are present in both free and bound forms. Several *in vivo* studies have

shown that polyphenols in beer are bioavailable. Maillard compounds, particularly melanoidins, have been shown to have antioxidant effects *in vitro*.
- Beer antioxidants have been shown to have metal reducing power, the ability to scavenge free radicals and a protective effect against DNA oxidative damage.
- Beer antioxidant capacity, estimated at about 210 μmol Trolox/100 ml by FRAP assay (mean value between lager and dark beer), is lower than that of red wine and higher than that of white wine.
- Dark beer exhibits greater antioxidant capacity than lager and alcohol-free beers. The antioxidant capacity of alcohol-free beer is considerably lower than that of lager.
- Beer is a contributor to the total antioxidant capacity of diet. The consumption (150 ml/person/day) in Spain means around 3% of the total antioxidant capacity of the Spanish diet. A higher contribution can be expected in other countries where beer consumption is higher. For instance, the consumption in the United States (226.8 ml/person/day) is equivalent to 244 μmol Trolox/day by FRAP assay or 174 μmol Trolox/day by ABTS assay.
- Further research is needed to elucidate the contribution of beer to other diets, as well as its potential role in the prevention of chronic diseases, which is associated with the intake of antioxidants.

Antioxidant Activity of Beer's Maillard Reaction Products: Features and Health Aspects

Franco Tubaro Department of Chemical Sciences and Technology, University of Udine, Udine, Italy

Abstract

The capability of a mixture of compounds to quench peroxyl radicals is measured by comparing the kinetics of a reaction between these and the carotenoid crocin and the competition that other antioxidants have for the same peroxyl radicals. This kinetic approach uses a source of peroxyl radicals to evaluate the capacity of other compounds or a mixture of compounds to quench their intrinsic reactivity. Single compounds as well as complex mixtures may be analyzed by kinetic data processing. Overall antioxidant capacity, relative to that of Trolox C (the hydrophylic substitute of vitamin E) may be calculated. As examples of the use of this test, the antioxidant capacity of Maillard reaction products (MRPs are the condensation products of amino acids reacting with sugars when heated) from a standard mixture of glicine and glucose a model system cookie as close as possible to a real solid food the direct comparison of 12 craft beers with 10 commercial industrial beers were performed. Blood samples of 18 healthy volunteers were also withdrawn and analyzed before, during and after a 15-day period of daily intake of a beer particularly strong in antioxidants.

The solid model system was composed of wheat starch, glucose, lysine, water and butter. The antioxidative effect was compared with that of the reference antioxidant Trolox C; the maximum action of MRPs as peroxyl radical scavengers was found to be around 5% that of Trolox C. The contribution of sugar and an amino acid to antioxidant MRPs formation was evaluated by considering models without glucose or lysine. MRPs antioxidant action was found to increase with the browning of models up to a high browning level. The compounds formed when further browning occurred did not contribute to an increase in antioxidant activity. The model without added glucose showed slight browning due to starch hydrolysis or the reaction of lipids with lysine, but antioxidant action was negligible.

Liquids as beer and human plasma were easily compared to a 1 mM solution of Trolox C. Lagers had up to 2.8 mM equivalents of Trolox C, while in some dark craft beers the antioxidant activity reached 12 mM equivalents of Trolox C. Wide differences were noticed between industrial and craft beers, due to the much higher amounts of flavonoids in the latter. Human plasma rarely exceed 2 mM equivalents of Trolox C, but a 15% increase in the status of antioxidants has been observed after 2 weeks of treatment with a daily ingestion of 375 ml of a strong dark beer.

List of Abbreviations

ABAP	Azobis-amidinopropane
EDTA	Ethylen diamine tetra acetic acid
GC	Gas chromatography
HPLC	High performance liquid chromatography
KCl	Potassium chloride
MRP	Maillard reaction products
PUFA	Poly unsaturated fatty acids
TBA	Tiobarbituric acid
TRAP	Total radical trapping antioxidant potential

Introduction

Lipid oxidation of polyunsaturated fatty acids (PUFA) has been extensively analyzed in the last decades (Terao, 1990), in relation to their oxidative stability and the development of off-flavors in foods (Frankel, 1993), but also as a major important mechanism of cellular function derangement in many diseases (Halliwell and Gutteridge, 1990). Moreover, the toxicity of lipid oxidation products (Addis and Warner, 1991) highlights the relevance of technology of food processing in lowering the formation of toxic compounds.

The natural antioxidant content of foods is considered a major health-protecting factor, by supplying the human body with an exogenous antioxidant protection (Gey *et al.*, 1991; Block, 1992; Ames *et al.*, 1993). Furthermore, it is reasonable to assume that the reduction of the content of oxidized toxic components in foods, brought by the ingestion of antioxidants, must be significant for human health.

The capability of measuring overall antioxidant capacity of a food, therefore, may be very useful in food chemistry, to possibly expand information obtained from tests with single antioxidants.

Accelerated stability tests are the usual procedure for evaluating food antioxidants. A lipid matrix is exposed to various oxidizing conditions, and the effect of the antioxidant is calculated from the induction period prior to the rapid oxidation phase (Frankel, 1993). Oxidation is usually mea-sured by the production of specific compounds or oxygen consumption. Although useful for practical purposes, these procedures have been questioned for either the variability of conditions to produce oxidation products or the precision of the analytical procedure applied (Läubli and Bruttel, 1986).

There is a simple procedure for analyzing the antioxidant capacity of complex matrices (beers and Maillard reaction products – MRPs) which is expressed relative to the soluble analog of α-tocopherol, Trolox C on a concentration basis.

The description of the method needs a brief definition of the peroxidative process and of the antioxidant mechanism to which the analysis has been addressed, highlighting the kinetics of the reactions involved in the antioxidant effect. PUFA, after extraction of an allylic hydrogen atom by an initiator, react extremely fast with molecular oxygen, forming a peroxyl radical (Hasegawa and Patterson, 1978). Several different mechanisms are responsible for the initiation of peroxidation: the production of free radicals may happen by unimolecular homolysis of weak bonds, radiolysis, photolysis or electron transfer from transition metal ions (Pryor, 1976). The bond which most frequently undergoes a homolytic or heterolytic decomposition through the above mechanisms is the O—O bond of a hydroperoxide (Terao, 1990), thus this mechanism of initiation of lipid peroxidation is usually referred to as "hydroperoxide dependent" (Ursini *et al.*, 1991).

Peroxyl radicals react with other PUFA to yield hydroperoxides and a new carbon-centered radical, thus driving the peroxidation chain reaction (Ursini *et al.*, 1991). The reported rate constant for this propagation reaction is 36/M/s for linoleic acid (Barclay *et al.*, 1989) and increases exponentially by increasing up to six the number of double bonds (Micossi *et al.*, 1996). The length of the chain reaction is determined by the availability of substrates (PUFA and oxygen) and by the ratio between propagation and termination reactions by radical–radical interaction (Porter, 1990).

Inhibition of initiation, a primary antioxidant effect, is brought about by physical or chemical procedures preventing the formation of free radicals from pre-existing lipid hydroperoxides (reduction of hydroperoxides, protection from light, sequestration of metals, inhibition of lipoxygenases, etc.). On the other hand, free radical scavengers or chain breaking antioxidants are molecules which specifically quench peroxidation driving radicals, so shortening the chain reaction length. The theoretical targets of this antioxidant effect are carbon-centered radicals, peroxyl radicals and alkoxyl radicals.

As a matter of fact, it is almost impossible for an antioxidant to compete with oxygen for the interaction with a pentadienyl radical since the reaction is extremely fast (Hasegawa and Patterson, 1978), although reversible. The same kinetic limitation applies to alkoxyl radicals, which react with PUFA with a rate constant increasing with the insaturation of the fatty acid chain from 8.8×10^6 to 2.05×10^7/M/s (Small Jr. *et al.*, 1979). It is extremely difficult for the antioxidant reaction to kinetically overhelm the pro-oxidant reaction as the reactivity of the radical involved is very high. Moreover, the actual involvement of the reaction between alkoxyl radicals of fatty acids and a PUFA is questioned owing to their rearrangement. In fact, alkoxyl radicals may cyclize into the adjacent site of insaturation to form, upon oxygen addition, an epoxide-peroxyl radical (Labeque and Marnett, 1988), or undergo β-scission to form, in subsequent reactions, aldehydes and peroxyl radicals (Esterbauer *et al.*, 1990).

The propagation driving reaction between a peroxyl radical and a PUFA, on the other hand, has a limited rate constant (Barclay *et al.*, 1989; Micossi *et al.*, 1996), thus a competitive reaction may take place in which an antioxidant, reacting with a much higher rate constant, can actually spare PUFA.

The first requirement for a free radical scavenger to be an antioxidant is, therefore, the kinetic advantage of having the rate constant of the reaction with a peroxyl radical much higher than that of the propagation reaction between a peroxyl radical and a PUFA. The second requirement is that the radical of the antioxidant has to react with PUFA with a rate constant much lower than the one of peroxyl radical. This highlights the concept that the measurement of just the rate constant of the reaction between a compound and peroxyl radicals (often taken as an index of antioxidant capacity) could be misleading in terms of a real antioxidant effect, when the radical produced is still reactive enough to substitute for peroxyl radicals in the propagation reaction. In the case of an efficient antioxidant such as Trolox C, the rate constant of the antioxidant reaction is several orders of magnitude higher than the rate constants of the chain transfer pro-oxidant reactions (Mukai *et al.*, 1993).

The procedure for measuring antioxidant activity is based on kinetic constraints of the antioxidant effect: (i) the high rate constant of the reaction with peroxidation

driving peroxyl radicals and (ii) the low rate constant of the propagation reaction (if any) of the radical of the antioxidant. By this procedure the capability of a compound (or the mixture of compounds) to quench peroxyl radicals, is measured in terms of Trolox C equivalents (on a concentration basis), by analyzing the kinetics of competition of a parallel reaction where peroxyl radicals bleach the carotenoid, crocin.

As an example, glucose and glycine undergo a Maillard reaction, and the products exhibit antioxidant properties. A high number of beers were also analyzed by this procedure, underlining the differences between simple lagers, amber beers and dark beers.

It is also well known that in a food product which undergoes a heat treatment, compounds with amine groups and free reducing functions of sugars may cause browning reactions, generally called the Maillard reaction. On the other hand, in a lot of foods containing only small amounts of lipids (about 1%), oxidation reactions may cause rancidity phenomena, almost always during storage, in such a way as to limit the shelf-life of foods themselves. Most often, in foods which undergo processing and/or storage, both reactions can occur. Intensive international research to study the antioxidative action of Maillard reaction intermediates and final products has been carried out (Eiserich *et al.*, 1992; Mastrocola and Munari, 2000).

It has been shown that the products obtained from heating model solutions of sugars and amino acids, are able to reduce the degree of oxidation in lipid substrates (Lingnert and Hall, 1986; Kitts and Hu, 2005). Among all of the mechanisms put forward to explain the antioxidative activity of the MRP, the following have been considered: the inactivation of free lipidic radicals, the inhibition of peroxide formation (Eichner, 1981), the ability of MRPs to sequestrate metallic ions, the catalysts of the first oxidation steps (Yamagushi *et al.*, 1981; Yen *et al.*, 2005) and their action as oxygen traps (Lingnert and Waller, 1983).

