Ferric-Reducing Antioxidant Power It has been argued that the ability to reduce iron has little relationship to the radical quenching processes (H transfer) mediated by most antioxidants. However, oxidation or reduction of radicals to ions still stops radical chains, and reducing power reflects the ability of compounds to modulate redox tone in plasma and tissues. The FRAP mechanism is totally electron transfer rather than mixed SET and HAT, so in combination with other methods can be very useful in distinguishing dominant mechanisms with different antioxidants. In addition, because reduced metals are active propagators of radical chains via hydroperoxide reduction to RO$^{\bullet}$, it would be interesting to evaluate whether high FRAP values correlate with the tendency of polyphenols to become pro-oxidants under some conditions. This has been shown for some flavones and flavanones (Cao *et al.*, 1997) which also have high FRAP values.

The experiments were based in the measurement of the absorbance of the hop extracts after extraction with four different solvents at time 0 (beginning of the measurement) and after 4 and 30 min. The change of absorbance ($\Delta A = A_{4\,min} - A_{0\,min}$ and $\Delta A = A_{30\,min} - A_{0\,min}$) was calculated. In Figure 45.5 the change in absorbance from 0 to 30 minutes for all solvent extracts is presented, as well as with the effect of the solvent to the change of absorbance (ΔA) for the two time measurements (4 and 30 min). It can be seen from the results that the change in absorbance between 0 and 30 min for the 60% ethanol hop extract is significantly higher ($p < 0.05$) than the other extracts. Between 0 and 4 min the ethanol extract has significantly lower ($p < 0.05$) change in absorbance than the other extracts. There is also a significant difference ($p < 0.05$) in ΔA for the methanol extracts after 4 and 30 min. No other significant difference was observed. 60% ethanol and methanol extracts changed significantly the reducing capacity of antioxidants present in hops based on the ferric ion.

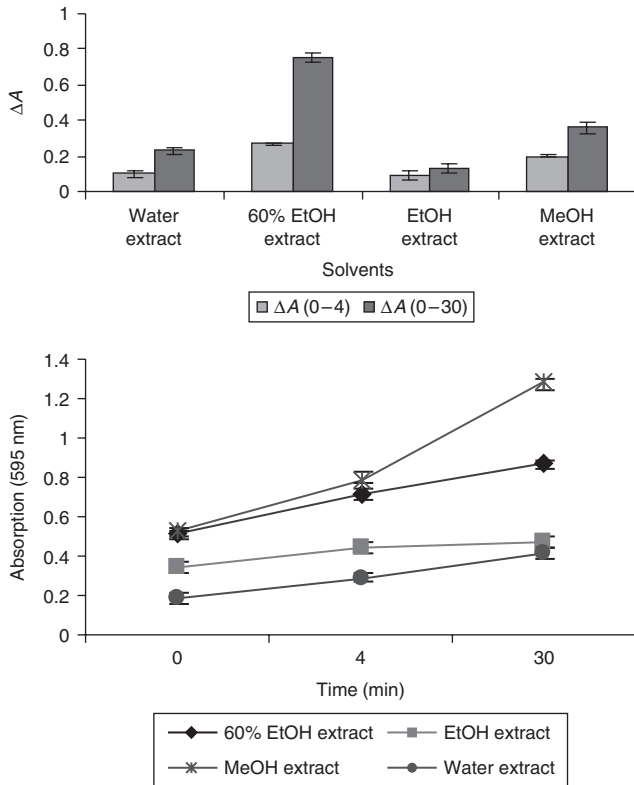
The FRAP assay evolves from assays that rely on the hypothesis that the redox reactions proceed so rapidly that all reactions are complete within 4 and 6 min, respectively, but in fact this is not always true. FRAP results can vary tremendously depending on the time scale of analysis. Fast-reacting phenols that bind the iron or break down to compounds with lower or different reactivity are best


Figure 45.5 Change of absorbance ($\Delta A = A_{4\,min} - A_{0\,min}$ and $\Delta A = A_{30\,min} - A_{0\,min}$) and absorption readings taken at 0, 4, and 30 min.

analyzed with short reaction times (e.g. 4 min). However, some polyphenols react more slowly and require longer reaction times for detection (e.g. 30 min). That is why in our experiment absorbance was measured at 4 min as well as at 30 min. The order of reactivity of a series of antioxidants can vary tremendously and even invert, depending on the analysis time (Pulido *et al.*, 2000). These authors recently examined the FRAP assay of dietary polyphenols in water and methanol. The absorption (A_{593}) slowly increased for polyphenols such as caffeic acid, tannic acid, ferulic acid, ascorbic acid, and quercetin, even after several hours of reaction time. Thus, a single-point absorption endpoint may not represent a completed reaction. In contrast to other tests of total antioxidant capacity, the FRAP assay is simple, speedy, inexpensive, and robust and does not require specialized equipment.

Acknowledgments

Summary Points

- Hops (*Humulus lupulus* L.) contains polyphenols (natural antioxidants), which are believed to be effective nutrients in the prevention of oxidative stress-related diseases such as cancer and heart diseases.
- Hops and its extracts retard oxidative degradation of lipids as it is shown by the Rancimat test.
- Hops antioxidant constituents, mainly phenolic compounds, are free radical scavengers as shown by the DPPH assay. Hence, they can protect foods against spoilage caused by radical chain reactions.
- Antioxidant capacity of hops was also determined by the FRAP assay, which was used to measure reducing power of hop antioxidants.
- Antioxidant capacity tests can be categorized into two groups: assays for radical scavenging ability and assays that test the ability to inhibit lipid oxidation under accelerated conditions.
- Antioxidants can deactivate radicals by two major mechanisms, HAT and SET. The end result is the same, regardless of mechanism, but kinetics and potential for side reactions differ.
- The F-C assay, which was used to determine the total phenolic compounds, has for many years been used as a measure of total phenolics in natural products, but the basic mechanism is an oxidation/reduction reaction and, as such, can be considered as another method to determine antioxidant capacity.
- The influence of the hop variety, storage, and production procedures still has to be investigated in detail to be able to draw the utmost benefit for the brewing technology.

The Antioxidant Capacity of Beer: Relationships Between Assays of Antioxidant Capacity, Color and Other Alcoholic and Non-alcoholic Beverages

Justin A. Fegredo, Rachel Meynell, Alan K.H. Lai, Max C.Y. Wong, Colin R. Martin, Helen Wiseman and **Victor R. Preedy** Department of Nutrition and Dietetics, King's College London, London, UK

Abstract

The antioxidant capacity of foods and beverages has attracted considerable interest, since antioxidants are believed to possess protective properties against numerous pathologies. However, research into the antioxidant capacity of beers worldwide is limited. In Britain, beers represent approximately half of the alcoholic beverage market and are therefore a significant contributor to dietary antioxidant intake. The major antioxidants, phenolic compounds, are derived from the "hop" and malt components, and their concentration has been shown to correlate with total antioxidant capacity (TAC). As a result, assays to determine TAC are useful tools to derive the antioxidant potential of foods and beverages.

In this chapter, we present our findings on the TAC of several types of alcoholic beverage including ales and lagers (both bottled and draft), fruit beers and red wines. In addition, we investigate the relationship between beer color and TAC, and comment on the validity of systems such as that devised by the European Brewery Convention. For example, we show correlations between TAC when assessed by the ferric reducing ability of plasma assay with the darkness ($p < 0.01$), chroma ($p < 0.05$) and chromaticity x or relative redness ($p < 0.01$).

We intend that this chapter provides sufficient insight and motivation to investigate the specific role of beer in health and disease prevention.

List of Abbreviations

CIE	Commission Internationale de l'Eclairage
EBC	European Brewery Convention
FRAP	Ferric reducing ability of plasma
ORAC	Oxygen radical absorbance capacity
TAC	Total antioxidant capacity
TP-FCR	Total phenols by Folin–Ciocalteu reagent

Introduction

In recent years the role played by antioxidants and free radicals in health and aging has been increasingly acknowledged. One area of particular advancement is the degree of interest into dietary sources of antioxidants. Whilst red wine has been the target of much scientific interest (Frankel *et al.*, 1995), beer is increasingly recognized as a rich source of bioavailable dietary antioxidants (Montanari *et al.*, 1999; Nardini *et al.*, 2006), which are able to exert several positive effects on health (Halliwell and Gutteridge, 1999).

Antioxidants in Beer

Beer is composed of numerous constituents including a variety of phenolic and non-phenolic compounds (Gerhauser, 2005). The former, which are naturally occurring substances in fruit, vegetables, nuts, seeds and beverages (Katalinic *et al.*, 2004), are the most widely studied constituents of beer's antioxidant fraction, and are derived from both the "hop" (20–30%) and malt (70–80%) components (Gerhauser, 2005). "Hops," the dried ripe flowers of a twining vine (*Humulus lupulus* Linnaeus), are added to beer to prevent bacterial activity and provide the characteristic bitter taste (De Keukeleire, 2000), and contain 4–14% phenolic compounds by weight. These include phenolic acids, prenylated chalcones, flavanoids, catechins and proanthocyanidins (Gerhauser, 2005). The malt component, derived from the germination of grains, such as barley, contains an overall phenolic mass of 1.0–1.9 mg/g of dry matter (Maillard *et al.*, 1996). Aside from ingredients used in the brewing process, some authors have suggested that phenolic compounds such as gallic acid (Barroso *et al.*, 1996) may be leached from the oak casks or kegs used in the storage of alcoholic beverages (Escalona *et al.*, 2002). However, at present such research is confined to studies involving red wines and spirits.

Phenolic Compounds and Antioxidant Protection

The concentration of phenolic compounds is correlated well with total antioxidant capacity (TAC) (Minussi *et al.*, 2003; Pellegrini *et al.*, 2003; Pulido *et al.*, 2003; Katalinic *et al.*, 2004), and is therefore of substantial importance when considering the antioxidant potential of beverages such as beer. The ability of phenolic compounds to act as reducing agents (and hence antioxidants) is mediated by the hydrogen donating properties of their hydroxyl groups, in addition to their metal chelating ability (Brown *et al.*, 1998). The correlation between phenolic content and TAC can be extended across both alcoholic and non-alcoholic beverages ($r^2 = 0.849-0.981$) (Pulido *et al.*, 2003).

Several studies have demonstrated the high *in vitro* TAC of beers (Montanari *et al.*, 1999; Pellegrini *et al.*, 2003) and subsequent investigation has shown that this antioxidant component is indeed bioavailable (Ghiselli *et al.*, 2000). Preliminary studies have revealed a rapid rise in plasma phenolic compounds which peaks at 30 min following ingestion of beer, suggesting an absorption mechanism located in the proximal gastrointestinal tract (Nardini *et al.*, 2006). However, much further clarification is required regarding the kinetic handling of antioxidant compounds, including the time and site of absorption and the influence of ethanol on their metabolic fate (Vinson *et al.*, 2003).

Assessment of Antioxidant Protection

The quantification of TAC is perhaps of greater meaning than measurement of individual antioxidant constituents (such as phenolic compounds) because TAC acknowledges both synergistic interactions between antioxidant compounds and the contribution of antioxidant components which are at present unidentified. We have measured the TAC of numerous beers from around the world using the ferric reducing ability of plasma (FRAP), oxygen radical absorbance capacity (ORAC) and total phenols by Folin and Ciocalteu's reagent (TP-FCR) assays (Benzie and Strain, 1996; Re *et al.*, 1999; Singleton *et al.*, 1999; Naguib, 2000). Details of the procedures used can be found in Chapter 97.

Validity of Assays for Total Antioxidant Capacity

No well-established consensus exists regarding the choice of assay for measurement of TAC, and as a result studies employ a variety of different techniques thereby rendering their results incomparable. For example, the FRAP and TP-FCR assays measure solely the reducing capacity of a test substrate in the absence of free radicals (Huang *et al.*, 2005), whilst the ORAC assay offers superior measurement of the "radical scavenging ability" of an antioxidant

substrate (Huang *et al.*, 2005). Furthermore, assay conditions are non-physiological (e.g. the TP-FCR assay is conducted at room temperature; the FRAP assay is conducted at pH 3.6; all assays are conducted in the absence of biological matrix (Pulido *et al.*, 2003); etc.) making the results interpretable with only limited biological relevance. Finally, only the ORAC assay is allowed to reach completion and thus incorporate both length and degree of inhibition of oxidation into a final value; the FRAP and TP-FCR assays employ an endpoint technique in which time of completion is arbitrarily set (Huang *et al.*, 2005). Due to the differential meaning of each assay, it is recommended that at least two discrete methods should be employed in the quantification of TAC (Schlesier *et al.*, 2002; Huang *et al.*, 2005) for example one to measure "radical quenching ability" and another to measure "reducing ability." Further details on both the mechanism and limitations of each assay may be found in Chapter 97.

Total Antioxidant Capacity of Beverages

We have measured the TAC of ale ($n = 31$), lager ($n = 37$), fruit beer ($n = 1$), orange juice ($n = 8$) and red wine ($n = 43$), using the FRAP, ORAC and TP-FCR assays. Significant correlations exist between the FRAP and ORAC ($p < 0.01$) and FRAP and TP-FCR ($p < 0.01$) assays, as can been seen in Figures 46.1 and 46.2. We will thus use the FRAP assay as the basis for further discussion.

Analysis revealed that the FRAP value (in mmol per liter) of red wine was over four times than that of any other beverage ($p < 0.01$), and that the mean FRAP of ale was approximately 16% (although non-significantly) higher than that of lager (Figure 46.3). The fruit beer (FRAP, 6.4 mM) was noted
Figure 46.1 Correlation between the FRAP and ORAC assays. FRAP and ORAC were used to assess the TAC of ales and lagers from around the world.

to have a higher TAC than orange juice, ale or lager. The particular fruit beer tested was a blend of 70% white beer with 30% pure fruit juice (Specialist Brand Development, 2007), with the latter probably serving to explain the higher observed TAC. Orange juice was noted to have a higher TAC than either ale or lager, perhaps due to its greater concentration of carotenoids, terpenes and free radical scavenging vitamins (such as ascorbic acid – naturally occurring but sometimes

added artificially) (Pulido *et al.*, 2003). After controlling for the portion size in which each beverage is commonly consumed (bottled ale, 500 ml; bottled lager, 330 ml; draft beer, 1 UK pint or 568 ml; glass of orange juice, 250 ml; large glass of red wine, 175 ml), the FRAP (in mmol per serving) provided by red wine was still substantially larger than that of any other beverage, however the quantity of antioxidants was less than three times that provided by a typical portion of draft ale. In addition, one portion of draft ale provided a greater (though non-significant) antioxidant mass than a portion of orange juice (Figure 46.4). Notwithstanding, one must exercise caution in such calculations, because serving size is highly variable. As an example, bottles of both ale and lager may be 330 or 500 ml capacity whilst servings of wine in UK pubs may range from 125 to 175 ml.

The "hop" component, which provides the characteristic bitter taste of beer, may be more abundant in bitter ales (Gorinstein *et al.*, 2000). Hop extracts release several phenolic compounds during brewing (e.g. procyanidins, epicatechin and ferulic acid) and may thus account for the increased antioxidant capacity of beers with "bitter" properties (Gorinstein *et al.*, 2000). In mild ales, the opposite
Figure 46.2 Correlation between the FRAP and TP-FCR assays. FRAP and TP-FCR were used to assess the TAC of ales and lagers from around the world.
Figure 46.3 FRAP of beer, orange juice and red wine. Data are expressed as mean ± SEM (ale, $n = 31$; lager, $n = 37$; fruit beer, $n = 1$; orange juice, $n = 8$; red wine, $n = 43$). The FRAP assay was used to assess the TAC of several beverages. One-way analysis of variance (ANOVA; fruit beer excluded) found a significant difference in FRAP between beverage groups ($p < 0.001$). *Post hoc* analysis using Bonferroni adjustment revealed that FRAP of red wine was significantly higher than that of any other beverage ($p < 0.05$).
Figure 46.4 FRAP of beer, orange juice and red wine by serving size. Data are expressed as mean ± SEM (bottled ale, $n = 20$; bottled lager, $n = 30$; draft ale, $n = 11$; draft lager, $n = 7$; orange juice, $n = 8$; red wine, $n = 43$). The FRAP assay was used to assess the TAC of several beverages. TAC measured was subsequently controlled for by the portion size in which these beverages are commonly served (bottled ales, 500 ml; bottled lagers, 330 ml; draft ales and lagers, 1 UK pint = 568 ml; orange juice, 250 ml; red wine, 175 ml). One-way analysis of variance (ANOVA) found a significant difference in FRAP per portion size between beverage groups ($p < 0.001$). *Post hoc* analysis using Bonferroni adjustment revealed that FRAP of red wine was significantly higher than that of any other beverages ($p < 0.05$). There were no significant differences between FRAP obtained from ales, lagers or orange juices. In interpreting this, one needs to consider that there is a great deal of variability in "serving" size. For example, in the UK, bottled beer may be in servings of 300 or 500 ml, whilst red wine may be served in portions of 125–175 ml.

is true, and the phenolic profile is occupied by a greater proportion of malt than hop polyphenols (Gorinstein *et al.*, 2000). Malt phenols comprise 70–80% of the phenolic compounds sourced from beer and their antioxidant potential is, as a general rule, less than hop derived polyphenols (Mikyska *et al.*, 2002). This may explain why Asian beers, which are generally less bitter (and thus contain lower quantities of hop), have lower FRAP values (Figure 46.5).

The Color of Beer

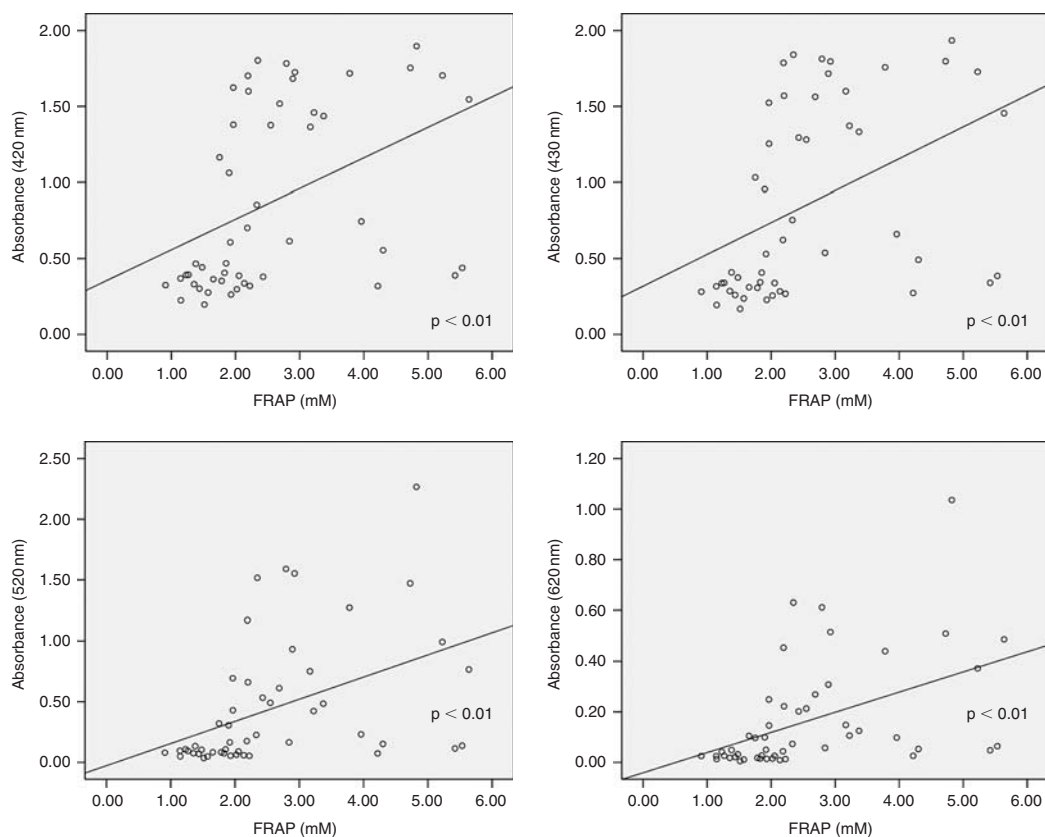
Beer color is the result of several compounds such as Maillard reaction products (especially melanoidins), polyphenols and artificial coloring agents. Color is influenced by brewing conditions such as temperature and pH. The intensity of beer color has been suggested to reflect phenolic content (Mann and Folts, 2004) and offer some indication of *in vivo* antioxidant protectiveness (Begolli *et al.*, 1996). Indeed, several systems, for example the European Brewery Convention (EBC) color scheme (Committee of the EBC, 1975), have used optical density to grade beers according to their color. In our studies we have noted correlations between the TAC and absorbance (four wavelengths: 420, 430, 520, 620 nm; Figure 46.6)
Figure 46.5 FRAP of bottled beer according to area of origin. Data are expressed as mean ± SEM. The FRAP assay was used to assess the TAC of bottled beers from Britain, Germany and Asia. One-way analysis of variance (ANOVA) found a significant difference in FRAP between beverage groups ($p < 0.01$). *Post hoc* analysis using Bonferroni adjustment revealed that FRAP of Asian beers was significantly lower than that of UK or German beers ($p < 0.05$). Asian beers were sourced from a variety of countries including Japan, Korea, Thailand, India, Singapore and Vietnam.


Figure 46.6 Correlation between the FRAP assay and absorbance at 420, 430, 520 and 620 nm. Data demonstrate the significant correlation between the FRAP assay (a widely used assay for TAC and spectrophotometric absorbance of beers at 420, 430, 520 and 620 nm using a cell with a 10 mm light path).

and between TAC and EBC grading (Figure 46.7). Optical density alone, however, cannot be used to quantify the color of a beer, since color perception involves a complex interplay between the spectral reflectance curve, nature of illumination and biological variation in retinal physiology (International Commission on Illumination, 2004). Several models have been proposed to describe color, for example the widely used Commission Internationale de l'Eclairage (CIE) $L^*a^*b^*$ (L, lightness; a, location on red–green continuum; b, location on yellow–blue continuum) and CIE $L^*C^*h^*$ (L, lightness; C, chroma; h, hue) systems (International Commission on Illumination, 2004) which involve the use of Cartesian coordinates to define color by pointing to a unique point in a three-dimensional color space (Figure 46.8). Other systems, for example chromaticity (International Commission on Illumination, 2004), seek to qualify color according to its dominant wavelength (corresponds to hue) and purity (corresponds to saturation or chroma); details given in Figure 46.9. Whilst some authors have used the CIE $L^*a^*b^*$ system to characterize beer color (Coghe et al., 2003), we felt that lightness, L, was the only reliable variable in this system because use of a (red–green) or b (yellow–blue) introduced the confounding factors of whether increased antioxidant capacity was due to, for example, increased redness or decreased greenness (Figure 46.8). We did not correlate h (hue) from the CIE $L^*C^*h^*$ system for a similar reason. Using the CIE chromaticity values (x, y and z; collectively correspond to hue) we found that TAC was significantly and positively correlated with relative redness (x, $p < 0.01$) and greenness (y, $p < 0.05$) but inversely correlated with blueness (z, $p < 0.01$)

(Figure 46.10). Furthermore, we found that FRAP was negatively correlated with lightness L of the beer (hence positively correlated with darkness, $p < 0.01$; Figure 46.11) and positively correlated with color saturation or chroma C ($p < 0.05$; Figure 46.12).
Figure 46.8 Three-dimensional color spaces: CIE $L^*a^*b^*$ and CIE $L^*C^*h^*$. Figure adapted from an online source (The Tintometer Ltd, 2006), where color images are available.

CIE chromaticity diagram
Figure 46.9 Two-dimensional color: CIE chromaticity (International Commission on Illumination, 2004). Any color may be said to be comprised of three primary colors; the tristimulus values of a color are the quantities of each primary color component (X, corresponds to red; Y, corresponds to green; Z, corresponds to blue). The use of tristimulus values to define color is inherently fragile, because color is affected by luminance. Chromaticity, on the other hand, expresses each primary color as a ratio to the total (e.g. $x = X/X + Y + Z$) and is thus irrespective of luminance. Given measurements of x and y, it is therefore mathematically possible to calculate z, ($x + y + z = 1$) which is therefore somewhat redundant. Consequently, the hue of a color can now be expressed in a two-dimensional color space. The value for tristimulus Y is approximately proportional to luminosity, thus chromaticity expressed as Yxy accounts for both hue and luminosity. Figure adapted from an online source (The Tintometer Ltd, 2006), where a color version is available.
Figure 46.7 Correlation between the FRAP assay and EBC color. Data demonstrate the significant correlation between the FRAP assay and the EBC color rating (Committee of the EBC, 1975). EBC color is calculated by measuring absorbance at 430 nm with a light path of 10 mm and multiplying the result by 25.
Figure 46.10 Correlation between the FRAP value and chromaticity x, y and z of beer. Data demonstrate the correlation between the FRAP assay and the chromaticity coordinates x, y and z of several beers ($n = 50$). Chromaticity is a system used to quantify color by way of dominant wavelength (hue) and luminosity (International Commission on Illumination, 2004). Positive correlations between FRAP and chromaticity x and y demonstrate that TAC is greater in redder and greener beers, respectively. The negative correlation between FRAP and chromaticity z demonstrates that TAC is lower in beers with a more bluish hue.
Figure 46.11 Correlation between the FRAP assay and lightness of beer. Data demonstrate the correlation between the FRAP assay and the lightness "L" of several beers ($n = 50$). The negative correlation between FRAP and lightness demonstrates that TAC is greater in darker beers.
Figure 46.12 Correlation between the FRAP assay and chroma of beer. Data demonstrate the correlation between the FRAP assay and the chroma "C" of several beers ($n = 50$). Chroma can be defined as the saturation or vividness of color (International Commission on Illumination, 2004). The positive correlation between FRAP and chroma demonstrates that TAC is greater in more vivid and color-saturated beers.

Conclusion and Future Directions

A number of interesting and contemporary topic areas in the fields of biochemistry, public health and nutrition are involved in the assessment of the antioxidant capacity of beer. On a public health basis, it is important to realize the paradox that exists between any health recommendations made on consumption of certain types of beers over other beverages,

and knowledge of the highly detrimental binge-drinking culture that has evolved in Britain. Nonetheless, the importance of dietary antioxidants in the prevention of disease is well recognized, and it is our intention that this chapter provides sufficient insight and motivation to investigate further the specific role of beer in health and disease prevention.

Summary Points

- Beer is a complex beverage with a high TAC which is comparable to fruit juice.
- Different types of beer exhibit different TAC: ales are higher than lagers.
- The TAC of high-antioxidant beverages cannot be considered in isolation, but must be evaluated with respect to the portion size in which the beverage is consumed.
- When portion size is taken into account, a draft portion of the fruit beer we tested provided 98% of the antioxidant content found in a large (175 ml) glass of red wine. Draft portions of ale and lager provided 42% and 27%, respectively.
- The color of beers serves as an indicator of TAC: darker, more saturated, vivid and redder beers contain the highest quantity of antioxidants.

Biological Properties of Beer and Its Components Compared to Wine

Giuseppe Iacomino, Idolo Tedesco and Gian Luigi Russo Institute of Food Sciences, National Research Council, Avellino, Italy

Abstract

Increasing evidence supports the health benefits of moderate consumption of alcohol as part of a healthy lifestyle. Numerous studies suggest that moderate drinking of beer is associated with lower rates of cardiovascular disease, cancer and osteoporosis. Recent researches in bioactive principles revealed many notable properties of hop compounds. Scientific evidence has accumulated over the last years pointing to the potential anticancer activities of selected hop-derived beer constituents. A generalized radical scavenging activity was described for most beer polyphenolic components, and a protection against DNA oxidative damage was reported. In this chapter, we will discuss the potential chemopreventive role and helpful effects on health of beer and its constituents compared to wine.

List of Abbreviations

ROS	Reactive oxygen species
NF-κB	Nuclear factor-kappa B
Akt	Serine/threonine protein kinase
CYP1A1	Cytochrome P450, family 1, subfamily A, polypeptide 1
CYP1B1	Cytochrome P450, family 1, subfamily B, polypeptide 1
CYP1A2	Cytochrome P450, family 1, subfamily A, polypeptide 2
PhIP	2-amino-1-methyl-6-phenylimidazo [4,5-*b*]pyridine
FRAP	Ferric reducing antioxidant power
EGCG	Epigallocatechin gallate
DMBA	Dimethylbenz[a]antracene
PMA	Phorbol myristate acetate
ERK1/2	Extracellular signal-regulated kinase 1/2
PKC	Protein kinase C
Cdk1/4	Cyclin-dependent kinase 1/4
pRb	Retinoblastoma protein
Bax	Bcl-2-associated X protein
Bcl	B-cell leukemia

Introduction

Growing evidence supports the health benefits of moderate consumption of alcohol as part of a healthy lifestyle, whereas it is widely recognized that alcohol abuse exerts negative effects on health (Rehm *et al.*, 2003). Numerous studies evaluating the relative benefits of wine, beer and spirits, suggest that moderate drinking of any alcoholic beverage is associated with lower rates of cardiovascular disease (Corrao *et al.*, 1999). Apparently, beer drunk in moderation can help protect again heart disease, cancer and osteoporosis (Kondo, 2004). The positive association between moderate intake of alcoholic beverages and low risk for cardiovascular diseases has been linked to their polyphenol content. A recent study showed that the acute consumption of dealcoholized beer may reduce thrombogenic activity in young adults with beneficial effects on coronary artery disease development (Bassus *et al.*, 2004). Urologists suggest beer as an antidote agent against kidney stones formation (Curhan *et al.*, 1996).

Alcoholic beverages are produced from raw materials by fermentative processes (Rainbow and Float, 1990). The most consumed types of commercially alcoholic products are wine, beer and spirits. Beer and wine contain vitamins and other nutrients usually absent from distilled spirits: in addition, beer also contains large quantities of carbohydrates (Moll, 1991). Beer is obtained from malted cereal grains (typically barley and corn or rice) by yeast fermentation. Hops (*Humulus lupulus*) and water are added. Temperature and pH during mashing can affect color, flavor, alcohol content and other fine changes in the beer.

In Table 47.1, the national beer consumptions *per capita* is reported and compared to those of wine.

Except for Luxemburg, where both beer and wine consumption is relatively high, it is worthwhile to note that countries traditionally drinking wine (e.g. France and Italy) consume only modest amounts of beer, and vice versa (e.g. Czech Republic and Germany), whereas moderate consumption of red wine generates the "French Paradox"

Table 47.1 Worldwide beer consumption

Countries	Per capita annual consumption (l)	
	Beer[a]	Wine[b]
Czech Republic	156.5	6.3
Germany	115.8	24.2
Australia	109.9	20.5
Austria	109.0	30.4
Ireland	106.0	12.4
Luxemburg	106.0	59.2
United Kingdom	95.6	16.9
Belgium	91.5	24.1
Slovakia	88.4	11.8
Lithuania	87.5	5.6
Denmark	86.7	28.9
Finland	84.0	7.4
United States	81.6	8.7
Spain	80.6	34.5
The Netherlands	78.1	20.9
New Zealand	77.0	15.8
Poland	75.0	1.3
Estonia	75.0	6.1
Hungary	72.2	31.5
Canada	68.3	8.9
Cyprus	62.2	15.2
Portugal	61.7	46.7
South Africa	59.2	9.1
Russia	58.9	3.4
Sweden	50.5	15.8
Greece	40.0	27.7
Latvia	36.6	4.9
France	33.5	57.2
Italy	29.7	52.9
China	22.1	0.8

Source: [a] Adapted from Assobirra (2006) and referred to 2004–2005 data. [b] Adapted from the Wine Institute, California (www.wineinstitute.org). Data are referred to 2001 consumption and include both white and red wines.

(Constant, 1997), referring to its beneficial effect on health – quite little is known about the effects of moderate consumption of beer on human health (Kondo, 2004). The positive activity of red wine has usually been associated to its high content in polyphenols (Tedesco *et al.*, 2000; Scalbert *et al.*, 2005). Recent papers indicate that beer components might also exert similar beneficial effects on health (Gerhauser, 2005; Rivero *et al.*, 2005) and moderate beer consumption is supposed to be part of a healthy diet (Romeo *et al.*, 2006). A recent search on PubMed (http://www.pubmed.com) revealed that more than 3,700 studies have been published on this topic.

In this chapter, we will focus on the antithetical relation between beer drinking and the increase risk of diseases, as far as the potential chemopreventive role and helpful effects on health of beer or its constituents, compared to wine.

Beer Components Compared to Wine

Beer has a low alcohol content, but an extremely complex chemical composition; in fact, several hundred beer constituents have been so far characterized, as reviewed (Gerhauser, 2005). From a nutritional point of view, beer is more abundant in proteins (ranging 2.0–4.8 g/l) and vitamins compared to wines. Beer contains B type vitamins, including B12, B6 and folate derived from the barley used during production of beer (Flanzy, 1970; Romeo *et al.*, 2006). Beer does not contain fat or cholesterol and is low in free sugars. Furthermore, it is lower in calories than other drinks; calories, ranging from 15 (non-alcoholic beer) to 41 kcal/100 ml (lager beer), come largely from its alcohol content. Beer is a good source of soluble fiber derived from the cell walls of malted barley (Biles and Emerson, 1968). A liter of beer contains an average of 20–60% of the recommended daily intake of fiber, depending on the specific type. In fact, significant amounts of soluble dietary fiber are found in beer (0.4 and 6.2 g/l) (Gromes *et al.*, 2000) compared to red wine (0.94–1.37 g/l) and white wine (0.19–0.39 g/l) (Díaz-Rubio and Saura-Calixto, 2006).

In addition, beer contains a well-balanced array of minerals, such as phosphoric acid (90–400 mg/l), potassium (330–1,100 mg/l), magnesium (60–200 mg/l) and a very low amount of sodium (40–230 mg/l) (Bamforth, 2002). Finally, beer is a good source of bioavailable silicon extracted during the mashing process (Bellia *et al.*, 1994; Powell *et al.*, 2005). The median silicon level of beer is 18.0 mg/l, with no significant difference in the levels of the different beers by geographical origin or type of beer. Recent studies confirmed that serum and urinary silicon levels increased considerably following beer consumption indicating that the mineral in beer is present chiefly in a monomeric form and is readily bioavailable (Sripanyakorn *et al.*, 2004).

Natural antioxidants are found in fruits, vegetables and beverages such as wine and tea. They are also present in high levels in beer, deriving from both the malt (barley) and hops used as ingredients (Shahidi and Naczk, 1995; Paganga *et al.*, 1999). The total amount of antioxidants in the beverage depends on the beer types and therefore the raw materials and the brewing process used. Beer contains more than twice as many antioxidants as white wine per drink, although only half the amount in red wine (Suter, 2001). Relatively recent studies showed that the antioxidant content of blood is raised following beer consumption suggesting that the antioxidants in beer are readily absorbed (Ghiselli *et al.*, 2000). Moreover, phenolic components of wine and beer are quantitatively and qualitatively different because grape contains polyphenols different from those present in barley and hops used in beer production. Furthermore, polyphenols derived from hop are likely to be different from those of malt, about 20–30% of beer polyphenols derive from hop, whereas 70–80% originate from malt (Benitez *et al.*, 1997).

Table 47.2 Comparison between phenolic constituents of beer and wines

Structural classes	Beer (mg/l)	Red wine (mg/l)	White wine (mg/l)
Benzoic acid derivatives			
Gallic acid	Up to 0.2[a]	Up to 19.77[b]	Up to 0.57[b]
Protocatechuic acid	Up to 0.3[a]	Up to 2.36[b]	Up to 0.45[b]
Flavan-3-ols			
(+)-Catechin	Up to 5.4[a]	Up to 18.76[b]	Up to 11.23[b]
(−)-Epicatechin	Up to 1.1[a]	Up to 23.19[b]	Up to 16.95[b]
Cinnamic acids			
Caffeic acid	Up to 0.3[a]	Up to 5.60[b]	Up to 3.66[b]
Ferulic acid	Up to 6.5[a]	Up to 0.27[b]	Up to 0.52[b]
Flavonoles			
Quercetin	Up to 10[a]	Up to 21.06[c]	8.35[c]
Kaempferol	16.4[a]	Up to 2.37[c]	2.69[c]
Flavanones			
Isoxanthohumol	0.04–3.44[a]	–	–
8-Prenylnaringenin	0.001–0.24[a]	–	–
6-Prenylnaringenin	0.001–0.56[a]	–	–
Chalcones			
Xanthohumol	0.002–1.2[a]	–	–
Alpha-acids	~1.7[a]	–	–
iso-Alpha-acids (*cis* and *trans*)	0.6–100[a]	–	–
Proanthocyanidins	21–25[d]	105.45–366.08[e]	2.76–13.30[e]
Stilbenes			
trans-Resveratrol	–	0.114.3[f]	0.026–0.142[g]

Source: [a]Gerhauser (2005); [b]del Alamo *et al*. (2004); [c]Rodriguez-Delgado *et al*. (2001); [d]Gu *et al*. (2004); [e]Sanchez-Moreno *et al*. (2003); [f]Mark *et al*. (2005); [g]Dourtoglou *et al*. (1999).

Major, structural constituents of beer include simple phenols, benzoic and cinnamic acid derivatives, coumarins, catechins, oligomeric proanthocyanidins, prenylated chalcones, flavonoids (flavanones, flavones, flavonoles), alpha- and iso-alpha-acids derived from hop (Gerhäuser *et al*., 2002) (Chapter X). Dark beer contains the highest total phenolic (489 ± 52 mg/l) and melanoidin (1.49 ± 0.02 g/l) contents with a 2-fold difference observed when compared to the alcohol-free beer. Beer antioxidant activity is strongly correlated with the total polyphenol content and with the melanoidin content (Rivero *et al*., 2005; Tedesco *et al*., 2005).

The main flavanols found in beer are (+)catechin, (−)epicatechin, gallocatechin and epigallocatechin, found either as monomers, or commonly connected to form flavanoids (dimers, trimers or larger polymers). Flavanoids (oligomers of flavanols), found at level of approximately 15 mg/l, have a basic structure of two aromatic rings linked by a three carbon unit and are variously hydroxylated and sometimes glycosylated or methylated. Alpha-acids

or humulones are converted during wort boiling to iso-alpha-acids or isohumulones, which impart the typical bitter taste to beer (De Keukeleire, 2000). Table 47.2 summarizes the different phenolic composition between beer and wines.

It is clear that few classes of compounds, such as flavan-3-ols and flavonoles (Table 47.2), are present in comparable amounts in both beverages. Others are preferentially contained in red wine (benzoic acid derivatives), while ferulic acid is higher in beer compared to wines (Table 47.2). On the opposite, there are classes of molecules mainly present in red wines (stilbenes and proanthocyanidins), or exclusively in beer (flavanones and chalcones; Table 47.2).

Risks Associated to Beer Consumption Compared to Wine

Potential chemopreventive benefits deriving from beer consumption cannot leave out the analysis of the negative health effects deriving from alcohol consumption (Rehm *et al*., 2003; Hingson *et al*., 2005). The amount of alcohol in "a drink" can vary considerably depending on the size of the glass and the alcoholic strength. It will differ slightly across world according to historic traditions and customs. "A drink" of beer is usually defined as a 350 ml glass. Its resulting alcohol content is of about 18 g, very similar to a wine serving.

Beer drinking is obviously associated to alcohol consumption, since alcohol-free beer represents only the 2–3% of the beer market. Alcohol abuse contributes to a variety of acute and chronic illness, from injuries resulting from traffic accident to cardiovascular disease and cancer (Rehm *et al*., 2001, 2003). An exhaustive analysis on alcohol consumption and cardiovascular disease found that this association can be described as a J-shaped curve, to indicate that, low-moderate consumption, compared with abstinence from alcohol, is associated with lower risk for cardiovascular disease and mortality, with the lowest risk set at 20 g/day (about one drink of beer) (Corrao *et al*., 2000). The relationship reverses in the case of an averaged intake of more than 72–89 g/day, where the risk significantly increases over the abstainers (Corrao *et al*., 2000). Chronic alcoholism leads to the obverse effect, although beer drinkers had significantly lower serum concentrations of homocysteine than did those consuming wine or spirits (Blasco *et al*., 2005), it is worthwhile to note that hyperhomocysteinemia is considered a significant risk factor for vascular diseases.

There is also convincing evidence that high alcohol consumption is related to increased incidence in different types of cancer (Smith-Warner *et al*., 1998; Dennis, 2000; Bagnardi *et al*., 2001; Ellison *et al*., 2001).

Moderate alcohol consumption increases the risk of breast cancer (Linos *et al*., 2007), most probably by elevating estrogen and androgen levels, suggesting that alcohol drinking might also influence other hormone-related malignancies,

such as ovarian cancer (Genkinger *et al.*, 2006). The latter has been reported to be associated with increased cancer risk in wine, but not in beer consumption (Chang *et al.*, 2007).

Alcohol abuse is also related to chronic health costs other than cardiovascular disease and cancer, such as cirrhosis or pancreatitis (Kozarevic *et al.*, 1983; Rodés *et al.*, 1999). However, it has been described a link between cirrhosis and excessive consumption of liquor, but not beer or wine (Gruenewald and Ponicki, 1995).

Differently than wine, beer may contain undesired components, such as nitrosamine that has been shown to increase the risk of cancer in animals and humans (Riboli *et al.*, 1991). Food constituents and the physical make-up of the beverage can provoke nitrosamine formation. Volatile *N*-nitrosamines were known to be generated during the traditional malting process in beer. Fortunately, modern techniques in malt drying process drastically reduces molecule content to ~0.074 μg/kg (about 2–3% respect to the original concentration) (Izquierdo-Pulido *et al.*, 1996). For moderate beer drinkers, these levels of nitrosamines are unlikely to constitute a hazard (Tricker and Preussmann, 1991). In fact, nitrates and nitrites originating from beer are quite lower than those in vegetables and meat products (Dich *et al.*, 1996).

Beer may also contain biogenic amines, notably tyramine; thus, the consumption of beer must be restricted in patients receiving monoamine oxidase inhibitor drugs (Izquierdo-Pulido *et al.*, 2000). Other risks that may derive from beer consumption are gout (Eastmond *et al.*, 1995) and sensitivity to cereal proteins (Ellis *et al.*, 1990).

Since beer originates from cereals, it is at risk of ochratoxin contamination, a class of compounds with teratogenic, genotoxic, mutagenic and carcinogenic capacities (Creppy, 1999). However, the vast majority of industrial beers are produced from uncontaminated grain and do not contain significant levels of ochratoxins (Long, 1999).

Chemopreventive Effects of Hops and Beer Compounds Compared to Bioactive Molecules Present in Wine

A modern and complete definition of chemoprevention includes the use of natural or pharmacological agents to suppress, arrest or reverse carcinogenesis at its early stages (Sporn and Suh, 2002). Many dietary compounds have been identified as potential chemopreventive agents (Russo *et al.*, 1999; Iacomino *et al.*, 2001; Russo *et al.*, 2005). These include vitamins, minerals, carotenoids, antioxidants, anti-inflammatory agents, *n*-3 polyunsaturated fatty acids and the large class of phytochemicals (polyphenols, isothiocyanates, organosulfur compounds) (Liu, 2004; Gerhauser *et al.*, 2006). The majority of chemopreventive agents are available in, and consumed from, vegetables and also from beverages, such as green tea,

beer and wine (Meydani, 2001; Liu, 2003; Polidori, 2003; Lee *et al.*, 2004; Liu, 2004; Daviglus *et al.*, 2005). However, the mode of action of many of these agents is not completely understood (Russo, 2007). Chemopreventers exert a variety of biological activities and can be divided into two major groups: cancer-blocking and cancer-suppressing agents. The former prevents carcinogens to hit their cellular targets by several mechanisms including enhancing carcinogen detoxification, modifying carcinogen uptake and metabolism, scavenging reactive oxygen species (ROS) and other oxidative species, enhancing DNA repair mechanisms (Furst, 2002). Cancer-suppressing agents inhibit cancer promotion and progression after that the formation of pre-neoplastic cells occurred.

In the next paragraphs, we are going to review selected biological effects of specific beer components and beer extract which can result beneficial in preventing chronic and degenerative pathologies, underlying the differences existing with respect to bioactive molecules present in wine. We will not discuss antioxidant and cardio-protective activities of beer since extensively reported in different sections of the present book (Chapters X and Y).

Chemopreventive activity of compounds specifically present in beer

Recent studies revealed many notable properties of bioactive compounds present in hops, that justify the increasing interest of pharmaceutical firms in hops (or derivatives), as a potential source of novel drugs. Almost all hop secondary metabolites exhibit measurable bioactive effects (Kondo, 2004). Scientific evidence accumulated over the last years are in agreement with the potential anticancer activities of selected hop-derived beer constituents, such as prenylflavonoids (including xanthohumol, isoxanthohumol and hop bitter acids), exclusively present in beer compared to wine (Table 47.2) (Chapter X).

Based on the previous definition, potential chemopreventive effects have been suggested for the following beer components: vitamins, soluble fiber, silicon and polyphenolic antioxidant compounds (Bamforth, 2002).

Recently, attention has been devoted to hop prenylflavonoids, a group of plant secondary metabolites that are significantly and, among alcoholic beverages, exclusively present in beer with respect to wine (Table 47.2).

Xanthohumol (3′-[3,3-dimethylallyl]-2′,4′,4-trihydroxy-6′-methoxychalcone) is the principal prenylated flavonoid of the female inflorescences of the hop plant. The molecule is formed in lupulin glands by a specialized branch of flavonoid biosynthetic pathway that involves prenylation and *O*-methylation of the polyketide intermediate chalconaringenin (Stevens and Page, 2004). The fate of xanthohumol as hops is processed into beer has been investigated, about 20–30% is transformed in isoxanthohumol (Stevens *et al.*, 1999) (Chapter X).

Xanthohumol exhibits protective effects against a variety of disease including osteoporosis, cardiovascular pathologies and cancer (Vanhoecke *et al.*, 2005; Albini *et al.*, 2006). It has been characterized as a broad-range anticancer agent in *in vitro* and *ex vivo* in B-chronic lymphocytic leukemia cells (Miranda *et al.*, 1999; Lust *et al.*, 2005). There are several ways by which xanthohumol may exert its activities. As an example, the molecule may cause apoptosis of cancer cells, and it may also prevent angiogenesis or blood vessel growth by repressing both the NF-κB and Akt pathways (Albini *et al.*, 2006). Furthermore, xanthohumol inhibits the family of cytochromes P450 enzymes (Henderson *et al.*, 2000a, b). It also induces activity of the phase II enzymes quinone reductase (Miranda *et al.*, 2000), which contributes to cellular detoxification from carcinogens. Recent studies demonstrated that xanthohumol inducing downregulation of NF-κB activation in benign prostate hyperplasia can prevent prostate cancer cell proliferation (Colgate *et al.*, 2007). Substitutions on the chalcone structure have been found to profound influence the anticarcinogenic effects of derivatives. Xanthohumol metabolism in rat and human liver microsomes has also been investigated (Yilmazer *et al.*, 2001). Preliminary studies have shown that xanthohumol is absorbed from the digestive tract in rats (Hanske *et al.*, 2005; Hussong *et al.*, 2005; Hijova, 2006); more investigations are necessary to evaluate the bioavailability of the molecule in humans.

In addition, the chemopreventive effects of beer flavanones (i.e. isoxanthohumol and 8-prenylnaringenin) and chalcones (i.e. xanthohumol) (Table 47.2) have been associated to the inhibition, at nanomolar concentration, of phase I cytochrome P450 (phase I monooxygenase enzymes), responsible for the activation of procarcinogens. Cytochrome P450 enzymes are known for their role in the metabolism of drugs and other foreign compounds. Therefore, modulation of this enzymatic system can interfere with the metabolism of xenobiotics, producing effects of pharmacological and toxicological importance (Nebert and Dalton, 2006). Some prenylflavonoids such as xanthohumol, isoxanthohumol and 8-prenylnaringenin have been shown to inhibit the ethoxyresorufin-*O*-deethylase activity of recombinant human CYP1A1 and CYP1B1, and acetanilide 4-hydroxylase activity of CYP1A2 (Henderson *et al.*, 2000b). These enzymatic activities are involved in heterocyclic amines activation, such as 2-amino-3-methylimidazo[4,5-*f*]quinoline) and PhIP (2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine), among the most potent mutagens found in cooked food and potentially carcinogenic in humans (Felton and Knize, 1991; Hatch *et al.*, 1992; Sugimura, 1997). The metabolic activation of aflatoxin B1 as measured by aflatoxin B1-protein binding mediated by human CYP1A2 was also markedly inhibited by 8-prenylnaringenin and isoxanthohumol (Henderson *et al.*, 2000b).

As an example of the synergistic activity of beer components in inhibiting cell proliferation and inducing programmed cell death, we recently investigated the cytotoxic effects of several lyophilized beer extract on HL-60 cell line, derived from a human leukemia (Tedesco *et al.*, 2005). Firstly, we screened 48 commercially available beers for total polyphenol content. We found a strong correlation between the beer antioxidant activity, evaluated by the ferric reducing antioxidant power assay (FRAP assay), and the total phenolic content (Folin–Ciocalteau's assay). In addition, it was worthwhile to note that: (i) the antiproliferative and apoptogenic activity of lyophilized extracts was only associated to beers with high polyphenol content; (ii) these effects were synergic, since single molecules present in the lyophilized extract, when tested on HL-60 cells at exactly the same concentrations present in the original beer (usually in the micromolar range), did not show the same effect on cell growth and/or apoptosis, as the whole extract and (iii) among three different sources of polyphenolic antioxidants tested (beer, wine and green tea), only beer extracts did not increase peroxide concentration in the cell medium. On the opposite, preparation of crude polyphenols from other sources, such as green tea and red wine, increased enormously H_2O_2 concentration (Tedesco *et al.*, 2005).

Chemopreventive activity of compounds exclusively present in wine, not in beer

According to Table 47.2, three classes of compounds are abundantly present in red wine compared to beer: benzoic acids derivatives, catechins and epicatechins, proanthocyanidins and stilbenes. For all of them chemopreventive activities have been described.

Gallic acid and its structurally related compounds are found widely distributed in fruits and plants. Many published studies report the *in vitro* effects of gallic acid, its esters and gallic acid catechin derivatives on phase I and phase II enzymes. An antimutagenic effect (Ames test) may be observed through inhibition of CYP activation of indirectly acting mutagens and/or by scavenging of metabolically generated mutagenic electrophiles (Ow and Stupans, 2003). Similarly, grape seed proanthocyanidins are active in chemoprevention with particular emphasis on the involvement of matrix metalloproteinases in prostate cancer (Katiyar, 2006) and intestinal neoplasia (Hoensch and Kirch, 2005). The class of flavan-3-ols, including catechins, epicatechins and EGCG (catechin (–)-epigallocatechin-3-gallate, abundantly present in green tea polyphenols) represent main targets in anticancer research (Moyers and Kumar, 2004). Several studies suggest that EGCG and other catechins are poorly absorbed and undergo substantial biotransformation to species that include glucuronides, sulfates and methylated compounds. However, preclinical research is promising, and EGCG appears to be ready for further study in phase II and III trials (Moyers and Kumar, 2004). Finally, resveratrol is the main stilbene present in red wine. Several *in vivo* studies, recently reviewed, sustain resveratrol efficacy in inhibiting or retarding tumor growth

and/or progression in animal models inoculated with malignant cell lines, or treated with tumorigenesis-induced drugs (benzo-[α]pyrene, DMBA, azoxymethane) (Ulrich *et al.*, 2005). *In vitro*, resveratrol and its analogs trigger numerous intracellular pathways leading to cell growth arrest. These include inhibition of ERK1/2-mediated signal transduction pathways, inhibition of PMA-dependent PKC activation, downregulation of β-catenin expression, block of cell cycle progression by inhibition of Cdk1 and Cdk4 kinase activities, activation of pRb, induction of apoptotic events, such as activation of caspases, p53 and Bax and inhibition of Bcl2 (Aziz *et al.*, 2003; Ulrich *et al.*, 2005).

Conclusion

Beer contains molecules positively associated with health. Recently, attention has been devoted to prenylflavonoids, a group of plant secondary metabolites that are significantly present in hop plant. Xanthohumol is the principal prenylated flavonoid of the female inflorescences of the hops and it is of general interest to humans since it is present in diet, possesses significant biological activities and an exceptional broad spectrum of inhibitory mechanisms of carcinogenesis. Consistently, xanthohumol modulates the activity of enzymes involved in carcinogen metabolism and detoxification. Furthermore, the molecule is able to scavenge ROS, including hydroxyl- and peroxyl radicals, and to inhibit superoxide anion radical and nitric oxide production.

Much has been written about the favorable impact on health of moderate consumption of wine. Critical assessment of the literature, however, indicates that among alcoholic beverages, beer also possesses such beneficial effects in countering cardiovascular heart disease (Chapters XXX). Additionally, beer can positively contribute to a healthy diet providing B vitamins, minerals, antioxidants and fiber. Urologists recommend beer as an ideal beverage to control kidney stones formation. Finally, numerous studies showed the anticancer effects of beer and beer components. Besides these encouraging data, more case-control studies are necessary to fully evaluate the favorable aspects of beer drinking.

Summary Points

- Moderate beer consumption is supposed to be part of a healthy diet.
- From a nutritional point of view, beer is more abundant in proteins (ranging 2.0–4.8 g/l) and vitamins derived from the barley used during its production, compared to wines.
- Beer is a good source of soluble fiber derived from the cell walls of malted barley. A liter of beer contains an average of 20–60% of the recommended daily intake of fiber.

- Phenolic components of wine and beer are quantitatively and qualitatively different because grape contains polyphenols different from those present in barley and hops used in beer production. A generalized radical scavenging activity was observed in most of beer polyphenolic component.
- Beer antioxidant activity is strongly correlated with the total polyphenol content.
- Recent studies revealed many notable properties of bioactive compounds present in hops, that justify the increasing interest of pharmaceutical firms in hops (or derivatives), as a potential source of novel drugs.
- Scientific evidence accumulated over the last years is in agreement with the potential anticancer activities of selected hop-derived beer constituents, such as xanthohumol and isoxanthohumol, and hop bitter acids.

The Absorption and Metabolism of Phenolic Acids from Beer in Man

Mirella Nardini, Fausta Natella, Andrea Ghiselli and Cristina Scaccini National Research Institute for Food and Nutrition Research, Via Ardeatina, Rome, Italy

Abstract

In spite of the wide literature describing the biological effects of phenolic compounds, scarce data are available on their absorption from diet and metabolism in humans. Recently, a renewal interest has been focused on beer, a common beverage with low ethanol content and rich in phenolic compounds, particularly caffeic, vanillic, *p*-coumaric, sinapic, syringic and ferulic acids. In this study, the absorption in humans of phenolic acids from beer was studied. Firstly, a recently developed hydrolytic procedure was applied to quantitatively measure total (free plus bound) phenolic acids in beer. Secondly, we measured plasma concentration of phenolic acids in samples collected before and 30 and 60 min after beer administration in healthy humans. The results obtained show that the most of phenolic acids are present in beer as bound forms and only a small portion can be detected as free forms. Moreover, phenolic acids from beer are absorbed from the gastrointestinal tract and are present in blood after being largely metabolized to the form of glucuronide and sulfate conjugates. The extent of conjugation is related to the chemical structure of phenolic acids, the monohydroxy derivatives showing the lowest conjugation degree and the dihydroxy derivatives showing the highest one.

List of Abbreviations

CAF	Caffeic acid
p-COU	*p*-Coumaric acid
EDTA	Ethylendiaminetetracetic acid
FER	Ferulic acid
HPLC-ECD	High pressure liquid chromatography with electrochemical detection
4-OH-PA	4-Hydroxyphenylacetic acid
SIN	Sinapic acid
SPE	Solid-phase extraction
VAN	Vanillic acid

Introduction

Oxidative stress has been recognized to be involved in several pathological conditions, such as atherosclerosis, diabetes, neurodegenerative diseases, cancer and in the aging. Antioxidants present in our daily diet may afford protection against oxidative-related diseases. In particular, beverages account for a very high proportion of dietary antioxidant intake in the Mediterranean diet (Pulido *et al.*, 2003). Among dietary antioxidants, phenolics are by far the most abundant in human diet. Plant phenolics received particular attention in the past 10 years due to their putative role in the prevention of several human diseases associated with oxidative stress, including atherosclerosis and cancer (Block *et al.*, 1992; Renaud and deLorgeril, 1992; Scalbert and Williamson, 2000). The total polyphenols intake has been reported to be in the order of 1 g/day (Scalbert and Williamson, 2000). For individuals regularly consuming wine, coffee, beer and tea, these beverages are likely to be the major sources of phenolic compounds. Coffee is the main contributor, followed by red wine, fruit juice, beer, tea. A major class of polyphenols is represented by phenolic acids, which are widely distributed in diet, mostly in fruits, vegetables, coffee, wine, beer and olive oil (Herrmann, 1989; Clifford, 1999). The average phenolic acids intake has been reported to be in the order of 200 mg/day within a large range, depending on the nutritional habits (Herrmann, 1989; Clifford, 1999; Scalbert and Williamson, 2000). Phenolic acids occur in food mainly as esterified forms with organic acids, sugar, lipids (Herrmann, 1989). Recently, a renewal interest has been focused on beer, a common beverage rich in phenolic compounds, with low ethanol content. In a previous study we demonstrated that beer is able to increase human plasma antioxidant capacity, probably through its phenolic components (Ghiselli *et al.*, 2000). In this study, the absorption in humans of phenolic acids from beer was studied, focusing on the measurements of plasma concentrations of both free (non-conjugated)

and conjugated forms of phenolic acids. Moreover, a new hydrolytic procedure to measure the total phenolic acids content of beer was successfully applied (Nardini et al., 2002a). Most of the procedures described in the literature to detect bound phenolic acids in food take advantage of alkaline hydrolysis to release bound forms of phenolic acids (Fenton et al., 1980; Krygier et al., 1982; Kozlowska et al., 1983; Maillard and Berset, 1995). However these procedures lead to a considerable loss of several phenolic acids, particularly caffeic acid (Krygier et al., 1982; Maillard and Berset, 1995), which is one of the most abundant phenolic acids in plant-derived food and beverages. The new hydrolytic procedure used allowed the qualitative and quantitative measurement of total (free plus bound) phenolic acids in beer (Nardini and Ghiselli, 2004).

Study Design and Samples Treatments

The study was approved by the Ethical Committee of the National Institute for Food and Nutrition Research. Ten healthy subjects (25–45 years) were recruited. Participants were non-smokers, either non-drinkers or social drinkers (<28 and <14 g ethanol/day, for males and females, respectively). They were asked to avoid coffee, wine, beer, tea and fruit juices the day preceding the experiment. Fasting subjects received 500 ml of beer in combination with 27 g of crackers in the morning. The beer used in this study was an Italian brand containing 4.5% ethanol. The phenolic acids content of crackers, given to avoid undesirable effects of ethanol in fasting conditions, was not relevant with respect to the amount of phenolic acids present in beer. In a subsample of three subjects, 500 ml beer without crackers, or 27 g crackers without beer, were administered in fasting conditions as control. Blood was collected into ethylendiaminetetracetic acid (EDTA)-containing vacutainers before (time 0) and 30 and 60 min after ingestion of beer, crackers or beer plus crackers. Plasma prepared by centrifugation (1,000 × g for 20 min at 4°C) was acidified at pH 3.0 and stored at −80°C.

Plasma samples were treated for phenolic acids extraction essentially as previously described (Nardini et al., 2002b), with minor modifications concerning the source and purity of the enzymes used to hydrolyze conjugated phenolic acids. Aliquots of plasma (1 ml), added with 200 ng o-coumaric acid as internal standard, were deproteinized as previously described (Nardini et al., 2002b), then the dried residues treated according to one of the following four procedures: no hydrolytic treatment, to detect free (non-conjugated) phenolic acids; β-glucuronidase treatment, to hydrolyze glucuronide conjugates; sulfatase treatment, to hydrolyze sulfate conjugates; sequential β-glucuronidase–sulfatase treatment, to hydrolyze glucuronide, sulfate and sulfoglucuronide conjugates.

Plasma non-conjugated phenolic acids

The dried residue from deproteinization was extracted with ethyl acetate as already reported (Nardini et al., 2002b). The residue obtained after extraction was dissolved in 0.5 ml water, vortexed for 5 min, the pH brought to 7–8 with NaOH and loaded on a LC-SAX tube (Supelco, Bellefonte, PA, USA) for solid-phase extraction (SPE). After washing with 1 ml water, phenolic acids elution was eluted with 1 ml of buffer containing 1N acetic acid/methanol (90:10). The eluant was brought to pH 3.0, filtered and aliquots analyzed by high pressure liquid chromatography with electrochemical detection (HPLC-ECD). This procedure allows the detection of free, non-conjugated phenolic acids in plasma sample.

Plasma glucuronides

The dried residue obtained by deproteinization was dissolved in 0.5 ml 0.2M K-phosphate buffer pH 6.8, vortexed for 5 min then incubated at 37°C for 2 h with 776U β-glucuronidase (EC 3.2.1.31, type IX A from E. coli). At the end of incubation, the pH was brought to 3.0, 300 mg NaCl added and the sample was extracted as already described (Nardini et al., 2002b). The final residue was suspended in 0.5 ml water and processed for SPE as above described. This procedure allows the measure of free plus glucuronide conjugates of phenolic acids present in plasma sample. The amount of glucuronides was calculated by subtracting the value of free, non-conjugated phenolic acids obtained with the above reported procedure.

Plasma sulfates

The dried residue obtained by deproteinization was dissolved in 0.5 ml of 0.1M Na-acetate buffer pH 5.0, vortexed 5 min then incubated at 37°C for 2 h with 70U sulfatase (type H-1 from Helix pomatia, containing β-glucuronidase) and 26 mM D-saccharic acid 1,4-lactone monohydrate, an inhibitor of β-glucuronidase. At the end of incubation, the pH was brought to 3.0, 300 mg NaCl added and the sample was extracted as already described (Nardini et al., 2002b). The final residue was resuspended in 0.5 ml water and processed for SPE as above described. This procedure allows the measure of free plus sulfates conjugates of phenolic acids present in plasma sample. The amount of sulfates was calculated by subtracting the value of free, non-conjugated phenolic acids obtained with the above reported procedure.

Plasma total phenolic acids

The dried residue obtained by deproteinization was dissolved in 0.5 ml 0.2M K-phosphate buffer pH 6.8, vortexed for 5 min then incubated at 37°C for 2 h with 776U

β-glucuronidase (EC 3.2.1.31, type IX A from *E. coli*). At the end of incubation, the pH was brought to 5.0 with HCl and sample incubated at 37°C for 2 h with 70 U sulfatase (type H-1 from Helix pomatia, containing β-glucuronidase). After incubation, the pH was brought to pH 3.0 with HCl, 300 mg NaCl added and sample extracted as already described (Nardini *et al.*, 2002b). The final residue was resuspended in 0.5 ml water and processed for SPE as above described. This procedure allows the measure of total phenolic acids (non-conjugated, glucuronides, sulfates and possible mixed sulfate/glucuronide conjugates) present in plasma sample. For each single phenolic acid, the amount obtained with this incubation, subtracted the amount of the respective non-conjugated form, glucuronides and sulfates derivatives obtained with the above reported procedures, should represent the amount of mixed sulfate/glucuronide conjugates in the sample.

Beer treatment for phenolic acid extraction

Beer samples were degassed by sonication and treated for free (non-hydrolyzed samples) and total (free plus bound, hydrolyzed samples) phenolic acids determination.

For free phenolic acids measurements, beer (0.5 ml) was added with 1 μg isoferulic acid as internal standard, acidified at pH 3.0 and added with 300 mg NaCl. Samples were extracted three times with ethyl acetate (4 × vols) by 5 min vortexing. After each extraction samples were centrifuged and supernatant collected. The pooled organic phases were dried under nitrogen flow. The residue was dissolved in methanol and diluted with sample buffer (1.25% glacial acetic acid, 7% methanol in water) prior to HPLC-ECD analysis. For total phenolic acids measurements, beer (0.5 ml) was subjected to alkaline hydrolysis with 4.5 ml 2N NaOH containing 10 mM EDTA and 1% ascorbic acid, in the presence of 1 μg isoferulic acid as internal standard. After incubation at 30°C for 30 min, 0.5 ml aliquot was acidified to pH 3 with HCl, added with 300 mg NaCl and extracted as above reported. Phenolic acids recovery, performed by adding known amounts of pure phenolic acids to beer samples (protocatechuic, vanillic, caffeic, syringic, *p*-coumaric, ferulic, sinapic, *o*-coumaric, 4-hydroxyphenylacetic acids, as representative of beer phenolics), was found to be in the range of 95.4–104.0% and 94.0–102.9% in non-hydrolyzed and hydrolyzed beer samples, respectively. Further, the addition of known amounts of chlorogenic acid to beer samples resulted in the almost complete recovery of caffeic acid released upon hydrolysis (98.7 ± 4.3% of expected value).

HPLC instrumentation

The HPLC consists of a Perkin-Elmer Series 4 Liquid Chromatograph (Perkin-Elmer, Norwalk, CT, USA) with a gradient pump, column thermoregulator and autosampling injector (Gilson, Beltline, Middleton, WI, USA) equipped with an electrochemical coulometric detector (Coulochem II, ESA, Bedford, MA, USA). Turbochrom chromatography workstation software was used for data processing. Operating conditions were as follows: column temperature, 30°C; flow rate, 1 ml/min; ECD at +600 mV; sensitivity range 100–200 nA. Chromatographic separation was performed on a Supelcosil LC-18 C_{18} column (5 μm particle size, 250 × 4.6 mm i.d.) including a C_{18} guard column (Supelco, Bellefonte, PA, USA). For gradient elution mobile phases A and B were employed. Solution A contained 1.25% glacial acetic acid in water; solution B was absolute methanol. For beer samples analyses the following gradient was used: 0–25 min, from 98%A, 2%B to 76%A, 24%B, linear gradient; 26–45 min, 76%A, 24%B; 46–53 min, from 76%A, 24%B to 55%A, 45%B, linear gradient; 54–55 min, 55%A, 45%B; 56–86 min, 98%A, 2%B. For plasma samples analyses the following gradient was used: 0–25 min, from 93%A, 7%B to 76%A, 24%B, linear gradient; 26–45 min, 76%A, 24%B; 46–53 min, from 76%A, 24%B to 55%A, 45%B, linear gradient; 54–55 min, 55%A, 45%B; 56–86 min, 93%A, 7%B. Prior to HPLC analysis, all samples were filtered using Millex-HV filters (Millipore) with 0.45 μm pore size. Stock solutions of standard phenolic acids prepared in methanol (1 mg/ml) were stored at −80°C and used within 1 week. Working standard solutions were prepared daily by dilution in sample buffer (1.25% glacial acetic acid, 7% methanol in water).

Data evaluation, quantitation and statistical analysis

For calibration curve, appropriate volumes of the stock standard solutions were diluted with sample buffer. Three replicates of standards at four concentration levels (20, 100, 200 and 500 ng/ml) were analyzed. For quantitative determination, peak areas in the sample chromatogram were correlated with the concentrations according to the calibration curve. Data presented are means ± SD or SE as specified. Statistical analysis was performed by a one-factor analysis of variance (ANOVA, Scheffe's method) for multiple comparison or paired *t*-test as specified. Probability of $p < 0.05$ was considered statistically significant.

Results

Phenolic acids in beer

Beer contains appreciable amounts of several phenolic acids whose chemical structures are shown in Figure 48.1. Figure 48.2 shows the beer content of both free and total (free plus bound) phenolic acids and their derivatives. 4-Hydroxyphenylacetic acid and *p*-coumaric acid were present in beer mainly as free, unbound forms (76.2% and 69.8% of the total, respectively). A moderate increase of

Hydroxycinnamic acids	R_1	R_2
p-Coumaric	H	H
Caffeic	OH	H
Ferulic	CH_3O	H
Sinapic	CH_3O	CH_3O

Benzoic acid derivative	R_1	R_2
Vanillic	CH_3O	H
Figure 48.1 Chemical structures of the main phenolic acids present in beer. Caffeic acid: 3,4-dihydroxycinnamic acid; ferulic acid: 4-hydroxy-3-methoxycinnamic acid; vanillic acid: 4-hydroxy-3-methoxybenzoic acid; p-coumaric acid: 4-hydroxycinnamic acid; sinapic acid: 3,5-dimethoxy-4-hydroxycinnamic acid.
Figure 48.2 Phenolic acids content of beer before and after hydrolysis. Phenolic acids content was measured in non-hydrolyzed samples and in samples submitted to alkaline hydrolysis as reported in Methods section. Values are expressed as mg/l of beer and represent means ± SD (n = 3). 4-OH-PA, 4-hydroxyphenylacetic acid; VAN, vanillic acid; CAF, caffeic acid; p-COU, p-coumaric acid; FER, ferulic acid; SIN, sinapic acid. *Values are significantly different from those measured in non-hydrolyzed samples (p ≤ 0.05 by ANOVA).

these compounds after hydrolysis was observed. Differently, the amount of vanillic, caffeic, ferulic and sinapic acids dramatically increased (≥100% of the value measured in non-hydrolyzed samples) in hydrolyzed beer in the respect of non-hydrolyzed samples. Caffeic, ferulic and sinapic acids were present in beer mainly as conjugated forms, the free and non-conjugated forms amounting to 18.6%, 17.3% and 7.8% of total, respectively. Vanillic was present in beer

equally as bound and free forms, the latter amounting to 52.5% of total. The content of free phenolic acids measured in our beer is in agreement with data reported in the literature (Hayes *et al.*, 1987; Achilli *et al.*, 1993; Shahidi and Naczk, 1995; Gorinstein *et al.*, 2000). Ferulic acid was by far the most abundant phenolic acid in beer.

Absorption of phenolic acids from beer in humans

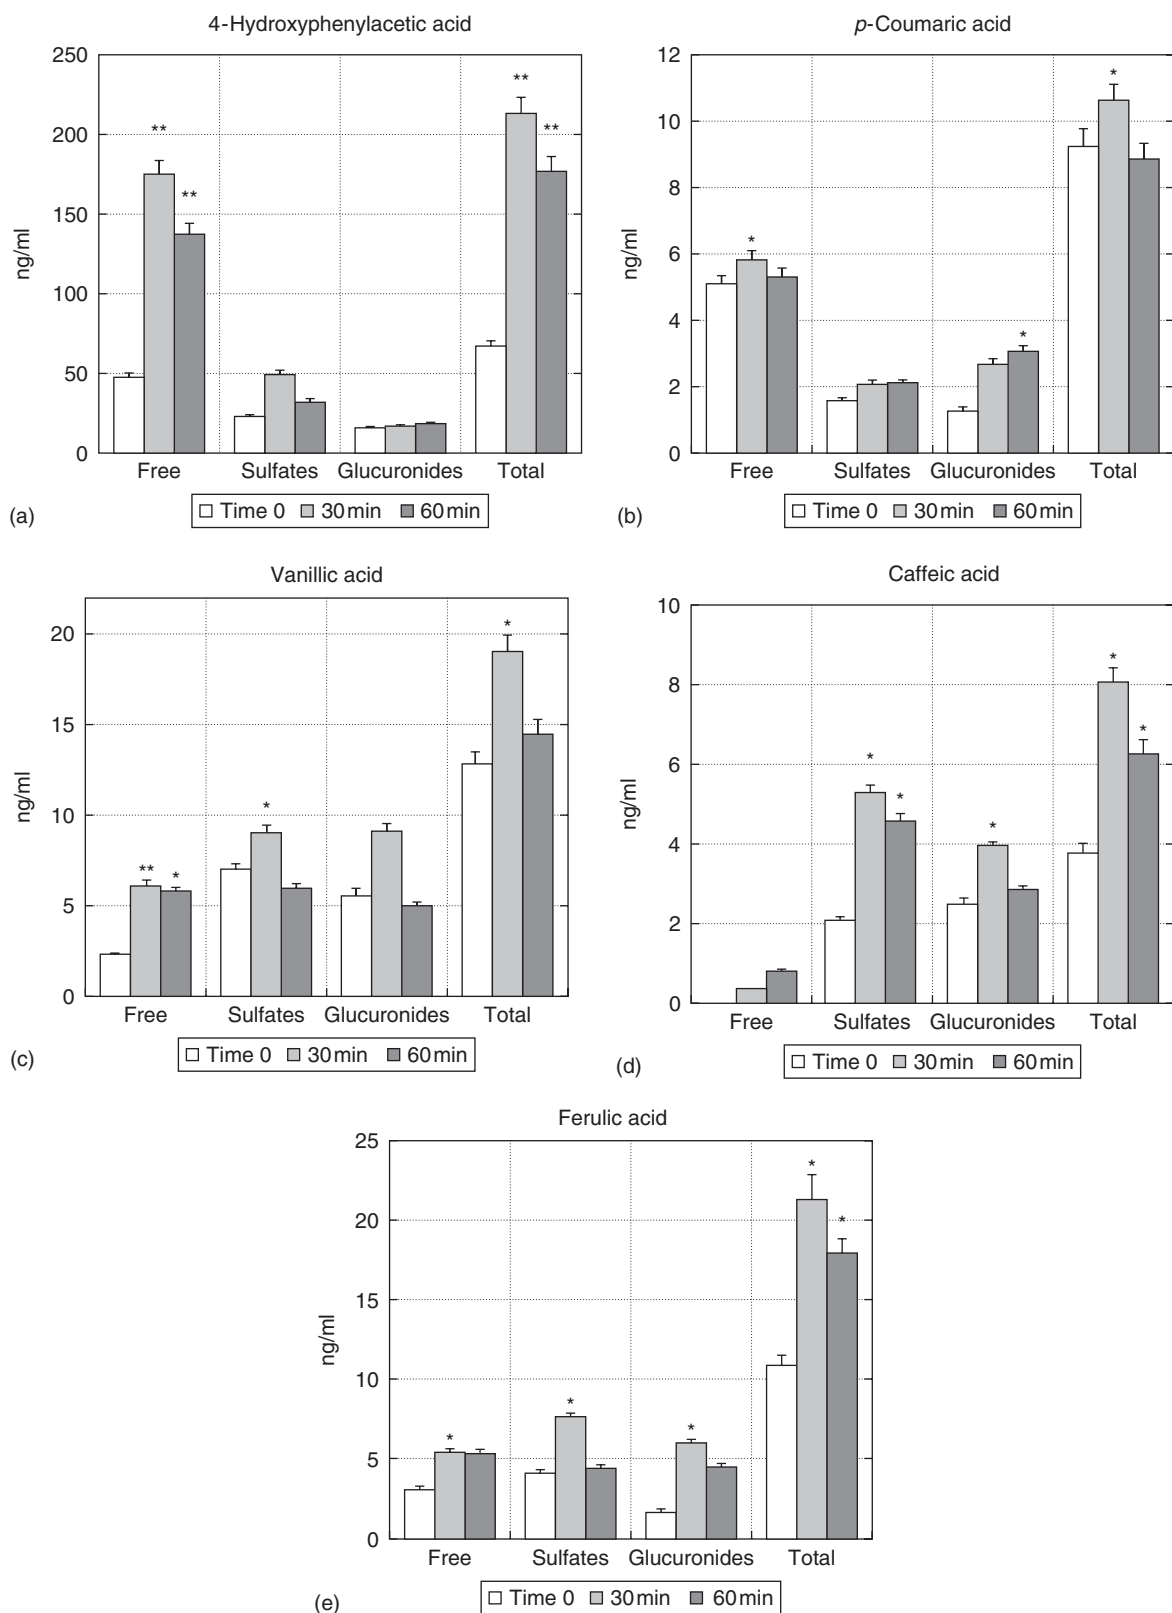
To study the absorption of phenolic acids from beer, plasma samples were collected before and after beer plus crackers administration and analyzed for phenolic acids content, both as free (non-conjugated) and conjugated forms. The different procedures applied allowed the detection of non-conjugated phenolic acids, glucuronide conjugates, sulfate conjugates and total phenolic acids (non-conjugated + glucuronide conjugates + sulfate conjugates + sulfoglucuronide conjugates). Beer plus crackers administration resulted in a fast, significant increase of phenolic acids concentrations in plasma. The concentration of total 4-hydroxyphenylacetic acid increased three- to fourfold at both 30 and 60 min with respect to time 0, the free, non-conjugated forms amounting to 70.8%, 82.2% and 77.4% of total at time 0, 30 and 60 min, respectively (Figure 48.3a). A slight, not significant increase in the concentration of sulfate conjugates was measured at 30 and 60 min, with respect to time 0. Non-conjugated and total p-coumaric acid significantly increased 30 min after beer and crackers administration with respect to time 0, the non-conjugated form amounting to 54.4%, 54.7% and 59.5% of total at time 0, 30 and 60 min, respectively (Figure 48.3b). Glucuronate derivatives of p-coumaric acid significantly increased at 60 min after ingestion with respect to time 0, while no significant change was observed for sulfate conjugates at any time after ingestion. A significant increase in non-conjugated form, sulfate conjugates and total vanillic acid was observed at 30 min after beer plus crackers administration with respect to time 0, while a slight, not significant increase in the glucuronate conjugates was observed at 30 and 60 min with respect to time 0. Differently from 4-hydroxyphenylacetic and p-coumaric acids, vanillic acid was present in plasma mainly as conjugated forms, the non-conjugated forms amounting to 17.2%, 31.6% and 39.3% of total at time 0, 30 and 60 min, respectively (Figure 48.3c). The most of caffeic acid was present in plasma as sulfate and glucuronate derivatives, the non-conjugated forms amounting to 0%, 4.4% and 12.7% of total at time 0, 30 and 60 min, respectively (Figure 48.3d). In particular, a significant increase in sulfate and glucuronate conjugates and total caffeic acid was observed at 30 min after beer plus crackers administration with respect to time 0, while at 60 min a significant increase in sulfate conjugates and total caffeic acid was measured with respect to time 0. A significant increase in non-conjugated form, sulfate conjugates, glucuronate


Figure 48.3   Plasma phenolic acids levels in 10 different subjects before and after beer plus crackers administration. Plasma samples separated from blood collected just before (time 0) or after (30 and 60 min) beer plus crackers administration were analyzed for non-conjugated and conjugated phenolic acids as reported in Methods section. (a): 4-hydroxyphenylacetic acid; (b): *p*-coumaric acid; (c): vanillic acid; (d): caffeic acid; (e): ferulic acid. Values are means $\pm$ SE. *p $\leqslant$ 0.05; **p $\leqslant$ 0.01 with respect to time 0 by paired *t*-test.

conjugates and total ferulic acid was measured at 30 min after beer plus crackers administration with respect to time 0, the non-conjugated form amounting to 27.8%, 25.2% and 29.0% of total at time 0, 30 and 60 min, respectively (Figure 48.3e). Total ferulic acid was also significantly higher at 60 min after ingestion with respect to time 0.

We failed to quantitatively measure sinapic acid in plasma due to both the low amount present in the samples and the interference from other unidentified components in the chromatograms.

Administration of crackers alone did not result in any significant increase of plasma phenolic acids concentrations at 30 and 60 min after ingestion with respect to time 0. Further, administration of beer alone resulted in plasma phenolic acids levels similar to those obtained after beer plus crackers ingestion in three different subjects (data not shown).

Discussion

The results obtained show that phenolic acids from beer are rapidly absorbed and circulate in human plasma as both free and conjugated forms, mainly glucuronates and sulfates. The fast absorption of phenolic acids, with a maximum peak at 30 min, suggests that it could take place in the proximal part of the intestine. Due to the presence of both free and bound forms of phenolic acids in beer, plasma circulating phenolics might be derived from the direct absorption of the free forms present in beer, by *in vivo* hydrolysis of the bound forms present in beer as well, or both. In the past, conjugated forms of phenolic compounds, although widely present in our diet, were considered not bioavailable in humans. However, more recently phenolic acids have been described to be absorbed from their bound forms present in food, both in humans and in rats (Azuma *et al.*, 2000; Andreason *et al.*, 2001a, b; Rechner *et al.*, 2001; Nardini *et al.*, 2002b; Lafay *et al.*, 2006). Esterases with the ability to hydrolyze hydroxycinnamate esters at appreciable rates have been described in humans and rats (Andreason *et al.*, 2001a). The cinnamoyl esterase activity is distributed all along the small and large intestine and it is present both in the mucosa and in the lumen. Moreover, bacteria in the gastrointestinal tract of mammals are also capable of releasing free phenolic acids from their bound complexes (Buchanan *et al.*, 1996; Kroon *et al.*, 1997; Wende *et al.*, 1997; Plumb *et al.*, 1999; Andreason *et al.*, 2001b; Couteau *et al.*, 2001). Both glucuronidation and sulfation occur at various extents during absorption of phenolic acids from beer. Glucuronidation and sulfation are two well-known ways of detoxification leading to increased solubility of compounds to promote their excretion. The most of 4-hydroxyphenylacetic acid was present in plasma as non-conjugated form ($>70\%$) and this is in agreement with the hydrophilic feature of this compound, due to the presence of a polar acetyl group and one hydroxyl group on the

aromatic ring. *p*-Coumaric acid, which possesses a propenoic side chain and an hydroxyl group on the aromatic ring, was present as free, non-conjugated form at levels lower than that observed for 4-hydroxyphenylacetic acid (54–59% of the total), but considerably higher than those observed for ferulic, vanillic and caffeic acids, which instead circulate mainly as conjugated forms, with a slight prevalence of sulfates with respect to glucuronate forms. The presence of a methoxyl group in addition to the hydroxyl group on the aromatic ring of both vanillic acid and ferulic acid decreases their hydrophilicity, with respect to both 4-hydroxyphenylacetic acid and *p*-coumaric, and may account for the extensive conjugation observed (61–83% of the total for vanillic acid; 71–75% of the total for ferulic acid). Similar results have been obtained after ferulic acid administration in rats, with plasma levels of conjugated ferulic acid amounting to 76% of the total ferulic acid (Rondini *et al.*, 2002). Caffeic acid, in spite of the two hydroxyl groups in the ortho position on the aromatic ring, was present in plasma almost exclusively as conjugated forms (87–100% of the total) with a prevalence of sulfates with respect to glucuronates. A similar result has been obtained for plasma caffeic acid after coffee drinking in humans (Nardini *et al.*, 2002b). Our results demonstrated that once absorbed from beer, phenolic acids are extensively conjugated to sulfates and glucuronates. Likely, the differences in the extent of conjugation are related to the different chemical features of phenolic acids and may reflect differences in the activity and specificity of both glucuronosyltransferases and sulfotransferases enzymes toward different phenolic acids. From our results, the monohydroxy derivatives showed the lowest degree of conjugation and the dihydroxy derivative showed the highest one, while the 3-methoxy-4-hydroxy derivatives (vanillic and ferulic acids) fell in the middle. On this regard, the evidence that caffeic acid circulates in human plasma almost exclusively as conjugated forms, particularly sulfate, may be explained by the high activity of intestine sulfotransferase SULT1A3 on catechol group (3,4-dihydroxy moiety) (Scalbert and Williamson, 2000). Moreover, human intestine glucuronosyltransferases appeared to be especially effective in conjugating the catechol unit. Since the antioxidant action as well as the prooxidant toxicity of caffeic acid is mainly related to its catechol unit (Shahidi and Wanasundara, 1992; Nardini *et al.*, 1995), it is of interest to note that the conjugating enzymes in human intestine seem to be especially active in conjugating this structure. This would imply that during the transport across the intestinal border, the catechol-type phenolic compounds might loose a significant part of their biological activity, due to glucuronidation and sulfation. Regarding the effect of the carbon side chain on the degree of conjugation, only minor differences were observed between ferulic acid, with a propenoic side chain, and vanillic acid, endowed with a carboxylic side chain. *p*-Coumaric acid, with a propenoic side chain, was conjugated to a higher degree with respect to

4-hydroxyphenylacetic acid, endowed with an acetyl group instead of the propenoic chain. From our data, mixed sulfate/glucuronide conjugates are present, if any, at very low levels, being the amount of total phenolic acids measured not significantly different from the theoretical amount calculated by addition of non-conjugated, glucuronide and sulfate conjugates.