During heat treatment of a complex system such as in food, the development of interaction products is affected by the change of chemical and physical characteristics, so that the results obtained on models do not necessarily describe phenomena occurring in food. Several studies have been carried out to apply the results obtained on simple models to complex food systems. Furthermore, some conventional methods used to assess lipid oxidation are influenced by the presence of MRPs (tiobarbituric acid (TBA) formation of hexanal by gas chromatography (GC), etc.) and it is difficult to evaluate the action of MRPs on lipid oxidation.

The antioxidative activity of water-soluble compounds obtained by extraction from food model systems of various compositions heated for different times were studied. The methodology used in this work, which involved comparison with a reference antioxidant, demonstrates the antioxidative action of compounds which are able to interact with peroxyl radicals and thus act as radical scavengers.

The multiform nature of the primary antioxidant effect renders extremely vague its quantitative analysis, thus the measurement of "total radical trapping antioxidant potential" (TRAP) has been introduced for evaluating plasma antioxidant capacity (Ghiselli *et al.*, 1994; Rice-Evans and Miller, 1994). These tests adopt different free radical generating systems – thermo-labile diazocompounds or ferryl myoglobin – and the oxidation of either plasma lipids or of a reporter molecule as the event to be analyzed. Thus, as far as the formation of peroxyl radicals is concerned, these tests account for a "chain breaking antioxidant" effect, since the used radicals mimic the reactivity of peroxidation driving lipid-peroxyl radicals.

The basic requirement of lag-time based tests is that the rate constant of the reaction of an antioxidant with peroxyl radicals has to be much higher than that of the molecule to be protected, thus very limited oxidation of the latter takes place until the antioxidant is almost completely consumed. However, when different antioxidants are compared, this approach overlooks the difference among their rate constant for the reaction with peroxyl radicals. Different antioxidants, therefore, within a wide range of rate constants for the above reaction, produce the same lag.

Competition kinetics has been widely used in free radical research, for example in pulse radiolysis experiments (von Sonntag and Schuchmann, 1994) and the produced result is a relative rate constant for the reaction with a given radical. Since the chain breaking antioxidant capacity of a complex mixture, such as plasma, is the sum of the concentration of different antioxidants multiplied by their specific rate constant for the reduction of peroxyl radicals, the antioxidant effect can be reported with respect to the concentration of a reference antioxidant (Trolox C), the rate constant of which is known.

The Kinetic Competition Test

2,2′-Azobis (2-amidinopropane) dihydrochloride (ABAP) was purchased from Waco Chem. USA, Inc. Richmond VA; Trolox C, glucose and glycine from Janssen Chimica, Geel Belgium; potassium hydrogen phosphate from Carlo Erba, Milano Italy; Saffron and Trolox C from Sigma Chemical Co. St. Louis MI. All solvents for high performance liquid chromatography (HPLC grade) were from J.T. Baker Milano Italy. Crocin (8,8′-diapo-ψ,ψ-carotenedioic acid bis [6-O-β-D-glucopyranosyl-β-D-glucopyranosyl] ester) was prepared from saffron (Crocus sativus, Sigma, Italy) by methanolic extraction after being washed with ethylic ether to eliminate possible interferring substances (Bors *et al.*, 1984). The concentration of crocin in methanol was calculated from the absorbtion coefficient ($\varepsilon = 1.33 \times 10$/M/cm at 443 nm).

The original kinetic test (Bors *et al.*, 1984) was modified by introducing diazo-compounds to produce peroxyl radicals

and by using solvents of different polarity to allow the analysis of either hydrophilic or lipophilic compounds.

Reactions were carried out at 40°C and the bleaching rate of crocin, linear 1–1.5 min after the addition of the diazocompound, was recorded for 10 min. Blanks without crocin were run to rule out spectral interferences between the molecule under analysis and crocin.

For hydrophilic compounds ABAP was the radical generator. The hydrophilic reaction mixture contained: 1 ml of 10% ethanol in water, 1 ml of 10 mM phosphate buffer pH 7, 12 μM crocin (from a 1.2 mM methanolic stock solution) and variable amounts of the sample containing the antioxidant to be analyzed. Samples were added either in water or ethanol, maintaining the final concentration of the latter constant. The reaction was started by the addition of 5 mM ABAP (from a fresh 0.5 M solution in water) to the complete reaction mixture pre-equilibrated at 40°C. This procedure was used for Trolox C (as reference compound), for Maillard reaction products in hydrophylic extracts and for beers and plasma samples.

Carbon-centered radicals, generated by thermal decomposition of the diazo-compound (reaction 1), add molecular oxygen yielding peroxyl radicals (ROO$^\bullet$), in a diffusion controlled reaction (reaction 2) (Bors *et al.*, 1987; Pryor *et al.*, 1993). These radicals bleach the carotenoid crocin, thus allowing the measurement of the reaction rate by following the specific absorbance decrease at 443 nm (Bors *et al.*, 1984). In the presence of an antioxidant, competing with crocin for the reaction with radicals, the bleaching rate (reaction 3) slows down, providing that: (i) the antioxidant is able to react with peroxyl radicals (reaction 4) and (ii) the rate of the interaction between the radical of the antioxidant and crocin (reaction 5) is slower than the rate of reaction 3.

$$R - N = N - R \xrightarrow{\text{(heat)}} 2\,R^\bullet + N_2 \qquad (1)$$

$$R^\bullet + O_2 \longrightarrow ROO^\bullet \qquad (2)$$

$$ROO^\bullet + Crocin \longrightarrow ROOH + Crocin^\bullet \,(\text{bleached}) \qquad (3)$$

$$ROO^\bullet + AntiOx \longrightarrow ROOH + AntiOx^\bullet \qquad (4)$$

$$AntiOx^\bullet + Crocin \longrightarrow AntiOx + Crocin^\bullet (\text{bleached}) \qquad (5)$$
The crocin bleaching by a peroxyl radical ($-\Delta A_o$), corresponding to $V_o = K_c[C]$, decreases in the presence of an antioxidant competing for the peroxyl radical and, according to the competition kinetics (Bors *et al.*, 1984, Tubaro *et al.*, 1996), the new bleaching rate (V) corresponds to:

$$V = V_o \times \frac{K_c[C]}{K_c[C] + K_a[A]}$$

where:

$$V_o = K_1 \times [ROO^\bullet] \times [C] \qquad K_c = K_1 \times [ROO^\bullet]$$

$$V_a = K_2 \times [ROO^\bullet] \times [A] \qquad K_a = K_2 \times [ROO^\bullet]$$

and:

V_o = rate of the reaction of crocin with ROO$^\bullet$

V_a = rate of the reaction of the antioxidant under study with ROO$^\bullet$

K_1 = rate constant for the reaction between ROO$^\bullet$ and crocin

K_2 = rate constant for the reaction between ROO$^\bullet$ and antioxidant

[C] = concentration of crocin

[A] = concentration of antioxidant

By transforming, the bleaching rate of crocin ($-\Delta A_o$) decreases in the presence of an antioxidant to a new value ($-\Delta A_a$) fitting the straight line equation:

$$\frac{-\Delta A_o}{-\Delta A_a} = \frac{V_o}{V} = \frac{K_c[C] + K_a[A]}{K_c[C]} = 1 + \frac{K_a}{K_c} \times \frac{[A]}{[C]}$$

The slope K_a/K_c, calculated from the linear regression of the plot of [A]/[C] vs. V_o/V, indicates the relative capacity of different molecules to interact with ROO$^\bullet$. When molecules which, although reacting with peroxyl radicals, are transformed into radicals able to react with crocin and thus, by analogy, to propagate peroxidation, this kinetic approach produces ratios K_a/K_c lower than the actual ratio between the absolute rate constants. Thus, this test averages the antioxidant capacity with a possible pro-oxidant effect of the sample.

Experimental Maillard reaction products

A procedure for preparing a mixture of Maillard reaction products was adopted by dissolving 13.3 g of glucose and 6.7 g of glycine in 80 ml of water and heating the mixture at 90°C in closed vials. The antioxidant capacity was analyzed on samples taken at 0, 3, 6 and 15 h and diluted 1:10 with 0.1 M phosphate buffer pH 7.

A more complex model system (model A) was made to simulate a butter biscuit formulation by mixing together 70.25 g of pure wheat starch with 3.4 g of anhydrous glucose (Carlo Erba, Milan, Italy), 1.35 g of l-lysine (Sigma, Italy), 21 g of concentrated butter (Prealpi, Varese, Italy) and 4 g of distilled water. In the same way, two reference systems were prepared, respectively, without glucose or lysine (models B and C), keeping the proportion of the other components unchanged.

Small amounts of each dough (10 g ± 0.5) were placed in small paper containers and then cooked at 140°C for 0, 10, 20, 30 or 40 min.

After cooking, water soluble compounds formed in the biscuits during the heat treatment, were extracted with a solution of 0.4 M KCl (Carlo Erba, Milan, Italy). The salt is used to increase the polarity of the medium and so promote the extraction of the hydrosoluble compounds. For each kind of dough, 5 g of pounded biscuit were dissolved in 20 ml of KCl solution. The system was homogenized using a Polytron apparatus (Kinematica AG, PT 3,000) for 1 min to facilitate suspension of the particles and the successive phase of extraction. Samples were centrifuged for 5 min at 5,000 rpm at 0°C (refrigerated centrifuge ALC, R.C.F. Meter, 4,233R) and the aqueous phase was filtered through filter paper (Whatman No. 4), mixed again with 10 ml of the KCl solution and centrifuged again as described above. The aqueous phase was then frozen and stored (−18°C) for about 15 h in hermetically sealed containers. Each extraction was carried out twice.

Before each determination of the antioxidative capacity of the extract, potential interference by the compounds of the extracts, on both rate and evolution of the crocin bleaching was evaluated. It has been shown that the variation of absorption of the extracts after reaction with the free radicals, under the experimental conditions described above, was negligible (Abs = 0.043–0.048).

To express the molar concentration of the antioxidative substances present in the extracts, it was necessary to acknowledge that all the dry matter of the extracts was able to exert an antioxidative action. As the nature and the concentration of these substances in the extracts were unknown, the results have been expressed as equivalents of antioxidative efficiency in comparison with the reference antioxidant: Trolox (6-hydroxy-2,5,7,8-tetramethyl-chroman-2-carbonsalt, Aldrich, Germany), even though it is not present in the extracts. Consequently, extracts were compared with a 1 mM solution of Trolox C.

Since the antioxidant capacity of a complex mixture is the sum of the products of each antioxidant multiplied by its rate constant, it can be functionally expressed as $K_a \times$ [A], where [A] is the concentration of a given antioxidant and K_a its rate constant for the reaction with peroxyl radicals. Thus, the antioxidant capacity of a complex mixture such as plasma is analyzed as follows.

According to the competition kinetics, by plotting the bleaching rates obtained using the solution under analysis (e.g. plasma) as it would be 1 mM of antioxidant, a ratio ka/kc is obtained. By dividing this value by the K_a/K_c of Trolox C, a millimolar concentration of Trolox C accounting for plasma antioxidant capacity is calculated.

Plasma samples

Blood samples were obtained from 18 healthy subjects (12 men and 6 women equally distributed between who would have beer to drink all 15 days of the trial and who would swap to a hydroalcoholic beverage after the first

week). Plasma was immediately prepared using 5 mM EDTA (ethylen diamino tetra acetic acid) or 200 mg/l heparin. Plasma samples were analyzed immediately or frozen at −20°C and analyzed within 3 days.

Beer samples

The antioxidant capacity of different beers was measured by the same procedure. Craft beers and industrial beers were centrifuged at 3,000 rpm for 5 min, and immediately analyzed.

The kinetic competition test was applied to all samples. Chain breaking antioxidants are molecules which interact with free radicals produced during lipid peroxidation, thus inhibiting the free radical chain propagation. Their efficiency depends on several factors, among which the kinetic constraints of the reaction involved are particularly relevant. The described kinetic procedure was addressed to the capacity of a compound or a complex mixture of compounds to react with peroxidation driving peroxyl radicals, producing a hydroperoxide and the radical of the antioxidant, the reactivity of which affects the final result. Thus, this kinetic analysis provides information on the average between antioxidant and pro-oxidant effects. This extends information obtained just from the measurement of the rate constant of the interaction between antioxidant and peroxyl radical, and could be particularly relevant in analyzing complex mixtures.

Competition kinetics has been used for the analysis of radical reactions induced by pulse radiolysis (von Sontag and Schuchmann, 1994) and for the measurement of relative rate constant of antioxidants reacting with hydroxyl and alkoxyl radicals (Bors et al., 1984). The latter test has been modified by introducing diazo-compounds as a source of peroxyl radicals at a constant rate, a procedure widely adopted for analyzing antioxidants (van Amsterdam et al., 1992).

The results of the analyses of the antioxidant capacity of the water soluble analog of α-tocopherol, Trolox C in the hydrophilic system is reported in Figure 43.1. In these plots, V_o/V indicates the ratio of bleaching rates in the presence of different molar ratios between the antioxidant and crocin. These data indicate that experimental results fit the kinetic model (R values > 0.98 and intercept close to 1). Thus, according to the kinetic equation, the slope of the regression fitting of experimental data indicates the antioxidant capacity of the analyzed compound (Tubaro et al., 1996). It is worth noting that, in different solvents the relative efficiency of the chromanol ring with respect to crocin slightly changes. This highlights the concept that different antioxidants must be compared under the same experimental conditions. Nevertheless, these observed differences of chromanol (or crocin) reactivity as a function of the solvent are minimal in comparison with the differences among different antioxidants (van Amsterdam et al., 1992; Ursini et al., 1994).
Figure 43.1 Kinetic plot for the competition between crocin and Trolox C for peroxyl radicals. The slope of the regression fitting indicates, according to the kinetic equation, the antioxidant capacity of the antioxidant. In three repeated measurements the interassay variability was <10%. The equation for Trolocx C was $y = 0.667x + 0.994$; $R^2 = 0.997$.

Antioxidant activity of Maillard reaction products

The described kinetic procedure, set up for the analysis of the antioxidant capacity of single molecules, was extended to complex mixtures (extracts from biscuits, craft and industrial beers, human plasma) where neither the concentration of antioxidants present nor their actual number were known. In fact, the overall antioxidant capacity of a complex mixture corresponds to the sum of each antioxidant concentration times its rate constant for the interaction with a peroxyl radical. Moreover, compounds possibly present in the mixture, which, upon interaction with the peroxyl radical, produce new radicals, reactive with crocin, by affecting crocin bleaching rate, decrease the antioxidant capacity of the mixture, as measured by the kinetic test (as an example, Figures 43.2 and 43.3 shows how craft beers are more antioxidant than industrial beers).

Trolox C as reference compound and the hydrophilic solvent have been used to analyse MRP which are known to play an antioxidant effect (Eichner, 1981).

The antioxidant capacity was measured on a mixture of glucose and glycine, heated to produce a mixture of MRP and analyzed at 3, 6 and 15h. In this test the hydrophilic reaction mixture was used and, for the competition kinetics analysis, the molar concentration of the antioxidant was calculated by dividing the slope of the kinetic test of the mixture of glucose and glycine content by the slope of the kinetic test of Trolox C. Table 43.1 shows that the antioxidant capacity of the mixture progressively increases: after 3h of heating, almost 600g of glucose–glycine contained the antioxidant effect of one gram of Trolox, while just 31g had the same effect after 15h (0.667/0.0215 = 31). This result was supported by controls showing that at room temperature, or when glucose or glycine were heated independently, no antioxidant effect was produced (not shown).
Figure 43.2 Antioxidant activity of lagers. Six craft beers (lagers; dark histograms) were compared to five industrial beers light found on the local markets. Antioxidant activity is expressed in mM equivalents of Trolox C. Bars indicate mean and the standard deviation of three measurements.
Figure 43.3 Antioxidant activity of amber beers. Four craft beers (amber beers idark histograms) were compared to three industrial beers light found on the local markets. Antioxidant activity is expressed in mM equivalents of Trolox C. Bars indicate the mean and standard deviation of three measurements.

It is possible to assert that hydrosoluble substances produced by heat treatment of the complex model system (defined as non-enzymatic browning products) are able to exert a radical scavenger effect. This antioxidative activity is proportional to the browning of the model and the variations of both parameters are statistically correlated ($r = 0.8872$; $p \leqslant 0.05$).

Table 43.2 shows the values of the antioxidative activity of the extracts deriving from the more complex MRP system. While model A had both ingredients necessary for the production of MRPs, the other reference model systems had the Maillard reaction limited or prevented by absence of the sugar (model B) or of the amino acid (model C) in the formulation. In both cases, it can be seen that products extracted from systems submitted to heat treatment for 40 min did not display significant antioxidative activity.

This test is, therefore, particularly appropriate for analyzing the antioxidant capacity of complex mixtures, such as plasma, where several molecules could react with peroxyl radicals producing radicals with different oxidation potential. The final fate of the radical of the antioxidant will discriminate between good antioxidants and propagators of chain reaction, and the analysis of the antioxidant capacity of a complex mixture must take in account all these effects.

Table 43.1 Kinetics of crocin bleaching inhibition by MRP[a]

Sample time	Competition kinetics equation	R	MRP/Trolox C
MRP 3h	$y = 1.12 \times 10^{-3}x + 1.007$	0.99	0.0017
MRP 6h	$y = 5.39 \times 10^{-3}x + 0.808$	0.99	0.0081
MRP 15h	$y = 21.50 \times 10^{-3}x + 1.007$	0.99	0.0322

Notes: The slope of the regression fitting indicates, according to the kinetic equation, the antioxidant capacity of the antioxidant. In three repeated measurements the interassay variability was <10%. MRP antioxidant activity is related to that of Trolox C measured in the same conditions.

[a]The simple hydrophilic reaction mixture was used. The ratio MRP/Trolox C indicates the relative slope differences between MRPs at different times and Trolox C measured in the same conditions.

Table 43.2 Kinetics of crocin bleaching inhibition by MRP[a] for models B and C total sample time is 40 minutes as for model A

Sample time	Competition kinetics equation	R	MRP/Trolox C
Model A			
MRP 0min	$y = 1.02 \times 10^{-4}x + 1.02$	0.98	Undetectable ($<10^{-3}$)
MRP 10min	$y = 2.29 \times 10^{-3}x + 1.01$	0.99	0.0034
MRP 20min	$y = 1.03 \times 10^{-2}x + 1.01$	0.99	0.0154
MRP 30min	$y = 1.67 \times 10^{-2}x + 1.01$	0.99	0.0250
MRP 40min	$y = 1.30 \times 10^{-2}x + 0.99$	0.99	0.0195
Model B			
MRP (?)	$y = 2.34 \times 10^{-4}x + 1.007$	0.98	Undetectable ($<10^{-3}$)
Model C			
MRP (?)	$y = 6.30 \times 10^{-5}x + 1.007$	0.66	Undetectable ($<10^{-3}$)

Notes: The slope of the regression fitting indicates, according to the kinetic equation, the antioxidant capacity of the antioxidant. In three repeated measurements the interassay variability was <10%. MRP antioxidant activity is related to that of Trolox C.

[a]The complex hydrophilic reaction mixture was used. The ratio MRP/Trolox C indicates the relative slope differences between MRPs at different times and Trolox C measured in the same conditions. See text for details.

Although the pro-oxidant effects so far observed are actually rather limited it is worth noting that they could be relevant when analyzing plasma under different nutritional and pathological conditions.

The antioxidant capacity of plasma is obtained by measuring its bleaching ratio after measuring that of a 1 mM solution of Trolox C. This has been calculated by dividing the slope of the plot obtained with plasma (considered as a 1 mM solution of antioxidant) by the slope obtained with Trolox C.

The procedure is extremely simple and rapid, one sample being fully processed in 10 min if a multiple cell spectrophotometer is used. The intra-assay variation of plasma samples in repeated measurements was less than 8%.

Plasma, when quickly and carefully prepared, taking care to avoid hemolysis, can be stored at −20°C for 3–5 days without any appreciable loss of antioxidant capacity.

No major differences have been noticed by using 5.0 mM EDTA or 200 mg/l heparin as anti-coagulant. However, since EDTA has some antioxidant capacity, although appreciable at concentrations much higher than those used in the test, heparin has been preferred for the standardized procedure.

One of the most attractive applications of this procedure is the analysis of the post prandial plasma, when several components introduced with diet could play relevant antioxidant or pro-oxidant effects. We report here the effect of beer, taken daily for 15 days, as an example of application of the procedure.

Plasma antioxidant capacity has been measured before, during and after the ingestion by nine healthy subjects of a dark beer (12 mM equivalents of Trolox C) for 15 days, and differences were measured comparing their antioxidant plasma levels to those of other nine subjects who interrupted the beer ingestion after 1 week and passed onto an hydroalcoholic mixture of 8% ethanol in water. In all subjects, the dark beer produced a pronounced increase of plasma antioxidant capacity (15% respect to the original value) after the first week of the trial, which was mantained constant at this level for the rest of the testing period. Those who consumed ethanol after the first week had slightly lower capacity at the end of the trial (Figures 43.4 and 43.5). A typical pattern, where an increase was followed by a steady constant level, was observed in all subjects, although the time course presented an individual variability suggesting different rates of uptake and clearance of antioxidant compounds (not shown).
Figure 43.4 Antioxidant activity of dark beers. Two craft beers (dark bars) were compared to two industrial beers found on the local markets. Antioxidant activity is expressed in mM equivalents of Trolox C. Bars indicate the mean and standard deviation of three measurements.
Figure 43.5 Human plasma antioxidant variations due to the ingestion of dark beer. A panel of nine volunteers consumed dark craft beer no. 1 (see Figure 43.4) for 2 weeks, while another nine volunteers consumed an alcohol solution (8%) after 1 week. Antioxidant activity are expressed by the ratio between mM equivalents of Trolox C at the beginning of the test and after 1 and 2 weeks.

The assessment of plasma antioxidant status is a fundamental parameter to define an oxidative stress produced by either a reduced intake or an increased consumption of antioxidants.

From a thermodynamic point of view, every couple of species with a reduction potential lower than that of the couple peroxyl radical/hydroperoxide could play an antioxidant role since the radical nature is transferred to a species with a decreased tendency to propagate the reaction. This is the thermodynamic support to the well-known sequence of redox reactions from a hydroperoxyl radical, to tocopherol to ascorbate (Scarpa et al., 1984). Nonetheless, during this progressive "discharge of the oxidation capacity" from strong oxidants to progressively weaker oxidants (Cadenas, 1997), some intermediates could still promote the oxidation of targets which are supposed to be protected, and consequently it has been shown that tocopheroxyl radical can oxidize lipids (Bowry and Stocker, 1993).

From a kinetic point of view, the antioxidant must react faster than the target to be protected with the oxidant, and

the radical of the antioxidant must be minimally reactive or, more frequently, undergo one of the reactions leading to annihilation of its radical nature (reaction with another radical, disproportion, reaction with another antioxidant), at a rate faster than that of its reaction with the target to be protected.