The most relevant conclusion of our study is that the plasma concentration of conjugated forms of vanillic, ferulic and caffeic acids largely exceeds that of free, non-conjugated forms. While the biological activity of phenolic acids has been widely studied and described in the literature in the last decade, scarce or no data are available on the potential biological activity of their metabolites. Indeed, glucuronidation and sulfation might affect the biological activity of the parent free, non-conjugated compounds. As mentioned above, the conjugation of the catechol unit might result in a partial lost of biological activity for those phenolics endowed with a 3,4-dihydroxy unit. It has been described that quercetin glucuronides and quercetin 3-O-sulfate still retain antioxidant activity, although to a less degree with respect to non-conjugated quercetin (Manach *et al.*, 1998). Ferulic acid glucuronide, endowed with a sugar moiety beside the hydrophobic ferulic acid unit, showed an antioxidant activity stronger than that of ferulic acid (Ohta *et al.*, 1997).

From our results, plasma concentration of phenolic acids ranged between 0.05 and 0.07 μM for caffeic acid and *p*-coumaric acid and reached 0.11 μM for vanillic and ferulic acid at 30 min after beer plus crackers administration. 4-Hydroxyphenylacetic acid reached higher concentration in plasma in respect to the other phenolic acids, amounting to 1.40 and 1.17 μM at 30 and 60 min, respectively. 4-Hydroxyphenylacetic acid is a metabolite of tyrosine other than of various phenolic compounds (Mani *et al.*, 2003) and a discrete amount of tyrosine is present in beer (Pulido *et al.*, 2003). Hence, plasma 4-hydroxyphenylacetic acid might be derived either from the absorption of 4-hydroxyphenylacetic acid present in beer as such, or from the post-absorption metabolism of phenolic acids and tyrosine contained in beer as well. Noteworthy, no appreciable increase in plasma concentration of 4-hydroxyphenylacetic acid and other phenolic acids was observed at 30 and 60 min after ingestion of crackers alone with respect to time 0. Although the plasma concentrations of phenolic acids measured seem quite low, it must be kept in mind that they were obtained after a single administration of 500 ml beer, containing about 10 mg of the phenolic acids under study. This value is quite far from the average daily intake of phenolic acids, which has been calculated in the order of 200 mg/day (Herrmann, 1989; Scalbert and Williamson, 2000).

Synergistic effects might also occur *in vivo*. Further, an accumulation of phenolic acids and their metabolites might occur in many tissues (lung, heart, liver) as reported for 3-palmitoyl-catechin, epigallocatechin gallate and resveratrol (Das and Griffiths, 1969; Bertelli *et al.*, 1996; Suganuma *et al.*, 1998).

The antioxidant and biological activity of the metabolites of phenolic acids with respect to the parent compounds and possible synergistic interactions *in vivo* need to be investigated.

Summary Points

- Dietary antioxidants afford protection against oxidative-related human diseases, such as atherosclerosis, aging and cancer.
- Plant phenolics are by far the most abundant dietary antioxidants.
- Beer is a common beverage rich in phenolic compounds, mainly phenolic acids (caffeic, ferulic, vanillic, *p*-coumaric, 4-hydroxyphenylacetic acids).
- The content of phenolic acids has been quantitatively measured in beer, taking advantage of a specific hydrolytic procedure.
- Phenolic acids from a single beer administration are absorbed and extensively metabolized in man. Phenolic acids and their metabolites are found in human plasma at concentrations ranging from 0.05 to 1.4 μM within 1 h from beer drinking.

Caloric Compensation in Response to Beer Consumption

Neil E. Rowland Department of Psychology, University of Florida, Gainesville, FL, USA

Abstract

Excessive caloric intake, leading to obesity and associated metabolic diseases, is one of the most urgent health care problems facing many nations with post-industrial economies. In this chapter, we discuss critically the premise that caloric intake is in fact regulated, and the ways in which calories in liquid beverages including beer may or may not be offset by compensatory reductions in food intake.

List of Abbreviations

kcal   Kilocalorie
NA   Non-alcoholic
ml   Milliliter

Introduction

It is generally acknowledged that ingestion of food and water is under the joint control of factors internal and external to the organism.

So reads the opening sentence of an insightful theoretical review written by Toates (1981). And now we find ourselves a quarter century downstream, awash in an obesity epidemic. Environmental factors are often ignored *viz*: "Although environmental factors contribute to changes in the incidence of obesity over time, individual differences in weight are largely attributable to genetic factors" (Friedman, 2004). Others believe that the environment has a much more influential role, but as Astrup *et al.* (2004) note, exactly which environmental factors can or do have an effect on body weight in free-living average humans are not clear.

The incidence of obesity in the human population, defined by the body mass index, is a threat to the health and health prospects of individuals in many nations ranging from post-industrial like the United States to the Pacific Islands in which the traditional lifestyle has been transformed almost overnight (Shell, 2002). While ethnic and presumptive genetic factors are of some importance, the increased incidence of obesity in countries of long-standing adequacy in the public food supply is of great concern and is almost certainly due to environmental pressures. So how has our food world changed in the past 25 years? I see three major types of change:

1. Easier or more continuous food availability, for example vending machines, "TV dinners."
2. Increased caloric yield, as fat content or portion size, of popular fast or junk foods.
3. Increased consumption of beverages containing calories, especially soft drinks.

Beer is, of course, also a caloric beverage and in this chapter I will consider the effects of beer within the context of overall caloric consumption and possible weight gain.

Homeostasis

The word homeostasis was introduced by Canon in the 1920s to describe the ensemble of physiological mechanisms that underlie the observed state of relative constancy found in many physiological measurements in healthy people and animals. In modern medicine, blood tests are common and substantial deviations from these norms are used to diagnose illness. Canon recognized that the concentrations of some of these substances seem tightly regulated – for example, deviations in blood sodium concentration of only a few percent are lethal – and others such as blood glucose have a much wider allowed range. However, the idea that these systems have ideal or average values (also known as set points) that are actively defended was intuitively appealing and was widely applied.

In the case of food intake, two major theories were advanced about 50 years ago. These are the glucostatic (Mayer, 1953) and the lipostatic (Kennedy, 1953) hypotheses. Both recognized two essential points. First, since food intake in most species occurs as meals or episodically then the rate at which digested food is entering the body will fluctuate from very high just after a meal to zero during a prolonged fast. Second, the needs of our tissues for metabolic fuels are continuous; even when we are at rest or asleep, our brain, heart, kidneys, and many other tissues consume energy at a rate only slightly slower than when we are awake and active. To manage this physiological problem, the body has internal stores of energy which serve as buffers. Soon after a meal, nutrients are entering the body faster than the tissues need energy, so the excess is stored as fat or glycogen. Hours after a meal or during fasting, nutrients are no longer entering, so fat or glycogen stores are mobilized to meet the fuel needs. This is in many ways similar to the way most of us try to manage our money: we are paid episodically but have continuous expenses so we use a bank or credit account as a buffer. Mayer and Kennedy realized that for this to work in the realm of energy balance, the body must have mechanisms to sense either circulating and/or stored energy status. Mayer (1953) focused on blood glucose level as a correlate that these sensors could use to assess energy status (i.e. body weight), while Kennedy (1953) focused on overall regulation of body fat. Fat is by far the largest energy stored in the body and changes in the body weight of adults reflect mostly changes in body fat mass.

These theories are fundamentally homeostatic insofar as deviations of correlate(s) of body weight from a biologically programmed range initiate proportional corrective changes in feeding behavior and energy expenditure to bring the weight back to that range. Numerous blood-borne correlates of weight and feeding, as well as many direct neural pathways, have since been discovered and studied as candidate mechanisms by which the brain can be appraised of peripheral nutrient status and adjust behavior (for reviews, see Schwartz *et al.*, 2000; Berthoud, 2002).

The problem is this: if homeostasis were a powerful mechanism, then none of us would be obese and we would maintain the same weight throughout our adult lives. Unfortunately, this does not seem to be the case. What is true is that if energy (measured in joules or kilocalories where 1 kcal = 4.2 J) consumed over a representative period of time exceeds energy expenditure (metabolism, muscular effort, etc.) over the same time then most or all of the excess calories will end up stored as fat. And even a very small error in balancing this equation over time will add up to a lot of fat! There have been many studies performed to examine constancy of caloric intake over time, and in particular what factors produce poor regulation of overall intake. Note that in the homeostatic model level of exercise is irrelevant because increases or decreases in energy expended should automatically produce parallel changes in

food consumption. This also does not seem to be the real state of affairs, but discussion of this is beyond the scope of the present chapter. In the present chapter, I will consider specifically the compensation for liquid calories, including alcohol and beer.

Laboratory Animal Experiments

Behavioral experiments in animals can tell us a lot about the physiological capabilities of the systems that produce feeding but without the high level social and cognitive factors that are additionally prominent in human consumption. The studies I will report below all use rats; their advantages include availability of domesticated strains with genetic homogeneity, and that their omnivorous style of feeding behavior and digestive systems are similar to humans.

Sugar solutions

Many investigators have shown that providing rats with a concentrated solution of a sweet sugar in addition to their standard maintenance chow diet produces obesity. A typical result from Ackroff and Sclafani (1988) is shown in Figure 49.1. In this experiment, two groups of adult female rats were fed chow (11% fat, 26% protein, 63% carbohydrate, in powdered form) or chow plus a bottle of concentrated sucrose solution (32%) for 30 days. These were both freely available at all times, along with water. Figure 49.1 shows that the group with sucrose consistently consumed approximately 25% more calories than the chow group, and as a result gained about four times as much weight. These rats were initially ~240 g, so the weight gain in the sucrose group represents almost a 1% increase in body weight per day, with no signs of slowing. These investigators also reported the separate intakes from chow and sucrose. The sucrose group decreased their intake of chow by about 75% relative to chow only controls, a decrease of some 60 kcal per day, but their 80 kcal per day intake of sucrose led to a net increase in calories consumed. Another way of stating this is that their compensatory reduction in chow intake was about 0.75 kcal per kcal of sucrose consumed.

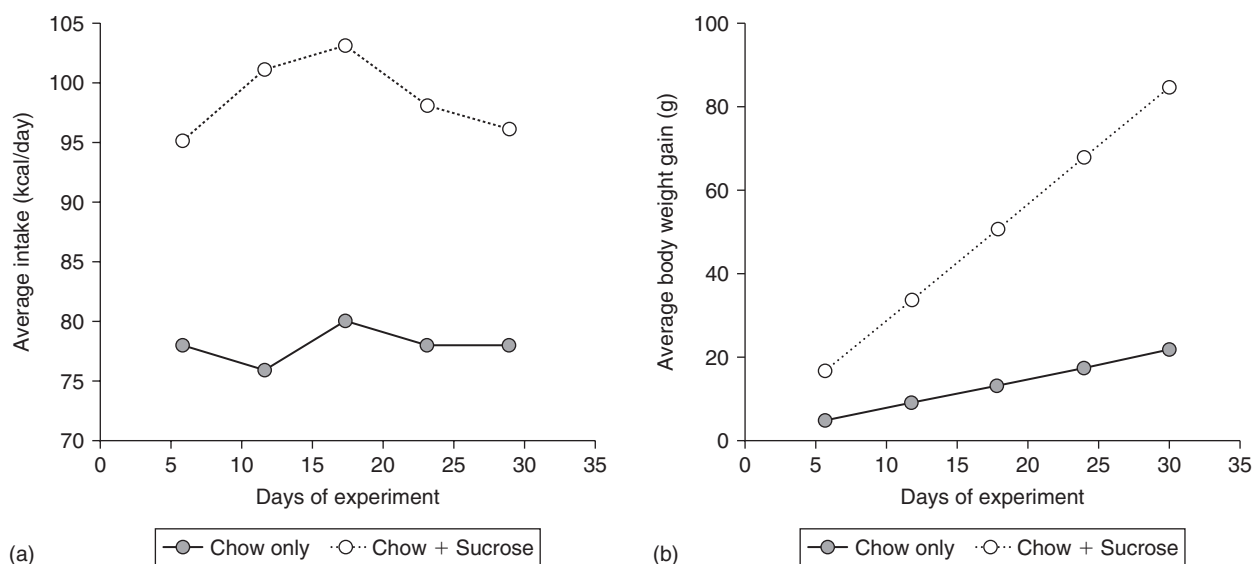
It could be argued that the rats were forced into this situation because they have to eat at least some chow to get essential protein and minerals, but an important counterargument is that the animals were under no obligation to consume any sucrose. Similar results are seen with other maintenance diets and using solutions or gels of other carbohydrates (reviewed by Sclafani, 1987). More important is the observation that giving rats a similar choice but with the sucrose (or other pure sugars) in a solid or powdered form does not produce overeating and subsequent weight gain (Sclafani, 1987; Sclafani *et al.*, 1988). Thus, sugars that are in concentrated solution or hydrated gels seem to selectively override normal mechanisms that regulate caloric


Figure 49.1 (a) Left panel shows average daily energy intake (kcal) of rats fed chow only (filled symbols) or with access to chow and a 32% solution of sucrose (open symbols). (b) Right panel shows the mean weight gain from initial during the course of the study by the rats in these two dietary conditions. The intakes and weight gains were significantly higher in the sucrose + chow condition. *Source*: These graphs are redrawn from data in Figures 1 and 2 in Ackroff and Sclafani (1988).

intake. This effect is often ascribed to the sweet taste and high palatability of these commodities.

Beer

Beer is a complex solution containing several carbohydrates, a small amount of protein, and numerous trace compounds including polyphenols, flavonoids, and isohumulones (e.g. Yajima *et al.*, 2005; Jastrzebski *et al.*, 2007), and alcohol typically around 5% by volume. The carbohydrates alone impart a partly sweet flavor, but the isohumulones in particular impart the characteristic bitter component. Alcohol alone also has a slightly unpleasant taste. Thus, experiments using beer in rats cannot be interpreted easily in terms of overall sweet or bitter taste. The component of alcohol can largely be removed by using non-alcoholic (NA) beer which has also been termed near-beer, although I will use the term NA beer.

Richter (1953) was the first to report the intake of beer in rats. The beer in his study was reported to be 4.4% by volume ethanol and 4.0% sugars and dextrins. Male rats had free access to dry McCollum diet (a forerunner of today's chows) and either water or beer. When water was available, during the initial phase, their daily intake was ~30 ml, but when beer only was available their intake rose over weeks from ~40 to ~70 ml/day. They also showed a concurrent reduction in food intake of ~1 kcal per kcal beer consumed, and as a result their weight gain was normal.

Richter (1940) earlier had found similar results for caloric compensation using plain ethanol solutions, results repeated more comprehensively by Cornier *et al.* (2002). The overall conclusion is that rats will consume large

Table 49.1 Approximate energy content of NA and alcoholic beer

Beverage	kcal/ml	Fraction of calories contained as alcohol
NA beer[a]	0.21	<10
NA beer + 5% by volume ethanol[b]	0.45	57
NA beer + 10% by volume ethanol	0.71	73

[b] A 5% by volume ethanol solution is ~4% by weight ethanol.

amounts of alcohol, and notably beer, when it is the only fluid available and at least over several weeks show no increase in weight gain. Rats often consume in excess of 25% of their body weight per day in beer and as a result exhibit signs of intoxication (Lancaster *et al.*, 1987; see McGregor and Gallate, 2004, for review). McGregor and Gallate have also shown that rats will show beer-motivated behavior, for example, by licking a spout many times to obtain a small drop of beer.

We have used a protocol in which beer consumption was voluntary rather than forced (Rowland *et al.*, 2005). In our study, adult male and female rats were given continuous access to powdered rat chow from a jar in their home cage. In the first phase of the study, only water was available to drink, and intakes were measured over several days. In the second phase, the rats received chow and a choice of water and NA beer (Table 49.1). And in the last two phases of the experiment, 5% and 10% by volume ethanol was added to
Figure 49.2 (a) Left panel shows the mean daily volume of NA beer with either 0%, 5%, or 10% added alcohol in adult male and female Sprague–Dawley rats. Each bar is the average of 4 days of data collection and five to six animals. (b) The right panel shows the number of kilocalories estimated to be contained in that beer. The rats also had free access to chow and water, but those intakes are not shown. *Source*: These graphs are redrawn from data in Table 1 and Figure 1 of Rowland *et al.* (2005).

the beer. Food intake was measured daily, but there were few changes across days, so the intakes for each phase were averaged and are shown in Figure 49.2. During the water only phase, rats consumed 40–50 ml water. When NA beer was also available, they consumed almost three times this volume per day. Even though the caloric density of NA beer is low, the high volume consumed ensured that almost 30% of their normal caloric intake came from the fluid. Concurrently, they reduced food intake, slightly more accurately in males than in females. When alcohol was added to the beer (5% is close to an average beer), volume intakes dropped dramatically, and the calories became only a small fraction of the total intake. Nonetheless, caloric compensation was accurate. These findings are consistent with the result of Lancaster *et al.* (1987) in which rats voluntarily drinking beer initially ate more but later ate less than control rats with no beer, but there were no group differences in body weight.

Although water intake was not measured in our published study (Rowland *et al.*, 2005), in a pilot study we did measure concurrent intakes of water and NA beer, and NA beer with 5% or 10% alcohol added. The preferences for beer over water are shown in Figure 49.3, along with results that were obtained in a similar protocol by Samson *et al.* (1998). In both cases, the preference for NA beer was attenuated as alcohol was added, although the slope was steeper in our study. There were some procedural differences that might account for this including the fact that Samson *et al.* used young male rats while we used older and heavier males as well as females. Also, the brand of NA used was different (O'Doul's by Samson *et al.* and Coors in our work) and in very preliminary tests we found that rats drank more NA Coors than O'Doul's – which is why we used Coors in our published studies.
Figure 49.3 Intakes of beer relative to concurrently available water, expressed as % of total intake from beer; as a function of the amount of alcohol added to NA beer. *Source*: Shown are data redrawn from Samson *et al.* (1998) and unpublished data (2003) from a similar study from our laboratory.

In additional studies, to try to increase the amount of ethanol consumed, we mixed alcohol with a sweet vehicle (Polycose® comprised of oligosaccharides) in either a liquid or a gel form (Rowland *et al.*, 2005). This did increase caloric intake, but the calories so consumed were accurately compensated by reductions in chow intake. Body weights were not recorded routinely in these studies, but since intake was conserved there is no reason to expect major weight changes.

To summarize the main findings with beer in rats:

- Rats drink large amounts of NA beer, presumably because they like the taste, and compensate accurately for the calories in it by reducing chow intake.
- Rats do not like the taste of alcohol, and so addition of alcohol to NA beer decreases its intake substantially, but again there is accurate caloric compensation.
- When rats have no choice of fluid other than beer (Richter's work), they consume larger volumes than if water was available, and again compensate for calories.
- These results contrast with findings using solutions or gels of pure concentrated carbohydrates, when caloric intakes are very high and are not compensated, and so cause increased daily caloric intake and resultant weight gain.

Human Experiments

To what extent do these findings extrapolate to the much more varied and socially complex alimentary world of humans? It is much more difficult to assess accurately over a long period the compensation in food intake for alcohol consumed in humans. Buemann *et al.* (2002) performed a short-term study in which young men ate a dinner served with beer, wine, or a soft drink, and the total calories consumed were monitored. They found that under some conditions, energy intake was slightly higher with alcoholic drinks than in the soft drink condition, but there was no control when a non-caloric beverage was available.

In another study, Orozco and de Castro (1994) studied adults who habitually consumed low to moderate amounts of alcohol during a 6-day normal (alcohol) period and for a 6-day period when they abstained from alcohol. Subjects maintained food and beverage diaries to report energy consumption as well as estimates of energy expenditure. Energy intake was higher by about 10% (241 kcal/day) during the alcohol phase than during the abstinence phase. However, energy expenditure was also higher during the alcohol phase; for example, heart rate was higher, subjects had increased waking time and increased overall exercise level. Thus, little or no net change in energy balance was observed between the two conditions. Other evidence suggests that, in addition to any effects on movement-related expenditure, alcohol directly influences one or several metabolic processes to decrease overall efficiency (Camargo *et al.*, 1987; Lieber, 1991; Suter *et al.*, 1994) and therefore minimize weight gain.

Complementary conclusions have been drawn from studies in which body mass index or other estimates of obesity have been examined along with estimates of alcohol consumption in cross-sections of specific populations. The common result, in both males and females of several ethnicities, is that low to moderate alcohol consumption is not associated with an increased level of obesity

(Wannamethee *et al.*, 2004, 2005; Pucarin-Cvetkovic *et al.*, 2006). However, high levels of consumption, often defined as three or more drinks per day, are associated with higher levels of obesity. These studies are unable to assess concurrent food intake with any degree of accuracy, so the similarity of body mass index in low or moderate drinkers and non-drinkers suggests that over years there is no net change in energy balance. It is not clear whether this is because the alcohol calories reduce food intake or because the drinkers increase energy expenditure. Lastly, in these studies, there did not seem to be a significant difference between drinkers for whom beer was the main beverage or those who consumed different alcoholic beverages.

In humans:

- Low to moderate alcohol consumption may be associated with increased energy intake, thus an incomplete compensation for the calories in the beverage.
- This seems to be offset by increased energy expenditure in the form of exercise or other activity, and decreased metabolic efficiency.
- Cross-sectional studies also indicate that low to moderate alcohol consumption is not associated with weight gain relative to age matched non-drinkers.
- Beer is no more or less likely to influence weight than other alcoholic beverages.

Conclusions

Animals seem to be able to monitor their energy intake relatively accurately and that at low levels of energy in beverages, with or without alcohol, they reduce their food intake by a commensurate amount. However, when the beverage is of high density and palatability (e.g. sucrose) then compensation breaks down and animals gain weight. It should be noted that the rat studies differ from the human environment insofar as they have not been performed when highly palatable alternative foods to the sucrose are available. The evidence in humans suggests that low to moderate habitual alcohol consumption does not lead to increased weight gain, but this may be a result of increased energy expenditure rather than compensation in food intake. Human studies have not been performed under conditions in which people are asked to restrain their food intake (i.e. diet), but it would be interesting to know whether the energy expenditure or other metabolic effects of alcohol carry over into mild caloric restraint or restriction and thus could actually improve weight loss on a diet.

Beer and Adiposity

S. Goya Wannamethee Department of Primary Care and Population Sciences,
Royal Free and University College Medical School, London, UK

Abstract

The relationship between alcohol and adiposity has been con-
flicting. There is a widespread belief that drinking beer pro-
motes abdominal fat ("beer belly") and that wine has little or
no such effect. This chapter reviews the epidemiological evi-
dence in population studies on the influence of the type of
alcohol on adiposity measures including body weight and cen-
tral adiposity. The association between alcohol and adiposity
appears to be greater for abdominal adiposity (waist circumfer-
ence and waist-to-hip-ratio) than for general adiposity (body
mass index). Overall, evidence from cross-sectional and pro-
spective studies supports the concept that alcohol, in particular
beer and spirits, is a risk factor for obesity, as one might expect
if the energy derived from alcohol consumption was added to
the usual dietary calorie intake. There is no convincing evi-
dence that wine is protective against abdominal fat deposition.

List of Abbreviations

Introduction

Increased body weight and, in particular, abdominal obe-
sity are associated with increased cardiovascular disease risk
(Rimm *et al.*, 1995; Lakka *et al.*, 2002). In many developed
countries the average alcohol intake in those who drink
is about 10–30 g/day or 3–9% of the total energy intake
(Westerterp *et al.*, 1999) and the efficiency of alcohol for
the maintenance of metabolizable energy is the same as for
carbohydrate (Rumpler *et al.*, 1996). Alcohol suppresses
the oxidation of fat, favoring fat storage and can serve as
a precursor for fat synthesis (Prentice, 1995; Suter *et al.*,
1997a). Moderate alcohol consumers usually add alcohol
to their daily energy intake rather than substituting it for
food, thus increasing energy balance (Suter *et al.*, 1997a).

On the basis of this it would seem surprising if alcohol did
not contribute directly to body weight. However, the rela-
tionship between "alcohol consumption and body weight
remains an enigma to nutritionists and in many instances
paradoxical" (Jequier, 1999). While laboratory studies on
energy and nutrient balances show that alcohol is a nutri-
ent that is efficiently utilized by the body and that alcohol
calories do count, the epidemiological evidence is conflict-
ing (Prentice, 1995; Suter *et al.*, 1997a; Westerterp *et al.*,
1999). In several reviews of studies of the alcohol and obe-
sity relation, most of which are cross-sectional in nature, the
association between alcohol intake and body weight has
been inconsistent and has varied between men and women
(Hellerstedt *et al.*, 1990; McDonald *et al.*, 1993; Suter
et al., 1997a; Westerterp *et al.*, 1999). In men the associa-
tion between alcohol and body weight has been found to
be almost equally positive or non-existent but in women
the majority of cross-sectional studies report an inverse
relationship (Hellerstedt *et al.*, 1990; Colditz *et al.*, 1991;
Wannamethee and Shaper, 1992; McDonald *et al.*, 1993;
Gutierrez-Fisac *et al.*, 1995; Suter *et al.*, 1997a; Rosmond
et al., 1999; Westerterp *et al.*, 1999; Bobak *et al.*, 2003;
Lukasiewicz *et al.*, 2003; Wannamethee *et al.*, 2003, 2005;
Nicolosi *et al.*, 2006). Evidence from a number of studies
suggests that in drinkers, fat is preferentially deposited in
the abdominal area (Suter *et al.*, 1997a) and that alcohol
may be more associated with abdominal obesity than with
general obesity (Dallongeville *et al.*, 1998; Wannamethee
et al., 2005). Several factors have been proposed which may
explain the inconsistencies between studies, including the
suggestion that the effect of alcohol on adiposity is influ-
enced by the type of drink (Suter *et al.*, 1997a). There is a
widespread belief that drinking beer promotes abdominal
fat ("beer belly") (McDonald *et al.*, 1993) and that wine
has little or no such effect (Duncan *et al.*, 1995; Vadstrup
et al., 2003). Beer's fattening reputation may have more
to do with the lifestyle of those who drink it (Barefoot
et al., 2002; Ruidavets *et al.*, 2004; Johansen *et al.*, 2006).
It has also been postulated that the effects of alcohol on
body weight and fat distribution may also differ accord-
ing to whether the alcohol is consumed with meals or not

(Suter *et al.*, 1997a) and by the pattern of drinking (Dorn *et al.*, 2003). The aim of this chapter is to review the epidemiological evidence in population studies for beer as a risk factor for overweight and obesity, and compare the effects of beer drinking with other types of beverage including wine and spirits.

Total alcohol and body weight

In the majority of cross-sectional studies, inverse associations between alcohol and body mass index (BMI) have been shown in women (Hellerstedt *et al.*, 1990; Colditz *et al.*, 1991; McDonald *et al.*, 1993; Gutierrez-Fisac *et al.*, 1995; Suter *et al.*, 1997a; Dallongeville *et al.*, 1998; Rosmond *et al.*, 1999; Westerterp *et al.*, 1999) whereas in men positive or no associations have been reported (Hellerstedt *et al.*, 1990; Wannamethee and Shaper, 1992; McDonald *et al.*, 1993; Gutierrez-Fisac *et al.*, 1995; Suter *et al.*, 1997a; Dallongeville *et al.*, 1998; Westerterp *et al.*, 1999; Bobak *et al.*, 2003; Wannamethee *et al.*, 2003, 2005). It is not clear why alcohol may promote leanness in women although it has been suggested that the calories from alcohol are added to energy intake from other sources in men, and that the energy from alcohol intake displaces sucrose in women (Howarth *et al.*, 2001). Cross-sectional analyses are limited in assessing cause and effect. The patterns of higher obesity rates in non-drinkers compared to drinkers commonly seen in women may reflect history of dieting or current dieting to lose weight. The higher BMI levels in non-drinkers may in part be due to self-selection bias. Women who are more prone to weight gain for reasons other than alcohol may abstain from drinking because of their belief that alcohol causes weight gain.

There have been relatively few prospective studies of the relation between type of alcohol and weight gain in men and women, and the findings have been inconsistent. Early data from the Framingham study showed that both men and women who took up drinking have increased their alcohol intake during follow-up experienced weight gain (Gordon *et al.*, 1983). In a study of over 12,000 Finns, heavier drinking (>75 g/week) in men and (>10 g/week) in women were associated with increased risk of weight gain (>5 kg), although the prevalence of obesity was inversely associated with alcohol intake in women (Rissanen *et al.*, 1991). This suggests that the higher BMI levels in female non-drinkers in cross-sectional studies may in part be due to self-selection bias. In a study of over 2,000 Chinese adults, alcohol was associated with a significant weight gain in men; in women only a small but positive association was seen (Bell *et al.*, 2001). Strong evidence supporting the effects of alcohol on obesity and weight gain comes from the British Regional Heart Study (BRHS) (Wannamethee *et al.*, 2003). The prevalence of men with high BMI (≥28 kg/m²) tended to increase with increasing alcohol intake. An examination of the association between changes

in alcohol intake and body weight over 5 years showed stable heavy drinkers (≥30 g/day; 1 UK unit is approximately 10 g/alcohol) and new heavy drinkers to have the greatest weight gain and the highest prevalence of obesity (Wannamethee *et al.*, 2003). Light and moderate drinkers showed no increased risk in weight gain compared to non-drinkers. These positive findings in heavier drinkers have been confirmed in recent prospective analyses carried out in a US cohort of over 40,000 female nurses aged 29–42 years at baseline in 1989 (Nurses II Health Study) (Wannamethee *et al.*, 2004). An inverse relationship was seen between alcohol and BMI in cross-sectional analyses but in prospective analyses light-to-moderate drinkers (up to 30 g/day) had significantly lower risk of weight gain (>5 kg) over 8 years than non-drinkers, but heavy drinkers (≥30 g/day/3 UK units/day) had the highest risk of weight gain (>5 kg). These prospective data support the concept of alcohol as a risk factor for obesity. However, weak positive or no association has been reported between alcohol and weight change and weight gain in five prospective studies from the United States (French *et al.*, 1993; Gerace *et al.*, 1996; Kahn *et al.*, 1997; Fogelholm *et al.*, 2000; Sherwood *et al.*, 2000). In these studies, data by levels of alcohol consumption were not presented and the average intake in these populations is not known. In two US studies an inverse association was seen between alcohol and weight gain (Colditz *et al.*, 1990; Liu *et al.*, 1994). This may be due to the small number of subjects who drank >2 drinks/day and the characteristics of the non-drinkers. It appears likely that higher levels on a regular basis are required to have an effect on body weight. Intervention studies are inconclusive. Cordain *et al.* (1997) reported that the addition of 35 g/day of wine to the daily energy requirements during a period of 6 weeks does not affect body weight or energy metabolism. This is consistent with the findings in the BRHS and Nurses II Health Study in which up to 30 g (3 UK units) was not associated with weight gain.

Alcohol and body fat distribution

Evidence from a number of studies suggests that in drinkers, fat is preferentially deposited in the abdominal area (Suter *et al.*, 1997a). In contrast to the cross-sectional relationship between alcohol and body weight, which has been found to be almost equally positive or non-existent in men and negative in women, more recent studies tend to report positive associations between alcohol and body fat distribution in men and women. In the French MONICA study, no association was seen between alcohol and BMI in men and an inverse association was seen in women (Dallongeville *et al.*, 1998). However, alcohol consumption was positively associated with waist-to-hip ratio (WHR) independent of BMI in both men and women (Dallongeville *et al.*, 1998). Positive associations between alcohol and fat distribution

have also been reported in studies from Switzerland (Suter *et al.*, 1995, 1997b), US men and women (Laws *et al.*, 1990; Slattery *et al.*, 1992; Duncan *et al.*, 1995), Italian women (Armellini *et al.*, 1993) and in Japanese men (Sakurai *et al.*, 1998). In the Italian Bollate Eye Study, alcohol was inversely associated with BMI in women with non-drinkers showing the highest BMI and light drinkers the lowest. But moderate-to-heavy drinking was associated with higher waist circumference (WC) than both non-drinkers and light drinkers (Leite *et al.*, 2006). In men, moderate-to-heavy drinkers showed the highest mean levels of BMI and WC. The findings of a stronger and more positive association between alcohol and central adiposity as measured by the WHR or WC than with BMI in several of these studies suggest that alcohol is more associated with abdominal obesity than with general obesity. In the BRHS a positive relationship was seen with both central and general adiposity but the effects as measured by the standardized regression coefficients were greater for WC and WHR than for BMI and % body fat (measures of total adiposity) and the increase in percentage of men with large WC was more marked than the increase in rates of obesity as measured by BMI (Wannamethee *et al.*, 2005).

Beer and calories

It has been suggested that the type of alcohol consumed might explain the discrepant results in studies of alcohol and body weight. Alcohol contains almost twice the calories of protein and carbohydrate foods (7 cal/g of alcohol). According to the British Beer and Pub Association (BBPA), a glass of beer with a typical 4.6% alcoholic volume has not only fewer calories than a similar measure of wine, but also milk or fruit juice. Spirits, meanwhile, contain more than six times the calories of beer, and when mixed with a soft drink, the calorie-count soars even higher. Although beer

has fewer calories than wine, it comes in pints while wine is served in smaller measures (Table 50.1).

Beer and lifestyle characteristics

Alcohol is metabolized primarily by the liver and used immediately as energy or stored in the liver or in the rest of the body as fat. Since beer contains more carbohydrate and thus more usable energy per unit of ethanol than most wines or spirits, the common belief is that beer drinkers are on average more obese than either wine or spirit drinkers (Suter *et al.*, 1997a). For example in the BRHS of men aged 60–79 years, beer drinkers overall showed the highest mean WC and BMI supporting the beer belly concept. Wine drinkers were the lightest (Figure 50.1). Research into drinking suggests that this may have more to do with the lifestyle of those who drink beer. Alcoholic beverage preference has found to be associated with dietary habits, social class and lifestyle factors including smoking, exercise

Table 50.1   Alcohol and calories

Beer	4.6% alc	41 calories
Wine	12.0% alc	77 calories
Spirits	40% alc	250 calories
Milk	0	64 calories
Orange juice	0	42 calories
Standard measure alcohol		
Beer	12 oz.	150 calories

and BMI. Table 50.2 shows the characteristics of beer, wine and spirit drinkers using data from the rescreening phase of the BRHS in men aged 60–79 years. There is evidence that wine drinkers have healthier diets and are less likely to smoke and tend to be of higher socioeconomic status. Wine drinkers had lower total fat intake and higher intakes of vitamin C reflecting higher intake of fruits. Beer drinkers had the highest fat and carbohydrate intake. These findings are consistent with previous observations reported in the United States (Barefoot *et al.*, 2002), France (Ruidavets *et al.*, 2004) and Denmark (Johansen *et al.*, 2006) indicating that wine drinkers have healthier diets than other drinkers. Adjustment for total calories and lifestyle characteristics attenuated the differences and the findings were not significant although beer drinkers still showed the highest mean WC and BMI (Figure 50.1).

Beer, spirits, wine and adiposity

The common belief is that drinking beer promotes abdominal fat distribution and that wine in contrast has no such effect and may even have beneficial effects on metabolism.

Some studies have reported differing effects of type of beverage on body weight and fat distribution and observed no effect or even an adverse effect with wine (Duncan *et al.*, 1995; Vadstrup *et al.*, 2003). Others have not and shown a positive effect of wine on abdominal fat (Slattery *et al.*, 1992; Dallongeville *et al.*, 1998; Wannamethee *et al.*, 2005).

Cross-sectional Studies   In a US study of 12,000 men and women aged 45–64 years, the WHR of those consuming >6 beer drinks/week was significantly greater than non-drinkers, while those drinking >6 wine drinks/week
Figure 50.2   Prevalence (%) of central obesity (WC > 102 cm) in relation to weekly beer, wine and spirits consumption in men aged 60–79 years. 1 drink = 10 g/alcohol. *Source*: Data from the BRHS (1998–2000).

the WHR was significantly lower than non-drinkers. The findings were regarded as supporting the popular concept of the "beer belly" (Duncan *et al.*, 1995). By contrast, in another US study (CARDIA), beer, wine and liquor were all positively associated with WHR in white men (Slattery *et al.*, 1992). In a study of some 3,500 French men and women aged 35–64 years drawn from three distinct geographic areas of France (MONICA centers), wine was the main source of alcohol (67% of intake). Wine and beer consumption was positively and strongly associated with WHR in women, but only poorly associated with WHR in men (Dallongeville *et al.*, 1998). In the Czech MONICA survey, where beer was the predominant drink, beer was positively associated with WHR in non-smokers but not with the BMI (Bobak *et al.*, 2003). No association was seen between beer and WHR in women but an inverse association was seen for BMI. Findings from the BRHS show a strong positive relationship between alcohol intake and central obesity (WC > 102 cm) in beer and spirit drinkers; no association was seen with wine drinking (Figure 50.2). In the adjusted analyses, after adjustment for lifestyle characteristic, dietary fat, time taken with meal and each of the other type of alcohol, a positive association was seen between weekly alcohol intake and mean WC for all types of drink although the effect was strongest in beer drinkers (Figure 50.3) which suggests that alcohol *per se* rather than any alcoholic beverage consumption is associated with increased abdominal fat deposition.

Several studies have however failed to find any association between beer and adiposity. In the SU.VI.MAX intervention study on the effects of antioxidant supplement on chronic diseases in men and women, spirit was positively associated with BMI and WHR in both men and women, a J-shaped relationship was seen for wine but no association was seen for beer drinking (Lukasiewicz *et al.*, 2003). In the Nurses I Health Study and the Health Professionals Follow-up study, the lack of relationship between alcohol
Figure 50.3 Adjusted mean WC in relation to weekly beer, wine and spirits consumption in men with no diagnosed myocardial infarction, stroke or diabetes. Adjusted for age, social class, smoking, physical activity, other pre-existing cardiovascular disease, total fat intake, time taken with meal and other types of alcohol. 1 drink = 10 g/alcohol. *Source*: Adapted from Wannamethee *et al.* (2005).

intake and BMI was similar for men who drank only wine and those who drank only beer (Colditz *et al.*, 1991). In the Spanish national survey (Gutierrez-Fisac *et al.*, 1995) there appeared to be a positive association between wine intake and the prevalence of obesity in women and between spirit intake and obesity in men. No significant trends of association were observed for beer or wine in men, or for beer or spirits in women. In a cohort of Swedish women (Rosmond *et al.*, 1999), wine was inversely associated with BMI while beer and spirits showed no association. In another Swedish study in women, spirits were associated with WHR but no association was seen between beer and wine consumption (Lapidus *et al.*, 1989). In a study of Caucasian-American and African-American men, liquor drinking was associated with a greater tendency for greater central adiposity but beer drinking was unrelated (Dorn *et al.*, 2003). In the Japanese study of male self-defense, officials' abdominal obesity was associated with Japanese spirits but not with other types of alcohol (Sakurai *et al.*, 1998). The differences in findings between studies may be associated with unrecorded differences in lifestyle or differences in nutritional characteristics between wine, spirit and beer drinkers. It may also be due to the type of beverage which is most common. It is also suggested that the lack of association between beer and fat distribution in some studies may be due to mean consumption per day being too low to show any association (Lukasiewicz *et al.*, 2003), as a minimum level of alcohol may be required (>3 drinks/day) to increase fat distribution.

Prospective Studies   Only a few studies have examined the association between type of alcohol intake and obesity on a prospective basis. Strong evidence to support beer as

a risk factor for overweight and obesity comes from the Copenhagen City Heart Study (Vadstrup *et al.*, 2003). In this population-based study of 6,886 men and women, the authors explored the relations between both total alcohol intake and different types of alcoholic drinks and WC after 10 years. The subjects were asked about the average weekly number of drinks of beers, wines and spirits, and assigned according to their total alcohol consumption to one of seven groups ranging from <1 drink/week to >69 drinks/week. Moderate-to-high consumption of alcohol was associated with later high WC in both men and women and this was seen for beer and spirit consumption. The odds ratios of having a high WC (<102 cm in men, >88 cm in women—levels associated with increased CVD risk) showed a linear increase in both men and women. The adjusted relative odds (95% CI) were 1.65 (1.07–2.55) in men and 2.16 (0.86–5.14) in women who drank >28 beverages/week of total alcohol compared to those who drank 1–6 beverages/week. Men who drank >21 beers/week had odds ratio of having a large WC after 10 years of 1.63 (0.99–2.67) and women drinking >14 beers/week had odds ratio of 2.53 (0.92–6.34), compared to men and women who drank no beer. Additionally, for spirits, there was an increase in both men and women. The relative odds for having a large WC for men who drank 14–21 glasses of spirits/week compared to those who drank <1/week was 1.89 (95% CI 0.81–4.36) and 3.12 (95% CI 1.12–8.52) for women who drank >14 glasses of spirits/week. By contrast, moderate-to-high wine consumption showed no positive effect and may have the opposite effect. The relative odds for having a large WC for men who drank 14–20 glasses wine/week compared to those who drank <1/week was 0.88 (95% CI 0.39–1.94) and 0.88 (95% CI 0.44–1.69) for women who drank >14 glasses of wine/week. In the recent Danish MONICA study of men and women, beer and spirits were associated with increases in WC in women but not in men (Halkjaer *et al.*, 2004).

Influence of drinking with meals

It has also been postulated that the effects of alcohol on body weight and fat distribution may differ according to whether the alcohol is consumed with meals or not (Suter *et al.*, 1997a) although data are limited. There has been suggestion that wine drinkers may take their alcohol more frequently with meals than other drinkers and consume it more slowly which in consequence may have lesser effect on adiposity (Suter *et al.*, 1997a). Regular alcohol use at meals may increase total energy expenditure by potentiating normal-dietary-induced thermogenesis (Suter *et al.*, 1997a). In the BRHS, wine drinkers were more likely to drink with meals than other drinkers (see Table 50.2) but total alcohol intake (≥21 drinks/week) is positively associated with adiposity irrespective of whether the alcohol is usually drunk with meals or separately, and is thus unlikely to explain the
Figure 50.4 Total alcohol intake and adjusted mean WC in relation to timing of alcohol intake in relation to meals. Adjusted for age, social class, smoking, physical activity, pre-existing cardiovascular disease, dietary intake and type of drink. *Source*: Adapted from Wannamethee *et al.* (2005).

differences in finding between studies (Figure 50.4). The lack of heavy wine drinkers and the multiple healthy lifestyle characteristics associated with light-to-moderate wine drinking (Barefoot *et al.*, 2002; Ruidavets *et al.*, 2004) are more likely to explain why many studies have shown no association or even inverse associations with adiposity for wine.

Mechanisms

The mechanisms involving alcohol and abdominal fat deposition are not clearly established but endocrine changes reflected by various hormonal changes including increased cortisol secretion appear to be involved (Zakhari, 1993; Kissebah *et al.*, 1994). These hormones are involved to a certain extent in the regulation of energy balance and affect fat-tissue enzymatic activities which may promote abdominal fat deposition (Suter *et al.*, 1997a).

Conclusion

Higher total alcohol intake ($\leq$21 UK units/week) is associated with increased adiposity and the effects appear to be greater for abdominal adiposity (WC and WHR) than for general adiposity (BMI). Findings from more recent prospective population studies suggest that light-to-moderate drinking is not associated with weight gain but that heavier levels (>3 drinks/day; >30 g alcohol/day) contribute to weight gain and obesity in men and women. *There is no clear evidence that the effects of alcohol differ according to the type of drink.* It appears that central and general adiposity are increased at $\geq$3 drinks/day. In many studies, the number of heavier wine drinkers ($\geq$21 UK units/week) is very small and this may explain the lack of positive effect in wine drinkers. There is no convincing

evidence that wine is protective against abdominal fat deposition. Overall evidence from cross-sectional and prospective studies support the concept that alcohol, in particular beer and spirits, is a risk factor for obesity, as one might expect if the energy derived from alcohol consumption was added to the usual dietary calorie intake.

Summary Points

- Higher total alcohol intake ($\geq$21 UK units or 30 g alcohol/week) is associated with increased adiposity.
- The association between alcohol and adiposity appears to be greater for abdominal adiposity (WC and WHR) than for general adiposity (BMI).
- There is no clear evidence that the effects of alcohol on adiposity differ according to the type of drink.
- Evidence from cross-sectional and prospective studies suggests that alcohol in particular beer and spirits are a risk factor for obesity.
- There is no clear evidence that wine protects against abdominal fat deposition.

Relationship Between Exercise and Beer Ingestion in Regard to Metabolism

Tetsuya Yamamoto Division of Endocrinology and Metabolism, Department of Internal Medicine, Hyogo College of Medicine, Nishinomiya, Japan

Abstract

Beer contains various substances, such as water, ethanol, purines, and carbohydrates, which, especially ethanol, may affect the metabolism of carbohydrates, lipids, and purines in the body, while physical activity including exercise is also an important factor. Therefore, the effect of the relationship between exercise and beer ingestion on body metabolism is important. Exercise increases the serum concentration of urate by enhanced adenine nucleotide degradation and elevated lactate concentration in blood, while beer ingestion increases the serum concentration of urate by enhancing adenine nucleotide degradation and elevating lactate concentration in blood because of the ethanol and purines contained in beer. Accordingly, exercise combined with beer ingestion increases the serum concentration of urate synergistically. In addition, exercise increases the plasma concentration and urinary excretion of oxypurines (hypoxanthine and xanthine) by enhanced adenine nucleotide degradation, while the ingestion of beer also increases those by enhanced adenine nucleotide degradation and a slight inhibition of xanthine dehydrogenase. However, in our previous study, the increases in plasma concentration and urinary excretion of xanthine were lower with the combination of exercise and beer ingestion as compared to beer ingestion alone, which indicated that exercise reduces the beer-induced inhibition of xanthine dehydrogenase activity and abrogates the increase of xanthine induced by beer. Exercise also increases the plasma concentration of uridine (a pyrimidine nucleoside), presumably by adenosine triphosphate (ATP) consumption-induced pyrimidine degradation, while beer ingestion also increases it presumably by that same process as well as because of the uridine contained in beer. Therefore, a combination of exercise and beer ingestion may increase the plasma concentration of uridine synergistically. Further, exercise increases insulin sensitivity and improves hyperglycemia, while long-term beer ingestion has been shown to decrease fasting insulin levels, though the carbohydrate contents in beer transiently raise insulin and plasma glucose levels. Accordingly, a combination of beer ingestion and exercise may improve the metabolism of carbohydrates including insulin and glucose, if moderate beer ingestion and aerobic exercise are performed separately. Exercise decreases the levels of low density lipoprotein (LDL), triglyceride, and total cholesterol, while both exercise and beer increase high density lipoprotein (HDL). Therefore, a combination of exercise and beer ingestion may reduce the risk of cardiovascular diseases through their synergistic effects on serum lipoprotein levels. In addition, in regard to the effects of exercise on beer ingestion and vice versa, it is suggested that moderate amounts of beer consumed during an evening will not significantly compromise physiological functioning the next morning, while individuals who exercise may consume larger quantities of beer as compared to them who do not.

List of Abbreviations

ATP	Adenosine triphosphate
LDL	Low density lipoprotein
HDL	High density lipoprotein
MSU	Monosodium urate monohydrate
URT1	Urate transporter 1
ADP	Adenosine diphosphate
AMP	Adenosine monophosphate
IMP	Inosine monophosphate
XMP	Xanthosine monophosphate
S-AMP	Adenylosuccinic acid
NAD	Nicotinamide adenine dinucleotide
NADH	Nicotinamide adenine dinucleotide reduced form
NH_3	Ammonia
UDP	Uridine diphosphate
UTP	Uridine triphosphate
VLDL	Very low density lipoprotein
LDLr	LDL receptor
VO_2max	Maximal oxygen consumption or maximal oxygen uptake

Introduction

Throughout the world, people consume beer as an alcoholic beverage. Beer contains various substances, such as water, ethanol, electrolytes, protein, and carbohydrates (Table 51.1) (Mangum *et al.*, 1986), as well as considerable amounts of purines, which contribute to hyperuricemia, as compared to other alcoholic beverages. (Table 51.2) (Kaneko, 2006). Each of these substances, especially ethanol, may have effects on the metabolism of carbohydrates, lipids, and purines in the body (Hartung *et al.*, 1990; Rimm *et al.*, 1999; Carlsson *et al.*, 2000; Koppes *et al.*, 2005; Yamamoto *et al.*, 2005). On the other hand, physical activity including exercise is an important factor, which has an effect on metabolism (Yamamoto *et al.*, 1997b; Jennings *et al.*, 1986; Thompson *et al.*, 2001; Herzberg, 2004; Kelley *et al.*, 2006). Therefore, it was considered important to investigate the effects of a combination of exercise and beer

on metabolism, and determine whether beer affects exercise capacity and if exercise is related to beer ingestion volume. In this chapter, findings regarding these points will be reviewed.

Effects of Exercise and Beer on Uric Acid

Gout is a disease, manifested by recurrent attacks of acute arthritis, deposits of monosodium urate monohydrate (MSU) in and around the joints of the extremities, renal disease involving interstitial tissues and blood vessels, and uric acid nephrolithiasis with a background of hyperuricemia (Figures 51.1 and 51.2), while it is also associated with conditions related to metabolic syndrome (Choi *et al.*, 2005). Thus, it is important for patients with gout to control the plasma concentration of urate. Rigorous muscle exercise increases urate concentration in plasma by two major mechanisms, one of which is abrupt adenosine

Table 51.1   Contents analysis of Budweiser beer

Iron	0.03 ppm

triphosphate (ATP) degradation (Figure 51.3). In human muscle tissue in which xanthine dehydrogenase activity is negligible, the end-product of ATP degradation is hypoxanthine, which leaks into the blood stream and is transported to the liver, where it is converted to xanthine and uric acid by xanthine dehydrogenase. Muscular exercise increases ATP degradation in muscles. As a result, excessively produced hypoxanthine is converted to uric acid and increases the plasma concentration of urate. The other mechanism that increases the plasma concentration of urate is lactic acid production. During urate anion exchanger (URAT1) in the proximal tubules, lactate is secreted. Since the secretion of lactate is coupled with the reabsorption of uric acid during URAT1 (Figure 51.4) (Enomoto *et al.*, 2002), an increased blood concentration of lactate causes a decreased urinary excretion of uric acid. Further, exercise increases lactic acid production via increased glycolysis and leads to hyperuricemia. Therefore, both accelerated ATP degradation and lactic acid produced in exercising muscles increase the plasma concentration of urate following rigorous exercise.

Alcoholic beverages, especially beer, increase the concentration of urate in serum (Lieber, 1965; Faller and Fox, 1982; Yamamoto *et al.*, 1993; Yamamoto *et al.*, 1995; Yamamoto *et al.*, 1997a; Yamamoto *et al.*, 2002) and the ethanol in alcoholic beverages increases ATP degradation in the liver (ATP -> ADP -> AMP -> IMP -> inosine -> hypoxanthine -> xanthine -> uric acid) (Figure 51.5). Further, large amounts of ethanol increase the blood concentration of lactate (Figure 51.6) (Lieber, 1965). Beer contains considerable amounts of various purines, especially guanosine, as compared to other alcoholic beverages (Table 26.1) (Yamamoto *et al.*, 2002), and those purines are metabolized to uric acid in the body after beer ingestion. In our previous study (Yamamoto *et al.*, 2002), regular beer (10 ml/kg body weight) increased the plasma concentration of urate by 30 μmol/l, while freeze-dried beer (0.34 g/kg body weight) also increased that by 20 μmol/l. Since 10 ml of regular beer contains 0.34 g of content when freeze-dried, the amount of purines in freeze-dried beer are the

Figure 51.3 Mechanism of exercise-induced hyperuricemia. Rigorous exercise accelerates ATP degradation (ATP -> ADP -> AMP -> IMP -> inosine -> hypoxanthine -> xanthine -> uric acid) and lactic acid production, both leading to hyperuricemia.

same as those in regular beer. These results indicate that the contents of beer contribute to an increase in urate in blood (Figure 51.7). Accordingly, beer may cause a greater increase in the plasma concentration of urate than other alcoholic beverages.

Since exercise is similar to beer ingestion in terms of the mechanism of increase in plasma concentration of urate, it was considered important to determine to what degree a combination of the two increased the plasma concentration of urate and a study was recently conducted (Ka *et al.*, 2003), with the protocol which is shown in Figure 51.8. Six healthy males participated in the experiments, which included a combination of exercise for 30 min (VO$_2$max 70%) and beer ingestion (10 ml/kg body weight), as well as each of those alone.

In the exercise alone experiment, the plasma concentration of urate was increased by 12% at 1 h after exercise, as compared with the reference value before the exercise (Figure 51.9). On the other hand, in the experiment of beer ingestion alone, the plasma concentration of urate was increased by 8% 1 h after the beginning of the beer ingestion, as compared with the reference value obtained before ingestion. In contrast, in the combination experiment (beer ingestion following exercise), the plasma concentration of urate was increased by 29% at 1 h after exercise, as compared with the reference value obtained before exercise. The increase in plasma concentration of urate (87 ± 16 μmol/l) in the combination experiment was greater than the sum of increases measured during the same period in the beer ingestion and exercise alone experiments (58 ± 25 μmol/l) (p < 0.05). Beer ingestion (10 ml/kg body weight) increased the plasma

Figure 51.8   Experimental protocol for beer ingestion alone, exercise alone, and those in combination experiments.

concentration of urate by both ethanol-induced purine degradation and purine ingestion, and also increased the urinary excretion of uric acid (Table 51.3). Further, the increase in urinary excretion of uric acid in the combination experiment was less than the sum of increases over the same period in the beer ingestion and exercise alone experiments (11 ± 17 vs. 53 ± 38 μmol/h).

Those findings indicated that the plasma concentration of urate increased synergistically with the combination of beer ingestion and exercise, as the amount was greater than the sum of increases by each separately.

Uric acid is the end-product of purine degradation in humans and its plasma concentration is regulated by both the production and excretion of uric acid. Although an increased lactate concentration in blood inhibits urinary uric acid, a moderate amount of beer ingestion does not increase the blood concentration of lactate enough to significantly inhibit the urinary excretion of uric acid. Therefore, the production of uric acid by beer ingestion mainly caused an increase in the plasma concentration of urate. In contrast, the high blood concentration of lactate caused by exercise seems to enhance the increase in plasma concentration of urate caused by the beer-induced production of uric acid, as well as that induced by exercise, via a hyperlactatemia-induced inhibition of urinary uric acid excretion. In addition, though the blood concentration of lactate in the subjects immediately after exercising for 30 min in exercise alone experiment was not different from that in the combination experiment (Table 51.4), it was higher at 1 h after finishing exercise in the combination experiment than at the same period in the exercise and beer ingestion alone experiments (Table 51.4). This finding suggests that the decrease in blood concentration of lactate after exercise is disturbed by the metabolism of ethanol in the liver. Further, the production of uric acid induced by a combination of exercise and beer ingestion as well as the prolonged high blood lactate concentration may have a synergistic effect on the increase of plasma urate concentration.

In fact, the urinary excretion of uric acid did not increase in the third period of the combination experiment, though it was increased in the third period of the beer ingestion experiment (Table 51.3). In addition, the increase in urinary excretion of uric acid from the first to the third period of the combination experiment was less than the sum of increases over the same periods in the beer ingestion and exercise experiments (11 ± 17 vs. 53 ± 38 μmol/h).

From these results, we concluded that the production of uric acid induced by a combination of exercise and beer ingestion, as well as a prolonged high blood lactate concentration, provide a synergistic effect toward an increase of plasma urate concentration. Beer ingestion following exercise is a common habit of Japanese men and those in combination seems to

increase the plasma concentration of urate to a greater degree than either one alone, which may induce a gouty attack in patients with gout. Therefore, it is better for such patients to refrain from beer ingestion following exercise.

Effects of Exercise and Beer Ingestion on Oxypurines (Hypoxanthine and Xanthine)

Oxypurines (hypoxanthine and xanthine) are precursors of uric acid, which is produced via purine degradation (Figure 51.5). The plasma concentration and urinary excretion of uric acid are markedly increased in patients with xanthine dehydrogenase deficiency, as well as gout patients treated with xanthine dehydrogenase inhibitor (allopurinol). On the other hand, the plasma concentration and urinary

excretion of hypoxanthine are also markedly increased by enhanced purine degradation in the organ, in which xanthine dehydrogenase activity is negligible. A typical scenario is muscular exercise (Yamamoto *et al.*, 1994; Ka *et al.*, 2003). Hypoxanthine as a purine degradation end-product is excessively produced in muscles during exercise and leaks into blood stream, when the intensity is beyond the anaerobic threshold, where it is transported to the liver, and then converted to xanthine and uric acid by xanthine dehydrogenase (Figure 51.3). As a result, the plasma concentrations of xanthine and uric acid, as well as hypoxanthine, are increased by muscle exercise. On the other hand, beer containing ethanol and purines increases the plasma concentration and urinary excretion of oxypurines, especially xanthine, as well as the ratio of lactate/pyruvate, which suggests an increase in the level of the cytosolic nicotinamide

The increase in the urinary excretion of xanthine from the first to the third period in the beer ingestion experiment was greater than that in the combination experiment.

adenine dinucleotide reduced form (NADH) (Yamamoto *et al.*, 1995; Yamamoto *et al.*, 1997a; Yamamoto *et al.*, 2002).

Both the degradation of purines in beer and the ethanol-induced degradation of adenine nucleotide increase the plasma concentration of purine bases. However, an increase in NADH slightly inhibits xanthine dehydrogenase activity during beer ingestion (Yamamoto *et al.*, 1995), and the plasma concentration and urinary excretion of xanthine are increased to a greater degree than those of hypoxanthine by ethanol ingestion, as demonstrated in our recent beer ingestion study (Yamamoto *et al.*, 2002).

Nevertheless, our recent study of a combination of exercise and beer ingestion disclosed that the increase in plasma concentration and urinary excretion of xanthine was lower in the combination experiment than in the beer ingestion alone experiment, indicating that exercise relieves the increase of xanthine induced by beer (Tables 51.5 and 51.6) (Ka *et al.*, 2003).

Further, beer ingestion decreased the blood concentration of pyruvate, though the combination of exercise and beer did not do so (Table 51.7). Exercise produces pyruvic acid together with lactic acid via glycolysis in exercised muscles, after which the pyruvic acid is partly transported to the liver and metabolized to lactic acid with the conversion of NADH to nicotinamide adenine dinucleotide (NAD). Further, exercise increases adenine nucleotide degradation and produces NH_3 by the deamination of adenosine monophosphate (AMP) in exercised muscles. In the combination experiment, the blood concentration of NH_3 markedly increased (Table 51.8). Such produced NH_3 is transported to the liver and removed through the mediation of glutamate dehydrogenase to form glutamate and NAD from 2-ox-oglutarate, NH_3, and NADH. As a result, NAD may increase and NADH may decrease in the cytosol of liver cells (Tischler *et al.*, 1977). Therefore, it is suggested that a decrease in the concentration of NADH in cytosol reduces the beer-induced inhibition of xanthine dehydrogenase activity, leading to decreases in the plasma concentration and urinary excretion of xanthine.

Effects of Exercise and Beer on Uridine

Uridine is a pyrimidine nucleoside, that consists of uracil and ribose, and forms a part of RNA that is not necessary for endogenous synthesis of nucleic acids, though it plays

Figure 51.11 Insulin concentrations in men according to alcohol intake and type of alcoholic beverage consumed. Wine and beer decreased insulin concentrations in men.

an important role in the synthesis of glycogen. Further, it has been suggested that uridine has an action that causes vascular muscle constriction (Macdonald *et al.*, 1987).

Plasma uridine is increased by muscular exercise, ethanol ingestion, fructose infusion, and xylitol infusion, which are well known to enhance adenine nucleotide degradation and lead to an increase in the plasma concentration of purine bases (Yamamoto *et al.*, 1997a, b, 1998). Since uridine diphosphate (UDP) is phosphorylated to uridine triphosphate (UTP) using ATP as a phosphate donor, an abrupt decrease in ATP reduces the production of UTP and enhances pyrimidine degradation (UDP -> UMP -> uridine), resulting in an increase in the plasma concentration of uridine (Figure 51.10). Exercise increases uridine in exercised muscles, while ethanol ingestion also increases uridine in the liver. The uridine produced in these organs leaks into the blood stream, causing an increase in plasma concentration. In addition, beer, which contains considerable amounts of uridine, increases the plasma concentration of uridine. Therefore, a combination of exercise and beer ingestion seems to increase the plasma concentration of uridine to a greater degree than exercise or beer ingestion alone, though there are no data known to have been reported to support that speculation.

Effects of Exercise and Beer on Insulin and Glucose

A number of studies have demonstrated that exercise increases insulin sensitivity and improves hyperglycemia (Jennings *et al.*, 1986; Thompson *et al.*, 2001), while others have shown that insulin-mediated glucose is increased in the whole body and skeletal muscles in humans by physical training (Rodnick *et al.*, 1987; Mikines *et al.*, 1989; Dela *et al.*, 1992; Dela *et al.*, 1995). In addition, it was
reported that adipose tissues as well as muscles play a role in the increase in insulin-mediated glucose uptake caused by exercise (Stallknecht *et al.*, 2000). These favorable effects seem to provide cardiovascular benefits.

Ethanol ingestion causes hyperglycemia or hypoglycemia depending on whether glycogen stores are adequate. However, since beer contains carbohydrates, its ingestion increases the plasma concentration of glucose. In a previous study (Nishioka *et al.*, 2002), beer (0.8 ml of ethanol equivalent/kg body weight) increased the levels of blood glucose by 26.7% and insulin by 5.1-fold. On the other hand, in another study of the relationship between alcohol intake and fasting insulin (Konrat *et al.*, 2002), an inverse relationship between beer or cider consumption and fasting insulin level, as well as that between wine consumption and fasting insulin level, were shown in non-diabetic French men (Figure 51.11). Further, in a report on the relationship between alcohol consumption and Type 2 diabetes mellitus (Carlsson *et al.*, 2000), it was speculated that consumption of large quantities of beer may increase the occurrence of Type 2 diabetes. Together, these results (acute effects of beer ingestion, effects of long-term beer ingestion, and effects of consumption of large quantities of beer) suggest that though the carbohydrate content in beer transiently raises insulin and plasma glucose levels, the decrease in fasting insulin level caused by long-term beer ingestion is associated with a cardio-protective effect in non-diabetic moderate drinkers, but not heavy drinkers, as reported by Keil *et al.* (1997).

Although the effects of a combination of exercise and beer ingestion have not been reported by others, the effects of a combination of alcohol consumption and exercise have been shown (Heikkonen *et al.*, 1998). According to that study, acute alcohol intake (1.5 g/kg of body weight) immediately before exercise inhibited an increase in the level of glucose in plasma after a single bout of rigorous exercise and slightly decreased plasma glucose levels during recovery from exer-

cise, indicating that alcohol interferes with the metabolism of carbohydrates during and after anaerobic exercise. However, since consumption of moderate amounts of alcoholic beverages including beer may improve the metabolism of carbohydrates (Carlsson *et al.*, 2000) and aerobic exercise also improves that metabolism (Jennings *et al.*, 1986; Thompson *et al.*, 2001), a combination of moderate beer ingestion and exercise may improve the metabolism of carbohydrates including insulin and glucose, if performed separately.

Effects of Exercise and Beer Ingestion on Serum Lipids

Aerobic exercise has been shown to reduce the risk of cardiovascular disease (CVD) (Berlin and Colditz, 1990; Kohl II, 2001), which is at least partially mediated by changes in circulating lipoproteins. Aerobic exercise decreases low density lipoprotein (LDL), triglyceride, and total cholesterol levels, while it increases high density lipoprotein (HDL) (Tran *et al.*, 1983; Halbert *et al.*, 1999; Hata and Nakajima, 2000; Leon and Sanchez, 2001), though prolonged exercise is needed to reduce LDL-cholesterol. In addition, chronic exercise was shown to decrease oxidized LDL (Herzberg, 2004). It is considered that these changes may reduce the risk of CVD. The acute effects of exercise on triglycerides and HDL-cholesterol seem to be ascribable to energy expenditure, leading to reductions in levels of intramuscular triglycerides (Thompson *et al.*, 2001), which in turn may decrease serum triglyceride and increase serum HDL-cholesterol levels.

On the other hand, moderate alcohol consumption has also been shown to reduce the risk of CVD (Moore and Pearson, 1986; Marmot and Brunner, 1991; Maclure, 1993), which might be partially mediated by an increase in the level of HDL. A previous study found that beer, wine, and spirits consumption each increased HDL-cholesterol levels (Koppes *et al.*, 2005). Further, a recent animal study (Degrace *et al.*, 2006) demonstrated that moderate levels of beer consumption reduced liver triglycerides and aortic cholesterol deposits in LDL receptor-deficient and apo B-expressing [LDLr(-/-) apoB(100/100)] mice. Moderate beer (0.57 g of ethanol/kg of body weight/day) or ethanol-free beer consumption over a period of 12 weeks each increased HDL-cholesterol and VLDL-cholesterol levels, with no changes in LDL-cholesterol. In addition, liver triglyceride contents were decreased in both experiments. In contrast, cholesterol accumulation was attenuated in the whole aortas of mice with moderate beer consumption, but not in those that received ethanol-free beer. These results suggest the beneficial effects from unidentified components in beer toward atherosclerosis development, which are ascribable to changes in lipoprotein levels that are slightly enhanced by the ethanol in beer. From these findings, we concluded that a combination of exercise and beer ingestion may reduce the risk of CVD through their synergistic effects on serum lipoproteins.

Beer Ingestion-Induced Change in Exercise Capacity

In a previous study (Mangum *et al.*, 1986), acute effects of beer on physical responses following submaximal exercise were reported. Beer (1.25 ml/kg of body weight) was administered 15 min prior to exercise, which was performed for 45 min at 50% VO_2max at 5 min intervals. Heart rate, Na, K, and Cl values determined following exercise were not different between subjects who ingested beer and those who did not, suggesting that beer has no obvious benefit as a replacement fluid during exercise. In another study, ingestion of moderate amounts of beer over an evening did not significantly compromise physiological functioning in adult females the next morning. However, the number and severity of hangover symptoms (headache, dizziness, nausea, upset stomach, tremors, fatigue, dry mouth, and irritability) were increased, as was the rate of decision-making errors. Those results suggested that a mild hangover has little effect of maximal muscle strength like grip strength. On the other hand, O'Brien (1993) showed that alcohol consumption at night decreased VO_2max the next afternoon, though it was unclear from the results whether residual fatigue or hangover caused aerobic performance to decrease, or if there was an interaction between fatigue and hangover that produced the observed effects since the subjects were subjected to two different VO_2max tests in less than 24 h.

Exercise-Induced Changes in Beer Ingestion Volume

Several studies (Segovia *et al.*, 1989; Thorlindsson *et al.*, 1990) have reported that physical exercise was negatively related to the frequency of drinking. Those results suggested that favorable outcomes of exercise, such as increased academic performance, emotional stability, memory, and job satisfaction, along with decreases in work-related stress and negative emotions such as depression, might be associated with a lowered consumption of alcohol (Watten, 1995). On the other hand, results of a nationwide survey comprising more than 13,000 Norwegian inhabitants aged 15–60 years old (Saglie, 1994) suggested that sports participation was positively correlated with beer consumption. In addition, in another general population study conducted in Norway comprising 994 women and 1,000 men (Watten, 1995), it was found that the frequency of exercise, irrespective of type of sport, was related to increased consumption of wine, but not of beer, liquor, or total yearly consumption of alcohol among men and women. These two studies suggest that men and women who exercise regularly might consume more beer or wine, as compared to those who do not.

Summary points

- Exercise combined with beer ingestion increases the serum concentration of urate synergistically.
- Exercise reduces the beer-induced inhibition of xanthine dehydrogenase activity and abrogates the increase of xanthine induced by beer.
- Exercise combined with beer ingestion increases the plasma concentration of uridine.
- A combination of exercise and beer ingestion may improve the metabolism of carbohydrates including insulin and glucose, if moderate beer ingestion and aerobic exercise are performed separately. In addition, it may reduce the risk of cardiovascular diseases through their synergistic effects on serum lipoprotein levels.

Estrogenicity of Beer: The Role of Intestinal Bacteria in the Activation of the Beer Flavonoid Isoxanthohumol

Sam Possemiers, Willy Verstraete and Tom Van de Wiele   Laboratory of Microbial Ecology and Technology (LabMET), Ghent University, Gent, Belgium

Abstract

For many centuries, hops (*Humulus lupulus* L.) have been used as essential ingredient in beers, providing the typical bitterness and hoppy flavor. However, for the last few years the plant has gained increasing attention as a source of prenylflavonoids and in 1999, 8-prenylnaringenin was identified as the most potent phytoestrogen known so far. However, despite this high activity, health effects related to the presence of 8-prenylnaringenin in beers were always considered negligible because of the concentrations ($<100\,\mu g/l$). In this chapter we show that introducing the aspect of bioavailability into the discussion of estrogen exposure after beer consumption can drastically change this vision. Upon ingestion, prenylflavonoids reach the liver and large intestine, where they can be transformed into metabolites with different biological activity. Special attention is given to isoxanthohumol, the main prenylflavonoid in beers present in 10–30 higher concentrations than 8-prenylnaringenin, in the role of a potential pro-estrogen by virtue. After all, isoxanthohumol has the potential for a substantial degree of metabolic activation: *O*-demethylation into 8-prenylnaringenin would increase its relative estrogenic potency from 0.001 to 0.4. Recent work shows that some isoxanthohumol indeed might be activated into 8-prenylnaringenin in the liver. However, the most important activation would occur in the colon. Here, intestinal bacteria can produce 8-prenylnaringenin from isoxanthohumol with high efficiency. As it was shown that a large fraction of ingested isoxanthohumol reaches the colon, this process could easily 10-fold increase the 8-prenylnaringenin exposure after beer consumption. One drawback is that this process only occurs in one-third of humans due to interindividual differences in intestinal microbiota. Therefore, new strategies are now being developed to increase the 8-prenylnaringenin production in all individuals. In conclusion, these recent findings about increased 8-prenylnaringenin exposure can give new insights in the scientific question whether moderate beer consumption can lead to specific health outcomes.

List of Abbreviations

DMX	Desmethylxanthohumol
E_2	17β-Estradiol
ERα/β	Estrogen receptor α/β
ADME	Absorption, distribution, metabolism and excretion
CYP	Cytochrome P450 enzyme
T_{max}	Time needed to reach maximum plasma concentrations of an ingested compound
O-DMA	*O*-Desmethylangolensin
SECO	Secoisolariciresinol
SHIME	Simulator of the human intestinal microbial ecosystem
UGT	UDP-glucuronosyltransferases

Historical Perspective

History of hop use

Hops (*Humulus lupulus* L.) are known since ancient times and nowadays mainly used in the beer industry because of the presence of favorable secondary metabolites, produced in yellow glandular trichomes, termed lupulin glands, that cover the bracteoles of the female inflorescences (hop cones) (Figure 52.1). Although several hundreds of metabolites are being produced in these unique glands, the most important compounds for the brewing industry are the bitter acids, which give beer its typical bitter flavor and ensure foam and bacterial stability, and the hop essential oils, which give beer its typical "hoppy" aroma.

However, despite its long history of cultivation, the use of hop in beers is not as old as the history of beer itself, dating back to at least 1750 BC when the Sumerians discovered how to use yeast for the fermentation of barley into beer (Ross *et al.*, 2002). Prior to the use in beer, hops were cultivated as early as 736 BC by German monks for medicinal

Figure 52.1 Lupulin glands from hops, present in the female hop cone. In commercial hop production, female hop vines are trained to climb strings up to 5–10 m high. On lateral arms, the plants produce the typical female inflorescences, called hop cones. Covering the bracteoles of these cones, the plant produces numerous yellow glandular trichomes. In these trichomes, called lupulin glands, hops can efficiently secrete large amounts of specific secondary metabolites. At harvest, the vines are cut down and the cones are stripped off.

purposes. Probably one of the first historical applications of hops was the treatment of insomnia, stress and anxiety because of its mild sedative effects. Some other reported applications include stimulation of the digestive tract, the use as diureticum or to clean the blood and as bacteriostatic and anti-inflammatory agent (Neve, 1991). Burgess (1964) writes that hop sprouts were already used as a salad in the first century AD. And hop sprouts were also eaten by the poor in medieval times as a substitute for asparagus. Next to this, hop stems were used in some cases to make cloth and paper and in a number of other traditional applications.

Hops were probably first added to beer in the twelfth century by German monks (Burgess, 1964; Neve, 1991). In those days, it was popular to use a variety of fruits, herbs and spices to flavor beer (so-called gruit beer). In northern central Europe and north-west Europe, *Myrica gale* L. (sweet gale or bog myrtle) was used since ancient times as

principal beer additive (Behre, 1999). However, when the production of beer increased in the fourteenth century and the brewers started to export their beer, the importance of hops in beer was more and more appreciated. Because of the bacteriostatic properties of hops, hopped beers could be preserved much longer than gruit beer and the use of hops allowed the brewers to market their beers further from its production site (Burgess, 1964). When finally rumors were spread that drinking beer from sweet gale was harmful and could lead to blindness and even death, the use of *Mirica* completely declined (Behre, 1999). The enacting of the "Reinheitsgebot" (Purity law) by Wilhelm IV, the Lord of Bayern, eventually made from hops a standard ingredient in beer. Many aspects of this law, ordering that beer must be made from barley, water and hops, were adapted by other countries and since the nineteenth century, the main application of hops is to make beer.

Renewed interest in hops as a source of prenylflavonoids

Renewed interest in the alternative use of hops arose at the end of the last century when hops were acknowledged to be a source of prenylflavonoids with possible health beneficial effects, mainly related to its estrogenic properties (Milligan *et al.*, 1999). However, even before this discovery a recurring suggestion has been for many years that hops have a powerful estrogenic activity. Already in 1953, Koch and Heim reported that hops contain "the equivalent of 20–300 μg estradiol/g" (Koch and Heim, 1953). In those days, hops were picked by hand and the need for massed labor at harvest time led to the migration of many whole families from the entire region surrounding the hop region to the hop fields. According to folk legends, women who started picking hops regularly began to menstruate 2 days after arriving to pick hops, indicating the presence of an estrogenic substance. Other reports stated that brewery sludge baths, containing about 30% hop extracts were taken in Germany for the treatment of gynecological disorders (Fenselau and Talalay, 1973). However, the lack of identification of the responsible compound resulted in contradictory reports whether or not hops would really show estrogenic activity.

A first attempt for structure identification was made by Verzele *et al.* (1957) and Verzele (1986), who isolated the chalcone xanthohumol (X) from hops and, without any proof, attributed the estrogenic properties of hops to this compound. However, the real identification of the structure was only established in 1988 by Hänsel and Schulz (1988). Earlier, in 1972, Nastainczyk reported in his Ph.D. thesis the isolation of a "pro-estrogen" from hops which could be isomerized to a mixture he called the "hop estrogen" (Chadwick *et al.*, 2006). Hänsel and Schulz showed that a new chalcone, desmethylxanthohumol (DMX), was Nastainczyk's pro-estrogen, which can be isomerized into a mixture of 8-prenylnaringenin and 6-prenylnaringenin. Finally, the definitive unambiguous identification was made in 1999 when Milligan *et al.* (1999) identified 8-prenylnaringenin as a potent phytoestrogen present in hops.

The final discovery of 8-prenylnaringenin as a phytoestrogen immediately led to numerous studies in which the estrogenic activity of 8-prenylnaringenin was elucidated *in vitro* and *in vivo*. This showed that 8-prenylnaringenin was the first ERα selective phytoestrogen with only 25-fold lower affinity for the latter receptor than 17β-estradiol (E_2), the endogenous female reproductive hormone (Overk *et al.*, 2005). Its *in vitro* biological activity on the ERα receptor would be in the range of 5–600 times weaker than E_2 (Milligan *et al.*, 1999; Schaefer *et al.*, 2003; Matsumura *et al.*, 2005; Zierau *et al.*, 2005), making it far more active compared to the other known phytoestrogens. Interestingly, the concentrations needed to cause (negative) *in vivo* biological effects, such as uterine growth and vaginal mitosis, were 20,000 times higher compared to E_2.

Estrogenicity of Beer: Fact or Fiction?

Prenylflavonoids in hops

As hops are mainly used for beer production, beer is the most important dietary source of hop compounds. Prenylated flavonoids are found in a limited number of plant families, of which the Moraceae–Cannabaceae (with *Humulus lupulus* L.), Leguminosae and Asteraceae host about 80% of the ca. 1,100 known prenylflavonoids (Barron and Ibrahim, 1996). However, as none of the other plants can be identified as rich nutritional sources of prenylated flavonoids in the Western diet, beer may very well represent the most important dietary source of prenylflavonoids.

Within the female hop cone, xanthohumol would be the principal flavonoid (Figure 52.2), present at high concentrations in the lupulin glands (0.1–1% of cone dry weight) (Stevens *et al.*, 1999b) with large differences depending on the variety and flowering stage (De Keukeleire *et al.*, 2003). This prenylated chalcone is accompanied by at least 13 related chalcones, present in 10–100-fold lower concentrations, from which desmethylxanthohumol is the most important (Stevens and Page, 2004). The hop chalcones are accompanied by a number of prenylated flavanones, from which isoxanthohumol (IX), 8-prenylnaringenin and 6-prenylnaringenin are the most important. Although concentrations of these flavanones have been determined in different hop varieties (Stevens *et al.*, 1997; Rong *et al.*, 2000), some authors question whether the array of prenylflavonoids are in part the result of decomposition during drying and storage (Hänsel and Schulz, 1988; Stevens *et al.*, 1997). The presence of chalcone isomerases, enzymes which convert chalcones in the corresponding flavanones by ring closure, has been shown in hops, yet not in the lupulin glands (Stevens *et al.*, 1997). However, even without the presence of a chalcone isomerase, chalcones would isomerize chemically. Xanthohumol has one free hydroxyl available for ring closure, yielding the prenylflavanone IX, whereas desmethylxanthohumol has two free hydroxyls that can participate in cyclization, yielding two flavanones 8-prenylnaringenin and 6-prenylnaringenin. This could explain the small amounts of the flavanones in comparison to xanthohumol and desmethylxanthohumol (Stevens *et al.*, 1997). Furthermore, it has been shown that the exposure to alkali during the extraction and purification process further favor the isomerization, yielding higher prenylflavanone amounts (Verzele *et al.*, 1957). Therefore, some authors now consider 8-prenylnaringenin as an artifact, rather than a real compound present in hops (Chadwick *et al.*, 2004).

Exposure to 8-prenylnaringenin after beer consumption

The final content of prenylflavonoids in beer strongly depends on the production process and more specifically
Figure 52.2 Prenylflavonoids in hops. The main prenylflavonoid in the female hop cone is the prenylchalcone xanthohumol (X) next to low concentrations of desmethylxanthohumol (DMX). During extraction of the hop cones and further processing, the chalcones can isomerize into the prenylflavanones isoxanthohumol (IX), 8-prenylnaringenin and 6-prenylnaringenin (6-PN).

Table 52.1 Prenylflavonoid contents (g/100g; average ± standard deviation) in different hop products

	Hop products		
	Pellets (type 45)	Ethanolic extract	CO$_2$ extract
Xanthohumol	0.62 ± 0.01	3.75 ± 0.05	0.089 ± 0.001
Isoxanthohumol	<LOD	0.17 ± 0.01	<LOD

LOD: limits of detection.
Source: After Magalhaes *et al.* (2007).

on the way hops are introduced in the brewing kettle. Hops are either introduced as pellets or as extracts. Pellets are basically hop cones which are ground and pressed into a small form, facilitating storage, handling and dosage (Magalhaes *et al.*, 2007). Hop extraction involves milling, pelleting and remilling, passing a solvent through a column to collect the resin components and finally remove the solvent. Ethanol was one of the first solvents used to extract flavor and bitter compounds from hops but has the disadvantage of low selectivity resulting in high impurity and solvents are difficultly removed. Therefore, the selected and easily removable supercritical CO$_2$ is currently the most accepted solvent (Gardner, 1993). However, as hop pellets and extracts differ in the concentration of prenylflavonoids, the choice for one form has a crucial impact on the final prenylflavonoid content (Table 52.1). Pellets of course still contain all flavonoids and so do ethanolic extracts because of the low selectivity of the solvent. On the contrary, polar compounds such as flavonoids cannot be excreted with supercritical CO$_2$ leading to very low prenylflavonoid concentrations in the extract (Magalhaes *et al.*, 2007) and in the final beers brewed with these extracts (Stevens *et al.*, 1999b; Rong *et al.*, 2000).

Although xanthohumol and (lower amounts of) desmethylxanthohumol are the main prenylflavonoids in the hop cone, their abundance in beer is much lower in favor of the corresponding prenylflavanones. This is also related to the production process. Stevens *et al.* (1999a) showed that upon introducing hops, 95% of the prenylflavonoid fraction consists of X, desmethylxanthohumol and 3′-geranylchalconaringenin. However, during the wort boiling much of the xanthohumol and all of the desmethylxanthohumol is converted by thermal isomerization into isoxanthohumol and a mixture of 6-prenylnaringenin and 8-prenylnaringenin. Later in the production process the isomerization of xanthohumol continues leading in their example to a 98% conversion into IX. Therefore, isoxanthohumol and lower quantities of 6-prenylnaringenin and 8-prenylnaringenin are the main prenylflavonoids in beers (Table 52.2).

Although isoxanthohumol concentrations often are in the range of 1 mg/l depending on the origin of the hops and brewing process, the 8-prenylnaringenin concentrations generally are much lower and normally below 100 μg/l. This is in agreement with other groups who quantified 8-prenylnaringenin concentrations in Belgian, German and other European beers and found concentrations in the range of undetected up to 20 μg/l (Tekel *et al.*, 1999), 21 μg/l (Rong *et al.*, 2000) and 138 μg/l (Schaefer *et al.*, 2005).

Biological relevance of 8-prenylnaringenin exposure?

There is currently a considerable interest whether moderate beer consumption can influence human health (De Keukeleire, 2003). Because of the risks associated with high alcohol intake (Fund, 1997), clinical guidelines

Table 52.2 Prenylflavonoid contents in beer and dietary supplements

generally do not recommend the consumption of alcohol-containing beverages. Red wine is about the only beverage escaping this judgment, often referred to as the "French Paradox" (Kopp, 1998; Avellone *et al.*, 2006). However, more and more studies now conclude that moderate beer consumption would equally protect against these lifestyle-related diseases (Klatsky *et al.*, 1997; Cleophas, 1999; Di Castelnuovo *et al.*, 2002) indicating that moderate beer consumption should not unconditionally be contemplated as negative. This may be related to direct protective effects of moderate alcohol consumption (Giles and Sander, 2005), but additional benefits might also be associated with specific non-alcohol components in beer, such as isohumulones (Kondo, 2004; Nozawa *et al.*, 2006).

In view of the recent findings on the potent biological activity of 8-prenylnaringenin, an extra question was recently added to this discussion: Are any (positive or negative) endocrine effects to be expected related to moderate beer consumption? Much attention has recently been given to the presence of endocrine-active substances in the human diet and possible associated health risks (Jefferson and Newbold, 2000; Rasier *et al.*, 2006). As previously mentioned, 8-prenylnaringenin would be the most potent phytoestrogen currently known with much higher

activity than other dietary compounds with estrogenic activity, and therefore this question should indeed be carefully considered when assessing the health effects of moderate beer consumption. Yet, the final 8-prenylnaringenin concentrations in beers are generally below 100 µg/l, resulting in a total estrogenicity of beers which is still 500–1,000-fold lower than the concentration needed for harmful *in vivo* activity (~100 mg/l) in rat experiments (Milligan *et al.*, 2002). Therefore, it is generally agreed that with the current knowledge, no detrimental health effects are to be expected through moderate beer consumption (Milligan *et al.*, 1999; Stevens and Page, 2004).

But what about the positive effects of long term exposure to very low concentrations of dietary estrogens? Many reports now conclude positive effects on for instance bone density of long term exposure to ultra-low doses (0.25 mg/day) of E_2 (Prestwood *et al.*, 2003; Kenny *et al.*, 2005; Peeyananjarassri and Baber, 2005; Appt *et al.*, 2006). Based on the absolute 8-prenylnaringenin concentrations in beer, even these kinds of effects probably should not be expected. However, one important factor often is not taken into consideration: the aspect of bioavailability and possible biotransformation reactions inside the human body. Biotransformation of food components has evolved to

facilitate the elimination of potentially toxic substances through the production of polar, and usually less active, metabolites (Coldham *et al.*, 2002). However, in certain cases, biotransformation may confer a substantial increase in the biological activity. Therefore, the rest of this chapter will handle with all possible aspects of the bioavailability and biotransformation of prenylflavonoids from hops with respect to question whether uptake of hops can lead to significant exposure to the potent phytoestrogen 8-prenylnaringenin. Special attention will be given to IX, the main prenylflavonoid in beers and hop products, in the role of a potential pro-estrogen by virtue. After all, isoxanthohumol has the potential for a very substantial degree of metabolic activation: *O*-demethylation into 8-prenylnaringenin would increase its relative estrogenic potency from 0.001 to 0.4 (Coldham *et al.*, 2002).

Isoxanthohumol as Pro-estrogen: Activation into 8-Prenylnaringenin

Bioavailability

The term bioavailability has been the subject of much debate. Originally, the term mainly related to the extent and rate of absorption from the gut. Subsequently, the importance of distribution, metabolism and excretion were recognized, leading to a "biodelivery" concept of bioavailability. Current definitions have been extended to encompass the concept of "bioefficacy." Therefore, for flavonoids bioavailability now refers to the effectiveness of a compound to elicit a biological response in a target tissue (Rowland *et al.*, 2003). Ideally, this response should be monitored with a sensitive functional marker (e.g. plasma homocysteine for folate). In reality, however, no such marker is available for flavonoids and bioavailability can only be assessed based on data from absorption, distribution, metabolism and excretion (ADME).

Absorption and distribution of flavonoids

Flavonoids mainly occur in food as glycosides, bound to sugar moieties, but sometimes also as aglycones. For instance, naringenin is present in citrus fruits bound to glucose or rutinose molecules, but in tomatoes it is present as free naringenin. Many aglycones can readily be absorbed in the small intestine and depending on the sugar moiety and position on the flavonoid, deglycosilation of flavonoid glycosides can occur by mammalian β-glucosidases in the small intestine, followed by absorption of the aglycon (Bugianesi *et al.*, 2002; Walle, 2004; Wang *et al.*, 2006). Others, however, reach the colon intact where deglycosilation occurs by bacterial enzymes (Erlund *et al.*, 2001; Cermak *et al.*, 2006; Wang *et al.*, 2006). Due to extensive phase I and II metabolism in the intestinal wall during absorption and in the liver (see below), a major fraction of

the absorbed flavonoids is excreted back into the intestine through the bile as glucuronides and/or sulfates and reaches the colon where bacterial β-glucuronidases and sulfatases can release the flavonoid aglycon (Hu *et al.*, 2003a; Liu *et al.*, 2003; Walle *et al.*, 2004). In most cases flavonoids mainly occur in plasma as phase II conjugates which can be excreted in urine or reach specific target organs to exert biological activity.

Few studies have been performed on the pharmacokinetics of hop prenylflavonoids. Whereas the absorption of xanthohumol would be low (Avula *et al.*, 2004; Nookandeh *et al.*, 2004) 8-prenylnaringenin is easily taken up from the gut, probably by passive diffusion (Nikolic *et al.*, 2006). After 8-prenylnaringenin administration to rats, dogs and postmenopausal women, rapid almost complete absorption ($T_{max} = 1.5\,h$) was noted, followed however by extensive presystemic elimination (>50%) via the bile. Enterohepatic circulation resulted in a secondary plasma peak ($T_{max} = 7$–$10\,h$) (Rad *et al.*, 2006). This rapid elimination would be due to extensive phase II metabolism. This was confirmed *in vivo* as conjugates dominated over free 8-prenylnaringenin in both plasma and urine (Schaefer *et al.*, 2005; Rad *et al.*, 2006). Plasma concentrations showed a good dose response relation but conjugation was less efficient at high dose. Within 48 h, respectively 5–10% and 20–30% of the ingested dose were excreted in urine and feces, in the latter predominantly as free 8-prenylnaringenin (Rad *et al.*, 2006). Although no data are published on isoxanthohumol absorption and distribution, one of our recent studies with germ-free rats indicates that isoxanthohumol would also be well absorbed, but that presystemic elimination also excretes a major fraction of the absorbed isoxanthohumol back into the intestine. Therefore, about 35% of the ingested dose was excreted in the feces of germ-free rats. This would mean that, in the presence of intestinal bacteria, a large fraction of the ingested isoxanthohumol becomes substrate for the bacterial enzymes in the colon.

Liver metabolism of flavonoids: production of 8-prenylnaringenin from IX?

Liver metabolism of dietary compounds can include a variety of reactions including condensation, cyclization, hydroxylation, dehydroxylation, alkylation, *O*-dealkylation, halogenation, dehydrogenation, double-bond reduction, carbonyl reduction and ring degradation (Das and Rosazza, 2006). For flavonoids, cytochrome P450 (CYP) hydroxylation of the B ring, leading to catechol formation, and/or A ring would be the major site of hepatic metabolism (Nielsen *et al.*, 1998). For instance, naringenin, the nonprenylated analog of 8-prenylnaringenin, mainly is hydroxylated on the 3′ position, yielding eriodictyol (Breinholt *et al.*, 2002) and also for the isoflavone phytoestrogens daidzein and genistein A and B ring hydroxylation is the main route of hepatic metabolism (Hu *et al.*, 2003b). Methylated

flavonoids often are demethylated in the liver. The methylated isoflavones formononetin and biochanin A are O-demethylated into respectively daidzein and genistein (Hu et al., 2003b; Lania-Pietrzak et al., 2005) and demethylation on both the A and B rings has been shown for a number of flavonoids (Nielsen et al., 1998; Breinholt et al., 2002; Kagawa et al., 2004; Wen and Walle, 2006).

However, due to the presence of the prenyl side chain, hepatic metabolism seems to be different for prenylflavonoids. Using rat liver microsomes as a model, Yilmazer et al. (2001) showed that phase I metabolism of xanthohumol yielded four metabolites. The formation of three of them involved epoxidation of the prenyl group in the A ring. The fourth metabolite was formed by hydroxylation of the B ring of X, yielding a catechol structure. This shows that the prenyl group in the A ring of prenylflavonoids would be the major site of hepatic phase I metabolism by CYP enzymes and not hydroxylation of the B ring. In a recent study on xanthohumol transformation by human liver microsomes, the prenyl group also was the primary site of metabolism (Nikolic et al., 2005). However, the most abundant metabolite was not a cyclization product of xanthohumol but a trans-X

alcohol after oxidation of the terminal methyl group of the prenyl chain.

Phase I metabolism of the flavanones isoxanthohumol and 8-prenylnaringenin also mainly took place on the prenyl chain. 8-Prenylnaringenin metabolism yielded four major metabolites (Nikolic et al., 2004). Two were identified as cis- and trans-8-prenylnaringenin alcohol, from which the latter was more abundant and could further be oxidized to trans-8-prenylnaringenin aldehyde. The fourth was oxidized on the 3′ position yielding 8-prenyleriodictyol. Incubation of human hepatocytes with 8-prenylnaringenin revealed that phase II metabolism mainly involved 7-O-glucuronidation on the A ring of 8-prenylnaringenin and its alcohol metabolites (Nikolic et al., 2006). Isoxanthohumol metabolism showed to be very similar as for 8-prenylnaringenin (Nikolic et al., 2005), yielding the cis- and trans-IX alcohol as main metabolites (Figure 52.3).

The most interesting finding however was that, although not the most abundant, one metabolite of isoxanthohumol was identified as 8-prenylnaringenin, indicating demethylation of isoxanthohumol in the liver. Although O-demethylation of chalcones (Sanchez-Gonzalez and Rosazza, 2004) and
Figure 52.3 Liver metabolism of 8-prenylnaringenin. Main phase I and II metabolites of 8-prenylnaringenin. Xanthohumol (X) may chemically be converted into isoxanthohumol (IX) in the intestine, increasing the isoxanthohumol concentration. Phase I metabolism of isoxanthohumol mainly yields cis- and trans-alcohols of the prenyl group but may also be an extra source of 8-prenylnaringenin by hepatic O-demethylation of IX.

non-prenylated analogs of 8-prenylnaringenin on the A ring (Nielsen *et al.*, 1998; Ibrahim *et al.*, 2003) has been shown, no demethylation of xanthohumol into desmethylxanthohumol was found (Yilmazer *et al.*, 2001) and previous attempts to activate isoxanthohumol into 8-prenylnaringenin with liver enzymes were unsuc-cessful (Coldham *et al.*, 2002). Therefore, although 8-prenylnaringenin was only a minor metabolite in this study, this was the first report of the role of isoxanthohumol as a pro-estrogen, being activated into the potent phytoestrogen 8-prenylnaringenin by human liver enzymes such as CYP1A2 (Guo *et al.*, 2006).

Metabolism of flavonoids by intestinal bacteria

While many recent studies focus on the absorption of flavonoids and the importance of liver phase I and II metabolism toward their final biological activity, it is often forgotten that a major fraction of ingested flavonoids reaches the colon directly or through enterohepatic circulation (see above). Here, the aglycones can be absorbed from the colon or act as substrate for the indigenous bacterial community with their extensive metabolic potential. In many cases bacterial metabolism of polyphenols leads to a decrease in biological activity. However, in some cases specific bacterial transformations give products with increased biological properties compared to the parent compounds. Therefore, bacterial degradation and specific transformation will be discussed separately.

Microbial Biotransformation Activity   When considering the metabolism of hop components by intestinal bacteria, it is important to first give an overview of their metabolic potency toward compounds that reach the large intestine. The human large intestine harbors an incredibly diverse microbial ecosystem comprising 400–500 species at concentrations of 10^{12} microorganisms per gram gut content, the highest recorded for any microbial habitat (Whitman *et al.*, 1998). For many years it was believed that the main purpose of the large intestine was the resorption of water and salt by the body and the facilitated disposal of waste materials. However, it has now become clear that this diverse group of colon bacteria play a key role in many processes that are in direct relationship with our body. Numerous studies show the role of intestinal microorganisms in the synthesis of short chain fatty acids that provide energy to the colon epithelium (Cummings and Englyst, 1987), the stimulation of the gut immune system (Salminen *et al.*, 1998), the synthesis of vitamins K and B (Conly and Stein, 1992) and the colonization resistance against exogenous pathogens (Hopkins and Macfarlane, 2003).

Most resident colon microbiota typically perform fermentation processes taking care of carbohydrate and protein breakdown, but it has become clear that many bacterial groups are also capable of transforming xenobiotic compounds (Macdonald *et al.*, 1983; Ilett *et al.*, 1990; Aura *et al.*, 2002). The metabolic potency of the intestinal microbiota is considered to be enormous, rivaling that of the liver in the number of biochemical reactions and transformations in which it participates (Macfarlane and Macfarlane, 1997). In contrast to the oxidative and conjugative reactions from the phase I and II enzymes in the enterocytes and hepatocytes, the bacterial metabolism is more reductive, hydrolytic and even of degradative nature with a great potential for both bioactivation as detoxification of xenobiotics (Table 52.3) (Ilett *et al.*, 1990). Additionally, intestinal microbiota also interferes with the human biotransformation process through the enterohepatic circulation of xenobiotic compounds. Once released in the intestinal lumen, liver conjugates may be hydrolyzed again by bacterial enzymes such as β-glucuronidase, sulfatase and glucosidases. This would negate the detoxification cycle and delay the excretion of many exogenous compounds since the original compounds or phase I metabolites are more prone to intestinal absorption than their phase II conjugates.

Degradation of Flavonoids in the Colon   Colonic metabolism of dietary flavonoids has been extensively studied and associations between the urinary excretion of simple phenolic structures, such as hippuric acid derivatives, and bacterial degradation of flavonoids have been shown in many studies (Gonthier *et al.*, 2003; Gao *et al.*, 2006). It is clear that the metabolites are formed by microbial action, as lower recovery was found in human and animal studies where antibiotics were dosed prior to the flavonoid uptake (Gott and Griffiths, 1987; Kohri *et al.*, 2001) and as phenolic metabolites were not detected in germ-free rats (Griffiths and Barrow, 1972).

Bacterial flavonoid degradation follows a very general pattern in which many non-specific metabolites are formed, such as hydroxylated phenylpropionic acids. The consequence is that a relatively small number of phenolic degradation products are formed in the colon from the extremely diverse group of natural flavonoids (Rechner *et al.*, 2004). Already in 1956 it was shown that flavonoid degradation involves ring fission of the heterocyclic C ring (Booth *et al.*, 1956). More studies have elucidated the complete degradation pathway (Braune *et al.*, 2001; Cermak *et al.*, 2006). With naringenin as example, the degradation starts with isomerization of the flavanone's C ring at the hetero atom into the corresponding chalcone phloretin (Figure 52.4). After reduction into a dihydrochalcone, further splicing takes place at the carbonyl moiety, yielding phloroglucinol and 3-(4-hydroxyphenyl)propionic acid. The metabolite 3-(4-hydroxyphenyl)propionic acid may be dehydroxylated into 3-phenylpropionic acid and the mixture can be absorbed from the colon. Both components often are recovered as such or conjugated in urine (Felgines *et al.*, 2000), but may also be subjected to β-oxidation and glycination in

Source: After Ilett *et al*. (1990).
Figure 52.4   Colonic degradation of naringenin by intestinal bacteria. Degradation of naringenin by intestinal bacteria yields 3-(4-hydroxyphenyl)propionic acid and phloroglucinol. Whereas the former may further be transformed to 3-phenylpropionic acid, the latter is completely degraded by intestinal bacteria.

the liver, yielding hippuric acid and 4-hydroxyhippuric acid (Rechner *et al.*, 2004). In contrast, phloroglucinol hardly ever is recovered as final metabolite, as it can be degraded into acetate, butyrate and CO_2 (Krumholz and Bryant, 1986; Brune and Schink, 1992).

Important to notice is that colonic degradation of flavonoids is highly variable because of two main reasons. Firstly, small differences in substitution pattern of flavonoids lead to major changes in colonic degradation (Griffiths and Smith, 1972; Lin *et al.*, 2003; Simons *et al.*, 2005). The major factor determining rapid degradation is the presence of a 5- and 7-OH on the A ring plus a 4′-OH on the B ring. Methoxy groups however, both on A or B ring significantly slow bacterial degradation. A good example of these differences is the degradation of the isoflavone phytoestrogens. Genistein, having all necessary OH groups, is rapidly degraded into 2-(4-hydroxyphenyl)propionic acid and phloroglucinol (Schoefer *et al.*, 2002), whereas daidzein, lacking the 5-OH, may be transformed into *O*-desmethylangolensin (*O*-DMA) but is not fully degraded into phenolic acids (Schoefer *et al.*, 2002). Secondly, large interindividual differences were noted in the degradation of specific flavonoids. This has led to the separation of individuals into high, moderate and low flavonoid degraders (Erlund, 2004; Simons *et al.*, 2005).

As degradation of flavonoids leads to a decrease in biological activity, especially when the structure of the parent compound is necessary to interact with specific targets in the human body such as estrogen receptors, knowledge about the intestinal degradation of prenylflavonoids from hops is crucial toward the understanding of possible health-related effects of these beer compounds. In our first report about intestinal metabolism of prenylflavonoids from hops (Possemiers *et al.*, 2005), we showed that isoxanthohumol and xanthohumol would have a high metabolic stability, whereas 8-prenylnaringenin was sensitive toward bacterial degradation. However, these preliminary conclusions were based on long term (8 days) batch incubations. Short term experiments under more relevant intestinal conditions (Possemiers *et al.*, 2006) showed that 8-prenylnaringenin also has a remarkably high intestinal metabolic stability compared to the non-prenylated naringenin. These results would have the important implication that, in contrast with easily degradable flavonoids (Rechner *et al.*, 2004; Cermak *et al.*, 2006), the fraction of 8-prenylnaringenin reaching the colon would have an increased bioavailability, as high metabolic stability favors the possibility of being absorbed from the colon to exert systemic biological effects.

Colonic Activation of Phytoestrogens: Activation of Isoxanthohumol into 8-Prenylnaringenin Next to degrading active dietary compounds into less active metabolites, a number of bacterial transformations are also known leading to the production of metabolites with increased biological activity. The best example of a transformation leading to more active metabolites is the activation of

phytoestrogens inside the human intestine (Figure 52.5). Until recently, the two most dominant well-known dietary phytoestrogens were the isoflavones from soy and the lignans present in flaxseed, grains, nuts, fruit . . .. For these two groups, it is now commonly accepted that the biological activity of these compounds largely depends on the metabolic potential of the intestinal bacteria (Rowland *et al.*, 1999; Raffaelli *et al.*, 2002; Turner *et al.*, 2003).

The isoflavones daidzein and genistein are present predominantly as glucosides in most commercially available soy products. Glucosides originating from food which escaped deconjugation in the small intestine, as well as phase II glucuronides and sulfates excreted in the gut through enterohepatic circulation, can be deconjugated (De Boever, 2001; Choi *et al.*, 2002; Tsangalis *et al.*, 2002). It was previously mentioned that genistein is much more susceptible to bacterial degradation than daidzein. Many reports have shown however, that the latter isoflavone not only can partially be degraded into *O*-DMA, but may also be transformed into equol. The production of equol, named after *equus* (Pike *et al.*, 1999) as it was first found in horse urine (Marrian and Haslewood, 1932), was shown to be performed exclusively by bacteria as antibiotic treatment decreased equol production (Blair *et al.*, 2003) and as equol was not produced in germ-free rats (Bowey *et al.*, 2003). As many *in vitro* (Lund *et al.*, 2004; Muthyala *et al.*, 2004; Turner *et al.*, 2004; Messina *et al.*, 2006) and *in vivo* studies (reviewed in Atkinson *et al.*, 2005) indicate that equol would exert increased health beneficial effects, the intestinal bacteria have a crucial role in the activation of soy phytoestrogens.

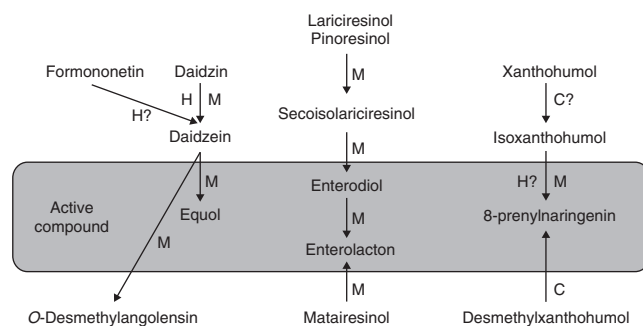
A similar story is true for lignans. These plant compounds are present in foods as inactive glycoside precursors (Liggins *et al.*, 2000) but can be activated inside the human intestine into the active mammalian lignans (enterolignans) enterodiol and enterolactone (Setchell *et al.*, 1981a, b;


Figure 52.5 Metabolism of phytoestrogens in the human body. The most relevant groups of phytoestrogens, the isoflavones, lignans and prenylflavonoids, are present in food as less active precursors. Inside the human body, they can be activated into the respective active metabolites equol, enterodiol + enterolactone and 8-prenylnaringenin. Although some transformations are of chemical origin (C) or catalyzed by human enzymes (H), microbial enzymes (M) have a crucial role in the generation of the final metabolites for each group of phytoestrogens.

Clavel *et al.*, 2006). The main dietary precursors are identified as secoisolariciresinol (SECO), matairesinol and recently lariciresinol and pinoresinol (Milder *et al.*, 2005). As this transformation again was shown to be performed uniquely by bacteria (Bowey *et al.*, 2003) and as the enterolignans would have increased biological activity (McCann *et al.*, 2005; Kuijsten *et al.*, 2006; Saarinen *et al.*, 2006; Zeleniuch-Jacquotte *et al.*, 2006), it can be concluded that intestinal bacteria also determine health effects related to lignan intake.

But might this also be happen with this new group of phytoestrogens from hops? In 2002, it was suggested that isoxanthohumol might act as a pro-estrogen *in vivo* supposing it could be demethylated into 8-prenylnaringenin after uptake in the human body (Coldham *et al.*, 2002) and in 2005, urinary 8-prenylnaringenin excretion was indeed detected after isoxanthohumol consumption by healthy men (Schaefer *et al.*, 2005). Although this was attributed to liver metabolism (see above), the intestinal microbial community might very well be responsible for this transformation, as a number of bacteria have been identified as capable to demethylate methoxylated aromates (Table 52.4).

And indeed, incubation of fecal samples with isoxanthohumol learned that intestinal bacteria are capable of *O*-demethylation of isoxanthohumol into 8-prenylnaringenin (Possemiers *et al.*, 2005). Using a dynamic *in vitro* model of the intestinal tract, designated the simulator of the human intestinal microbial ecosystem (SHIME) (Figure 52.6), we further unravelled this process and showed activation of isoxanthohumol mainly occurs in the distal part of the colon, leading up to 80% 8-prenylnaringenin production (Possemiers *et al.*, 2006). And whereas 8-prenylnaringenin was only a minor liver metabolite of IX, the only intestinal metabolism of the latter compound was the activation into 8-prenylnaringenin. Moreover, the definitive role of bacterial enzymes in this process was recently shown by the fact that no 8-prenylnaringenin production was noted

in germ-free rats (manuscript submitted). Therefore, we were the first to show that intestinal processes not only determines the activity of isoflavones and lignans, but that this is also valid for this new group of phytoestrogens, the prenylflavonoids.

But we discovered also another interesting parallel with the other groups of phytoestrogens. For isoflavones and lignans it is well known that the extent of bacterial metabolism is highly variable between individuals. It has been observed that only about 30–50% of humans have the intestinal metabolic potential to produce equol (Lampe *et al.*, 1994; Atkinson *et al.*, 2004; Atkinson *et al.*, 2006).

O-DMA production would occur in 80–90% of the individuals (Kelly *et al.*, 1993). As wide ranges in the production of the mammalian lignans also have been observed (Lampe *et al.*, 1994; Hutchins *et al.*, 2000; Atkinson *et al.*, 2006), interindividual differences in the intestinal bacterial community result in interindividual differences in the exposure to certain phytoestrogen metabolites.

Very similar observations were made for hop phytoestrogens. Only about 35% of *in vitro* tested intestinal microbial communities produced medium or high amounts of 8-prenylnaringenin from isoxanthohumol (Possemiers *et al.*, 2005; Possemiers *et al.*, 2006), separating individuals in high, moderate and low 8-prenylnaringenin producers (Figure 52.7). As clear cut correlations were found between the intestinal potential to activate isoxanthohumol and urinary 8-prenylnaringenin excretion after isoxanthohumol administration *in vivo* (Possemiers *et al.*, 2006), it was shown that differences in the intestinal bacterial community also for hop phytoestrogens result in interindividual differences in the exposure to the active phytoestrogen.

Probiotics to Increase 8-Prenylnaringenin Exposure After Beer Consumption?   Because of these marked interindividual differences in the metabolism of and exposure to phytoestrogens, differences in the health outcome of phytoestrogen consumption can also be expected. As this indicates that increased exposure to the active metabolite is favorable, the next question therefore would be: What can we do about it? How can one change the phytoestrogen metabolism status in individuals, making them exposed to increased amounts of the active metabolites? The answer could be simple: by introducing bacteria capable of metabolizing the precursors from food inside the intestine of non-producers, or in other words the use of specific probiotics to increase the intestinal production of bioactive metabolites.

A first attempt to apply this strategy to phytoestrogen metabolism has been made in our group by Decroos *et al.* who isolated a consortium capable of equol production (Decroos *et al.*, 2005, 2006). These positive results encouraged us to apply the same strategy for hop phytoestrogens. After screening a number of candidate demethylating bacteria strains (Table 52.4), only one bacterium, *Eubacterium limosum*, was found which could efficiently convert isoxanthohumol into 8-prenylnaringenin after a selection procedure. Administration of the strain to fecal samples increased the 8-prenylnaringenin production in these samples (Possemiers *et al.*, 2005). Last years, this bacterium has gained increasing attention because of its beneficial effects on the colonic environment in inflammatory bowel disease, possibly attributed to its butyrate-producing capacity (Kanauchi *et al.*, 2002, 2005). Therefore, the bacterium would be a suitable candidate probiotic to increase intestinal 8-prenylnaringenin production. Administration of the bacterium to the SHIME and rats increased both butyrate and 8-prenylnaringenin production, confirming this potential application (manuscript submitted).

Estrogenicity of Beers: A New Perspective

Consequences of bioavailability on biological activity

Because of the extremely diverse metabolic potential of the liver, many studies now focus on the influence of liver phase I metabolism toward final biological activity, mainly by using liver microsomes. However, although CYP-mediated metabolism of flavonoids has been shown *in vitro* in liver microsomes, it has never been shown to be important *in vivo* or in intact hepatocytes where conjugative metabolism may be expected to compete with oxidation (Otake *et al.*, 2002; Walle, 2004). This was also observed for 8-prenylnaringenin. Whereas, liver microsome incubations yielded a number of phase I metabolites (Nikolic *et al.*, 2004), 80% of the 8-prenylnaringenin metabolites produced by hepatocytes consisted of the phase II 7-*O*-glucuronide of 8-prenylnaringenin. In view of the exposure to 8-prenylnaringenin after beer consumption, one consequence of this would be that phase I activation only plays a minor role and that mainly isoxanthohumol conjugates can be expected after passage through the liver. This is confirmed by the fact that no 8-prenylnaringenin could be detected after administering isoxanthohumol to germ-free rats.

Figure 52.7 Interindividual differences in intestinal production of 8-prenylnaringenin. Interindividual differences in the conversion of isoxanthohumol into 8-prenylnaringenin by intestinal bacteria derived from 51 individuals. Statistical two-step cluster analysis revealed three groups with significantly different means ($p < 0.01$). Individuals were separated in low (a), moderate (b) and high (c) 8-prenylnaringenin producers. *Source*: After Possemiers *et al.* (2006).

A second consequence of extensive phase II metabolism is the observation that the oral bioavailability of flavonoid aglycones generally is very low (Liu *et al.*, 2003; Walle *et al.*, 2004). This means that mainly the conjugates circulate through the body and can exert systemic effects. Although glucuronides/sulfates sometimes remain biologically active or even have increased activity (Manach *et al.*, 1998; Fang *et al.*, 2003), conjugation can also decrease the biological activity. However, two remarks should be made. A number of flavonoids might already have effects in the intestine itself, for example protective effects of xanthohumol against colon cancer (Gerhauser *et al.*, 2002), leading to a high biological activity independent of (low) oral bioavailability (Scalbert *et al.*, 2002; Walle *et al.*, 2004). Moreover, many reports now describe that both conjugation and deconjugation can occur in the tissues at cellular level, which may influence the amount of active aglycon in the tissues (Santner *et al.*, 1984; Zhu *et al.*, 1996; Spencer *et al.*, 2004).

A last, and for hops most important, consequence of enterohepatic circulation is that a major fraction of the ingested flavonoids reach the colon where they become substrates for bacterial enzymes. Hop prenylflavonoids were shown to be metabolically stable against colonic degradation, making them good substrates for absorption from the colon or specific metabolic processes, in this case the demethylation of the pro-estrogen isoxanthohumol into the highly potent 8-prenylnaringenin. As our studies showed that the intestinal bacteria are responsible for *in vivo* demethylation of IX, the combination of an extensive liver first-pass effect, a high metabolic stability of prenylflavonoids and a good absorption of 8-prenylnaringenin from the gut create ideal circumstances for efficient intestinal activation of isoxanthohumol and increased exposure to 8-prenylnaringenin after beer consumption.

Beers and estrogens

Estrogen Exposure After Beer Consumption When reviewing the prenylflavonoid composition of beers (Table 52.2) and taking the recent knowledge about isoxanthohumol transformation into account, it is clear that the picture now looks completely different. These recent findings show that the final exposure to the potent phytoestrogen is not only dependent on the original 8-prenylnaringenin concentrations in beers, but also on the amount of isoxanthohumol which is being transformed into 8-prenylnaringenin inside the human colon. As the isoxanthohumol concentrations in beers often are in the range of one to a few mg/l, the amount of isoxanthohumol in beers is generally 10–30 times higher than the 8-prenylnaringenin amounts. If isoxanthohumol is efficiently transformed in the intestine and if 8-prenylnaringenin is well absorbed from the colon, this process could easily 10-fold increase the circulating 8-prenylnaringenin concentrations.

As further studies are needed to investigate the final biological relevance of these findings, one can now only hypothesise about whether or not regular moderate beer consumption could lead to exposure to biologically active 8-prenylnaringenin concentrations. Even when all isoxanthohumol would be converted into 8-prenylnaringenin, the final 8-prenylnaringenin concentrations will still be much below the reported concentrations leading to negative effects in rats, 100 mg/l drinking water (Milligan *et al.*, 1999) or 68 mg/kg body weight (Christoffel *et al.*, 2006; Rimoldi *et al.*, 2006). Conclusions about positive effects of long term exposure to low 8-prenylnaringenin concentrations are even more difficult to make as extrapolation of *in vitro* results is very difficult and no long term studies have been published in which low 8-prenylnaringenin concentrations were dosed. However, some indications of biological activity can be given based on data from hop-based dietary supplements. These supplements generally contain a daily dose of about 100 μg 8-prenylnaringenin (Table 52.2) and claim specific biological effects such as alleviating menopausal discomforts. Although many of these claims lack thorough scientific background (Coldham and Sauer, 2001), a first prospective placebo controlled study was recently published which indicated that a hop supplement, standardized on 100 μg 8-prenylnaringenin/day, exerted favorable effects on vasomotor symptoms and other menopausal discomforts after 6 weeks (Heyerick *et al.*, 2006). However, these supplements also contain 10–20-fold higher isoxanthohumol concentrations. In view of the recent findings, the active 8-prenylnaringenin dose inducing the effect may be higher due to intestinal activation of IX. But nevertheless, if further studies show that these hop supplements really have beneficial health outcome, similar effects might also be expected from moderate beer consumption as the prenylflavonoid composition in beers are similar as in these medicinal products (Table 52.2).

Interindividual Variability One major drawback for positive biological effect of both beers and hop-based supplements, based on *in vivo* activation of the pro-estrogen IX, is the reported interindividual variation in the intestinal potential to produce 8-prenylnaringenin. If this process only efficiently occurs in one-third of humans, this would imply that, after consumption of identical amounts of hop-containing products, some people could be exposed to at least 10-fold higher 8-prenylnaringenin doses because of their intestinal capacity to transform IX. This would then also lead to interindividual differences in biological health effects. The fact that in the previously mentioned study on the effect of hops on menopausal complaints (Heyerick *et al.*, 2006), high variability was found in the response to the product, separating individuals in responders and non-responders, is a further indication of the importance of the (variable) intestinal activation of isoxanthohumol and absorption of 8-prenylnaringenin.

Future Perspectives From the brewers point of view, the valuable constituents of hops are mainly the bitter (alpha) acids and hop oils. Normally, hops are added to the boiling wort as the alpha acids isomerize under these conditions into the bitter isoalpha acids. As the hop oils, providing the hoppy flavor to beer, are evaporated or degraded during wort boiling, "late hopping" (hop dosage at the end of the wort boiling) can be used to increase the hoppy flavor. However, in view of the recent findings on the biological activity of hop prenylflavonoids, it might also be interesting to increase the polyphenol content in beers to create "bioactive beers." Because of the beneficial properties attributed to X, strategies are now being developed to increase the xanthohumol concentrations in beer up to several mg X/l (Wunderlich et al., 2005). But in the same line of thinking it would also be interesting to increase the amounts of isoxanthohumol in beers, which can be activated in the intestine. Diverse extraction methods by ethanol and CO_2 at different pressures lead to residues that contain more than 30% X. Using these X-enriched hop products, several brewing studies led to the production of beers with isoxanthohumol concentrations greater than 8 mg/l (Wunderlich et al., 2005).

However, this would imply the efficient intestinal conversion of isoxanthohumol into 8-prenylnaringenin and this is exactly hampered by interindividual differences in the intestinal transformation potential. Therefore, two extra strategies could be developed to ensure that everybody would be exposed to similar 8-prenylnaringenin concentrations. One could try to increase the 8-prenylnaringenin concentrations in beer by implementing a prefermentation step in the process to convert isoxanthohumol with our selected bacterium into 8-prenylnaringenin in the hop extract or beer intermediate. An alternative would be to create a "probiotic beer" by combining an IX-rich beer with the appropriate bacterium which can activate the isoxanthohumol in the intestine. There is currently already interest toward possible probiotic effects of beer consumption. Some beers still contain living yeast to which probiotic properties are now attributed (Kuhle et al., 2005). Moreover, some beers are produced by lactic acid fermentation, so there might be interest in the exploration of "probiotic healthy beers."

In conclusion, even though these recent findings may have important biological consequences, the final question remains whether beer will ever have a "healthy image" or in other words: Does the average beer consumer like to associate drinking a beer with health effects? A recent survey among menopausal women to investigate a possible market for a beer which would relieve menopausal complaints, learnt that women cannot imagine to buy or order a special "menopause beer" but rather buy pharmaceuticals (personal communication). Therefore, the recent findings about intestinal activation of isoxanthohumol might mainly find its applications among the producers of hop-based dietary supplements and pharmaceuticals.

Summary Points

- Hop is an essential ingredient in beer providing bitterness and taste.
- It contains the most potent phytoestrogen, 8-prenylnaringenin. This compound mimics the activity of the female sex hormone estradiol and may be applied in the relief of menopausal complaints.
- The concentration in beer is too low for eliciting a positive health effect.
- Recent research has shown that another hop compound, isoxanthohumol (IX), can be converted by gut bacteria to the more potent 8-prenylnaringenin.
- This isoxanthohumol is present at much higher concentrations in beer. As it was shown that a large fraction of ingested isoxanthohumol reaches the colon, this process could easily 10-fold increase the 8-prenylnaringenin exposure.
- New strategies are being developed to increase the conversion of isoxanthohumol into 8-prenylnaringenin by means of health-promoting bacteria.
- These recent findings about increased 8-prenylnaringenin exposure can give new insights in the scientific question whether moderate beer consumption can lead to specific health outcomes.

Effects of Beer Ingestion on Body Purine Bases

Yuji Moriwaki and Tetsuya Yamamoto Division of Endocrinology and Metabolism, Department of Internal Medicine, Hyogo College of Medicine, Nishinomiya, Japan

Abstract

Increased adenosine triphosphate (ATP) degradation and diminished uric acid elimination are considered to be the major causes of alcohol-induced hyperuricemia. In addition, the ingestion of beer, which contains considerable amounts of various purines that might augment the hyperuricemic effect of alcohol, may lead to a greater increase in the plasma concentration of uric acid than other alcoholic beverages. A clinical study of the effects of beer drinking on plasma concentration and urinary excretion of oxypurine (hypoxanthine and xanthine, precursors of uric acid) clearly showed that increased ATP degradation followed beer ingestion. However, freeze-dried beer, which contains no alcohol, and low-malt beer also increased the plasma concentration of uric acid, while purine-free low-malt beer did not, which clearly indicated that the purines present in beer cause an increase in the plasma concentration of uric acid. Further, epidemiological studies and experiments regarding the effects of long-term beer drinking have shown that beer has a deleterious effect on serum uric acid concentration. Therefore, patients with gout should be encouraged to refrain from drinking large amounts of beer regularly.

Introduction

Alcohol consumption increases adenosine triphosphate (ATP) degradation in the liver, leading to an increased production of uric acid (Faller and Fox, 1982; Yamamoto et al., 1995; Nishioka et al., 2002; Yamamoto et al., 2002), while large amounts of alcohol increases the blood concentration of lactic acid, which inhibits uric acid excretion by the kidneys (Lieber, 1965). These two mechanisms, uric acid overproduction and uric acid under excretion, are considered to be the major contributors to alcohol-induced hyper uricemia. In addition, fermented drinks are considered to augment the hyperuricemic effect of alcohol and increase the risk of gout, since they contain greater concentrations of purines than distilled drinks (Gibson et al., 1984). Among alcoholic beverages, beer contains considerably

greater amounts of various purines, including guanosine, adenosine, xanthine, and guanine (Yamamoto et al., 2002). Although findings of a case-control study suggested that the high purine content in beer might play an important role in the risk of gout by augmenting the hyperuricemic effect of alcohol (Gibson et al., 1983), definitive data have become available only recently. According to recent studies, beer seems to affect the concentrations of body purine bases to a greater degree than other alcoholic beverages.

Little is known regarding the effects of beer drinking on the plasma concentration and urinary excretion of purine bases other than uric acid, though there are several studies on the effect of beer on plasma uric acid (Eastmond et al., 1995; Nishioka et al., 2002; Yamamoto et al., 2002). In the present review, the effects of beer drinking on the plasma concentration and urinary excretion of oxypurine (hypoxanthine and xanthine), as well as those of uric acid, are described. However, before discussing the effects of beer drinking on body purine bases, it is important to separately examine the effects of alcohol and purines present in beer.

Effects of Alcohol on Body Purine Bases

Lieber administered alcohol to non-gouty heavy drinkers and found an increase in blood lactic acid and uric acid levels, along with a concomitant decrease in urinary uric acid excretion. From those results, he proposed that lactic acid formed during the metabolism of alcohol interfered with the urinary excretion of uric acid, leading to increased plasma levels of uric acid (Lieber, 1965).

Thereafter, Puig and Fox proposed that alcohol-enhanced abrupt ATP consumption was also involved in increased levels of plasma purine bases as a mechanism of alcohol-induced hyperuricemia (Puig and Fox, 1984), as they had earlier found increases in both plasma oxypurine levels and urinary oxypurine excretion after the administration of acetate (Faller and Fox, 1982). During the conversion of acetate to acetyl-CoA, ATP is dephosphorylated to adenosine monophosphate (AMP) and, since ATP is converted

to AMP in this pathway, 2 mol of high-energy phosphate is consumed for each mole of alcohol metabolized. Although most of the AMP formed is re-synthesized to ATP, a small part of AMP may enter the pathway of adenine nucleotide degradation, leading to uric acid production.

Later, it was shown that acetaldehyde decreased ATP, while it increased AMP, adenosine diphosphate (ADP), glyceraldehyde 3-phosphate + dihydroxyacetone phosphate, and hypoxanthine levels in erythrocytes (Yamamoto *et al.*, 1995). Further, the addition of pyruvate to erythrocyte incubation medium prevented the acetaldehyde-induced changes described above, indicating that pyruvate was converted to lactic acid by lactic dehydrogenase together with the conversion of nicotinamide adenine dinucleotide reduced form (NADH) to nicotinamide adenine dinucleotide (NAD) in erythrocytes (Yamamoto *et al.*, 1993). These results suggest that the conversion of NAD to NADH plays an important role in glycolysis and glycolytic ATP production. Since acetaldehyde is metabolized to acetate, coupled with the conversion of NAD to NADH in erythrocytes, it is strongly suggested that inhibition of the reduction in redox potentials of nicotinamide adenine nucleotides by pyruvate prevents acetaldehyde-induced inhibition of glycolysis, glycolytic ATP production, and adenine nucleotide degradation. In fact, after consuming alcohol, the concentrations of AMP, ADP, and glyceraldehyde 3-phosphate + dihydroxyacetone phosphate in erythrocytes increase and that of pyruvic acid in blood decreases significantly, with a concomitant increase in the plasma concentration and urinary excretion of oxypurine in healthy subjects (Yamamoto *et al.*, 1993), suggesting that acetaldehyde-induced adenine nucleotide degradation in erythrocytes may contribute to the increase in plasma concentration of oxypurine caused by alcohol. Therefore, it is also considered that glycolysis inhibition reduces glycolytic ATP synthesis, while a decrease in the concentration of inorganic phosphate in the cytosol enhances adenine nucleotide degradation.

In addition, purines present in beer contribute to increases in plasma concentration and urinary excretion of purine bases. Therefore, in the following section, the effects of beer on body purine bases are discussed from the viewpoint of purines present in beer, since the effects of alcohol on body purine bases are commonly observed with the consumption of all alcoholic beverages.

Effects of Purines in Beer on Body Purine Bases

Effects of short-term beer drinking on body purine bases

In a previous study (Gibson *et al.*, 1983), patients with gout were found to drink greater amounts of alcoholic beverages than control subjects. Although the daily intake of most nutrients, including total purine nitrogen, was similar,

41% of the subjects with gout consumed more than 60 g of alcohol daily. Further, it was demonstrated that the intake of purine nitrogen, half of which was derived from beer, was higher in those with gout who consumed more than 60 g of alcohol daily. From those results, it was suggested that the effects of ingested purines, half of which were derived from beer, had a clinical effect on serum uric acid, augmenting the hyperuricemic effect of alcohol. They also demonstrated that consumption of beer containing 53 g of ethanol and 70.6 mg of purine nitrogen over 4 h increased the plasma concentration of uric acid, though an equal volume of artificial fruit juice sweetened with glucose did not, suggesting that both the purines and alcohol in beer contributed to the increases in plasma concentration and urinary excretion of uric acid (Gibson *et al.*, 1984). In addition, the same study group suggested that the relatively large amounts of guanosine present in beer may be more quickly reabsorbed and rapidly converted to uric acid in humans, since guanosine is more readily absorbed than other nucleosides, nucleotides, or bases in animals (Gibson *et al.*, 1983). In another study, it was demonstrated that beer (0.8 ml ethanol equivalent/kg body weight) increased the serum concentration of uric acid by 13.6%, while whisky or Japanese distilled liquor (0.8 ml ethanol equivalent/kg body weight), which contains very low levels of purines, did not affect the serum concentration of uric acid (Nishioka *et al.*, 2002). Together, these results strongly suggest that the effects of purines present in beer on plasma uric acid levels are not negligible. Consequently, regular beer is considered to have a deleterious effect on uric acid metabolism and patients with gout are recommended to severely regulate their consumption.

Studies on the effects of beer on plasma concentration and urinary excretion of purine bases (hypoxanthine, xanthine, and uric acid) are scarce. However, one study demonstrated that regular beer (10 ml/kg body weight) significantly increased the plasma concentrations of hypoxanthine and xanthine by 3.5- and 4.7-fold, respectively, 30 min after ingestion, and increased the urinary excretion of hypoxanthine and xanthine by 4.0- and 4.5-fold, respectively, when measured 1 h after ingestion (Figures 53.1 and 53.2).

Further, in those subjects the plasma concentration of uric acid increased by 6.5% at 30 min, 9.6% at 60 min, and 4.2% at 90 min after ingestion. On the other hand, the urinary excretion of uric acid was not changed throughout the experimental period (Yamamoto *et al.*, 2002) (Figures 53.3 and 53.4).

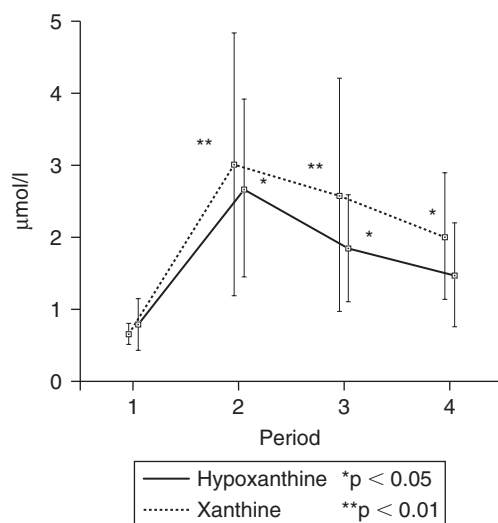
Low-alcohol and alcohol-free beer are becoming popular, and various kinds of non-alcoholic beer from various countries are available to consumers, however, there has been no detailed study regarding the effects of non-alcoholic beer on the plasma concentration and urinary excretion of purine bases. It was previously demonstrated that ingestion of regular beer (10 ml/kg body weight) by healthy male subjects increased the plasma concentration of uric acid


Figure 53.1 Changes in plasma concentrations of hypoxanthine and xanthine after ingestion of regular beer.

Figure 53.2 Changes in urinary excretion of hypoxanthine and xanthine after ingestion of regular beer.

Figure 53.3 Changes in plasma concentrations of uric acid after ingestion of regular beer.
Figure 53.4 Changes in urinary excretion of uric acid after ingestion of regular beer. Regular beer did not have an effect.

Figure 53.5 Effects of non-alcoholic (freeze-dried) beer on the plasma concentration of uric acid.

by approximately 0.50 mg/dl, while freeze-dried beer (0.34 g/kg body weight), which contained no alcohol, also increased that by approximately 0.34 mg/dl (Yamamoto *et al.*, 2002) (Figure 53.5).

Since 10 ml of regular beer contains 0.34 g of content when freeze-dried, the amount of purines in freeze-dried beer is the same as in regular beer. However, freeze-dried beer did not have an effect on the plasma concentrations and urinary excretion of hypoxanthine and xanthine, suggesting that the purines were converted to uric acid via hypoxanthine and xanthine in the liver and small intestine with the absence of alcohol in the freeze-dried beer (Yamamoto *et al.*, 2002) (Figures 53.6 and 53.7).

In another study, the effect of alcohol-free beer (1.5 l) on uric acid metabolism was studied in four gout patients, and

Figure 53.6 Effects of non-alcoholic (freeze-dried) beer on the plasma concentrations of hypoxanthine and xanthine.
Figure 53.7 Effects of non-alcoholic (freeze-dried) beer on the urinary excretion of hypoxanthine and xanthine.

the results showed that there was no increase in the plasma concentration of uric acid (Eastmond *et al.*, 1995). However, the discrepancies between those findings remain unclear.

Beer contains isohumulones, bittering agents derived from hops, which may also have some unknown effects on body purine bases. Since favorable effects of isohumulones on lipid metabolism have been reported, further studies of their effects on purine metabolism are required.

In light of the hyperuricemic effect of purines in beer, low-malt beer (*happo-shu*) and purine-free *happo-shu* have been recently developed in Japan. The former contains a lower amount of malt and a considerable amount of purines, while the latter contains the same lower amount of malt and a very low level of purines (Yamamoto *et al.*, 2004).
Figure 53.8 Effects of regular and purine-free *happo-shu* (low-malt beer) on the plasma concentration of uric acid.

Ingestion of regular *happo-shu* (10 ml/kg body weight) increased the plasma concentration of uric acid, while that of purine-free *happo-shu* did not, which clearly indicates that the purines present in the former caused an increase in the plasma concentration of uric acid (Figure 53.8).

That study also demonstrated the effects of purines in regular *happo-shu* on the plasma concentration and urinary excretion of oxypurine. The urinary excretion of hypoxanthine and xanthine increased after drinking regular *happo-shu*, as did the plasma concentration of xanthine, as compared with purine-free *happo-shu*, whereas the plasma concentration of hypoxanthine with regular *happo-shu* was not significantly different from that following drinking of purine-free *happo-shu*. These results indicate that purines in regular *happo-shu* increase the production of oxypurine (Figures 53.9 and 53.10).

The plasma concentrations of uric acid and oxypurine may increase as blood alcohol level increases (6.5–10 mmol/l). Therefore, purine-free *happo-shu* seems to be better than beer in regards to its effect on plasma uric acid only within a range of 6.5–10 mmol/l of blood alcohol, since an increase in the ingested volume of purine-free *happo-shu* raises the plasma concentration of uric acid.

Both alcohol-free beer and purine-free *happo-shu* have deleterious effects on uric acid metabolism, though to a lesser degree than regular beer. Therefore, even when ingesting non-alcohol beer or purine-free *happo-shu*, consumption of a large amount of these beverages as an alternative to regular beer should be avoided by gout patients.

Effects of long-term beer drinking on body purine bases

Present knowledge of beer-induced hyperuricemia is mainly based on data obtained from a variety of short-term experiments, and it remains unclear whether long-term beer
Figure 53.9   Effects of regular and purine-free *happo-shu* (low-malt beer) on the urinary excretion of hypoxanthine and xanthine.
Figure 53.10   Effects of regular and purine-free *happo-shu* (low-malt beer) on the plasma concentrations of hypoxanthine and xanthine.

drinking has the same effect on uric acid that has been found in short-term studies. It is considered important to investigate the effect of long-term moderate beer drinking on the increase of uric acid concentration in plasma, since such an increase may induce a gouty attack in patients with pre-existing hyperuricemia. According to Ka *et al.*, who studied the effects of long-term moderate beer drinking on the plasma concentrations and urinary excretion of purine bases, daily consumption of 15 ml/kg body weight of beer for 3 months significantly increased the plasma concentration and urinary excretion of uric acid, as compared with the values before starting the experiment (Ka *et al.*, 2005).

In contrast, uric acid and creatinine clearance remained unchanged throughout the study. Accordingly, it was suggested that the enhanced adenine nucleotide degradation induced by beer plays a role in the increases in plasma concentration and urinary excretion of uric acid. In addition, when the subjects were divided into two groups, those who

did not regularly drink more than 15 ml/kg body weight of beer and those who regularly drank more than 15 ml/kg body weight daily, the plasma concentration and urinary excretion of uric acid were significantly increased only in the latter group (Figures 53.11 and 53.12).

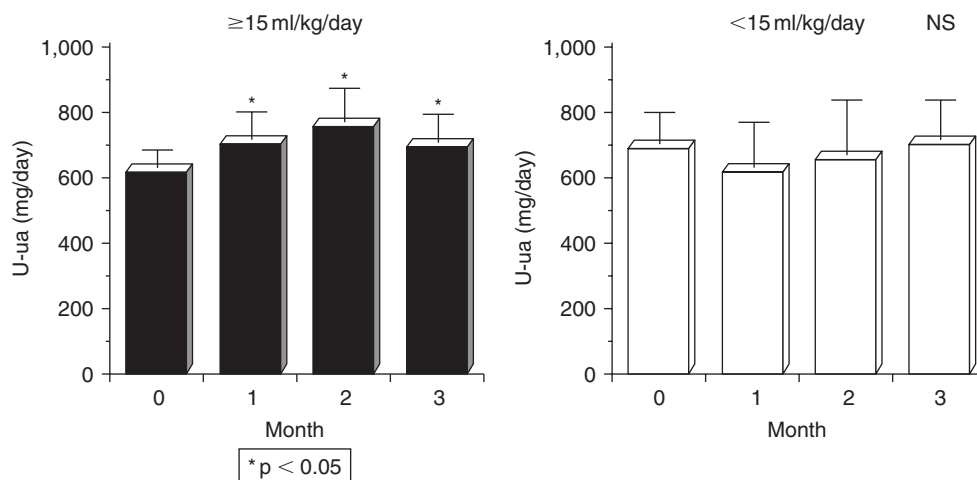
However, values for the 24-h urinary excretion of oxypurines and plasma concentration of oxypurines were not increased during the 3-month-experimental period, suggesting that the effects of long-term moderate beer drinking on the plasma concentrations and urinary excretion of oxypurines are limited, and have a short duration. These results indicate that the production of uric acid caused by beer drinking is a significant contributor to the increase in plasma uric acid concentration in subjects who regularly drink more than 15 ml/kg body weight of beer daily. Therefore, patients with gout should be encouraged to refrain from drinking large amounts of beer on a daily basis.
Figure 53.11 Effects of long-term beer drinking (3 months) on the plasma concentration of uric acid according to drinking habits.


Figure 53.12 Effects of long-term beer drinking (3 months) on the urinary excretion of uric acid according to drinking habits.

Epidemiological studies of the effect of beer drinking on serum uric acid

Using data from a retirement health examination of 2,487 male Japan Self Defence Force officials, it was demonstrated that among four different types of alcoholic beverages (beer, shochu, sake, and whisky) only beer consumption was significantly associated with an elevated level of serum uric acid (Kono *et al.*, 1994). On the contrary, results of a cross-sectional study of Japanese male office workers suggested that the increased risk of alcohol-induced hyperuricemia did not vary according to the type of alcoholic beverage consumed (Sugie *et al.*, 2005).

Recently, a retrospective study using data from 14,809 participants over the age of 20 in The Third National Health and Nutrition Examination Survey (NHANES III)

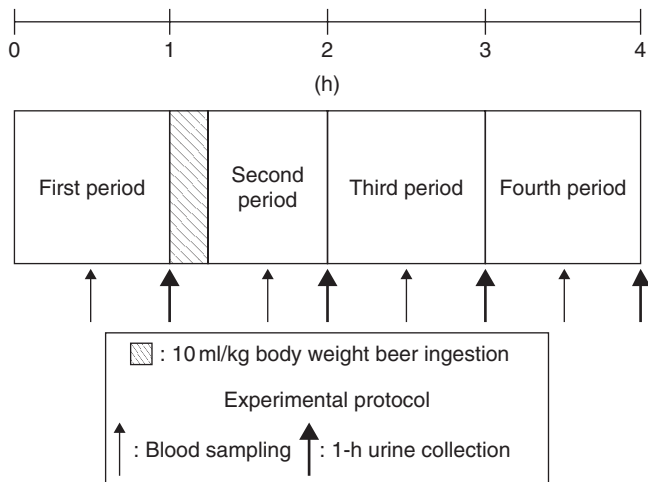
in the United States demonstrated that alcohol consumption, especially beer, was significantly associated with serum uric acid level (Choi and Curhan, 2004). Moreover, their prospective study of 47,150 male health professionals aged 40–75 years old conducted over 12 years showed that the risk of gout varied depending on the type of alcoholic beverage, as beer increased the risk of gout more than twice as much as did spirits, even though the alcohol content per serving was less for beer than spirits (12.8 g vs. 14.0 g), while two 4-oz glasses or more of wine per day was not associated with an increased risk of gout (Choi *et al.*, 2004). These findings suggest that the large purine content present in beer may play an important role in increased serum uric acid concentration and the incidence of gout, though whether other non-alcoholic offending factors are present in beer or some defending factors in wine remains unknown.


Figure 53.13 Experimental protocol used to investigate the short-term effects of various kinds of beer drinking on the plasma concentration and urinary excretion of purine bases. After an overnight fast except for water consumption, the subjects completely void their urine, after which the first 1-h urine samples are collected (first period). After the first urine samples are collected, beer (10 ml/kg body weight) containing 5.5% alcohol is ingested within 10 min. The second urine samples are collected after 1 h (second period), the third between 1 and 2 h (third period), and the fourth between 2 and 3 h (fourth period) after beer ingestion. The first, second, third, and fourth blood samples are drawn with heparinized syringes at the mid-point of the respective 1-h urine collections.

Prevention of Beer-Induced Increases in Plasma and Urinary Excretion of Purine Bases: Effects of Allopurinol

It has been suggested that ingestion of alcohol together with allopurinol (xanthine dehydrogenase inhibitor that inhibits the conversion of hypoxanthine to xanthine and xanthine to uric acid) decreases the conversion of allopurinol into oxypurinol, an active metabolite of allopurinol, while it increases the urinary excretion of allopurinol, which may reduce the hypouricemic effect of oxypurinol (Kaneko et al., 1990). In a recent study, the effects of allopurinol (300 mg) administered 13 h prior to ingesting beer (10 ml/kg body weight) on plasma and urinary excretion of purine bases were compared with beer drinking (10 ml/kg body weight) alone and allopurinol (300 mg) intake alone (Ka et al., 2006). With the pre-administration of allopurinol, the beer-induced increases in plasma concentration and urinary excretion of hypoxanthine were markedly increased as compared with beer alone. On the other hand, the sum of increases in plasma concentrations of purine bases by beer alone was greater than that by the pre-administration of allopurinol. In addition, allopurinol administration inhibited the beer-induced increase in plasma concentration of uric acid. These results suggest that abrupt adenine nucleotide degradation may increase the plasma concentration and urinary

excretion of hypoxanthine under a condition of low xanthine dehydrogenase activity, which is mostly ascribable to allopurinol. Further, the differences in the sum of increases in plasma concentrations of purine bases with and without the pre-administration of allopurinol were largely ascribable to a greater increase in urinary excretion of hypoxanthine. Also, allopurinol intake is suggested to be effective to control the rapid increase in plasma uric acid caused by drinking alcoholic beverages.

A common experimental protocol used to study the short-term effects of various kinds of beer on the plasma concentration and urinary excretion of purine bases is indicated in Figure 51.13.

Summary Points

- Beer contains considerable amounts of various purines as compared to other alcoholic beverages.
- The high purine content augments the hyperuricemic effect of alcohol contained in beer.
- Beer consumption increases the plasma concentrations and urinary excretion of hypoxanthine and xanthine.
- Both alcohol-free beer and *happo-shu* (low-malt beer) have deleterious effects on uric acid metabolism.
- Long-term alcohol consumption, especially beer, is significantly associated with increased serum uric acid levels.
- An epidemiological study showed that serum uric acid levels increased with increasing amounts of beer or liquor intake, though beer caused a larger increase.
- Pre-administration of allopurinol was found to be effective to control the rapid rise in plasma uric acid concentration caused by beer drinking.

Neuropharmacological Activity of *Humulus Lupulus* L.

Paola Zanoli and Manuela Zavatti Department of Biomedical Sciences, Section of Pharmacology and National InterUniversity Consortium for the Study of Natural Active Principles (CINSPAN), University of Modena and Reggio Emilia, Modena, Italy

Abstract

The traditional use of hops in the treatment of sleep disturbances has been supported by experimental studies performed in rodents, as described in the present chapter. An inhibitory influence on the central nervous system was suggested by the finding of a reduction in locomotor behavior together with an enhancement of pentobarbital hypnotic activity, following the oral administration of hop extracts. A lipophilic hop extract showed an antidepressant-like activity in an animal model of behavioral despair, without a significant anxiolytic activity. Among hop components, the bitter acids have been carefully investigated for their role in the neuropharmacological activities of hops. In particular, the fraction containing α-acids has been recognized to be mainly responsible for the sedative effects of hops. On the other hand the fraction containing β-acids appears to exert a central stimulatory activity, probably due to a reduction in the GABAergic activity. This hypothesis is supported by its effects in animal models of sedation and convulsions as well as in electrophysiological studies on cerebellar granule cells in culture.

Clinical trials specifically related to the sedative properties of hops are still inadequate since human studies were mainly performed using valerian–hop combination extracts.

List of Abbreviations

H. lupulus	*Humulus lupulus*
i.p.	Intraperitoneally
b.w.	Body weight
GABA	γ-Aminobutyric acid
CNS	Central nervous system
EPM	Elevated plus maze
FST	Forced swimming test
$5\text{-}HT_6$	5-Hydroxy-triptamine (serotonin) receptor type 6
ML_1	Melatoninergic receptor type 1
A_1	Adenosine receptor type 1

Introduction

Humulus lupulus L. (Cannabinaceae) is a dioecious twining perennial plant, widely cultivated throughout the temperate regions of the world. The female inflorescences (hop cones or "hops") (Figure 54.1) made up of membranaceous bracts contain a resinous yellow substance named lupulin. Hops are collected in the late summer and used in the brewing industry to add bitterness, flavor and aroma to beer.

In the traditional medicine the dried flowers were recommended for the treatment of sleep disturbances, restlessness, mania, toothache and earache.

The use of hops as a mild sedative came from the observation of fatigue, tiredness and sleepiness symptoms in the hop pickers, apparently due to resin absorption during harvesting or processing hops (Tyler, 1987). The tranquilizing and sleep-enhancing properties of *H. lupulus* were cited in old manuals of *Pharmacology and Pharmacognosy* (Fluckiger and Hanbury, 1879; Maisch, 1892; Schleif and Galludet, 1907; Greenish, 1909; Culbreth, 1927; Gathercoal and Wirth, 1936) as well as in modern textbooks of *Phytotherapy* (Newall *et al.*, 1996; Schulz *et al.*, 2001; Capasso *et al.*, 2003). The German Commission E Monographs advised to use the plant in the treatment of "discomforts during restlessness or anxiety and sleep disturbances" (Blumenthal, 1998).

Figure 54.1 The female inflorescences (hops) of *Humulus Lupulus* L.

A sedative-like activity of hops was observed in different animal species: frog (Staven-Groenberg, 1928), pigeon (Sikorski and Rusiecki, 1938), goldfish (Bouchardy, 1953) and golden carp (Grumbach and Mirimanoff, 1955). The administration of single components of hops allowed to suggest humulone and lupulone as responsible for the marked sedative effects observed in pigeons and small birds (Sikorski and Rusiecki, 1938). The prenylated acylphloroglucinols (humulone, lupulone and their analogs) are still under investigation for their neuropharmacological properties, as further described in the present chapter. On the other hand, prenylated flavonoids of hops are receiving an increasing attention primarily for the antioxidant and chemopreventive properties (xanthohumol) (Stevens and Page, 2004) and for the estrogenic activity (8-prenylnaringenin) (Chadwick et al., 2006).

Experimental Studies

The first investigation on the neuropharmacological effects of *H. lupulus* was performed by Hänsel and Wagener (1967). The oral administration of lupulone or ethanol hop extract (500 mg/kg body weight) in mice failed to influence motor activity and pentobarbital sleeping time. The lack of a clear sedative effect was also reported in human subjects treated with 250 mg of a lipophilic hop extract for 5 days (Stocker, 1967).

Subsequently, Bravo et al. (1974) intraperitoneally (i.p.) injected different types of the plant extract in mice for evaluating locomotor behavior. A different reduction in the spontaneous motor activity without a myorelaxant effect was observed in dependence of the solvent used in the extraction procedure. The ether extract was the most active in comparison with the aqueous and alcoholic ones. However, this effect was seen only at high doses (1 ml of hop extract 10%/20 g. b.w.).

In the study of Lee et al. (1993) a not well-identified hop extract was i.p. injected in mice at doses from 100 to 500 mg/kg b.w. Hypothermic, analgesic and anticonvulsant effects were found 30 min after the injection. Moreover, a reduction in the spontaneous motor activity together with a prolonged pentobarbital-induced sleeping time suggested a mild hypnotic activity.

The results of these studies, summarized in Table 54.1, might suggest a neurodepressant property of *H. lupulus*; but the different extraction procedures as well as the undefined composition of the administered preparations make still questionable the identity of the active sedative principle/s.

A degradation product deriving from hop constituents during storage, 2-methyl-3-butene-2-ol, was examined by Wohlfart et al. (1983). A high dose of the compound (206.5 mg/kg i.p. in rats) was needed to obtain a decline of motility by 50%. A higher dose (800 mg/kg i.p.) produced a narcotic effect in mice for about 8 h (Hänsel et al., 1980). Considering the small amount of 2-methyl-3-butene-2-ol detected in the commercially available hop extracts (maximum content 0.15%), a significant contribution of this compound to the sedative activity of hops can be reasonably excluded (Hänsel et al., 1982).

Few studies investigated the effects of hop flavonoids. Myrcene displayed analgesic activity in mice (Rao et al., 1990; Lorenzetti et al., 1991) but it was excluded to be responsible for the sedative effects of hops (Hänsel et al., 1980). During boiling wort with hops, myrcene gives rise to myrcenol which has been shown to prolong pentobarbital-induced sleeping time, when injected in mice, and to potentiate GABA receptor response *in vitro* (Aoshima et al., 2006).

Table 54.1 Behavioral effects of hop extracts or single components in laboratory animals

Effect	Hop extract/component	Laboratory animal	References
Reduced spontaneous motor activity	Ether > alcoholic > aqueous extract	Mice	Bravo et al. (1974)
Hypothermic, analgesic, anticonvulsant, reduced motor activity, prolonged pentobarbital-induced sleeping time	Non-identified hop extract	Mice	Lee et al. (1993)
Narcotic	2-Methyl-3-butene-2-ol	Mice	Hänsel et al. (1980)
Reduced motility	2-Methyl-3-butene-2-ol	Rat	Wohlfart et al. (1983)
Analgesic	Myrcene	Mice	Rao et al. (1990), Lorenzetti et al. (1991)
Prolonged pentobarbital-induced sleeping time	Myrcenol (produced from myrcene during boiling)	Mice	Aoshima et al. (2006)
Prolonged pentobarbital sleeping time, antidepressant	CO_2 extract, α-acid fraction	Rat	Zanoli et al. (2005)
Increased animal ambulation, increased rearings, reduced percentage of sleeping rats, antidepressant, worsened picrotoxin-induced seizures	β-Acid fraction	Rat	Zanoli et al. (2007)
Reduced spontaneous locomotor activity, increased ketamine-induced sleeping time, hypothermic	Ethanolic, CO_2 extract, α-acids, β-acids, hop pure oil	Mice	Schiller et al. (2006)

Our recent studies examined the neuropharmacological effects of a CO_2 hop extract and two single fractions containing α-acids (humulone and its analogs) and β-acids (lupulone and its analogs). The CO_2 extract was dissolved in Tween 80 (10%) and water, β-acid fraction in Tween 80 (5%) and water, while the α-acid fraction was solubilized in peanut oil. The activity of each substance was compared with one of the respective vehicles. The solutions were administered at different dosages (from 2.5 to 20 mg/kg b.w.) by oral gavage 60 min before the behavioral tests. We utilized a series of experimental models widely validated for the analysis of substances affecting central nervous system (CNS) functions. The evaluation of locomotor behavior was performed placing the single rats in the center of a square black-painted arena (100 × 100 cm) with 50 cm high walls. The animals were continuously filmed for 10 min by a camera and a detailed analysis was carried out by a computerized system. The results reported in Figure 54.2 show that only β-acid fraction was able to alter the locomotor activity of rats. This fraction increased ($p < 0.05$ vs. vehicle group) animal ambulation, particularly in the central area of the open field, while the CO_2 extract and the α-acid fraction did not significantly affect the length of rat pathways (Zanoli *et al.*, 2005, 2007). Examples of rat pathways in the open field arena following the different pharmacological treatments are reported in Figure 54.3. The rats placed in the unfamiliar environment of the open field are used to rear upon their hind feet. Comparing the rearings displayed by the different experimental groups of rats, it is clearly evident that only β-fraction significantly increased the number of rearings during the test (Figure 54.4). The results of these experiments suggested a different pharmacological profile of the two fractions of bitter acids: β-fraction appears to exert a stimulatory effect, while α-acids had no significant influence on animal locomotor behavior. With the aim of clarifying this crucial point, the influence on pentobarbital-induced sleeping time was investigated. The three substances were orally

administered 60 min before the i.p. injection of pentobarbital sodium (35 mg/kg). As reported in Table 54.2, the CO_2 extract and the α-fraction significantly prolonged sleeping time in comparison with pentobarbital plus vehicle treated rats. On the other hand β-fraction did not affect sleeping time but strongly reduced the percentage of sleeping rats. Therefore, the fraction containing β-acids appears to exert

an opposite effect (stimulatory) in comparison with α-fraction and CO_2 extract, both displaying a sedative effect.

For evaluating the anxiolytic activity of hop extract and its fractions, rats were submitted to the elevated plus maze (EPM) test, which is extensively validated as a tool to screen anxioselective effects of drugs. Animals were tested in a plus-shaped maze elevated above the floor level, with two wall-closed arms and two opposite open arms. Rats exposed to EPM tend to avoid the open arms and prefer to stay in the enclosed arms: there is an inverse correlation between anxiety levels and the exploration of the open arms. Thus, the substances that elicit an increase in the number of entries and in the time spent in open arms are considered anxiolytic drugs.

During the 5-min test, the number of entries and the time spent in open and closed arms were recorded. The hop extract and α-fraction were unable to affect these parameters, while β-fraction significantly increased the open arm entries only at the highest dose (10 mg/kg), suggesting hence a modest anxiolytic-like activity (Table 54.3). The effect of a classic anxiolytic drug (diazepam) is reported for comparison.
Figure 54.5 Immobility time of rats during forced swimming test. The substances (CO_2 extract, α- and β-acids) were orally administered three times (24 h, 5 h and 1 h) before the test. Imipramine (I), used as standard antidepressant drug, was orally administered (24 h, 5 h and 1 h before the test) at the dose of 20 mg/kg. The histograms represent the mean ± SEM ($n = 8$) of the immobility time of rats during 5-min test. *$p < 0.05$, **$p < 0.01$ vs. vehicle treated animals (V) (Anova followed by Dunnett's test). *Source*: The data were adapted from our previous papers (Zanoli *et al.*, 2005, 2007).

For a better knowledge about the neuropharmacological activity of hop extract and its fractions, we submitted rats to the forced swimming test (FST), a standard method for screening potential antidepressant agents. In the FST, animals are placed in a cylinder of water, from which they cannot escape during a 15-min pretest. This condition is thought to induce a state of behavioral despair, since the animals become immobile, remaining in a floating position without swimming or climbing. The duration of immobility is evaluated in a 5-min test session performed 24 h after the pretest. Antidepressant drugs, administered between the pretest and test periods, decrease the duration of immobility. The histograms reported in Figure 54.5 show that all the three substances at the dose of 5 mg/kg (and also at 10 mg/kg for the extract) significantly reduced the immobility time of rats. It must be underlined that a repeated schedule of administration (24 h, 5 h and 1 h before the test) was adopted for all compounds, including imipramine used as reference drug.

The results obtained in FST clearly demonstrate an antidepressant activity of hop extract as well as the two fractions. At our knowledge, it is the first demonstration of this type of activity for *H. lupulus*. Moreover these findings demonstrate a similar effect of the three substances, differently from the results related to the locomotor behavior and to the pentobarbital-induced sleep.

The issue related to the sedative activity of hops and its constituents has been resumed very recently by Schiller *et al.* (2006). Ethanolic and CO_2 extracts were orally administered in mice with the aim of checking their influence on body temperature, locomotor activity and ketamine-induced sleeping time. A hypothermic effect together with a reduction in motility and an increase in sleeping time brought the Authors to confirm the traditional use of hops in sleep disorders. In the same experimental conditions the authors tested the effects of different fractions of hop extract. Both fractions containing

α- and β-acids were able to prolong ketamine-induced sleeping time, but it must be stressed that the fraction containing β-acids needed an approximately six times higher dosage to significantly potentiate the narcotic event. This last result seems to suggest a contribution of β-acids to the sedative activity of the plant. The discrepancy between these results and our findings should be elucidated taking into consideration several factors (raw material, condition of storage, extraction procedure, type of solvent), besides the different applied dosages.

Molecular Mechanisms

Till now we have investigated a possible interaction of β-acid fraction with the GABA-benzodiazepine neurotransmitter system. The reduction in the hypnotic effect of pentobarbital in β-acids treated rats, suggested a decreased GABAergic activity. To validate our hypothesis we investigated the influence of β-acids on picrotoxin-induced seizures. The significant increase in the seizure severity and in the lethal effect observed in β-acids pretreated rats, in comparison with control ones, demonstrated that a reduction in the GABAergic activity could play an important role in the behavioral effect of β-acids (Figure 54.6). Electrophysiological studies performed on cerebellar granule cells in culture showed a reduction in GABA currents when β-acid fraction was applied together with GABA (Figure 54.7). On the other hand the capacity of hop extract to interact with benzodiazepine recognition sites was excluded by radioreceptor binding assays performed in our laboratories (Zanoli *et al.*, 2007).

Studies previously performed by Abourashed *et al.* (2004) demonstrated the capacity of a hop dried extract to bind serotoninergic 5-HT$_6$ receptors as well melatoninergic ML$_1$ receptors. The involvement of these receptors in sleep disturbances or in the regulation of circadian rhythm, respectively, has been demonstrated (Pickering and Niles, 1990; Shen *et al.*,
Figure 54.6 Influence of β-acids on picrotoxin-induced seizures. The animals pretreated with vehicle or β-acids were subcutaneously injected, after 60 min, with picrotoxin (5 mg/kg). The severity of picrotoxin-induced seizures was evaluated according to a modified behavioral scale (for details see Zanoli et al., 2007). Each column represents the mean ± SEM ($n = 6$). *$p < 0.05$ (Anova followed by Dunnett's test), **$p < 0.05$ (Fisher test). *Source*: The data were adapted from our previous papers (Zanoli et al., 2007).
Figure 54.7 Influence of β-acids on GABA currents in cultured cerebellar granule neurons. (a) Cerebellar granule cells in culture at 8 days *in vitro*. Calibration bar: 10 μm. (b) Whole-cell recordings of currents evoked by GABA 1 μM alone or in presence of hop β-acids 50 μg/ml (holding potential –60 mV). pA = picoAmpère; s = seconds. *Source*: The data were adapted from our previous papers (Zanoli et al., 2007).

1993). It must be underlined that the tested extract did not contain bitter acids, because a hydrophilic solvent was used in the extraction procedure (Abourashed et al., 2004).

The role of adenosine receptors in the sleep-inducing activity of a valerian–hop combination (Ze 91019) has been investigated by Müller et al. (2002). Ze 91019 as well as the valerian extract therein exhibited a partial agonist activity at A_1 adenosine receptors, while hop extract alone failed to exert a similar effect. Therefore an adenosine-mediated mechanism can be excluded to play a role in the sedative property of hops.

Clinical Studies

The clinical investigations on the efficacy of hop preparation in sleep disturbances generally refer to hops given in combination with other sedative herbs. A randomized, double-blind, controlled trial in patients suffering from sleep disorders showed equivalent efficacy and tolerability between a hop–valerian preparation and a benzodiazepine drug (Schmitz and Jackel, 1998). Sleep quality was determined by psychometric tests, psychopathologic scales and sleep questionnaires. This study pointed out the lack of withdrawal symptoms following hop–valerian treatment for 2 weeks, differently from benzodiazepine therapy.

The pharmacodynamic effects of a commercially available mixture of valerian and hops (Ze 91019) were studied in young adult patients using quantitative topographical electroencephalography (Vonderheid-Guth et al., 2000). A clear effect at the CNS level was observed 4 h after the intake of high dosage of the mixture (1,500 mg valerian plus 360 mg hops).

A multicenter, randomized and placebo-controlled study was conducted in 184 patients with mild insomnia, nightly administered with a combination of standardized extracts of hops (83.8 mg) and valerian (374 mg) for 28 days (Morin et al., 2005). Sleep parameters were measured by daily diaries and polysomnographic assays. The combination hops–valerian showed to have a modest hypnotic effect, improving sleep without producing significant residual effects and rebound insomnia. The lack of residual sedative effects had been previously stressed by Gerhard et al. (1996) in healthy volunteers, receiving a hop–valerian combination or flunitrazepam, used as reference drug. The objective measurement of cognitive psychomotor performance and the subjective questionnaires on well-being led to emphasize impairment of vigilance in the morning after ingestion of the benzodiazepine drug, while more alertness and activity were observed in patients treated with the herbal remedy. Therefore, the valerian–hop combination can be considered, a useful and safe alternative to the classic sedative drugs (Gerhard et al., 1996; Schmitz and Jackel, 1998; Kubish et al., 2004; Morin et al., 2005). However, no meaningful information regarding the potential clinical efficacy of hops alone can be extrapolated from these studies due to the presence of valerian in the clinical formulations.

Conclusions

Since a long time *H. lupulus* has been traditionally a reputed sedative herbal remedy and is used in the treatment of sleep disturbances. Previous (Bravo *et al.*, 1974; Lee *et al.*, 1993) and recent (Zanoli *et al.*, 2005, 2007; Schiller *et al.*, 2006) experimental studies performed in rodents confirmed the sedative properties of hops, even if there are some discrepancies in the results. As a whole, a reduced motility together with a prolonged pentobarbital-induced sleeping time was found. In our experimental conditions, hop extract failed to affect locomotor behavior, but it must be stressed that our dosages were much lower than the ones used in the other studies. However, the sleep-promoting activity of hops was confirmed by our findings of an enhanced pentobarbital hypnotic activity in hop extract treated rats.

Among hop components, the bitter acids have been studied to check their role in the sedative effect of the plant. The authors (Zanoli *et al.*, 2005; Schiller *et al.*, 2006) agree on the sedative property of α-acids, but they found opposite effects following the administration of β-acids. In fact, our experiments showed a stimulatory influence of β-fraction on CNS, probably due to an antagonistic effect on GABA neurotransmission (Zanoli, 2007).

The other hop components have been poorly investigated. Only one study reported an increase in ketamine- and ether-induced sleeping time by administering hop oil in mice, suggesting its contribution to the sedative effect of *H. lupulus* (Schiller *et al.*, 2006). In addition hop oil was demonstrated to cause a small potentiation of GABA response *in vitro* (Aoshima *et al.*, 2006).

In conclusion, the sedative effect of hops is confirmed by several experimental studies, but the antidepressant activity has been recognized only recently (Zanoli *et al.*, 2005, 2007). The common antidepressant effect of the bitter acids and the extract opens up new therapeutic perspectives for this medicinal plant. It might be an alternative herbal medication with a beneficial profile of efficacy and safety. In fact, St. John's Wort is commonly used in the treatment of moderate depressive disorders, but in recent years its pharmacological interactions with several drugs have been reported. More experimental studies are needed to further elucidate the neuropharmacological properties of *H. lupulus*, with particular attention for the antidepressant activity.

Summary Points

- Hop cones have been used in traditional medicine to treat sleep disturbances since a long time.
- Experimental evidence of the sedative property of hop extract has been supported by the finding of a reduced motor behavior and an enhanced pentobarbital hypnotic activity in hop extract treated animals.
- A CO_2 hop extract, as well as its α- and β-acid fractions, showed an antidepressant effect in an animal model of behavioral despair.
- Among hop components the fraction containing α-bitter acids has been recognized to play a main role in the sedative effect of hops.
- On the other hand, the fraction containing β-bitter acids seems to exert a stimulatory influence on CNS.
- No clinical trials utilizing hop extract alone have been performed till now.

Beer: Effects on Saliva Secretion and Composition

H.S. Brand, M.L. Bruins, E.C.I. Veerman and A.V. Nieuw Amerongen Section of
Oral Biochemistry, Department of Basic Dental Sciences, Academic Centre for Dentistry (ACTA),
Amsterdam, The Netherlands

Abstract

We investigated the effects of beer consumption on salivary
secretion rate, pH, uric acid and amylase concentration. Ten
healthy volunteers consumed either 300 ml top-fermented beer
or the same volume of non-alcoholic beer at 1 week intervals.
The consumption of beer induced a transient reduction in the
volume of chewing-stimulated whole saliva after 15 min. No
significant changes were observed in the salivary pH and con-
centrations of uric acid and amylase.

Introduction

Uric acid (Figure 55.1), the final oxidation product of
purine metabolism, is normally excreted in urine. Excessive
accumulation of uric acid in tissues leads to a type of arthri-
tis known as gout. This disease is characterized by deposi-
tion of large crystalline aggregates in joints leading to an
agonizingly painful attack (Kumar *et al.*, 1997).

Alcohol intake is associated with an increased risk of gout.
This risk varies substantially according to the type of alco-
holic beverage: beer confers a higher risk than spirits or wine
(Choi *et al.*, 2004). This is probably related to a beer-induced
increase in plasma concentration of uric acid. The ingestion
of regular beer by healthy volunteers resulted in a statistical
significant increase in the plasma concentration of uric acid
after 30 min (Yamamoto *et al.*, 2002; Ka *et al.*, 2003). An
Figure 55.1 Uric acid. Structural formula of uric acid.

elevation of plasma uric acid concentration was also reported
for patients with gout drinking beer (Gibson *et al.*, 1984).

Recently, it has been shown that uric acid can be quanti-
fied in saliva (Meucci *et al.*, 1998; Inoue *et al.*, 2003). The
concentration of uric acid in saliva correlates significantly
with the serum concentration (Veerman *et al.*, manuscript
in preparation). Therefore, the aim of this study was to
investigate whether consumption of beer affects the salivary
uric acid concentration.