In conclusion, a very complex array of reactions could take place when a biological matrix as plasma is challenged with a free radical generating system. Our analytical approach is addressed to the kinetic evaluation of the antioxidant effect, taking also in account the effect of molecules, possibly present, which, following fast free radical oxidation, are transformed into radicals which are still oxidant.

In agreement with the most popular TRAP tests, the kinetic approach shows that the large majority of antioxidant capacity of plasma from fasting subjects, as analyzed by this test, is accounted for by ascorbate, urate and proteins, while the effect of vitamin E is minimal, due to its low concentration (Tubaro et al., 1998).

Nevertheless, this test is more precise than lag-time based tests, taking in to the correct account also the weak antioxidant which is overestimated when the antioxidant capacity is measured at the time before massive oxidation of the target.

This analytical approach seems ideal for assessing the effect of nutrition on plasma antioxidant status as far as it concerns the reduction of peroxidation driving peroxyl radicals. In this respect, the evidence of a substantial increase of antioxidant capacity brought about by drinking beer confirms that this very popular beverage could be an important source of physiologically relevant antioxidants.

Conclusion

The principal aim of this experimental work was the evaluation of the antioxidative activity regarding the peroxyl radical scavenging capacity of compounds developed during the heat treatment of a complex food system. Simple and more complex MRPs have been considered (Bressa et al., 1996; Tubaro et al., 1996), and the real application on a popular drink such as dark beer, with many flavonoids and MRPs has been studied. Differences between industrial and craft beers have been underlined, and the influence of a powerfull beer on the antioxidant activity of plasma in human subjects has been quantified (Tubaro et al., 2005).

Summary Points

- Antioxidants are able to quench peroxyl radicals, which are responsible for many degenerative processes in human beings.
- A kinetic competition test is used to measure the antioxidant capacity of many different types of foods, beverages and biological samples.

- MRPs are formed when amino acids (from proteins) and sugars (from polysaccharides) interact in the presence of heat.
- The total amount and exact chemical nature of MRPs in any food is unknown, as any cooking process forms them.
- A relevant antioxidant activity in these products is easily measured, and the potential benefits on humans can be evaluated in controlled conditions. The measurement of a total antioxidant status of volunteers before and after the ingestion of antioxidants may underline how a beer can increase the body's protection from free radicals.

Beer Affects Oxidative Stress Due to Ethanol:
A Preclinical and Clinical Study

Antonio Gasbarrini Institutes of Pathology, Catholic University of Rome, Rome, Italy

Abstract

The oxidation of ethanol (ETOH) and its metabolites increase the production of superoxide anion and hydrogen peroxide, leading to initiation of peroxidation. The sensitivity to peroxidation is due to the overall balance between prooxidants and antioxidants. On the other hand, an increase of the antioxidant activity in blood of subjects with a moderate alcohol intake has been recently indicated as a possible protective mechanism. Beer has many non-alcoholic components with antioxidant properties such as vitamins, minerals, organic and inorganic salts, and phenolic compounds. The present chapter summarizes the results obtained by our laboratory on the effects of different alcoholic beverages, including beer, in both animals and humans. In particular, both preclinical and clinical studies showed that ETOH *per se* seems to decrease antioxidant parameters and increase lipoperoxidation. However, some of these changes appear to be attenuated when ETOH is consumed in beer. This aspect could be related to the counteracting effects of other antioxidant components.

List of Abbreviations

ADP	Adenosine diphosphate
ATP	Adenosine triphosphate
CD	Conjugated diene
ETOH	Ethanol
FFM	Free fat mass
FM	Fat mass
GSH	Reduced glutathione
HDL-C	High-density lipoprotein cholesterol
LPO	Lipid hydroperoxide production
MDA	Malondialdehyde
MEOS	Microsomal ethanol oxidation system
NADPH	Nicotinamide adenine dinucleotide phosphate
OFR	Oxygen-free radicals
TBA-RS	Acid-reactive substance
TRAP	Total plasma antioxidant potential

Introduction

Consumption of high doses of alcohol is able to damage several organ systems in the body (Lieber, 1992). A relationship exists between patterns of alcohol intake and the development of clinical manifestations (Lieber, 1995). Among the possible mechanisms involved in the pathogenesis of tissue injury, mortality and morbidity related to alcohol abuse, great attention has been recently devoted both to alcohol induced nutritional disorders (Preedy *et al.*, 1997; Addolorato *et al.*, 1997a, 1998, 2006) and alcohol related oxidative stress (Addolorato *et al.*, 2001; Lieber, 2005). The oxidation of ethanol (ETOH) and its metabolites increase the production of superoxide anion and hydrogen peroxide, leading to initiation of peroxidation (Krikun *et al.*, 1984; Gasbarrini *et al.*, 1996). The sensitivity to peroxidation is due to the overall balance between prooxidants and antioxidants (Gasbarrini *et al.*, 1996). Antioxidant protection includes both enzymatic and non-enzymatic defense systems (Gasbarrini *et al.*, 1996). In alcoholics a depletion of ascorbic acid, glutathione, selenium and vitamin E that the body stores has also been reported (Addolorato *et al.*, 1997b).

A synergistic hepatotoxic effect between alcohol and ischemia–reperfusion injury has been reported (Addolorato *et al.*, 2001). Alcohol metabolism and long-term anoxia

are both able to induce a final perturbation of different cellular functions mediated by the production of oxygen-free radicals (OFR) (Caraceni *et al.*, 1997; Rouach *et al.*, 1997; Mantle and Preedy, 1999). In particular, the chronic administration of high doses of ETOH is associated with an increase in the production of superoxide, hydroxyl radical, hydrogen peroxide and alcohol-derived free radicals and a decrease in both enzymatic and nonenzymatic antioxidant systems (Shaw *et al.*, 1983; Tanner *et al.*, 1986; Addolorato *et al.*, 1997b). Moreover, the reoxygenation phase that follows a period of prolonged anoxia is characterized by a massive formation of OFR which is considered a major cause of liver injury occurring in post-ischemic reperfusion (McCord, 1985; Koo *et al.*, 1992; Gasbarrini *et al.*, 1997; Addolorato *et al.*, 2001).

On the other hand, an increase in the antioxidant activity in blood of subjects with a moderate alcohol intake has been recently indicated as a possible protective mechanism against coronary heart disease mortality (Gorinstein *et al.*, 1997), in addition to the alcohol related action on the high-density lipoprotein (HDL), cholesterol (Rapaport, 1989) and on platelet aggregation (Renaud and De Lorgeril, 1992). Wine and beer – the most common ETOH-containing beverages in developed countries – have many non-alcoholic components with antioxidant properties (Maxwell *et al.*, 1994; Rimm *et al.*, 1996). Wine has been found to contain antioxidants, vasorelaxants and stimulants to antiaggregatory mechanisms (Maxwell *et al.*, 1994; Rimm *et al.*, 1996). Beer also contains many different substances with nutritional value, such as vitamins, minerals, organic and inorganic salts, and phenolic compounds. Among these compounds, phenols, essential in determining the taste and in maintaining the foam, are well-documented antioxidants (Bors *et al.*, 1984; De Whalley *et al.*, 1990; Chimi *et al.*, 1991; Nardini *et al.*, 1995) contributing to physical and chemical stability of the packaged beer. Phenolic acids from beer seems to be absorbed from the gastrointestinal tract and extensively metabolized in humans (Nardini *et al.*, 2006).

The present chapter summarizes the recent results obtained by our laboratory on the effects of different alcoholic beverages, including beer, in both animals and humans.

Beer Affects Oxidative Stress Due to ETOH: A Preclinical Study

Animal studies suggested that the daily consumption of beer may have beneficial effects, including the prevention of carcinogenesis and osteoporosis (Kondo, 2004).

As regard to oxidative stress, a preclinical study was conducted by our laboratory to evaluate some parameters of redox status in liver and antioxidant status in plasma of rats chronically fed a beer-containing diet (Gasbarrini *et al.*, 1998). Plasma antioxidant capacity, resistance of
Figure 44.1 Resistance of lipoproteins in control conditions (continuous line) and to oxidative modification (dashed line). *Source*: Reprinted from Gasbarrini *et al.* (1998), with kind permission of Springer Science and Business Media.

lipoproteins to oxidative modifications and sensitivity of the livers to an oxidative stress such as the ischemia–reperfusion injury were investigated. The clamping of the hepatic hilus for a prolonged period of time, in leading to a consumption of reduced substrates coupled with a loss of adenosine triphosphate (ATP), is a prelude to the formation of free radicals when the liver is newly exposed to reoxygenation.

In this study, sixty Wistar male rats were divided in three groups fed with three different isocaloric diets for 6 weeks: group A with an alcohol-free diet; group B with a beer-containing diet (30% w/w) and group C with an ETOH-supplemented diet (1.1/100 g, the same as in the beer diet). At the end of the feeding period, rats were analyzed for plasma and liver oxidative status. Some livers were isolated and exposed to ischemia–reperfusion to assess the additional oxidative stress determined by reperfusion.

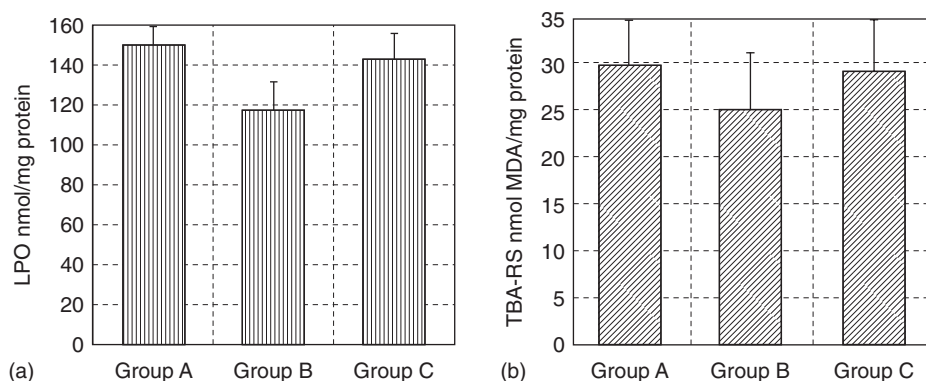
The results of the study evidenced that there were no statistically significant differences among the three dietary groups for thiobarbituric acid-reactive substance (TBA-RS) and total phenols. Uric acid was markedly higher in group C than in groups A and B. Total plasma antioxidant potential (TRAP) was significantly higher in groups B and C than in group A. Conversely, α-tocopherol appeared to be significantly higher in the control group than in the two alcohol groups. The resistance of lipoproteins to oxidative modification was measured both by recording the kinetics of conjugated diene (CD) formation (Figure 44.1) and by measuring lipid hydroperoxides and TBA-RS concentration after a 1-h incubation (Figure 44.2). Lipoproteins from


Figure 44.2 Resistance of lipoproteins to oxidative modification assessed by measuring (a) lipid hydroperoxides (LPO) and (b) acid-reactive substance (TBA-RS) concentrations after a 1-h incubation. *Source*: Reprinted from Gasbarrini *et al*. (1998), with kind permission of Springer Science and Business Media.

Table 44.1 Reduced glutathione (GSH), ATP and TBA-RS concentrations in the livers of rats exposed to the beer and ETOH diets and in controls

	N	GSH (nmol/mg protein)	ATP (pmol/mg protein)	TBA-RS (nmol MDA/mg protein)
Group A (control)	6	1.07 ± 0.04	1.14 ± 0.06	0.99 ± 0.05
Group B (beer)	18	1.10 ± 0.10	1.17 ± 0.10	1.01 ± 0.04
Group C (ETOH)	6	0.99 ± 0.02	1.00 ± 0.02	1.18 ± 0.02

group B showed a slight (although not statistically significant) propensity to resist lipid peroxidation with respect to groups A and C. In fact, as regards the kinetics of CD formation (Figure 44.1), lipoproteins from group B were the most resistant. Moreover, lipid hydroperoxide production (LPO) and TBA-RS concentration after a 1-h incubation (Figure 44.2) tended to be lowest in lipoproteins from group B.