Materials and Methods

Ten healthy volunteers participated in this study: seven
men and three women with a mean age of 32 years (rang-
ing from 23 to 50 years). They were instructed to abstain
from alcohol at least 16 h prior to the experiment and to
abstain from smoking, eating and drinking caffeine con-
taining beverages and tooth brushing at least 1 h prior to
the experiment (Hoek *et al.*, 2002). All experiments took
place between 9.30 and 12.30 a.m. to avoid potential
effects of diurnal variation on the composition of saliva
(Hardt *et al.*, 2005). This study was approved by the
Medical Ethic Committee of the Vrije Universiteit Medical
Centre, Amsterdam, The Netherlands.

In a crossover design, the volunteers consumed either
300 ml top-fermented beer (Palm, Steenhuffel Breweries,
Belgium, 5.2% alcohol) or 300 ml non-alcoholic beer
(Amstel Malt, Zoeterwoude, The Netherlands, <0.1% alco-
hol) within 5 min. Both beers were served at 8°C. The time
interval between both experimental conditions was 1 week.

Immediately before the consumption of beer and 15, 30,
45, 60, 90 and 120 min later, chewing-stimulated whole
saliva was collected in pre-weighed tubes for 5 min (Bots *et al.*,
2004; Brand *et al.*, 2004). During the collection of saliva,
the volunteers chewed one flat piece of 5×5 tasteless wax
(Parafilm "M," Pechiney Plastic Packaging, Chicago, USA).

The salivary flow rates were determined gravimetrically,
assuming 1 g = 1 ml, using an analytical balance (Sartorius
MP8, Göttingen, Germany). Within 5 min of collection,

the salivary pH was measured using a PHM 240 Sentron 1001 (Radiometer, Copenhagen, Denmark). Subsequently, the salivary samples were transferred to Eppendorf vials and centrifuged at 10,000 g for 10 min. The clarified supernatant was stored at −20°C.

The salivary concentrations of uric acid and amylase were quantified by capillary electrophoresis, using benzoic acid as an internal standard (BioFocus C2000, Biorad, Hercules, USA).

All data are expressed as mean ± SD. The overall differences of the salivary parameters were statistically analyzed with analysis of variance (ANOVA) for repeated measures, followed by paired Student's t-tests where appropriate. The statistical analysis was performed using the statistical software package SPSS version 10.0. All levels of significance were set at p < 0.05.

Results

Consumption of 300 ml top-fermented beer induced changes in the flow rate of parafilm-chewing-stimulated
Figure 55.2 Saliva secretion rate after beer consumption. Flow rate of chewing-stimulated whole saliva before and after consumption of 300 ml beer (white bars) or non-alcoholic beer (gray bars). Data are expressed as mean ± SD (n = 10). *p < 0.05 vs. top-fermented beer at T = 0, #p < 0.05 vs. non-alcoholic beer at T = 15.
Figure 55.3 Salivary pH after beer consumption. The pH of chewing-stimulated whole saliva before and after consumption of 300 ml beer (white bars) or non-alcoholic beer (gray bars). Data are expressed as mean ± SD (n = 10). No statistical significant differences were observed between beer and non-alcoholic beer.

whole saliva (Figure 55.2). A transient decrease in flow rate was observed 15 min after beer consumption (−15% vs. baseline values), which was not observed after consumption of non-alcoholic beer. The salivary pH did not differ between both experimental conditions (Figure 55.3).

Neither top-fermented beer nor non-alcoholic beer did induce significant changes in the salivary uric acid concentration (Figure 55.4) or uric acid output (Figure 55.5). The salivary amylase concentration (Figure 55.6) and amylase output (Figure 55.7) were not significantly affected too.

Discussion

This study demonstrated that consumption of a relatively small amount of top-fermented beer induced a transient decrease in saliva secretion after 15 min (Figure 55.2). This result is in agreement with a previous study by Enberg
Figure 55.4 Salivary uric acid concentration after beer consumption. Uric acid concentration of chewing-stimulated whole saliva before and after consumption of 300 ml beer (white bars) or non-alcoholic beer (gray bars). Data are expressed as mean ± SD (n = 10). No statistical significant differences were observed between beer and non-alcoholic beer.

Data are expressed as mean ± SD ($n = 10$). No statistical significant differences were observed between beer and non-alcoholic beer.

et al. (2001), who observed a decrease in parafilm-chewing-stimulated saliva secretion after acute consumption of 0.6–0.7 g alcohol/kg body weight in a soft drink. After consumption of that much higher amount of alcohol than in our study (0.2–0.3 g alcohol/kg body weight), a maximum decrease in parafilm-chewing-stimulated saliva secretion (−40%) was observed after 45 min. A reduction of 50% in parotid salivary flow rate after ingestion of a large dose of alcohol has also been reported (Dutta *et al.*, 1984). On the other hand, rinsing of the mouth with 15 ml beer (Coors, 4% alcohol) induced a 93% increase in unstimulated parotid saliva secretion during 5 min (Guinard *et al.*, 1998). However, one has to realize that under non-stimulated conditions, the secretion rate of parotid saliva is very low and will react rapidly to any type of stimulus.

Consumption of 300 ml beer did not induce significant changes in salivary uric acid concentrations (Figure 55.4). Probably, the increase in the plasma concentration of uric acid after consumption of beer (Yamamoto *et al.*, 2002; Ka *et al.*, 2003) is too limited to affect the saliva concentration.

We also did not observe a statistical significant change in salivary amylase concentration (Figure 55.6) or output after the consumption of beer (Figure 55.7). This may be related to the relatively small volume amount of alcohol consumed in our study. In rats, acute administration of a high dose of alcohol caused a significant reduction in stimulated parotid secretion (Scott *et al.*, 1989) and reduced the protein synthesis in all major salivary glands (Proctor *et al.*, 1993). Ingestion of a high dose of alcohol by humans also caused a decrease in parotid salivary flow rate (Dutta *et al.*, 1984) and stimulated whole saliva flow rate (Enberg *et al.*, 2001), with a concomitant reduction in salivary amylase activity and output (Enberg *et al.*, 2001).

Saliva is of paramount importance for the maintenance of oral health (Nieuw Amerongen and Veerman, 2002). Although our study showed that acute consumption of 300 ml of beer has only a limited effect on salivary secretion, frequent intake of beer may reduce salivary flow rate more extensively and for a longer time. This may impair the beneficial effects of saliva on oral health, especially in adolescents with a high frequency of (binge) drinking (Andersson *et al.*, 2002).

Summary Points

- Consumption of 300 ml top-fermented beer induces a transient decrease in salivary flow rate after 15 min.
- Consumption of 300 ml beer has no effect on salivary uric acid concentration and output.
- Consumption of 300 ml beer has no effect on salivary amylase concentration and output.

Beer and Celiac Disease

Glen P. Fox Department of Primary Industries & Fisheries, Queensland Grains Research Laboratory, Plant Science – Wheat, Barley and Oats, Toowoomba Qld., Australia

Abstract

Celiac disease is a serious disease which can cause a number of symptoms including headache, nausea, cramps and diarrhea. The disease affects thousands of individuals in our communities. Like a number of diseases, celiac disease appears to be on the rise in the Western world. Celiacs react to particular peptides sequences found in a protein group found in barley, wheat and related species. As barley and wheat are the dominant cereals used in the production of beer, and the toxic peptides survive the brewing process, then celiacs can suffer reactions to beer. Grains such as sorghum or buckwheat are suitable alternatives and have the necessary grain components to provide full bodied beer that celiacs can enjoy without the risk of reaction. While, there may be limited choices for suitable beers, improvements in plant genetics as well as understanding of brewing with alternative grains should allow celiacs to enjoy their favorite drop in the future.

What Is Celiac (Coeliac) Disease?

A roman physician, Galen, first described the condition in about 250 AD and Samuel Gee again noted a similar condition in 1888. However, Dickie (1950), a doctor from The Netherlands, was the first to identify the link between wheat and his celiac patients. The food shortages during World War II had a positive impact on his patients during which they presented themselves less frequently with symptoms. After the war, when bread was more available, the incidence of their symptoms increased.

Celiacs react to a particular protein group found in some cereal grains, namely wheat, barley, rye and triticale. This protein group, gluten, is a mixture of gliadin and glutenin protein subgroups. These proteins stimulate T cells in the intestinal lamina proporia of celiac patients, although a minimum length and specific sequences of the protein are required for the T cells to recognize the toxic protein (Solid, 2002). The result for the patients is a range of symptoms including malabsorption of food and chronic diarrhea associated with anemia, rickets, inhibited growth, bloating, bulky stools, a blistering rash on the buttocks and mouth ulcers. Recently, Wiesner (2004) presented an excellent review of the disease symptoms as well as links between celiac disease and other serious diseases such as diabetes and possibly some cancers. Wiesner (2004) also highlighted the causative protein sequences from problematic plant species that were responsible for inducing reactions.

Celiac disease affects the small intestine. In a healthy body, the small intestine has "villi," tiny finger-like projections, visible under the microscope (Figure 56.1a). They provide a large surface area over which we absorb nutrients such as vitamins, folic acid, iron and calcium. In sufferers of celiac disease, the villi are attacked by the immune system (Figure 56.1b) and are eventually destroyed (Figure 56.1c). This results in nutrients in food passing through the digestive system without being absorbed (malabsorption), leading to vitamin and mineral deficiencies. In addition, a particular component of wheat (and related species) protein (gluten) causes the more serious symptoms of the disease.

Individuals can be born with celiac disease but the results of this type of immune system attack on the intestine can also appear in fully grown adults. Small children usually become symptomatic when they are weaned off liquids onto solids. They present with weight loss, refusal to feed, irritability, abdominal swelling and diarrhea. Certain groups of people are at greater risk for developing celiac disease and it is more common in individuals from families that already have the condition (being linked to the HLA DQ3 gene).

Celiac Disease Linked to Other Diseases

Celiac disease is more likely to occur in insulin dependent diabetics, people with Down's syndrome, sarcoidosis, infertility, IgA antibody deficiency and certain autoimmune diseases such as thyroid disease, rheumatoid arthritis, Addison's disease and Sjorgens syndrome of dry eyes and mouth. Celiac sufferers absorb fewer nutrients from their diet and so may develop nutritional deficiencies. Fifty percent are at risk of developing osteoporosis or fractures from calcium deficiency. There is a twofold increased risk
Figure 56.1   Healthy (a), damaged (b) and destroyed (c) villi of the small intestine (as seen under the microscope) (Fraser, 2005: www. netdoctor.co.uk).

of cancers of the mouth, throat and gullet as well as intestinal lymphomas and carcinomas. There is a strong link with insulin dependant diabetes through the HLA DQ3 gene. People with Down's syndrome are 43 times more likely to develop celiac disease but will often develop a milder spectrum of symptoms.

A certain amount of cross-reactivity occurs between grains, fruits and vegetables of similar classes and this should be borne in mind when trying to understand the various effects of different food groups. For example if a person is allergic to peanuts, then there is a high risk of being allergic to other members of the legume family including beans, peas, lentils, carob, senna and liquorice. However, foods from divergent food families may also cross-react, for example "celery-spice-carrot-mugwort syndrome." This may be due to the presence of other allergens such as lipid transfer protein (LTP), common to fruit, grasses and vegetables. LTP is heat and digestion resistant and can cause more severe systemic allergic reactions. As stated above, LTP is present in grasses (including barley) and, with its thermolabile properties, it survives the malting and brewing process to be present in beer. LTP has been shown to inhibit protease enzymes (Jones, 2005) and may have a positive contribution to beer foam (Evans and Sheehan, 2002).

Testing Your Foods

For celiacs to adhere to a strict gluten diet, they must be confident that the food labeled "gluten-free" is not contaminated with even trace amounts of gluten. A number of tests have been developed to screen "gluten-free" foods.

Enzyme-linked immunosorbant assays

Denery-Papini *et al.* (1999) reviewed a number of immunochemical assays for their efficacy at testing food products containing gluten. Enzyme-linked immunosorbant assays (ELISA) have been used for a number of years with success based on the development of antibodies to the suspected peptide. These assays have been applied to raw materials as well as the processed food products. However, there have been problems with ELISA. Kanerva *et al.* (2006) demonstrated the use of ELISA where by using different substrates the level of gluten protein groups could be under- or over-estimated. This work was shown when screening for barley contamination in oats samples adulterated with barley flour.

In specific relation to barley, malt or beer, ELISA has successfully been used to detect storage proteins in barley and malt (Skerritt, 1988; Skerritt and Henry, 1988) as well as to detect residual barley and malt protein in beers (Sheehan and Skerritt, 1997; Kanerva *et al.*, 2005), particularly in beer foam (Evans and Sheehan, 2002). Sorell *et al.* (1998) developed an ELISA specifically for detecting the "celiac" peptide in barley hordeins (the homologous protein group to the wheat gliadin protein). This ELISA also detected the common peptide between wheat, rye and oats. Kanerva *et al.* (2005) used an ELISA system, designed to detect gluten, to determine the presence of peptides in beer. There was considerable variation between beer types as the beer was produced from a range of cereals including barley, corn, rice, wheat and buckwheat. A number of beers had levels of gluten below the threshold recommended by the World Health Organization (WHO). These results suggest that beers can be produced from barley, with the appropriate adjunct source, may be suitable for celiacs.

Polymerase chain reaction

An alternative to the protein detection systems described above is the use of DNA. A number of the genes that are translated into the proteins that cause the celiac response

have been sequenced. The use of DNA markers rather than protein markers may offer a more accurate measure of the "celiac" peptides. Dahinden *et al.* (2001) reported a new DNA-based method using the polymerase chain reaction (PCR) to identify contamination of wheat, barley or rye gluten components in "gluten-free" food products. Sandberg *et al.* (2003) used real time (RT) PCR to detect gluten contamination in "gluten-free" foods. While Olexová *et al.* (2006) also described a PCR method to detect gluten proteins in the so-called "gluten-free" flours and bakery products.

Statistics

Celiac disease has been reported in countries around the world, with varying levels of occurrence between 1:80 in Australia, 1:130 in the United States and Canada and 1:300 in the United Kingdom. However, actual diagnosis of suspected patients varies between countries including 1:2 in Finland, 1:8 in Australia and 1:20 in the United States. Of particular note is that most of these countries also have a strong affinity with beer consumption. However, the increasing level of celiac disease or gluten intolerance within these populations means that many people cannot enjoy beer that has been produced using conventional techniques and grain sources.

Celiacs and Beer

Beer has been consumed as either a social beverage or for medicinal purposes for over 10,000 years. Traditionally, beer has been produced from barley although it can be brewed from a number of different grains, including wheat, sorghum, rice or maize. The process of making beer has been described in detail in previous chapters. However, the composition of the raw materials and the brewing style has a significant impact on final flavor and quality. Barley is the most common solid raw material used in brewing. Through a series of complex biochemical reactions (carried out in temperature controlled vessels), it is structurally modified to produce a food source for yeast to ferment as well as provide compounds that impact on color, flavor and taste.

Protein is one of the important components in barley that impacts on quality. There are four groups of proteins:

1. albumins,
2. globulins,
3. glutenins and
4. prolamins.

Each of these groups have differing solubilities but more importantly, differing functionalities. In cereals, the major protein component is the prolamin group. However, there are many protein groups or individual proteins that contribute to the final product of beer, such as enzymes responsible for the degradation of storage proteins and starch to produce amino acids or glucose which will be a food source for yeast or individual barley proteins (foam-positive proteins, LTPs or protein Z) that can survive the rigors of the malting and brewing processes more or less intact – impacting on product quality (Evans and Sheehan, 2002). In addition, a number of protein inhibitors as well as storage protein groups have been identified in foam using the latest mass spectrometry techniques (Hao *et al.*, 2006).

The most abundant protein group in barley consists of the prolamin storage proteins (called hordeins in barley) located in the endosperm around starch granules. During malting and brewing these proteins provide a food source, either to the growing embryo or to the growing yeast cells throughout fermentation, as well as providing amino acids for enzyme synthesis. The prolamins are large water-insoluble molecules that are made up of all amino acids but especially rich in *proli*ne and glut*amin*e (prolamins). These are the antagonistic proteins in barley, wheat, rye and triticale that are responsible for the celiac reaction when suffers eat food or drink beverages produced from these grains. While other grains such as sorghum or maize may have high ratios of glutamine and proline, it is the amino acid sequence that lends itself to being problematic. It has been reported that a few small peptides are responsible for the reaction by celiacs. These small peptide sequences are PSQQ, PQQP and QQQP. These peptides occur in varying quantities within each of the storage protein families (which are usually characterized by molecular weight and/or presence of sulfur amino acids). Brewing grains such as wheat and barley have a high proportion of these repeat motifs. Tatham and Shewry (1995) highlight that the S-poor barley hordeins had no PQQP peptide. However, this and the other peptides exist in the S-rich hordein fractions. This also applies to the various wheat gliadin and glutenin protein groups, while other grains such as rice, maize and sorghum have no PQQP sequences.

Evolution and Homology of Proteins

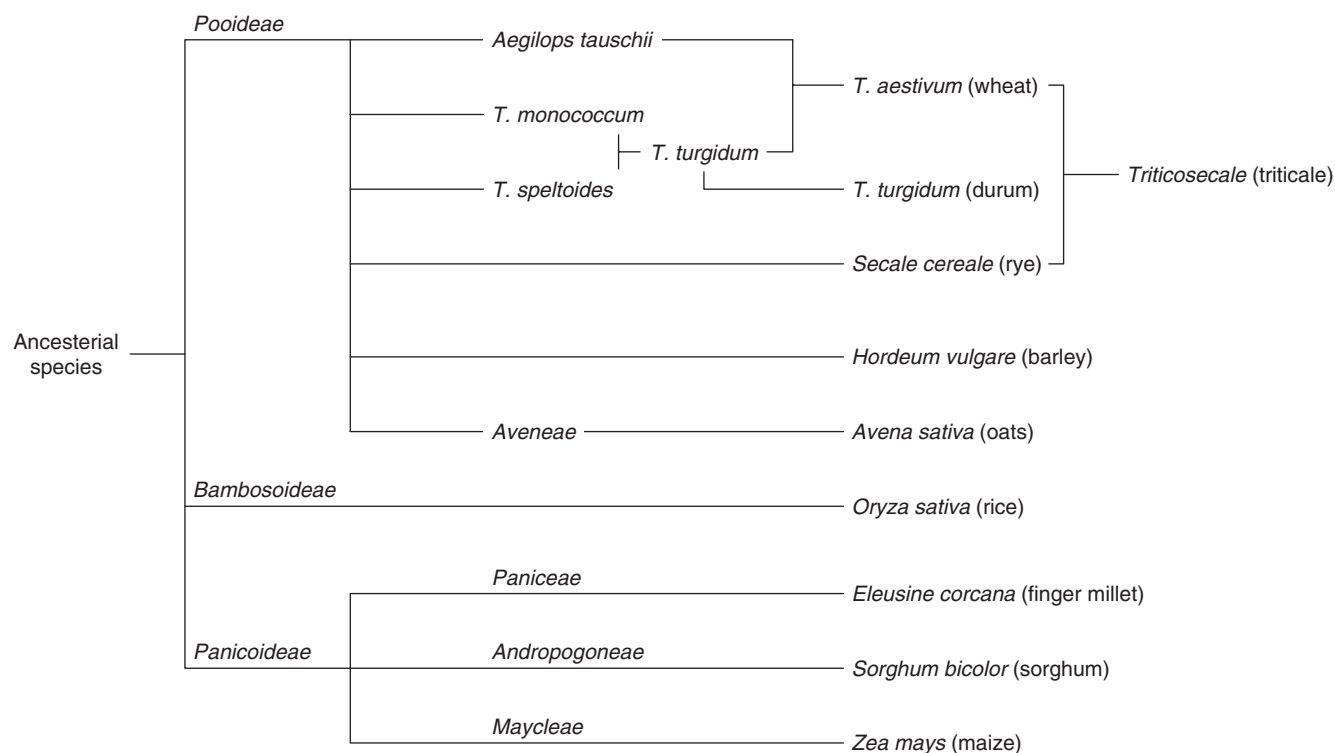
Modern grass species are thought to have evolved from a single ancient family of grains (Figure 56.2) and as such there is considerable similarity in their structure and composition. The more closely related species, wheat, rye, triticale, barley and oats, evolved from the Pooideae subfamily and as such have similar properties in starch and protein. Importantly those species in the Pooideae family appear to be the grains solely responsible for the celiac reaction. The more distantly related tropical species such as sorghum, maize and rice have starch and protein properties that are different to the related wheat species. This evolutionary divergence has resulted in a variation in the protein and as a consequence these tropical crop species do not affect celiacs.


Figure 56.2   Evolutionary relationship between economically important species that impact on celiac disease.

Surviving the Brewing Process

This group of proteins, whether in a barley or wheat malt beer, are degraded during the production of malt as well as during the initial brewing stages. However, small residual peptides survive in the beer and play a role in foaming properties. These peptides are soluble in initial stages otherwise they would precipitate out during mashing or boiling. However, under certain conditions they can become hydrophobic and be involved in foam formation (bubble size and stability, retention time) and foam lacing/cling, after a period they again become soluble.

In addition, there are varying quantities of hordein peptides in different beer styles (ales and lagers) as well as within beer styles (stouts, bitters or brown ales). This is a result of the malting process, modifying the grain that is optimal for the beer style being produced, as well as the brewing process to produce that beer style. Ellis *et al.* (1990) used specifically designed ELISAs to detect residual hordein proteins and peptides in beer. The results showed that regardless of beer style (ales or lagers) or within a group of ale styles (brown, bitter or stout), there were still toxic levels of peptides. Kanerva *et al.* (2005) also demonstrated the presence of prolamin fractions in a range of beers using barley, wheat, corn, rice and buckwheat as raw materials. There was considerable variation between the lager and wheat beers but of note is that the wheat beers using barley and wheat had over 6,000 units of prolamin while the lager beers from barley, corn, rice or buckwheat ranged from not

detected to 12 units. Again this shows that the brewing style as well as raw material will impact on final prolamin content in the beer. The selection of the appropriate raw materials and brewing style could produce beer with little or no prolamin content.

In addition, toxic levels were also detected in wort and hence concentrated wort (malt extract). As malt extract is used as a color or flavoring agent in foods or confectionery products, the presence of prolamins makes any product containing malt extract a problem to any celiac or gluten sensitive person.

Suitable Grains for Brewing

Over the last decade or so, as celiac disease has been more precisely diagnosed and food manufacturers have customized their products, brewers have also investigated the options of "gluten-free" beers. Recently, a number of studies have shown how to optimize malt production and brewhouse performance using non-traditional brewing grains such as sorghum, millet and buckwheat to produce beer that is acceptable not only in aroma, color and flavors but more importantly it is "gluten-free."

Sorghum

Sorghum (*Sorghum bicolor*) is a common summer crop used as a food source in African countries but only as

animal feed in Western countries such as the United States and Australia. Beer has been produced from sorghum in many African countries for decades, either because there was no other grain source available or through preference. However, compared to barley or wheat beers, sorghum beers have been historically lower in quality. Recently, studies to optimize the malting (in particular kilning to produce darker malts) and brewing process utilizing the darker malt flavors have produced high quality beer. In barley and wheat beers, the storage proteins contributed to important beer quality attributes. However, for sorghum the structure of the storage proteins differs somewhat to barley and wheat in that sorghum has lower levels of proline and there are no reported toxic protein sequences.

Buckwheat

Buckwheat is a traditional feed crop in Central and Eastern Europe and Asia, with China currently the largest producer followed by the Russia and the Ukraine (Death, 2004). There are three species of buckwheat, with common buckwheat (*Fagopyrum esculentum* Moench) being the dominant species while *F. tataricum* and *F. emargimatum* are the minor species (Marshall and Pomeranz, 1981; Mazza and Oomah, 2005). Buckwheat is a pseudo-cereal and does not actually belong to the cereal family. It is a dicotyledon rather than a monocotyledon but does exhibit similar characteristics to cereals in that it seed with a starchy endosperm and non-starch aleurone layer (Aufhammer, 2000; Bonafaccia *et al.*, 2003).

The protein composition and structure of buckwheat is quite different to that of cereals. Globulins are the most abundant protein found with less than 3% prolamins (Ikeda *et al.*, 1991). Within the globulin family there are two major groups, namely 13S and 8S globulins. Compositionally these proteins show high levels of lysine, arginine and aspartic acid. There is a low level of glutamic acid and a particularly low level of proline, compared to barley or wheat (Pomeranz and Robbins, 1972), resulting in the protein being non-reactive.

Options for the Future

The incidence of celiac disease and gluten intolerance appears to be on the rise. This suggests that a larger proportion of beer consumers will be unable to consume beer produced from barley or wheat. Hence, an increase in the production of beer manufactured from celiac friendly grains will be required. However, as stated previously, these species are often either inefficient for processing or exhibit flavor problems.

A number of options exist to remedy this situation. Firstly, through genetic engineering it may be possible to change the structure of barley and wheat so as the protein structure and composition does not cause the celiac reaction. Also using

the same approach it may also be viable to improve the structure of sorghum or other grains that currently produce beer with less desirable flavors or are less efficient in producing high-quality malt and beer.

A second approach that utilizes mutation breeding may produce celiac friendly grains from barley or wheat and not therefore fall under the legal minefield of genetic modification technology. Mutation breeding is not subject to the same legal constraints as genetic modification. While the process of nuclear or chemical treatment may be considered by some undesirable, these grains are not considered to be genetically modified. This approach is also possible for those celiac friendly grains such as sorghum, where mutation breeding increases the malting enzyme levels or reduces tannins that produce off-flavors.

A third option is to carry out detailed studies on wild (ancestral) germplasm. Some of these wild types may be structurally or compositionally distinct from their domesticated descendants. However, one such study has shown that for a wheat related species (*Triticum monococcum*) this may not be possible (Pogna, 2002).

A fourth option may be the use of medication. Hartmann *et al.* (2006) showed that endogenous enzymes (proteases) produced from germinating grains break down the toxic peptides. These enzymes are active at temperatures and pH conditions that could allow them to be used as an oral medication for celiacs.

Conclusion

The incidence of celiac disease appears to be increasing and is linked to a number of other disorders. As a consequence for the brewing industry, celiac suffers cannot enjoy flavorsome and healthy beer produced from wheat or barley. While beer can be produced from other grain species, there are differences in the malt and beer quality. In addition, some of these other species, such as buckwheat or millet, are not produced in broadacre farming systems, like wheat or barley.

Genetic improvement in the protein composition of the traditional grains, barley and wheat, would assist in acceptance for raw materials in beers that celiacs could consume as these grains are well known and processing for beer is understood. However, improvements in the non-traditional grains will also ensure adoption into traditional malting and brewing production systems.

Summary Points

- Celiac disease is a serious disorder that affects around 1:100 people.
- Serious health effects include headaches, malabsorption of food, diarrhea and bloating.
- A group of small peptides found in barley, wheat and related species cause the reactions.

- These peptides survive the brewing process and have been identified in beer.
- Beer can be produced from grains such as sorghum or buckwheat as they do not have these "toxic" peptides.

The Effect of Beer and Other Alcoholic Beverages on the Esophagus with Special Reference to Gastroesophageal Reflux

H. Seidl and C. Pehl Department of Gastroenterology, Hospital Bogenhausen, Academic Teaching Hospital, Munich, Germany

Abstract

Patients with gastroesophageal reflux disease (GERD) complain often about heartburn after ingestion of beer and other alcoholic beverages. In several studies, an induction of gastroesophageal reflux (GER) was observed after intake of beer and other alcoholic beverages like white wine, red wine, whiskey, and vodka in healthy volunteers and/or in patients with GERD. The magnitude of reflux after consumption of beer is significantly less than white wine and comparable to red wine in healthy volunteers. In contrast, the amount of reflux induced by beer seems to be similar to that of white wine in patients with GERD.

The ingredients responsible for the reflux induction by beer and the other alcoholic beverages are unknown. It could be demonstrated that the ethanol content *per se*, the acidic pH of the beverages and their high osmolality are not responsible for its effect on the esophagus. GER seems to be induced locally by alcoholic beverages and not systemically via the blood stream.

Thera are no data in the literature about the effects of beer on esophageal motory function, while there are several data about the effects of white wine. White wine depresses the lower esophageal sphincter pressure and disturbs esophageal primary and secondary peristalsis.

Chronic intake of alcoholic beverages like beer increases the risk of squamous cell cancer of the esophagus, while it is unclear whether alcoholic beverages increase also the risk for esophageal adenocarcinoma.

List of Abbreviations

GER Gastroesophageal reflux
GERD Gastroesophageal reflux disease
LES   Lower esophageal sphincter

Introduction

Gastroesophageal reflux (GER) is the reflux of gastric contents – mainly gastric acid secretions – into the esophagus. GER can occur postprandially in healthy people without symptoms. In contrast, gastroesophageal reflux disease (GERD) is characterized by an increased magnitude of reflux which provokes symptoms (heartburn, acid regurgitation) and/or damages the esophageal mucosa (reflux esophagitis).

Feldman and Barnett reported that intake of beer, white wine, and red wine provoke heartburn in 60%, 63%, and 68%, respectively, of patients with GERD (Feldman and Barnett, 1995). The induction of heartburn by alcoholic beverages might be the result of a local irritating effect on the damaged mucosa as seen after ingestion of orange juice (Lloyd and Borda, 1981). On the other hand, alcoholic beverages might favor the occurrence of GER by stimulating gastric acid secretion which has been demonstrated for beer and wine (McArthur *et al.*, 1982; Lenz *et al.*, 1983; Peterson *et al.*, 1986; Singer *et al.*, 1987; Teyssen *et al.*, 1997). In chronic alcoholics with upper GI-complaints, reflux esophagitis is one of the most common findings in upper GI endoscopy pointing to a relationship between the intake of alcoholic beverages and GER (Tonnesen *et al.*, 1987).

The following article will report on the effects of alcoholic beverages on the esophagus with special focus on the effects of beer.

Alcoholic Beverages and GER

The induction of GER was reported for the first time after intake of high-proof alcoholic beverages like whiskey and vodka in healthy volunteers (Kaufman and Kaye, 1978; Vitale *et al.*, 1987). After this initial reports, further studies in healthy volunteers observed also an induction of GER after ingestion of commonly consumed alcoholic beverages like white wine, red wine, and beer (Pehl *et al.*, 1993; Grande *et al.*, 1997; Pehl *et al.*, 1998). Pehl *et al.* (1993) directly compared the effects of white wine and beer on GER in healthy volunteers. The volunteers received 300 ml of white wine (Kluesserather St. Michael, Winzergenossenschaft Moselland eG, Bernkastel-Rues, FRG; 7.5 v/v, pH 3.2), beer

(Heller Bock, Augustiner-Braeu Wagner KG, Munich, FRG; 7.0 v/v, pH 4.5) and tap water (pH 6.4), each, together with a standardized meal. Both alcoholic beverages induced GER compared to tap water in the first hour after intake, but the amount of GER was significantly higher after intake of white wine than after intake of beer (Figure 57.1). Despite being a short lasting effect (Figure 57.2), more than half of the healthy volunteers would be classified as pathologic refluxers when drinking wine during the investigation period (300 ml white wine with lunch and 400 ml white wine at night). Keeping in mind that red wine and beer were not administered to the same healthy volunteers, it seems that the magnitude of GER induction by these two alcoholic beverages is comparable (Figures 57.1 and 57.3). Both alcoholic beverages induce significantly more GER than water and significantly less GER than white wine (Pehl *et al.*, 1993, 1998). The assumption of a comparable effect of beer and red wine on GER induction is strengthened by an abstract of Pehl *et al.* (2004) presented at the German Congress for Internal Medicine. They compared the effect of white wine, red (rose-colored) wine, beer, and water on GER and on the duodeno-GER in healthy volunteers. All alcoholic beverages induced significantly more GER than water. The magnitude of GER was highest after ingestion of white wine (significant compared to both other alcoholic beverages) and nearly identical after ingestion of red wine and beer. None of the alcoholic beverages induced duodeno-GER.

GERD patients demonstrate higher reflux parameters, measured by esophageal 24 pH-metry, than healthy volunteers (Stein *et al.*, 1992; Vaezi *et al.*, 1995). Therefore, it could be speculated whether the already increased reflux in these patients will be further increased by ingestion of an alcoholic beverage. Pehl *et al.* (2006) tested this hypothesis in 25 GERD patients, 7 females and 18 males (median age 54 years, range 24–84 years). A reflux esophagitis was seen in 15 of these patients during endoscopy (nine grade I, four grade II, one grade III, and one grade IVb (Barrett's esophagus) according to Savary Miller classification (Savary and Miller, 1978). The other 10 patients had a pathological result of 24-h pH-metry according to the authors normal values. All patients consumed alcoholic beverages weekly to daily (<40 g/day in males, <30 g/day in females), but nobody was addicted to alcohol. Each patient was studied twice with a minimum of 2 days apart for 3 h by pH-measurement after ingestion of 300 ml white wine (Kluesserather St. Michael, Moselland Winzergenossenschaft, Bernkastel-Kues, Germany; *n* = 17), 500 ml beer (Augustiner Hell, Augustiner Braeu, Munich, Germany; *n* = 8), or tap water (all patients) within 30 min in a randomized order together with a standardized meal. Five hundred milliliter beer (1 bottle) was administrated, since this is the usual ingested volume of the kind of offered beer. Furthermore, different volumes of wine and beer were applied to compensate for the different alcohol concentration (wine 8.6 v/v, 300 ml = 20.64 g ethanol; beer 5.2 v/v, 500 ml = 20.8 g ethanol).
Figure 57.1 Effect of beer, white wine, an acid beverage, and water on GER in healthy volunteers. Percentage of time (%) with esophageal pH < 4 (data represent median) in the first hour after ingestion of 300 ml white wine, beer, water, and Seven Up together with a standardized meal in healthy volunteers (adapted from Pehl *et al.* (1993), reprinted with kind permission of Springer Science and Business Media).
Figure 57.2 Time course of reflux induction in healthy volunteers. Percentage of time (%) with esophageal pH < 4 (data represent median) in the first, second, and third hour after ingestion of 300 ml white wine, an adapted ethanol solution, and water together with a standardized meal in healthy volunteers (adapted from Pehl *et al.* (1993), reprinted with kind permission of Springer Science and Business Media).

The percentage of time esophageal pH < 4, that is, GER, during the postprandial hours was significantly increased after both alcoholic beverages compared to tap water (Figure 57.4). An increase of the percentage of time pH < 4 was observed in 14 out of 17 patients after ingestion of wine and in all but one patient after ingestion of beer (Figure 57.5). Statistical analysis revealed no difference in the magnitude of reflux induction between wine and beer. However, it has to be realized that no direct comparison of beer and white wine was done in the GERD patients, while beer and white wine were applied to every healthy volunteer in the above mentioned study of Pehl *et al.* (1993). A decrease in
Figure 57.3 Differences in reflux induction between white wine and red wine. Percentage of time (%) with esophageal $pH < 4$ (data represent median) in the first hour after ingestion of 300 ml white wine, red wine, and water together with a standardized meal in healthy volunteers (adapted from Pehl *et al.* (1998), reprinted with permission).

Figure 57.5 Individual reflux data with and without ingestion of an alcoholic beverage. Scatter graph of the percentage of time (%) esophageal $pH < 4$ during 3h after ingestion of an alcoholic beverage (rhombic points = white wine, square points = beer) and tap water together with a standardized meal in 25 patients with GERD (Pehl *et al.,* 2006), reprinted with permission.

Figure 57.4 Induction of GER in patients with reflux disease. Percentage of time (%) esophageal $pH < 4$ (data represent median) during 3h after ingestion of 300 ml white wine, beer, and water together with a standardized meal in patients with GERD (adapted from Pehl *et al.* (2006)), reprinted with permission.

Figure 57.6 Time course of reflux induction in patients with GERD. Percentage of time (%) esophageal $pH < 4$ (rhombic points), number of reflux episodes (square points), and mean reflux duration (triangle) during the first, second, and third hour after ingestion of an alcoholic beverage (white wine or beer; dark line) and tap water (dotted line) together with a standardized meal in patients with GERD (data represent median; Pehl *et al.* (2006)), reprinted with permission.

the percentage of time $pH < 4$, in reflux frequency, and in mean reflux duration was seen postprandially over time after ingestion of all three beverages (Figure 57.6). Nevertheless, all three reflux parameters remained increased during each of the three postprandial hours after both alcoholic beverages compared to tap water. Thus, it seems that the GER enhancing effect of alcoholic beverages acts for a longer time period in GERD patients (Figure 57.6) than in healthy volunteers (Figure 57.2). Separating the GERD patients in those with and without reflux esophagitis, a significant induction of GER was observed in both groups by ingestion of an alcoholic beverage. Postprandial percentages of time $pH < 4$ were slightly higher in patients with compared

to those without reflux esophagitis after ingestion of water as well as after intake of an alcoholic beverage in this study. However, the magnitude of reflux induction was not significantly different in patients with and without reflux esophagitis. Considering gender, ingestion of alcoholic beverages induced GER in women as well as in men.

It might be assumed that the ethanol content is responsible for the effects of alcoholic beverages on GER. In line with this assumption are data about a decrease in lower esophageal sphincter (LES) pressure and an increase in simultaneous contractions and in failed peristalsis provoked by intravenous administration of ethanol in healthy volunteers (Hogan *et al.*, 1972; Keshavarzian *et al.*, 1990).

However, the administered volume of ethanol in these studies resulted in signs of intoxication in nearly all volunteers. No effect on sphincter pressure and the frequency of abnormal esophageal contractions was seen by intravenous administration of a lower dose of ethanol (Mayer *et al.*, 1978). Pehl *et al.* (1993, 1994) directly compared the effects of white wine and an ethanol solution, adapted in alcohol content to white wine, on GER in healthy volunteers. Significant differences in the magnitude of reflux induction were observed between white wine and the ethanol solution despite similar blood levels of alcohol, while no significant difference was detectable between the ethanol solution and tap water (Figure 57.2). These data demonstrate that the ethanol content of an alcoholic beverage is, at least alone, not responsible for the effects of an alcoholic beverage on GER. However, esophageal exposure to ethanol might potentiate the deleterious effects of refluxed acid to the esophageal mucosa (Salo, 1983; Bor *et al.*, 1999). Yet, the ethanol concentration which is necessary for this co-toxic effect remains unclear. Bor *et al.* reported noxious effects of 10% ethanol on rabbit esophagus, while Salo did not observe noxious effects on rabbit esophagus for 20% ethanol, but for 40% ethanol.

Another mechanism which is assumed to be responsible for the induction of heartburn after intake of a beverage is its pH, since Feldman and Barnett (1995) observed a relationship between heartburn and low pH of non-alcoholic beverages. Therefore, the reported difference in the magnitude of reflux induction between white wine and beer might be the result of its different pH. However, several data argue against an effect of the pH of a beverage on the genesis of GER and heartburn. First, white wine induced a much higher amount of GER in healthy volunteers than red wine despite only small differences in pH (3.2 and 3.4, respectively) (Pehl *et al.*, 1998). Second, intake of Seven Up® with a similar pH of 3.2 like white wine did not induce GER in healthy volunteers (Pehl *et al.*, 1993). Third, orange juice and tomato juice provoke GER in GERD patients even after neutralization to a pH of 7 (Lloyd and Borda, 1981). Thus, beverages can provoke heartburn by a direct irritating effect independent of its pH. The local irritating effect may be amplified in GERD patients by the break-down of intercellular tight junctions by GER facilitating the entrance of acid and beverages into the epithelial layer where these substances come into contact with sensory nerve endings (Tobey *et al.*, 1996).

One of these substances, respectively, mechanisms which are responsible for the stimulation of the sensory nerve endings might be the osmolality of beverages, since Lloyd and Borda (1981) demonstrated a relationship between high osmolality of beverages and the occurrence of heartburn. While osmolality seems to be related to the induction of heartburn in sensitized patients by local irritation, it seems not to be related to the induction of GER. The amount of GER induced by white wine, red wine, and beer in healthy volunteers is significantly different (Pehl *et al.*, 1993, 1998), while all these alcoholic beverages are characterized by high osmolalities. In the studies of Pehl *et al.* (1993, 1998), the osmolalities of the applied white wine was 1,710 mosmol/l, of red wine 1,805 mosmol/l, and of beer 1,650 mosmol/l. Similarly, Becker *et al.* (1989) did not report an effect of meals with different osmolalities on GER in healthy volunteers and GERD patients. In addition, neither an ethanol solution with low osmolality nor an isovolumetric ethanol solution with high osmolality induces significantly more GER than tap water (Pehl *et al.*, 1993, 1994).

Alcoholic Beverages and Lower Esophageal Sphincter

The LES is a high-pressure zone at the junction between esophagus and stomach created by tonically active muscle fibers of the esophageal wall. The LES acts as a barrier against GER. A progressive decrease of LES pressure is seen in relation to an increasing severity of GERD (Stein *et al.*, 1992). In healthy volunteers, a decrease of LES pressure was reported after whiskey, but not after vodka (Hogan *et al.*, 1972; Keshavarzian *et al.*, 1990). Different effects on LES pressure were also observed after intake of white wine and red wine in healthy volunteers (Pehl *et al.*, 1998). While red wine did not decrease LES pressure, an impairment of LES pressure was seen after ingestion of white wine. These different effects of white wine and red wine might be the reason for the enhanced GER after white wine compared to red wine in healthy volunteers. No data exist in the literature to the effect of beer on LES pressure in healthy volunteers, GERD patients or chronic alcoholics. Moreover, the effect of alcoholic beverages on LES pressure might be habituation dependent. Keshavarzian *et al.* (1990) demonstrated that the inhibitory effect of intravenous ethanol on LES pressure was less in chronic alcoholics compared to healthy volunteers, indicating the development of tolerance. In addition, the infusion of ethanol returned the increased contraction amplitude seen in withdrawing alcoholics to normal values.

Reflux across the LES can be the result of three mechanisms (Dent *et al.*, 1988). Most of the reflux episodes occur during a LES relaxation, either swallow induced or transient. Transient LES relaxations are a vagal reflex triggered by gastric distension, for example, to permit belching after meal. In GERD, transient LES relaxations are increased in number and/or more often accompanied by a reflux event (Sifrim and Holloway, 2001). GERD patients with a lowered LES pressure can further reflux during an increase in abdominal pressure, for example during bending down, so-called "stress reflux." "Free reflux" can occur during prolonged periods of absent LES pressure which can be observed in some GERD patients postprandially. Pehl *et al.* (1998) could demonstrate that the decrease in LES pressure provoked by the intake of white wine changed the reflux

pattern of the healthy volunteers with occurrence of stress and free reflux. In contrast, reflux after intake of red wine, which did not decrease LES pressure, was nearly exclusively during LES relaxations as seen normally in healthy volunteers. This data demonstrate together with the reported unchanged number of LES relaxations after white wine and red wine compared to tap water that the main mechanism of GER induction after alcoholic beverages must be a higher percentage of LES relaxations accompanied by a reflux event. Since beer increases GER comparable to red wine and less than white wine in healthy volunteers, it can be assumed that beer does not decrease LES pressure and induce GER by a higher number of reflux events during LES relaxations.

As already stated, beer and white wine induce GER in GERD patients to the same magnitude (16), while white wine is a more potent stimulator of GER in healthy volunteers (Pehl et al., 1993, 1998). It can be speculated that the different effects of these beverages on LES pressure and the reflux pattern seen in healthy volunteers will not be relevant in GERD patients with an already preexisting decreased LES pressure. In these patients, beer and white wine might stimulate each type of reflux equally or the pressure reducing effect of white wine is equalized by the stronger stimulatory effect of beer on gastric acid secretion (Singer et al., 1987).

Alcoholic Beverages and Esophageal Motility

Alcoholic beverages do not only increase the frequency of reflux episodes, their intake seems also to impair reflux clearance resulting in a prolonged reflux duration. A prolongation of the mean reflux duration, in part significantly, was seen after ingestion of beer, white wine, and red wine in healthy volunteers and GERD patients (Pehl et al., 1998, 2006). In a reflux model with installation of 15 ml 0.1N HCl into the esophagus, a significantly enhanced number of swallows were needed to rise esophageal pH above five after oral ingestion of whiskey or white wine (Dent et al., 1988; Pehl et al., 2000). In line with these data, Pehl et al. (2002) registered a significantly increased number of peristaltic contractions necessary to rise esophageal pH > 4 after white wine induced reflux episodes. Esophageal acid clearance is a two step process (Helm et al., 1983, 1984). Initially, volume clearance takes place which needs one to two peristaltic sequences, either swallow induced ("primary") or induced by esophageal distension due to reflux ("secondary"). This volume clearance is the prerequisite before saliva, swallowed with every primary peristaltic sequence, can neutralize the residual acidic layer occupying the esophageal mucosa.

Data regarding the effect of alcohol on salivary output are controversial. A diminished, an unchanged, and

an increased basal and/or stimulated salivary flow is reported in chronic alcoholics with and without liver cirrhosis (Bonnin et al., 1950; Kissin and Kaley, 1974; Duerr et al., 1975; Abelson et al., 1976; Silver et al., 1986; Dutta, 1989, 1992). A stimulation of salivary flow was observed after oral intake but not after intragastric instillation of high-proof alcoholic beverages such as whiskey, brandy, sherry, and gin (Winsor and Strongin, 1933; Chittenden et al., 1898). Thus, these beverages seem to stimulate salivation by local irritation. No data exist in the literature on the effect of beer on salivary flow. For wine, only data after ingestion of red wine are reported. Martin and Pangborn (1971) observed a stimulation of salivary flow with a greater stimulatory effect of red wine with an ethanol content of 12 v/v than with either 6 or 20 v/v. To our knowledge, no data exist about the effect of beer on salivary output.

Defects in esophageal peristalsis are reported in chronic alcoholics (Winship et al., 1968; Keshavarzian et al., 1987; Keshavarzian et al., 1992). In short-time stationary esophageal manometry in healthy volunteers, an impaired wet swallow induced primary peristalsis with increased frequencies of simultaneous contractions and failed peristalsis were reported after ingestion of high-proof alcoholic beverages (Hogan et al., 1972; Mayer et al., 1978). In contrast, Pehl et al. (2000, 2002) did not observe an influence of ingestion of white wine on wet swallow induced primary peristalsis. Similarly, no disturbance of peristalsis but even an increase in contraction amplitude was seen after intake of red wine during 24-h manometry (Grande et al., 1997). Likewise, by continuous measurement of pH and motility during 90 min, Pehl et al. (2002) also did not observe any effect of white wine on swallowing rate, contraction rate, contraction amplitude, and the rate of primary, secondary, simultaneous, and non-propagated contractions. However, when they separately analyzed the periods with esophageal pH < 4, an increased incidence of simultaneous contractions and of failed peristalsis, which insufficiently cleared reflux (Kahrilas et al., 1988; Massey et al., 1991), was seen after ingestion of white wine compared to tap water. Thus, at least ingestion of white wine results in a disturbed motility response after onset of GER which prolongs acid clearance. While primary peristalsis is thought to be the predominant motility pattern which clears the esophagus from refluxed material during daytime (Bremner et al., 1993; Anggiansah et al., 1997), secondary peristalsis seems to become more important for esophageal acid clearance during sleep (Orr et al., 1981; Schoeman et al., 1995) when saliva production and swallow induced primary peristalsis are strongly decreased (Schneyer et al., 1956; Castiglione et al., 1993). The reported disturbance in triggering secondary peristalsis by intra-esophageal air injection after ingestion of white wine (Pehl et al., 2000) could therefore become important for acid clearance when wine is ingested in the evening shortly before going to bed. Unfortunately, no data on the effect of beer on esophageal motility are reported in the literature.

Beside a disturbed acid clearance, prolonged reflux episodes can also be the result of repeated reflux events ("re-reflux") into the esophagus when luminal pH is still acidic from the previous reflux event (Shay and Richter, 1998; Shay *et al.*, 2003). Shay and Richter (1998) demonstrated that re-reflux is even the main mechanism for long-lasting GER episodes. In a study in healthy volunteers (Pehl *et al.*, 2002), signs of re-reflux were observed during half of the reflux episodes after ingestion of white wine but only during 20% of the reflux episodes after ingestion of tap water. Thus, induction of reflux episodes seems to be more important than a disturbance of acid clearance for the increased percentage of time with esophageal pH < 4 after intake of alcoholic beverages.

Local or Systemic Action of Alcoholic Beverages on Esophageal Function

Hogan *et al.* (1972) and Mayer *et al.* (1978) demonstrated that ethanol can influence esophageal function systemically via the blood stream. In healthy volunteers, they observed an increase in failed esophageal peristalsis and in simultaneous contractions as well as a decrease in pentagastrin stimulated LES pressure after intravenous application of an ethanol solution resulting in blood ethanol concentrations of 0.7% to 2.0%. However, several data argue against a systemic action of alcoholic beverages on esophageal function. No correlation between the blood ethanol concentration and the observed esophageal effects was determined in the Hogan's study (1972). Additionally, white wine exerted deleterious effects on esophageal function, while an ethanol solution did not effect esophageal function despite similar blood ethanol concentrations (Pehl *et al.*, 1994). Furthermore, the reported time effects are strong arguments for a local mechanism. An increase in GER is already observed in the first 10 min after intake of beer (Shoenut *et al.*, 1998). Similarly, the decrease in LES pressure is already seen in the first 10 min after ingestion of white wine and does not further decrease in the next 10-min periods (Pehl *et al.*, 1994). Acid clearance is also prolonged immediately after ingestion of white wine and the disturbance of acid clearance diminishes within 1 h after ingestion, while blood ethanol concentration increases within the first hour after drinking (Pehl *et al.*, 2000). Last, no disturbance in triggering of secondary peristalsis was seen in healthy volunteers and chronic alcoholics by intravenous administration of ethanol (0.8 g/kg) (Keshavarzian *et al.*, 1992), while a disturbed triggering was observed after ingestion of 300 ml white wine in healthy volunteers (Pehl *et al.*, 2000).

Locally, alcoholic beverages can act by a direct toxic effect or via nerves or GI hormones. Direct depressive effects on smooth muscle cells and on nerve function are reported for ethanol (Inove and Frank, 1967; Sunano and Miyazaki, 1968; Littleton, 1978; Keshavarzian *et al.*,

1994). However, as stated above, the ethanol content is not the main ingredient responsible for the effects of alcoholic beverages on esophageal function. There are no data in the literature on the effect of alcoholic beverages on smooth muscle function. Effects of alcoholic beverages on nerve function are only reported in abstract form (Pehl *et al.*, 1996). In the reported study, white wine did not influence the EEG potentials evoked by intra-esophageal electrical stimulation. These evoked esophageal potentials are transferred to the CNS by vagal afferents.

Another mechanism by which alcoholic beverages might exert its effects is the release of GI hormones. Several data exist about the release of gastrin by alcoholic beverages. A release of gastrin is seen after ingestion of beer, white wine, and red wine, but not after intake of high-proof alcoholic beverages like whiskey, gin, and cognac (Lenz *et al.*, 1983; Singer *et al.*, 1983, 1987, 1991; Peterson *et al.*, 1986; Hajnal *et al.*, 1989, 1990, 1993; Chari *et al.*, 1996). The release of gastrin was, at least in some studies, higher after intake of beer than after intake of wine. Straathof *et al.* (1997) observed a decrease in LES pressure and an increased percentage of GER during transient LES relaxations by administration of gastrin in a dose resembling the postprandial state. However, three other studies did not find a decrease of LES pressure by gastrin (Freeland *et al.*, 1976; Jensen *et al.*, 1980; Allescher *et al.*, 1995). Another GI hormone acting on esophageal function is cholecystokinin (CCK). The CCK release postprandially seems to be related to the meal-induced decrease of LES pressure. Beer is a potent stimulator of CCK release (Masclee *et al.*, 1993; Katschinski *et al.*, 1994; Zerbib *et al.*, 1998), while only a small stimulation is seen by intake of white wine and no release after ingestion of Gin (Hajnal *et al.*, 1989, 1990, 1993; Chari *et al.*, 1996). Since white wine induces GER even stronger than beer, CCK cannot be the sole substance responsible for the effects of alcoholic beverages on GER induction.

Alcoholic Beverages and Esophageal Cancer

Chronic consumption of alcoholic beverages is a risk factor for esophageal cancer (Bagnardi *et al.*, 2001). This risk increases with an increasing daily dose of ingested alcoholic beverages (Tuyns *et al.*, 1977; Bagnardi *et al.*, 2001). Bagnardi *et al.* performed a meta-analysis of published data about the relation between alcohol consumption and the risk of cancer. From 28 studies with 7,239 cases, they calculated a pooled relative risk (and 95% confidence interval) of 1.51 (1.48–1.55), 2.21 (2.11–2.31), and 4.23 (3.91–4.59) for esophageal cancer in patients consuming 25, 50, or 100 g of alcohol per day. They calculated an especially increased risk of esophageal cancer in women with regular intake of alcoholic beverages. Smoking strongly enhances the esophageal cancer risk of drinkers by acting synergistically in

carcinogenesis (Tuyns *et al.*, 1977; Bagnardi *et al.*, 2001). According to type of esophageal cancer, alcoholic beverages are surely a risk factor for esophageal squamous cell cancer (Brown *et al.*, 1994; Vaughan *et al.*, 1995; Wu *et al.*, 2001; Bollschweiler *et al.*, 2002; Lindblad *et al.*, 2005), while there are conflicting data whether consumption of alcoholic beverages are a risk factor for esophageal adenocarcinoma.

Several researchers attempted to determine whether different types of alcoholic beverages have different effects on cancer risk. Compared to wine, the cancer risk of beer was reported to be similar (Williams and Horn, 1977; Doll *et al.*, 1999), increased (Graham *et al.*, 1990; Gammon *et al.*, 1997) or decreased (Barra *et al.*, 1990; Bosetti *et al.*, 2000). Other alcoholic beverages possibly linked to the esophageal cancer risk are the intake of liquor (Williams and Horn, 1977; Brown *et al.*, 1994; Bahmanyar and Ye, 2006), spirits (Doll *et al.*, 1999), apple brandy, and hard cider (Tuyns *et al.*, 1979; Yamada *et al.*, 1992).

There is no evidence that alcohol by itself can cause cancer by acting as a complete carcinogen. However, animal studies have indicated that alcohol can have a co-carcinogenic or cancer-promoting effect. For example, Yamada *et al.* (1992) observed an exaggerated nitrosamine bioactivation by intake of beer and other alcoholic beverages in rats. Nitrosamines and other carcinogens like polycyclic hydrocarbon or acetaldehyde can be found in alcoholic beverages (Blot, 1992; Poschl *et al.*, 2004). In addition, metabolism of ethanol by alcohol dehydrogenase results in the formation of acetaldehyde, which is a potent carcinogen (Salaspuro, 2003). The enzyme alcohol dehydrogenase is, beside the liver, already localized in the upper GI tract (Vaglenova *et al.*, 2003). Bacterial flora of the oropharynx and in the upper GI tract can contribute to the local accumulation of acetaldehyde due to bacterial metabolism of ethanol (Homann *et al.*, 1997a, b, 2000). Smoking can further increase the formation of acetaldehyde by inducing changes in the oral bacterial flora (Homann *et al.*, 2000; Poschl *et al.*, 2004). It becomes obvious from these data why drinking and smoking potentiate its cancer risks. In addition, genetic polymorphisms of the alcohol dehydrogenase gene and the acetaldehyde dehydrogenase gene seem to be linked to an increased risk of esophageal (squamous cell) cancer risk due to higher blood and salivary acetaldehyde levels (Yokoyama *et al.*, 1996; Visapaa *et al.*, 2004).

Summary

Beer, like other alcoholic beverages, has deleterious effects on esophageal function. Its intake can induce heartburn and GER in healthy volunteers and GERD patients. The effects of beer seem to be locally transmitted by acting on acid secretion, reflux induction, and esophageal motility. In addition, chronic consumption of beer increases the risk for esophageal cancer, especially for squamous cell cancer.

Summary Points

- Intake of beer induces GER in healthy volunteers.
- Intake of beer induces GER in patients with GERD.
- The magnitude of reflux induction is less after beer than after white wine in healthy volunteers, but seems to be similar in reflux patients.
- There are no data on the effect of beer on esophageal peristalsis, while depressive effects were reported for whiskey, vodka, and white wine, but not for red wine.
- Other ingredients than ethanol are responsible for the effects of alcoholic beverages on esophageal function.
- The effects of alcoholic beverages on esophageal function seem to be induced locally.
- Chronic consumption of beer and other alcoholic beverages increase the risk for esophageal cancer (i.e. of squamous cell cancer).
- The cancer risk of alcoholic beverages is potentiated by smoking.

Effects of Beer on the Gastric Mucosa as Determined by Endoscopy

Andreas Franke and Manfred V. Singer Department of Medicine II (Gastroenterology, Hepatology and Infectious Diseases), University Hospital of Heidelberg at Mannheim, Mannheim, Germany

Abstract

It is clinically well known that alcohol consumption, especially in excess, may cause acute gastrointestinal bleeding and hemorrhagic gastritis. Induction of hemorrhagic lesions was endoscopically proven for pure ethanol solutions in concentrations between 40% and 80% by several studies. However, the data on the effect of alcoholic beverages and their corresponding ethanol concentrations is rare. Only in one study the effect of beer, some other alcoholic beverages and their appropriate control solutions (4% and 10% v/v ethanol and isotonic saline) was endoscopically examined in humans. Additionally, the time-dependent course of potential lesions was determined. According to these results, beer induces gastric mucosal injury in healthy non-alcoholic volunteers that are endoscopically detectable 30, 60 and 240 min after the application. After 24 h those lesions are completely healed. However, the injury by 4% ethanol is significantly stronger than that of beer. Beer may contain ingredients that protect the gastric mucosa against the damaging action of ethanol.

Introduction

In some, mostly uncontrolled, endoscopic studies in humans ethanol in high concentrations (40–80% v/v) was shown to damage gastric mucosa (Agrawal *et al.*, 1986; Tarnawski *et al.*, 1987; Cohen *et al.*, 1989, 1990; Kobayashi *et al.*, 1991; Konturek *et al.*, 1992; Loguercio *et al.*, 1993). However, the physiological relevance has been challenged since in everyday life it is not pure ethanol that is consumed, but palatable alcoholic beverages. Moreover, beer and wine contain ethanol in much lower concentrations.

As early as 1833, William Beaumont (1833) observed in a patient suffering from a gastric stoma due to a gunshot injury that consumption of different alcoholic beverages caused gastric mucosal erythema and erosions, which appeared after 4–5 days of abstinence. Over 100 years later, Palmer (1954) investigated 34 subjects within 6 h after ingestion of alcoholic beverages, the type of beverage is not

specified in the publication. Thirty (of 34) had acute gastritis findings, based on patchy hyperemia, erosions, petechiae and purulent exsudate. In 22 subjects, gastroscopy was repeated after 7–20 days of abstinence from alcohol, at which point gastric mucosa appeared normal. Laine and Weinstein (1988) characterized the endoscopic features of hemorrhagic and erosive gastric lesions in 148 alcoholic patients (50–330 g mean pure ethanol consumption), who underwent upper gastrointestinal endoscopy for gastrointestinal bleeding. In 20 patients, subepithelial hemorrhages were predominantly found in the proximal stomach.

The effect of moderate amounts of beer in non-alcoholic individuals was uninvestigated until Knoll *et al.* (1998) studied the effect of some commonly consumed alcoholic beverages and their corresponding ethanol concentrations and amounts on gastric mucosa in healthy humans.

Study Design

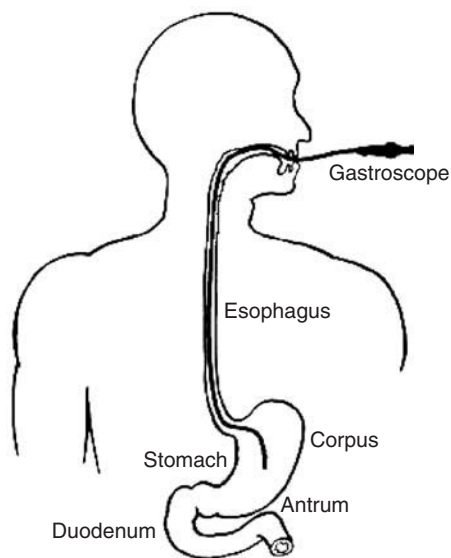
Knoll *et al.* (1998) carried out the first endoscopy between 9.00 a.m. and 10.00 a.m. on day 1 (Figure 58.1), after the healthy volunteers have fasted overnight. All remaining gastric juice was carefully aspirated through the suction channel of the endoscope. One of the following test solutions (100 ml each) was sprayed onto the mucosa of the anterior wall of the antrum: beer (4.5% v/v), 4% (v/v) ethanol and isotonic saline solutions. Moreover, white wine, whiskey and their corresponding ethanol solutions (10% and 40% (v/v), respectively) were tested. Endoscopists and subject were blinded to the kind of instilled solution; 30 min later a second endoscopy was done to aspirate the remaining test solution out of the stomach. The endoscopic appearance of fundic, antral and duodenal mucosa was assessed before, immediately after, and 30, 60, 240 min and 24 h after instillation. The endoscopically visible mucosal lesions were scored by three independent endocopists using the Tarnawski grading system (Table 58.1). The integrated endoscopic scores over the examination time were calculated and compared between the test solutions.


Figure 58.1 Gastroscopy. Anatomy and endoscopy of the upper gastrointestinal tract.

Table 58.1   Classification of gastric mucosal inflammation

0	Normal mucosa
1	Marked diffuse hyperemia
2	Single hemorrhagic lesion (1 mm or larger)
3	2–5 hemorrhagic lesions
4	6–9 hemorrhagic lesions
5	10 or more hemorrhagic lesions or larger area of confluent hemorrhage

Source: Tarnawski endoscopic grading system (Tarnawski *et al.*, 1987).

Effect of Beer and Its Control Solutions

Intragastric beer instillation induced 30 and 60 min after instillation of single erosions in the antrum and fundus (Figure 58.2a and b). After 240 min, these findings were nearly unchanged, and after 24 h normal mucosa was detected in all subjects (Figure 58.3). Duodenal mucosa was normal at all time points.

After intragastric instillation of isotonic saline either no or up to five lesions in the antrum and fundus were observed at 30 min (Figure 58.3). After 60 min these lesions were still present and after 240 min they were disappeared in the fundus. At 24 h normal mucosa was observed in all subjects. Duodenal mucosa was normal at all time points.

Intragastric instillation of 4% ethanol produced either no lesions, hyperemia or single lesions in the antrum and hyperemia in the fundus in all subjects at 30 min (Figure 58.3). These findings were unchanged after 60 and 240 min and they were no longer demonstrable after 24 h. Again, duodenal mucosa was normal at all time points.

Comparison between the mean endoscopic score for beer and its corresponding ethanol content (4% (v/v)) resulted in a significant higher score for 4% ethanol than for beer at
Figure 58.2 Changes of gastric mucosa after alcoholic beverages: (a) gastric mucosa of the antrum as seen before, (b) after instillation of beer and (c) after instillation of whiskey.
Figure 58.3 Effect of beer and its control solutions on gastric mucosa. Mean endoscopic scores in response to beer, 4% (v/v) ethanol and isotonic saline on the mucosa of the fundus. *p < 0.05 vs. corresponding ethanol solution (4% v/v).

60 min in the fundus (Figure 58.3). At all other time points the mean scores in the antrum and fundus in response to beer and 4% ethanol were not significantly different. However, 4% ethanol significantly increases the 24-h integrated endoscopic score in the fundus, but not in the antrum, as compared to beer (Figure 58.4).

Effect of Other Alcoholic Beverages and Higher Ethanol Concentrations

White wine, whiskey, 10% and 40% (v/v) ethanol induced also significant hyperemia and hemorrhagic lesions after intragastric application.

Intragastric instillation of white wine induced hyperemia and/or up to five erosions in the antrum and fundus at 30 min, with a maximum at 60 min. At 240 min, these lesions were still present, but to a lesser degree. Normal mucosa was found after 24 h.

The corresponding ethanol solution (10% v/v) produced two to more than ten erosions in the antrum and fundus at 30 min. After 60 and 240 min, these findings were unchanged. Lesions were still present, but to a lesser degree after 24 h.
Figure 58.4 Effect of some alcoholic beverages and corresponding ethanol concentrations on gastric mucosa. Integrated endoscopic scores over 24 h in the fundus in response to beer, wine and whiskey and the corresponding ethanol content (4%, 10% and 40% v/v) in comparison with the control. The results are expressed as means of 6 subjects and 11 subjects (whiskey). #p < 0.05 compared with control (★) or with corresponding ethanol content (☆).

The comparison between white wine and 10% ethanol resulted in a significantly higher score in the antrum at 24 h and in a significantly higher 24-h integrated endoscopic score in the antrum and fundus (Figure 58.4).

Whiskey caused hyperemia and up to more than 10 erosions in the fundus and antrum within 30 min (Figure 58.2c). This was still present after 60 min and to a lesser degree after 240 min and 24 h. The corresponding ethanol solution (40% v/v) resulted in a significantly higher score in the fundus at 240 min and in a significantly increased 24-h integrated endoscopic score in the antrum and fundus (Figure 58.4).

Conclusions

This study demonstrates that beer induces gastric mucosa injury. Other alcoholic beverages like wine and whiskey also damage the gastric mucosa. Hemorrhagic lesions can last for more than 24 h after consumption of whiskey. Ingestion of ethanol also in lower concentrations (4% and 10% v/v) causes hemorrhagic erosions in the antral and fundic gastric mucosa. In case of 10% (v/v) ethanol and higher concentration (40% v/v), but not after 4% (v/v) ethanol, erosions were still present after 24 h. This suggests that ethanol in concentrations of over 10% breaks the gastric mucosal barrier. Davenport found in dogs that ethanol in concentrations higher than 8–14% damages the mucosal barrier and allow thereby diffusion of hydrogen ions from the lumen into the mucosa, which induced a potential difference (Davenport, 1967; Singer *et al.*, 1983).

Alcoholic beverages and pure ethanol may induce gastric lesions by direct toxic effects as well as by an increased gastric acid response (Singer *et al.*, 1983, 1987, 1991). Pure ethanol in low concentrations (1.4% and 4%) is a mild stimulant of gastric acid secretion, whereas in higher concentrations (5–40%), it has either no inhibitory effect, or a mild one (Singer *et al.*, 1983). On the other hand, alcoholic beverages with low ethanol content (beer and wine) are strong stimulants of gastric acid output and gastrin release (Singer *et al.*, 1987, 1991). It is possible that alcoholic beverages may contain some unknown non-alcoholic ingredients that protect the mucosa against the damaging effect of ethanol and hydrochloric acid. It is also possible that the high buffer capacity of the proteins, and other ingredients of alcoholic beverages, reduces the damaging effect of the ethanol.

Summary Points

- Beer and other alcoholic beverages (e.g. wine and whiskey) may induce gastric mucosal injury.
- Intragastric administration of ethanol in concentrations of 4%, 10%, 40% and higher also causes mucosal lesions in the gastric fundus and antrum, but not in the duodenum.
- Mucosal lesions after beer or corresponding ethanol concentration occur within 30 min, reach maximum after 60–240 min and are disappeared after 24 h, whereas lesions after 10% and 40% or after whiskey last more than 24 h.
- Mucosal injury caused by alcoholic beverages is less pronounced than by the corresponding ethanol concentrations.
- Non-alcoholic ingredients in beer (and other alcoholic beverages) may have protective effects on ethanol-induced mucosal injury.

The Effect of Beer and Its Non-alcoholic Ingredients on Secretory and Motoric Function of the Stomach

Andreas Franke and Manfred V. Singer Department of Medicine II (Gastroenterology, Hepatology and Infectious Diseases), University Hospital of Heidelberg, Mannheim, Germany

Abstract

Alcoholic beverages produced by fermentation like beer and wine strongly stimulate gastric acid secretion, whereas those produced by distillation (e.g. whisky, gin) have no stimulatory effect. Pure ethanol affects gastric acid secretion dose dependently: lower ethanol concentrations (1.4% and 4% v/v) have a mild, but significant stimulatory effect, whereas higher ethanol concentrations have no effect (5–10% v/v) or even a mild inhibitory effect (20% and 40% v/v). Non-alcoholic ingredients in alcoholic beverages produced by fermentation have to be responsible for the strong stimulation of gastric acid secretion. After separation by chromatography maleic acid and succinic acid could be identified to be responsible for the strong stimulatory effect of beer on gastric acid secretion.

Alcoholic beverages and corresponding pure ethanol concentrations (4%, 10% and 40% v/v) are significantly slower emptied from the stomach than water: Gastric emptying of beer and wine, alcoholic beverages produced by fermentation, but not that of alcoholic beverages produced by distillation (e.g. whisky), is significantly slower than that of their corresponding ethanol solutions. Beer, other alcoholic beverages such as wine and whisky, and corresponding ethanol solutions (4% and 10% v/v) also inhibit gastric emptying of solid meals. The inhibitory effect results from a deceleration of the emptying phase, whereas in the initial lag-phase, the period of time between the end of consumption and the start of gastric emptying is unaffected by the alcoholic beverages.

List of Abbreviations

w/v	Weight per volume
v/v	Volume per volume
MAO	Maximal acid output

Introduction

It is a popular belief that alcoholic beverages (e.g. beer and wine) improve digestive functions when consumed alone or together with meals. However, information about the effects of alcoholic beverages on gastric secretion and motility were scanty for a long time. Controlled studies on the effect of alcoholic beverages as well as their alcoholic and non-alcoholic content on gastric secretory and motor function were only published during the last two decades.

It is about 100 years ago that after uncontrolled experiments with alcohol a stimulatory effect on gastric acid secretion was suggested (Chittenden et al., 1898; Beazell and Ivy, 1940). In the early 1980s the first systematic and controlled studies on the effect of pure ethanol and commonly ingested alcoholic beverages on gastric acid secretion have been published (McArthur et al., 1982; Lenz et al., 1983; Singer et al., 1983; Peterson et al., 1986). Singer et al. (1987) compared the effect of different ethanol concentrations with the maximal acid output (MAO) induced by pentagastrin stimulation. They found that the effect of ethanol on gastric acid secretion in healthy humans is differentiated and concentration dependent: low concentrations (1.4% and 4.0% v/v) have a mild stimulatory effect on gastric acid output. Higher concentrations of pure ethanol (up to 40% v/v) have either no or if at all a mild inhibitory effect (Figure 59.1).

In contrast, alcoholic beverages with low ethanol concentration such as beer and wine are powerful stimulants of gastric acid output (Figure 59.2) (Singer et al., 1991). Oral ingestion or gastric instillation of beer causes a stimulation of acid output to 95% of the MAO produced by pentagastrin stimulation (MAO). Red and white wines increase gastric acid output to 61% of MAO (Singer et al., 1991).

On the other hand, beverages with a higher alcohol content, such as whisky, gin or cognac (ethanol concentration of approximately 40% v/v), do not stimulate gastric acid output (Singer et al., 1987) (Figure 59.2).

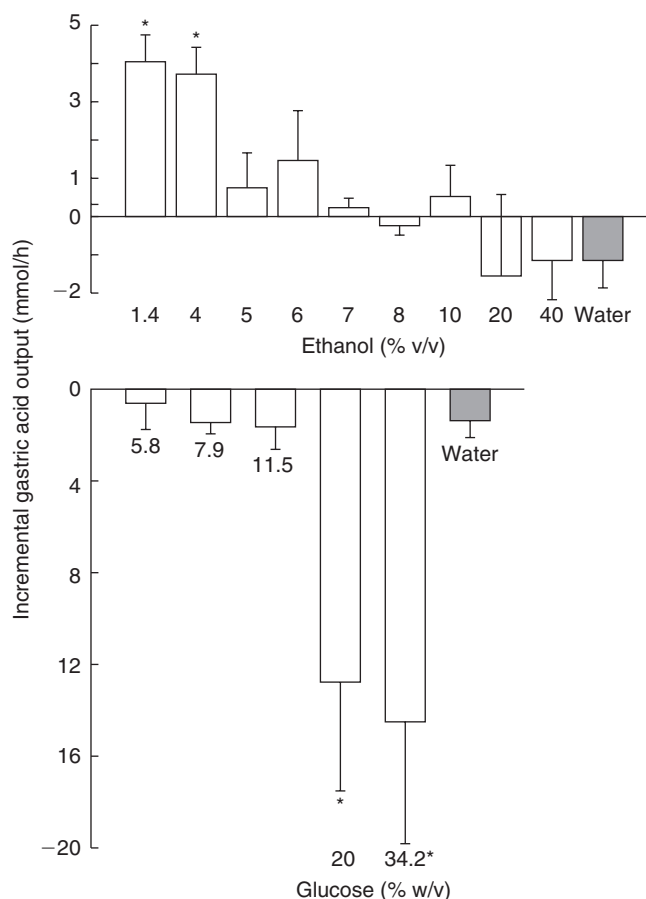
The ethanol content in beer (4% v/v) and wine (10% v/v) is only partially or not at all responsible for the marked gastric acid secretory response to beer and wine. Thus, non-alcoholic ingredients in beer and wine are most likely responsible for the stimulatory effect of these alcoholic beverages.


Figure 59.1 Effect of ethanol and glucose on gastric acid secretion. Effect of intragastric instillation of ethanol, distilled water and glucose on incremental 1-h gastric acid output. The 7.9%, 11.5%, 20% and 34.2% (w/v) glucose solutions are equivalent to 1.4%, 4%, 10% and 20% ethanol (v/v), respectively. Results are mean ± SEM of six subjects. *$p < 0.05$ compared with both distilled water and the isotonic glucose control solution. *Source*: Reprinted from Singer *et al.* (1987). Copyright 1987, with permission from the American Gastroenterological Association.

Singer *et al.* (1991) studied the effect of beer and its known ingredients before and after fermentation on gastric acid secretion (Figure 59.3). The effect of magnesium, calcium, amines, vitamins, organic acids, purines, amino acids and phenols in concentrations and amounts comparable to beer was examined. They found that none of the 11 tested ingredients of fermented beer (alone or in combination) nor hop extract had any significant effect (Table 59.1). However, finished beer (6 weeks old) and new beer were potent stimuli of acid output. Before the addition of yeast, preproducts of beer were considerably less potent. Thus, first and finished wort caused only a minor acid response (48% and 46% of MAO, respectively). Foreign fermentation in first and finished wort is presumably the reason for the stimulatory effect because glucose solution in concentrations seen in wort (11.5% w/v) does not stimulate acid secretion (Figure 59.1). However, after addition of

yeast which results in fermentation of the glucose solution, it is a potent stimulator of acid secretion. Lyophilization of beer at pH 11.0 and dialysis (cutoff molecular weight 1,000) removed the stimulatory substances. The addition of yeast to finished wort and the following alcoholic fermentation are the essential steps for the stimulatory effect of beer (Singer *et al.*, 1991).

Teyssen *et al.* (1999) further separated and specified the gastric acid stimulatory ingredients of beer. They used yeast-fermented glucose which has the same stimulatory effect on gastric acid secretion than beer (Table 59.1) as a simple model of fermented alcoholic beverages. Yeast-fermented glucose was stepwise separated by liquid chromatography and the separated solutions were tested in volunteers for their effect on gastric acid secretion (Table 59.1). Lyophilized-fermented glucose, substances with a molecular weight lower than 1,000, anions with a molecular weight lower than 1,000, anions with a molecular weight lower than 700 and the non-bound fractions of anions at pH 1.0 with a molecular weight lower than 700 had significant stimulatory effect on gastric acid secretion (Table 59.1). The fraction of non-bound anions at pH 1.0 with a molecular weight lower than 700 was further separated until five carboxylic and dicarboxylic acids were left: acetic acid, L(+)-lactic acid, oxalic acid, maleic acid and succinic acid. Their mixture at the same concentrations as in beer significantly stimulated gastric acid output. All acids together increased gastric acid output up to 94% of incremental MAO and 99% of the response to fermented glucose. When tested separately, oxalic acid, acetic acid and L(+)-lactic acid had no stimulatory effect. However, maleic acid and succinic acid significantly increased gastric acid output by 76% and 70%, respectively (Table 59.1). Given together in concentrations present in beer, maleic acid and succinic acid significantly increased gastric acid output by 100% of fermented glucose. Thus, the dicarboxylic acids, maleic acid and succinic acid were identified to be responsible for the strong stimulatory effect of alcoholic beverages produced by fermentation like beer or wine. The mechanisms of actions remain to be elucidated.

Motility

Only few studies have examined the effect of alcoholic beverages like beer on gastric motility, although consumption of alcoholic beverages before, after or with a meal is commonly thought to improve digestive functions. There exist some studies on the effect of pure ethanol on gastric motility. All studies on the effect of alcoholic beverages or ethanol on gastric motility relate on the gastric emptying rate of the gastric content, since it is the clinical decisive parameter of gastric motility and represents the sum of gastric motor activity. The mechanism and the regulation is different between the gastric emptying of liquids and that of solid meal. Gastric emptying of liquids is mainly under the
Figure 59.2 Effect of alcoholic beverages on gastric acid secretion. Gastric acid secretion (mmol/h) after instillation of different types of alcoholic beverages (hard liquors, aperitifs, wine, champagne and beer) compared to the MAO of pentagastrin. influence of the tone of the fundus, whereas gastric emptying of solids is regulated by the activity of the antrum and the pylorus. This has to be considered when the effect of alcoholic beverages and ethanol on gastric emptying is studied.

In 1970, the first study on the gastric emptying rate of ethanol was conducted by Cooke (1970). He examined different ethanol solutions (6, 8, 12 and 16 g/100 ml) and found that ethanol concentrations of 8 g/100 ml and more (12 and 16 g/100 ml) were delayed emptied from the stomach when compared to water or the lowest ethanol concentration tested (6 g/100 ml). However, there was no dose-dependent effect of the higher ethanol concentrations.

Kaufmann and Kaye (1979) studied the gastric emptying of ethanol and isocaloric glucose solutions to identify the impact of the caloric content of ethanol for its inhibitory effect. They compared gastric emptying of three isocaloric solutions (each with a volume of 750 ml): pure ethanol (80 ml), a mixture of ethanol (40 ml) and dextrose (63.3 g) and pure dextrose (126.6 g). They found that dextrose had a more pronounced inhibitory effect than its isocaloric ethanol amount.

Moore *et al.* (1981) examined the role of the ethanol content of red wine for its gastric emptying rate. They compared gastric emptying of red wine (9.5 g ethanol/dl) with that of a low-alcoholic red wine solution (1.3 g ethanol/dl), in

Table 59.1 Effect of beer and its constituents on gastric acid secretion

Test solution	Effect	Reference
Beer	>93% of MAO	Singer *et al.* (1987)
First wort	48% of MAO	Singer *et al.* (1991)
Hop extract	No effect	
Finished wort	46% of MAO	
New beer	76% of MAO	
Ingredients of beer: 4% ethanol, amines, phenoles, magnesium, calcium, amino acids, phenols, vitamins, organic acids, purines, pyrimidines (alone or in combination)	No effect	Singer *et al.* (1991)
Beer, lyophilized	pH dependent	Singer *et al.* (1991)
pH 2.5	67% of beer	
pH 7.0	53% of beer	
pH 11.0	20% of beer	
Beer, dialyzed (mol wt > 1,000)	No effect	Singer *et al.* (1991)
Unfermented glucose (11.5% w/v)	No effect	Singer *et al.* (1991), Teyssen *et al.* (1997)
Fermented glucose (11.5% w/v)	97% of MAO	Singer *et al.* (1991), Teyssen *et al.* (1997)
Ingredients of fermented glucose		Teyssen *et al.* (1999)
Lyophilized fermented glucose	100% of FG	
Substances with mol wt > 1,000	No effect	
Substances with mol wt < 1,000	102% of FG	
Cations and neutral substances (mol wt < 1000)	No effect	
Anions (mol wt < 1,000)	104% of FG	
Anions (mol wt < 700)	72% of FG	
Anions (mol wt < 700) at pH 1.0	78% of FG	
Fractions of anions with mol wt < 700 at pH 1.0		Teyssen *et al.* (1999)
Acetic acid	No effect	
Oxalic acid	No effect	
L(+)-lactic acid	No effect	
Succinic acid	70% of FG	
Maleic acid	76% of FG	
Maleic acid and succinic acid	100% of FG	

Note: Effect of beer, modified beer and selected ingredients of beer or fermented glucose (11.5% w/v) on gastric acid secretion in relation to maximal acid output, or to that of beer or fermented glucose. mol wt = molecular weight, FG = fermented glucose.

which major parts of the ethanol were exchanged by iso-caloric amounts of medium-chain triglycerides. Gastric emptying rates were not significantly different if normal or dealcoholized, isocaloric red wine were applicated.

The first controlled study on the effect of alcoholic beverages was conducted by Franke *et al.* (2004). They studied the gastric emptying of beer, red wine, whisky, corresponding ethanol solutions (4%, 10%, 40% v/v) and isocaloric and isovolumetric controls. Ethanol solutions even in low concentrations (4% v/v) were slower emptied from the stomach than water (Figure 59.4). There was no dose-dependent effect between 4% and 10% (v/v). Beer, red wine and whisky were also slower emptied. Alcoholic beverages produced by fermentation (beer and red wine) were significantly slower emptied than their corresponding ethanol concentrations (4% and 10% v/v). However, whisky, an alcoholic beverage produced by distillation, inhibited gastric emptying to the same degree than the corresponding ethanol solution (40% v/v). Presumably, non-alcoholic ingredients in those alcoholic beverages produced by fermentation alone are important additional inhibitory factors.

Jian *et al.* studied in 1986 the effect of an ethanol solution (approximately 25% v/v) on gastric emptying of a solid meal and found an inhibitory effect by ethanol (Jian *et al.*, 1986). Barboriak and Meade (1970) showed that whisky also inhibited gastric emptying of a solid meal.