As regard to the sensitivity of liver to ischemia–reperfusion injury, liver concentrations of reduced glutathione (GSH) and TBA-RS did not differ in the three groups after 6 weeks of experimental diet. Conversely, ATP appeared to be slightly lower in the livers of rats exposed to the ETOH diet (Table 44.1). After 60 min of ischemia, liver concentration of GSH and ATP decreased significantly in all groups ($p < 0.01$). GSH values at the end of ischemia did not differ between groups. In livers of rats exposed to ETOH diet (group C), ATP was significantly lower ($p < 0.05$) when compared to the control (group A) and to the beer group (group B) (Figure 44.3). During reperfusion, ATP and GSH recovered progressively in all groups. TBA-RS remained almost stable after ischemia, while it increased significantly during reperfusion (Figure 44.3) in all groups ($p < 0.01$). The livers obtained from rats of group C appear to be more sensitive to ischemia–reperfusion injury, showing a higher formation of TBA-RS during reperfusion

(even if not statistically significant when compared to the other groups) (Figure 44.3).

The results of our preclinical study are in line with previous studies that reported no changes in lipid peroxidation values in rats chronically supplemented with ETOH when they were fed a well-balanced diet (Shaw *et al*., 1984). However, we observed a certain amount of oxidant damage represented by the significantly lower plasma values of vitamin E in groups B and C than in group A. In liver, the basal TBA-RS values did not show any significant difference in any group; nevertheless its significant increase after the ischemia–reperfusion injury supported the toxic effect of ETOH. A toxic effect of ETOH in our study was also represented by the low values of ATP found in the livers of ETOH-fed rats which, probably, resulted from a direct effect of ETOH on ATP degradation (Puig and Fox, 1984; Addolorato *et al*., 1997b) with consequent increase of plasma uric acid, responsible for a paradoxical action on plasma antioxidant capacity (Lieber, 1988). Since ETOH *per se* does not have any antiperoxidative capacity, vitamin E decreased and total phenolics did not show any modification, uric acid was responsible – at least in part – for the increase in plasma antioxidant capacity found in ETOH-fed rats.

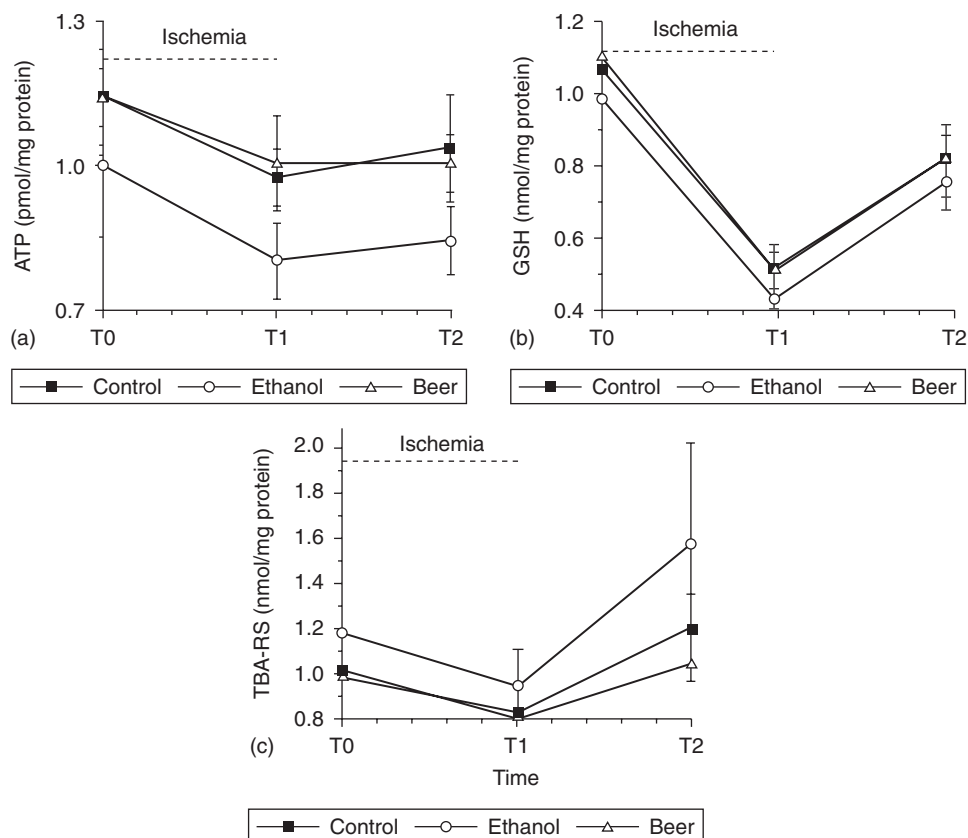
LPO and TBA-RS concentration in lipoproteins tended to be lowest in the beer group with a 20% inhibition of the production of intermediate and end products of lipid


Figure 44.3 (a) ATP, (b) GSH and (c) TBA-RS of rat livers measured at baseline (T0), during ischemia (T1) and reperfusion (T2). *Source*: Reprinted from Gasbarrini *et al.* (1998), with kind permission from Springer Science and Business Media.

peroxidation, indicating a possible propensity to resist lipid peroxidation in the group of rats exposed to the beer-containing diet. When the livers were exposed to ischemia–reperfusion, the beer diet appeared to influence the event. In particular, after ischemia, liver concentrations of GSH and ATP decreased significantly in all groups, in livers of ETOH-fed rats. However, energy status appeared to be significantly lower when compared to the control and to the beer group.

Reoxygenation represents an event characterized by hyperproduction of free radicals, probably triggered by a high concentration of oxidizable substrates and the restored availability of oxygen (Caraceni *et al.*, 1994a, b). In our study, after reperfusion, ATP and GSH progressively recovered in all groups studied; lipid peroxidation was observed in all groups. However, in livers of ETOH-fed rats a greater increase of lipid peroxidation was observed when compared to the control and to the beer group. In conclusion, the minor compounds present in beer appeared to be able to counteract some of the toxic action exerted by ETOH itself. In this connection, a subsequent study has been performed by Rodriguez *et al.* (2001) to verify the real antioxidant role of some beer compounds. These authors have used rat

liver microsomes to compare the effectiveness of prenylated chalcones and flavones from hops and beer to inhibit lipid peroxidation induced by Fe^{2+}/ascorbate, Fe^{3+}-adenosine diphosphate/nicotinamide adenine dinucleotide phosphate (Fe^{3+}-ADP/NADPH) and tert-butyl hydroperoxide. All the chalcones, with or without prenyl groups, were found to exhibit antioxidant activity in the iron/ascorbate system. Moreover, the results showed that some of flavonoids inhibited the system of lipid peroxidation in almost the same degree as the Fe^{2+}/ascorbate system, but did not interfere with the activity of NADPH cytochrome P450 reductase activity of rat liver microsomes.

Beer Affects Oxidative Stress due to ETOH: A Clinical Study

In humans, the possible protective effect of alcoholic beverages has been reported in several studies. In particular, alcohol appears to be a protective factor if consumed in moderate amount (25–30 g/die) and regularly during meals (Vogel, 2002). Several studies suggested that this protective effect seems to be independent from the type

Table 44.2 Plasma concentrations of malondialdeide (MDA), GSH, alpha-tocopherol (vitamin E) and ATP of the four groups examined at the start of the study (T0) and after 30 days (T1)

Group	Redox parameters	T0 (±SD)	T1 (±SD)	%
A	MDA	0.94 ± 0.04	1.03 ± 0.05*	9.5
	GSH	1.19 ± 0.04	1.14 ± 0.03*	−4.2
	E vitamin	10.33 ± 1.08	8.83 ± 1.34*	−14.5
	ATP	0.83 ± 0.11	0.81 ± 0.02	−2.4
B	MDA	0.89 ± 0.07	1.06 ± 0.05*	19.0
	GSH	1.17 ± 0.05	1.11 ± 0.03*	−5.1
	E vitamin	9.82 ± 0.64	6.63 ± 0.84*	−32.4
	ATP	0.82 ± 0.03	0.80 ± 0.02	−2.3
C	MDA	0.95 ± 0.04	1.02 ± 0.03*	7.3
	GSH	1.20 ± 0.04	1.10 ± 0.05*	−9.0
	E vitamin	10.47 ± 0.83	8.62 ± 1.07*	−17.6
	ATP	0.91 ± 0.04	0.80 ± 0.03*	−12.0
D	MDA	0.98 ± 0.05	1.02 ± 0.04	4
	GSH	1.17 ± 0.04	1.16 ± 0.04	−0.8
	E vitamin	9.74 ± 1.15	9.72 ± 1.53	−0.2
	ATP	0.91 ± 0.04	0.92 ± 0.05	1

Notes: No significant difference in ATP, GSH, MDA and vitamin E was found in controls before and after the 30-day study period. MDA significantly increased in all subjects exposed to ETOH ($p < 0.05$); a significant decrease in plasma levels of GSH and of vitamin E was found in all subjects which assumed ETOH ($p < 0.05$). ATP significantly decreased in group C ($p < 0.05$). %: variation between T1 and T0 expressed in percentage.

*$p < 0.05$ (respect to T0).

of beverage consumed (Gaziano *et al.*, 1999) although microcompounds contained in the alcohol beverages result involved in this mechanism (Renaud *et al.*, 1999). Other than the antioxidant action of the microcompounds (Miyagi *et al.*, 1997), several factors have been suggested to maintain the protective effects of the moderate intake of alcohol beverages, including the increase of high-density lipoprotein cholesterol (HDL-C) (Gaziano *et al.*, 1993), of the fibrinolysis processes (Aikens *et al.*, 1997; Dimmitt *et al.*, 1998; Grenett *et al.*, 1998), of vasodilation (Venkow *et al.*, 1999), decrease in blood pressure levels (Hatton *et al.*, 1992), protection against ischemia–reperfusion injury (Chen *et al.*, 1999; Addolorato *et al.*, 2001), inhibition of proliferation and migration of vascular smooth cells (Hendrickson *et al.*, 1998, 1999).

Taking into account our preclinical results, a clinical study has been more recently conducted by our laboratory (Addolorato *et al.*, 2008). In particular, the influence of 30 days of a moderate amount of beer, wine and spirit administration in healthy subjects on oxidant/antioxidant status and body composition has been evaluated. Forty non-smoking male healthy social drinker subjects were randomly divided into four groups. Group A: received 40 g of ETOH per day in lager type beer; group B: 40 g of ETOH per day in red wine; group C: 40 g of ETOH per day in spirit and group D (control group): maintained abstinence from alcohol during the study period. Plasma malondialdehyde (MDA, a lipoperoxidation marker), GSH, α-tocopherol (E vitamin) and ATP were evaluated at the start and at the

end of the study. Moreover, the main biochemical blood parameters including total cholesterol, triglycerides, HDL-C and liver parameters were assessed. All subjects underwent to nutritional status evaluation. The results of the study (Table 44.2) evidenced a significant increase of MDA and a significant decrease in GSH in all subjects exposed to ETOH ($p < 0.05$) (Figure 44.4). Moreover, plasmatic levels of ATP significantly decreased in group C ($p < 0.05$) while this parameter was stable in groups A and B (Figure 44.4). In the control group (D), all the investigated blood parameters remained unmodified while in the three alcohol exposed groups some modifications were observed, in particular in HDL-C ($p < 0.05$). As regard to nutritional status evaluation, fat mass (FM) resulted increased in subjects who drank beer (group A) and wine (group B) and decreased in subjects exposed to spirit (group C) (Table 44.3). Free fat mass (FFM) was stable in subjects exposed to beer and wine and increased in subjects exposed to spirit (Table 44.3).

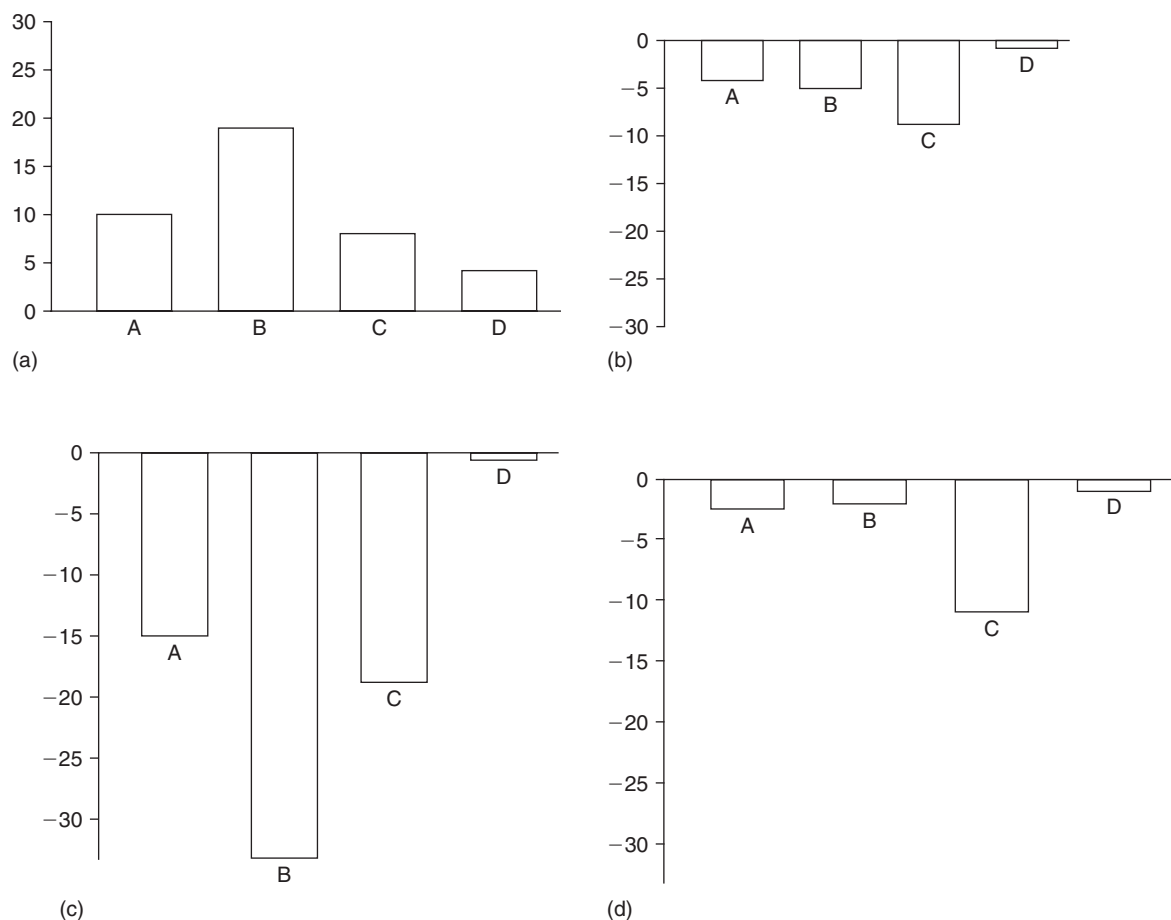
The clinical data obtained in our laboratory showed that a short-term (30 days) ETOH consumption – although in low doses – was able to determine a decrease of antioxidant status in plasma. However, while a significant ATP reduction was observed in subjects exposed to spirit, ATP levels were unmodified when ETOH consumed by beer or wine, at the same way of subjects not exposed to alcohol (group D). Since ATP represents a parameter of the energy level and antioxidant status (Gasbarrini *et al.*, 1996), these results could indicate that the decrease in plasma parameters of antioxidant status appear to be attenuated when


Figure 44.4 Plasma concentrations of (a) malondialdehyde (MDA), (b) GSH, (c) α-tocopherol (vitamin E) and (d) ATP of the groups examined at the start (T0) and the end (T1) of the study. A significant increase of MDA was found in all subjects exposed to ETOH (group A: +9.5%; group B: +19.0%; group C: +7.3%) (p < 0.05). On the other hand, GSH (group A: −4.2%; group B: −5.1%; group C: −9.0%) and vitamin E (group A: −14.5%; group B: −32.4%; group C: −17.6%) significantly decreased in all subjects exposed to ETOH (p < 0.05). A significant decrease of plasma levels of ATP was found only in group C (−12.0%; p < 0.05).

ETOH is consumed in beer or wine. Moreover, these clinical data are also in line with the alcohol related oxidative stress reported both in animals (Addolorato *et al.*, 2001) and humans (Lieber, 2005).

A previous clinical study was performed in healthy nonsmoking men, consuming red wine, beer or spirit, investigating the effects of low alcohol doses on antioxidant compounds (Van der Gaad *et al.*, 2000) showed different results from our data with respect to glutathione and E vitamin. The differences between the two studies could be partially related to the possible different genetic and/or environmental factors between the two population evaluated (The Netherlands and Italy). Another possible difference could be related to the different antioxidant capacity of alcoholic beverages originating from different countries, as recently suggested (Meynell *et al.*, 2006).

Another interesting feature observed in our study is represented by the increase of HDL-C, observed in all subjects exposed to ETOH but not in the control group. This result

is in line with previous similar data by Gaziano *et al.* (1993, 1999) and could be related to the possible protective effects of moderate amount alcohol intake on cardiovascular diseases (Lucas *et al.*, 2005).

Finally, as regard to the possible effects of moderate alcohol intake on nutritional status, FM decreased in subjects drinking spirit and increased in subjects drinking wine and beer, although these modifications were not significant. ETOH represents a high energy substrate providings 7.2 kcal (29.7 kJ) per gram; however, these calories are defined "empty," since they are not fully utilizable (Lieber, 1993). Accordingly, a previous study from our laboratory showed malnutrition and decrease in FM in chronic alcoholic patients (Addolorato *et al.*, 1997a). These effects were mainly due both to an increase of energetic expenditure related to the microsomal ethanol oxidation system (MEOS) induction, and to an increase of fat oxidation related to the mitochondria system induction due to free radicals action (Addolorato *et al.*, 1998). These data seem

Table 44.3 Weight, body mass index (BMI), fat mass (FM), free fat mass (FFM) and total body water examined in the four groups at the start (T0) and at the end of the study (T1)

C	Weight (kg)	77.1 ± 8.03	77.72 ± 8.36
	BMI (kg/m^2)	24.02 ± 2.14	22.22 ± 2.3
	FM (kg)	16.2 ± 4.35	14.62 ± 4.91
	FFM (kg)	60.9 ± 6.15	63.1 ± 6.33
	TBW (l)	42.5 ± 5	44.2 ± 5.5
D	Weight (kg)	76 ± 6	76 ± 6
	BMI (kg/m^2)	24.19 ± 2.02	24.26 ± 2.09
	FM (kg)	14.23 ± 5.49	14.4 ± 5.78
	FFM (kg)	62.01 ± 3.79	62.08 ± 3.89
	TBW (l)	43.71 ± 2.96	43.77 ± 3.03

Note: No significant changes in BMI, FM, FFM and TBW were found in all subjects before and after the study period. FM resulted increased in subjects of groups A and B and decreased in group C.

to be similar to the ones of the present study (Addolorato *et al.*, 2008). Consequently, it could be supposed that these mechanisms may occur also with moderate doses of ETOH consumed by itself. Conversely, when the same quantities of ETOH are contained in alcohol beverages as beer or wine, it is conceivable that the free radical action on the MEOS and mitochondria systems could be counterbalanced by the non-alcoholic compounds with antioxidant action. In this case FM could be increased since drinking during meals determines a prompt alcohol oxidation in competition with the metabolism of other nutrients (Sonko *et al.*, 1994; Addolorato *et al.*, 1997a).

Conclusion

In conclusion, ETOH *per se* seem to be able to increase oxidative damage both in animals and humans, even if it is consumed in moderate amounts. However, both animal and human data suggest that these damages appear to be attenuated when ETOH is assumed in beer. This aspect could be related to the counteracting effects of other antioxidant components.

Summary Points

• The oxidation of ETOH and its metabolites produce superoxide anion and hydrogen peroxide, leading to initiation of peroxidation.

• On the other hand, a moderate alcohol intake increases the antioxidant activity in blood and it has been recently indicated as a possible protective mechanism.
• Beer has many non-alcoholic components with antioxidant properties such as vitamins, minerals, organic and inorganic salts and phenolic compounds.
• Both animal and human studies showed that ETOH *per se* seems to decrease antioxidant parameters and increase lipoperoxidation.
• When ETOH is assumed in beer, some of these alterations appear to be attenuated.
• This aspect seems to be related to the counteracting effects of other antioxidant components present in the beer.

Antioxidant Capacity of Hops

C. Proestos and M. Komaitis Laboratory of Food Chemistry, Agricultural University of Athens, Iera Odos, Athens, Greece

Abstract

Beer is a polyphenol-rich beverage that has recently been reported to reduce the incidence of coronary heart disease and cancer. Some of the mechanisms by which this effect occurs have already been elucidated and include antioxidant, antiinflammatory, antimutagenic, antiangiogenic, estrogen-interfering, and cell cycle regulating actions of its phenolic compounds. The antioxidant capacity of hop polyphenols is probably one of the main reasons for the health-promoting properties attributed to beer. In the present paper, the phenolic substances of hops were identified and quantified by RP-HPLC-UV-vis (reversed-phase–high-performance liquid chromatography–ultraviolet–visible), after comparison with reference standards. The antioxidant capacity tests can be categorized into two groups: assays for radical scavenging ability and assays that test the ability to inhibit lipid oxidation under accelerated conditions. The inhibition of lipid oxidation of the extracts was determined with the Rancimat test using sunflower oil as a substrate. Protection factors (PF) were greater than 1 (1.3 and 1.1 for ground material and methanol extracts) which indicates inhibition of lipid oxidation. Free radical scavenging activity was measured using the stable free radical 1, 1-diphenyl-2-picrylhydrazyl (DPPH). Results were compared with standard compounds (butylated hydroxytoluene (BHT) and ascorbic acid). IC_{50} value (concentration of substrate that causes 50% loss of the DPPH activity) of hop methanol extract (49.8) was found to be similar to BHT (18.5) and to other standard phenolic compounds for example ferulic acid (32.4). On the contrary, ascorbic acid IC_{50} value was lower than of hop extracts. The higher the antioxidant capacity, the lower is the value of EC_{50}. The FRAP (ferric-reducing antioxidant power) assay was also employed to measure the reducing power of antioxidants in hops. The change of absorbance ($\Delta A = A_{4\,min} - A_{0\,min}$ and $\Delta A = A_{30\,min} - A_{0\,min}$) was calculated. It can be seen from the results that the change in absorbance between 0 and 30 min for the 60% ethanol hop extract is significantly higher (p < 0.05) than the other extracts. Between 0 and 4 min the ethanol extract has significantly lower (p < 0.05) change in absorbance than the other extracts. There is also a significant difference (p < 0.05) in ΔA for the methanol extracts after 4 and 30 min. Total phenol concentration of the extracts was estimated with Folin–Ciocalteu reagent using gallic acid as a standard.