The effect of beer, red wine, corresponding ethanol solutions (4% and 10% v/v) and isocaloric and isovolumetric control solutions on gastric emptying of solid meals were studied by Franke *et al.* (2005): beer and red wine induced a significant prolongation of gastric emptying of the meal (Figure 59.5). Corresponding ethanol solutions (4% and 10% v/v) also inhibited gastric emptying. However, red wine, but not beer, induced a significantly slower emptying than their corresponding ethanol solutions (10% and 4%, respectively). No differences between the ethanol solutions and isocaloric glucose solutions concerning the gastric half emptying time of the meal were detected, but the slope of gastric emptying was different: whereas the initial lag-phase (the period of time between end of consumption of the meal and begin of gastric emptying) was prolonged by glucose solutions, the lag-phase was nearly unchanged by
Figure 59.4 Gastric emptying of alcoholic beverages. Antral half emptying time (t(1/2)) of the test and control solutions as determined by ultrasonography. Results are means ± SEM of 10 subjects. G = glucose (w/v), E = ethanol (v/v). Whisky (125 ml) and E 40% (125 ml) were diluted with 125 ml water. *p < 0.05 compared with water, #p < 0.05 compared with respective pure ethanol solution.
Figure 59.5 Effect of alcoholic beverages on gastric emptying of a meal. Gastric half emptying time (t(1/2)) of a solid meal with the test solutions. Results are means ± SEM of eight subjects with each meal. G = glucose (w/v), E = ethanol (v/v). *p < 0.05 compared with water, #p < 0.05 compared with the corresponding ethanol solution.
Figure 59.6 Effect of alcoholic beverages on the lag-phase of gastric emptying. Gastric lag time (t(lag)) of a solid meal with the test solutions. Results are means ± SEM of eight subjects with each meal. G = glucose (w/v), E = ethanol (v/v). *p < 0.05 compared with water, #p < 0.05 compared with the corresponding pure ethanol solution.

ethanol or alcoholic beverages (Figure 59.6). Thus, compared to isocaloric glucose solutions alcohol induces an earlier begin of a slower gastric emptying. The mechanism by which this is mediated remains elucidated.

Concerning chronic effects of alcohol on gastric motility the data is scanty and inconsistent. While Keshvarzian et al. (1986) did not detect any effect on gastric emptying of solid test meals 3–10 days after alcohol abstinence,

Wegener *et al.* (1991) found a dose-related inhibitory effect on gastric emptying rate of solid test meals in actively drinking and symptomatic alcoholics. However, gastric retention may play a role in the development of malnutrition in alcoholics (Sankaran *et al.*, 1994).

Summary Points

- Beer and other alcoholic beverages produced by fermentation (e.g. wine) are powerful stimulators of gastric acid secretion.
- Corresponding ethanol concentrations (4% and 10% v/v) have only a mild stimulatory effect on gastric acid secretion.
- Alcoholic beverages produced by distillation (e.g. whisky, gin) have no stimulatory effect on gastric acid secretion.
- Maleic acid and succinic acid, non-alcoholic contents of alcoholic beverages produced by fermentation (especially beer), are responsible for the strong stimulatory effect.
- Beer and other alcoholic beverages produced by fermentation (e.g. wine), but not alcoholic beverages produced by distillation (e.g. whisky), are significantly slower emptied from the stomach than their corresponding ethanol solutions (4%, 10% and 40% v/v).
- Non-alcoholic ingredients in beer and red, which still have to be identified, are responsible for this additional effect compared to pure ethanol solutions.
- Beer and other alcoholic beverage, as well as corresponding ethanol solutions (4% and 10% v/v) prolong gastric emptying of solid meals.
- The inhibitory effect of beer is induced by a slower emptying phase, whereas the initial lag-phase is unchanged.

The Effect of Beer and Its Non-alcoholic Constituents on the Exocrine and Endocrine Pancreas as Well as on Gastrointestinal Hormones

Peter Feick, Andreas Gerloff and Manfred V. Singer Department of Medicine II (Gastroenterology, Hepatology and Infectious Diseases), University Hospital of Heidelberg at Mannheim, Mannheim, Germany

Abstract

The possible adverse effect of excessive alcohol consumption on the pancreas has been known since many years. Alcohol (ethanol) is generally consumed in the form of alcoholic beverages which contain numerous non-alcoholic compounds. On gastric acid secretion it has been convincingly demonstrated that alcohol and alcoholic beverages have markedly different effects. In this chapter we provide an overview about the effect of beer and different non-alcoholic constituents of beer on the pancreas and their possible interaction with molecular mechanisms leading to "alcoholic" pancreatitis, diabetes and pancreatic carcinoma. The present data indicate that pancreatic enzyme secretion in humans is stimulated by non-alcoholic constituents of beer which are generated by alcoholic fermentation of glucose. Natural phenolic compounds (e.g. quercetin, resveratrol) of beer have been shown to exert different effects on the pancreas in *in vitro* experiments, such as inhibition of pancreatic enzyme output, of pancreatic stellate cell activation and of pancreatic cancer growth. However, some compounds, for example resveratrol and catechins, showed also protective effects against oxidative stress and on experimentally induced acute pancreatitis or experimentally induced diabetes in rats. Bioavailability and efficacy of these compounds are summarized at the end of this chapter.

List of Abbreviations

α-SMA	α-Smooth muscle actin
AP-1	Activator protein 1
BB/E rat	Biobreeding/Edinburgh rat
BSDL	Bile salt-dependent lipase
b.w.	Body weight
cAMP	Adenosine-3′,5′-cyclic monophosphate
CCK-OP	Cholecystokinin octapeptide
COX	Cyclooxygenase
ERK	Extracellular signal-regulated kinase
GST	Glutathione *S*-transferase
GTC	Green tea catechin
IL	Interleukin
iNOS	Inducable nitric oxide synthase
MAO	Maximal acid output
MAP kinase	Mitogen activated protein kinase
MCP-1	Monocyte chemoattractant protein 1
NF-κB	Nuclear factor-kappa B
PDGF	Platelet derived growth factor
PKC	Protein kinase C
PSC	Pancreatic stellate cell
RWE	Red wine polyphenolic extract
SAP	Severe acute pancreatitis
SD-rats	Sprague–Dawley rats
SEM	Standard error of the mean
SOD	Superoxide dismutase
STZ	Streptozotocin
TNF	Tumor necrosis factor
TPA	12-*O*-tetradecanoylphorbol-13-acetate

Introduction

Chronic excessive consumption of alcoholic beverages is clearly associated with chronic pancreatitis. While the role of alcohol (ethanol) in the development of pancreatitis has been intensively investigated over the past 30 years, the role of non-alcoholic constituents was hardly considered. However, alcoholic beverages contain numerous non-alcoholic compounds. For example, up to now in beer more than 2,000 and in wine more than 1,000 organic and inorganic constituents were identified. As outlined briefly below and described by Franke *et al.* in detail in another chapter of this encyclopedia, evidence has been conclusively provided that alcoholic beverages and ethanol have markedly different effects on gastric acid secretion.

Some of the non-alcoholic constituents have been shown to be biologically active, although these compounds were

often not studied in respect of the effects of alcoholic beverages. Evidences accumulate that these compounds could have a critical role in inducing metabolic, pathological and functional changes *in vivo* and *in vitro*.

This chapter summarizes the published data about the effect of beer on the pancreas in comparison to ethanol. Furthermore, it will focus on the impact of different non-alcoholic constituents of beer on the pancreas and it will discuss their possible beneficial or adverse effects on molecular mechanisms leading to "alcoholic" pancreatic diseases.

Alcohol Consumption and Pancreatitis

Chronic calcifying pancreatitis is the alcohol-related disease of the pancreas (for review see Sarles, 1991; Singer and Müller, 1995). It is characterized by progressive and irreversible destruction of pancreatic structure and function: loss of acinar tissue, dilated and distorted ducts and significant fibrosis (DiMagno *et al.*, 1993). The disease usually begins as an acute process of a sudden and severe inflammation. Recurrent attacks of acute pancreatitis, which may last for several years, lead to the chronic phase of disease characterized by the development of chronic pain, pancreatic calcifications and exocrine as well as endocrine insufficiency (Apte and Wilson, 2003).

Epidemiological data indicate that heavy alcohol consumption causes pancreatitis in humans. Patients develop clinical manifestations of chronic pancreatitis after the consumption of more than 80 g alcohol per day (equivalent to approximately 2 l of beer) for average 18 ± 11 years for men and 11 ± 8 years for women (Durbec and Sarles, 1978). An increased risk to develop the disease has already been reported in patients with moderate alcohol consumption as low as 20 g ethanol/day. This risk increases logarithmically with higher amounts of alcohol consumption (Durbec and Sarles, 1978). However, only about 5–10% of clinically documented alcoholics develop symptoms of pancreatitis (Gumaste, 1995). Thus, a simple dose-related injury model for the development of the disease must be rejected (Durbec and Sarles, 1978; Worning, 1998).

Another issue which has been proposed to lead to chronic pancreatitis is the consumption of a specific type of alcoholic beverage. However, alcoholic chronic pancreatitis is observed in patients with a dominant consumption of beer, wine, hard liquor as well as other alcoholic beverages (Wilson *et al.*, 1985; Haber *et al.*, 1995). Therefore, the development of pancreatitis does not seem to be related to a specific type of alcoholic beverage. While alcohol exposure is obviously necessary, several lines of evidence suggest that alcohol alone cannot explain pancreatic inflammation, and that one or more additional factors must be also involved in the development of chronic pancreatitis. The other cofactors are yet to be determined, but could be environmental, genetic, race or concomitant risk factors such as smoking and nutrition (for reviews see Schneider and Singer, 2005; Schneider *et al.*, 2005; Chowdhury and Gupta, 2006).

Effects of ethanol and alcoholic beverages on the exocrine pancreas

The normal function of the exocrine pancreas is synthesis and release of digestive enzymes such as trypsin, chymotrypsin, amylase and lipase after stimulation by a meal. Altered secretion of these enzymes can lead to pancreatitis. Because hypersecretion of pancreatic enzymes has been observed in chronic alcoholics, a general impression is that ethanol stimulates basal (interdigestive) pancreatic exocrine secretion (Niebergall-Roth *et al.*, 1998). However, in the literature alcohol consumption demonstrates various effects on pancreatic exocrine secretion (Table 60.1) which may be due to different experimental conditions (Schneider *et al.*, 2005). The action of ethanol is affected by several variables such as: duration of alcohol consumption, administration route, the secretory state of the gland, species and accompanying dietary regimen. In addition, alcohol is commonly consumed as a tasteful beverage that is a complex mixture of non-alcoholic compounds with possible influence on pancreatic secretion.

Table 60.1   Major findings in studies with humans and ethanol-fed animals on pancreatic exocrine secretion

Acute ethanol administration
- Oral and intragastric ethanol administration increases pancreatic bicarbonate and protein secretion
- Intravenous ethanol administration reduces basal and hormonally stimulated pancreatic bicarbonate and protein secretion
- Non-alcoholic constituents of beer may increase pancreatic secretion

Chronic ethanol administration
- In human alcoholics, the basal pancreatic enzyme secretion is increased
- In human alcoholics, the viscosity of the pancreatic juice is enhanced
- In human alcoholics, the pancreatic juice contains a higher concentration of proteins
- In human alcoholics, the pancreatic bicarbonate secretion is decreased
- In human alcoholics, an enhanced ratio of trypsinogen levels to pancreatic secretory trypsin inhibitor levels is present in the pancreatic juice
- In ethanol-fed animals, a diet rich in fat and protein increases the concentrations of enzymes in the pancreatic juice

Note: Acute and chronic ethanol administration results in changes in pancreatic exocrine secretion in humans and animals which may contribute to the development of pancreatic damage.

Effects of Ethanol, Alcoholic Beverages and Their Non-alcoholic Constituents on Gastric Acid Secretion   Before describing their effects on the pancreatic enzyme output, the different effects of ethanol and beer on gastric acid output will be described first.

Low concentrations ($<4\%$ v/v) of pure ethanol are only a mild stimulant of gastric acid output with a response equal to about 23% of the pentagastrin-stimulated gastric acid output (maximal acid output, MAO) (Figure 60.1). Higher concentrations of ethanol (5–40% v/v) have either no effect or a mildly inhibitory one (Singer *et al.*, 1987). None of the ethanol concentrations tested increase plasma gastrin concentrations.

In contrast, beer is a powerful stimulant of gastric acid output with a response equal to about 85% of MAO (Figure 60.1) as well as of gastrin release. Other alcoholic beverages with low ethanol content produced by fermentation (e.g. wine and champagne) are also powerful stimulants whereas distilled alcoholic beverages with a higher ethanol content (e.g. whisky and cognac) do not stimulate gastric acid output (Figure 60.1) or release of gastrin (Singer *et al.*, 1987; Teyssen *et al.*, 1997).

The ethanol content in beer (4% v/v) can be only partially responsible for the marked gastric acid secretory response to beer. Therefore, non-alcoholic ingredients are most likely responsible for the stimulatory gastric action of beer and the other alcoholic beverages.

The gastric-stimulatory substances have been identified as the dicarboxylic acids, maleic acid and succinic acid, which are produced during the process of alcoholic fermentation (Teyssen *et al.*, 1999). The surprising outcome of this investigation was that these dicarboxylic acids do not stimulate gastrin release. Therefore, it is hypothesized that maleic acid and succinic acid induce gastric acid output by a direct yet unknown mechanism.

Effects of Ethanol, Alcoholic Beverages and Their Non-alcoholic Constituents on Pancreatic Exocrine Function   Ethanol can be metabolized by the pancreas by different pathways. Oxidative metabolism generates acetaldehyde and non-oxidative metabolism generates fatty acid ethyl esters with both having damaging effects on the pancreas (reviewed in Schneider *et al.*, 2002). The role of ethanol and its metabolites in pancreatitis has been studied since many years and is summarized in several reviews (Go *et al.*, 2005; Schneider and Singer, 2005; Schneider *et al.*, 2005; Chowdhury and Gupta, 2006). It is also not in the focus of this chapter and, thus, the effects of pure ethanol on the exocrine pancreas will be outlined only briefly (Table 60.2).
Figure 60.1   Effect of beer, different types of alcoholic beverages and ethanol on gastric acid secretion of healthy human subjects. One hour incremental gastric acid output in response to beer and various alcoholic beverages produced by fermentation or distillation, and to different concentrations of ethanol as well as to fermented glucose and to the combination of maleic acid and succinic acid in concentrations found in finished beer. For comparison the maximal acid output in response to pentagastrin and gastric acid output to control solutions (isotonic glucose, 5.76 w/v, and distilled water) are also shown. Results are means $\pm$ SEM from at least six subjects. *p < 0.05 for the difference with isotonic glucose control solution, **p < 0.05 in comparison to isotonic glucose control solution and distilled water. *Source*: Adapted from Singer *et al.* (1987) and Teyssen *et al.* (1997, 1999).

Acute Effects of Ethanol In Vivo   Intravenous administration of ethanol appears to be the most adequate method to investigate direct effects of alcohol on pancreatic cells *in vivo* (Singer, 1985; Singer and Goebell, 1985; Singh and Simsek, 1990). With this route of administration, ethanol leads to a dose-dependent inhibition of the basal and hormonally stimulated pancreatic bicarbonate and enzyme output in humans and different animal species (Niebergall-Roth *et al.*, 1998). Although the inhibitory action of ethanol on pancreatic secretion has been suggested to be a consequence of a cholinergic mediation, this mechanism was never proven in humans. Thus, the exact mechanisms remain unclear. Ethanol has no further inhibitory effects on pancreatic amylase output after premedication with atropine (Kolbel *et al.*, 1986).

Acute Effects of Ethanol In Vitro   The application of ethanol to isolated pancreatic acini led to an increase of basal amylase secretion, but decreased the cholinergic or secretagogue-mediated amylase release (Uhlemann *et al.*, 1979; Ponnappa *et al.*, 1987; Nakamura *et al.*, 1991). These

Table 60.2   Major findings with animal models of acute and chronic ethanol administration on pancreatic morphology

Major findings with animal models of acute ethanol administration
- Ethanol administration (intragastrically, intraperitoneally, intravenously) with physiological stimulation (CCK, secretin) and obstruction of the pancreatic duct results in acute pancreatitis
- Ethanol administration enhances the vulnerability of the pancreas to develop acute pancreatitis and limits pancreatic regeneration from acute pancreatitis
- Ethanol administration selectively reduces pancreatic blood flow and microcirculation
- Cigarette smoke enhances ethanol-induced pancreatic ischemia
- Ethanol administration increases free oxygen radical generation in the pancreas
- Ethanol metabolites directly damage the pancreas

Major findings with animal models of chronic ethanol administration
- Dietary fat potentiates ethanol-induced pancreatic injury
- Ethanol administration increases free oxygen radical generation in the pancreas
- Ethanol administration increases pancreatic acinar cell mRNA expression and glandular content of digestive and lysosomal enzymes
- Ethanol administration decreases the number of muscarinic receptor sites
- Ethanol administration limits pancreatic regeneration after temporary obstruction of the pancreatic duct and further aggravates already induced pancreatic damage
- Ethanol administration sensitizes pancreatic acinar cells to endotoxin-induced injury
- Ethanol administration enhances the vulnerability of the pancreas to pancreatitis caused by CCK-OP

Note: Experimental studies have provided various insights into the mechanisms, whereby alcohol damages the pancreas. It is likely that several mechanisms act together and increase the risk to develop alcoholic chronic pancreatitis.

Source: Reviewed in Schneider *et al.* (2002); originally published by Schneider *et al.* (2005).

investigations have shown that acute ethanol administration influences pancreatic secretion through the production of cAMP, an increase of cytosolic free calcium concentrations, an inhibition of calcium efflux, the inhibition of cholecystokinin-receptor binding and impairment of microtubule function (Niebergall-Roth *et al.*, 1998).

Chronic Effects of Ethanol In Vivo   In human alcoholics, basal pancreatic enzyme output was increased compared with non-alcoholics (Sahel and Sarles, 1979; Renner *et al.*, 1980; Planche *et al.*, 1982; Brugge *et al.*, 1985). Viscosity of the pancreatic juice was enhanced in alcoholic subjects and this rise was correlated with increased protein concentrations (Harada *et al.*, 1980). The volume of pancreatic juice was similar in controls and alcoholics, thereby indicating a true hypersecretion of pancreatic proteins in chronic alcoholics (Sahel and Sarles, 1979). The pancreatic bicarbonate secretion was significantly lower in human alcoholics than in non-alcoholics (Sahel and Sarles, 1979; Renner *et al.*, 1980), whereas basal plasma concentrations of secretin, cholecystokinin (CCK) and gastrin remained unchanged (Singer *et al.*, 1985; Singh and Simsek, 1990; Niebergall-Roth *et al.*, 1998). Administration of a diet rich in fat and protein resulted in an increase of the concentrations of enzymes in the pancreatic juice in animals (Devaux *et al.*, 1990; Niebergall-Roth *et al.*, 1998). In some dogs, a decreased flow rate of the pancreatic juice together with protein plug formation was found (Devaux *et al.*, 1990).

Studies of the effects of chronic alcohol intake on hormonally stimulated pancreatic secretion revealed that pancreatic bicarbonate output remains unaffected. However, alcoholics have an increased enzyme response on exogenous administration of CCK (Sahel and Sarles, 1979; Rinderknecht *et al.*, 1985). In addition, an enhanced ratio of trypsinogen levels to pancreatic secretory trypsin inhibitor levels was found in the pancreatic juice from chronic alcoholics (Rinderknecht *et al.*, 1985). This alteration of the normal ratio in favor of trypsinogen may facilitate premature activation of pancreatic proenzymes within the pancreas with an increased risk of subsequent pancreatic autodigestion (Rinderknecht *et al.*, 1985).

In summary, the ethanol-induced altered pancreatic secretion might contribute to the development of alcoholic chronic pancreatitis. However, the exact mechanisms still remain to be identified.

Effects of Beer on Pancreatic Exocrine Function In Vivo   Intragastric administration of beer in a volume (250 ml) that does not alter plasma ethanol concentrations causes a significant stimulation of basal pancreatic enzyme output (Figure 60.2) (Chari *et al.*, 1996). The stimulatory effect might be mediated by the hormones CCK and gastrin which are released after oral or intragastric administration of beer (Table 60.3) (Chari *et al.*, 1996). Intragastric administration of ethanol in concentrations similar to beer (4% v/v) has no effect on pancreatic enzyme output (Figure 60.2). Therefore, non-alcoholic constituents might be responsible for the stimulatory effect of beer on pancreatic enzyme secretion in

humans. Intragastric administration of fermented glucose in a concentration (11.5% w/v) found in finished wort, a preproduct of beer, but not non-fermented glucose induced an increase in pancreatic enzyme secretion similar to that of beer (Figure 60.2). This finding indicates that alcoholic fermentation of glucose might be the essential event generating as yet unknown pancreatic secretagogues in beer (Chari et al., 1996).
Figure 60.2 Effect of beer, ethanol and fermented glucose on pancreatic enzyme output of healthy human subjects. The 150 min integrated trypsin response (left) and amylase response (right) to intragastric beer, ethanol (4% v/v) and fermented glucose (11.5% w/v) as well as to the corresponding caloric (glucose, 5.76% w/v), osmotic (glucose, 11.5% w/v) and volumetric (water) control solutions were determined. Results are means ± SEM of six subjects. *p < 0.05 in comparison to ethanol and all control solutions. Source: Adapted from Chari et al. (1996).

The intragastric administration of an higher amount of beer (850 ml) elevated plasma ethanol concentrations but did not affect the basal pancreatic enzyme output (Hajnal et al., 1989). It was suggested that the direct inhibitory effect of circulating ethanol neutralized the stimulatory effect of non-alcoholic components of beer. The basal enzyme output also remained unchanged after intragastric application of white wine and gin.

In addition, the meal-stimulated pancreatic enzyme output was inhibited by intragastric beer, but also by white wine and gin, although postprandial plasma CCK and gastrin concentrations were increased by beer and wine (Table 60.4) (Hajnal et al., 1990; Niebergall-Roth et al., 1998). Since ethanol plasma levels were concurrently elevated in these studies, the inhibitory effect of circulating ethanol on pancreatic secretion might have neutralized the stimulatory effect of a meal as well as that of beer and white wine.

Effects of Beer on Pancreatic Exocrine Function In Vitro
In vitro experiments with the rat pancreatic acinar tumor cell line AR4-2J which in its differentiated state retains much of the characteristics of pancreatic acinar cells and is a common model to study stimulus–secretion coupling have shown that beer dose dependently increased amylase release (Figure 60.3). Incubation of AR4-2J cells with ethanol (10–400 mM) had no effect on basal protein secretion whereas hormone-stimulated amylase secretion was dose dependently inhibited at ethanol concentrations of more than 100 mM (Feick et al., 2003). Maleic acid and succinic acid, the non-alcoholic compounds of beer and other fermented alcoholic beverages that maximally increase gastric acid output, had alone or in combination with ethanol in concentrations found in beer no effect on basal protein

Figure 60.3 Effect of beer and ethanol on enzyme output of differentiated pancreatic acinar AR4-2J cells. The 60-min amylase release induced by 1%, 5% and 10% (v/v) of beer in incubation medium as well as by equivalent ethanol concentrations was determined. The results are expressed as percentage of maximal amylase secretion induced by 100 nM cholecystokinin (CCK). *$p < 0.01$ in comparison to basal secretion from unstimulated cells.

secretion (Gerloff *et al.*, unpublished). Therefore, non-alcoholic substances of beer other than these dicarboxylic acids might be responsible for the stimulatory effect of beer on pancreatic enzyme output.

Polyphenolic compounds of beer

One of the differentiating characteristics among alcoholic beverages is their polyphenol composition. In this context wine contains more abundant polyphenols – more than beer and liquors (Bujanda, 2000). In beer more than 50 polyphenolic compounds were identified (Piendl, 2005). About 75–85% of these polyphenols derive from malt and 15–25% from hop. The polyphenol content of each beer is largely affected by the type and the sort of corn (barley, wheat), the type of hop as well as by the different processes to get malt, wort and hop extract. Table 60.5 shows the concentrations

Table 60.5 Concentrations of various non-alcoholic compounds found in beer

Compound	Concentration (mg/l)	Reference
Quercetin	0.7–20	Piendl (2005)
Resveratrol	0.34–3.4	Tedesco *et al.* (2005)
Maleic acid	110	Piendl (1980)
Succinic acid	16	Piendl (1980)
Rutin	Under 0.1	Piendl (2005)
Catechin	0.5 to over 20	Piendl (2005)
Epicatechin	0.8 to over 20	Piendl (2005)
Ellagic acid	1.0–10	Piendl (2005)
Folic acid	0.086	Piendl (2005)

of some phenolic substances and other non-alcoholic constituents found in beer. The first such polyphenols studied were *quercetin* and *rutin* followed more recently by *resveratrol* (Deschner *et al.*, 1991; Bujanda, 2000).

Quercetin is a naturally occurring flavonoid present in a variety of plants and in beer and wine and has important anti-degenerative properties (Maxwell *et al.*, 1994). *Rutin* is the glycosidic form of quercetin and is one of the flavonoids most abundantly consumed in foods. It has anti-inflammatory and anti-mutagenic properties (Janbaz *et al.*, 2002). *Resveratrol* is a phenolic phytoalexin present in grape skins and wines (especially red wines) and was also found in beer. Among a variety of biological effects it has a potent anti-inflammatory function *in vitro* (Bujanda, 2000). *Ellagic acid* is a polyphenol mainly found in fruits (raspberries, strawberries), nuts (walnuts) and wood, but also in beer and wine (Masamune *et al.*, 2005; Piendl, 2005). It has a variety of biological activities including antioxidant, anti-inflammatory and anti-fibrotic effects (Masamune *et al.*, 2005). *Catechins* are phytoalexins which are found in green tea, various vegetables and fruits and particularly in paring of grapes of red wines as well as beer. In several studies the anti-oxidative and radical-scavenging properties of *catechins* have been reported (Yang and Wang, 1993; Noroozi *et al.*, 1998). In the following sections the effects of different polyphenols on the pancreas are described (Table 60.6).

Table 60.6 Studies on the effects of non-alcoholic constituents of beer on the pancreas

Compound	Experimental design	Effect on pancreas	Species	Reference
Quercetin	In vitro 10–100 μM Isolated pancreatic acini	Inhibition of agonist-induced amylase release and of PKC activity	Rat (SD)	Lee et al. (1988)
Resveratrol	In vitro 10–100 μM	Inhibition of bile salt-dependent lipase (BSDL) activity Reduction of secreted and intracellular BSDL	Human (purified BSDL), rat (purified BSDL, AR4-2J cell line)	Sbarra et al. (2005)
	In vivo 20 mg/kg b.w. Experimentally induced pancreatitis	Decrease of elevated amylase, malondialdehyde and myeloperoxidase levels Increase of pancreatic superoxide dismutase Reduction of turbidity ascitic fluid, pancreatic edema, necrosis and inflammatory cell infiltration	Rat (SD)	Li et al. (2006)
	In vivo 10 mg/kg b.w. Experimentally induced pancreatitis	Reduction of elevated serum amylase and lipase activities and reduction of changes of serum glucose, calcium and creatinine and aspartate aminotransferase Increase of serum concentration of triglyceride and urea nitrogen to normal level Reduction of extent of tissue edema, acinar vacuolization and total histological damage	Rat (Wistar)	Szabolcs et al. (2006)
	In vivo 2 mg/day Experimentally induced pancreatitis	Decrease of elevated serum activity of amylase Less pronounced necrotic changes of pancreata	Rat (Wistar)	Lawinski et al. (2005)
	In vivo 10 mg/kg b.w. Experimentally induced pancreatitis	Decrease of NF-κB activation in peritoneal macrophages Reduction of iNOS expression and of TNF-α, IL-1 and NO serum levels	Rat (SD)	Ma et al. (2005)
	In vivo 30 mg/kg b.w. Experimentally induced pancreatitis	Reduction of NF-κB expression and of TNF-α and IL-8 level in pancreatic tissue	Rat (SD)	Meng et al. (2005)
Ellagic acid	In vivo 1% w/w	Increase of glutathione S-transferase expression	Rat (Wistar)	Nijhoff and Peters (1994)
	In vitro ≤25 μg/ml PSCs	Inhibition of PDGF-induced proliferation and migration of PSCs and of phosphorylation of PDGF β-receptor, ERK and Akt Decrease of expression of α-SMA, procollagen I and III and MCP-1 Inhibition of transformation of freshly isolated PSCs	Rat (Wistar)	Masamune et al. (2005)
Catechin (green tea extract)	In vivo 0.1% solution (80% catechins)	Protective effect against N-nitrosobis(2-oxopropyl)amine-induced oxidative damage	Syrian golden hamster	Takabayashi et al. (1997, 2004)
	In vivo 0.2% solution (91.2% catechins) Experimentally-induced pancreatitis	Decrease of elevated serum amylase activity and lipid peroxides concentration Protection of pancreatic tissue	Rat (Wistar)	Takabayashi et al. (1995)

α-SMA: α-smooth muscle actin; BSDL: bile salt-dependent lipase; b.w.: body weight; ERK: extracellular signal-regulated kinase; IL: interleukin; iNOS: inducible nitric oxide synthase; MCP-1: monocyte chemoattractant protein 1; NF-κB: nuclear factor-kappa B; PDGF: platelet derived growth factor; PKC: protein kinase C; PSC: pancreatic stellate cell; SD: Sprague–Dawley; TNF: tumor necrosis factor.

Effects of different non-alcoholic constituents of beer on the exocrine pancreas

As described above chronic ethanol consumption significantly increases basal pancreatic enzyme output, protein concentration in the pancreatic juice and the viscosity of pancreatic juice. Investigation of the effects of non-alcoholic compounds of alcoholic beverages have been undertaken to facilitate our understanding of their direct effects.

In a former study the effect of quercetin on stimulated amylase release in isolated rat pancreatic acini was investigated (Lee et al., 1988). Quercetin inhibited amylase release stimulated by carbachol in a time- and dose-dependent manner. In addition, quercetin partially inhibited amylase release induced by various agonists such as cholecystokinin C-terminal octapeptide (CCK-OP), calcium ionophore A23187 and protein kinase C (PKC) activator 12-O-tetradecanoylphorbol-13-acetate (TPA) whereas vasoactive intestinal polypeptide-induced amylase release was potentiated. Since quercetin also inhibited PKC activity in a dose-dependent manner, the ability of quercetin to decrease agonist-stimulated amylase release may be ascribed – at least in part – to quercetin-induced inhibition of PKC activity.

A recent study compared the effects of resveratrol and a whole red wine polyphenolic extract (RWE) on the pancreatic bile salt-dependent lipase (BSDL) in vitro (Sbarra et al., 2005). Resveratrol and RWE inhibited human and rat BSDL activity in a dose-dependent manner. Furthermore, resveratrol (but not RWE) decreased the expression and secretion of BSDL in AR4-2J cells. Our own data suggest that resveratrol induces activation of an actin cytoskeleton-controlled protein tyrosine phosphatase leading to a decrease of protein tyrosine phosphorylation in AR4-2J cells which is involved in bombesin-stimulated amylase secretion (Feick et al., 2006).

Effects of Non-alcoholic Constituents of Beer upon Oxidative Stress Oxidative stress is another important event that may play a role in pancreatic injury. Evidence of oxidative stress has also been reported in the pancreas of patients with alcoholic chronic pancreatitis (Schneider et al., 2005). In general, oxidative stress results from an imbalance between the production of free radicals or reactive oxygen species (highly reactive molecules with the potential to damage lipid membranes, intracellular proteins and DNA) and the anti-oxidant defense mechanisms within the cell (including glutathione, the enzymes glutathione peroxidase, superoxide dismutase (SOD, an internal anti-oxidase) and catalase) (Apte et al., 2005).

The effect of resveratrol on pancreatic oxygen free radicals was investigated in rats with severe acute pancreatitis (SAP) (Li et al., 2006). Histological examinations showed that the resveratrol treatment after SAP induction led to a significant reduction of turbidity ascitic fluid, pancreatic edema, necrosis and inflammatory cell infiltration as compared to the SAP group. In addition, serum amylase was significantly diminished by resveratrol. Furthermore, resveratrol

treatment inhibited the formation of the lipid peroxidation product malondialdehyde and increased the pancreatic SOD. Measurement of myeloperoxidase (MPO) as degree for neutrophil sequestration which is another source of oxygen free radicals during acute pancreatitis showed a reduction of this enzyme in the resveratrol-treated group. In conclusion, resveratrol had a protective effect on pancreatic damage by lowering oxidative free radicals and reducing tissue infiltration of neutrophils.

A chemoprotective effect of ellagic acid and flavone has been shown by enhancing the glutathione S-transferase (GST) detoxification system in the pancreas of male Wistar rats (Nijhoff and Peters, 1994). Studies on GST isozyme expression levels showed an ellagic acid-increased expression of GST-μ by 160% and a flavone-induced increase of GST-π expression by 200%. Ellagic acid and flavone had no significant effect on pancreatic GST enzyme activity and glutathione content.

Certain catechins have anti-oxidative properties by eliminating superoxide and hydroxyl radicals. Thus, it could be shown that a 0.1% solution of green tea catechins (GTC) as drinking water had a protective effect against the oxidative stress in pancreas and liver induced by the carcinogen N-nitrosobis(2-oxopropyl)amine in Syrian golden hamsters (Takabayashi et al., 1997). GTC inhibited the increase of 8-hydroxydeoxyguanosine content in nuclear DNA which is a biomarker of DNA oxidative damage, as well as lipid peroxidation confirming the protective effect of catechins on oxidative stress. In contrast, GTC in combination with a high fat diet may increase oxidative stress in pancreas but may slightly suppress oxidative stress in liver (Takabayashi et al., 2004).

Effects of Ethanol and Non-alcoholic Constituents of Beer upon Pancreatic Stellate Cells Pancreatic stellate cells (PSCs) are the main source of extracellular matrix synthesis leading to pancreatic fibrosis and are activated by growth factors, inflammatory cytokines, alcohol, its metabolites and oxidative stress (Apte et al., 2006).

Recently, it has been shown, that ellagic acid has crucial effects on a number of cell functions of PSCs in vitro (Masamune et al., 2005). Ellagic acid inhibited the platelet derived growth factor (PDGF)-induced proliferation and migration in a dose-dependent manner without affecting cell viability. At a concentration of 10 μg/ml ellagic acid inhibited PDGF-induced tyrosine phosphorylation of PDGF β-receptor and the activation of the downstream signaling pathways (ERK and Akt). Furthermore, ellagic acid significantly inhibited several key functions of PSCs including AP-1 and MAP kinases activation, α-SMA gene expression, MCP-1 production and collagen expression in a dose-dependent manner. In addition, ellagic acid blocked the transformation of freshly isolated PSCs from quiescent to myofibroblast-like phenotype in culture. Taken altogether ellagic acid seems to be a potential candidate for the treatment of pancreatic fibrosis and inflammation.

Effects of Non-alcoholic Constituents of Beer upon Pancreatitis Induced in Animals   Several animal models have been developed to induce acute pancreatitis (Siegmund *et al.*, 2005). In some recent studies a protective effect of resveratrol on experimentally induced acute pancreatitis could be demonstrated.

Szabolcs *et al.* (2006) examined the effect of resveratrol on CCK-OP-induced acute pancreatitis in male Wistar rats. Pretreatment with resveratrol ameliorated CCK-induced changes of laboratory parameters such as amylase, lipase, glucose, calcium, creatinine and aspartate aminotransferase activities as well as the serum concentration of triglyceride and urea nitrogen. However, resveratrol showed no effect on the reduced pancreatic Cu/Zn-SOD and glutathione peroxidase activity and on the elevated MPO activity and tumor necrosis factor alpha (TNF-α) concentration in the pancreatitis rats. Histopathologically, the pancreas showed a reduced extent of tissue edema, acinar cell vacuolization and focal tissue necrosis after resveratrol treatment. Since no inhibition of nuclear factor-kappa B (NF-κB) activation by resveratrol has been found, it was concluded that the beneficial effects of resveratrol seem to be mediated by the anti-oxidant effect of resveratrol or by an anti-inflammatory mechanism independent of NF-κB.

In contrast to this, activation of NF-κB in macrophages is involved in the inflammatory response of rats with sodium taurocholate-induced SAP. Resveratrol decreased the NF-κB activation as well as iNOS expression in peritoneal macrophages (Ma *et al.*, 2005). In addition, in resveratrol-treated SAP rats serum levels of TNF-α, IL-1 and NO were also reduced. Histological examinations of the pancreas showed an attenuation of various pathological manifestations by resveratrol as compared to SAP group. These results were confirmed by a second study showing an inhibitory effect of resveratrol on expression of NF-κB and the levels of TNF-α and IL-8 in pancreatic tissues of SAP-rats (Meng *et al.*, 2005).

Less pronounced necrotic changes of rat pancreata as well as a decrease of serum amylase activity were also found by treatment with resveratrol for 8 days before induction of acute pancreatitis with free radicals (tert-butyl hydroperoxide) in male Wistar rats (Lawinski *et al.*, 2005). In summary, resveratrol may be considered as an agent for reducing the inflammatory response in acute pancreatitis.

Similar results were found for the effect of catechins on DL-ethionine-induced acute pancreatitis (Takabayashi *et al.*, 1995) and on cerulein-induced pancreatitis (Takabayashi and Harada, 1997) in male Wistar rats showing a protective effect of catechins on experimental-induced pancreatitis in rats, too.

Alcohol Consumption and Diabetes

Diabetes mellitus is a metabolic disorder that is rapidly reaching epidemic proportions, and the World Health Organization has predicted that by 2025, 300 million people will be affected worldwide (Su *et al.*, 2006). Alcohol consumption is associated with type 2 diabetes in a U-shaped manner, indicating a decreased risk of moderate consumers (5–30 g of alcohol per day in the order of 30%) compared with heavier consumers (30 g or more of alcohol per day) or abstainers (Carlsson *et al.*, 2005; Koppes *et al.*, 2005). The beneficial effect of moderate alcohol consumption seems to be equal in women and men as well as consistent across different ethnic groups. High consumers have an increased risk of type 2 diabetes compared to moderate consumers, but whether they have an increased risk compared to low consumers or abstainers is less clear (Carlsson *et al.*, 2005). In patients with type 1 diabetes alcohol is a recognized risk factor for hypoglycemia 12–16 h after the consumption of an alcoholic beverage (Lange *et al.*, 1991). While it seems that the kind of beverage does not influence the association between alcohol consumption and the risk of diabetes for older women with type 2 diabetes (Beulens *et al.*, 2005), Wannamethee *et al.* (2003) showed different effects of various alcoholic beverages on serum insulin concentration in men. Depending on the number of drinks per day, beer and wine showed an inverse effect on blood insulin concentration, whereas spirit had no significant influence.

Recently there has been renewed interest in the use of plant compounds (flavonoids) as antidiabetic compounds since they possess strong anti-oxidant effects resulting in the regeneration of β-cells and protection of pancreatic islets against cytotoxic effects such as oxidative stress (Ihara *et al.*, 1999). Streptozotocin (STZ) and alloxan are the most common substances to induce experimental diabetes in rat to mimic the human situation and to simplify studies on the effects of therapeutic substances on diabetes (Table 60.7).

Effects of non-alcoholic compounds of beer on experimentally induced diabetes in rats

Effects of Epicatechin   Chakravarthy and co-workers examined the regeneration of β-cells in alloxan-induced diabetic rats by (–)-epicatechin (Chakravarthy *et al.*, 1981, 1982). Treatment of albino rats with epicatechin for 5 days after alloxan administration resulted in blood sugar levels, β-cell counts and serum insulin levels within normal range. In contrast, untreated diabetic rats showed necrosis and reduction of β-cells, increased blood sugar level and decreased serum insulin level. Epicatechin *per se* had no effect on these parameters and did not cause any toxic effect, too. Another study of Kim *et al.* (2003) investigated the effect of epicatechin on the toxic effect, too STZ in Sprague–Dawley (SD)-rats. The intraperitoneal administration with epicatechin twice a day over a 6-day period resulted in significantly reduced blood glucose level as compared to the diabetic rats. Immunohistochemical analysis showed a significant decline of β-cells to 8.5 ± 2.1% in STZ-rats whereas the pretreatment with epicatechin caused a recovery to 60% as compared to normal control rats. The increase of insulin release

Table 60.7 Effects of non-alcoholic compounds of beer upon diabetes

Compound	Experimental design	Results	Species	Reference
Epicatechin (30 mg/kg b.w., twice a day, 24 h after alloxan treatment for 5 days)	*In vivo* Alloxan-induced diabetes Intraperitoneal administration	Reduction of increased blood glucose levels Increase of glucose-induced insulin secretion Increase β-cell counts	Rat (albino)	Chakravarthy *et al.* (1981, 1982)
Epicatechin (30 mg/kg b.w., twice a day, 6 h after STZ treatment for 6 days)	*In vivo/in vitro* STZ-induced diabetes Intraperitoneal administration Isolated islets of Langerhans	Reduction of increased blood glucose levels Protection of β-cells Increased reduced insulin release Inhibited nitrite production	Rat (SD)	Kim *et al.* (2003)
Epicatechin (30 mg/kg b.w., twice a day, for 9 days after STZ-treatment)	*In vivo* STZ-induced diabetes Spontaneous diabetes Intraperitoneal/oral administration	No significant effect on increased blood glucose levels Failed to maintain body weight	Rat (Wistar, BB/E)	Bone *et al.* (1985)
Quercetin (10 and 15 mg/kg b.w./day, for 10 days after STZ-treatment)	*In vivo* STZ-induced diabetes Intraperitoneal administration	Reduction of increased levels of blood glucose, plasma cholesterol and triglyceride Increase of hexokinase activity	Rat (SD)	Vessal *et al.* (2003)
Quercetin (15 mg/kg b.w./day, 3 days pretreatment and for 4 weeks after STZ-treatment)	*In vivo* STZ-induced diabetes Intraperitoneal administration	Reduction of increased blood glucose levels Protection of β-cells Increase of reduced serum insulin levels and anti-oxidant enzyme activities Decrease of elevated blood malondialdehyde levels	Rat (SD)	Coskun *et al.* (2005)
Resveratrol (0.1–0.75 mg/kg b.w., up to three applications/day, 7 days after STZ-treatment for 2 weeks)	*In vivo* STZ-induced and STZ + nicotineamide-induced diabetes Gastric intubation	Reduction of increased levels of blood glucose and of plasma triglyceride Prevention of decreased body weight Increase of glucose uptake by insulin-sensitive tissues	Rat (SD)	Su *et al.* (2006)

b.w.: body weight; BB/E rat: biobreeding/Edinburgh rat; SD: Sprague–Dawley; STZ: Streptozotocin.

as well as the decrease of nitrite concentration indicated a protective effect of epicatechin against the diabetogenic activity of STZ. However, in the study of Bone *et al.* (1985) epicatechin failed to reverse and to halt the progression of diabetes in STZ-induced diabetic Wistar rats and spontaneously diabetic BB/E rats *in vivo*.

Effects of Quercetin   Intraperitoneal administration of quercetin showed no effect on plasma glucose concentration in control animals, but significantly reduced elevated blood glucose level of STZ-induced diabetic rats within 8–10 days (Vessal *et al.*, 2003). Lowering of plasma cholesterol and triglyceride levels as well as the significant increase of hexokinase activity by quercetin supplied further evidences for the regenerative action of quercetin on pancreatic islet cells. Coskun *et al.* (2005) showed an increase of the lowered serum insulin levels in STZ-diabetic Wistar rats by quercetin. Quercetin also significantly

decreased the elevated blood malondialdehyde level and increased the reduced anti-oxidant enzyme activities. Immunohistological staining of pancreatic islet cells showed a decrease in hydropic degeneration, degranulation, necrosis and an increase of the area of insulin immunoreactive β-cells (Coskun *et al.*, 2005).

Effects of Resveratrol   Studies in STZ-induced and STZ plus nicotinamide-induced (strong vs. moderate inducer of diabetes) diabetic SD-rats showed that oral administration of resveratrol resulted in a dose-dependent decrease of the plasma glucose concentrations with a maximal glucose-lowering activity at a dose of 0.5 mg/kg b.w. (Su *et al.*, 2006). Moreover, hypoglycemic activity of resveratrol was confirmed in normal rats. Chronic administration of resveratrol over a period of 14 days significantly reduced plasma glucose and plasma triglyceride concentrations in both types of diabetic rats compared with resveratrol-untreated

control animals. In addition, resveratrol generally ameliorated diabetic symptoms in STZ-rats: it prevented decrease of b.w., increased glucose uptake by insulin-sensitive tissues (soleus muscle, hepatocytes and adipocytes) and promoted glycogen synthesis by hepatocytes (Su et al., 2006).

Effects on non-alcoholic compounds of beer on insulin release *in vitro*

Effects of Epicatechin   Since insulin deficiency is the main reason for the development of diabetes mellitus various studies on the effect of flavonoids on insulin release were performed (Table 60.8). Hii and Howell (1984) showed that (−)epicatechin increased glucose-induced insulin secretion from isolated islet cells in a dose-dependent manner whereby 1 mM epicatechin produced the greatest response to both 2 and 20 mM glucose. The addition of 0.05 mM epicatechin to culture medium of adult rat islets containing 5.5 or 20 mM glucose caused an increase in DNA synthesis suggesting that the regenerative effect of epicatechin in experimental diabetic rats may be a direct effect on β-cell replication (Hii and Howell, 1984). The stimulatory effect of epicatechin on insulin secretion in pancreatic islet cells seems to be mediated, at least in part, via alterations in Ca^{2+} fluxes (Hii and Howell, 1985) and in cyclic nucleotide metabolism (Ahmad et al., 1991) and depends on the age of the experimental rats (Ahmad et al., 1991).

Other flavonoids have different effects on insulin secretion of islet cells (Hii and Howell, 1985). They were able to stimulate (quercetin), or to reduce (chrysin, naringenin) insulin secretion or they had no significant effect (catechin, flavone). The stimulation occurred only in the presence of 20 mM glucose, suggesting that cell functions are affected by flavonoids only when the cells are fully activated. Quercetin may, at least in part, exert its effect on insulin release via changes in Ca^{2+} uptake (Hii and Howell, 1985).

Effects of Resveratrol   Resveratrol showed no effect on insulin secretion from INS-1 cells (Zhang et al., 2004), whereas incubation of freshly isolated islets from Wistar rats with resveratrol resulted in a significant and concentration-dependent inhibition of glucose-induced insulin secretion (Szkudelski, 2006). Insulin secretion induced by insulin secretagogues other than glucose (leucine and glutamine) was also inhibited by resveratrol, suggesting that glucose transport or metabolism is not crucial for the inhibition of insulin secretion by resveratrol. However, the PKC activator TPA completely suppressed the inhibitory effect of resveratrol on glucose-induced insulin secretion suggesting that the effect of resveratrol on insulin secretion involves the inhibition of PKC activity.

Effects of Anthocyanins and Anthocyanidins   Proanthocyanidins are polyphenols which are present mainly in cacao liquor but also in beer and wine (Madigan et al.,

1994; Stevens et al., 2002). Proanthocyanidins are effective scavengers of radicals which are cleaved to anthocyanidins by oxidative hydrolysis (Cheynier, 1992). Jayaprakasam et al. (2005) studied the effect of 50 μg/ml of various anthocyanins (cyanidin-3-glucoside, delphinidin-3-glucoside, cyanidin-3-galactoside and pelargonidin-3-galactoside) and anthocyanidins (cyanidin, delphinidin, pelargonidin, malvidin and petunidin) on glucose-induced insulin release from INS-1 cells. Both, anthocyanins and anthocyanidins increased glucose-induced insulin secretion whereby the most potent anthocyanin was delphinidin-3-glucoside. The comparison of different anthocyanins indicated that the number of hydroxyl groups at the second ring played an important role in their ability to stimulate insulin secretion. Among the anthocyanidins tested, pelargonidin was the most active one whereas the others did not significantly increase insulin secretion.

Effects of Salicylic Acid   Salicylic acid is the primary immune hormone in plants and is among other things a non-alcoholic constituent of beer. Sodium salicylate is known to be a cyclooxygenase inhibitor. In this regard Walsh and Pek (1984) investigated the effect of sodium salicylate on glucose (16.7 mM)-stimulated insulin secretion from isolated perfused pancreas of SD-rats. Glucose-induced insulin release was slightly but not significantly increased by sodium salicylate. Since sodium salicylate decreased the total prostaglandin 2 release to less than 1% of control, the authors concluded that inhibition of cyclooxygenase did not play any role in glucose-induced insulin release (Walsh and Pek, 1984).

Tran et al. (2002) showed that pretreatment of isolated pancreatic islets with 20 mg/dl sodium salicylate for 45 min prevented the IL-1β-induced decrease in insulin secretion in such a rate that glucose-stimulated insulin secretion was not significantly different from control. Furthermore, treatment of islets with sodium salicylate prevented IL-1β-induced NF-κB activation. Sodium salicylate also inhibits IL-1β-induced increase of COX-2 and EP3 gene expression indicating that its positive effect on pancreatic β-cell function includes inhibition of prostaglandin signaling pathways (Tran et al., 2002). Sodium salicylate (250 μM) prevented also the increased apoptosis rate of human islets cultured on extracellular matrix induced by either IL-1β or high glucose concentration (Zeender et al., 2004). Furthermore, sodium salicylate decreased cAMP release (Metz et al., 1982), and showed effects on ionic fluxes (decrease in Ca^{2+} influx, activation of K^+ channels) and β-cell membrane potential that can partly account for the sodium salicylate-induced changes in pancreatic β-cell function (Fujimoto and Metz, 1984; Chapman and Pattinson, 1987; Drews et al., 1992).

In conclusion, flavonoids showed insulin-like and insulin-stimulatory effects when tested on insulin target tissues *in vitro* and *in vivo* and had protective effects on experimental diabetes possibly by reduction of oxidative stress and/or by conservation of pancreatic β-cell viability.

Table 60.8 Effects of non-alcoholic constituents of beer upon insulin secretion

Compound	Experimental design	Results	Species	Reference
Epicatechin (30 mg/kg b.w. twice a day for 4 days *in vivo*, <1,000 μM *in vitro*)	*In vivo/in vitro* Isolated islets of Langerhans	Increase of glucose-induced insulin secretion via changes in Ca^{2+}-uptake Increase of DNA replication of β-cells	Rat (Wistar)	Hii and Howell (1984, 1985)
Epicatechin (200 μM–1 mM)	*In vitro* Isolated islets of Langerhans	Increase of cAMP content Biological activity depends on age of rats	Rat (Charles Foster)	Ahmad *et al*. (1991)
Quercetin (10 and 100 μM)	*In vitro* Isolated islets of Langerhans	Increase of glucose-induced insulin secretion via changes in Ca^{2+}-uptake	Rat (Wistar)	Hii and Howell (1985)
Resveratrol (1–100 μM)	*In vivo* Isolated islets of Langerhans	Decrease of glucose-, leucine- and glutamine-induced insulin secretion	Rat (Wistar)	Szkudelski (2006)
Catechin (0.1 and 1.0 mM)	*In vitro* Isolated islets of Langerhans	No effect on glucose-induced insulin secretion	Rat (Wistar)	Hii and Howell (1985)
Flavone (100 μM)	*In vitro* Isolated islets of Langerhans	No effect on glucose-induced insulin secretion	Rat (Wistar)	Hii and Howell (1985)
Anthocyanins/anthocyanidins (50 μg/ml)	*In vitro* INS-1 cell line	Increase of glucose-induced insulin secretion	Rat	Jayaprakasam *et al*. (2005)
Sodium salicylate (1.2 mM)	*In vitro* Isolated perfused pancreas	Increase of glucose-induced insulin secretion Decrease of prostaglandin 2 release	Rat (SD)	Walsh and Pek (1984)
Sodium salicylate (1.25 mM)	*In vitro* Isolated islets of Langerhans	Prevention of IL-1β-induced decrease in insulin secretion and NF-κB activation Inhibition of IL-1β-induced COX-2 and EP3 gene expression	Rat (Wistar)	Tran *et al*. (2002)
Sodium salicylate (250 μM)	*In vitro* Isolated islets of Langerhans	Protection of human β-cells against IL-1β- or high glucose-induced apoptosis and loss of function	Human	Zeender *et al*. (2004)
Sodium salicylate (1.25 mM)	*In vitro* Isolated islets of Langerhans	Increase of glucose-induced insulin secretion Inhibition of basal and theophylline-induced cAMP accumulation	Rat (SD)	Metz *et al*. (1982)
Sodium salicylate (0.5–10 mM)	*In vitro* Isolated islets of Langerhans	Increase of glucose-induced insulin release Decrease of Ca^{2+}-efflux Inhibition of glucose-induced electrical activity in β-cells	Mouse (Naval Medical Research Institute)	Drews *et al*. (1992)
Sodium salicylate (1.25 mM)	*In vitro* Isolated neonatal islets of Langerhans	Increase of glucose-induced insulin secretion	Rat (SD)	Fujimoto and Metz (1984)

b.w.: body weight; cAMP: adenosine-3′,5′-cyclic monophosphate; COX: Cyclooxygenase; EP3: prostaglandin E3 receptor; SD: Sprague–Dawley.

Bioavailability of Polyphenols

An important aspect of critical consideration of *in vitro* results and their transferability to *in vivo* models is the fact that non-alcoholic constituents are extensively altered during metabolism so that, in general, the molecular forms reaching the peripheral circulation and tissues are different from those in foods. In the case of polyphenols the resulting metabolites are conjugates which are chemically distinct from their parent compounds, differing in size, polarity and ionic form displaying a different physiologic behavior as compared to the native compounds (for review see Kroon *et al.*, 2004). For example, Day *et al.* (2001) showed that the plasma of volunteers fed fried onions (containing quercetin-4-glucoside and quercetin-3,4-di-glucoside) contained a mixture of 12 discrete quercetin conjugates. The same authors demonstrated *in vitro* that the anti-oxidant activity of quercetin conjugates is, on average, about half of aglycone, and that there are significant variations according to the position of conjugation (Day *et al.*, 2000).

In addition, a recent study showed that, at least for quercetin and quercetin-3-glucoside, the alcohol content of red wine is a major factor responsible for the uptake of polyphenols in mucosal tissue of Wistar rats (Dragoni *et al.*, 2006). Vice versa, Hey and Haslund-Vinding (2006) showed that the type of alcoholic beverage consumed determines the amount of absorbed alcohol. Therefore, it is crucial to use only physiologically relevant compounds and their metabolites at appropriate concentrations in the study of biological responses to non-alcoholic constituents of alcoholic beverages.

Summary Points

- Beer has a stimulatory effect on exocrine pancreas secretion whereas ethanol in concentration found in beer (4% v/v) has no effect.
- Non-alcoholic constituents of beer seem to be responsible for the stimulatory effect of beer. These substances are generated during fermentation.
- Maleic acid and succinic acid, the non-alcoholic compounds of beer and other fermented alcoholic beverages that maximally increase gastric acid output, have alone or in combination with ethanol in concentrations found in beer no effect on basal protein secretion.
- Non-alcoholic constituents of beer other than these dicarboxylic acids must be responsible for the stimulatory action of beer on exocrine pancreas.
- There is accumulating evidence that natural phenolic compounds of plants found in alcoholic beverages exert different effects on the pancreas.
- Particularly *resveratrol* protects the pancreas against prooxidative activity of hydroperoxide and inhibits inflammation. It is anticipated that *resveratrol* could serve as a therapeutic compound in managing acute pancreatitis through different pathways.

- Other non-alcoholic constituents of alcoholic beverages such as quercetin, epicatechin exert also protective effects *in vitro*.
- In *in vitro* studies bioavailability and efficacy of non-alcoholic constituents has to be considered because the compounds are extensively altered *in vivo* after ingestion.
- Alcoholic beverages contain much more non-alcoholic ingredients. The effects of these ingredients are still unknown.
- The effect of the combination of the different substances acting alone on the pancreas has been scarcely or not at all examined.
- Therefore, caution is required in attempting to draw firm conclusions on the effect of alcoholic beverages on defining alcoholic etiology of pancreatic diseases.

Beer and the Liver

Rajaventhan Srirajaskanthan Centre of Gastroenterology, Royal Free Hospital, London, UK
Victor R. Preedy Nutritional Sciences Research Division, School of Biomedical and Health Sciences, Department of Nutrition and Dietetics, King's College London, London, UK

Abstract

This chapter examines the evidence supporting the link between alcohol and liver disease. There is clear evidence that excessive alcohol consumption is associated with liver disease; this is true for all different types of alcoholic beverages. However, it is apparent that some beverages are more harmful, particularly spirits compared to wine or beer, although this is contentious. For example, the threshold value for the increases in serum gamma glutamyl transferase is higher with beer than alcohol in general. The interpretation of this is complicated by the evidence showing that alcoholics change their preference for a particular beverage type as liver disease progresses. Thus, in one study on cirrhotic patients, pre-alcoholics preferred beer as opposed to more ardent spirits in chronic alcoholics. There are other confounding issues. For example, there is a substantial body of evidence to support the notion that wine and beer drinkers have different diets. The importance of this relates to the observation that diet modulates the effect of alcohol. Thus, in patients with cirrhosis there is a positive correlation with beer consumption and ingestion of pork-related products. In contrast, there is a negative correlation between wine consumption and ingestion of pig products in patients with cirrhosis. There is also evidence that beer alters the biochemistry of the liver directly, for example modulating the response to ischemic stress and increasing enzymes involved in detoxification. However, light beers and dark beers have different effects on the liver. Unfortunately, this distinction between beer types has not been investigated in depth in clinical studies and this merits further investigation.

List of Abbreviations

ATP	Adenosine triphosphate
GGT	Gamma glutamyl transferase
RR	Relative risk
SDR	Standard death rate
WHO	World Health Organization

Introduction

The first section of this chapter will focus on the rise in cirrhosis related to alcohol consumption. Thereafter the putative role of beer in liver disease is examined. Confounding factors including the contribution of the diet are also discussed, particularly the differences between beer and wine drinkers. Finally we review the effects of beer on liver biochemistry. This data show that beer has specific effects on the liver, compared to ethanol alone and there are also differences in the responses to consumption of light and dark beers.

Liver Disease Associated with Alcohol Consumption

There is a general consensus regarding the causal role of alcohol and risk of alcoholic liver disease, especially cirrhosis (Preedy and Watson, 2005). Alcohol is thought to be the underlying cause of cirrhosis in 39% of men and 18% of women worldwide (Rehm *et al.*, 2003a). It is accepted that long-term heavy alcohol intake is required to cause cirrhosis; however, there are still questions regarding the minimal threshold above which alcoholic liver disease can occur. It has been shown that a consumption of 20 g of alcohol a day led to a twofold increase in cirrhosis when compared to individuals with no intake (Anderson, 1995). This issue is further complicated by underlying influences of body weight and gender. Studies have shown that ethanol intakes of 3.2 g/kg for males and 2.0 g/kg for females are required to cause cirrhosis (Mezey *et al.*, 1988). Other studies have shown that between 0.5 and 1.0 g/kg of alcohol per day can lead to cirrhosis in females (Norton *et al.*, 1997).

Within the United Kingdom, there has been a steady state of alcohol consumption from the 1980s to 2004, with a total rise of 2.5%. However, interestingly there has been a much higher increase in liver cirrhosis (Figure 61.1).
Figure 61.1 The changing rates of cirrhosis. The falling rates of cirrhosis in France and Italy are associated with a fall in alcohol consumption over the corresponding time period. There is a worrying rise in cirrhosis rates in some countries like Estonia. In the United Kingdom there has been a rise in cirrhosis rates over the last 10 years, this rise is marked and has not correlated with a dramatic rise in alcohol consumption. Note that the data report 5-year intervals except for the last two entry points which depict a 1-year interval. SDR, standard death rate.

A recent paper showed that cirrhosis rates have increased greatly, by 64% in England and Wales over the period from 1987–1991 to 1997–2001 (Leon and McCambridge, 2006). Of particular concern is the observation that cirrhosis rates in Scotland have doubled (increased 104%) over the period from 1987–1991 to 1997–2001. Why this has occurred remains unclear. Some cases of cirrhosis will be related to increased prevalence of hepatitis C which has been on the rise; however, this will only account for a small percentage of the total increase.

Other non-alcohol-related causes of cirrhosis have remained at a stable level over the past decade (Leon and McCambridge, 2006); however, there are increasing numbers of patients being diagnosed with non-alcoholic steatohepatitis and consequent cirrhosis, for example in the United States (Clark, 2006; Farrell and Larter, 2006). It is possible that the number of individuals drinking may have reduced and yet the total consumption has increased. However, studies have shown no significant change in the number of people abstaining from alcohol within the United Kingdom. The pattern of drinking in the United Kingdom has changed over the last few years and this is thought to be partly responsible for the increased rate of cirrhosis. The number of individuals involved in binge drinking and heavy drinking has increased markedly.

There has been a 924% increase in cirrhosis rates in women between ages 25 and 44 years, between 1970 and 1990 (WHO, 2004). This increase is mainly due to an increase in alcohol consumption *per se* women and a change in drinking practices. The effects of alcohol on women occur at different levels of consumption than in

males. Beneficial mortality rates have been noted to occur in women with an intake of 1.5–4.9 g of alcohol a day (i.e. 1–3 drinks per week). However, increased mortality was noted with an intake of 30 g a day (i.e. 18 drinks per week) (Sijbrands *et al.*, 1995).

Beer and Other Beverage Consumption Within Europe

Within Europe there have been clear trends and changes in consumption of alcohol, and more importantly there is a clear difference in drinking patterns within countries in Europe (Figures 61.2 and 61.3). There is evidence supporting that the "binge" drinking culture which is particularly problematic in the United Kingdom is related to the higher incidence of alcohol-related morbidity and mortality (Mukamal *et al.*, 2005). It has been shown that mortality rates are higher in binge beer drinkers when compared to non-binge drinkers, independent of the total alcohol consumption of alcoholic drinks (Kauhanen *et al.*, 1997). Deaths due to injuries and external causes were increased in binge drinkers; however, in addition there were an increased number of deaths secondary to myocardial infarction.

In Sweden there had also been a small rise in alcohol consumption over the last few years, however, there has been a decrease in cirrhosis rates. So the cause of this difference is unclear but it may be related to the type of beverage being consumed or the nature of alcohol consumption (Stokkeland *et al.*, 2006) or other hitherto unexplained factors.

In Central Europe there are a group of previous communist countries including Maldova Romania and Hungary in which rates of cirrhosis have increased even though legal alcohol sales have not increased. In these countries studies looking into the use of privately/homemade alcohol have found that these confer a greater risk of developing cirrhosis (Szucs *et al.*, 2005). Since there is no formal method of assessing total consumption of illegal or homemade ethanol, then only estimates can be made (Leon *et al.*, 1997; Rehm *et al.*, 2003b). Figure 61.4 clearly shows that unrecorded beverage consumption can be very high, and values range from 11% to 53% per region.

Beer in Relation to Wine and Spirits and Their Beneficial Effects

There is clear evidence that moderate intake of alcohol on a regular basis has a protective effect on overall mortality (Thun *et al.*, 1997). Alcohol consumption and mortality show a J-shaped curve, so moderate drinkers have a lower overall mortality than non-drinkers and then as alcohol consumption increases there is a sharp rise in mortality (Thakker, 1998; Gutjahr *et al.*, 2001). There has been a clear trend in many European countries over the last 20 years that although alcohol consumption has increased slightly, there has been an overall decrease in cirrhosis rates (Stokkeland *et al.*, 2006).
Figure 61.2 Consumption of beer within Europe between 1980 and 2003. It can be seen that there is a general trend to harmonization between Europe A countries (e.g. United Kingdom, France and Spain) and Europe B + C countries (e.g. Albania, Estonia and Poland). Note that year-related data sets are episodic, that is, dates are not sequentially patterned. Europe A covers Andorra, Austria, Belgium, Croatia, Czech Republic, Denmark, Finland, France, Germany, Greece, Iceland, Ireland, Israel, Italy, Luxembourg, Malta, Monaco, The Netherlands, Norway, Portugal, San Marino, Slovenia, Spain, Sweden, Switzerland and the United Kingdom. Europe B covers Albania, Armenia, Azerbaijan, Bosnia and Herzegovina, Bulgaria, Georgia, Kyrgyzstan, Poland, Romania, Slovakia, the Former Yugoslav Republic of Macedonia, Tajikistan, Turkmenistan, Turkey, Uzbekistan and Yugoslavia. Europe C covers Belarus, Estonia, Hungary, Kazakhstan, Latvia, Lithuania, Republic of Moldova, Russian Federation and Ukraine. Data from WHO Health Trends in Europe database.
Figure 61.4 The percentage of the total unrecorded alcohol consumption. There is a large proportion of unrecorded alcohol intake from countries in Africa and South-East Asia. The high levels of consumption per drinker relative to the total consumption in some regions are due to the percentage of the population that abstain from alcohol and the number of children under the age of 15 years which contributes to the population. *Source*: Figure adapted from data in Rehm *et al.* (2003a, b).
Figure 61.3 Trends in consumption of beer in specific countries around the world. The fall in beer consumption seen in the United Kingdom has been offset by an increased wine consumption. The reverse has occurred in Italy, where increased beer consumption has been associated with a decrease in wine consumption. Note that year-related data sets are episodic, that is, dates are not sequentially patterned in that a 1992 entry is included. Data sets for India, China and Russia in the period leading up to the 1980s are difficult to distinguish on these graphical scales since they are very low (though increasing in recent years).

There is some evidence to suggest that different alcoholic beverages have different overall protective effects; most research has looked into wine and its apparent cardio-protective effect. Furthermore work has illustrated that wine drinkers have a lower risk of death from all causes (Gronbaek *et al.*, 2000; Klatsky *et al.*, 2003). The cause for this difference in mortality between wine, beer and spirits has been postulated to be related to the possible carcinogenic nitrosamines present in beer (Castegnaro, 1988; Kubacki *et al.*, 1989; Tricker and Preussmann, 1991) and whether wine has additional cardio-protective or anticarcinogenic properties beyond that of ethanol (Gronbaek *et al.*, 2004). There have been some studies looking into mortality and cirrhosis in patients with a predominant intake of beer, wine and spirits. A longitudinal study has been carried out on 30,000 plus individuals looking at their drinking habits and beverage preference (Gronbaek

et al., 2004). Of this cohort of individuals, 282 developed cirrhosis and the study concluded that wine drinkers appeared to be at a lower risk of becoming heavy and excessive drinkers. It also suggested that a person who prefers beer is more likely to become a heavy or excessive drinker (Gronbaek *et al.*, 2004).

In a cohort study of 128,934 patients over a 20-year follow-up, they found that the mortality was lowest in the wine drinking group in comparison to the beer and spirits groups (Klatsky *et al.*, 2003). There was no difference between types of wine consumed. Interestingly from this study they looked at frequency of beer, wine and liquor consumption, it was found that liver cirrhosis was not increased in individuals drinking beer or wine more than once a month; however, it was increased in individuals consuming spirits. However, this result is of questionable significance since there is no clarification of exact frequency of drinking or the quantity of alcohol being consumed (Klatsky *et al.*, 2003).

A Swedish study looking at mortality in relation to liver disease secondary to alcohol concluded that the increase in cirrhosis that occurred in the early 1970s coincided with an increase in sales of spirits; however, though spirit sales declined, the cirrhosis rates remained stable. The sale of beer is currently the same as it was in 1970; however, the sale of wine has increased over this time period, though this increase in wine consumption has not led to the increase in cirrhosis that was seen in the 1970s with the increased sale of beer (Stokkeland *et al.*, 2006).

An examination of different types of alcoholic beverages and their associated mortality has been conducted where the relative risk was set at 1.00 for subjects that never drank wine (Becker *et al.*, 2002). The data showed that individuals who drank between three and five glasses of wine a day have a reduced risk of all cause mortality (0.51 relative risk, RR) (Becker *et al.*, 2002). Though this beneficial effect was not illustrated with beer at the same level of consumption, spirits showed an increased mortality at this consumption. There was a slight significant decrease in relative risk in individuals who drank beer weekly (0.95 RR). However, wine consumption is not associated with a decreased risk of alcoholic cirrhosis in heavy drinkers (Pelletier *et al.*, 2002).

Further analysis of the large Copenhagen study, the results of which were discussed earlier, has been done by the same group. They looked specifically at the risk of alcohol-induced cirrhosis in patients who consume different beverages. The results from their study concluded that increased alcohol consumption was associated with increased alcohol-induced cirrhosis. They found individuals who drank more than 5 drinks a day had a much higher risk (14–20 RR) of developing cirrhosis than those who did not drink or were light drinkers. Within the cohort that drank they found that individuals who had no intake of wine, that is, were predominately drinking spirits or beer, had a higher risk of developing cirrhosis than those who had 30% or 50% of their intake as wine (Gronbaek *et al.*, 2004).

Specific Beverage Intake and Association with Cirrhosis

Prior to the early 1970s there was a clear association between alcohol consumption and the cirrhosis mortality rates; however, as stated earlier with the Swedish study there has been an increase in alcohol consumption and yet a decrease in cirrhosis mortality rates. The cause of this is unclear, some have postulated that it is related to increased alcoholism treatment and the medical management of cirrhosis (Noble *et al.*, 1993; Smart and Mann, 1993). The other cause is thought to be related to a change in the distribution of alcohol consumption and the type of alcohol consumed. The analysis of beverage specific associations with cirrhosis is important because certain beverages may indicate certain drinking patterns associated with cirrhosis. Studies showed wine and spirits to be associated with cirrhosis (Whitlock, 1974; Smith and Burvill, 1985). A time series analysis looking at the United States from 1949 to 1994 also showed spirits to be associated with cirrhosis rates (Roizen *et al.*, 1999).

There is evidence that spirit drinkers are more likely to have a poorer nutritional state which would in turn makes them at increased risk to develop cirrhosis. Using a combined cross-sectional time series method for a group of predominantly beer consuming countries, Kerr *et al.* (2000) concluded that alcohol consumption is the best marker of predicting cirrhosis mortality rates. Spirit consumption was found to have a significant association with cirrhosis mortality. However, there was no association between beer and cirrhosis mortality in this group of countries where beer is the predominant beverage. The cause of this link between spirits and cirrhosis rates is yet to be elucidated; it may be related to the beverage or could be related to habits and associated social state of the individuals who consume spirits. Since heavy drinkers may not have a large income they may drink the cheapest available alcohol, which would be spirits, considering their high alcohol content per bottle, although this would be subjected to geographical variations in availability, drinking culture and taxation (the latter effectively dictating affordability in some countries with high taxes on alcohol). In some countries (say in wine producing regions), individuals who drink exclusively spirits are rare (see below; Hoffmeister *et al.*, 1999).

Threshold Values for Inducing Changes in the Liver

One population-based study from Germany has addressed the issue of whether beers confer a protective effect on the liver by examining drinking histories and serum gamma glutamyl transferase (GGT) activities of 15,000 individuals (Hoffmeister *et al.*, 1999). Of the male and female subjects 50% and 12% were mainly beer drinkers, respectively, whereas wine drinkers comprised 30% and 42% of the male and female population, respectively. Only 2.3% and 1.9% of the male and female subjects, respectively,

were classified as mainly spirit drinkers. As expected, the study showed increasing GGT activities in response to increasing levels in alcohol intake. Effectively, increases in serum GGT provide a surrogate measured of liver damage. However, the threshold value (defined as "the point within a model at which GGT concentrations start to rise after a linear performance before") (Hoffmeister *et al.*, 1999) for beer in men was 42 g/day compared to 26 g/day for unspecified alcohol intake, in general. This suggests that compared to unspecified alcohol ingestion, beer is less damaging. For wine the threshold value for men was 51 g/day but this was not significant (Figure 61.5). For women threshold values for the three beverage categories were much lower and a similar pattern was observed: that is, in the order of unspecified alcohol, beer and wine intakes. However, none of these data for threshold values for women attained statistical significance (Figure 61.5; Hoffmeister *et al.*, 1999).

Changes in Beverage Preference in Disease: From Beer to Spirits

Part of the problem in ascribing a particular beverage type to the development of a specific disease entity relates to the changing pattern of beverage preference. In one study drinking histories were examined prospectively in 70 patients with alcohol-derived cirrhosis (those with cirrhosis of viral origin were excluded) (Campollo *et al.*, 2001). Patients were classified as either (i) pre-alcoholics, (ii) critical alcoholics or (iii) chronic alcoholics in their periods of alcoholism (Figure 61.6). Weekly mean alcohol ingestion rates were 3, 48 and 252 g/day for the three categories, respectively. Subjects in the early pre-alcoholic stage clearly showed a preference for beer whereas those classified as chronic alcoholics had a preference for beverages with higher alcohol contents such as tequila and pure ethanol (Figure 61.6; Campollo *et al.*, 2001).

However, the aforementioned study does not prove that beer is less harmful than more potent alcoholic drinks, and more controlled and detailed studies are required. For example, there are periods of overlapping drinking preference and also diet has a role in the development of liver disease. It is very unusual for individuals to consume a single beverage type. In a study of over 50,000 men and women in Northern California, only 15% of drinkers had a preference for a beverage type. Furthermore just over 20% of those with a particular preference used exclusively their preferred beverage (Klatsky *et al.*, 1990).
Figure 61.5 The relationship between beverage types and threshold levels for increasing serum GGT. Drinking histories and GGT activities were obtained for 15,000 individuals. Threshold values were defined as "the point within a model at which GGT concentrations start to rise after a linear performance before" (Hoffmeister *et al.*, 1999). For beer in men threshold value was 41.6 g/day compared to 26.3 g/day for overall alcohol intake in general. Other threshold values did not attain statistical significance. *, significant; NS, not significant. *Source*: Data adapted from Hoffmeister *et al.* (1999).
Figure 61.6 Changes in beverage preference in liver disease. Changes in beverage preference in a set of 70 alcoholics with cirrhosis were examined prospectively (those with cirrhosis of viral origin were excluded). Those classified as "pre-alcoholic" showed periods of drunkenness of 1–6 times a year and those classified as "critical" were drunk 1–3 times a month. "Chronic alcoholics" were drunk 1 or more times a week. Weekly mean alcohol ingestion rates were 3, 48 and 252 g/day for the three categories, respectively. The early pre-alcoholic stage clearly shows a preference for beer, whereas those classified as chronic alcoholics had a preference for beverages with higher alcohol contents (tequila and pure ethanol). *Source*: Data adapted from Campollo *et al.* (2001).

Changes in drinking preference during the stages of alcohol could reflect the socio-geographical circumstances of the individual: for example, beverage cost is a modulating factor in drinking preference (Cook and Moore, 2002). Supply by family members also increases alcohol consumption in the form of beer, wine and spirits whereas those receiving education about alcohol misuse is an important modulator in reducing the consumption of beer, but not wine and spirits (Lundborg, 2002).

The Compounding Influence of Diet

There is a substantial body of evidence to suggest that diet is an important modulatory of disease and alcohol is no exception. There is a positive correlation between pork consumption and cirrhosis mortality (Nanji and French, 1985; Bode *et al.*, 1998). In an analysis of beer and wine drinking in relation to alcoholic liver disease, it was shown that in patients with alcoholic hepatitis there was a significant correlation between beer consumption and pork intake ($r = 0.43$; $p = 0.004$), offal ($r = 0.36$; $p = 0.016$) and total pig products ($r = 0.47$; $p = 0.001$) (Bode *et al.*, 1998). In subjects with alcoholic cirrhosis, positive correlations were significant for beer consumption vs. offal intake ($r = 0.36$; $p = 0.032$) and beer consumption vs. intake of total pig products ($r = 0.45$; $p = 0.007$) (see also Figure 61.7 where simple regression analysis data are displayed) (Bode *et al.*, 1998). In contrast, only one statistically significant relationship for wine drinkers was observed, namely for total pig products and wine consumption but the data were negatively correlated ($r = -0.37$; $p = 0.027$) (Bode *et al.*, 1998). Overall the data show that there is a correlation between pig product consumption and cirrhosis, and this relationship is modulated by beverage type, particularly with respect to beer (Bode *et al.*, 1998).

More recent studies have investigated the difference between the diet of beer and wine drinkers (Johansen *et al.*, 2006). These studies show that beer drinkers consumed foods that were less healthy than the wine drinkers: that is, beer drinkers ate more butter, carbonated drinks, chips, lamb, margarine or butter, pork, sausages and sugar but less cooking oil, fruit and vegetables, low fat cheese, meat, milk, olives and poultry (Johansen *et al.*, 2006).

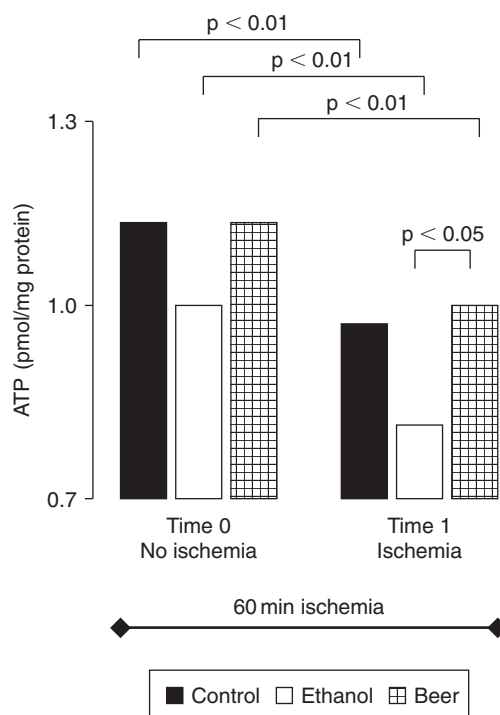
The importance of this putative diet–beer interaction merits concern only if there is sufficient direct evidence to support the contention that the severity of alcoholic liver disease can indeed be modulated by diet. Well-controlled systematic laboratory animal studies have compared the effects of alcohol feeding with different dietary fats in the form of either corn oil, pork lard or beef tallow (Nanji *et al.*, 1989). Surprisingly, features of alcoholic liver disease were not apparent in rats fed beef fat and ethanol. On the other hand, rats fed alcohol with pork fat had minimal to moderate features. Rats fed corn oil diet developed
Figure 61.7 The relationship between beer intake and ingestion of pig products. The data show the relationship between ingestion of beer and pig products in cirrhotic subjects. The line is best-fit obtained using regression analysis from a data set encompassing 35 cirrhotic subjects where p = 0.001. *Source*: Data adapted from Bode *et al.* (1998).


Figure 61.8 The effect of ischemia on liver ATP in control, ethanol- and beer-fed animals. The data show mean ATP levels in livers of rats fed a control diet or a diet containing beer. Ethanol provided 2.5% of total energy intake. In response to ischemia (clamping of the hepatic pedicle for 60 min) liver ATP in liver of control, ethanol- and beer-fed rats decreased. However, ATP levels in beer-fed animals were higher than levels fed the ethanol-containing diet. *Source*: Data adapted from Gasbarrini *et al.* (1998).

the most severe lesions in response to alcohol (Nanji *et al.*, 1989). These results show that the type of fat is instrumental in contributing to the severity of the lesions in alcohol-fed rats possibly via Ito cell activation (Nanji *et al.*, 1989).
Figure 61.9 The effect of different beer types on liver cytochrome b_5 and CYP1A2 apoprotein. Animals were infused for 21 days with a total enteral preparation fed either 3.5% ethanol or an equivalent amount of ethanol in the form of either light (lager) or dark (stout) beer. The data show mean cytochrome b_5 and CYP1A2 apoprotein in livers of control and treated rats which was increased in liver of rats fed the dark beer. *Source*: Data adapted from Hidestrand *et al.* (2005).

Figure 61.10 The effect of different beer types on the liver CYP4A1 apoprotein and mRNA. Animals were infused for 21 days with a total enteral preparation containing either 3.5% ethanol or an equivalent amount of ethanol in the form of either light (lager) or dark (stout) beer. The data show mean CYP4A1 apoprotein and mRNA levels in livers of control and treated rats which was increased in rats fed the dark beer. Note that no data for the CYP4A1 mRNA in the lager group were presented by the authors. *Source*: Data adapted from Hidestrand *et al.* (2005).

Protective Components in Beer: Are They Beneficial to the Liver?

A number of studies have shown that beer contains protective elements on the form of anti-oxidants (Bourne *et al.*, 2000; Denke 2000; Pulido *et al.*, 2003). Thus, it would not be surprising to find that, compared to say pure alcohol, consumption of moderate amounts of beer is protective to the liver. This was addressed in a study where animals were fed a diet containing pure ethanol or the same amount of ethanol in the form of beer (Gasbarrini *et al.*, 1998). In these aforementioned studies the contribution of ethanol to the overall energy ingested was low, that is, at 2.5% of total energy; or 1.1 g ethanol per 100 ml of diet. At the end of 6 weeks there were no significant changes in adenosine triphosphate (ATP), glutathione, or thiobarbituric acid reacting substances in liver of rats fed ethanol or beer compared to controls (Figure 61.8; Gasbarrini *et al.*, 1998).

In response to ischemia (clamping of the hepatic pedicle for 60 min) liver ATP in liver of control, ethanol- and beer-fed rats decreased ($p < 0.01$). However, ATP concentrations in beer-fed animals were higher than levels fed the ethanol-containing diet (Figure 61.8; Gasbarrini *et al.*, 1998). This suggests that protective element within beer may be hepato-protective.

Interestingly there has been some work on the biochemical effects of different beers (i.e. light and dark beers) on enzyme induction (Hidestrand *et al.*, 2005). Dark beer increased cytochrome b_5, CYP1A2 apoprotein, CYP4A1 apoprotein and CYP4A1 mRNA in liver of rats fed (Figures 61.9 and 61.10). In contrast, the activity of and CYP4A was reduced in *in vitro* activity assays which were subsequently ascribe to a blocking mechanism where a component of stout or stout metabolism blocked CYP4A activity (Hidestrand *et al.*, 2005). Thus light and dark beers have different effects on the liver: dark beers appear to have components that interact with hepatic metabolism.

The relevance of this relates to the suggestion that consumption of darker beers is associated with an increased risk of rectal cancer. Roasting grain, used in darker beers and stouts, produces pro-carcinogen compounds such as aromatic amines and polycyclic aromatic hydrocarbons (Hidestrand *et al.*, 2005). These induce P450 CYP1A1 enzymes, which convert the aforementioned pro-carcinogenic compounds to analytes (i.e. carcinogens) that induce cancer. However, contrary evidence also suggests that induction of CYP1A1 imparts a biological advantage as CYP1A1 facilitates a faster clearance rate of toxic compounds (Hidestrand *et al.*, 2005). Unfortunately, there are few or no clinical studies which have investigated the effects of beer types on liver disease.

Conclusion

There is a beneficial effect in morbidity and mortality with low to moderate alcohol consumption in both men and women, this applies to beer, wine and spirits; however, the evidence supporting wine is the strongest and most studied. High consumption of alcohol leads to alcoholic liver disease, and no specific beverage has been shown to be less harmful than any other. However, there is some evidence that the nutritional value of beer and its possible anti-oxidant properties are of additional benefit beyond that of alcohol alone.