Introduction

Beer is a complex alcoholic beverage made from barley (malt), hop, water, and yeast. It is rich in nutrient as well as non-nutrient components including carbohydrates, amino acids, minerals, vitamins, and phenolic compounds. Phenolic constituents of beer are derived from malt (70–80%) and hops (20–30%) (Knorr, 1978; De Keukeleire, 2000). Structural classes include simple phenols, benzoic- and cinnamic-acid derivatives, coumarins, catechins, di-, tri- and oligomeric proanthocyanidins, (prenylated) chalcones, and flavonoids as well as alpha- and *iso*-alpha-acids derived from hops. Compounds belonging to different structural classes have distinct profiles of biological activity in *in vitro* test systems, and in combination might lead to enhanced effects. Scientific evidence has accumulated over the past 10 years pointing to the cancer and coronary heart disease preventive potential of selected hop-derived beer constituents, i.e. prenylflavonoids including xanthohumol and isoxanthohumol, and hop bitter acids.

The hop plant (*Humulus lupulus* L., Cannabinaceae) is used as a tranquilizer or is used to add bitterness to the beer. The hop cones (female inflorescences), are widely used in the brewing industry to add bitterness and aroma to beer. Several flavonoids such as chalcones and flavanones with prenyl or geranyl side chains have been identified in hops and beer (Stevens *et al.*, 1997, 1998, 1999b). As phenolic compounds, these flavonoids may be responsible for the antioxidant activity of beer, which is higher than that of green tea, red wine or grape juice (Vinson *et al.*, 1999). The dried hop cones contain 4–14% polyphenols, mainly phenolic acids, chalcones, flavonoids, catechins, and

proanthocyanidins (Stevens *et al.*, 1998; De Keukeleire *et al.*, 1999; Taylor *et al.*, 2003). In addition, hops provides a resin containing monoacyl phloroglucides, which are converted to hop bitter acids during the brewing process (De Keukeleire, 2000; De Keukeleire *et al.*, 2003). Barley polyphenols undergo changes during the malting and brewing process and are less well characterized than phenolic compounds from hops. However, specific proanthocyanidins from barley and malt have been separated and quantified (Madigan *et al.*, 1994; McMurrough and Baert, 1994; Friedrich *et al.*, 2000).

Interest in employing antioxidants from natural sources to increase the shelf life of foods is considerably enhanced by consumer preference for natural ingredients and concerns about the toxic effects of synthetic antioxidants. Selection of a suitable extraction procedure can increase the antioxidant concentration relative to the plant material. In view of the differences between the extraction techniques, it is obvious that extracts from the same plant material may widely vary with respect to their antioxidant concentration and pattern. The concentration of individual antioxidants in plant extracts determined by HPLC is the preferred way to provide standardized information. However, the antioxidant pattern is usually rather complex, thus making the prediction of a mixture's potency based on compositional data difficult. Therefore, the employment of specific assays to test the antioxidant capacity of the extracts – including synergistic effects is required. A variety of tests expressing antioxidant capacity has been suggested. The tests can be categorized into two groups: assays for radical scavenging ability and assays that test the ability to inhibit lipid oxidation under accelerated conditions. The antioxidant reactions involve multiple steps including the initiation, propagation, branching, and termination of free radicals. The antioxidants which inhibit or retard the formation of free radicals from their unstable precursors (initiation) are called the "preventive" antioxidants, and those which interrupt the radical chain reaction (propagation and branching) are the "chain-breaking" antioxidants (Ou *et al.*, 2001). Test systems that evaluate the radical scavenging ability of antioxidants aim to simulate basic mechanisms involved in lipid oxidation by measuring either the reduction of stable radicals or radicals generated by radiolysis, photolysis, or the Fenton reaction (Blois, 1958; Madsen *et al.*, 1996). Accelerated test systems mainly include lipids, which rapidly oxidize to simulate a long induction period in a short time. To accelerate oxidation, an increase in temperature is often used. This study compares assays used in the laboratories of the authors for the assessment of the antioxidant capacity of hops.

The method of reversed-phase HPLC coupled with a UV-vis multiwavelength detector was used for the determination of hop polyphenols. This method enables the collection of on-line spectra and simultaneous quantification in several wavelengths of the phenolic compounds examined.

Experimental techniques used in the analysis of hops

Standards   Gallic acid, gentisic acid, *p*-coumaric acid, vanillic acid, ferulic acid, syringic acid, (+)-catechin, quercetin, apigenin, naringenin, eriodictyol were purchased from Sigma-Aldrich (Steinheim, Germany). Luteolin was from Roth (Karlsruhe, Germany). Caffeic acid was from Merck (Darmstadt, Germany). (−)-Epicatechin and ascorbic acid were from Fluka AG (Buchs, Switzerland). Rutin was from Alexis Biochemicals (Lausen, Switzerland). Hydroxytyrosol, *p*-hydroxybenzoic acid, and BHT (butylated hydroxytoluene) were a kind donation from the National Agricultural Research Foundation (N.AG.RE.F., Greece). Quantification was done via a calibration with standards (external standard method). All standards were prepared as stock solutions in methanol. Working standards were made by diluting stock solutions in 62.5% aqueous methanol containing BHT 1 g/l, and 6 mol/l HCl to yield concentrations ranging between 0.5 and 25 mg/l. Stock/working solutions of the standards were stored in darkness at −18°C.

Solvents and Reagents   Methanol, acetone, acetic acid, dichloromethane were pro analysis (p.a.), acetonitrile and glacial acetic acid were HPLC grade, and sodium acetate and iron chloride all purchased from Sigma-Aldrich (Steinheim, Germany). Water was supplied by a Milli-Q water purifier system from Milipore (Bedford, MA, USA). The Folin–Ciocalteu reagent was from Merck (Darmstadt, Germany), 1, 1-diphenyl-2-picrylhydrazyl (DPPH) was obtained from Sigma-Aldrich (Steinheim, Germany), and TPTZ, 2,4,6-Tri(2-pirydil)-*s*-triazine was from Fluka (Buchs, Switzerland).

Plant Material   Hop (*Humulus lupulus* L.) was obtained commercially and dried in the air (at 25°C in the dark). It was analyzed within 3 months of collection.

Sample Preparation   The extraction method used for dried samples had as follows: 40 ml of 62.5% aqueous methanol containing BHT (1 g/l) was added to 0.5 g of dried sample. Then 10 ml of 6 mol/l HCl were added. The mixture was stirred carefully. In each sample nitrogen was bubbled for ca. 40–60 s. The extraction mixture was then sonicated for 15 min and refluxed in a water bath at 90°C for 2 h. The mixture was then filtered and made up to 100 ml with methanol (Justesen *et al.*, 1998), furthermore filtered quickly through a 0.45 μm membrane filter (Millex-HV) and injected to HPLC. To prevent enzymic oxidation, extraction of the polyphenols from plants with boiling alcohol is essential and should be adopted routinely (Harborne, 1998). For this reason all steps were carried out in dark (flasks were covered with aluminum foil) and under nitrogen atmosphere (the headspace above the plant extract was under an inert atmosphere created by a stream of nitrogen).

HPLC Analysis The analytical HPLC system employed consisted of a JASCO high-performance liquid chromatograph coupled with a UV-vis multiwavelength detector (MD-910 JASCO). The analytical data were evaluated using a JASCO data processing system (DP-L910/V). The separation was achieved on a Waters Spherisorb® 5 μm ODS2 4.6 × 250 mm column at ambient temperature. The mobile phase consisted of water with 1% glacial acetic acid (solvent A), water with 6% glacial acetic acid (solvent B), and water-acetonitrile (65:30 v/v) with 5% glacial acetic acid (solvent C). The gradient used was similar to that used for the determination of phenolics in wine (Parrilla *et al.*, 1999) with some modifications: 100% A 0–10 min, 100% B 10–30 min, 90% B/10% C 30–50 min, 80% B/20% C 50–60 min, 70% B/30% C 60–70 min, 100% C 70–105 min, 100% A 105–110; post time 10 min before next injection. The flow rate was 0.5 ml/min and the injection volume was 20 μl. The monitoring wavelength was 280 nm for the phenolic acids and 320 and 370 nm (flavones, flavonoles). The identification of each compound was based on a combination of retention time and spectral matching.

Antioxidant Capacity Tests

Rancimat Test This assay tests the ability to inhibit lipid oxidation under accelerated conditions.

Samples of sunflower oil (3.5 g) containing 0.02% w/w methanol or acetone extract or 2% w/w ground material were subjected to oxidation at 110°C (air flow 20 l/h). The standard compounds (0.02% addition) were also examined. Induction periods, *IP* (h), were recorded automatically. The protection factors (PF) were calculated according to the following formula: ($PF = IP_{extract}/IP_{extract}$) (Exarchou *et al.*, 2002).

Determination of the Total Phenolic Content Total phenolic content was measured by the Folin–Ciocalteu assay (Kähkönen *et al.*, 1999). Quantification was performed with the hydrolyzed samples. Results were expressed as mg of gallic acid/g dry sample.

DPPH Assay The DPPH$^{\bullet}$ (Figure 45.1) radical is one of the few stable organic nitrogen radicals, commercially available, which bears a deep purple color. This assay is based on the measurement of the reducing ability of antioxidants toward DPPH$^{\bullet}$. The ability can be evaluated by measuring the decrease of its absorbance. The widely used decoloration assay was first reported by Brand-Williams *et al.* (1995). This antioxidant assay is based on measurement of the loss of DPPH color at 517 nm after reaction with test compounds (Bondet *et al.*, 1997) and the reaction is monitored by a spectrometer. Experiments were carried out according to the
Figure 45.1 The structure of DPPH$^{\bullet}$ radical.

method of Blois (1958) with a slight modification. Briefly, a 1 mmol/l solution of DPPH radical solution in methanol was prepared and then, 1 ml of this solution was mixed with 3 ml of sample solution in different concentrations after extraction with different solvents (methanol, water, dichloromethane). Dichloromethane was removed in a rotary evaporator at 40°C and the residue was dissolved in methanol. After 30 min, the absorbance was measured at 517 nm. The %DPPH radical scavenging is calculated from the equation: %DPPH radical − scavenging = [($Abs_{control} − Abs_{sample})/Abs_{control}$] × 100.

The DPPH solution without sample solution was used as a control. The inhibitory concentration 50 (IC_{50} or EC_{50}) value of extracts (the concentration that causes a decrease in the initial DPPH concentration by 50%) was calculated by using the calibration %DPPH radical − scavenging =f (concentration (μg/ml) and expressed in μg/ml). Results were compared with ascorbic acid, BHT and some phenolic compounds which were used as standards.

Ferric-Reducing Antioxidant Power The FRAP assay was originally developed by Benzie and Strain (1996) to measure reducing power in plasma, but the assay subsequently has also been adapted and used for the assay of antioxidants in botanicals (Benzie and Szeto, 1999; Gil, 2000; Ou *et al.*, 2002; Proteggente *et al.*, 2002; Pellegrini *et al.*, 2003). The reaction measures reduction of ferric 2,4,6-tripyridyl-*s*-triazine (TPTZ) to a colored product (Figure 45.2) (Benzie, 1996).

Herein a ferric salt, TPTZ is used as an oxidant. FRAP is carried out under acidic (pH 3.6) conditions. The assay involves the following procedures: The oxidant is prepared by mixing TPTZ (2.5 ml, 10 mmol/l in 40 mmol/l HCl), 25 ml of acetate buffer, and 2.5 ml of $FeCl_3.H_2O$ (20 mmol/l). The conglomerate is referred to as "FRAP reagent." To measure FRAP value, 300 μl of freshly prepared FRAP reagent is warmed to 37°C and a reagent blank reading is taken at 593 nm; then 10 μl of sample (extracted with water, ethanol, 60% ethanol and methanol) and 30 μl of water are added. Absorbance readings are taken at 0, 4, and 30 min. The change of absorbance ($\Delta A = A_{4\,min} − A_{0\,min}$ and $\Delta A = A_{30\,min} − A_{0\,min}$) is calculated.

Fe^{3+} – TPTZ + reducing antioxidant $\Longrightarrow$ Fe^{2+} – TPTZ (intense blue at 595 nm)

Table 45.1   Summary of the amount of detected phenolic constituents (mg/100 g dry sample) of hops

Structural classes	mg/100 g dry sample
Benzoic acidderivatives	
p-Hydroxy benzoic acid	0.8
Vanillic acid	2.9
Gallic acid	0.3
Syringic acid	0.5
Cinnamic acids	
p-Coumaric acid	0.7
Caffeic acid	0.6
Ferulic acid	6.4
Flavan-3-ols (Catechins)	
(+)-Catechin	4.9
(−)-Epicatechin	1.1
Flavonoles	
Kaempferol	14.2
Quercetin	8.1
Rutin	2.0

Results derived form HPLC Analysis Using the aforementioned procedure, the phenolic substances present in hop extract were separated and quantified. HPLC with a UV-vis multiwavelength detector was used since all phenolic compounds show intense absorption in the UV region of the spectrum. The present method is simple, easy to use, and effective enough for the identification and quantification of major phenolic compounds. A similar technique has been reported by other authors, for the analysis of major flavonoid aglycones (Mattila *et al.*, 2000; Justesen and Knuthsen, 2001). Spherisorb® ODS2 stationary phase, which was used in this study to separate phenolic acids and flavonoids in the aforementioned wavelengths, produced satisfactory results. After extraction and acid hydrolysis the content of phenolic substances was determined. Quantification was done via a calibration with standards (external standard method). A typical HPLC chromatogram of hop extract is presented in Figure 45.3.

The amount of phenolic compounds (phenolic acids and flavonoids) detected in the analyzed sample is shown in Table 45.1. Results are expressed in mg/100 g dry sample. The most abundant phenolic acids were ferulic (6.4 mg/100 g dry sample) and vanillic acid (2.9 mg/100 g dry sample). Flavan-3-ols (Catechins), (+)-Catechin, and (−)-epicatechin were also detected (4.9 and 1.1 mg/100 g dry sample, respectively). Kaempferol, quercetin and rutin (quercetin 3-o-rhamnose glycoside) were the most abundant flavonoids detected (14.2, 8.1, and 2.0 mg/100 g dry sample, respectively). The levels of phenolic compounds were similar to those reported in previous investigations of these compounds in hop plant (Stevens *et al.*, 1998; De Keukeleire *et al.*, 1999; Stevens *et al.*, 2002).

Phenolic compounds are found usually in nature as esters and rarely as glycosides or in free form (Rice-Evans *et al.*, 1996). Thus hydrolysis was needed for their identification and quantitative determination. Flavonoids are also present in plants in the form of glycosides. Any flavonoid may

Table 45.2 Total phenolics in hops *(Humulus lupulus* L.) extracts and their antioxidant capacity (expressed as PF values)

Family species	Part examined	Drying method	Total phenolics[b] (mg gallic acid/g dry sample)	PF[c] (ground material)	PF (methanol extracts)	PF (acetone extracts)
Cannabinaceae *Humulus lupulus*	Leaves + flowers	Air[a]	6.9 ± 0.1	1.3	1.1	1.0

[a] Air: air drying.
[b] Mean of triplicate assays.
[c] PF: protection factor.

occur in a plant in several glycosidic combinations. For this reason, hydrolysis was used to release the aglycones which can be further investigated by HPLC. The data presented in Tables 45.1 are considered as indicative of phenolic content of these aromatic plants. Among others, time of harvest, and storing conditions, are considered responsible for the observed variations in the phenolic contents.

Antioxidant Capacity Tests

Total Phenolic Content (Folin–Ciocalteu (F-C) Assay) and Rancimat Test   The antioxidant capacity (expressed as PF values) and the total phenolic content of hop extract are shown in Table 45.2. There is always the controversy over what is being detected in total antioxidant capacity assays only phenols, or phenols plus reducing agents plus possibly metal chelators. The F-C assay has for many years been used as a measure of total phenolics in natural products, but the basic mechanism is an oxidation/reduction reaction and, as such, can be considered another antioxidant method. The original F-C method developed by Folin (1927) originated from chemical reagents used for tyrosine analysis in which oxidation of phenols by a molybdotungstate reagent yields a colored product with λ_{max} at 745–750 nm. The method is simple, sensitive, and precise. However, the reaction is slow at acid pH, and it lacks specificity. Singleton and Rossi (1965) improved the method with a molybdotungstophosphoric heteropolyanion reagent that reduced phenols more specifically; the λ_{max} for the product is 765 nm. They also imposed mandatory steps and conditions to obtain reliable and predictable data: (1) proper volume ratio of alkali and F-C reagent; (2) optimal reaction time and temperature for color development; (3) monitoring of optical density at 765 nm; and (4) use of gallic acid as the reference-standard phenol. Lack of standardization of methods can lead to several orders of magnitude difference in detected phenols. Hence, continued efforts to standardize the assay are clearly warranted.

The outcome of the Rancimat test supports the hypothesis that hop extracts are good sources of natural antioxidants such as phenolic compounds. This method offers an efficient, simple and automated assay. Chain-breaking antioxidants react with peroxyl radicals, introducing a lag period into the peroxidation process that corresponds with the time taken for the antioxidant to be consumed. Hop methanol and acetone extracts, at the low concentration tested, produced good protection against autoxidation for sunflower oil. When ground material was added to sunflower oil, PF were slightly higher compared to the addition of methanol and acetone extracts (Table 45.2). In the same table the PF values for the standard compounds (0.02% addition) examined ranged from 1.2 to 1.5 for all phenolic acids, except for gallic acid which had $PF = 4.5$. (+)-Catechin hydrated and (−)-epicatechin had PF values 1.8 and 2.5, respectively, whereas the flavonoids (rutin, quercetin, apigenin, luteolin, eriodictyol, and naringenin) had PF values ranging from 1 to 1.2. The PF value for hydroxytyrosol was 1.4 and 1.8 for BHT. PF were greater than 1 (1.3 and 1.1 for ground material and methanol extracts) which indicates inhibition of lipid oxidation. The higher the PF, the better the antioxidant capacity. The effect of hop methanolic extract on the stability of sunflower oil during accelerated oxidation conditions was comparable with the effect of BHT. Bearing in mind that BHT is a pure compound while the extracts are complex mixtures containing ineffective substances in terms of their antioxidant activity or even some amount of pro-oxidant compounds, it could be supposed that hops contains very strong constituents retarding lipid peroxidation.

DPPH Assay   The DPPH method is widely used to test the ability of compounds to act as free radical scavengers or hydrogen donors, and to evaluate antioxidant capacity. The parameter EC_{50} ("efficient concentration" value) otherwise called the IC_{50} value, is used for the interpretation of the results from the DPPH method and is defined as the concentration of substrate that causes 50% loss of the DPPH activity (color). The higher the antioxidant capacity, the lower is the value of EC_{50}. This can be a disadvantage in interpretation of results. That is why results are presented graphically as a bar chart and in numerical form. IC_{50} values of hop extracts were found to be similar to BHT and ascorbic acid values (Table 45.3). In the same table the IC_{50} values of some standard phenolic compounds are also presented.

All the IC_{50} values of the hop extracts (extracted with methanol, water, and dichloromethane) were determined

Table 45.3 Representative IC$_{50}$ values of hop extracts and standard compound tested

Hops and standard compounds	IC$_{50}$[a] (μg/ml)		
	Methanol	Water	Dichloromethane
Humulus lupulus L.	49.8	98.6	505.5
Quercetin	16.6	–	–
(−)-epicatechin	15.1	–	–
(+)-catechin	19.5	–	–
Kaempferol	21.2	–	–
Ferulic acid	32.4	–	–
Ascorbic acid	3.9	–	–
BHT	18.5	–	–

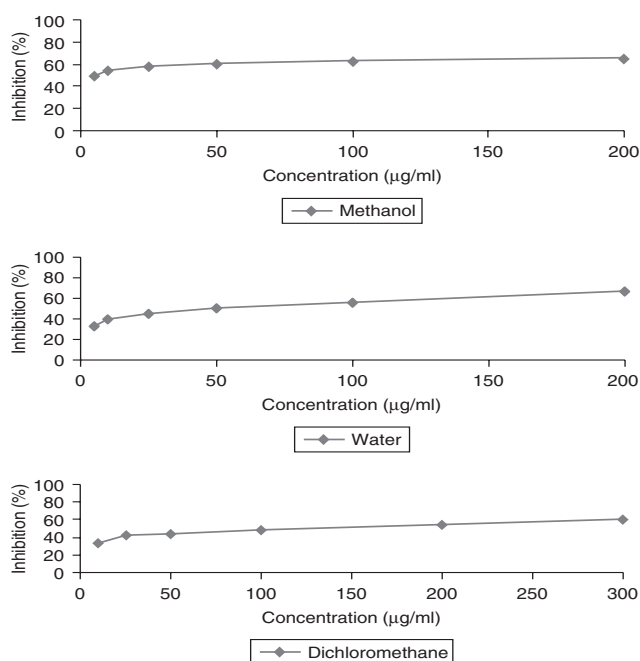
[a] IC$_{50}$: (inhibitory concentration 50, expressed in μg/ml).


Figure 45.4 %DPPH radical scavenging against concentration (μg/ml) curves used to determine the IC$_{50}$ values of hop extracts.

from the curves plotted in Figure 45.4. These curves show the %DPPH radical scavenging against concentration (μg/ml). The IC$_{50}$ values of hop extracts for all solvents were much higher than the values of all the standard compounds tested. Hence, the antioxidant capacity of hops was not as high as the standard compounds. Methanol extract has given better antioxidant capacity compared to other solvent extracts.

The test is simple and rapid and needs only a UV-vis spectrophotometer to perform, which probably explains its widespread use in antioxidant screening. The assay is not a competitive reaction because DPPH is both a radical probe and oxidant. DPPH color can be lost via either radical reaction (HAT) or reduction (SET) as well as unrelated reactions, and steric accessibility is a major determinant of the reaction. Thus, small molecules that have better access to the radical site have higher apparent antioxidant capacity with this test. DPPH is a stable nitrogen radical that bears no similarity to the highly reactive and transient peroxyl radicals involved in lipid peroxidation. Many antioxidants that react quickly with peroxyl radicals may react slowly or may even be inert to DPPH due to steric inaccessibility. DPPH is also decolorized by reducing agents as well as H transfer, which also contributes to inaccurate interpretations of antioxidant capacity.