Summary Points

- Liver disease is clearly correlated with high levels of alcohol intake; however, the exact threshold required to cause disease is not known. The threshold is different for men and women.
- One population study shows the threshold value (defined as "the point within a model at which GGT concentrations start to rise after a linear performance before") for beer in men is higher than for overall alcohol.
- Subjects in the early pre-alcoholic stage show preference for beer whereas those classified as chronic alcoholics had a preference for beverages with higher alcohol contents.
- It is very unusual for individuals to consume a single beverage type.
- Beer drinkers consumed foods that are less healthy than the wine drinkers.
- Overall the data show that there is a correlation between pig product consumption and cirrhosis, and this relationship is modulated by beverage type, particularly with respect to beer.
- In response to ischemia, liver ATP in liver of control, ethanol- and beer-fed rats decreased. However, ATP concentrations in the liver of beer-fed animals were higher than levels found in the livers of animals fed the ethanol-containing diet, suggestive of hepato-protection by beer.

- Light and dark beers have different effects on the liver: dark beers appear to have components that interact with hepatic metabolism.
- There are few or no clinical studies that have investigated the effects of beer types on liver disease.

Beer Consumption and Homocysteine

D.A. de Luis and R. Aller Institute of Endocrinology and Nutrition, Medicine School and Unit of Investigation, Hospital Rio Hortega, University of Valladolid, Valladolid, Spain

Abstract

Hyperhomocysteinemia has received increasing attention during the past decade and has joined hypertension, obesity, dyslipemia, smoking, and diabetes mellitus as an independent risk factor for cardiovascular disease. Chronic alcohol ingestion has also been associated with increased homocysteine levels. However, drinking beer may have a special health benefit not attributable to other alcohol-containing beverages. Contrary to wine, little is known about potential cardio protective effect of beer whose high content of vitamins B may have beneficial effects on homocysteine metabolism. One of the first studies, which showed an inverse relation between beer consumption and homocysteine levels, were designed by our group in patients with diabetes mellitus type 2. Our study's hypothesis is based on previous studies. Folate, vitamins B12 and B6 were assessed in chronic alcoholics and healthy volunteers. Mean serum homocysteine was twice as high in chronic alcoholics than in non-drinkers. However, beer consumers had significantly lower concentrations of homocysteine compared with drinkers of wine or spirits. Other cross-sectional population study with a high amount of patients has been performed with residents of Pilsen (Czech Republic). By categories of beer intake, subjects with intake of 1l daily or more had significantly lower tHcy and higher folate concentrations than those that reporting lower daily beer intake. However, some studies have not demonstrated this inverse association. The conflicting results may derive in part from confounding by the interaction of alcoholic beverage consumed. Other confounding factors may play a role in all studies, changing direction of the results secondary to bias such as race-ethnicity, genetic background, age, cigarette smoking, and amount of ethanol. As we can see interaction in different factors present in some type of patient could modify the results of previous and further studies in this topic area to relate beer consumption and homocysteine.

List of Abbreviations

BHMT	Betaine–homocysteine methyltranspherase
B12	Vitamin B12
CBS	Cistathionine-β-sintetase
CI	Confidence interval
MAT	Methionine adenosiltranspherase
MTHFR	Methylentetrahydrofolato reductase
OR	Odds ratio
P5P	Pyridoxal 5′-phosphate
SAM	S-adenosyl-methionine
tHcy	Total homocysteine

Introduction

Homocysteine is a non-essential sulfur-containing amino acid formed from the demethylation of an essential amino acid, methionine (Figure 62.1). Epidemiologic studies have

shown that elevated total homocysteine (tHcy) concentration in the blood is an independent risk factor for occlusive vascular diseases. Several possible mechanisms that may underlie the positive association between homocysteine concentration and risk for heart disease include oxidation of cholesterol, toxic effects on endothelial cells, impaired platelet activity, and increased smooth cell proliferation (Figure 62.2).

Coenzymes of folate, vitamin B12, riboflavin, and pyridoxine vitamins are essential in homocysteine metabolism. Homocysteine is either remethylated to methionine or transsulfurated to cysteine. Folate, riboflavin, and vitamin B12 coenzymes are needed for the remethylation pathway, whereas pyridoxine coenzyme is required for the transsulfuration pathway (Figure 62.1). Decreased circulating concentrations of folate, riboflavin, vitamin B12, and pyridoxine are associated with increased serum tHcy concentration. Hyperhomocysteinemia has received increasing attention during the past decade and has joined hypertension, obesity, dyslipemia, smoking, and diabetes mellitus as an independent risk factor for cardiovascular disease. In addition to its main role in cardiovascular disease, hyperhomocysteinemia has been implicated in a variety of other clinical conditions (de Luis et al., 2004) (Table 62.1).

Studies of healthy men and women indicate that certain genetic and acquired determinants can modify total plasma homocysteine. For example, women tend to have lower basal levels than men (Tucker et al., 1996), and neither contraceptives nor hormone replacement therapy seem to significantly alter the levels. The above-mentioned sex differences in homocysteine concentrations persist even in elderly populations. Nevertheless, epidemiological evidence has shown homocysteine levels to be 45% lower in westernized

adult black South Africans than in age-matched white adults, revealing racial genetic differences in homocysteine metabolism too (Vermaak et al., 1991).

Nutrition impacts homocysteine concentrations in both men and women. Those individuals in the lowest quartiles for serum folate and vitamin B12 (nutrients which impact homocysteine metabolism) have significantly higher concentrations of homocysteine, and men in the lowest quartile of serum pyridoxal 5'-phosphate (P5P, the bioactive form of vitamin B6) also have increased homocysteine concentrations (Lusier Cacan et al., 1996).

The objective of this chapter is to review the evidence in the literature in this interesting association between beer consumption and homocysteine levels and the theorical heart protective effect of regular beer consumption.

Drinking Habits and Homocysteine

Coffee consumption and homocysteine

Drinking habits have been associated with homocysteine levels. An association between coffee consumption and the concentration of tHcy in plasma has been reported. A positive dose–response relation between coffee consumption and plasma homocysteine levels was observed. This association was most marked in males and females consuming greater than eight cup of coffee per day (Nygard et al., 1997). Chronic alcohol ingestion has also been associated with increased homocysteine levels (Cravo et al., 1996).

Beer consumption and homocysteine

However, drinking beer may have a special health benefit not attributable to other alcohol-containing beverages, according to results of a Dutch trial published (Van der Gaag et al., 2000). In that report, consumption of red wine and gin raised blood levels of homocysteine, an abovementioned product linked to increased risks of several diseases but most definitively to heart disease. The increase in homocysteine resulting from wine or gin consumption, almost 10%, was statistically significant. Beer drinking,

in contrast, had no detrimental effect on homocysteine levels. Contrary to wine, little is known about potential cardio protective effect of beer whose high content of vitamins B may have beneficial effects on homocysteine metabolism. It was proved that group B vitamins originate in beer from the malted barley. Germination promotes a three to sixfold increase in the level of riboflavin, a doubling of the level of niacin and almost a doubling of the level of folate (Walker and Baxter, 2000). The cyanocobalamin, that is vitamin B12, as a corrinoid compound is known to be produced only in animals and micro-organisms. It originates in beer from yeasts. Therefore, its content in different beers may vary largely according to the brewing process. The largest amount of vitamin B12 is contained in some type of beers, where yeasts are added at the end of the brewery yeasts.

Epidemiological Studies

Results of our group

One of the first studies, which showed an inverse relation between beer consumption and homocysteine levels, realized in this topic area were designed by our group in patients with diabetes mellitus type 2, a model of disease with high cardiovascular risk (de Luis *et al.*, 2003) (Tables 62.2 and 62.3). In previous studies, high homocysteine levels (tHcy) have been associated with an increased risk of cardiovascular events and microangiopathy in diabetic patients (Smulders *et al.*, 1999; Stabler, 1999). This association between homocysteine and chronic complications of diabetes mellitus could be explained with different mechanisms; direct toxic effect on vascular endothelium and an indirect effect on the normal methylation in endothelial cells (Weir and Molloy, 2000). Direct toxic effects of homocysteine could be mediated by damage to vascular endothelial cells, resulting in vascular events, such as microvascular disease and cardiovascular events (Figure 62.2).

Studies in diabetic populations

The relationship between tHcy levels and dietary intake remained controversial. Above-mentioned relation with coffee consumption may be clear. The postprandial as well as long-term effect of methionine intake from proteins has been investigated, and probably only causes a marginal change in the tHcy levels (Stolzenberg *et al.*, 1999). In contrast it is clear that dietary intakes (Allen *et al.*, 1993) or plasma levels of folate and vitamin B12 are inversely related to tHcy concentration. Deficiencies of these vitamins may cause a moderate or even severe hyperhomocysteinemia, and an increased tHcy level is a sensitive marker of disturbed function or both folate and vitamin B12. Few studies have been realized in diabetic populations; it has been reported that ethanol consumption, especially heavy alcohol drinking, increases the risk of atherosclerosis assessed

by intimal medial thickness in type 2 diabetic patients (Cooper *et al.*, 2002). However, the mechanism by which heavy alcohol drinking accelerates the development of atherosclerosis in diabetic patients is not known. Type of alcoholic beverages has been related with different decrease in cardiovascular risk (Wannamethee and Shaper, 1999), perhaps beer with a high concentration of folic acid and vitamin B12 could modify tHcy levels (Jayasinghe, 2000).

In a population of young adults with type 1 diabetes, chronic cigarette smoking seems to adversely affect plasma tHcy levels (Targher *et al.*, 2000). In our population (patients with diabetes mellitus type 2), no correlation was detected with smoking habit and tHcy levels (de Luis *et al.*, 2003). Alcohol consumption has been related with tHcy, a moderate consumption may be associated with reduced tHcy levels, whereas a chronic high alcohol consumption is associated with elevated tHcy (Huktberg *et al.*, 1993; Cravo *et al.*, 1996), possibly via impaired folate or vitamin B12 function (Gloria *et al.*, 1997). An elevation of tHcy was detected in a diabetic population (Sakuta *et al.*, 2005). In this study, the mechanisms by which ethanol consumption leads to tHcy elevation is not clear, a 42% of ethanol consumed from beer, whereas 41% was from spirits (whiskey and shochu). Beer, as above-mentioned, is a rich source of folate (Table 62.4). However, the elevation of tHcy in heavy drinking diabetic subjects may not be ascribed to folate in beer as it is known that tHcy is inversely associated with folate. Thus, these authors postulate that ethanol consumption itself, rather than nutrients in alcoholic beverage, are associated with the observed interaction effect between ethanol consumption and diabetes prevalence for tHcy. This effect between ethanol consumption and diabetes prevalence for tHcy cannot be explained by decrease levels of vitamin B12 (plasma levels of vitamin B12 in this group of diabetic patients was increased). The association is not explained by renal dysfunction or glycaemic control, this interaction may be explained by a direct effect of ethanol consumption of diabetic patients.

In our area (Spain), the composition of locally consumed beers is high in folic acid 4.1 μg/100 ml and 0.14 μg/100 ml of vitamin B12. This inverse relation between beer consumption and tHcy concentrations in our diabetic patients (de Luis *et al.*, 2003) has been described by Mayer

et al. (2001), too. Beer is a beverage with a high ratio of vitamin B12 and folic acid (Table 62.5) and an interaction between nutrients composition of beer and tHcy may explain this association.

Studies in other populations

Our study's hypothesis is based on previous studies. In this previous study (Cravo *et al.*, 1996), folate, vitamins B12, and B6 were assessed in 32 chronic alcoholics and 31 healthy volunteers by measuring blood vitamin concentrations as well as serum homocysteine concentrations. In chronic alcoholics, serum P5P and red blood cell folate concentrations were significantly lower than in the control subjects. Mean serum homocysteine was twice as high in chronic alcoholics than in non-drinkers. However, beer consumers had significantly lower concentrations of homocysteine compared with drinkers of wine or spirits. These results suggest that by interfering with folate or vitamin B6 metabolism, chronic alcohol intake may impair the disposal of homocysteine through the transmethylation or transsulfuration pathways, but beer consumers could improve this fact secondary to a better vitamin dietary intakes from beer (Table 62.6).

Other studies with a high amount of patients have been performed. For example, Mayer *et al.* (2001) designed a cross-sectional population-based survey, residents of Pilsen (Czech Republic). Population series included 292 males and 251 females aged 35–65 years, with a mean age of 53.4 years. Beer intake was associated with blood folate and vitamin B12 concentrations positively and with tHcy concentration negatively. By categories of beer intake, subjects with intake of 1 l daily or more had significantly lower tHcy and higher folate concentrations than those that reporting lower daily beer intake. These authors concluded that moderate beer consumption may help to maintain the tHcy levels in the normal range due to high folate content. These data are in agreement with a previous large epidemiological

Table 62.6 % RDA of folic acid with 500 ml of beer consumption

	Mg of folic acid as RDA	Per 500 ml of beer
Male	200	1.21
Female	200	11.96
Female with lactancy	400	24.16
Female with pregnancy	300	12.5

Note: Percentage of recommended dietary allowance (RDA) with 500 ml of beer consumption in different situations and gender.

study (the Caerphilly cohort), this cohort has suggested a link between beer consumption and lower tHcy concentration in men aged 50–64 years (Ubbink *et al.*, 1998).

Physiology of Beer Consumption and Homocysteine Levels

This association between beer intake and homocysteine levels could have other implications on the endothelial function. In a cross-over study (Zilkens *et al.*, 2003), 16 healthy men either substituted their usual alcohol intake with a 0.9% alcohol beer or maintained their usual alcohol intake during sequential 4-week periods. At the end of each period homocysteine and endothelial function (E-selectin, von Willebrand factor, endothelin-1) were assessed. The subjects reduced their alcohol intake from 72 to 8 g per day. The decrease in alcohol intake resulted in reductions in total cholesterol, high-density lipoprotein cholesterol and homocysteine. There was no effect of alcohol on endothelial function. These authors summarized that reduction in alcohol intake in healthy moderate-to-heavy drinkers did not improve endothelial function but improved cholesterol and homocysteine levels. The improvement of homocysteine levels could be secondary to the decrease of alcohol consumption or to the increase of folate intake with beer (two hypotheses with the same result).

The kinetics of homocysteine metabolism after beer consumption has been studied, too (Beulens *et al.*, 2005). Ten healthy men and nine healthy postmenopausal women were studied in a controlled randomized trial. They consumed beer or alcohol-free beer (men: 4 units/day; women: 3 units/day) during 3 weeks, separated by a 1-week washout. On days 5, 10, 15, and 20 of each period, homocysteine (tHcy) levels were measured. Plasma tHcy and *S*-adenosyl methionine/*S*-adenosyl homocysteine ratio were not affected by consumption of beer or alcohol-free beer. Plasma P5P (microgram/liter) increased during consumption of beer, whereas it decreased during consumption of alcohol-free beer. Changes over time of plasma vitamin B6 (microgram/liter) were similar to changes in plasma pyridoxal-5-phosphate. Serum vitamin B12 was higher after 3 weeks consumption of alcohol-free beer as compared with beer consumption. Changes in serum methionine, cysteine,

cystathionine, and plasma folate were not different between beer-drinking and alcohol-free beer-drinking periods. As we can see the alcohol–homocysteine interaction is complex, perhaps with different effects depending on type of beverage and course of drinking habit (acute or chronic). Although chronic alcohol consumption clearly increases Hcy concentration, the effects of moderate and regular consumption of alcohol are debated in epidemiological studies. This is paradoxical since the coronary protective effect of alcoholic beverages has been established. However, a negative correlation between Hcy and alcoholic beverages has been described in some above-mentioned studies, more especially in beer-drinkers (Schlienger, 2003).

Some authors have explored different drinking patterns with tHcy levels. In a cross-sectional study of 2,126 men have been tested the relationship between preference of alcoholic beverages and atherosclerotic risk factors (tHcy) (Rouillier *et al.*, 2006), using a complicated statistical method (hierarchical clustering method), determined six drinking patterns, "low drinkers," "high quality wines," "beer and cider," "digestives," "local wines," and "table wines," according to the intake of alcoholic beverages. Logistic models estimated the relative risk of abnormal markers in the drinking patterns compared with low drinkers. The results showed that abstainers had high total plasma homocysteine (tHcy), even after full adjustment (odds ratio (OR) = 1.6, 95% confidence interval (CI): 1.0–2.8). Drinkers of high quality wine had low lipoprotein (a) (a new cardiovascular risk factor), high tHcy and high body mass index; beer drinkers had high tHcy and waist circumference. Drinkers of digestives had high triacylglycerol; after adjustment they were at risk of low apolipoprotein A-I. Local wine drinkers were similar to low drinkers. Table wine drinkers had high apolipoprotein B, high triacylglycerol, and high waist-to-hip ratio. These authors suggest that preference of alcoholic beverage could indicate groups at specific risks of atherosclerotic disease with complex relationships between drinking patterns and homocysteine levels and other cardiovascular risk factors.

Other study in this unclear area (Sakuta *et al.*, 2005) analyzed the relation between tHcy and daily ethanol consumption (beer and others) in middle-aged Japanese men (974 subjects). These authors detected that plasma tHcy was positively associated with consumption of whiskey but not with consumption of shochu (Japanese spirits), sake, beer, or wine. ORs of an increase in daily intake of 30 ml ethanol for hyperhomocysteinemia (>14.0 μmol/l) were 2.58 (95% CI, 1.29–5.14) for whiskey, 1.08 (0.78–1.50) for shochu, 0.99 (0.59–1.66) for sake, 0.98 (0.58–1.63) for beer, and 1.70 (0.31–9.50) for wine in a multivariate logistic regression analysis adjusted by other cardiovascular risk factors such as the daily number of cigarettes smoked, physical activity, and vegetable consumption. These data show that local drinking pattern and perhaps genetic background of each ethnicity could modify the relation between beverage type and tHcy levels (Sakuta *et al.*, 2005).

Analysis of Confounding Factors

Drinking habits as a confounding factor

The conflicting results may derive in part from confounding by the interaction of alcoholic beverage consumed or type of beer (Table 62.7). In 1996, a cross-sectional study measuring tHcy and red blood cell folate concentrations was conducted in 1,196 middle-aged women and men from the French Supplementation with Antioxidant Vitamins and Minerals Study. Intakes of alcohol, energy, coffee, and B vitamins were assessed by six separate 24-h dietary records from the previous year. In this study, tHcy concentrations were positively associated with wine intake in the women and with beer intake in the men, without association with the consumption of spirits was observed. The association between beer consumption and tHcy concentrations in the men was modified by the consumption of wine; the association was positive in wine drinkers, whereas an inverse trend was seen in those who drank no wine (Mennen *et al.*, 2003). This data confirm the hypothesis that beer drinking is inversely related to tHcy in persons who drink no wine. It is possible that B-vitamin content of beer (vitamins B6 and B12 and folate) is enough to counteract the tHcy-increasing effect of the alcohol in the beer, but not enough to compensate the effects of the alcohol in wine consumed in the same period. Apparently, the betaine content in wine is too low to counteract the negative effects of alcohol on tHcy. Nevertheless, in the same area the beer and wine consumptions can change with the time as in Spain (Figure 62.3), with a high increase in beer consumption.

Other confounding factors

Other confounding factors may play a role in all studies, changing direction of the results secondary to bias. Some of above-mentioned studies have demonstrated different results due to no control in these factors. For example, an age-dependent increase in tHcy can be related to a decline in renal function, all studies without creatinin as a control factor could misclassify the results of association of beer consumption and tHcy (Norlund, 1998). Furthermore, elevated serum tHcy in older populations can also be attributed to low blood folate concentrations and an increased incidence

of vitamin B12 deficiency resulting from malabsorption of vitamin B12 by the aging gut (Van Asselt *et al.*, 1998).

Race-ethnicity was associated with serum tHcy, too. Among all the race-ethnicity groups examined, non-Hispanic whites had the highest serum tHcy concentrations. Mean serum tHcy concentrations in non-Hispanic whites were 0.8 and 1.1 μmol/l higher than those of non-Hispanic blacks and Mexican-Americans, respectively (Ganji and Kafai, 2006).

Other confounding factor is genetic background. Elevated tHcy can be attributed to point mutation (cytosine to thymidine substitution at nucleotide 677) in the gene that encodes N^5,N^{10}-methylenetetrahydrofolate reductase (MTHFR; EC 1.7.99.5). The 677C→T mutation results in reduced activity of MTHFR; activity is reduced to 34% in *TT* and 71% in *CT* relative to *CC* (Ma *et al.*, 1996). MTHFR is required for the conversion of N^5,N^{10}-methylenetetrahydrofolate to 5-methyltetrahydrofolate, which is a methyl donor for remethylation of homocysteine to methionine. Individuals who are homozygous for the 677C→T mutation have increased circulating tHcy when dietary folate intake is low (Jacques *et al.*, 1996). As far as we have known, all the studies mentioned in our chapter did not have a genetic background analysis to explain relation between beer consumption and tHcy levels.

Several studies have reported a positive association between cigarette smoking and tHcy concentration. A positive association between serum cotinine concentration and serum tHcy has been described. Cotinine is a metabolite of nicotine with a half-life of 20 h. Absorbed nicotine is directly related to the serum cotinine concentration. Serum cotinine is a better indicator of smoking than is self-reported information because individuals tend to underreport cigarette smoking and different persons inhale cigarette smoke differently. Also, serum cotinine reflects passive smoking. Serum cotinine concentration was correlated with number of cigarettes smoked in the NHANES III. By using serum cotinine rather than number of cigarettes smoked as a

Table 62.7 Vitamin composition in different type of beers (per 100 ml) in our area

	Folic acid (μg)	B12 (μg)	B6 (mg)

Figure 62.3 Changes in beer consumption in our country. A decrease of wine consumption and an increase of beer consumption in ml/person/day in Spain is observed above. (National Institute of Statistical Sciences).

measure of smoking, association between biochemical smoke and serum tHcy has been demonstrated (Ganji and Kafai, 2006). The exact mechanism by which cigarette smoking increases tHcy is not known. However, the association between smoking and tHcy can be explained by low concentrations of blood folate, vitamin B12, and vitamin B6 in smokers. Consumption of beverage and smoking habit goes joint in almost all subjects; the lack of analysis of this association can bias the results. As we can see, interaction in different factors present in some type of patient could modify the results of previous and further studies in this topic area.

The last confounding factor could be the amount of ethanol. Status of vitamin B12, B6, and folate is related with tHcy levels, but amount of ethanol disturbs vitamin metabolism. For example, the etiology of folate deficiency in alcoholism can be ascribed to several causes, such as poor absorption, decreased hepatic uptake and retention, and increase urinary excretion. The effects could be due to a direct toxic effect or a poor nutrition status. For example, a low jejunal uptake of labeled folic acid has been detected in malnourished alcoholic patients (Halsted *et al.*, 1971). An inhibition of jejunal folate hydroxilase in miniature pigs fed ethanol for 11 months has been later demonstrated, suggesting that toxic effect of ethanol could also play an important role in the pathogenesis of folate malabsorption. Liver concentrations of vitamin B12 were significantly lower in alcoholics compared with non-drinkers, perhaps alcoholism is associated with impaired retention of cobalamins in tissues, followed by an accumulation of this vitamin in the plasma. Intracellular depletion of vitamin B12 could lead to an intracellular accumulation of N^5-methyltetrahydrofolate because of the irreversible reaction that forms it and because its removal is prevented by impairment of the vitamin B12-dependent methylation of homocysteine. Intracellular accumulation of N^5-methyltetrahydrofolate would ultimately lead to intracellular depletion of folate because N^5-methyltetrahydrofolate is a poor substrate for polyglutamation, which is a vitamin B12-dependent process required for cellular retention of folates.

Chronic alcoholics have low concentrations of vitamin B6, too. This deficiency is due in part to acetaldehyde, a product of ethanol oxidation, which displaces protein-bound vitamin B6, thereby exposing this coenzyme to the action of phosphatases. Vitamin B6 serves as a coenzyme for cystathionine beta synthase and serine transhydroxymethylase; therefore, the hyperhomocysteinemia in alcoholics could be due in part to the impairment of one or both of these enzymes. Serine transhydroxymethylase catalyzes the conversion of tetrahydrofolate into methylenetetrahydrofolate. After reduction, the resulting methylenetetrahydrofolate will then donate its methyl group to homocysteine in a vitamin B12-dependent reaction. Therefore, inhibition of serine transhydroxymethylase could ultimately affect the remethylation of homocysteine.

Summary Points

- Homocysteine is a non-essential sulfur-containing amino acid formed from the demethylation of an essential amino acid, methionine.
- Hyperhomocysteinemia has received increasing attention during the past decade and has joined hypertension, obesity, dyslipemia, smoking, and diabetes mellitus as an independent risk factor for cardiovascular disease.
- Chronic alcohol ingestion has also been associated with increased homocysteine levels. However, drinking beer may have a special health benefit not attributable to other alcohol-containing beverages, with an inverse relation with homocysteine levels.
- The hypothesis of a reduction in Hcy induced by the beer contents has been described in an interventional study. The vitamins contained in beer may well be at the origin of this beneficial effect.
- Subjects with intake of 1l daily or more had significantly lower tHcy and higher folate concentrations than those that reporting lower daily beer intake.

However, some studies have not demonstrated this inverse association. The conflicting results may derive in part from confounding by the interaction of alcoholic beverage consumed. Other confounding factors may play a role in all studies, changing direction of the results secondary to bias such as race-ethnicity, genetic background, age, cigarette smoking, and amount of ethanol.

Alcohol, Beer, and Ischemic Stroke

Kenneth J. Mukamal Division of General Medicine & Primary Care Beth Israel Deaconess Medical Center, Boston, MA, USA

Abstract

In contrast to the consistent associations of beer and alcohol intake with lower risk of coronary heart disease, their corresponding associations with risk of stroke are more complex and nuanced. In recent cohort studies of alcohol use and ischemic stroke, the association is of modest magnitude, with risk ratios approximating 0.8, and the lowest risk among less-than-daily drinkers. Consumers of 3 or more drinks per day clearly have a higher risk of ischemic stroke, and heavy intake may also acutely trigger strokes. In addition, alcohol use is generally associated with a roughly dose-dependent higher risk of hemorrhagic stroke throughout the full range of intake. These same relationships have generally been seen with both beer and other alcoholic beverages, with only limited evidence that beer intake may not confer as low a risk as wine. The mechanisms that underlie the lower risk of ischemic stroke among moderate drinkers have not yet been definitively explored. The higher risks of hypertension and atrial fibrillation that accompany heavy drinking may explain its association with ischemic stroke, and the antithrombotic effects of alcohol may mediate its link with hemorrhagic stroke.

List of Abbreviations

ADH	Alcohol dehydrogenase
CI	Confidence interval
HDL-C	High-density lipoprotein cholesterol
INR	International normalized ratio

Introduction

Although the relationship of alcohol consumption and coronary heart disease has been extensively addressed in literally dozens of studies (Maclure, 1993; Corrao *et al.*, 2000; Di Castelnuovo *et al.*, 2002), alcohol consumption has also been associated with other cardiovascular diseases, including congestive heart failure and peripheral arterial disease (Djousse *et al.*, 2000; Walsh *et al.*, 2002; Bryson *et al.*, 2006). Among the most challenging of the cardiovascular diseases to be

associated with beer and alcohol intake is stroke (or cerebrovascular accident). In fact, Arthur Klatsky, a pioneer in the study of population-wide health effects of alcohol intake including stroke (Klatsky *et al.*, 2001, 2002) has termed this association an "epidemiological labyrinth" (Klatsky, 2005).

In this chapter, we review the difficulties inherent in the study of risk of stroke, current epidemiological evidence regarding the relationships of beer and alcohol intake with risk of ischemic and hemorrhagic stroke, and review both experimental and observational evidence regarding potential mechanisms that may play important roles in the etiology of observed associations.

A primary consideration in understanding the association of alcohol and beer intake with stroke is the extraordinary heterogeneity inherent in the clinical syndrome of stroke (Table 63.1). In general, stroke comprises two main types – ischemic and hemorrhagic – and several subtypes of each (e.g. atherothrombotic, lacunar, embolic, subarachnoid hemorrhage, intracerebral hemorrhage). The pathogeneses of these main and subtypes differ substantially, and hence alcohol appears to have decidedly different associations with each.

Main Text

Alcohol use and ischemic stroke

Ischemic stroke, the most common type in the United States and Europe, is the result of vascular occlusion of an intracerebral artery, whether by local thrombosis or distal embolism. It is noteworthy that two of the strongest chronic risk factors for ischemic stroke are hypertension and atrial fibrillation (AF)(Manolio *et al.*, 1996), both of which have been attributed to heavy drinking (see below). Thus, even though ischemic stroke shares an atherosclerotic and thrombotic etiology with coronary heart disease, the particular factors that most strongly predict ischemic stroke risk appear to be the subset of cardiovascular risk factors exacerbated by heavy alcohol use. As a consequence, it may not be surprising that the apparent inverse association of moderate alcohol intake with ischemic stroke risk occurs at a lower

Table 63.1　Major types and subtypes of stroke

Type	Lay definition	Subtype	Characteristics
Ischemic stroke or cerebral	Blockage in an artery feeding the brain	Atherothrombotic	Narrowing in large outer arteries, often by cholesterol plaques
Infarction		Embolic	Blockage by clots or other material becoming free and lodging downstream in arteries
		Lacunar	Blockage in small, deep arteries of the brain
Hemorrhagic	Bleeding from an artery into or around the brain	Subarachnoid	Leakage from blood vessels coursing outside the brain
		Intracerebral	Disruption of blood vessels inside the brain itself

Note: Stroke, or cerebrovascular accident, occurs when brain tissue dies related to loss of blood providing it with nutrients and oxygen. Two major types, and five major subtypes of these, are commonly recognized, based on their causes and characteristics.

dose of alcohol, and with a lower magnitude of risk reduction, than does the corresponding association with coronary heart disease risk. It is also unsurprising that heavy drinking is consistently associated with higher stroke risk.

For many years, observational studies of the relationship of alcohol consumption and risk of ischemic stroke, in substantial part case-control studies, suggested a relatively strong inverse relationship (Camargo, 1989; Reynolds *et al.*, 2003). For example, in the Nurses' Health Study cohort, Stampfer and colleagues documented 66 incident ischemic strokes and found relative risks of 0.3 (95% confidence interval (CI), 0.1–0.7) for intake of 5–14 g of alcohol per day, and 0.5 (95% CI, 0.2–1.1) for intake of 15 g/day or more (Stampfer *et al.*, 1988). Another excellent early example is a large case-control study from Gill and colleagues in Birmingham, UK, who documented 621 cases of stroke and a similar number of employed controls from the general population (Figure 63.1) (Gill *et al.*, 1991). In this study, the relative risks for ischemic stroke were 0.6 among consumers of 1–90 g/week and 0.7 among consumers of 100–390 g/week; the relative risks for total stroke (of which ischemic strokes comprised over half) were similar.

However, more recent studies have called this magnitude of lower risk into question. In particular, the reliance on case-control methodology in earlier studies may have introduced bias in at least three ways. First, case subjects with stroke may not recall their usual alcohol consumption with the same accuracy that control subjects do, especially if the stroke has influenced their cognitive or expressive functions in even subtle ways. Second, some patients with stroke may cut back on their alcohol intake in the days or weeks prior because of transient ischemic symptoms that herald the onset of the index stroke. Because of biases in reporting, such patients are apt to recall recent intake more adeptly and to report their usual intake as lower than it may have been prior to such symptoms. Finally, case-control studies are
N = 621 stroke cases, 573 controls

Figure 63.1　The relationship of alcohol use and risk of total and ischemic stroke in a case-control study conducted in Birmingham, UK. Consumers of <10 g/week (~1 drink per week) were the reference category (dotted line). The *y*-axis indicates odds ratios (OR) for ischemic (■ bars) and all-cause stroke (□ bars). In this older but very large case-control study, light drinking categories were associated with lower risk of total or ischemic stroke, but heavy drinking (32 drinks per week or more) was associated with a twofold higher risk.

limited to interviewing relatively healthy stroke survivors. If alcohol consumption influences stroke severity in addition to stroke incidence, then the observed effects of alcohol in such studies will be combinations of effects of alcohol on the likelihood of having and of surviving a stroke.

Data from recent cohort studies have indeed suggested that the apparent benefit of moderate intake of alcohol or specific alcoholic beverages may have been overestimated. For example, in a meta-analysis restricted to 19 cohort studies, Reynolds and colleagues found that light drinking

(<12 g/day) was associated with a relative risk of 0.82 (95% CI, 0.73–0.92), but consumption of 12–50 g/day was not associated with lower or higher risk (Reynolds *et al.*, 2003). In contrast, among case-control studies, the relative risk associated with light drinking was 0.80 (95% CI, 0.67–0.97), but intake of 12–24 g/day was associated with a relative risk of 0.65 (95% CI, 0.44–0.96). Thus, light drinking was associated with ~20% lower risk of stroke in all studies, but only case-control studies suggested a lower risk with more moderate drinking.

Ischemic stroke vs. coronary heart disease

As described above, there are some similarities in the pathogenesis of ischemic stroke and coronary heart disease, and they are often grouped together as forms of "cardiovascular disease." Indeed, both coronary heart disease and ischemic stroke are vascular diseases characterized by the acute onset of tissue injury related to blood vessel occlusion superimposed on the chronic process of atherosclerosis within the vessel wall. Standard risk factors for coronary heart disease, such as tobacco smoking, diabetes, and hypertension, are risk factors for ischemic stroke as well.

However, they differ in important ways, and it is worthwhile to contrast the relationships of alcohol use and ischemic stroke with the corresponding relationship of alcohol use and coronary heart disease. Luckily, several large cohort studies have studied both outcomes with relationship to alcohol use, so the effects of alcohol on the two outcomes can be directly contrasted. A recent example is shown in Figure 63.2 that illustrates the differences in these relationships well.

In a cohort study among members of a single Californian insurance plan (Figure 63.2), Klatsky and colleagues reported that alcohol intake has a U-shaped association with hospitalization for ischemic stroke, with relative risks of 0.8 (95% CI, 0.7–1.0) among those who consumed 1 drink monthly-to-daily and 1.0 (95% CI, 0.8–1.2) among those who consumed 3 or more drinks per day (Klatsky *et al.*, 2001). In contrast, these authors found a direct inverse association between alcohol use and risk of coronary heart disease hospitalization, with relative risks of 0.6 among women and 0.7 among men who consumed 3 or more drinks per day (Klatsky *et al.*, 1997).

In results that are strikingly similar, we performed analyses of the Cardiovascular Health Study, a cohort study of 5,888 older adults funded by the National Heart, Lung, and Blood Institute. There was a lower risk of ischemic stroke confined to consumers of 1–6 drinks per week (hazard ratio 0.75; 95% CI, 0.53–1.06) (Mukamal *et al.*, 2005b). Again, there was direct, dose-dependent relationship between alcohol intake and risk of myocardial infarction, with the lowest risk among consumers of 14 or more drinks per week. Interestingly, we also found a U-shaped relationship of alcohol intake with prevalence of white matter lesions (a radiographic finding on MRI images of the
Figure 63.2 The dual relationships of alcohol intake with risks of hospitalization for myocardial infarction (MI) or ischemic stroke among members of the Kaiser Permanente cohort in northern California, US. Abstainers were the reference category. The *y*-axis indicates hazard ratios for myocardial infarction (☐ bars) and ischemic stroke (■ bars). The relationship between alcohol intake and risk of myocardial infarction (or heart attack) was linear, with lower risk with higher intake. In contrast, the relationship with ischemic stroke was U-shaped, with a much smaller benefit and at a smaller level of intake.

brain thought to reflect tiny ischemic lesions) in this population, with the lowest risk among consumers of 1–6 drinks per week (Mukamal *et al.*, 2001).

Ischemic stroke subtypes

Even within the category of ischemic stroke, several subtypes exist. These are sometimes classified as atherothrombotic, lacunar, and embolic. Atherothrombotic strokes reflect large-vessel *in situ* occlusion, most closely related to coronary heart disease. Lacunar infarcts are generally small, deep areas of infarction following small-vessel occlusion of penetrating arteries, while embolic strokes occur when clots or friable atherosclerotic deposits break free from the heart, aorta, or venous system (through right-to-left shunts). Dulli has emphasized how the heterogeneity of ischemic stroke may influence its association with alcohol intake (Dulli, 2002), but relatively few data exist to confirm this hypothesis.

To address this, we examined ischemic stroke risk in the Health Professionals Follow-up Study (Mukamal *et al.*, 2005a). Concordant with previous work, lower risk was restricted to consumers of an average of 0.1–9.9 g/day, and particularly those whose consumption was spread out over 3–4 days per week (hazard ratio 0.56; 95% CI, 0.31–1.02). This finding matches well with the other recent cohort studies described above, all of which point to consumption at least weekly but less than daily as conferring lowest risk. However, stroke subtype appeared to modify risk

substantially. Compared with abstention, the hazard ratios associated with intake of 0.1–9.9 g/day were 0.76 (0.50–1.15) for confirmed thrombotic stroke, but 2.20 (95% CI, 0.84–5.76) for confirmed embolic stroke, much as predicted from their respective pathogeneses. Unfortunately, large numbers of strokes cannot be conclusively categorized using standard classification schemes, and larger studies that attempt to classify ischemic stroke subtypes are needed to confirm these findings.

Adverse effects of heavy drinking on ischemic stroke

Little controversy exists regarding the relationship of heavier drinking with a higher risk of ischemic stroke (Reynolds *et al.*, 2003; Mukamal *et al.*, 2005a). This has long been a feared consequence of heavy drinking and again differs from the relationship of heavy drinking with coronary heart disease, where the existence of a true J-shape is far less clear (Maclure, 1993).

However, there has been some clarification in the magnitude of higher risk associated with heavy drinking over time. As seen in Figure 63.1, Gill and colleagues found that the risks of ischemic and total stroke were increased two- to threefold among the heaviest drinkers relative to abstainers in their case-control study (Gill *et al.*, 1991). In contrast, in our cohort study of health professionals, we found that consumers of 30.0 g or more per day of alcohol had approximately 45% higher risk than did abstainers (Mukamal *et al.*, 2005a). Some of this difference may reflect the greater extremes of drinking behavior found in case-control studies than among participants in long-term cohort studies, but it also likely reflects better control of confounding factors that tend to track with heavy drinking, including poor diet and smoking, and the advantages of a prospective design. In their meta-analysis of older cohort studies, Reynolds and colleagues found a relative risk associated with intake of >60 g/day of 1.98 among case-control studies but 1.63 among cohort studies (Reynolds *et al.*, 2003). Thus, while there is unequivocally higher ischemic stroke associated with heavy drinking, its magnitude is apt to be in the range of 50–60% above abstainers. Nonetheless, because heavy drinkers also tend to have other risk factors, their absolute risk can be sizable indeed.

Another development in this field has been a better understanding of the risk associated with individual episodes of heavy drinking, or binge drinking. Because binge drinking is extremely common even among otherwise moderate drinkers (Naimi *et al.*, 2003), any potential effects of such episodes can have widespread public health import. Hillbom and colleagues have evaluated the risk of recent drinking in a series of studies (Hillbom and Kaste, 1978, 1981, 1983; Hillbom *et al.*, 1995, 1999). In general, even single episodes of intake of 3 or more drinks or drinking to intoxication may acutely and transiently increase risk of ischemic stroke for the ensuing 24 h. For example, in a

study of Finnish younger adults (who are particularly apt to consume alcohol in binges), ischemic stroke patients were five- to sevenfold more likely to report heavy alcohol use in the preceding 24 h than were other hospitalized young adults (Figure 63.3).

Specific relationships of beer and other alcohol beverages with ischemic stroke

There has long been interest in whether specific non-alcoholic constituents of alcoholic beverages influence cardiovascular risk, with the greatest attention paid to polyphenolic constituents of red wine (Waddington *et al.*, 2004). A substantial amount of basic research has investigated the potentially protective properties of the diverse constituents of such beverages, reviewed elsewhere in this volume. In observational studies, this has generally taken the form of analyses examining the relative associations of beer, wine, and spirits with cardiovascular risk. Interestingly, for coronary heart disease, this approach has not necessarily shown a particular benefit for any given beverage (Rimm *et al.*, 1996; Cleophas, 1999), perhaps because the effects of ethanol itself make it difficult to detect the smaller effects of other components that are present in smaller concentrations. For stroke, this issue remains under active investigation.

We have investigated the relative effects of different beverage types with risk of ischemic stroke in two cohort studies.
N = 75 stroke cases, 133 controls

Figure 63.3 The relationships of alcohol intake in the preceding 24 h with risk of hospitalization for ischemic stroke among adults aged 16–40 in Helsinki, Finland. Controls were hospitalized for other acute illnesses. Abstainers were the reference category (dotted line). The *y*-axis indicates odds ratios for men (■ bars) and women (▢ bars). Patients hospitalized with ischemic stroke with severalfold more likely to report alcohol intake of more than 3 drinks in the last day than were other patients, suggesting that heavy alcohol intake can acute precipitate (or trigger) ischemic stroke.

In the Health Professionals Follow-up Study (Figure 63.4) (Mukamal *et al.*, 2005a), in which the beverages consumed in greatest quantity are beer and spirits (as is typical for American men), we found a significant difference between red wine and other beverages in their relationships with ischemic stroke risk. For beer, there was a relatively direct relationship, with a slight increase in risk with greater exposure. This contrasted with the dose-dependent lower risk associated with red wine intake.

We employed a similar approach in the Cardiovascular Health Study (Figure 63.5), where the relative levels of alcohol intake were considerably lower (as expected from the older age of participants) (Mukamal *et al.*, 2005b). In this case, wine intake (including both red and white) was again associated with a dose-dependent lower ischemic stroke risk. However, beer intake too was associated with significantly lower risk, particularly at intake of 1–6 drinks per week (hazard ratio 0.57).

Other cohort studies have tended to support the notion that beer intake is unlikely to confer lower risk of ischemic stroke than do other alcoholic beverages. In the Kaiser Permanente cohort, there was a slightly higher risk associated only with liquor intake after adjustment for total alcohol consumption, with no independent effects of wine or beer intake (Klatsky *et al.*, 2001). In the Copenhagen City Heart Study, another large prospective cohort study comprising over 13,000 adults, beer intake was not associated with risk of stroke, including the category of ischemic/other strokes, while wine intake between weekly and daily was associated with lowest risk (hazard ratio 0.59); liquor intake was also unassociated with risk (Truelsen *et al.*, 1998). However, wine intake in Denmark is strongly associated with favorable dietary and other lifestyle characteristics (Tjonneland *et al.*, 1999; Johansen *et al.*, 2006), making it likely that the lower risk observed for wine intake is at least partly the product of other factors.

In sum, at the present time, there is suggestive but clearly not definitive evidence that wine intake might be more strongly associated with lower ischemic stroke risk than other beverages, while beer intake tends to mirror the overall effects of alcohol intake.

Hemorrhagic stroke

Although not as common in Western countries, hemorrhagic stroke is a common stroke type in Asia, where most studies have been performed, and comprises subarachnoid and intracerebral subtypes. Hemorrhagic and ischemic stroke share some common risk factors – most notably hypertension – but also some important differences. Most important of these is thrombotic tendency, for antithrombotic medications tend to decrease risk of ischemic stroke but increase risk for hemorrhagic stroke. It has generally been assumed to be a dose-dependent increase in risk of
p = 0.01 for red wine vs. beer or liquor
N = 38,156 men free of cardiovascular disease

Figure 63.4 The relationships of alcoholic beverage intake with risk of incident ischemic stroke among men who were free of cardiovascular disease in the Health Professionals Follow-up Study. Abstainers from each beverage were the reference category. The y-axis indicates hazard ratios for red wine (■ bars), white wine (□ bars), beer (■ bars), and spirits (□ bars). Pairwise tests of the linear trends were significant for the comparisons of red wine with beer and liquor, suggesting that red wine (which appears to be associated with a lower risk of ischemic stroke in a dose-dependent manner) differs significantly from beer and spirits (where little relationship at all is seen).
N = 4,410 older adults free of cardiovascular disease

Figure 63.5 The relationships of alcoholic beverage intake with risk of incident ischemic stroke among older adults who were free of cardiovascular disease in the Cardiovascular Health Study. Abstainers from each beverage were the reference category. The y-axis indicates hazard ratios for wine (■ bars), beer (■ bars), and liquor (□ bars). In this population of older adults, both beer and wine were associated with lower risk of ischemic stroke, particularly with intake of 1–7 drinks per week. The differences among beverages in the highest category appear to reflect residual differences in how much of each beverage was actually consumed.

hemorrhagic stroke associated with alcohol use (Camargo, 1996). In a meta-analysis of case-control studies of intracerebral hemorrhage, Ariesen found summary odds ratios of 2.05 (95% CI, 1.35–3.11) for intake ≤56 g/day, and 4.11 (95% CI, 2.54–6.65) for intake >56 g/day (Ariesen *et al.*, 2003). However, in a comparable meta-analysis of cohort studies of subarachnoid hemorrhage, Feigin found an increased risk restricted to heavier intake (>150 g/week), with a summary relative risk of 2.1 (95% CI, 1.5–2.8) (Feigin *et al.*, 2005). In one of the largest studies to date, Klatsky and his colleagues at Kaiser Permanente found higher risk associated only with intake of 6 or more drinks per day (Klatsky *et al.*, 2002).

The contrasting associations of light-to-moderate drinking with ischemic and hemorrhagic stroke are largely consistent with Renaud's hypothesis that moderate drinking mediates its effects, at least in part, through activity on platelets and prothrombotic factors (Renaud and De Lorgeril, 1992). If this hypothesis is correct, light drinking would be expected to decrease risk of thrombotic events, such as myocardial infarction and ischemic stroke, but increase risk of bleeding in the brain and potentially other sites (Kaufman *et al.*, 1999), much as has been observed. An outstanding example of these contrasting associations was reported by Iso and colleagues in the Japan Public Health Center-based Prospective Study on Cancer and Cardiovascular Disease (Iso *et al.*, 2004), a sample of nearly 20,000 men with approximately equal numbers of hemorrhagic and ischemic strokes. Compared with occasional drinking, there was a clear dose-dependent increase in risk of hemorrhagic stroke with heavier alcohol use, with a 56–83% increase in risk even among consumers of 1–149 g/week. For ischemic stroke, the relationship was U-shaped, with lower risk among the lightest drinkers but 12% higher risk among the heaviest drinkers.

To date, there has not been extensive information available on whether beer differs from other alcoholic beverages in its association with hemorrhagic stroke. Klatsky and colleagues did not find evidence that beverage type was independently related to risk in their prospective cohort study, but this remains an important area of investigation, especially because of early evidence that homocysteine levels (which are beneficially lowered by beer) may be a risk factor for hemorrhagic stroke (Li *et al.*, 2003; Van Guelpen *et al.*, 2005).

Risk factors for stroke

Understanding the relationships of beer and alcohol intake with various risk factors for stroke may provide insight into the relatively complex set of associations observed in epidemiological studies. Four of the most prominent of these, based on their links to either stroke risk or beverage intake, are high-density lipoprotein cholesterol (for atherothrombotic stroke), atrial fibrillation (for embolic stroke), hypertension (for all types of ischemic stroke), and subclinical carotid atherosclerosis (for atherothrombotic stroke) (Table 63.2). We briefly review the effects of alcohol and beer on these risk factors – and how they are apt to influence ischemic stroke risk – below.

Atrial fibrillation

Atrial fibrillation is the most common chronic arrhythmia. It leads to ischemic stroke by disrupting the co-ordinated atrial contraction that characterizes atrial systole, leading to stasis and thrombus formation within the atrium. Risk of ischemic stroke is elevated as much as four- to fivefold among individuals with AF (Kannel *et al.*, 1998). Physicians have long recognized that binge drinking can trigger the onset of AF, sometimes termed the "holiday heart" syndrome (Greenspon and Schaal, 1983; Rich *et al.*, 1985). In a variety of observational studies, most analyses have suggested that only heavy drinking is clearly associated with higher risk (i.e. a threshold exists) (Rich *et al.*, 1985; Koskinen *et al.*, 1987; Ruigomez *et al.*, 2002; Djousse *et al.*, 2004; Mukamal *et al.*, 2005c). The largest such study to date suggested that AF risk does not increase until a chronic level of intake of at least 28 and probably 35 drinks per week (Mukamal *et al.*, 2005c). In this study, beer intake tended to be associated with higher risk only at the highest levels of intake, with a pattern similar to intake of spirits and to overall alcohol intake. Although other studies have suggested that risk may also be higher even among more moderate alcohol drinkers (Frost and Vestergaard, 2004), whether this reflects an effect of moderate drinking or occasional binge drinking among moderate drinkers is uncertain.

A related issue is whether alcohol can be consumed safely among adults with chronic AF, most of whom should be taking warfarin or similar anticoagulants. Although guidelines have often explicitly recommended that individuals taking

Table 63.2 Qualitative associations of alcohol and beer intake with ischemic stroke and four of its major risk factors

	Light–moderate alcohol intake	Heavier alcohol intake	Evidence that beer and alcohol differ?
Ischemic stroke	↑	↑↑	±
HDL-cholesterol	↑↑	↑↑	No
Atrial fibrillation	↔	↑↑	No
Blood pressure	↔	↑↑	No
Carotid atherosclerosis	↓	↑↑	No

Notes: Different amounts of beer and alcohol intake have varying effects on stroke and its major risk factors. Beer generally appears to be similar to other alcoholic beverages. Light–moderate drinking (less than 2 drinks daily for younger men, 1 drink daily for women and men over 65) often is linked to benefits in risk for ischemic stroke, good cholesterol (HDL), and atherosclerosis in the carotid arteries. Heavy drinking (3 drinks or more per day) is linked to detrimental effects on ischemic stroke risk and most of its risk factors.

warfarin abstain entirely (Weathermon and Crabb, 1999), the limited available data suggest that moderate drinkers do not have a higher risk of excessive anticoagulation than do abstainers, although binge drinkers may (Fihn *et al.*, 1993; Hylek *et al.*, 1998). In fact, in the Post CABG Trial, where participants were randomly assigned to low-dose warfarin or placebo following coronary artery bypass graft surgery, we found no evidence that alcohol intake adversely influenced average levels of the International Normalized Ratio (INR), a measure of anticoagulation, and the heaviest drinkers actually had the lowest risk of excessive INR values (Mukamal *et al.*, 2006).

Hypertension

Hypertension is, on a population basis, the most important risk factor for stroke. Almost 80% of individuals with a first stroke have hypertension (American Heart Association, 2007), and it increases the risk of both ischemic and hemorrhagic strokes. Approximately one in three US adults has hypertension, and it increases stroke risk as much as fourfold.

Somewhat similar to atrial fibrillation, alcohol intake has chiefly been associated with elevated blood pressure in a threshold manner, with higher risk predominately at levels of intake of 3 or more drinks per day or more (Klatsky, 1996). Lower levels of intake have even been associated with lower risk of hypertension in some cohort studies (Witteman *et al.*, 1990; Thadhani *et al.*, 2002), although this has not been universal (Trevisan *et al.*, 1987). The mechanism for the increase in blood pressure is uncertain, but a biphasic effect on blood pressure has been noted in experimental studies of alcohol administration (Abe *et al.*, 1994; Rosito *et al.*, 1999), with both higher and lower blood pressure noted depending on when measurement occurs. Randomized trials to lower blood pressure by encouraging reduction in alcohol intake have been encouraging (Puddey *et al.*, 1987, 1992), but the large PATHS trial found little effect of cognitive-behavioral alcohol reduction intervention program on blood pressure (Cushman *et al.*, 1998). Beer is not thought to differ from other alcoholic beverages in its effect on blood pressure (Stranges *et al.*, 2004).

A few cohort studies have addressed the effects of alcohol consumption among individuals with established hypertension. These have generally supported an inverse association with at least cardiovascular disease mortality (Palmer *et al.*, 1995; Malinski *et al.*, 2004), similar to that seen in the general population. How alcohol intake influences stroke risk among hypertensive individuals has not yet been conclusively studied.

High-density lipoprotein cholesterol

High-density lipoprotein cholesterol (HDL-C), commonly thought of as the "good cholesterol," is a key component of reverse cholesterol transport, the process of returning cholesterol to the liver for excretion in bile. HDL-C levels are strongly inversely associated with risks of both coronary heart disease and stroke (Boden, 2000; Sacco *et al.*, 2001).

Alcohol intake unequivocally increases levels of HDL-C. In a large meta-analysis of randomized trials of alcohol administration, there was a dose-dependent increase in HDL-C with greater alcohol intake, with a roughly 4 g/dl increase with consumption of 30 g/day (Rimm *et al.*, 1999). In observational studies, alcohol consumption is the lifestyle factor most closely correlated with HDL-C levels, with correlation coefficients of 0.2–0.4 in most studies (Giovannucci *et al.*, 1991; Ellison *et al.*, 2004). The effect may be non-linear at high doses of alcohol, where direct toxic effects of alcohol upon the liver may influence HDL production (Johansen *et al.*, 2003). Beer appears to have similar effects to other alcoholic beverages, based both on the similarity in its effect in the meta-analysis and based on a rigorous randomized trial that compared multiple alcoholic beverages using a Latin square design (Rimm *et al.*, 1999; van der Gaag *et al.*, 2001).

Carotid atherosclerosis

Unsurprisingly, atherosclerosis of the carotid arteries (typically measured by ultrasound) is a strong risk factor for stroke (O'Leary *et al.*, 1999; Lorenz *et al.*, 2006), presumably on the basis of its eventual role in vascular stenosis and occlusion and because it reflects atherosclerosis developing in other cerebral beds as well. In fact, it appears to predict stroke well even after accounting for traditional atherosclerotic risk factors (O'Leary *et al.*, 1999) and hence is particularly a key factor to evaluate in understanding the role of alcohol consumption in the occurrence of ischemic stroke.

A large number of studies have evaluated the cross-sectional or longitudinal association of alcohol intake with carotid intima-media thickness, a widely used measure of atherosclerosis in the common and internal carotid arteries (Demirovic *et al.*, 1993; Kiechl *et al.*, 1998; Kauhanen *et al.*, 1999; Bo *et al.*, 2001; Djousse *et al.*, 2002; Jerrard-Dunne *et al.*, 2003; Mukamal *et al.*, 2003; Zureik *et al.*, 2004; Schminke *et al.*, 2005). These have generally (Kiechl *et al.*, 1998; Bo *et al.*, 2001; Mukamal *et al.*, 2003), but clearly not universally (Demirovic *et al.*, 1993; Djousse *et al.*, 2002; Zureik *et al.*, 2004), yielded J-shaped associations, with the least atherosclerosis among light drinkers and the most among the heaviest drinkers, although it is often difficult to determine how well the associations with heavy drinking are controlled for the adverse lifestyle features of heavy drinkers. In those studies that have identified less carotid atherosclerosis among light drinkers, beer intake has generally been at least as strongly associated with lower intima-media thickness as other beverages (Figure 63.6) (Kiechl *et al.*, 1998; Mukamal *et al.*, 2003).
N = 4,247 older adults free of cardiovascular disease

Figure 63.6 The relationships of alcoholic beverage intake with carotid intima-media thickness among older adults who were free of cardiovascular disease in the Cardiovascular Health Study. Abstainers from each beverage were the reference category. The *y*-axis indicates differences in atherosclerosis of the carotid artery (based on intima-media thickness) associated with intake of wine (▨ bars), beer (■ bars), and liquor (☐ bars), compared with abstention from each beverage. Beer intake at 1–7 drinks per week was associated with the greatest decrease in atherosclerosis.

Genetic vulnerability to alcohol-related stroke

There is currently limited information on the degree to which specific variation in specific genes influences the relationship of alcohol intake with risk of stroke. The few studies that have evaluated specific variants provide some intriguing insights into pathways by which alcohol use may influence risk of stroke, both positively and negatively.

An important influence on the metabolism of ethanol from beer and other alcoholic beverages is genetic variation in the alcohol dehydrogenase (ADH) set of genes, located on chromosome 4q. One of these genes, ADH1C, encodes a Class I ADH enzyme product that has a common functional variant in Caucasian populations. Although this variant appears to influence risk of coronary heart disease among consumers of ethanol (Hines *et al.*, 2001; Djousse *et al.*, 2005), a nested case-control study of the Physicians' Health Study cohort found no such interaction with risk of total or ischemic stroke (Zee *et al.*, 2004), even though moderate alcohol intake was associated with a lower risk of stroke in this cohort (Berger *et al.*, 1999).

A gene of increasing interest for studies of alcohol use and chronic disease is apoE. The apoE lipoprotein is a key component of HDL particles and has a strong link to Alzheimer's disease. The carriers of the apoE4 allele of this gene appear to have an attenuated response to alcohol intake in their levels of HDL-C (Djousse *et al.*, 2002) and inflammatory markers (Mukamal *et al.*, 2004). Most importantly, we found that this gene appears to modify the

association of alcohol use with risk of ischemic stroke in the Cardiovascular Health Study (Mukamal *et al.*, 2005b). Among apoE4-negative participants, there was a typical U-shaped relationship, with lower risk among consumers of 1–6 drinks per week and similar risk among abstainers and the heaviest drinkers. In contrast, among apoE4 carriers, no level of intake was associated with lower risk, and consumers of 7 or more drinks per week had a significant twofold increase in risk relative to abstainers.

Finally, a gene–alcohol interaction has been noted in the Carotid Atherosclerosis Progression Study, where a variant in the interleukin-6 gene appears to modify the association of alcohol use with carotid atherosclerosis and interleukin-6 levels (Jerrard-Dunne *et al.*, 2003). This variant, located in the promoter, has been associated with interleukin-6 levels itself (Jenny *et al.*, 2002). In this study, alcohol intake had J-shaped relationships with both interleukin-6 levels and with carotid intima-media thickness, and the relationship with atherosclerosis was quite consistent across genotypes through intake of 30 g/day. Above this level, however, CC homozygotes had increased intima-media thickness relative to abstainers, while GG homozygotes had decreased thickness. Given the key role of interleukin-6 in systemic inflammation, this finding implicates inflammation as yet another potential mechanism by which alcohol may influence ischemic stroke risk.

The caffeinol hypothesis

A particularly novel application of alcohol to ischemic stroke in an entirely different context has been proposed by Aronowski and colleagues (Strong *et al.*, 2000; Aronowski *et al.*, 2003; Piriyawat *et al.*, 2003). Drawing on the concept of ischemic neuroprotection, in which neuronal death can be averted even after a transient ischemic insult by administration of neuroprotective agents, this group developed and tested a novel combination of caffeine and ethanol dubbed "caffeinol." Neither ethanol nor caffeine alone induced neuroprotection (Strong *et al.*, 2000). However, caffeinol at a dose of only 0.2 mg/kg of ethanol consistently reduced the volume of infarcted cerebral cortex when administered after occlusion of the common carotid and middle cerebral arteries. Daily ethanol administration prior to the ischemic insult produced tolerance to this neuroprotective effect (Aronowski *et al.*, 2003). A second group has confirmed this finding of neuroprotection (Belayev *et al.*, 2004), but a third group using a rabbit model found that it increased the incidence of intracerebral hemorrhage associated with administration of thrombolytic therapy (Lapchak *et al.*, 2004). Pilot studies to evaluate this combination in the treatment of acute stroke patients are underway, although early experience suggests that considerable vigilance may be necessary to maintain blood levels of ethanol in a relatively narrow therapeutic window (Piriyawat *et al.*, 2003).

Conclusions

In summary, there are complex relationships of alcohol use with different types of stroke, in part reflecting their heterogeneity. To date, evidence generally suggests a J-shaped relationship of alcohol use with ischemic stroke, with lower risk limited to consumers of approximately 1 drink every other day and clearly higher risk among consumers of 3 or more drinks per day, an association quite different from that seen for coronary heart disease. The risk of hemorrhagic stroke appears to rise in a graded fashion with greater alcohol intake. Beer intake seems to mirror the overall associations of alcohol use with these outcomes. The risks of hypertension and atrial fibrillation, two key risk factors for ischemic stroke, seem to be related primarily to alcohol use of 3 drinks per day or higher, while beer and other alcoholic beverages raise levels of HDL-C even at moderate doses. Ongoing work is needed to identify how particular genetic variants may modify these associations, and whether alcohol can also be harnessed as a neuroprotective agent to modify the potentially devastating outcomes of ischemic stroke.

Summary Points

- Alcohol intake of approximately 1 drink every other day is associated with a roughly 20% lower risk of ischemic stroke than abstention.
- Regular intake of 3 drinks per day or more increases risk of ischemic stroke by at least 45–50%, and binge drinking also acutely increases stroke risk.
- Beer appears to be similar to other alcoholic beverages in these associations.
- Alcohol intake increases risk of hemorrhagic stroke in a dose-dependent manner.
- Beer and alcohol intake increase risk of atrial fibrillation, a key stroke risk factor, but only at high levels of chronic consumption.
- Beer and alcohol intake increase risk of high blood pressure at levels of 3 drinks per day or more.
- Beer and alcohol intake increase levels of HDL-C, which may lower risk of ischemic stroke.
- The apoE4 allele, which increases risk of Alzheimer's disease, may also blunt the benefits and increase the risks of alcohol consumption.
- Alcohol combined with caffeine is currently being tested as a protective agent among patients who sustain acute ischemic strokes; in animals, this combination reduces stroke severity considerably.

Beer: Is It Alcohol, Antioxidants, or Both?
Animal Models of Atherosclerosis

Joe A. Vinson Department of Chemistry, Loyola Hall, University of Scranton, Scranton, PA, USA

Abstract

Beer is the most consumed alcoholic beverage in the world and also historically the oldest. There are several possible active ingredients, especially alcohol which has been amply demonstrated by epidemiological studies. In addition the polyphenol antioxidants may be bioactive. Beer contains moderate amounts of these antioxidants but the large per capita consumption of beer makes it a substantial contributor to beverage antioxidants. In the United States it ranks third and ahead of wine which is in fourth place. Ethanol may be an antioxidant depending on the model. The polyphenols are always antioxidants and are active at sub-micromolar levels in an *in vitro* model of atherosclerosis, the oxidation of lower-density lipoproteins. Beer polyphenols also bind to these proteins potentially protecting them from *in vivo* oxidation and slowing down the atherosclerosis process. Short-term animal studies have shown that beer without alcohol is indeed an *in vivo* antioxidant and that beer is equally as protective as red wine. Beer countered the oxidative stress of alcohol and was an antioxidant in several rat models. Animal atherosclerosis studies with beer gave mixed results. In a hamster model at equal dilution of red wine and beer, beer proved to be an equivalent inhibitor of atherosclerosis by hypocholesterolemic and/or antioxidant mechanisms. Lager beer at a human-equivalent dose in this model was a significant anti-atherosclerotic agent. In a genetic mouse model with a lipid profile similar to humans, beer without alcohol was an effective anti-atherosclerotic agent but beer combined with alcohol was more effective. Both types of beer influenced protein expression that could beneficially impact atherosclerosis. Alcohol enhances the protective effect of beer in this model. Long-term human studies are needed to compare beer with and without alcohol and thus determine the bioactive ingredient(s).

List of Abbreviations

HDL	High-density lipoprotein
LDL	Low-density lipoprotein
VLDL	Very low-density lipoprotein
HPLC	High-performance liquid chromatography
CVD	Cardiovascular disease
AAPH	2,2′-Azobis(2-amidinopropane)
SR-B1	Scavenger receptor-B1
LRP	LDL receptor-related protein
LCAT	Lecithin–cholesterol acyltransferase
ABCA1	ATP-binding cassette transporter A1
SREBP2	Sterol-regulatory element binding protein 2

Introduction

Beer is man's oldest fermented beverage made from malt and hops and produced in the Mesopotamia region around 4000 BC (Kondo, 2004) and is the most popular alcoholic beverage in the world today. In the United States beer is the most consumed alcoholic beverage (224 ml/day) and is far ahead of wine (24 ml/day) and distilled spirits (15 ml/day). This is 2004 availability data, not strictly consumption, from the US government (Economic Research Service, 2005). In most laymen's opinion, wine, especially red wine, would be considered the healthiest alcoholic beverage to consume because of the French paradox. This same view would be taken by many medical doctors and scientists. There have been several systematic reviews in the last 10 years comparing beer, wine, and spirits with respect to cardiovascular disease (CVD) with differing results. For instance Di Castelnuovo *et al.* (2002) found a stronger inverse association with wine (32% reduction) compared to beer (22%). An older review gave the same high marks for both beer and wine whose benefits were equal (Rimm *et al.*, 1996). The most recent meta-analysis of men with follow-up since 1986 found moderate alcohol consumption of either beer, wine, or spirits equally reduced risk of CVD (Mukamal *et al.*, 2006). However, all of these epidemiological studies are subject to confounding variables such as lifestyle which is typically healthier for wine drinkers as opposed to those who drink beer. The human trials

are flawed as they are short-term studies (usually last only 4 weeks) and typically use young subjects (20–40 years) and have not provided conclusive evidence to the question of which alcoholic beverage, wine or beer, is better for the heart (Rimm *et al.*, 2002) and whether alcohol is a necessary ingredient for CVD protection.

This review will include some information about the ethanol and the antioxidants in wine and beer and their relative antioxidant effectiveness. The oxidative theory of atherosclerosis will be explored and the *in vitro* and *ex vivo* experimental data relating beer and wine will be discussed. We have attempted to separate the antioxidants of beer from the alcohol in beer in this chapter. It will also cover animal studies which have involved beer and especially those which have compared wine and beer.

In Vitro Antioxidants

Polyphenol antioxidants in fruits, vegetables, and whole grains may well be the active ingredients responsible for the CV benefits of these foods and the beverages made from them including beer and wine. These compounds may act as antioxidants *in vivo* but also have the possibility of being cardio-protective by other mechanisms (Manach *et al.*, 2005a, b) such as endothelial function and hemostasis. The oxidative theory of atherosclerosis, first promulgated by Steinberg (1989), indicates the possible effectiveness of antioxidants for protection of the heart. Low density lipoprotein (LDL) oxidation in the sub-endothelial space is the initiating event of atherosclerosis. This theory has come under attack with the failure of tocopherol (vitamin E) in human supplementation trials to affect atherosclerosis and thus heart disease risk as reviewed by Bleys *et al.* (2006). It is our contention that antioxidants work best, not as isolated compounds consumed alone, but in the complete milieu of the food or beverage matrix containing a potpourri of nutrients and antioxidants.

Beer, like any plant-derived material, contains hundreds of compounds. Phenolic constituents of beer are derived from malt (70–80%) and hops (20–30%). Structural classes include simple phenols, benzoic and cinnamic acid derivatives, coumarins, catechins, di-, tri- and oligomeric proanthocyanidins (prenylated) chalcones, and flavonoids. One indication of this complexity is a recent high performance liquid chromatography (HPLC) examination of a freeze dried Israeli beer as shown in Table 64.1 (Jastrzebski *et al.*, 2007) indicated a total of over 9 mg/g of phenols yet only about 5 mg/g were identified. A more complete HPLC examination with electrochemical detection identified 27 phenolic compounds in beer (Jandera *et al.*, 2005). Phenolic acids make up the bulk of the individual compounds and these are the ones found as the metabolites (glucuronides and sulfates) after human consumption (Nardini *et al.*, 2006).

It is our hypothesis that alcoholic beverages that contain significant antioxidants should be more beneficial than

Table 64.1 Free polyphenols in an Israeli beer

Components	Concentration (mg/g)
Epicatechin	1.77
Quercetin	0.03
p-Coumaric acid	0.06
Gallic acid	0.08
Ferulic acid	0.18
Procyanidins	1.68
Flavonoids	1.40
Total polyphenols	9.33
Figure 64.1 Per capita contribution of polyphenol antioxidants from commonly consumed beverages in the United States in 2004.

those that have substantially less. For instance distilled spirits are very low in polyphenols. Red wine is substantially higher in these compounds than beer. We have compared wine and beer for free phenolic antioxidants. Next we examined consumption data. Using our Folin colorimetric assay, we averaged the results for red and white wines 3397 μM (Vinson, 1998) since market research indicates about equal preference (Tordsen *et al.*, 2004). We used the government data for consumption (Economic Research Service, 2005) and assumed consumption of lager beer which averaged 677 μM polyphenols. Porter beers have almost three times more polyphenols than lager beers and the difference is significant, $p < 0.001$. Beer provides 42 mg of catechin equivalents/day while wine has 24 mg per capita. Thus in spite of beer having considerably less antioxidant content than wine, it still was the number one source of antioxidants from alcoholic beverages in the US diet.

However, to put beer's contribution in perspective, we have measured polyphenols in a number of fruit juices (Vinson, 1998) and most recently tea and coffee. The per capita beverage consumption from beverages in the US diet is shown in Figure 64.1.

Beer is a distant third compared to coffee and tea. Thus comparing per capita consumption data would not find beer to be an important source of antioxidants in spite of its reputed cardiovascular benefits. However, it is the *in vivo*

Table 64.2 Comparison of antioxidant quality (IC_{50}) and lipoprotein-bound antioxidant effectiveness (CLT_{50}) of vitamins, beer and wine polyphenols, and beer and red wine. The lower number indicates the higher quality and greater effectiveness

Components	IC_{50} (μM)	CLT_{50} (μM)
Ascorbic acid	1.45	Not active
Tocopherol	2.40	54
Ferulic acid (beer)	0.54	N/A
Epicatechin (beer)	0.19	85
Gallic acid (wine)	1.25	N/A
Cyanidin (wine)	0.21	120
Catechin (wine)	0.67	N/A
Lager beer	0.30	390
Red wine	0.45	27

N/A = not analyzed.

effectiveness of beer that clearly deems it superior to tea and coffee with respect to heart disease. The mechanism of beer's polyphenols may not be as antioxidants in the body but by other mechanisms.

Alcohol, the other ingredient in both beer and wine, is in fact an *in vitro* antioxidant in some models. For instance, ethanol protected LDL from oxidation initiated by superoxide and hydroxyl radicals by conversion of these to the less oxidizing ethanoxy radical (Bonnefont-Rousselot *et al.*, 2001). We also saw an *in vitro* effect from ethanol and other alcohols in a chemiluminescence assay of albumin oxidation (Trevithick *et al.*, 1999). However, when LDL + VLDL is oxidized by cupric ions in a mechanism which produces peroxy radicals, then ethanol has no effect since it cannot produce a less oxidizing radical (Vinson and Hontz, 1995). The larger molecules in beer, the proanthocyanidins, were found to have antioxidant activity more than 10 times that of ascorbic acid or tocopherol for the inhibition of neuronal nitric oxidase synthase activity (Stevens *et al.*, 2002).

We compared wine and beer as to their effectiveness in preventing LDL + VLDL oxidation by cupric ion using our standard model for heart disease in a test tube (Vinson *et al.*, 2001a, b). The measure of antioxidant quality is the IC_{50} value which is the concentration to inhibit the lipoprotein oxidation 50%. Values for beer and wine polyphenols, a representative lager beer and red wine, and vitamin antioxidants are shown in Table 64.2 (Vinson *et al.*, 1999). The beer and wine polyphenols are better antioxidants than the vitamins. Ferulic acid has been found in human plasma after beer ingestion (Nardini *et al.*, 2006) and gallic acid and catechin have been found after red wine ingestion (Cartron *et al.*, 2003). Beer is a better antioxidant than red wine and the concentrations that would be active are possible physiologically since polyphenols (mostly metabolites) seldom reach a concentration in plasma $>1 \mu M$ (Manach *et al.*, 2005a, b).

A second and more relevant measure of antioxidants is lipoprotein-bound antioxidant effectiveness (Table 64.2).

This is the plasma concentration to increase the lag time of oxidation of LDL + VLDL isolated after equilibration for 2h of plasma with the antioxidant(s) (Vinson *et al.*, 2001a). The lag time in minutes is the time for all the bound antioxidants incorporated in the lipoprotein to become oxidized at which time the oxidation rate becomes much faster. These would include the vitamin E, retinol, and beta carotene from the diet as well as polyphenols from the diet and those polyphenols incorporated during plasma equilibration. Vitamin C is inactive as it does not bind to lipoproteins, being too water-soluble. The order of antioxidants is red wine > tocopherol > epicatechin > cyanidin (anthocyanins) $\gg$ lager beer $\gg$ ascorbic acid. In this assay red wine is much more potent than beer.

Animal Studies

Short term

Animal models represent a means to do the equivalent of large-scale long-term studies with humans and alcoholic beverages, a task only feasible with government funding.

One Japanese study focused on the comparison of alcohol-free red wine and beer given to rats (Kondo, 2004). They were given the same equivalent dose of alcohol, although alcohol was removed to determine the effect of the antioxidants in the two beverages. An equivalent of 150 ml of beer or 58 ml of red wine was given per kg of body weight to the animals and there was a control group given water. Plasma taken at 0 and 1h was examined by oxidation with a peroxy initiator, 2,2'-azobis(2-amidinopropane) (AAPH). Tocopherol is oxidized in the plasma and its disappearance kinetics were followed. Beer and red wine equally and significantly protected the plasma tocopherol from oxidation. In addition the intake of beer or red wine for 6 weeks equally suppressed the elevation of plasma lipid peroxides in animals given a vitamin E-deficient diet. These results indicate that the polyphenolic antioxidants in beer and red wine were absorbed into the plasma as seen in human studies and are equal in plasma antioxidant protection at the same dose of alcohol.

In this rat experiment the animals were given either a normal diet, ethanol-supplemented diet (1.1g/100g of food), or a beer-containing diet (30% w/w) containing the same concentration of ethanol for 6 weeks (Gasbarrini *et al.*, 1998). This is equivalent to a moderate consumption of beer for humans. Plasmas of the ethanol group were significantly elevated in uric acid. Urate is an antioxidant but also a risk factor for heart disease and stroke in humans (Bos *et al.*, 2006). LDL oxidation was exacerbated in the ethanol group and decreased in the beer group compared to the control group. Thus beer (presumable the polyphenol component) was an *in vivo* antioxidant and ethanol was a pro-oxidant in this animal model. Beer thus overcame and surpassed the oxidant effects of alcohol.

A comprehensive study with rats examined the effect of alcohol-containing red wine and beer and lyophilized and thus dealcoholized red wine and beer (Gorinstein et al., 1998). This was a 4-week supplementation with 2 ml of wine and 6 ml of beer or their lyophilized equivalents. The human dose equivalent was 350 ml of red wine or 1050 ml of beer/day. Compared to the control group given no alcohol, all treatments significantly decreased low density lipoprotein (LDL), high density lipoprotein (HDL), and triglycerides, and there was no difference among the experimental groups. The cholesterol/HDL ratio was increased by the wine and beer but the change was not significant. This animal study points out the differences between human and animal metabolism and biochemistry. Another positive benefit from this study was the significant 60% decrease in plasma lipid peroxides indicating that the beer and wine components were *in vivo* antioxidants. The fact that the results were equivalent for the alcohol and the non-alcohol groups indicates the lipid and antioxidant effects were probably due to the polyphenols in the wine and beer and not the alcohol.

Alcohol is proposed to be the cause of an HDL increase from alcoholic beverages in human studies. However, in the rat study just described, HDL was decreased by the alcohol-containing beer and wine. Interestingly, a recent mouse study investigated isohumulones, some of the bitter components of beer (Miura et al., 2005). These are hop-derived compounds formed from humulones during the wort boiling step of the brewing process. The mice were given an atherogenic diet for 1 week with or without the isohumulones. Although the dose was supra-physiological (1–3 g/kg diet), these compounds were found to raise plasma HDL in a dose–response manner by activating peroxisome proliferator-activated receptors and beneficially affected the expression of genes involved in lipid metabolism. The control group given the atherogenic diet suffered a 27% decrease in HDL and the group given the high dose of isohumulones had a 39% increase in HDL. Isohumulones in beer may provide some of the HDL-raising effect in humans and perhaps work in cooperation with the alcohol-raising mechanism.

Long term

Rabbit Model   The first comparative examination of alcoholic beverage and animal atherosclerosis was conducted in 1981 (Klurfeld and Kritchevsky, 1981). This elegant study examined alcohol, red wine, white wine, whisky, and beer given to cholesterol-fed rabbits. All alcohol groups experienced an increase in plasma HDL except for beer. The beer group had significantly lower liver cholesterol than the control and was superior to the other beverages in this respect. The red wine group had significantly less atherosclerosis than the controls, white wine, or whiskey. White wine, whiskey, and beer had no significant effect on atherosclerosis in this model although beer had less atherosclerosis than the control (30% reduction). The rabbit model has been criticized for having lipid metabolism dissimilar for humans, and for being a lipid storage disease rather than an atherosclerosis model since cholesterol levels are very high, in excess of 20 mM, an impossible level in humans. In addition pathogen-free rabbits do not develop atherosclerosis even with a high cholesterol diet, thus it is not a very relevant atherosclerosis model (Russell and Proctor, 2006).

Mouse Models   A mouse study compared the effect of lager beer and dark beer in two models: C57BL/6 mice given a high fat Western diet for 24 weeks for early atherosclerosis and the apoE-deficient given a normal diet for 12 weeks for mature atherosclerosis (Escola-Gil et al., 2004). The dosing of the ethanol control was 1.62% in the drinking water and the 5.4% beers were diluted appropriately to give the same ethanol dose. Water was also used for another control group. Red wine in the apoE model was previously shown to inhibit early but not mature (late) atherosclerosis (Hayek et al., 1997; Bentzon et al., 2001). Neither ethanol nor any type of beer had any significant effect on early or late atherosclerosis. Unfortunately, beer was not tested for early atherosclerosis by means of a short-term supplementation to apoE animals as was done by Hayek. In the apoE model of early atherosclerosis red wine was beneficial. The apoE model can be viewed as analogous to untreated, severely dyslipidemic humans (Russell and Proctor, 2006).

Illustrative of the different animal models of atherosclerosis is the study which used the human atherogenic lipoprotein profile LDLr$^{-/-}$ apoB$^{100/100}$ mouse (Degrace et al., 2006). They used a moderate dose of lager beer (0.57 g of ethanol/kg of body weight) or the equivalent volume of ethanol-free beer. Animals were supplemented for 12 weeks with a single dose given during 5 min. There was no effect on serum glucose, cholesterol, LDL, or triglyceride or on liver toxicity (alanine aminotransferase). Liver triglycerides were significantly decreased by both beers. As a measure of atherosclerosis the authors used total cholesterol in the aorta which had been previously validated by correlational analysis with histology of the aorta. Cholesterol accumulation was slightly reduced in the ethanol-free beer and significantly reduced in the beer group. Ethanol had a very slight protective effect in addition to the beer components. Both beer groups equally and significantly raised HDL and VLDL levels in the serum but beer was significantly more effective than ethanol-free beer in raising VLDL, the major carrier of triglycerides.

The mechanism of beer's beneficial effect on this model of atherosclerosis was investigated by gene expression analysis and the pertinent data are shown in Table 64.3.

Among all the genes studies, only SR-B1 was significantly down-regulated by both beers compared to the control. Ethanol-containing beer significantly down-regulated LDL receptor-related protein (LRP), lecithin–cholesterol acyltransferase (LCAT), and sterol-regulatory element binding protein 2 (SREBP2). This study used one-fifth of the

Table 64.3 Effect of beer (0.57 g ethanol/kg body weight) and an equivalent amount of ethanol-free beer on gene expression in a human atherogenic lipoprotein mouse model of atherosclerosis compared to the water control given for 12 weeks

Gene RNA levels	Beer	Ethanol-free beer
Liver lipoprotein uptake		
Scavenger receptor-B1 (SR-B1)	Down-regulates*	Down-regulates*
LDL receptor related protein (LRP)	Up-regulates	Down-regulates*
Hepatic lipase (HL)	No effect	No effect
VLDL receptor (VLDLr)	No effect	Down-regulates
Lipoprotein cholesterol transfer

Figure 64.2 Percent of aortal coverage by foam cells in hamster given an atherogenic diet for 10 weeks. The control groups were given different doses of ethanol and the experimental groups were given diluted lager and porter beer at two different dilutions. *Significantly different from the corresponding control group, †significantly different from the corresponding lager group. Note the dose-related reduction in atherosclerosis with ethanol and the beers.
Figure 64.3 Lag time of LDL + VLDL isolated from pooled plasmas from each of the hamster groups and oxidized under standard conditions at physiological pH and temperature. This time represents the amount of antioxidants bound to the lipoproteins with the longer time indicating more antioxidant activity. Note the dose–response effect of the two varieties of beer.

dose of ethanol as is the previous genetic mouse model, but the lipid profile and lack of effect of ethanol on the lipids in this study are more representative of the effect of moderate alcohol on humans. The benefits of the beer components, probably the polyphenols, are amplified by the presence of ethanol in the beverage.

Hamster Model The hamster is often used as a model of atherosclerosis as its lipid profile, when given a cholesterol and saturated fat diet, resembles humans with a preponderance of LDL compared to HDL. This is an early atherosclerosis model as aortic lesions are confined to fatty streaks and there are no advanced intimal lesions of myocardial infarcts (Russell and Proctor, 2006). Our hamster atherosclerosis study was the first to compare lager with a dark beer at two different doses. There were two control groups given 0.4% and 2% alcohol and four experimental groups given a Czech Urquell lager and porter at 1/10 and 1/2 dilutions. All liquids were sweetened with an artificial sweetener. The diets were supplemented with 0.2% cholesterol/ 10% coconut oil. The beer groups drank significantly more liquid with the ethanol groups. Yes, beer is better tasting than plain alcohol even to hamsters. There was no significant effect of the beers on HDL compared to the ethanol controls. Both beers at the high dose significantly decreased triglycerides and cholesterol. There was no effect of either beer at the low dose on lipids.

Figure 64.2 illustrates the effect of the beers on atherosclerosis (% of aorta covered with foam cells) and the lag time of LDL + VLDL oxidation of pooled plasmas in Figure 64.3. Ethanol seemed to have beneficial effect as the high ethanol control had less atherosclerosis than the low

ethanol control. This was also seen in our hamster atherosclerosis study with red wine (Vinson *et al.*, 2001b). In the red wine study ethanol increased triglycerides compared to the water control. Although we did not have a water control group in the beer study, there was one in the red wine hamster study. Ethanol was an *in vivo* antioxidant and significantly decreased lipid peroxides in the plasma relative to water and also increased the lag time of LDL + VLDL oxidation. Both beers significantly decreased atherosclerosis at the high dose, 56–67%. At the low dose only lager beer significantly decreased atherosclerosis, 21% vs. the control, p < 0.05. At this dose the lager beer was significantly more effective than the dark beer, p < 0.001. The human-equivalent dose is 1.25 l. The inability of dark beer

to inhibit atherosclerosis may be due to the fact that some of its antioxidants, such as the melandoins and Maillard products, are non-phenolic and may not be absorbed or be bioactive. Both beers increased the lag time, indicating an *in vivo* antioxidant effect of the polyphenols from the beer. There was a negative correlation of lag times with atherosclerosis at the high dose, Pearson correlation coefficient 0.9577, p = 0.07. This indicates a significant proportion of the atherosclerosis inhibition can be attributed to the antioxidants in the two beers at this dose. Although we did not compare beer to red wine during the same study, beer with 2% alcohol (half diluted) decreased atherosclerosis by 56% while red wine with 6.75% alcohol (half diluted) decreased it by 53%. Thus beer is certainly equal if not greater in effectiveness to red wine in the hamster model of atherosclerosis.

Summary Points

- Beer contains substantial levels of polyphenols antioxidants and beer is the number three source of beverage antioxidants in the US diet on a daily per capita basis.
- Compared to red wine, beer provides almost twice as many antioxidants in the US daily diet.
- In a rat study red wine and beer given at the same dose of alcohol were equally protective as *in vivo* plasma antioxidants.
- At the same dose of alcohol given to rats in a short-term study, beer was an *in vivo* antioxidant and ethanol was a pro-oxidant *in vivo*.
- In a 4-week study rats were given alcohol-containing red wine and beer at the same alcohol dose, or without alcohol. The beneficial lipid and antioxidant effects were equal for wine and beer and were not due to the alcohol.
- A mouse study given an atherogenic diet for a short period investigated the effect of isohumulones, the bitter principles in beer. These compounds at a high dose raised HDL and may work with ethanol in humans to improve that risk factor for CVD.
- A rabbit model was the first comparison of different alcoholic beverages on atherosclerosis. Red wine had the only significant benefit compared to ethanol control. Beer had no effect on atherosclerosis.
- Two genetic mouse models were examined at a fairly high dose of ethanol and beer. Neither ethanol nor any type of beer had any significant effect on early or late atherosclerosis.
- The most human relevant mouse model had a lipoprotein profile similar to humans. Beer significantly inhibited atherosclerosis and ethanol-free beer was almost as effective. Both beer groups significantly increased HDL. Beer and ethanol-free beer affected several genes involved in lipid receptor uptake and lipid metabolism. Beneficial effects of the beer polyphenols (hypothesized by this author) were amplified by the presence of ethanol.

- Beer polyphenols appear to contribute a large degree of CVD protection in the short- and long-term supplementation of animal models of atherosclerosis although ethanol is also beneficial.
- Long-term human supplementation studies must be performed to compare beer with and without alcohol and thus determine the bioactive ingredient(s).

Beer Inhibition of Heterocyclic Amines-Induced Carcinogenesis

Hajime Nozawa and Keiji Kondo Central Laboratories for Frontier Technology, Research Section for Applied Food Science, Kirin Holdings Co., Ltd., Takasaki, Gunma, Japan

Abstract

Antimutagenic and anticarcinogenic effects of beer on heterocyclic amines (HCAs)-induced carcinogenesis were studied *in vitro* and *in vivo*. Four commercial beers (two pilsner-type, black and stout) showed inhibitory effects against five HCAs, MeIQx, PhIP, Trp-P-2, Glu-P-1 and IQ, in the Ames assay using *Salmonella typhimurium* TA98 in the presence of rat S9 mix. The inhibitory effects of dark-colored beers (stout and black beers) were greater than those of pilsner-type beers. Dark-colored beers suppressed CYP1A2 activity in a dose-dependent manner, suggesting that inhibition of HCA activation is partly responsible for their strong antimutagenic effects. Single cell gel electrophoresis assay (comet assay) revealed that oral ingestion of pilsner-type and stout beers for 1 week significantly inhibited DNA damage in the liver cells of male ICR mice exposed to MeIQx (13 mg/kg, i.p.). Male Fischer 344 rats were orally received PhIP (75 mg/kg, 5 times a week for 2 weeks) and aberrant crypt foci (ACF) formation in the colon was analyzed after 5 weeks. The number of ACF was significantly reduced in rats fed a diet containing freeze-dried (FD) beer. Female Sprague-Dawley rats were orally received PhIP (85 mg/kg, 4 times a week for 2 weeks) and the tumors were pathologically examined at the end of the 22 weeks experiment. Tumor development was inhibited by FD beer intake in a dose-dependent manner. Tumor incidence (38.5%) and tumor multiplicity (0.8 ± 0.4) for the group fed a diet containing 4% FD beer were significantly reduced as compared with the control group (73.3% and 1.8 ± 0.7). In conclusion, our results suggest that intake of beer ingredients may reduce the risk of carcinogenesis caused by HCAs.

List of Abbreviations

ACF	Aberrant crypt foci
ACs	Aberrant crypts
FD beer	Freeze-dried beer
(I/PI)	Initiation and post-initiation
AIN	AIN-76A
AD	Adenomas
ADC	Adenocarcinomas
HCAs	Heterocyclic amines
IQ	2-Amino-3-methylimidazo[4,5-*f*]-quinoline
MeIQx	2-Amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline
Trp-P-2	3-Amino-1-methyl-5*H*-pyrido[4,3-*b*]indole
PhIP	2-Amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine
Glu-P-1	2-Amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole
MROD	Methoxy resorufin-*O*-demethylase
Comet assay	Single cell gel electrophoresis assay

Introduction

Heterocyclic amines (HCAs) exist in cooked meat and fried fish (Felton *et al.*, 1997) and this family of compounds exert a strong mutagenic effect in the Ames *Salmonella* mutagenicity assay (Sugimura, 1997). Carcinogenic studies in rodents demonstrated that they are carcinogens in colon, mammary, liver and prostate, and they may cause cancer in human (Ito *et al.*, 1991; Shirai *et al.*, 1997). Approximately 20 HCAs have been purified from the pyrolysates of amino acids and proteins; they are categorized as IQ type and non-IQ type. IQ type includes aminoimidazoles, such as IQ (2-amino-3-methylimidazo[4,5-*f*]-quinoline), MeIQx (2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline) and PhIP (2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine), and non-IQ type includes pyridoindoles and dipyridoimidazoles, such as Trp-P-1 (3-amino-1,4-dimethyl-5*H*-pyrido

[4,3-*b*]indole) and Glu-P-1 (2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole) (Nagao *et al.*, 1996; Sugimura *et al.*, 1996). HCAs are activated to mutagenic intermediates by *N*-oxidation reactions, which are catalyzed by hepatic cytochrome P-450 enzymes (especially CYP1A2). Further activation of these metabolites involves enzymatic esterification with acetyltransferases or sulfotransferases to produce reactive nitrenium ions, which form covalent bonds with DNA mainly at the N2 and C8 positions of guanine, and thereby cause mutation in cells (Minchin *et al.*, 1992; Turesky *et al.*, 1992; Chou *et al.*, 1995; Turesky *et al.*, 1998). Among them, PhIP is one of the most abundant HCAs (Felton *et al.*, 1986) and has been shown in rodents to cause colon, mammary and prostate cancers (Ito *et al.*, 1991; Shirai *et al.*, 1997). A high incidence of PhIP-DNA adducts in exfoliated ductal epithelial cells from human breast milk has indicated that humans are exposed to this mutagen daily (Gorlewska-Roberts *et al.*, 2002). PhIP is reasonably anticipated to be a human carcinogen based on sufficient evidence of carcinogenicity in experimental animals and supporting genotoxicity data by the US National Toxicology Program. Therefore, there is a growing interest in finding dietary factors with anticarcinogenic effects to reduce the mutagenic and carcinogenic risks caused by PhIP and other HCAs (Ohta *et al.*, 2000; Hagiwara *et al.*, 2002; Tavan *et al.*, 2002; Yamagishi *et al.*, 2002; Yang *et al.*, 2003; Hikosaka *et al.*, 2004).

It has been reported that many components from plant sources reduce the mutagenic activities of HCAs (Apostolides *et al.*, 1997; Edenharder *et al.*, 1997). Several molecular processes are involved in the defense against HCAs, such as direct interaction with non-activated or activated HCAs (Dashwood *et al.*, 1996), inhibition of enzymes involved in the activation of HCAs (Edenharder *et al.*, 1997), induction of detoxifying enzymes (Kensler, 1997) and amelioration of DNA repair or replication (Sanyal *et al.*, 1997). The Ames test using the bacteria *Salmonella* can be used to find chemopreventive agents with antimutagenic effects on HCAs. Although *in vitro* methods are convenient and used widely, it is important to assess antimutagenic activity with *in vivo* experiments since metabolism of a mutagen may be changed by chemopreventive agent or the chemopreventive agent itself may be metabolized after absorption. Single cell gel electrophoresis assay (comet assay) has been used to characterize chemopreventive agents against DNA damage in organs of rodents exposed to mutagens (Singh *et al.*, 1988; Sasaki *et al.*, 1997; Tice *et al.*, 2000; Kassie *et al.*, 2003). Detection of DNA adducts, which are considered to be an initiating event in chemical carcinogenesis induced by HCAs, is useful for evaluation of chemopreventive efficacy *in vivo* (Lin *et al.*, 2003). Aberrant crypt foci (ACF) are early morphological changes or hyperproliferative lesions found in the colon of carcinogen-treated rodents and considered to be putative preneoplastic lesions for colon cancer (Bird, 1987; Wargovich *et al.*, 2000). Oral administration of PhIP induces ACF in male F344 rats; thus, chemopreventive effects were assessed in this model (Takahashi *et al.*, 1997; Chewonarin *et al.*, 1999). It has been shown that PhIP induces mammary tumors in female rats, and this carcinogenesis model has been used to study anticarcinogenic effects of many dietary factors (Ohta *et al.*, 2000; Schut and Yao, 2000; Futakuchi *et al.*, 2002; Hirose *et al.*, 2002; Yamagishi *et al.*, 2002). Therefore, in this chapter, we evaluated the modulating effects of freeze-dried (FD) beer on PhIP-induced mammary carcinogenesis.

Beer is a low alcohol beverage brewed from natural ingredients, rich in vitamins, amino acids and minerals, and contains a number of micronutrients such as phenolic acids and polyphenols (Madigan *et al.*, 1994; Lapcik *et al.*, 1998). Beer or extracts of raw materials are cancer preventive against azoxymethane-induced carcinogenesis (Nozawa *et al.*, 2004b, 2005). Furthermore, previous studies demonstrated that the antimutagenic effects of beer against activated HCAs (Trp-P-2(NHOH), Trp-P-1(NHOH) and Glu-P-1(NHOH)) were exerted in the Ames assay. In addition, beer intake reduced the number of DNA adducts generated in the liver of mice by Trp-P-2 treatment (Arimoto-Kobayashi *et al.*, 1999; Kimura *et al.*, 1999; Yoshikawa *et al.*, 2002). Glycine-betaine and pseudouridine, both present in beer, have been identified as antimutagens against 2-chloro-4-methylthiobutanoic acid and *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine, respectively (Kimura *et al.*, 1999; Yoshikawa *et al.*, 2002). It has also been reported that several phenolic compounds derived from hops exert antimutagenic effect against HCAs through inhibition of CYP1A2 (Miranda *et al.*, 2000). In addition, hot water extract of hops showed antimutagenic effects against Trp-P-2(NHOH) (Arimoto-Kobayashi *et al.*, 1999). Therefore, the antimutagenic and anticarcinogenic activities of beer against HCAs were extensively studied using *in vitro* cell-based mutagenicity assays, *in vivo* mutagenicity assays (comet assay) and *in vivo* carcinogenesis experiment (Nozawa *et al.*, 2004a, 2006).

Beer Inhibition of HCAs-Induced Mutagenesis in the Ames Test

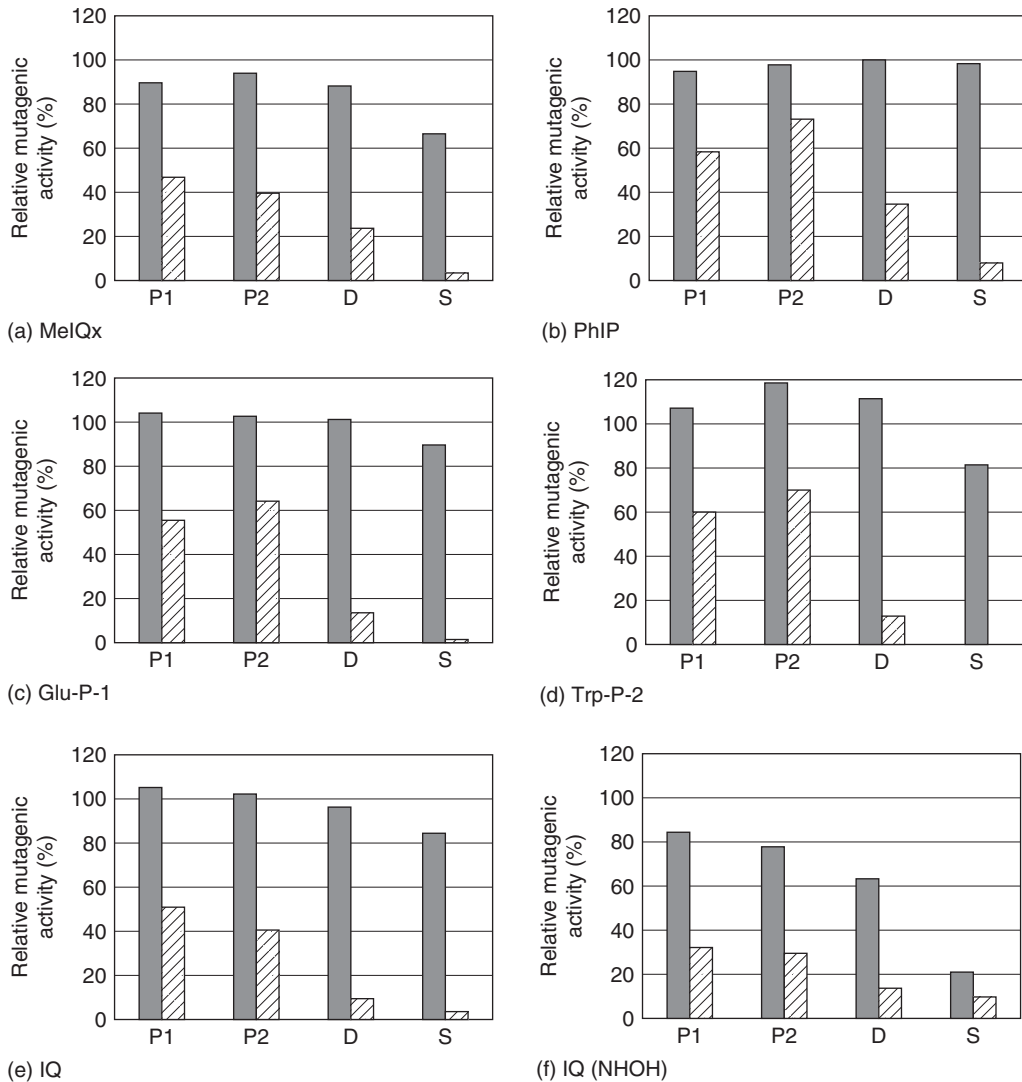
Two pilsner-type beers, P1 (beer B) and P2 (beer A, same beer as used in AOM-induced carcinogenesis experiments), a black beer (D) and a stout beer (S) were used for the antimutagenicity experiments. Ames test was conducted according to the method established by Ames *et al.* (1975). As shown in Figure 65.1, all samples of beer showed antimutagenic effects against all HCAs tested (MeIQx, PhIP, Glu-P-1, Trp-P-2 and IQ). For example, addition of 100 μl black, stout and two pilsner-type beers into the reaction mixture with MeIQx decreased the number of revertants by 75%, 95%, 53% and 60%, respectively (Figure 65.1a). Growth inhibitions and mutagenic effects of beer samples on bacterial cells were not observed. Dark-colored beers (stout and black beers)


Figure 65.1   Antimutagenic effects of beer against HCAs in *Salmonella typhimurium* TA98. Assays were performed in the presence (a–e) or absence (f) of rat S9, using duplicate plates per sample. Two pilsner-type beers (P1 and P2), black beer (D) and stout beer (S) were used. Beer samples were mixed at 10 μl (closed bar) or 100 μl (slashed bar) in reactions. Results are given as relative mutagenic activities in comparison with ethanol controls. MelQx, PhIP, Glu-P-1, Trp-P-2, IQ and activated IQ were used at 30 pmol, 10 nmol, 300 pmol, 50 pmol, 80 pmol and 20 pmol per plate, respectively (a–e). One hundred percent mutagenicity of ethanol control corresponds to 466(a), 286(b), 1,661(c), 1,417(d), 967(e) and 735(f) revertants.

had a greater antimutagenic effect than the pilsner-type beers (Figure 65.1a–e). Moreover, antimutagenicity of the beer samples was also observed against activated IQ (IQ-NHOH); black and stout beers exhibited stronger antimutagenic effects than pilsner-type beers (Figure 65.1f).

Beer Inhibition of CYP1A2 Activity

The inhibitory effect of beer on the activity of CYP1A2, an enzyme involved in the activation of HCAs, was examined by measuring methoxy resorufin-*O*-demethylase activity (Xu *et al.*, 1996). Dose-dependent inhibition of CYP1A2 by dark-colored beers (black and stout beers) was observed,

but the pilsner-type beers had no inhibitory effects (Figure 65.2). This suggests that the strong antimutagenic effects observed with dark-colored beers in the Ames tests could be partly attributed to the inhibition of CYP1A2.

Beer Inhibition of MeIQx-Induced DNA Damage in Liver Cells by Single Cell Gel Electrophoresis Assay

Male ICR mice at 8 weeks of age were fed a basal diet of AIN-76A and experimental drinks (stout beer (2 times diluted by water) and pilsner-type beer) or control drinks (5% ethanol and water) *ad libitum* for 1 week. Each
Figure 65.2 Inhibition of CYP1A2 activity with beer. Methoxy resorufin was used as a substrate for CYP1A2 in rat S9. Two pilsner-type beers, one black and one stout beer were added to the 100 µl of reaction mix at indicated amounts. Results are given as relative inhibitory activities in comparison with ethanol controls.

Figure 65.3 Induction of DNA damage in liver cells by MeIQx and its prevention by beer. Male ICR mice ($n = 3$) were given beer samples for 1 week and received intraperitoneal injections with MeIQx (13 mg/kg b.w.) or saline 3 h before sacrifice. One hundred nuclei were analyzed for each animal in the comet assay. Results are given as mean comet length ± SD. Statistical significance comparison results between experimental groups and controls are shown by * for $p < 0.05$.

treatment group consisted of three animals. They received intraperitoneal injections of MeIQx at a dose of 13 mg/kg body weight at 3 h before sacrifice (Sasaki *et al.*, 1997). Liver cells were prepared and analyzed by comet assay (Singh *et al.*, 1988; Pool-Zobel *et al.*, 1993; Tice *et al.*, 2000). MeIQx treatment induced significant DNA damage in liver cells: comet lengths in groups fed 5% ethanol or water as a drink were approximately 1.5-fold longer than those in the saline-treated control (Figure 65.3). Comet lengths in the groups fed either pilsner-type beer or stout beer were significantly shorter than those in the group fed 5% ethanol (20% and 26% reduction, respectively), indicating DNA damage induced by MeIQx was reduced by the intake of beer as a drink before administration of this mutagen.

Beer Inhibition of PhIP-Induced ACF Formation in Rat Colon

Analysis of ACF formation was performed according to previous reports (Takahashi *et al.*, 1997; Chewonarin *et al.*, 1999). Male Fischer 344 rats at 5 weeks of age ($n = 8$) were fed the AIN-76A basal diet or experimental diets containing FD samples of pilsner-type beer A for the experimental period of 5 weeks. The powder of FD beer A was mixed in the basal diet at a concentration of 0.5%, 1%, 2% and 4%. One week after the start of feeding experimental diets, PhIP in saline was given to the rats at a dose of 75 mg/kg body weight by daily oral gavage; the dose was given 10 times (days 8–12 and 15–19). All rats were weighed weekly and the animals were sacrificed at the end of the 5-week experimental period. ACF were distinguished from normal crypts by their increased size, prominent epithelial cells and increased pericryptal area according to established criteria (Bird, 1987). The numbers

of ACF and aberrant crypts (ACs) per rat were quantified (Nozawa *et al.*, 2004a, b). There were no significant differences in the daily consumption of diets and final body weights among the experimental and control groups (Table 65.1). The incidence of ACF was 100% in the control and experimental groups. Ingestion of FD beer at 1% and 2% in the basal diet during the whole experimental period (I/PI) reduced the number of ACF/colon by 54% and 45%, respectively (Table 65.1). Diets containing 0.5% and 4% FD beer were less effective in reducing the number of ACF/colon (33% and 19% reduction, respectively), suggesting the optimal effective dose to be between 1% and 2% (Table 65.1). The number of ACs/colon was significantly reduced in the groups fed FD beer at 0.5%, 1% and 2% (55%, 70% and 55% reduction, respectively). In addition, a significant reduction in the number of ACs/focus was observed in the group fed sample containing 1% FD beer (Table 65.1). The dosing level at 1% of FD beer in this animal experiment was estimated as 220 ml beer intake for humans (Nozawa *et al.*, 2004a).

Beer Inhibition of PhIP-Induced Mammary Carcinogenesis in Rats

Carcinogenesis experiments were conducted according to the established method reported previously (Ohta *et al.*, 2000; Kawamori *et al.*, 2001, 2002). Six-week-old female Sprague-Dawley rats were divided into four groups. They were fed either a basal high fat diet (control group, $n = 30$) or basal high fat diets containing FD beer A at 1% ($n = 30$), 2% ($n = 30$) or 4% ($n = 26$) (Table 65.2). One week after the start of feeding, rats received PhIP suspension in corn

Table 65.1 Effects of beer P2 (beer A) on PhIP-induced ACF formation in rat colon

Group	Incidence	Body weight (g)	Daily diet intake (g/rat)	Number of ACF/colon	Number of ACs/colon	Number of ACs/focus
AIN (control)	8/8	177.6 ± 12.0[a]	10.2	8.4 ± 3.3	18.5 ± 15.0	2.1 ± 0.8
0.5% FD Beer	8/8	182.8 ± 13.5	10.3	5.6 ± 3.0	8.4 ± 4.5[b]	1.5 ± 0.3
1% FD Beer	8/8	179.9 ± 3.2	10.1	3.9 ± 2.1[c]	5.6 ± 3.5[c]	1.4 ± 0.3[b]
2% FD Beer	8/8	182.3 ± 7.9	10.5	4.6 ± 2.2[b]	8.3 ± 4.5[b]	1.8 ± 0.6
4% FD Beer	8/8	176.1 ± 10.1	10.1	6.8 ± 2.7	12.0 ± 5.3	1.8 ± 0.3

[a] Results are shown in the table indicating mean ± SD.
[b,c] Statistical significance comparison results between experimental groups and controls are shown by $p < 0.05$ and $p < 0.01$, respectively.

Table 65.2 The composition of experimental diet

	g/kg Diet			
Ingredient	Group 1 (control)	Group 2 (1% FD beer)	Group 3 (2% FD beer)	Group 4 (4% FD beer)
Casein	235	235	235	235
DL-methionine	3.5	3.5	3.5	3.5
Corn starch	95	95	95	95
Sucrose	317	307	297	277
Cellulose	59	59	59	59
Corn oil	235.2	235.2	235.2	235.2
Salt mixture	41.1	41.1	41.1	41.1
Vitamin mixture	11.8	11.8	11.8	11.8
Choline bitartrate	2.4	2.4	2.4	2.4
ED beer	0	10	20	40

Note: Calorific content in each experimental group was same as control group by adjusting the sucrose content in each diet.

oil at a dose of 85 mg/kg by gavage 4 times weekly for 2 weeks. Palpable tumors were recorded weekly until 21 weeks. At 22 weeks all rats were sacrificed, and neoplastic lesions were examined macroscopically and scored. Then the lesions were measured with calipers, and the tumor volume was calculated using the formula (length)*(width)* (depth)*π/6 (Tayek *et al.*, 1986). After measuring the tumor size, they were immediately fixed with 10% neutral buffered formalin. The lesions were embedded in paraffin blocks, sectioned and stained with hematoxylin and eosin (H&E) for histopathological examination according to established criteria (Russo *et al.*, 1990).

Palpable breast tumors were observed in all groups of rats 8 weeks after the administration of PhIP (experimental week 11). The time courses of tumor incidence (the percentage of rats with tumors) and multiplicity (the number of tumors per rat) are shown for each experimental group in Figure 65.4. Tumor incidence in the groups fed diets containing 2% and 4% FD beer was lower than in the control group throughout the carcinogenesis experiment (Figure 65.4a). While tumor incidence in the group treated with 1% FD beer was higher than in the control group from 10 to 14 weeks, by 20 weeks it reached a similar value. The changes in tumor multiplicity mirrored those of tumor incidence. Feeding the rats diets

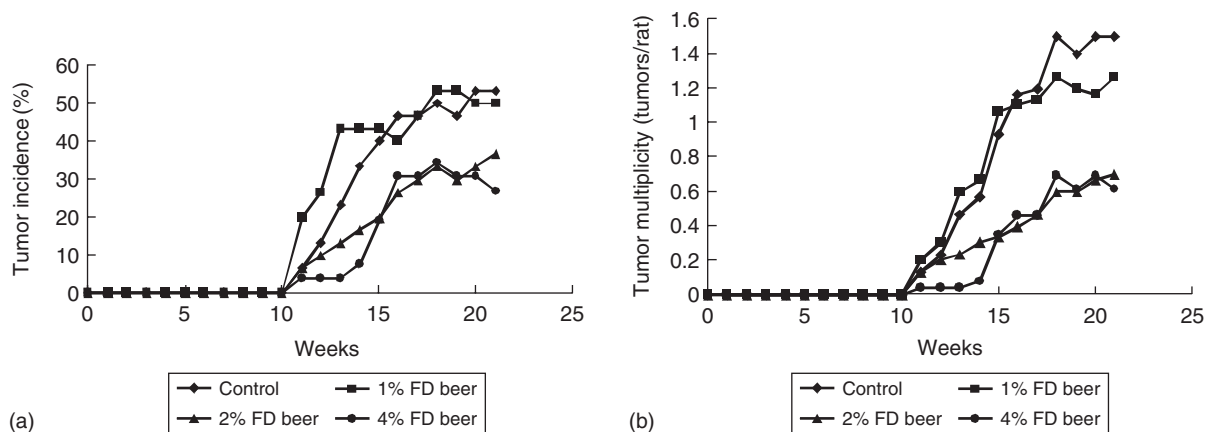
with 2% or 4% FD beer greatly reduced the tumor multiplicity compared to the control group, while only a slight decrease was noticed in the group fed the diet with 1% FD beer after 16 weeks (Figure 65.4b). Furthermore, there was a noticeable delay in the appearance of tumors in the group fed the diet with 4% FD beer until 13 weeks, when only one palpable tumor was found in one rat. The results of mammary tumor development in each group examined at week 22 are summarized in Table 65.3. Dose-dependent inhibition of tumor incidence and tumor multiplicity was observed following intake of FD beer. Tumor incidence in the control group and the groups fed FD beer at 1%, 2% and 4% was 73.3%, 63.3%, 53.3% and 38.5%, respectively. As compared to the control group, the tumor incidence of the 4% FD beer-fed group was significantly reduced to 53% of the control value ($p < 0.05$). Tumor multiplicity in the control group and the groups fed FD beer at 1%, 2% and 4% was 2.0 ± 0.4, 2.0 ± 0.5, 1.4 ± 0.3 and 0.8 ± 0.4, respectively. The decrease in the 4% FD beer group was also significant as it was reduced to 40% of the control value ($p < 0.01$). Dose-dependent suppression was also observed in tumor volumes. The values were 1.8 ± 0.7 cm^3, 1.5 ± 0.5 cm^3, 0.9 ± 0.3 cm^3 and 0.8 ± 0.4 cm^3 for the control, 1% FD beer, 2% FD beer and 4% FD beer groups, respectively.


Figure 65.4 Intake of FD beer dose-dependently inhibited mammary carcinogenesis in rats. Tumor incidence (a) and tumor multiplicity (b) were measured in female rats treated with PhIP and fed experimental diets, control (rhombus), 1% (square), 2% (triangle) or 4% (circle) FD beer.

Table 65.3 Tumor volume, tumor incidence and tumor multiplicity in carcinogenesis experiment

	Animals (n)	Average tumor volume (cm³)	Tumor incidence (%)	Tumor multiplicity
Control	30	1.8 ± 0.7[a]	22/30 (73.3)	2.0 ± 0.4
1% FD beer	30	1.5 ± 0.5	19/30 (63.3)	2.0 ± 0.5
2% FD beer	30	0.9 ± 0.3	16/30 (53.3)	1.4 ± 0.3
4% FD beer	26	0.8 ± 0.4	10/26 (38.5)[c]	0.8 ± 0.4[b]

[a] Values are given as the mean ± SEM.
Significantly different from Group 1: [b] $p < 0.05$; [c] $p < 0.01$.

Summary Points

- Antimutagenic activities of beer (two pilsner, black and stout) were observed against five HCAs, including MeIQx, PhIP, Glu-P-1, Trp-P-2 and IQ in the presence of rat S9 activation system in the Ames mutagenicity assay. Dark-colored beers (black and stout beers) exerted stronger antimutagenic effects than that of pilsner beer.
- These inhibitory effects were also observed when activated HCAs (IQ) were used in the Ames experiment, suggesting that some components with desmutagenic activity are present in all beers.
- Dark-colored beers inhibited CYP1A2 activity *in vitro*, however, pilsner-type beers did not show any inhibitory effects. It is indicated that the strong antimutagenic effects of dark-colored beers against HCAs observed in the Ames assays with S9 mix are partly due to inhibition of the activation of HCAs by CYP1A2.
- DNA damage in liver cells induced by MeIQx was protected by intake of both pilsner and stout beers in the single cell gel electrophoresis assay (comet assay). These antimutagenic effects of pilsner and stout beers *in vivo* were approximately the same degree.
- Intake of beer A inhibited the PhIP-induced ACF formation in rat colon. It is suggested that beer components with antimutagenic activity may contribute to the inhibition of ACF formation. Moreover, beer components

exerted anticancer promotion activity by the decreased average ACF size.
- In the PhIP-induced mammary carcinogenesis experiment, intake of beer A reduced the tumor incidence and tumor multiplicity. Overall, from these results, it is indicated that beer may reduce the risk of carcinogenesis caused by HCAs, the food-borne carcinogens.

Maize Beer Carcinogenesis: Molecular Implications of Fumonisins, Aflatoxins and Prostaglandins

Zodwa Dlamini, Zukile Mbita and Lindiwe Skhosana University of the Witwatersrand, Wits Medical School, Johannesburg, South Africa

Abstract

The most thirst-quenching beverage at the end of a hard-working day is beer, yet it is associated with detrimental effects to human health in many instances. Consumption of maize in the form of beer or food has risks associated with it. This is because of contaminations that are found in maize and the most prevalent contaminant found in maize is the fungus, *Fusarium*. Unfortunately this fungus is associated with cancer predisposition in both Africa and the rest of the world. These fungi are the sources of mycotoxins that have been shown to be cancer causing toxins as exemplified by fumonisin B_1 produced by another species of the genus *Fusarium*, that is *F. verticilloides*. These mycotoxins inhibit the apoptotic machinery by inhibiting the ceramide synthase thus leading to cell proliferation and tumorigenesis. Genetic alterations contribute hugely in the development of cancer in humans, such as the cancer of the esophagus, Kaposi's sarcoma and liver cancer. These alterations are abnormally found in tumor suppressors and oncogenes. Tumor suppressors like p53 are very important in the cell cycle control of which deregulation results in cancer development. Mutations in codon 249 of p53 have been linked to contamination of maize by aflatoxins.

Other mycotoxins, fumonisins, are involved in the production of reactive nitrogen species, which induce nitrative stress and are main contributors to carcinogenesis by inducing DNA damage leading to mutations of tumor suppressor gene like p53.

High intake of linoleic acid in a diet deficient in other polyunsaturated fatty acids and in riboflavin results in high tissue production of prostaglandin E2 (PGE2), which in turn causes inhibition of the proliferation and cytokine production. It has been postulated that this association is due to the conversion, in the stomach mucosa, of the linoleic acid contained in maize meal to PGE2. The proportion of non-esterified linoleic acid available in the stomach is therefore being an important factor in cancer predisposition. High levels of non-esterified linoleic acid in the diet cause increased production of PGE2 and profoundly affect the normal pH and fluid content that creates a predisposition to carcinogenesis. High linoleic acid diet contributes to oxidative stress leading to a marginal increase in oxidative DNA damage.

Intervention strategies that aim to reduce dietary exposure in the population need to focus on maize consumption in particular and educating communities that are main consumers of maize beer/products.

Introduction

Maize is a staple food in many African countries. In these countries, it is also used in the making of traditional maize beer. In the process of traditional beer making, the maize is fermented, cooked and fermented again. After the second fermentation, the product is sieved to produce a thick opaque liquid containing solid suspensions. In South Africa, mainly those with low socio-economic standards consume this type of beer because it is readily available and cost effective. Beer is the most thirst-quenching beverage at the end of a hard-working day or during festive seasons, yet it is associated with detrimental effects in most cases. Evolution of beer brewing dates back some thousand years during which there was poor sanitation in contrast to modern times. But during those days, there were few illnesses as compared to modern life, may be this can be attributed to other factors rather than beer drinking.

Fumonisins are a group of mycotoxins produced primarily by *Fusarium moniliforme*. *Fusarium* is a family of fungi that grow freely in maize (Isaacson, 2005). The occurrence of these organisms in maize is dependent on environmental factors and the storage of maize, for example, *Fusarium* grows maximally when the moisture content of the harvested corn is between 18% and 23% (Musser and Plattner, 1997). This shows that the way traditional maize beer is prepared, which involves double fermentation process, favors the growth of the *Fusarium* species. *Fusarium* produces a wide range of mycotoxins (about 28 types) called fumonisins,

fumonisin B_1 (FB_1) being the most prevalent in contaminated corn and the most toxic one (Musser and Plattner, 1997). This is a world problem; it does not only affect third world countries but also first world counties like Italy (Francheschi *et al.*, 1990). Unfortunately this fungus is associated with cancer predisposition in both Africa, where maize is used on a daily basis, and the rest of the world. These mycotoxins have been linked to carcinogenesis as exemplified by FB_1 produced by another species of the genus *Fusarium*, that is *F. verticilloides*. This toxin increases the risk of developing esophageal cancer. Beer drinking may not be a problem but contaminated maize that the beer is made from is being the bearer of the problem. Other crops like a hop plant have been documented to have a protective ability against different cancers (Miranda *et al.*, 1999; Chen and Lin, 2004). This does not mean that drinking beer from hops is completely safe because it also contains carcinogenic metabolites like acetaldehyde that has been documented to be responsible for promoting tumor growth (Salaspuro, 2003) (Figure 66.1).

FB_1, FB_2 and FB_3 are the ones present in naturally contaminated foods, with B_1 being the most toxic of the three. The toxicity of FB_1 is through inhibition of ceramide synthase that catalyzes the formation of dihydroceramide from sphingosine. This mechanism of action leads to antiapoptotic effects resulting to a variety of pathologies observed when this mycotoxin is consumed and backed by a high rate of human esophageal cancer and promotion of primary liver cancer (Figure 66.2) (Soriano *et al.*, 2005).

Fumonisins are also known to produce reactive nitrogen species (RNS). It has been reported that free radicals such as reactive oxygen species (ROS) and reactive nitrogen species (RNS), which induce oxidative and nitrative stress, are main contributors to oral carcinogenesis. The RNS (nitrosamines: nitrates and nitrites) are also produced by the reaction of ROS and other free radicals with nitric oxide (NO). The increase in ROS and RNS leads to the oxidative damage of the DNA and proteins, and possibly the promotion of esophageal squamous cell carcinoma. The oxidized proteins and DNA is a direct link between free radicals, antioxidants and esophageal squamous cell carcinoma (Bahar *et al.*, 2006) (Figure 66.3).

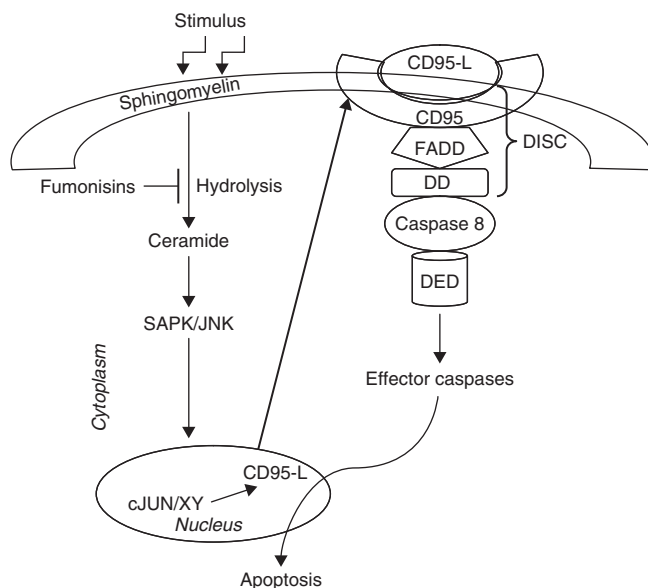
Aflatoxins are another family of fungal toxins that are carcinogenic to man and cause immunosuppression and growth reduction in animals. The consumption of maize is an important source of aflatoxin exposure. Higher AF-alb adducts have been correlated with higher *A. flavus* (CFU) infestation of maize (p = 0.006), higher aflatoxin contamination (ppb) of maize (p < 0.0001) and higher consumption frequencies of maize (p = 0.053) (Egal *et al.*, 2005).


Figure 66.2 The effects of fumonisins on the apoptotic machinery. FB_1 inhibits the activity of sphingosine *N*-acyltransferase (ceramide synthase) and this reduces the conversion of [3H]sphingosine to [3H]ceramide. This inhibits the ceramide apoptotic pathway and this inhibition promotes cell growth and carcinogenesis.

Figure 66.1 General effects of beer consumption. Alcohol metabolite, acetaldehyde, causes mutations in tumor suppressors and oncogenes by inducing replication errors and mutations and also aggravates the situation by interfering with the DNA repair mechanism to damage caused by alkylating agents. An example of predisposition to cancer development due to resultant mutation is the formation of K-Ras mutation where there may be either G to A transition or G to T transversion.

Figure 66.3 The effects of RNS resulting from fumonisins contaminated maize. Fumonisins reduce nitrates that are prevalent in the maize like in the vegetables, to nitrite that in turn form nitrosating agents in the stomach and form nitrosamines. High levels of nitrosamines induce tumor formation.

Interactions between hepatitis B virus (HBV) infection and exposure to aflatoxins have been linked to the development of hepatocellular carcinoma (HCC). Aflatoxins and HBV are major risk factors for HCC in high incidence areas for this cancer, namely South East Asia and parts of Africa. There is evidence from both epidemiological studies and animal models that the two factors can act synergistically to increase the risk of HCC (Sylla *et al.*, 1999). Aflatoxin contamination has been linked to mutation in a p53, a tumor suppressor gene responsible for cell cycle regulation. In several cancers, the distribution of mutation types and sites follow a specific pattern reflecting the effects of environmental mutagens. An example for such a "mutagen fingerprint" is p53 mutation at codon 249 in HCC in regions of the world characterized by high levels of the mutagen aflatoxin B_1 and endemic HBV infection (Le Roux *et al.*, 2005). Chronic infection with the HBV and exposure to aflatoxins in foodstuff are the main risk factors. A G to T transversion at codon 249 of the p53 gene {249(ser)} is commonly found in HCCs from patients in regions with dietary aflatoxins exposure (Stern *et al.*, 2001) (Figure 66.4).

Maize meal has also been reported to predispose to prevalent squamous cancer of the esophagus in Africa: The breakdown of esterified linoleic acid to the free form in stored meal leads to increased intragastric prostaglandin E2 (PGE2) production and a low-acid reflux. It has been reported that prevalent esophageal cancer in Africa is associated with the use of maize meal as a staple food and it is also used in making beer. This cancer has been shown to have a strong statistical association with the intake of foods based on maize in the meal form. The prevalence of esophageal cancer and association with the consumption of maize meal have also been shown in a region of Italy. An important factor is the breakdown of esterified linoleic acid to the free form in stored maize meal.

And this leads to excess production of PGE2 in the stomach. The excess of PGE2 is a basis for a low-acid duodenogastroesophageal reflux and that predisposes to tumorigenesis (Sammon and Iputo, 2006) (Figure 66.5).

The carcinogenic effects of fumonisins, aflatoxins and PGE2 are summarized in Table 66.1.

Health measures including poverty alleviation, health education, monitoring and control of maize meal storage and content may be required to reduce the incidence of this disease in Africa and worldwide. Intervention strategies that aim to reduce dietary exposure in the population need to focus on maize consumption in particular. Specific hepatitis virus B (HBV), hepatitis virus C (HCV) and aflatoxins biomarkers reveal the complexity of risks contributing to HCC and suggest further application of these biomarkers as intermediate end points in prevention, intervention trials and etiologic investigations. It should be remembered that alcohol works synergistically with smoking in cancer predisposition as is supported by many previous studies (Dlamini and Bhoola, 2005).

Maize Beer and Esophageal Cancer

Esophageal cancer is the sixth most common cancer in the world and the second most common in Black South African men (Dlamini and Bhoola, 2005). Esophageal cancer is caused by several factors: genetic (Wu *et al.*, 1979), lifestyle (like smoking) and socio-economic status (Craddock, 1992; Shepard *et al.*, 2005).

The content of fumonisins in the maize beer ranges between 43 and 1,329 ng/ml (Shepard *et al.*, 2005), and the FB_1 being the major analog. Regular drinkers take between 1,050 and 4,130 ml/day of the traditional beer. When these

Figure 66.4 The effects of aflatoxin contamination and HBV co-infection. The tumor suppressor protein p53 mediates cell cycle arrest, DNA repair and apoptosis when stimulated by different forms of cellular stresses. When activated, this "master protein" modulates its response depending on the type and intensity of the stress. When this master regulator is inactivated by possible effects of aflatoxins or hepatitis virus infection, the consequences are increased cell proliferation and tumor formation.

Figure 66.5 Effects of free linoleic acid from maize meal used for brewing maize beer. Free linoleic acids found in maize meal result in excess production of PGE2, lead to the decrease of the Bax/Bcl2 ratio resulting in the inhibition of the intrinsic apoptotic pathway, and this result in cancer.

Table 66.1 Predisposition to cancer due to maize contamination

Maize contaminant	Mode of action	Effect/s
Fumonisins	1. Reduce nitrates to reactive nitrogen species (nitrosamines) 2. Inhibit ceramide synthase	DNA damage and cancer predisposition Inhibition of ceramide apoptotic pathway leading to cell proliferation and carcinogenesis
Aflatoxins	p53 inactivation by mutations mostly at codon 249	p53 mutations lead to deregulation in the apoptotic machinery, cell cycle leading to tumorigenesis
Increased free linoleic acid in maize meal (used for making maize beer)	Leads to decrease in the Bax/Bcl2 ratio	Increased Bcl2 anti-apoptotic gene products lead to decrease in apoptosis and increased cell proliferation resulting in cancer formation

Note: Summary of effects of maize contaminants (aflatoxins, fumonisins) and increased levels of prostaglandins in maize meal used in maize beer brewing.

are translated into FB_1 consumption, the per capita exposure is between 6.5 and 25.4 µg/kg b.w./day, which is way above the recommended exposure limit of 2 µg/kg b.w./day set by the Food and Agriculture Organization (Shepard *et al.*, 2005).

Fumonisins present a threat in both human and animal health. In humans, these mycotoxins have been implicated in esophageal cancer (Nikander *et al.*, 1991; Rheeder *et al.*, 1992; Shepard *et al.*, 2005). The prevalence of esophageal cancer coincides with maize beer consumption in South Africa (Shepard *et al.*, 2005) and Tanzania (Nikander *et al.*, 1991). These mycotoxins reduce nitrate to nitrite, which leads to the synthesis of the carcinogenic nitrosamines (Isaacson, 2005). Nitrosamines are present in cigarette and alcoholic beverages including maize beer, hence cigarette smoking is always implicated in cancer development. *N*-nitrosamines have been reported to induce tumors of the esophagus (Myburg *et al.*, 2002) (Figure 66.3).

Fumonisins are also the causative agents of leukophalomacia in horses and pulmonary edema in pigs (Harrison *et al.*, 1990). In rats, fumonisins have been reported to cause lesions on the liver and esophageal cancer (Gelderblom *et al.*, 2001). Comparative toxicity studies of the *Fusarium* in different animal species showed that the major target organs differ in each species (Kriek *et al.*, 1981).

Predisposition to esophageal carcinoma is also linked to the form in which maize is consumed, for example, maize meal. Maize is milled before it can be used in a beer making process. In this form the esterified linoleic acid is broken down into free form. In the stomach freed linoleic acid promotes the excess production of PGE2, a proinflammatory bioactive lipid (Sammon and Iputo, 2006). Too much PGE2 predisposes the esophagus and the stomach to carcinogenesis. Downregulation of PGE2 is associated to an increased inhibition of cell growth and increased apoptosis in cancer cells (Lev-Ari *et al.*, 2006). Apoptosis inhibition in the body is a major cause of cancer development.

Any substance that alters the apoptotic gene expression will cause carcinogenesis.

Free linoleic acid is responsible for cancer predisposition of the esophagus and the stomach. This contrasts the effect of conjugated linoleic acids have. These have been reported to possess an anticarcinogenic effect (Park *et al.*, 2004). These linoleic acids exert this by decreasing the levels of PGE2 produced. Free linoleic acid has been implicated in the progression of breast cancer cell solid tumors in athymic nude mice through excess PGE2 production (Connolly *et al.*, 1999). PGE2 plays a key role in carcinogenesis by modulating different pathways like apoptosis induced by tumor necrosis-alpha (Nishimura *et al.*, 2006), mitochondrial apoptotic pathway through alteration of Bax/Bcl2 ratio to favor apoptosis (Park *et al.*, 2004) and interaction with prostaglandin dehydrogenase, PGDH (Mann *et al.*, 2006) (Figure 66.5).

Maize Beer and Kaposi's Sarcoma

Kaposi's sarcoma is a mesenchymal tumor associated with human herpes virus-8 (HHV-8) infection. Given the association between consumption of traditional maize beer and high serum ferritin, iron concentration, the association between Kaposi's sarcoma and maize beer consumption has been reported. The association between maize traditional beer and the development of Kaposi's sarcoma has been reported in East and Central Africa (Ziegler *et al.*, 2001). In South Africans, the association was also found, but it was marginal (Wojcicki *et al.*, 2003). The association can be explained by high concentration of ionized, bioavailable iron as a result of being brewed and fermented in iron-clad pots. The concentration of iron in traditional beer prepared in iron-clad pots is about 82 mg/l (Goedert *et al.*, 2002).

The pathogenic role of iron in cancer development and/or progression has been documented. Several pathways leading to cancer development that involve iron have been

described (Reichard and Ehrenberg, 1983; Cazzola *et al.*, 1990; Weinberg, 1996).

Iron and cell division

Iron is an essential element for dividing cells. It is involved in the incorporation of the enzymes that play a role in cellular metabolism. Iron also directly promotes the growth of some cancer cells by facilitating the reduction of ribonucleotides to deoxyribonucleotides (Cazzola *et al.*, 1990).

Iron and mutagenic hydroxyl radicals

Iron may promote the formation of mutagenic hydroxyl radicals (Weinberg, 1996). In humans excess iron has harmful consequences. Excess iron also accelerates oxidative catabolism of ascorbic acid (vitamin C), leading to deficiency of this vitamin (Kasvosve *et al.*, 2000). Vitamin C provides antioxidant protection because it is a free radical scavenger. In the presence of excess iron, vitamin C has a pro-oxidant activity. Iron gets trapped within ferritin as Fe^{3+} and enters the pores of the ferritin where it is converted to Fe^{2+}; vitamin C becomes oxidized in the process. Fe^{2+} then leaks out of the ferritin protein and generates free radicals (Delanghe *et al.*, 1998).

Iron and CD4 activity inhibition

Iron excess diminishes host defenses through inhibition of the activity of CD4 lymphocytes and through the suppression of the tumoricidal action of macrophages (Weinberg, 1996). During iron overload, excess iron is stored in parenchymal cells and macrophages, which interferes with $CD4^+$ proper functioning (Weinberg, 1996).

Iron and viral nucleic acid production by host cell

Iron can enhance the production of viral nucleic acids by the host (Boelaert *et al.*, 1996). The process involves free radicals and the activation of NF-κB (Gaynor, 1992). This may lead to development of Kaposi sarcoma, which is caused by HHV-8 (Wojcicki *et al.*, 2003).

Maize and Liver Carcinoma

Maize seems to be the target of fungal contaminations that consequently results in accumulation of aflatoxins, for example, aflatoxin B_1 (AB_1). Many staple food crops (maize, rice and wheat) are contaminated by *Aspergillus* molds that produce aflatoxin B_1. This toxin has been linked to prevalence of primary liver cancer in the Eastern Cape region of South Africa (van Rensburg *et al.*, 1990). Apparently this region uses maize as its staple food crop. Aflatoxins have been characterized

as one of the major risk factors of HCC (Hsia *et al.*, 1992; Wild *et al.*, 1993; Sylla *et al.*, 1999; Turner *et al.*, 2002). These studies suggest that maize beer drinking predisposes to liver cancer due to the maize contamination by aflatoxins.

Consumption of food contaminated with aflatoxins B_1 is enough to promote carcinogenic phenotypes. Different reports from different regions have highlighted the effects these aflatoxins have on carcinogenesis. It is probably not only due to aflatoxins consumption because these cases also have HBV and HCV infections. It is apparent that aflatoxins, HBV and HCV affect p53 cell death regulation, apoptotic modulation through mutation formation. Association of these mutations with aflatoxins and hepatitis virus accumulation suggests their involvement in hepatic carcinogenesis through p53 inactivation. Tumor suppressor, p53, mediates cell cycle arrest, DNA repair and apoptosis in response to different cellular stresses (Le Roux *et al.*, 2005). A common mutation that is found in p53 worldwide in HCC is at codon 249. This mutation may be the bases of pathogenesis caused by aflatoxins and hepatitis viruses. In China (Stern *et al.*, 2001) and India (Katiyar *et al.*, 2000), this type of mutation has been reported in HCC and also other parts of the world. This strongly points to p53 mutation involvement in HCC pathogenesis (Figure 66.5).

Summary Points

- Consumption of maize in the form of home brewed beer has major health risks associated with it.
- The health risks are associated with mainly the effects of mycotoxins associated with maize used in making home brewed maize beer in most low socio-economic populations.
- Mycotoxins that are culprits include both fumonisins and aflatoxins and these are linked to the pathogenesis of cancers that are prevalent in countries where maize is a staple diet and its storage leaves much to be desired.
- According to our knowledge in low socio-economic communities stored rotting maize is not discarded but is mainly used in making home brewed beer. This rotting maize is highly contaminated with mycotoxins that have a predisposition to cancer especially esophageal squamous cell carcinoma and liver cancer.
- Fumonisins are involved in generating RNS that are involved in DNA damage and mutations involving the tumor suppressors.
- The aflatoxins contaminated beer consumption and co-infection with HBV lead to liver cancer. HBV and aflatoxins are said to work synergistically in predisposition to liver cancer. The contamination with aflatoxins is associated with mutation in codon 249 of p53 tumor suppressor protein that is involved in cell cycle regulation.
- Grinding of maize corn to maize meal powder form (milling) that is used in home brewed beer making is also detrimental to human health. The process converts

esterified linoleic acid to a free form which leads to the accumulation of PGE2 that is implicated in carcinogenesis especially esophageal squamous cell carcinoma. This is attributed to the increased Bcl2 to Bax ratio leading to antiapoptotic effects.

- Storage of maize meal should be done in a way that inhibits its contamination with mycotoxins. The public should be encouraged to avoid making maize as staple food and also avoid, or at least limit, the consumption of maize beer. It can be a challenge to do this in poverty stricken third world countries that mainly depend on maize related foods for their survival.

The Relationship Between Beer Consumption and Lung Cancer

Douglas E. Paull and Alex G. Little Department of Surgery, Boonshoft School of Medicine, Wright State University, Dayton, OH, USA

Abstract

The study of beer consumption and the risk of lung cancer is complicated by the fact that beer drinkers have increased rates of cigarette smoking. Nonetheless, roughly one-half of all the retrospective case control and prospective cohort studies performed, in which the confounding effects of cigarette smoking have been carefully adjusted for, demonstrate a significant increase in the risk of the development of lung cancer among beer drinkers compared to non-drinkers. The increased risk is relatively moderate, odds ratio/relative risks between 1.3 and 2. The increased risk of lung cancer is most often limited to the heaviest beer consumers. Similar increases in lung cancer risk are demonstrated for consumers of hard liquor (whiskey, vodka, "spirits"). Moderate consumption of red wine clearly decreases the risk of lung cancer. Alcohol consumption is associated with worse outcomes among patients with established lung cancer. Data regarding lung cancer treatment outcomes and specific beer consumption are not available. Heavy alcohol consumption leads to more postoperative complications, primarily respiratory and infectious, among patients undergoing resection for early stage lung cancer. Further, heavy alcohol consumption correlates with less response to chemotherapy and worse survival in patients treated for advanced lung cancer. There are a number of molecular mechanisms that account for the increased risk of lung cancer among alcohol and beer consumers and the poor outcomes among alcohol consumers with lung cancer.

Abbreviations/Definitions

AWS – Alcohol withdrawal syndrome. Syndrome consisting of tremor; elevated pulse, respiratory rate, and temperature; insomnia; anxiety; and seizures associated with a sudden decrease in alcohol intake in an alcoholic patient.

Case control study. Unlike prospective cohort studies, case control studies are done after the fact. Patients who experienced an outcome (the *cases*) (e.g. lung cancer) are identified and then the number exposed to some risk factor (e.g. alcohol abuse) are counted. The *controls* are patients similar in relevant ways to the cases, but who did not experience the outcome (e.g. do not have lung cancer). The number of *controls* exposed to the risk factor can be counted and compared to the *case* group.

CI – Confidence interval. The probability that the *true* average, as opposed to the *observed* average, of a population is within the given limits. For example, if the *observed* mean age of a population is reported as 62 years (95% CI 58–64) then there is a 95% probability that the *true* mean age for the population lies between 58 and 64 years. The larger the population studied, the more powerful the study, and the more "narrow" the CI becomes for any given observation.

Cohort, prospective study. Two groups of patients, similar in most aspects except for some risk factor (e.g. alcohol usage) are followed over time for the development of a disease (e.g. lung cancer). The number of patients developing the disease are counted and compared among the two groups who differ only in exposure to the risk factor. Note the difference between this type of study and a case control study.

ECOG – Eastern Cooperative Oncology Group.

HR – Hazard ratio. Suppose we are comparing survival rates of lung cancer among alcohol abusers and non-abusers. Let us say that alcohol abusers are dying at twice the rate than non-abusers. The HR for alcohol abuse would be 2.0. The *HR* can be calculated for any given variable (e.g. alcohol abuse (yes/no), age, etc.). For every unit increase in the value of the variable studied, the risk of the event (in this case, death) changes by a factor equal to the *HR*.

Multivariate analysis. A more advanced statistical analysis that permits looking at variables all together rather than just one at a time. Let us consider the example of the dependent variable/outcome of respiratory failure following resection of lung cancer. Independent variables which might be associated with such an outcome include preoperative pulmonary function tests such as the forced expiratory volume in 1 s (FEV1) measured in liters, pack year smoking history (pack years), and/or alcohol abuse (drinks/day). This could be described in an equation as follows during a multivariate analysis:

$$\text{Respiratory failure} = (-2.0)\,\text{FEV1} + (1.2)\,\text{pack years} + (2.3)\,\text{drinks/day}.$$

The coefficients in the equation state that any unit increase in the independent variable (e.g. increase of 1 pack year of smoking) results in an increase in the mean value of the respiratory failure by a factor equal to the coefficient (e.g. 1.2 units for each increase in 1 pack year). In the example given, a larger preoperative FEV1 is associated with less respiratory failure following resection (negative coefficient), whereas an increase in preoperative smoking or drinking is associated with an increase in postoperative respiratory failure (positive coefficients).

NSCLC – Non-small cell lung cancer. Histologic type of lung cancer. Vast majority of lung cancer consists of NSCLC. Small cell lung cancer makes up the smaller remainder of cases. Treatment strategies are different for non-small cell and small cell lung cancer. There are a number of histologic sub-types making up NSCLC including: adenocarcinoma, squamous cell carcinoma, and large cell carcinoma.

NK cells – Natural killer cells. Lymphocytes, white blood cells, which attack and kill malignant cells in the body.

OR – Odds ratio. Used in comparing data from case control studies. The OR is the odds of exposure in cases/ odds of exposure in controls. For example, in a case control study involving alcohol abuse and lung cancer, the following data were obtained:

Group	Lung cancer	No lung cancer
Alcohol abusers	10	90
Non-abusers	5	95
Total	15	185

Odds of alcohol abuse among *cases* (patients with lung cancer) = (10/15)/(5/15) = 2.0.

Odds of alcohol abuse among controls (patients without lung cancer) = (90/185)/(95/185) = 1.0.

The *OR* would be 2.0/1.0 = 2.0.

In this study, patients with lung cancer were twice as likely to be alcohol abusers compared to patients without lung cancer, suggesting a relationship between alcohol abuse and the development of lung cancer.

p-value. The probability of obtaining a value of the test statistic as large or larger than the one computed from the data when in reality there is no difference between the two groups. For example, a study shows that the 5-year-survival rate was 30% for alcohol abusing patients with lung cancer and 60% for non-abusing patients, with a p-value of <0.05. The question is whether the observed survival differences between the two groups of patients are *real*, or simply due to the *random* variation associated with placing patients in one of the two groups. The smaller the p-value the more likely the differences are real. By convention, a p-value < 0.05 is considered statistically significant. In the study example above, there is less than a 5% chance that the observed differences in survival rates were simply

random events, and one would conclude that alcohol abuse was associated with worse survival among patients with lung cancer.

RR – Relative risk. The *RR* is similar to the OR. Whereas the OR is used for case control studies, the *RR* is utilized in cohort, prospective studies. The probability of an event (e.g. lung cancer) among people exposed to a risk factor (e.g. alcohol abuse) is compared to people who are not exposed to the risk factor (e.g. non-abusers). The data from such a hypothetical study are shown below:

Group	Lung cancer	No lung cancer	Total
Alcohol abuse	20	180	200
No alcohol abuse	5	195	200
Total	25	375	

The *RR* would be (20/200)/(5/200) = 4.0.

In this hypothetical study, alcohol abuse was associated with a 4 times greater chance of developing lung cancer.

Introduction

The purpose of this chapter is to examine the effects of alcohol-containing beverages, including beer, upon the epidemiology and treatment of lung cancer. Specifically, we hope to demonstrate that beer consumption: (1) increases the incidence of lung cancer and (2) leads to worse outcomes in the treatment of lung cancer.

For the purposes of this chapter, "alcohol," "total alcohol," and "overall alcohol" consumption refer to ingestion of any alcohol-containing beverage including beer, hard liquor, wine, or combination thereof. Consumption is converted into a universal unit since an individual may drink more than one type of alcohol-containing beverage. For example, in a given study, a patient drinking one glass of hard liquor and four cans of beer per day has a total alcohol consumption of five "drinks per day." Other studies have reported total alcohol consumption in grams/day, ounces/day, "whiskey equivalents"/day, and a variety of other units. "Hard liquor" consumption refers to ingestion of whiskey, vodka, or "spirits." Studies may variably report data for only total alcohol consumption, only specific beverage consumption (e.g. beer, wine, hard liquor), or both total alcohol and specific beverage consumption.

In reporting the risk associated with alcohol consumption and lung cancer, retrospective case control studies will report an odds ratio (OR), odds of exposure to alcohol in lung cancer patients (cases)/odds of exposure in patients without lung cancer (controls), while prospective cohort studies report a relative risk (RR), probability of lung cancer in patients drinking alcohol/probability of lung cancer in non-drinking patients (Glantz, 2005). These ratios

are derived by comparing the incidence of lung cancer at a given drinking level with the incidence of lung cancer among non-drinkers or to the lowest drinking level.

Lung cancer represents the most common cause of cancer death in most Western countries (Ahrendt *et al.*, 2000). The most important risk factor is cigarette smoking which accounts for over 90% of all lung cancer (Woodson *et al.*, 1999). Nonetheless, there is accumulating evidence suggesting a relationship between alcohol consumption, particularly beer or liquor, and the development of lung cancer, even when the confounding variable of cigarette smoking is carefully adjusted for. The relationship between alcohol use and the development of lung cancer is complicated by the fact that alcohol drinkers have different lifestyles than non-drinkers. Alcohol drinkers are more likely to be cigarette smokers, eat less fruits and vegetables, consume less vitamin A and folate, and have lower socioeconomic status than non-drinkers (Bandera *et al.*, 1992, 2001; Hu *et al.*, 2002; Benedetti *et al.*, 2006). Each of these co-variables is associated with a higher incidence of lung cancer. Even if alcohol consumption were not independently associated with the development of lung cancer, its modulation of other risk factors such as smoking and lifestyle would have important implications in the prevention of lung cancer.

Alcohol is not considered a carcinogen, but rather a promoter or co-carcinogen. Alcohol has been postulated to induce lung cancer by a number of molecular mechanisms. Acetaldehyde, the primary metabolite of alcohol, impairs DNA repair. Alcohol induces free radicals which cause cell membrane damage. Alcohol, via the cytochrome P450 system, alters the liver's metabolism of carcinogens, such as benzopyrenes, in cigarette smoke. The consumption of alcohol is associated with dietary deficiencies which lead to immunosuppression, impaired immunosurveillance, and the development of cancer. Finally, other substances contained within the alcohol beverages are carcinogenic, including asbestos, aromatic hydrocarbons, and pesticide residues (Bandera *et al.*, 2001). The relevant exposure period of alcohol in the development of lung cancer is different than for cigarette smoking. Lung cancer risk is closely associated with cigarette smoking levels 15 years prior to lung cancer mortality whereas recent alcohol consumption is more closely associated with lung cancer risk, again emphasizing smoking as a carcinogen, and alcohol as a promoter (Potter and McMichael, 1984). Alcohol use has been associated with p53 mutations in human lung cancer (Ahrendt *et al.*, 2000). The tumor suppressor protein p53 is the most commonly mutated gene in human cancers, including lung cancer. Gene expression profile analysis of lung cancer specimens has shown that alcohol drinkers have higher p53 mutation rates than non-drinkers. The results are not explained by cigarette smoking. Alcohol drinkers, who are non-smokers, have more frequent p53 mutations than non-drinkers.

The most conservative epidemiologic view is that any relationship between alcohol use and lung cancer is either explained by the confounding effects of cigarette smoking in non-adjusted studies, or by residual confounding even in those studies carefully adjusting for cigarette smoking (Carpenter *et al.*, 1998; Woodson *et al.*, 1999; Bandera *et al.*, 2001; Djousse *et al.*, 2002). However, on balance, there seems to be a relationship between alcohol consumption and the incidence of lung cancer after careful adjustment for cigarette smoking and other covariates. In those studies supporting a relationship, heavy alcohol consumption is most closely associated with an increased risk of lung cancer (Prescott *et al.*, 1999).

Total Alcohol Consumption and the Risk of Lung Cancer

Overview

Several collective reviews and meta-analyses regarding alcohol consumption and lung cancer have been published. Potter and McMichael were the first to emphasize the relationship between alcohol use and lung cancer risk (Potter and McMichael, 1984). Eight out of ten prospective studies they reviewed demonstrated that high alcohol consumers and alcoholics were at greater risk for lung cancer, even after adjustment for levels of cigarette smoking. Bandera reviewed eight case control and nine prospective cohort studies (Bandera *et al.*, 2001). Four of eight case control studies demonstrated a positive relationship between alcohol consumption and lung cancer risk. The results from cohort studies were inconsistent, and in those studies where a positive correlation was demonstrated, it was generally limited to higher levels of alcohol consumption. In the two studies of never smokers, one study demonstrated a positive relationship between alcohol consumption and lung cancer risk. Overall, it was concluded that the cumulative evidence suggested a relation between alcohol use and lung cancer. Similarly, another meta-analysis of 7 prospective studies and 3,137 lung cancer patients using pooled, adjusted RR demonstrated an association between lung cancer and alcohol use in never-smoking men (Freudenheim *et al.*, 2005).

Studies favoring a relationship between *total alcohol consumption* and lung cancer risk

A number of studies suggest a relationship between alcohol use and lung cancer (Table 67.1). Pollack investigated a cohort of 7,837 males of whom 89 developed lung cancer as part of the Honolulu Heart Study (Pollack *et al.*, 1984). A dose response was demonstrated between increasing alcohol consumption and increasing risk of lung cancer, even when adjusted for age and smoking. The adjusted incidence of lung cancer for those drinking ≥40 oz./month of alcohol was 130/100,000 person years as compared to 70/100,000 for non-drinkers. Interestingly, patients in this

Table 67.1 Results of studies of *total alcohol consumption* and the risk of lung cancer[a]

Study (year)[b]	Location	Number of lung cancer cases	Adjusted RR or OR of lung cancer	95% CI
Woodson (1999)	Finland	1,059	1.0	0.8–1.1
Bandera (1992)	New York	280	1.60	1.0–2.5
Benedetti (2006)	Canada	699	1.5	1.0–2.10
Hu (2002)	Canada	161	0.8	0.5–1.2
Potter (1984)	Hawaii	89	1.86	n/a
Carpenter (1998)	Los Angeles	261	0.68	0.33–1.41

Notes: All results reported are adjusted for smoking. In addition, studies variably adjusted for age, sex, race, education, body mass index, income, dietary intake of fruits and vegetables, dietary fat, exposure to environmental smoke, and/or family history of lung cancer. Adjusted RR (prospective cohort studies) or OR (retrospective case control studies) reported compares highest risk drinking level to either lowest risk drinking level or to non-drinkers. Table reflects highest value of adjusted RR or OR reported from study whether among men and women combined, men only, or women only.

n/a: not available/reported.
[a] *Total alcohol consumption* refers to the ingestion of any combination of alcohol-containing beverages including beer, wine, and hard liquor.
[b] Studies listed in order in which they appear in text of chapter. Every study cited in the text in which an OR or RR is reported for total alcohol consumption and lung cancer risk is listed in table.

study were light drinkers, suggesting that heavy consumption was not a prerequisite for increased lung cancer risk. Nonetheless, even in this carefully performed study, the authors warn of residual confounding from cigarette smoking. In a series of three prospective studies from Denmark involving 28,160 men and women, heavy alcohol consumption (≥41 drinks/week) was correlated with increased lung cancer risk, RR =1.57 (95% confidence interval (CI) 1.06–2.33, p = 0.002, adjusted for age, smoking, and education) (Prescott *et al.*, 1999).

In a case control study of 280 white male lung cancer patients and 564 controls, as part of the Western New York Diet Study, Bandera reported an OR of 1.6 (CI 1.0–2.5, p = 0.03, adjusted for age, education, and dietary intake of carotenoids and fat) among consumers of >22 drinks/month vs. those taking in 0–1 drinks/month (Bandera *et al.*, 1992). This relationship was limited to patients smoking ≥41 pack years.

Studies that do not favor a relationship between *total alcohol consumption* and lung cancer risk

Several prospective studies have failed to demonstrate a correlation between alcohol consumption and lung cancer risk. As part of the Alpha-Tocopherol Beta-Carotene Cancer Prevention Study in Finland, 1,059 lung cancer patients among 27,111 male smokers were studied (Woodson *et al.*, 1999). They found no association between total alcohol consumption and lung cancer in a regression model adjusted for

age, smoking, and intervention. In the Japan Collaborative Study for the Evaluation of Cancer Risk, a cohort study of 28,536 Japanese males including 377 lung cancer deaths, there was no association of increased mortality from lung cancer for light (<25 g/day), moderate (25–49.9 g/day), or heavy drinking (≥50 g/day) (Nishino *et al.*, 2006). Data from the Framingham Study and the Framingham Offspring Study including 9,238 participants and 269 cases of observed lung cancer, demonstrated similar overall findings (Djousse *et al.*, 2002). Although in crude analysis increasing alcohol consumption correlated strongly with an increasing incidence of lung cancer; these differences disappeared once adjusted for smoking. However, 89% of patients in that study drank <3 drinks per day, and therefore the influence of heavy alcohol use and lung cancer risk could not be fully evaluated. Interestingly, in the Offspring cohort, drinking >24 g/day was associated with an increased risk of lung cancer (RR = 2.0, CI 0.7–5.7, adjusted for age, sex, and smoking status).

A number of case control studies have demonstrated no relationship between alcohol use and lung cancer risk (Zang *et al.*, 2001; Freudenheim *et al.*, 2003). A study of 261 lung cancer patients and 615 population-based controls in Los Angeles County, found no association between total alcohol intake and lung cancer risk (Carpenter *et al.*, 1998). Pack years smoking was closely associated with the level of alcohol consumption. The number of pack years smoking was highest for those with highest alcohol consumption, again emphasizing the importance of residual confounding by cigarette use. In a study of males in

Uruguay involving 160 patients with adenocarcinoma of the lung and 520 hospitalized controls, there was an OR of 2.4 (CI 1.4–4.2, p < 0.001) for the risk of lung cancer in the crude analysis comparing the highest quartile of alcohol use to the lowest quartile of alcohol use (DeStefani et al., 2002). However, after adjustment for smoking, the effect was lost. The authors demonstrated that the greater care used to adjust for levels of smoking (pack years, current smoker, years since quitting, age started smoking) the less the effect of alcohol use upon the risk of lung cancer. The National Enhanced Cancer Surveillance System studied Canadian women who never smoked (Hu et al., 2002). There were 161 patients with lung cancer compared to 483 population-based controls matched for age and residence. Lung cancer patients had lower education level, income, and social class compared to controls. After adjustment for covariates, there was no association of total alcohol consumption and lung cancer risk.

Other aspects of *total alcohol consumption* and lung cancer risk

A case control study from the MD Anderson Cancer Center of 470 lung cancer patients and 472 population-based controls demonstrated a significant reduction of lung cancer risk among alcohol drinkers with increasing dietary folate consumption (OR = 0.48, CI 0.28–0.82, p = 0.002, highest vs. lowest quartile folate consumption, adjusted for age, sex, ethnicity, total energy intake, body mass index, family history of lung cancer, and pack years smoking) (Shen et al., 2003). These results support the hypothesis that the increased risk of lung cancer seen among alcohol consumers may be at least partly due to folate deficiency, and that the increased risk may be ameliorated by folate supplementation.

Among patients undergoing liver transplantation, Jimenez reported a higher incidence of lung cancer among alcoholic patients than among non-alcoholic patients (4.3% vs. 0.7%, p < 0.001) (Jimenez et al., 2005). The association, however, was largely attributed to heavy cigarette smoking among the alcoholic group. Alcoholic transplant recipients who developed lung cancer had uniformly advanced disease on presentation, and all died despite treatment with a mean survival of only 5.3 months. Such studies, as well as our own to be discussed later, suggest that not only does total alcohol consumption lead to an increased incidence of lung cancer, but that such consumption also leads to worse survival in patients with lung cancer.

Summary: *total alcohol consumption* and lung cancer risk

There are data from carefully performed prospective and case control studies, adjusting for cigarette smoking, to suggest that alcohol use is associated with an increased incidence of lung cancer. Taking into account the studies that fail to show this causative relationship, a reasonable conclusion is that the association between alcohol use and lung cancer risk is not great, and the effect is most evident among heavy alcohol users and abusers rather than mild to moderate users. Any association between alcohol use and lung cancer is weaker than that confirmed between alcohol use and, for example, oral cancers. The RR for oral cancer among alcohol users even after adjustment for smoking is much higher (RR = 8.8, CI 5.4–14.3, among males drinking ≥30 drinks/week vs. ≤1 drink/week, adjusted for smoking, age, race, study location, and respondent status) (Blot et al., 1988).

Although the independent effect of alcohol consumption upon the risk of lung cancer is relatively small, alcohol consumption is associated with lifestyles that are associated with lung cancer development. Efforts to curb alcohol consumption would be expected to favorably affect such additional behaviors and indirectly decrease lung cancer incidence. In the Working Well Trial in Washington State, a cohort study of 6,867 participants, a dose response between smoking and drinking alcohol was demonstrated (McClure et al., 2002). Baseline drinking level was the best predictor of the ability of an individual to quit smoking at a 4-year follow-up. These results demonstrate that efforts to curb alcohol drinking will lead to less cigarette smoking, and ultimately reduce lung cancer risk.

Beer Consumption and the Risk of Lung Cancer

Overview

Geography is important in investigation of specific alcohol-containing beverages and the incidence of lung cancer. Individuals of different cultures and regions in the world vary in which beverage is most popular. For example, beer, the most common alcoholic drink in the United States, has frequently been associated with an increased risk of lung cancer in US studies (Bandera et al., 2001). In these studies, the number of individuals drinking other beverages, such as wine, is often so limited as to exclude them from statistical analysis. In studies from Poland, where vodka drinking is more prevalent, that beverage has been associated with an increased risk of lung cancer (Rachtan, 2002). There are also different lifestyles, behaviors, and diets associated with the consumption of specific alcohol-containing beverages. Beer drinkers consume more total alcohol, smoke more cigarettes, have less education, and eat less vegetables and fruits than individuals who drink wine (McCann et al., 2003). Moreover, even among individuals within the same location, there can be widely different behaviors associated with consumption of sub-types of the same beverage. For example, malt liquor

Table 67.2   Results of studies of *beer consumption* and the risk of lung cancer[a]

[b] Studies listed in order in which they appear in text of chapter. Every study cited in the text in which an OR or RR is reported specifically for beer consumption and lung cancer risk is listed in table.

beer drinkers in Los Angeles County consume more total alcohol, combine smoking and drinking more often, and exhibit adverse social behaviors compared to "regular" beer drinkers (Bluthenthal *et al.*, 2005). Depending on the population studied, the beverage of choice, and the confounding variables involved and adjusted for; the results linking a specific beverage to lung cancer may appear inconsistent, especially if any true association is weak. Nonetheless, there are multiple studies implicating beer consumption with an increased risk of lung cancer, Table 67.2.

Studies favoring a relationship between *beer consumption* and lung cancer risk

In a collective review, 7 of 11 epidemiologic studies reviewed demonstrated a relationship between beer consumption and an increased risk of lung cancer and in two of those studies a dose response relationship was established (Bandera *et al.*, 2001). In a carefully performed study, adjusting for smoking/age/education/dietary intake of carotenoids, drinkers of >12 beers/month had a RR of 1.6 (CI 1–2.4, p = 0.003) compared to non-drinkers of beer (Bandera *et al.*, 1992). In a Canadian case control study involving 1,793 cases and 1,975 age/sex matched controls, there was an increasing OR of lung cancer with increasing beer intake (Benedetti *et al.*, 2006). The lung cancer OR was 1.2 (CI 0.9–1.7) and 1.5 (1.1–2.1) for men drinking 1–6 beers/week and ≥7 beers/week, respectively. These data were adjusted for age, smoking, ethnicity, income, and education. In a cohort study of 41,837 Iowa women, the

RR of lung cancer after adjustment for smoking was 2.0 (1.02–3.80) among those drinking ≥1 beer/week compared to those drinking <1 beer/week (Potter *et al.*, 1992).

Studies that do not favor a relationship between *beer consumption* and lung cancer risk

Several studies have failed to demonstrate a relationship between beer consumption and an increased risk of lung cancer (Pollack *et al.*, 1984; Woodson *et al.*, 1999; DeStefani *et al.*, 2002; Zatloukal *et al.*, 2003; Ruano-Ravina *et al.*, 2004), and in at least one study an inverse relationship was found (Carpenter *et al.*, 1998). In a study demonstrating no increased risk of lung cancer among "current" beer drinkers, an increased risk of lung cancer was demonstrated among "former" drinkers of beer (RR = 1.8, CI 1.1–3.0, adjusted for age, smoking, and occupation). The authors believed former beer drinkers had heavy consumption in the past, and that drinking cessation may have been due to health related problems (Chow *et al.*, 1992).

Summary: *beer consumption* and lung cancer risk

Mechanisms postulated to explain observed increases in lung cancer risk among beer drinkers include: higher levels of nitrosamines in beer (Bandera *et al.*, 2001); residual confounding due to smoking (Carpenter *et al.*, 1998; Zang

Notes: All results reported are adjusted for smoking. In addition, studies variably adjusted for age, sex, race, education, body mass index, income, dietary intake of fruits and vegetables, dietary fat, exposure to environmental smoke, and/or family history of lung cancer. Adjusted RR or OR reported compares highest risk hard liquor drinking level to either lowest risk drinking level or to non-drinkers. Table reflects highest value of adjusted RR or OR reported from study whether among men and women combined, men only, or women only.

[a] Only studies where *hard liquor consumption* specifically studied included. Hard liquor includes whiskey, vodka, and spirits. It does not include beer or wine consumption.
[b] Studies listed in order in which they appear in text of chapter. Every study cited in the text in which an OR or RR is reported specifically for hard liquor consumption and lung cancer risk is listed in table.

and Wynder, 2001; DeStefani *et al.*, 2002; McCann *et al.*, 2003); low fruit/vegetable consumption among beer drinkers (Benedetti *et al.*, 2006); and specific lifestyles among beer drinkers (McCann *et al.*, 2003). In summary, beer consumption, especially heavy beer consumption, even when adjusted for smoking, is associated with a moderately increased risk of lung cancer.

Hard Liquor Consumption and Lung Cancer Risk

The relationship between hard liquor consumption and the risk of lung cancer is similar to, if not greater in magnitude than, that described for beer. In studies demonstrating an association, there is usually an increased risk of lung cancer associated with heavy consumption of hard liquor. Confounding variables, especially cigarette smoking, are just as problematic.

In the Honolulu Heart Study where beer consumption was not associated with lung cancer risk, there was an increased risk of lung cancer for heavy whiskey consumption (≥50 oz. whiskey/month, RR = 2.62, p = 0.01, adjusted for age and smoking) compared to non-drinkers (Pollack *et al.*, 1984). Likewise, in the Los Angeles County Study in which beer consumption demonstrated a weak inverse correlation with lung cancer risk, consumption of hard liquor (≥1 drink/day) was strongly associated with lung cancer risk

compared to consumers of 0–3 drinks/month (OR = 1.87, CI 1.02–3.42, p = 0.06, adjusted for smoking, diet, age, race, and sex) (Carpenter *et al.*, 1998).

In a case control study of Polish women involving 242 cases of lung cancer and 352 healthy controls, drinking of vodka was strongly associated with an increased risk of lung cancer even among lifetime non-smokers (RR = 15.0, CI 2.34–96.0, p = 0.000, adjusted for age, passive smoking, diet, residence, and occupational exposure) (Rachtan, 2002). This study also yielded a comparison of the individual and collective effects of hard liquor consumption and cigarette smoking upon the increased risk of lung cancer. Lifelong non-drinkers who smoked had a RR of 10.5 (CI 5.75–19.2, p = 0.000), and those who both drank vodka and smoked had a RR of 20.2 (CI 11.7–35.0, p = 0.000). These trends are similar to those demonstrated for hard liquor consumption, cigarette smoking, and oral cancer (Kabat and Wynder, 1989; Castellsague *et al.*, 2004). Additional studies have supported a positive correlation between hard liquor consumption and lung cancer risk (Prescott *et al.*, 1999) (Table 67.3).

Several studies have demonstrated no association between hard liquor consumption and an increased risk of lung cancer (Hu *et al.*, 2002; Ruano-Ravina *et al.*, 2004). In one such study demonstrating no association between current hard liquor use and lung cancer risk, past use of hard liquor correlated with increased lung cancer risk (Chow *et al.*, 1992).

Table 67.4 Results of studies of wine consumption and the risk of lung cancer[a]

[b] Studies listed in order in which they appear in text of chapter. Every study cited in the text in which an OR or RR is reported specifically for wine consumption and lung cancer risk is listed in table.

Wine Consumption and Lung Cancer Risk

Whereas beer and hard liquor consumption are associated with an increased risk of lung cancer, mild to moderate wine consumption is associated with a decreased risk of lung cancer (Prescott *et al.*, 1999; DeStefani *et al.*, 2002; Freudenheim *et al.*, 2005; Benedetti *et al.*, 2006) (Table 67.4). More specifically, red wine is associated with a decreased lung cancer risk, and white wine is not (Ruano-Ravina *et al.*, 2004). Additionally, the dose response curve for wine and lung cancer risk is U-shaped (Bandera *et al.*, 2001). Mild to moderate consumption decreases the risk whereas heavy wine consumption increases the risk. Authors have speculated that red wine contains antioxidants including flavonoids and resveratrol which inhibit carcinogenesis (DeStefani *et al.*, 2002). Alternative explanations include the fact that mild to moderate wine drinkers have higher education, greater incomes, lower smoking, higher dietary fruits/vegetables, and less dietary fat than those who do not drink wine (McCann *et al.*, 2003).

Alcohol Consumption and Treatment Outcomes for Lung Cancer

Introduction

In addition to the risk of lung cancer development, there is evidence that alcohol use is an independent risk factor for poor outcomes in patients being treated for lung cancer (Paull *et al.*, 2005) (Figure 67.1). Heavy alcohol use specifically increases the morbidity and mortality of pulmonary
Figure 67.1 Overall survival of 36 alcoholic patients and 78 non-alcoholic patients with non-small cell lung cancer. *Source*: Reprinted from Paull *et al.* (2005), Copyright (2005), with permission from the Society of Thoracic Surgeons. Etoh = alcoholic (broken line) patients defined as having any of the following: (1) CAGE screening questionnaire ≥2; (2) consuming ≥5 drinks/day; or (3) having a current DSM IV diagnosis of alcohol abuse/dependence. Non-etoh = non-alcoholic (solid line). [a] Median survival in months (95% CI). [b] Gehans-Wilcoxon log rank test.

resection among patients with early stage, resectable lung cancer (Neuenschwander *et al.*, 2002; Paull *et al.*, 2004a). Alcohol abusers have more respiratory and infectious complications than non-abusing controls undergoing similar operations. Among patients with more advanced, unresectable lung cancer, alcohol abuse may decrease response rates to chemotherapy (Paull *et al.*, 2004b). These adverse

outcomes are not due to clinical cirrhosis, as these studies specifically excluded such patients. Furthermore, the worse outcomes associated with alcohol abuse do not appear to be solely due to differences in smoking, comorbidity, performance status, or nutritional status as these covariates have been adjusted for in multivariate analyses.

Alcohol abuse and the risk of pulmonary resection for lung cancer

Our group at University Affiliated VA Medical Center has studied alcohol abusing patients undergoing treatment for non-small cell lung cancer (NSCLC). Patients were classified as alcohol abusers if they exhibited any one of the following: CAGE screening questionnaire ≥ 2, consumption of ≥ 5 alcohol-containing drinks/day, or a current DSM IV diagnosis of alcohol dependence/abuse (303.90, 305.00). Using this classification, 32% of patients undergoing pulmonary resection for NSCLC were alcohol abusers. The alcohol-containing beverages consumed in this population included beer alone (47%), beer and hard liquor (33%), and hard liquor alone (20%).

Nineteen alcohol abusers were compared to 37 non-abusers undergoing resection for NSCLC. Despite similar pack years smoking, performance status, Charlson comorbidity, pulmonary function, stage of disease, operation, and operative blood loss, the two groups of patients had different postoperative outcomes (Paull et al., 2004a). Alcohol abusers had an increase in infectious complications (37% vs. 5%, p = 0.001) and respiratory failure (42% vs. 5%, p = 0.001). These data closely resembled that reported several years earlier (Neuenschwander et al., 2002) where patients consuming ≥ 5 drinks/day had a higher rate of infectious and respiratory complications (OR = 3.38, CI 1.02–11.2, p = 0.047). Whereas transfusion was believed to explain the findings in the latter study, in our study alcohol abuse was an independent and even stronger predictor of infectious and respiratory complications than transfusion in multivariate analysis. Alcohol abusers undergoing resection for NSCLC, as compared to non-abusers, had worse secondary outcomes including greater increase in postoperative Apache II scores (98% vs. 27%, p = 0.008), ventilator days (11.7 ± 7.4 vs. 0.7 ± 0.4, p = 0.04), fever days (3.9 ± 1.4 vs. 0.9 ± 0.3, p = 0.007), hospital days (26.1 ± 8.4 vs. 10.6 ± 1.8, p = 0.02), and costs ($49,526 ± 17,525 vs. $18,385 ± 3,260). Perioperative mortality was 16% (3/19) among abusers and 0% (0/37) for non-abusers.

Other studies support an increase of complications in alcohol abusing patients undergoing resection for NSCLC. One such study investigated the development of acute lung injury (ALI) following resection in 879 patients with NSCLC. ALI occurred in 4.2% patients (37/879), but was responsible for 43% of all perioperative deaths. In addition, ALI was associated with an increase in ICU and hospital

stays. In a multivariate analysis, there were four independent risk factors identified for the development of ALI: high intraoperative airway pressures, excess perioperative fluid administration, pneumonectomy, and alcohol abuse (OR = 1.9, CI 1.1–4.6, p = 0.01) (Licker et al., 2003).

Even in the absence of cirrhosis, alcohol abuse has a profound effect on postoperative physiology. Alcohol abuse is associated with immunosuppression, hematologic abnormalities, an exaggerated stress response, hypertension, cardiomyopathy, smoking, and comorbidities, all of which contribute to the 2–5 times increase in morbidity and mortality following surgeries (Tonnesen, 1992). In addition, the development of the alcohol withdrawal syndrome (AWS), which can occur despite prophylaxis, is associated with complications and death, as it was in one of three of the deaths in our study.

Despite the increase in postoperative morbidity and mortality experienced by alcohol abusers, long term survival following resection among operative survivors in our cohort of patients was similar for alcohol abusers and non-abusers (Paull et al., 2004a). Three-year survival was 58% and 61% for abusers and non-abusers, respectively. In a Cox Proportional Hazards Model, stage of disease (hazard ratio (HR) = 3.29, p = 0.03), not alcohol abuse (HR = 1.36, p = 0.61), was the best predictor of long term survival.

A patient with early stage NSCLC who is reasonably fit and has resectable disease should not be denied operation because of alcohol abuse. Efforts should focus upon the early identification of the alcohol abusing patient preoperatively, followed by detoxification and counseling, AWS prophylaxis, and an awareness of the increase in infectious and respiratory complications. The immunosuppression associated with alcohol abuse abates within 4 weeks, during which time smoking cessation efforts can be instituted.

Alcohol abuse and treatment outcomes in patients with advanced lung cancer

Few studies have examined the effect of alcohol abuse upon outcomes in patients with advanced, unresectable NSCLC. In a study of 74 such patients with stage III and IV NSCLC, 24 alcohol abusers have worse outcomes than 50 non-abusers (Paull et al., 2004b). Overall survival (9.5 vs. 13.8 months, p < 0.05) and progression-free survival (7.0 vs. 12.5 months, p = 0.02) were worse for abusers compared to non-abusers. In a Cox Proportionate Hazards Model, independent predictors of survival included alcohol abuse (HR = 1.82, p = 0.03) and ECOG performance status. Despite similar doses and toxicity of platin-based chemo-therapy, alcohol abuse was associated with lack of response to chemotherapy (response rates of 23% (3/13) for abusers vs. 59% (17/29) for non-abusers, p = 0.05). Alcohol abusers, compared to non-abusers were more likely to refuse at least one recommended component of their care (44%

vs. 3%, p = 0.001), less likely to receive multimodality treatment (50% vs. 80%, p = 0.05), and received a lower total dose of radiation (4,145 ± 611 vs. 5,468 ± 238 cGy, p = 0.03). These outcome disparities between alcohol abusers and non-abusers were not explained by differences in performance status, stage, comorbidity, smoking history, pulmonary function, liver enzymes, or nutrition.

Summary: alcohol consumption and treatment outcomes for lung cancer

In a study of 114 consecutive patients with NSCLC, of whom 36 were abusers, we examined the effect of alcohol abuse upon outcomes for patients while adjusting for covariates stage of disease, comorbidity, performance status, and smoking history (Paull *et al.*, 2005). Alcohol abuse was an independent predictor of disease-specific survival,

progression-free survival, and progression of disease or death within 12 months (Table 67.5).

Although this study would suggest otherwise, others have argued that alcohol abusers with lung cancer have worse outcomes as a function of increased comorbidities. In a study from the Josephine Ford Cancer Center of 1,155 lung cancer patients, alcohol abuse was an independent risk factor for an increase in comorbidity count (Tammemagi *et al.*, 2004). Furthermore, patients with a >3 comorbidity count were 4 times less likely to receive surgery for localized lung cancer and 5 times less likely to receive chemotherapy for advanced lung cancer.

The worse survival noted among alcohol abusers with lung cancer does not appear to be simply due to residual confounding by smoking or comorbidity. Alternative explanations include worse biologic behavior of tumors and/or impaired natural killer (NK) cell activity in alcohol abusers compared to non-abusers with lung cancer.

In a study of 188 patients with operable NSCLC, specimens were analyzed for p53 mutations using GeneChip and direct sequencing (Ahrendt *et al.*, 2003). Alcohol intake of even 1 drink/day was associated independently, after covariate adjustment, with an increase in p53 mutations. Furthermore, stage I NSCLC patients with p53 mutations had worse 4-year survival than wild-type patients (52% vs. 78%, respectively, p = 0.009).

In a laboratory animal model of lung tumor metastases, alcohol ingestion is associated with NK cell inhibition, and an increase in the number of metastases (Wu and Pruett, 1999). Studies in humans have demonstrated depressed NK cell activity in patients with alcoholic cirrhosis (Laso *et al.*, 1997) as well as in healthy volunteers consuming alcohol (Ochshorn-Adelson *et al.*, 1994). A study of social drinking examined the effects of drinking two cans of beer upon killer cell activity. Although NK cell activity was unaffected, interleukin 2-induced lymphokine activated killer cell activity was reduced compared to pre-alcohol blood samples (p < 0.01) (Bounds *et al.*, 1994). These studies would suggest that alcohol consumption impedes the immune system's ability to clear neoplastic cells, leading to either the development or progression of cancer. These findings, however, cannot be taken as definitive as other studies have not confirmed NK cell inhibition in chronic alcoholic patients or in healthy volunteers ingesting alcohol (Kronfol *et al.*, 1993; Li *et al.*, 1997).

Summary Points

- Alcohol consumption, even when adjusted for cigarette smoking, is associated with an increased risk of lung cancer.
- The study of alcohol consumption and lung cancer risk is complicated by the confounding effect of greater cigarette smoking among drinkers.
- The adjusted RR for lung cancer due to alcohol consumption (1–2 × non-drinkers) is less in magnitude than the RR for oral cancer due to alcohol consumption (8 × non-drinkers).
- Beer consumption is associated with an increased risk of lung cancer.
- Residual confounding by smoking is a major problem in the study of lung cancer among beer drinkers, as beer drinkers tend to have the greatest exposure to cigarette smoking.
- Heavy beer consumption (≥5 drinks/day, 60 oz.) is most closely related to the increased risk of lung cancer.
- The RR of lung cancer due to beer consumption is 1.2–2 times that of non-drinkers.
- Though the RR for lung cancer among beer drinkers is not high, the impact on society may be great in those countries, such as the United States, where the prevalence of beer drinking is high.

- The relationship between hard liquor and lung cancer is similar to that for beer.
- Wine, specifically red wine, consumed in mild to moderate quantities, reduces the adjusted risk of lung cancer roughly in half compared to wine non-drinkers.
- Heavy alcohol consumption, including beer, is associated with worse outcomes in the treatment of patients with lung cancer.
- Worse outcomes have been demonstrated for alcohol abusing patients receiving surgery for early stage as well as for those receiving chemotherapy for advanced stage lung cancer.
- The poor outcomes associated with heavy alcohol use are not solely due to differences in smoking history, comorbidity, performance status, or stage of disease.
- Alcoholic beverages, including beer, either promote the development of or lead to progression of lung cancer by a number of biologic mechanisms.

Phenolic Beer Compounds to Prevent Cancer

Clarissa Gerhäuser German Cancer Research Center, Division Toxicology and Cancer Risk Factors, Workgroup Chemoprevention, Heidelberg, Germany

Abstract

Beer is a rich source of dietary polyphenols that are derived from malt (70–80%) and hop (20–30%). Structural classes include simple phenols, benzoic- and cinnamic acid derivatives, coumarins, catechins, di-, tri- and oligomeric proanthocyanidins, (prenylated) chalcones and various flavonoids. We have tested 48 beer phenolics representing 10 different structural classes in a series of test systems indicative of cancer preventive potential. These test systems measured (i) antioxidant effects, for example scavenging of DPPH, superoxide anion, peroxyl and hydroxyl radicals, (ii) modulation of carcinogen metabolism by reducing phase 1 Cyp1A activity and induction of phase 2 NAD(P)H:quinone reductase (QR) activity, (iii) anti-inflammatory mechanisms through inhibition of inducible nitric oxide synthase induction and inhibition of cyclooxygenase 1 activity and (iv) estrogenic and anti-estrogenic effects in Ishikawa cell culture. Gallic acid, catechins, proanthocyanidins and flavonols such as quercetin demonstrated the broadest range of antioxidant activity with scavenging potential against all radicals tested. Quercetin and the hop-derived chalcone xanthohumol were most potent in modulating xenobiotics metabolism. Gallic acid and xanthohumol inhibited iNOS induction, whereas (+)-catechin and (−)-epicatechin were the most potent Cox-1 inhibitors. Overall it became clear that beer compounds belonging to different structural classes have distinct profiles of biological activity in these *in vitro* test systems. Since carcinogenesis is a complex process, combination of compounds with complimentary activities may lead to enhanced preventive effects.

List of Abbreviations

AAPH	2,2,-Azobis-(2-amidinopropane) dihydrochloride
ALP	Alkaline phosphatase
β-PE	β-Phycoerythrin
CD	Concentration required to double the specific enzyme activity
CEC	3-Cyano-7-ethoxycoumarin
CHC	3-Cyano-7-hydroxycoumarin
Cox-1	Cyclooxygenase 1
Cyp1A	Cytochrome P450 1A
DPPH	1,1-Diphenyl-2-picrylhydrazyl radicals
Em	Emission
Ex	Excitation
HHBSS	Hanks balanced salt solution containing 30 mM Hepes, pH 7.8
IC_{50}	Half-maximal inhibitory concentration
iNOS	Inducible nitric oxide synthase
NBT	Nitro blue tetrazolium
$O_2^{-\bullet}$	Superoxide anion radical
OD	Optical density
$OH^{\bullet}$	Hydroxyl radical
ORAC	Oxygen radical absorbance capacity
PMA	Phorbol myristate acetate
PMS	Phenazine methosulfate
QR	NAD(P)H:quinone reductase
$ROO^{\bullet}$	Peroxyl radical
SC_{50}	Half-maximal scavenging concentration
SOD	Superoxide dismutase
XO	Xanthine oxidase

Introduction

Advances in our understanding of the carcinogenic process at the cellular and molecular level made over the past few decades have led to the development of a promising new approach to cancer prevention, termed "chemoprevention" (Sporn and Newton, 1979). Chemoprevention aims to halt or reverse the development and progression of precancerous cells through use of non-cytotoxic nutrients and/or pharmacological agents during the time period between tumor initiation and malignancy (Kelloff *et al.*, 2006). There is a considerable time frame wherein the carcinogenic process could potentially be halted or reversed. Taking this into consideration, the validation and utilization of dietary components, natural products or their synthetic analogs as potential cancer chemopreventive agents in the form of

Figure 68.1 Chemical structures of typical phenolic compounds from beer, derived from 10 different structural classes. One typical representative of each class is given as an example.

functional foods or nutraceuticals has become an important issue in current health- and cancer-related research.

There are several lines of evidence suggesting beer as an interesting starting material for chemopreventive agent development. Beer is one of the most consumed beverages worldwide. It is a rich source of nutrient as well as non-nutrient components including vitamins. Beer contains a complex mixture of phenolic constituents, which are derived from malt (70–80%) and hop (20–30%). Structural classes include simple phenols, benzoic- and cinnamic acid

derivatives, coumarins, catechins, di-, tri- and oligomeric proanthocyanidins, (prenylated) chalcones and several classes of flavonoids (Figure 68.1).

Polyphenols have been linked to health promoting aspects including the prevention of cancer based on their antioxidant activity and other mechanisms (Yang *et al.*, 2001; Surh, 2003). Recently, several reports have demonstrated that feeding beer or freeze dried beer inhibited chemically induced mammary and colonic carcinogenesis in rats (Nozawa *et al.*, 2004a, b; Nozawa *et al.*, 2006).

Scientific evidence accumulated over the past 10 years points to the cancer preventive potential of selected hop-derived beer constituents including prenylated flavonoids and hop bitter acids (reviewed in Gerhauser, 2005), but a general comparison of beer constituents based on multiple activities relevant for cancer prevention has not been performed so far. To this end, we have investigated the potential cancer chemopreventive activity of 48 beer constituents belonging to 10 different classes of phenolics. Here we summarize the antioxidant activities of these compounds in five different test systems, their influence on the metabolic activation and detoxification of carcinogens, as well as anti-inflammatory properties. Selected hop compounds were also tested for estrogenic and anti-estrogenic properties. Parts of these results have been described previously (Gerhauser et al., 2002a, b; Gerhauser, 2005).

Materials and Methods

Chemicals

All cell culture media and supplements were obtained from Invitrogen (Eggenstein, Germany). Fetal calf serum was provided by PAA Laboratories (Pasching, Austria). β-Phycoerythrin (4 mg/ml), calcein AM, 4-methylumbel-liferyl phosphate (MUP), 7-hydroxy-4-methylcoumarin, 3-cyano-7-ethoxycoumarin (CEC) and 3-cyano-7-hydroxy-coumarin (CHC) were purchased from Molecular Probes (Mobitec, Göttingen, Germany). The human Ishikawa cell line was obtained from S. Mader, Department of Biochemistry, University of Montreal (Montreal, Canada). All other chemicals were purchased from Sigma Chemical Co. (Deisenhofen, Germany).

Source of phenolic beer compounds

The phytochemical analysis of unstabilized beer and a polyvinylpolypyrrolidone residue obtained during beer stabilization led to the isolation of a total of 51 compounds (Gerhauser et al., 2002b). Tyrosol, salicylaldehyde, vanillin, 4-hydroxyphenylacetic acid, o-coumaric acid, m-coumaric acid, chlorogenic acid, epicatechin gallate, kaempferol, quercetin, quercitrin, isoquercitrin, rutin and myricetin were also purchased from Sigma Chemical Co. (Deisenhofen, Germany). Syringic aldehyde was obtained from Fluka (Deisenhofen, Germany).

Test Systems to Detect Potential Cancer Chemopreventive Activity

Scavenging of diphenyl-picrylhydrazyl radicals

Radical scavenging potential was determined spectrophotometrically by reaction with 1,1-diphenyl-2-picrylhydrazyl (DPPH) free radicals in a microplate format at 515 nm

(van Amsterdam et al., 1992, with modifications). Briefly, test compounds dissolved in DMSO were treated with a solution of 100 μM DPPH in ethanol for 30 min at 37°C. Scavenging potential was compared with a solvent control (0% radical scavenging) and ascorbic acid (250 μM final concentration, 100% radical scavenging, used as a blank), and the half-maximal scavenging concentration (SC$_{50}$) was generated from data obtained with 8 serial 2-fold dilutions in a final concentration range of 2–250 μM tested in duplicates. Correction for colored samples was achieved by preparing identical dilutions of the sample in ethanol instead of DPPH solution.

Scavenging of superoxide anion radicals generated non-enzymatically by NADH and phenazine methosulfate

Ewing and Janero (1995) have developed a microassay system suitable for the rapid detection of superoxide anion radical (O$_2^{\bullet-}$) scavengers. Aerobic mixtures of NADH and phenazine methosulfate (PMS) generate O$_2^{\bullet-}$ via the univalent oxidation of reduced PMS. Nitro blue tetrazolium (NBT) can serve as a detector molecule for O$_2^{\bullet-}$ through reduction to a stable formazan product. The reaction mixture (in 0.25 ml total volume) consists of 50 mM phosphate buffer, pH 7.4, containing 0.1 mM EDTA, 50 μM NBT, 78 μM NADH and 3.3 μM PMS (final concentrations). For the assay, 25 μl test sample (stock solution of test compound or superoxide dismutase (SOD) enzyme as a positive control) is pipetted into a microplate well containing 200 μl freshly prepared 0.1 mM EDTA, 62 μM NBT and 98 μM NADH in 50 mM phosphate buffer, pH 7.4. The reaction is initiated by the addition of 25 μl freshly prepared 33 μM PMS in 50 mM phosphate buffer, pH 7.4, containing 0.1 mM EDTA. NBT reduction is continuously monitored at 560 nm over 5 min using a SpectraMax 340PC microplate reader (Molecular Devices, Sunnyvale, CA) in the kinetic mode and with the "automix" function activated. Alternatively, the optical density (OD) at 560 nm can be measured as an endpoint after 5 min of incubation. The percent inhibition of O$_2^{\bullet-}$-dependent NBT reduction by the test sample is calculated, and SC$_{50}$ values are generated from data obtained with 8 serial 2-fold dilutions in a final concentration range of 8–1,000 μM tested in duplicates. SOD (3 U/well) is used as a positive control.

Scavenging of superoxide anion radicals formed enzymatically by xanthine oxidase

Superoxide anion radicals were generated by oxidation of hypoxanthine to uric acid by xanthine oxidase (XO) and quantitated by the concomitant reduction of NBT (Ukeda et al., 1997) adjusted to a 96-well microplate format. The reaction mixture (170 μl), consisting of 50 mM sodium carbonate buffer, pH 9.4, 100 μM EDTA, 25 μM NBT

and 50 μM hypoxanthine, was mixed with test compounds (10 μl, in 100% DMSO, 5% final DMSO concentration) or DMSO (10 μl) as a solvent control. 1 U SOD (in 10 μl 50 mM sodium carbonate buffer, pH 9.4) was used as a positive control. The reaction was started by addition of 12 mU XO (in 10 μl buffer), and the rate of reduction of NBT was monitored for 6 min at 550 nm in a microplate reader (Spectramax 340, Molecular Devices). Alternatively, the yellow tetrazolium salt XTT [2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-2H-tetrazolium-5-carboxanilide], which forms a soluble orange formazan dye, was used. Under these conditions, the amount of XO was reduced to 3 mU and measurements were performed at 480 nm. V_{max} values were computed, and the SC_{50} was generated from the data obtained with 8 serial 2-fold dilutions of inhibitors in a final concentration range of 0.8–100 μM tested in duplicates. To exclude a direct inhibitory effect on XO, formation of uric acid was monitored directly at 290 nm under identical conditions as described above without addition of NBT or XTT. In the reaction mixture, 50 μM hypoxanthine was replaced by 100 μM xanthine.

Inhibition of phorbol myristate acetate-induced superoxide anion radical formation in HL-60 cells

Inhibition of phorbol myristate acetate (PMA)-induced superoxide radical formation in HL-60 human promyelocytic leukemia cells differentiated to granulocytes was detected by photometric determination of cytochrome c reduction (Pick and Mizel, 1981; Takeuchi *et al.*, 1994). Briefly, HL-60 cells at a density of 2×10^5 cells/ml were treated with 1.3% DMSO in RPMI 1640 medium containing 100 units/ml penicillin G sodium and 100 units/ml streptomycin sulfate supplemented with 10% fetal bovine serum at 37°C in a 5% CO_2 atmosphere for 4 days to induce terminal differentiation to granulocytes. Cells were harvested by centrifugation, washed twice with Hanks balanced salt solution containing 30 mM Hepes, pH 7.8 (HHBSS) and adjusted to a density of 2×10^6/ml. 2×10^5 cells/well (100 μl) were pre-incubated with test compounds (25 μl, in 10% DMSO) for 5 min prior to addition of 75 μl cytochrome c solution in HHBSS (5 mg/ml, 1.25 mg/ml final concentration); 25 μl SOD (600 U/ml in HHBSS, 12 U/well final concentration) was used as a positive control, all other wells obtained 25 μl HHBSS. Superoxide anion radical formation was started by addition of 25 μl PMA (0.55 mg/ml in HHBSS, 55 ng/ml final concentration). The plates were briefly shaken. After an incubation period of 30 min at 37°C, the reaction was stopped by chilling the plates on ice for 15 min. Finally, the plates were centrifuged, and cytochrome c reduction in the supernatant was determined at 550 nm using a microplate reader (Spectramax 340, Molecular Devices). The cell pellet was washed twice with PBS, and cell viability

was measured fluorimetrically by enzymatic hydrolysis of the fluorogenic esterase substrate calcein AM (250 nM in PBS, 100 μl/well) at 37°C in a Cytofluor 4000 microplate fluorescence reader (PE Applied Biosystems; excitation 485 nm, emission 620 nm). Using this method, we could avoid unspecific effects of reducing test compounds which falsify commonly used viability assays based on MTT [3-(4,5-dimethylthiazo-2-yl)-2,5-diphenyltetrazolium bromide] or XTT [2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-2H-tetrazolium-5-carboxanilide] bioreduction. The reaction was linear for at least 30 min. SC_{50} values (half-maximal scavenging concentration of PMA-induced superoxide burst) were generated from the results of 8 serial dilutions of inhibitors tested in duplicate. Only non-toxic inhibitor concentrations resulting in greater than 50% cell viability were considered to calculate scavenging potential.

Measurement of oxygen radical absorbance capacity

For the determination of peroxyl or hydroxyl radical absorbance capacity of test compounds, the oxygen radical absorbance capacity (ORAC) assay (Cao and Prior, 1999) was modified and adapted to a 96-well plate format. β-Phycoerythrin (β-PE) was used as a redox-sensitive fluorescent indicator protein, 2,2,-azobis-(2-amidinopropane) dihydrochloride (AAPH) as a peroxyl radical generator and H_2O_2-$CuSO_4$ as a hydroxyl radical generator. Results were expressed as ORAC units, where 1 ORAC unit equals the net protection of β-PE produced by 1 μM Trolox, a water-soluble Vit. E analog used as a reference compound. Briefly, for the $ORAC_{ROO}$ assay, reaction mixtures contained 170 μl 75 mM sodium potassium phosphate buffer, pH 7.0, 10 μl 9.43 nM β-PE in phosphate buffer and 10 μl of the inhibitor solution (1–5 μM final concentration) or phosphate buffer as a negative control, respectively. The reaction was initiated by addition of 10 μl 320 mM AAPH in phosphate buffer. For the $ORAC_{OH}$ assay, the reaction mixture contained 175 μl 75 mM sodium potassium phosphate buffer, pH 7.0, 10 μl 9.43 nM β-PE in phosphate buffer and 10 μl of the inhibitor solution (1–5 μM final concentration) or phosphate buffer as a negative control. The reaction was initiated by addition of 10 μl of a 1:1 mixture of H_2O_2 (12%) and $CuSO_4$ (0.36 mM in phosphate buffer). The decline of β-PE fluorescence was measured at 37°C until completion for 100 min using a Cytofluor 4000 fluorescent microplate reader (excitation wavelength Ex 530/25 nm, emission wavelength Em 585/30 nm). Results were expressed as ORAC units, where 1 ORAC unit equals the net protection of β-PE produced by 1 μM Trolox. Scavenging capacities > 1 ORAC unit were considered as positive. Current ORAC experiments are performed following the improved protocols by Ou *et al.* (2001, 2002) with fluorescein replacing β-PE as the fluorescent sensor.

Inhibition of Cyp1A activity

β-Naphthoflavone-induced H4IIE rat hepatoma cell preparations were used as a source of cytochrome P450 1A (Cyp1A) enzyme activity. Cyp1A activity was determined *via* the time-dependent dealkylation of CEC to CHC based on the method of Crespi *et al.* (1997, with modifications). Briefly, H4IIE rat hepatoma cells were cultured in 100 mm tissue culture dishes at a density of 5×10^4 cells/ml in MEME medium containing 100 units/ml penicillin G sodium, 100 units/ml streptomycin sulfate and 250 ng/ml amphotericin B supplemented with 10% fetal bovine serum at 37°C in a 5% CO_2 atmosphere. After a preincubation period of 24 h, Cyp1A was induced by addition of 10 μM β-naphthoflavone (dissolved in DMSO, 0.1% final concentration). Cells were harvested after 38 h by scraping in 1 ml/plate buffer P (200 mM potassium phosphate buffer, pH 7.4 containing 10 mM $MgCl_2$) and snap frozen in liquid nitrogen. For determination of Cyp1A activity, test compounds dissolved in 10% DMSO (10 μl, final concentration 0.5%) were pipetted to a 96-well microplate. A freshly prepared reaction mixture (100 μl), consisting of 5.2 μl 50 mm $NADP^+$ in water, 4.4 μl 150 mM glucose-6-phosphate in water, 0.5 U glucose-6-phosphate dehydrogenase, 0.1 μl 10 mM CEC (in DMSO) and 90.25 μl buffer P, was then added to each well. The reaction was started by addition of 90 μl cell lysate, passed once through a 27-gauge needle and diluted with buffer P to a final protein concentration of 50–100 μg/ml depending on Cyp1A activity. The rate of dealkylation of CEC to fluorescent CHC was measured for 45 min at 37°C in a Cytofluor 4000 microplate fluorescence reader (PE Applied Biosystems, reading every 2.5 min with prior shaking, excitation 408/20 nm, emission 460/40 nm). V_{max} values were computed, and the half-maximal inhibitory concentration (IC_{50}) was generated from the data obtained with 8 serial 2-fold dilutions of inhibitors in a final concentration range of 0.004–0.5 μM or 0.04–5 μM, respectively, tested in duplicates. Enzyme activities were calculated in comparison with a CHC standard curve and normalized to protein content determined by the BCA method (Smith *et al.*, 1985). α-Naphthoflavone as a known Cpy1A inhibitory compound was used as a positive control.

Determination of NAD(P)H:quinone reductase activity in mouse hepatoma cell culture

For the detection of phase 2 enzyme inducers, quinone reductase (QR) activity was measured in Hepa 1c1c7 cells as described previously (Prochaska and Santamaria, 1988). QR activity was determined by measuring the NADPH-dependent menadiol-mediated reduction of MTT [3-(4,5-dimethylthiazo-2-yl)-2,5-diphenyltetrazolium bromide] to a blue formazan. Protein was determined by crystal violet staining of an identical set of test plates. Induction of QR activity was calculated from the ratio of specific enzyme

activities of compound-treated cells in comparison with a solvent control, and CD values (concentration required to double the specific enzyme activity in μM) were generated. In addition, IC_{50} values for the inhibition of cell proliferation were calculated. Only non-toxic inhibitor concentrations resulting in greater than 50% cell viability were considered to calculate inducing potential.

Inhibition of LPS-mediated inducible nitric oxide synthase induction in murine macrophages

Inhibition of lipopolysaccharide (LPS)-mediated inducible nitric oxide synthase (iNOS) induction in murine Raw 246.7 macrophages was determined *via* the Griess reaction (Heiss *et al.*, 2001). Briefly, murine macrophages were cultured in DMEM medium containing 100 units/ml penicillin G sodium, 100 units/ml streptomycin sulfate and 250 ng/ml amphotericin B supplemented with 10% fetal bovine serum at 37°C in a 5% CO_2 atmosphere. Cells were plated at a density of $1-2 \times 10^5$ cells/well in DMEM in 96-well plates. After a preincubation period of 24 h, the medium was replaced by 170 μl serum-free DMEM. Inhibitors (10 μl in 10% DMSO, 8 serial 2-fold dilutions, final concentration range 0.8–50 μM) were added, and iNOS was induced by addition of 20 μl LPS solution (500 ng/ml in serum-free DMEM). After 24 h, iNOS activity was determined *via* the quantitation of nitrite levels according to the Griess reaction. Briefly, 100 μl aliquots of cell culture supernatants were incubated with an equal volume of Griess reagent (1% sulphanilamide/0.1% naphthylethylene diamine dihydrochloride/2.5% H_3PO_4) at room temperature for 10 min. The absorbance at 550 nm was determined in a microplate reader and compared to a nitrite standard curve. To determine cytotoxic effects of test compounds, residual cell culture medium was removed, cells were fixed at 4°C for 30 min with 50 μl ice-cold 10% trichloroacetic acid solution in water, washed five times with tap water and briefly dried. Cell numbers were estimated by sulforhodamin B staining (Skehan *et al.*, 1990). Generally, compounds were tested at non-toxic concentrations (cell staining > 50% of LPS-treated control cells).

Inhibition of cyclooxygenase activity

Cox activity was measured at 37°C by monitoring oxygen consumption during conversion of arachidonic acid to prostaglandins in a 1.0 ml incubation cell of an Oxygen Electrode Unit (Hansatech DW, based on a Clark-type O_2 electrode) according to Jang and Pezzuto (1997) with modifications. The reaction mixture, containing 0.1 M sodium potassium phosphate buffer, pH 7.4, 1 mM hydroquinone, 0.01 mM hemin and approximately 0.2 U Cox-1 in 100 μl microsome fraction derived from ram seminal vesicles as a crude source of Cox-1 (specific activity 0.2–1 U/mg protein), was incubated

with 10 μl DMSO (negative control) or inhibitor solution (10 mM in DMSO), respectively, for 90 s. The reaction was started by addition of 2 μl 50 mM arachidonic acid in ethanol (100 μM final concentration), and oxygen consumption was monitored for 20 s. For calculation, the rate of O_2 consumption was compared to a DMSO control (100% activity).

Determination of estrogenic and anti-estrogenic capacity in cultured Ishikawa cells

Measurement of the enhancement of alkaline phosphatase (ALP) activity in the Ishikawa human endometrial adenocarcinoma line allows the assessment of intrinsic estrogenic activity of test compounds. Anti-estrogenic effects are determined by co-treatment with β-estradiol and inhibitors. Cell culture conditions were essentially as described earlier (Littlefield *et al.*, 1990; Markiewicz *et al.*, 1992). Ishikawa cells were routinely maintained in α-MEM medium containing 100 units/ml penicillin G sodium, 100 units/ml streptomycin sulfate and 250 ng/ml amphotericin B supplemented with 10% charcoal-stripped fetal bovine serum at 37°C in a 5% CO_2 atmosphere. One day before the start of an experiment, the medium was changed to an estrogen- and phenol-red-free D-MEM/F-12 mix (1:1) (estrogen-free mix) containing L-glutamate and pyridoxine HCl (Gibco BRL), supplemented with 100 units/ml penicillin G sodium, 100 units/ml streptomycin sulfate, 250 ng/ml amphotericin B and 5% charcoal-stripped fetal bovine serum. For the determination of estrogenic activity, cells were trypsinized with 0.25% phenol-red-free trypsin/EDTA, passed through a 27-gauge injection needle to obtain a single-cell suspension, and plated in 96-well microplates at a density of 2×10^4/well in 200 μl estrogen-free mix. After a preincubation period of 24 h, the medium was replaced by 190 μl fresh estrogen-free mix. Test compounds (10 μl in 10% DMSO, 8 serial 2- or 5-fold dilutions, final concentration range $10^{-12}–10^{-5}$ M in duplicate) were added to a final volume of 200 μl, and the plates were incubated at 37°C in a humidified 5% CO_2 atmosphere for 72 h. Plates were washed three times with PBS (pre-warmed to 37°C), 50 μl/well 0.5% Triton X in PBS were added, and plates were kept at −80°C overnight. To determine ALP activity, plates were thawed at 37°C for 2 min, 100 μl/well 15 μM MUP in 1 M diethanolamine buffer, pH 9.8, containing 0.24 mM $MgCl_2$ were added, and plates were shaken thoroughly for 5 min on a microplate shaker. Dephosphorylation of MUP to fluorescent 4-methyl-7-hydroxy-coumarin (4-methylumbelliferon) was monitored for 45 min at 37°C (excitation 360 nm, emission 460 nm). ALP activity was determined from the rate of product formation (in arbitrary fluorescent units/min). Protein was determined by SRB staining of an identical set of test plates. For calculation of estrogenic activity, results were expressed as a percentage in comparison with a control

sample treated with 50 nM β-estradiol (set as 100%) to determine the half-maximal effective concentration.

For the determination of anti-estrogenic activity, the medium pre-incubated cells (as described above) were changed to 170 μl estrogen-free mix, and cells were treated simultaneously with test samples (10 μl in 10% DMSO) on 10 μl 10% DMSO as a solvent control, respectively, and 20 μl 50 nM β-estradiol in estrogen-free mix. Inhibition of ALP induction was calculated in comparison with the result obtained with the β-estradiol control set as 100%. Tamoxifen was used as a known anti-estrogenic reference compound and produced an inhibition of >50% at a test concentration of 0.5 μM.

Results

We have tested 48 beer constituents for cancer preventive potential in a battery of nine test systems suitable to detect antioxidant and radical scavenging activity (**5.1**), potential to inhibit the metabolic activation of xenobiotics by Cyp1A and to enhance phase 2 detoxification (**5.2**), anti-inflammatory and estrogenic/anti-estrogenic effects (**5.4**).

Antioxidant and radical scavenging capacity

It is well established that excessive production of reactive oxygen species (ROS) caused by immune diseases, chronic inflammation and infections leads to continuous oxidative stress and is causally linked with processes during tumor initiation, promotion and progression (Bartsch and Nair, 2006).

There are three major types of ROS: Hydroxyl radicals ($^{\bullet}$OH) are very reactive oxidants which attack all biomolecular targets (DNA, proteins, lipids …). Superoxide anion radicals ($O_2^{\bullet-}$) do not directly react with biological molecules, but are linked to toxic effects by secondary radical reactions. Other free radicals of the peroxyl type (ROO$^{\bullet}$) contribute by enhancement to oxidative stress (Valko *et al.*, 2006). We have established multiple test systems, including the DPPH radical scavenging assay, three systems to generate superoxide anion radicals (non-enzymatically, enzymatically and cellularly), and the oxygen radical absorbance capacity (ORAC) assay with peroxyl and hydroxyl radicals, to investigate the radical scavenging and antioxidant capacity of phenolic beer compounds. An overview of all tested compounds and their activities in these test systems is given in Table 68.1. To allow a comparison with chemical structures, numbering of the compounds was kept consistent with the Chapter 48. Some examples of phenolic beer constituents are shown in Figure 68.1.

DPPH Radical Scavenging The DPPH assay was included as it is a very simple test system which gives a first indication of radical scavenging potential of a test compound. Due to the bulky structure of the stable DPPH

Notes: n.d.: not determined; bold print indicates most potent activities.

[a] For chemical structures and further information see Chapter 48. Compounds 1, 2, 3, 4, 6, 7, 8, 9, 11, 12, 14, 19, 23, 32, 33, 37, 41, 42, 43, 45, 46, 47, 48, 51, 54, 59, 61, 63, 67, 69, 75, 80 have not been tested.

[b] The following *in vitro* test systems have been utilized: DPPH: Scavenging of the stable free radical diphenylpicrylhydrazyl; PMS/NADH: Scavenging of superoxide anion radicals generated non-enzymatically by phenazine methosulfate and NADH; X/XO: Scavenging of superoxide anion radicals generated enzymatically during the oxidation of hypoxanthine to uric acid by xanthine oxidase; ORAC: Oxygen radical absorbance capacity assay with peroxyl (ROO) and hydroxyl radicals (OH$^{\bullet}$).

[c] SC$_{50}$: Halfmaximal scavenging concentration; one ORAC unit equals the net protection of β-PE produced by 1 µM Trolox.
Figure 68.2 DPPH radical scavenging potential of phenolic beer compounds, expressed as the SC$_{50}$. Only classes with active representatives are shown.

radical, interaction with radical scavengers is sometimes hindered, leading to false negative results.

SC$_{50}$ values of active DPPH scavengers are depicted in Figure 68.2. Overall, it became apparent that the structural classes of catechins (flavan-3-ols), proanthocyanidins and flavonols were most potent in scavenging DPPH radicals.

Gallic acid [15] as a benzoic acid derivative with three hydroxyl groups was identified as potent DPPH radical scavenger. The catechins (+)-catechin [34], (−)-epicatechin [35], gallocatechin [36], epicatechin gallate [38] and 3′-O-methyl-catechin [39] were almost equally active in DPPH scavenging with SC$_{50}$ values of 12.7–16.9 µM. A glucosidic linkage at the OH group in position 7 as in [40] reduced the SC$_{50}$ in comparison with (+)-catechin [34] by about 50%. Procyanidin B$_3$ [44] and prodelphinidin C

[49] were even more potent than the respective subunits (+)-catechin [34] and gallocatechin [36], with SC$_{50}$ values of 7.6 and 9.7 µM. Interestingly, neither flavanones such as naringenin [56] nor flavones such as apigenin [62] were able to scavenge DPPH radicals. In contrast, the flavonols quercetin [70] and myricetin [74], which have an additional hydroxyl group in position 3 in comparison with flavones, were identified as good scavengers. A glycosidic linkage at the OH group in position 3 as in quercitrin [71], isoquercitrin [72] and rutin [73] reduced the scavenging potential by a factor of 2–3.

Superoxide Anion Radical Scavenging Superoxide anion radicals can be generated chemically, enzymatically or in living cells. We established test systems for all three methods.
Figure 68.3 Scavenging of superoxide anion radicals generated non-enzymatically in the PMS/NADH system by phenolic beer compounds. The antioxidant potential was expressed as the SC_{50}. Only classes with active representatives are compared.
Figure 68.4 Scavenging of superoxide anion radicals generated enzymatically in the xanthine/xanthine oxidase (X/XO) system by phenolic beer compounds. The antioxidant potential was expressed as the SC_{50}. Only results of active compounds are depicted. XN: xanthohumol [**53**]; 6-PN: 6-prenylnaringenin [**58**].

Non-enzymatic PMS/NADH System Non-enzymatically, an aerobic solution of PMS and NADH generates $O_2^{\bullet-}$. The assay was established according to Ewing and Janero (1995). In comparison with the other two $O_2^{\bullet-}$ assays described below, this method apparently generated the highest amount of $O_2^{\bullet-}$, since compounds had to be tested in an about 10-fold higher concentration range up to 1 mM to reach 50% radical scavenging. Results are summarized in Figure 68.3.

In good agreement with DPPH radical scavenging potential, the catechins (+)-catechin [**34**], gallocatechin [**36**] and epicatechin gallate [**38**] potently scavenged superoxide anion radicals, whereas the glucoside [**40**] was less active than the aglycon [**34**]. Again, procyanidin B$_3$ [**44**] and especially the trimeric proanthocyanidin prodelphinidin C [**49**] were more potent than the respective subunits (+)-catechin [**34**] and gallocatechin [**36**]. The flavanones isoxanthohumol [**55**] as well as naringenin [**56**] and its prenylated derivatives [**57**] and [**58**] showed weak potential to scavenge superoxide anion radicals in this system. Apigenin derivatives saponaretin [**65**] and saponarin [**66**] were more potent scavengers. Overall, the flavonol myricetin [**74**] with three OH groups in positions 3′, 4′ and 5′ of the flavonoid structure was identified as the most potent $O_2^{\bullet-}$ scavenger in this assay with a SC_{50} value of 24 μM.

Enzymatic X/XO System Oxidation of hypoxanthine to uric acid by XO leads to the enzymatic generation of superoxide anion radicals. Compounds were tested in a concentration range of up to 100 μM. Most consistently with the previous assays, catechins and proanthocyanidins were identified as the most potent superoxide radical scavengers as shown in Figure 68.4.

(+)-Catechin [**34**], gallocatechin [**36**], epicatechin gallate [**38**] and the glucoside [**40**] all resulted in about 50% scavenging at a concentration of 20 μM. The trimeric prodelphinidin C [**49**] as well as dimer [**52**] were even more potent scavengers, with SC_{50} values of 6.6 and 14.7 μM, respectively,

whereas procyanidin B$_3$ [**44**] was not able to scavenge superoxide anion radicals efficiently at concentrations below 100 µM. The hop-derived chalcone xanthohumol [**53**] was identified as a superoxide radical scavenger in the X/XO system, but not in the PMS/NADH assay. Consistently with the results obtained in the latter test system, flavanones and flavones were less potent scavengers than flavonols, and myricetin [**74**] was identified as the most potent O$_2^{\bullet-}$ radical scavenger with 50% scavenging of the generated radicals at a concentration of 5.3 µM. Concomitant detection of uric acid proved that the result was not falsified by direct inhibition of XO activity (data not shown).

Cellular System: PMA-Induced Superoxide Burst in Granulocytes Alternatively, superoxide anion radical formation

● Xanthohumol [**53**]   ▽ Saponaretin [**65**]   ■ 4-ketopinoresinol [**79**]

Figure 68.5 Dose-dependent inhibition of phorbol ester-induced superoxide burst in granulocytes by xanthohumol [**53**], saponaretin [**65**] and 4-ketopinoresinol [**79**]. Scavenging of superoxide anion radicals is shown as a percentage in comparison with a solvent control.

was detected in differentiated HL-60 human promyelocytic leukemia cells stimulated with PMA to generate superoxide anion radicals. Out of 48 compounds tested, only three were more than 50% inhibitory at a test concentration of 100 µM. Dose-dependent inhibition by xanthohumol [**53**], the flavone saponaretin [**65**] and the lignan 5-ketopinoresinol [**79**] is shown in Figure 68.5. These compounds inhibited the PMA-mediated superoxide production with SC$_{50}$ values of 5.5 µM [**53**], 4.7 µM [**65**] and 7.1 µM [**79**]. Interestingly, the lignan 5-ketopinoresinol [**79**] did not show potential to scavenge superoxide anion radicals in the two other assays. This indicated that 5-ketopinoresinol [**79**] may inhibit the signal transduction cascade induced by PMA.

Oxygen Radical Absorbance Capacity The ORAC assay is a well-established test system to identify peroxyl and hydroxyl radical scavengers. In the present study, the protocol using β-phycoerythrin (β-PE) as a redox-sensitive fluorescent indicator was adapted to a 96-well plate format. In our current screening assay, we have replaced β-phycoerythrin by fluorescein, due to higher stability of the fluorescence signal and lower price.

ORAC$_{ROO}$ Peroxyl radicals are generated at 37°C by the peroxyl radical generator AAPH. Trolox, a water-soluble Vit. E derivative, is generally used as a reference compound, and one ORAC unit is defined as the net protection of β-PE produced by 1 µM Trolox. For comparison, beer phenolics were also tested at a concentration of 1 µM. 35 out of 48 compounds demonstrated a higher peroxyl radical scavenging potential than Trolox at this concentration. Figure 68.6 summarizes only those compounds which were twice as potent as Trolox (equivalent to at least 2 ORAC units at 1 µM).

The simple phenol tyrosol [**5**], the benzoic acid derivatives protocatechuic acid [**13**] and gallic acid [**15**] as well as caffeic [**28**], ferulic [**29**] and chlorogenic acid [**31**]
Figure 68.6 Peroxyl radical absorbance capacity (ORAC$_{ROO}$) of phenolic beer compounds. Peroxyl radicals were generated by AAPH and β-phycoerythrin was used as a fluorescent indicator. One ORAC unit is defined as the net protection provided by 1 µM Trolox, a water-soluble Vit. E analog. Compounds were tested at a concentration of 1 µM.

were more potent peroxyl radical scavengers than Trolox. Overall, catechins and proanthocyanidins were the most potent antioxidants in the ORAC$_{ROO}$ assay. Gallocatechin [**36**] was only about half as active as (+)-catechin [**34**] and (−)-epicatechin [**35**], which had a peroxyl scavenging capacity of 4.0 and 4.7 ORAC$_{ROO}$ units, respectively. Esterification of gallic acid [**15**] with (−)-epicatechin [**35**] significantly increased peroxyl scavenging potential, and epicatechin gallate [**38**] was identified as the most potent compound with 7.8 ORAC$_{ROO}$ units. In contrast, blocking of free hydroxyl groups as in [**40**] reduced the scavenging potential in comparison with (+)-catechin [**34**]. Di- and trimeric proanthocyanidins procyanidin B$_3$ [**44**], prodelphinidin C [**49**] and [**50**] were more potent than the respective subunits (+)-catechin [**34**] and especially gallocatechin [**36**]. Quercetin [**70**], which produced 5.5 ORAC units, was identified as the most potent flavonol.

ORAC$_{OH}$ A combination of H$_2$O$_2$ and CuSO$_4$ was used in a Fenton-type reaction to generate hydroxyl radicals. Of notice, the potential of Trolox to scavenge hydroxyl radicals is quite low. Therefore the factor generated from the area between the fluorescence decay curve of the control reaction and that of 1 µM Trolox, which represents 1 ORAC$_{OH}$ unit, was quite low. Consequently, normalization to this factor produced relatively high ORAC$_{OH}$ values for most phenolic beer compounds. In 2002, the authors of the original ORAC$_{OH}$ assay published an improved method termed HORAC, which utilizes fluorescein as a fluorescent sensor, Co(II) fluoride/picolinic acid-H$_2$O$_2$ to generate hydroxyl radicals and gallic acid as a reference standard (Ou *et al.*, 2002). In our hands, 1 µM gallic acid was 3.3-fold more potent than 1 µM Trolox. For comparison with gallic acid equivalents (GAE), ORAC$_{OH}$ units summarized in Table 68.1 should be divided by 3.3.

Due to the high number of active compounds, Figure 68.7 shows only those compounds with ORAC$_{OH}$ values

above 4. Cinnamic [**24**], caffeic [**27**] and ferulic acid [**28**], gallocatechin [**36**], xanthohumol [**53**] and myricetin [**74**] were identified as the most potent hydroxyl radical scavengers of all beer phenolics investigated.

Modulation of carcinogen metabolism

In addition to the broad spectrum of antioxidant tests, we also investigated the influence of beer compounds to modulate activation and detoxification of xenobiotics. Cyp1A, which is, for example, involved in the activation of carcinogens from cigarette smoke or grilled meat, was used as a model phase 1 enzyme, and NAD(P)H:quinone reductase was tested as a phase 2 enzyme which is induced concomitantly with other phase 2 enzymes such as glutathione S-transferases. The results of all compounds which were able to modulate at least one of the activities of these enzymes are summarized in Table 68.2. Compounds which have not been tested in the assays described in Table 68.1 have also not been tested in these systems.

Cyp1A Inhibition   Microsomes of β-naphthoflavone-induced rat hepatoma cells were used as a source for Cyp1A activity, and the dealkylation of CEC was monitored over 45 min. As indicated in Figure 68.8a, none of the benzoic and cinnamic acid derivatives [**10–31**], catechins [**34–40**] and proanthocyanidins [**44–52**] inhibited Cyp1A activity more than 50% at the concentration limit of 5 µM. In contrast, xanthohumol [**53**], apigenin [**62**] and quercetin [**70**] were identified as extremely potent Cyp1A inhibitors, with IC$_{50}$ values of 0.02 µM. Glycosides such as saponaretin [**65**] and saponarin [**66**] as well as the quercetin derivatives quercitrin [**71**] and isoquercitrin [**72**] were considerable less active than the respective aglycons. The flavanones isoxanthohumol [**55**], naringenin [**56**] and 8- and 6-prenylnaringenin [**57, 58**] as well as the flavon tricin [**64**] potently blocked Cyp1A activity with IC$_{50}$ values below 0.5 µM. In addition, 1-methyl-1,3,4,9-tetrahydropyrano[3,4-b]indole
Figure 68.7   Hydroxyl radical absorbance capacity (ORAC$_{OH}$) of phenolic beer compounds. Hydroxyl radicals were generated by CuSO$_4$ and H$_2$O$_2$, and β-phycoerythrin was used as a fluorescent indicator. One ORAC unit is defined as the net protection provided by 1 µM Trolox, a water-soluble Vit. E analog. Compounds were tested at a concentration of 1 µM.

Notes: Bold print indicates most potent activities.

[a] Cyp1A: Inhibition of the enzyme activity of cytochrome P450 1A; QR: Induction of the specific activity of NAD(P)H:quinone oxidore-ductase (QR) in Hepa1c1c7 murine hepatoma cells; iNOS: Inhibition of lipopolysaccharide-mediated induction of inducible nitric oxide synthase (iNOS) in murine macrophages, measured *via* nitrite levels in cell culture supernatants; Cox-1: Inhibition of sheep-seminal vesi-cle-derived cyclooxygenase-1 enzymatic activity.
[b] IC$_{50}$: Halfmaximal inhibitory concentration. Values in parentheses indicate the percentage of inhibition at the indicated concentration.
[c] CD: Concentration required to double the specific activity of QR.
[d] IC$_{50}$: Concentration that results in 50% inhibition of cell viability.

[**78**] and 4-ketopinoresinol [**79**] displayed moderate Cyp1A inhibitory potential.

NAD(P)H:Quinone Reductase Induction   The well-described model of QR induction in cultured Hepa 1c1c7 mouse hepatoma cells was used to characterize the potential of our series of test compound to induce phase 2 xenobiotics metabolism. Antioxidants may induce phase 2 enzymes *via* transcription factor binding to the so-called antioxidant response element. CD values of QR are summarized in Table 68.2 and Figure 68.8b.

The chalcone xanthohumol [**53**] and quercetin [**70**] were identified as most potent inducers of QR activity

and we determined CD values of 1.7 and 2.6 µM, respectively. However, both compounds also displayed the highest cytotoxicity with IC$_{50}$-T values (concentration resulting in 50% inhibition of cell viability), of 7.4 and 14 µM (Table 68.2). Overall, the flavonols kaempferol [**68**], quercetin [**70**] and two quercetin glycosides quercitrin [**71**] and isoquercitrin [**72**] had a higher potential to induce QR activity than the flavanones isoxantho-humol [**55**], 8- and 6-prenylnaringenin [**57, 58**] and the naringenin derivative [**60**]. 1-Methyl-1,3,4,9-tetrahydro-pyrano[3,4b]indole [**78**] and the lignan 4-ketopinoresinol [**79**] induced QR activity with CD values of 33.9 and 6.0 µM, respectively.
Figure 68.8 Modulation of xenobiotics metabolism. (a) Inhibition of phase 1 Cyp1A activity by beer compounds, measured in β-naphthoflavone-induced H4IIE rat hepatoma cell homogenates by dealkylation of CEC to fluorescent CHC. For comparison of inhibitory potential, IC_{50} are shown of all compounds which resulted in > 50% inhibition at a test concentration of 5 μM. (b) Induction of NAD(P)H: quinone reductase activity as a marker phase 2 enzyme in Hepa 1c1c7 cell culture by beer compounds. Given are CD values of QR in μM.

Anti-inflammatory mechanisms

It is estimated that 18% of all cancer cases are related to chronic inflammatory processes. We therefore tested for potential to inhibit the induction of iNOS and the activity of cyclooxygenase 1 (Cox-1). Both enzymes are involved in the generation of inflammatory mediators in the form of nitric oxide and prostaglandins.

Inhibition of iNOS Induction in Murine Macrophages   Inhibition of iNOS induction was measured in LPS-stimulated Raw 264.7 murine macrophage cultures. As summarized in Table 68.2 and Figure 68.9a, only eight of all tested compounds were able to moderately inhibit iNOS induction, that is gallic acid [15], xanthohumol [53] and its cyclization product isoxanthohumol [55], apigenin [62], the flavonols kaempferol [68], quercetin [70] and quercitrin [71], as well as 4-ketopinoresinol [79], with IC_{50} values in the range of 18.7–40.6 μM. iNOS induction is mediated through activation of the NF-κB signaling pathway (Karin, 2006); therefore, it is likely that these compounds may inhibit iNOS induction by interfering with this pathway (Aggarwal and Shishodia, 2006).

Inhibition of Cox-1 Activity   We utilized sheep seminal vesicle microsomes as a source of Cox-1 and measured

oxygen consumption during the first step of prostaglandin production as an indication of Cox-1 activity. Notably, only the catechins [34–39], xanthohumol [53] and 8-prenylnaringenin [57] inhibited Cox-1 activity > 50% at concentrations below 100 μM. For (+)-catechin [34] and (−)-epicatechin [35] we determined IC_{50} values of 5.2 and 7.5 μM. Both compounds were clearly more potent than gallocatechin [36], epicatechin gallate [38] and 3′-O-methylcatechin [39]. A sugar linkage at the hydroxyl group in position 7 as in [40] completely abrogated Cox-1 inhibitory potential.

Estrogenic and anti-estrogenic activities

Hops have repeatedly been reported to possess estrogenic properties. Therefore, we investigated pro- and anti-estrogenic properties of xanthohumol [53] and the (prenylated) flavanones [55–58] derived from hops in Ishikawa cell culture. This human endometrial cancer cell line responds to estrogens with elevated ALP activity. Concomitant treatment with estrogens and test compounds allows the identification of anti-estrogens.

Dose-dependent induction of ALP activity is shown in Figure 68.10a. As reported previously (Gerhauser *et al.*, 2002a), xanthohumol [53] was identified as a pure anti-estrogen which did not induce ALP activity. In contrast,
Figure 68.9 Anti-inflammatory mechanisms. (a) Inhibition of LPS-mediated nitric oxide production in Raw 264.7 murine macrophages. IC_{50} are given. XN: xanthohumol [53], IXN: isoxanthohumol [55]. (b) Inhibition of oxygen consumption during *in vitro* prostaglandin formation by Cox-1. IC_{50} are shown of all compounds which resulted in >50% inhibition at a test concentration of 100 μM. XN: xanthohumol [53]; 8-PN: 8-prenylnaringenin [57].

Figure 68.10 Demonstration of estrogenic and anti-estrogenic effects by xanthohumol and selected flavanones. (a) Induction of ALP activity in Ishikawa cell culture as a measure of estrogenic properties. Dose–response curves of xanthohumol [53], isoxanthohumol [55], naringenin [56], 8-prenylnaringenin [57], 6-prenylnaringenin [57] are shown in comparison with β-estradiol as a percentage of maximum induction. (b) Anti-estrogenic potential of xanthohumol [53], isoxanthohumol [55], naringenin [56], 8-prenylnaringenin [57] and 6-prenylnaringenin [57]. Ishikawa cells were treated concomitantly with test compounds and 5 nM β-estradiol. Anti-estrogenic activity was determined as inhibition of β-estradiol-induced ALP activity, and IC_{50} values are depicted.

isoxanthohumol [55] demonstrated estrogenic potential and induced ALP in a concentration range of 0.1–1 μM. Naringenin [56] was about one order of magnitude less active than isoxanthohumol. Prenylation in position C8 strongly increased the estrogenic activity of naringenin by a factor of 10.000, since 8-prenylnaringenin [57] was equally estrogenic as β-estradiol used for comparison as a reference compound. This was expected, as 8-prenyl-naringenin [57] has been described as one of the most potent phytoestrogens identified so far (Milligan *et al.*, 2002; and references cited in Gerhauser, 2005). On the contrary, prenylation in position C6 as in 6-prenylnaringenin [58] only weakly enhanced the estrogenic potential of naringenin [56].

All five compounds were also tested for potential anti-estrogenic activity by concomitant application of the compounds in combination with β-estradiol (Figure 68.10b). Xanthohumol [53] and 6-prenylnaringenin [58] were most effective in inhibiting β-estradiol-mediated induction of ALP activity with IC_{50} values of 2.5 and 3.1 μM. Isoxanthohumol [55], naringenin [56] and 8-prenylnaringenin [57] also inhibited ALP induction, although at higher concentrations. Under *in vivo* conditions the overall response will most likely be an estrogenic effect due to the lower concentrations required for induction of ALP activity in comparison with those required for inhibition of β-estradiol-mediated induction of ALP.

Further Investigations with Xanthohumol

Of all compounds tested, xanthohumol [53] was identified as the most promising lead compound for cancer chemoprevention. In addition to the described activities, xanthohumol was tested for anti-proliferative activity. It decreased human recombinant DNA polymerase α activity and inhibited DNA synthesis in MDA MB 435 human breast cancer cells. This led to an arrest of the cell cycle in S-phase (Gerhauser *et al.*, 2002a). Poly(ADP-ribose)polymerase

(PARP) cleavage, activation of caspases-3, -7, -8 and -9 and downregulation of Bcl-2 protein expression were found to contribute to apoptosis induction in cultured human colon cancer cells (Pan *et al.*, 2005). Xanthohumol was also shown to induce cell differentiation in HL-60 human leukemia cells (Gerhauser *et al.*, 2002a) and demonstrated anti-angiogenic potential in a human *in vitro* anti-angiogenesis assay (summarized in Gerhauser, 2005).

Importantly, xanthohumol at nanomolar concentrations prevented carcinogen-induced preneoplastic lesions in mouse mammary gland organ culture (MMOC), providing a first direct indication for its chemopreventive potential (Gerhauser *et al.*, 2002a). Ongoing investigations determine mammary cancer preventive potential of xanthohumol in a long-term carcinogenesis model.

Summary Points

- Beer contains a complex mixture of phenolic compounds belonging to at least 10 different structural classes. In the present study, 48 beer compounds were tested in a series of *in vitro* bioassays indicative of cancer preventive potential. Notably, various structural classes of compounds had quite distinct profiles of activities.
- Overall, catechins and proanthocyanidins were identified as the most potent radical scavengers against DPPH, superoxide anion and peroxyl radicals. Cinnamic acids, xanthohumol and myricetin were most potent in scavenging very reactive hydroxyl radicals.
  With respect to modulation of xenobiotics metabolism, especially xanthohumol and various classes of flavonoids demonstrated potent effects: Xanthohumol, (prenylated) flavanones and the aglycons apigenin, quercetin and myricetin were identified as very potent inhibitors of Cyp1A activity at nanomolar concentrations. On the other hand, xanthohumol, flavanones and flavonols enhanced NAD(P)H:quinone reductase activity as an indication for elevated detoxification.
- Anti-inflammatory activity by inhibition of LPS-induced iNOS activity was provided by gallic acid, xanthohumol, isoxanthohumol, apigenin, selected flavonols and 4-ketopinoresinol, whereas catechins, xanthohumol and 8-prenylnaringenin were identified as Cox-1 inhibitors.
- Based on these results, it is likely that the combination of compounds with different activity profiles might enhance a potential biological effect *in vivo*. This aspect should be paid more attention in future studies.

Beer Inhibition of Azoxymethane-Induced Colonic Carcinogenesis

Hajime Nozawa and Keiji Kondo Central Laboratories for Frontier Technology, Research Section for Applied Food Science, Kirin Holdings Co., Ltd., Takasaki, Gunma, Japan

Abstract

Modulatory effects of beer intake on azoxymethane (AOM)-induced rat colonic carcinogenesis in male Fischer 344 rats were investigated. Single cell gel electrophoresis assay indicated that DNA damage of colonocytes, induced by a single AOM injection (15 mg/kg body weight), was significantly reduced in rats fed beer or malt extract for 2 weeks. Examination of aberrant crypt foci (ACF) formation in colonic mucosa, induced by AOM (15 mg/kg body weight, twice weekly), revealed that feeding of beer during the whole experimental period of 5 weeks significantly reduced the number of ACF by 35%. In the post-initiation protocol, a reduction in ACF formation by 26% was not significant. The efficacy in inhibition of ACF formation varied with the brand of beer. ACF formation was significantly reduced in rats treated with freeze-dried beer, but not with ethanol, suggesting that nonvolatile components of beer are responsible for the reduction. Significant suppression of ACF formation was observed in groups treated with hot water extract of malt, especially with extracts of colored malts, although no reduction was observed by feeding with hops extract. A long-term experiment of 42 weeks indicated that intake of beer decreased tumor incidence by 22% and decreased the number of neoplastic lesions, including adenocarcinomas and adenomas by 44%. These results suggest that components of beer have chemopreventive effects on colonic carcinogenesis induced by AOM and that intake of beer may contribute to a reduction in the risk of cancer susceptibility.

List of Abbreviations

ACF	Aberrant crypt foci
ACs	Aberrant crypts
AOM	Azoxymethane
FD beer	Freeze-dried beer
(I)	Initiation
(PI)	Post-initiation
(I/PI)	Initiation and post-initiation
AIN	AIN-76A
AD	Adenomas
ADC	Adenocarcinomas
Comet assay	Single cell gel electrophoresis assay

Introduction

The cancer process by which normal cells become progressively transformed to malignancy is now known to require the sequential acquisition of mutations that arise as a consequence of damage to the DNA. This damage may result from interactions of DNA with exogenous agents such as ionizing radiation, UV radiation, and chemical carcinogens. Around a century ago, it has already demonstrated that chemical carcinogens cause cancer in rodents, and it is now considered that cancer is caused by the process of sequenced steps summarized in Figure 69.1. The first step is called initiation process. This process includes multisteps of mutagenesis which leads normal cell to mutated (initiated) cell. The second process, promotion process, causes clonal expansion in initiated cell to form preneoplastic lesions or tumors. In the third process, progression process, tumors cause angiogenesis or metastasis to become more malignancy.

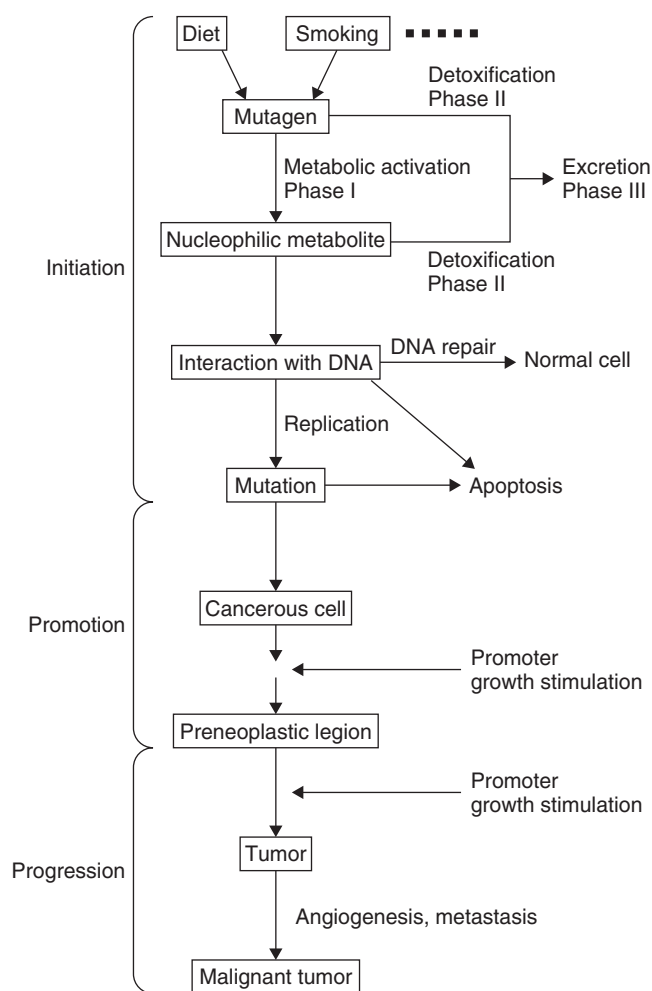
It is well recognized that in the fight against cancer, preventive strategies are in the long term better than therapy. The agents derived from dietary source or medicinal source are used for cancer chemoprevention to retard the progression of carcinogenesis or to inhibit carcinogenesis, leading to lowered risk of neoplastic diseases. Chemopreventive agents are generally categorized in five classes: antimutagens, antioxidants, antiinflammatory agents, signal transduction modulators, and hormone modulators by their molecular


Figure 69.1 Schematic representation of carcinogenesis. There are several steps in carcinogenesis and many targets exist for the preventive strategies for cancer incidences.

action in cancer prevention (Lieberman *et al.*, 1998). Some plant constituents, including antioxidative vitamins and phenolics, possess many biological functions, such as anti-inflammatory (Middleton and Kandaswami, 1992), anti-oxidative (Ho *et al.*, 1992), antimutagenic (Shiraki *et al.*, 1994; Arimoto-Kobayashi *et al.*, 1999), and antiangio-genetic (Paper, 1998) actions, related to cancer chemopre-ventive activity. The famous bioactive plant constituents which exert cancer chemopreventive effects are catechins, isothiocyanates, and isoflavones. Tea catechins exert anti-mutagenic and antiangiogenic activities (Rodriguez *et al.*, 2005). Isothiocyanates, for example sulforaphane from broccoli sprout, activate nrf2 (nuclear factor-erythroid 2 p45-related factor) and then induce phase II detoxifica-tion enzymes to prevent cancer initiation (Morimitsu *et al.*, 2002). Soy isoflavones are excellent chemopreventive agents against breast cancer by which exhibit antiestrogenic action *in vivo* (Cotroneo *et al.*, 2002).

For evaluation of cancer preventive activity, the typical approach is to screen *in vitro* or cell-based mechanistic assays, and then, to confirm the efficacy in animal carcinogenesis models with cancers or precancerous lesions as end points. For the screen *in vitro* or cell-based mechanistic assays, the battery of assays is designed to address various specific activi-ties associated with ability of cancer prevention, that is anti-mutagenicity, antiproliferation, and antioxidation. For the confirmation of the efficacy in animal carcinogenesis models, many chemically induced carcinogenesis models or trans-genic and gene knockout models have been developed (Steele *et al.*, 1994). Among chemical carcinogenesis models, AOM-induced colonic carcinogene-sis model is well established and utilized for the evaluation of chemopreventive agents. In the chemically induced carcinogenesis, those carcinogens are introduced to the experimental animals at a dose level high enough to induce a significant incidence and number of can-cers or preneoplastic lesions in a target tissue. The chemo-preventive agents are administered to animals before, at the same time, or after the treatment of carcinogen. The relative timing of the treatment of carcinogen and chemopreventive agent is useful in interpreting mechanistic insights for che-moprevention. For example, if the chemopreventive agents inhibit carcinogenesis when they are administered to ani-mals only before the carcinogen treatment, these agents most likely inhibit the initiation phase of carcinogenesis.

Beer, a low-alcohol beverage made primarily of malt and hops, is the most consumed type of alcohol in the world. Beer in moderation is recognized as a wholesome beverage because it is brewed by yeast from natural ingredients con-taining valuable substances in a harmonious composition nutritionally and some of which have been used in homeo-pathy for many hundreds of years. Beer is rich in amino acids, peptides, vitamins, and phenolic compounds derived from hops and malts, and thus may have some health benefits. In particular, it is rich in the B vitamins, for exam-ple niacin, riboflavin, pyridoxine (B6), and folate. The dried hop cones contain 4–14% polyphenols and these com-pounds are mainly phenolic acids, prenylated chalcones, flavonoids, catechins, and proanthocyanidins (Stevens *et al.*, 1998). In addition, hops provides a resin containing monoacyl phloroglucides, which are converted to hop bit-ter acids during the brewing process (De Keukeleire *et al.*, 2003). However, the majority (70–80%) of beer polyphenols are from malts. Barley polyphenols are not well characterized than hop polyphenols, although cathecins or proanthocyani-dins are derived from barley or malts. Recent research sug-gests that vitamin B6 in beer gives beer drinkers additional protection against cardiovascular disease compared to drink-ers of wine or spirits (Schlienger, 2003). Folate has been shown to be protective against cardiovascular disease and some cancers (Mayer *et al.*, 2001). In the epidemiological study, there is the evidence that high alcohol intake is related to carcinogenesis, especially to cancers of the mouth, phar-ynx, larynx, esophagus, and liver, and probable evidence for

an association between heavy drinking and colorectal cancer in men, and breast cancer in women (Potter, 1997). On the other hand, beer consumption was reported to significantly decrease the risk of prostate and colon cancer (La Vecchia et al., 1993; Jain et al., 1998). In the carcinogenesis experiments in rodents, there are some evidences. Nelson reported that beer significantly reduced the incidence of DMH (1,2-dimethylhydrazine)-induced tumors by 33% and the number of gastrointestinal tumors per rat from 2.91 ± 0.52 in the control group to 1.33 ± 0.43 in the beer-fed group, significantly (Nelson and Samelson, 1985). Hamilton incorporated high or low amounts of beer (23% or 12% of calories as alcohol in beer) into a liquid diet and the high beer group showed a significantly reduced incidence of tumors in the right colon (Hamilton et al., 1987). Moreover, beer intake reduced the chromosome damage of lymphocytes induced by X-ray radiation (Monobe and Ando, 2002). However, there are not enough evidences to clarify whether beer in moderation is cancer chemopreventive or not, and therefore, further detailed experiments are required. There are no experimental data for the relation between beer intake and whole steps of AOM-induced colonic carcinogenesis. In this chapter, modulating effects of beer on AOM-induced rat colonic carcinogenesis are stated (Nozawa et al., 2004, 2005).

Beer Inhibition of AOM-Induced DNA Damage in Colon Cells by Single Cell Gel Electrophoresis Assay

The single cell gel electrophoresis assay (comet assay) can be used to monitor DNA damage in individual organs of rodents exposed to mutagens (Singh et al., 1988; Sasaki et al., 1997). This assay is based on the ability of denatured DNA fragments to migrate out of the nucleus to form comet tails during electrophoresis under alkaline conditions (pH > 12.6) and has been used to examine the efficacy of chemopreventive agents in the initiation stage of carcinogenesis (Kassie et al., 2002; Guglielmi et al., 2003; Lazze et al., 2003). Male Fischer 344 rats at 5 weeks of age were fed a basal diet (CE2) and experimental drinks or a control drink (water) ad libitum for 2 weeks. In this experiment, experimental drinks were beer A (brewed from Munich malt, Pilsner malt, and hops), 1% (w/w) hot water extracts of hops and 5% (w/w) hot water extracts of malt. Each treatment group consisted of four animals and they received subcutaneous injections of AOM at a dose of 15 mg/kg body weight at 16 h before sacrifice. Three animals used as the vehicle controls were administered an equal volume of saline. Immediately after the sacrifice, colons were excised and colonocytes were prepared for comet assay (Singh et al., 1988; Pool-Zobel et al., 1993; Tice et al., 2000).

As shown in Figure 69.2, comet lengths of the colonocytes from untreated control animals were, on average,
Figure 69.2 Effects of beer A, malt extract, and hops extract on DNA damage in the rat colonocyte induced by AOM. Experimental drinks were fed to the animals ($n = 4$ for AOM treated and $n = 3$ for saline treated) for 2 weeks and colons were excised 16 h after AOM injection; 100 nuclei were analyzed for each animal in the comet assay. Bars indicate means ± SD values. Significantly different from the AOM control at *$p < 0.01$.

40 μm. AOM treatment induced significant DNA damage in colon cells: comet lengths in the group receiving water were 2-fold longer than those in the saline-treated control. Comet lengths in the groups fed either beer or malt extract were significantly shorter than those in the AOM-treated rats (37% and 36%, respectively), suggesting beer or malt extract inhibited AOM-induced DNA damage. A reduction in comet length of only 15% was observed in the hops extract group: this was not significant.

Beer Inhibition of AOM-Induced ACF Formation in Rat Colon

Aberrant crypt foci (ACF) are early morphological changes or hyperproliferative lesions found in the colon of humans and carcinogen-treated rodents: they are considered to be putative pre-neoplastic lesions for colon cancer (Bird, 1987; Roncucci et al., 1991; Pretlow et al., 1994). Azoxymethane (AOM)-induced colonic ACF in rats have been used to identify chemical agents that prevent colon cancer, including many dietary factors, especially those derived from plant sources (Olivo and Wargovich, 1998; Wargovich et al., 2000). In this chapter, ACF formation was investigated by three protocols over 5 weeks. Test samples, beer in liquid form or freeze-dried one (FD beer), were given to the animals during the whole experimental period of 5 weeks (I/PI), during initiation phase (I) and during post-initiation phase (PI). For the initiation (I) protocol, experimental samples were given for 17 days from the beginning of the experiment. For the post-initiation (PI) protocol, experimental samples were given 3 days after the second AOM injection until the end of the experiment. In all protocols for 1 week after the start of experiments, rats were treated with subcutaneous injections of AOM (15 mg/kg body weight) once a week for 2 weeks. ACF were distinguished

from normal crypts by their increased size, more prominent epithelial cells and their increased pericryptal area (Bird, 1987). The number of ACF and the number of aberrant crypts (ACs) per rat were quantified.

Typical ACF observed in rat colon by treatment with AOM are shown in Figure 69.3. Daily ingestion of beer A during the whole experimental period of 5 weeks (I/PI)

ACF
Figure 69.3 ACF with 4 ACs observed in the colonic mucosa of rat treated with AOM.

significantly reduced the number of ACF/colon by 35%, the total number of ACs/colon by 40%, and the number of ACF with 4 or more crypts/focus by 67% (Table 69.1). The inhibitory effect was less pronounced when beer A was introduced after the second AOM injection (PI): 26% reduction in ACF/colon, 33% reduction in ACs/colon, and 62% reduction in ACF with 4 or more crypts/focus. In the post-initiation protocol, a reduction in the total number of ACF was not significant. Intake of 5% ethanol in both protocols slightly reduced the number of ACF/colon, ACs/ colon, and ACF with 4 or more crypts, but these effects were not significant. It was observed that the extent of inhibition of beer on AOM-induced ACF formation varied among the brands of beer (Nozawa *et al.*, 2004).

Inhibitory Effects of FD Beer A on AOM-Induced ACF Formation

Since ethanol had only a small effect on AOM-induced ACF formation, the inhibitory effects of beer were thought to be attributable to the solid components. We evaluated the effects of various concentrations of FD beer A on AOM-induced ACF formation (Table 69.2). Animals

[a]Values are given as mean ± SD.
Significantly different from the AOM + AIN group: [b]$p < 0.05$; [c]$p < 0.005$.

were fed the AIN76-A basal diet containing 0.1%, 0.25%, 0.5%, 1%, 2%, or 4% FD beer for 5 weeks (I/PI). There were no significant differences in the daily consumptions of diets and final body weights among the experimental and control groups. A significant decrease in the number of ACF was observed by feeding FD beer at 1%, 2%, and 4% in the basal diet (28%, 31%, and 20% reduction, respectively). Diets containing 0.1%, 0.25%, and 0.5% FD beer were less effective with the same protocol, suggesting the optimal effective dose to be between 1% and 2%. These dosing levels for animal experiments were estimated as 265 and 530 ml beer intake for humans (Nozawa *et al.*, 2004).

We then compared the inhibitory effect of FD beer on AOM-induced ACF formation with that of piroxicam, a nonsteroidal antiinflammatory drug, in the three different protocols (I/PI, I, and PI in Table 69.3). Results indicated that feeding of 1% FD beer in the basal diet during the whole experimental period (I/PI) and initiation phase (I) significantly suppressed ACF formation; the total number of ACF was decreased by 28% and 30%, respectively. A weak suppressive effect was observed when the experimental diet was fed in the post-initiation phase (PI) (14%).

Piroxicam showed strong inhibition of ACF formation in the (I/PI) and (PI) protocols; the total number of ACF was decreased by 46% and 53%, respectively. No significant inhibition was observed in the (I) protocol.

Inhibitory Effects of Raw Materials on AOM-Induced ACF Formation

To investigate the nature of the inhibitory components in beer, AOM-injected animals were given malt or hops extracts during the experimental period of 5 weeks (I/PI). Treatment of animals with 5% malt extract significantly reduced the number of ACF, no decrease was observed in the group treated with 1% hops extract (Table 69.4). In addition, four different types of malt, Pilsner, Munich, Chocolate, and Caramel, were examined for their ability to inhibit ACF formation. While all types of malt extract significantly reduced the number of ACF, dark roasted malts were more effective than pilsner malt in reducing the number of ACF: Munich, Chocolate, and Caramel malts showed 28%, 28%, and 29% reduction, respectively (Table 69.5).

Table 69.7 Effects of beer A on AOM-induced tumor multiplicity in the colon of F344 rats

		Tumor multipulicity (tumors/animals)								
		Rectum		Middle colon		Proximal colon		Entire colon		
Group	Animals (n)	AD	ADC	AD	ADC	AD	ADC	AD	ADC	Total
Saline + water	13	0	0	0	0	0	0	0	0	0
AOM + water	22	0.14 ± 0.35^a	0.14 ± 0.47	0.32 ± 0.48	0.86 ± 0.83	0.09 ± 0.29	0.41 ± 0.73	0.55 ± 0.67	1.41 ± 1.10	1.95 ± 1.50
AOM + beer A	22	0	0.13 ± 0.47	0.09 ± 0.43^b	0.73 ± 0.70	0	0.14 ± 0.35^b	0.09 ± 0.43^c	1.00 ± 0.98^b	1.09 ± 1.15^c

[a] Values are given as mean $\pm$ SD.
Significantly different from the AOM + water group: [b] $p < 0.05$; [c] $p < 0.005$.

Beer Inhibition of AOM-Induced Colonic Carcinogenesis in Rats

Ninety-three rats were randomly divided into three groups, 40 rats for the AOM + water group, 40 rats for the AOM + beer A group, and 13 rats for the AOM untreated group (saline + water group). Rats received the basal diet (CE2) with water or beer *ad libitum* during the experimental period. Rats in the AOM + water and AOM + beer A groups received 2 subcutaneous injections of AOM (15 mg/kg body weight per week), rats in the saline + water group were injected with saline. Six rats each were taken from the AOM + beer A and AOM + water groups for the analysis

of ACF at 5, 16, and 24 weeks. At 42 weeks, all rats were sacrificed and colons were excised and examined for the presence of neoplastic. Each colon was divided into three parts: rectum colon (3 cm from anus), middle colon (3–15 cm part), and proximal colon (rest of the colon including cecum). The locations of all lesions were scored and these lesions were embedded in paraffin blocks, sectioned, and stained with hematoxylin and eosin (H&E) for histopathological analysis. Tumors were classified into carcinomas and adenomas according to published criteria (Ward, 1974).

The results of colon tumor development examined at week 42 are summarized in Tables 69.6 and 69.7. Tumors in the colon were classified as adenomas or adenocarcinomas.
Figure 69.4 Effects of beer A on AOM-induced ACF formation in the long-term experiment. Six rats were taken from the water- and beer-fed groups at 5, 16, and 24 weeks after the start of the experiment. Bars indicate means ± SD values. Significantly different from the water-control at *p < 0.05.

The incidence of adenomas and adenocarcinomas, and total tumor incidence in the entire colon were lower in the beer-fed rats than in the control group (41%, 18%, and 22% reduction, respectively). A decrease in the incidence of adenomas was detected in the proximal, middle, and rectum colons. The incidence of adenocarcinomas was not reduced in the middle and rectum colons, while there was a slight reduction in the proximal colon. Tumor multiplicity in the entire colon was significantly suppressed, by 44%, in the group given beer. The tumor multiplicity of adenocarcinomas in the proximal colon was significantly reduced by beer intake. A decrease in the number of ACF was observed at weeks 5, 16, and 24 in the beer-fed group (by 31%, 26%, and 20%, respectively) and the decrease was significant at week 16 (Figure 69.4). In conclusion, the cancer preventive effects of beer were observed using an AOM-induced colonic carcinogenesis model. Further studies are needed to clarify the components responsible and the underlying mechanisms. The results suggest that daily moderate consumption of beer may reduce the risk of cancer susceptibility in colon.

Summary Points

- Beer intake inhibited the AOM-induced colonic carcinogenesis in male Fischer 344 rats.
- Beer intake protected against DNA damage induced by AOM in the rat colonic mucosa by the single cell gel electrophoresis assay (comet assay).
- Beer intake inhibited the AOM-induced colonic ACF by the initiation treatment. Moreover, inhibitory trend in the ACF formation was observed by the post-initiation treatment. Taken together, beer ingredients exerted both antimutagenic and antipromotion activities.

- Beer intake inhibited the AOM-induced colonic tumor formation in the long-term experiments.
- Nonvolatile components of beer from raw materials are responsible for the inhibitory effects on AOM-induced colonic carcinogenesis. Alcohol in beer is not responsible for these inhibitory effects.

Biological Activities of Humulone

Hiroyasu Tobe Kochi National College of Technology, Department of
Materials Science and Engineering, Nankoku City, Kochi, Japan

Abstract

In the screening test for the substance to inhibit bone resorption, we found that humulone (HU) from beer hop extracts showed a strong inhibitory activity to bone resorption. The value of IC_{50} (50% inhibition of bone resorption) was 5.9 nM in pit formation assay. To study the mechanism of the action of HU, we studied the biological activity of HU as a bone resorption inhibitor with reference to prostaglandin biosynthesis. We found that HU inhibited the transcription of cyclooxygenase-2 (COX-2) gene of osteoblast MC3T3-E1 with an IC_{50} of 30 nM. The recent reports demonstrated a close relationship between COX enzymes and angiogenesis. We showed also that HU as a COX-2 inhibitor inhibited angiogenesis in chick embryo chorioallantoic membrane (CAM). The value of ED_{50} was 1.5 μg/CAM.

HU enhanced effectively the differentiation-inducing action of vitamin D to myelogenous leukemia cells in the concentration of 0.5–2.5 μM. HU also induced apoptosis (DNA fragmentation and cell death) in HL-60 cells in the concentration of 1–100 μg/ml.

List of Abbreviation

HU	Humulone
XH	Xanthohumol
PG	Prostaglandin
COX	Cyclooxygenase
DEX	Dexamethasone
NFκB	Nuclear factor kappa B
GRE	Glucocorticoid response element
VEGF	Vascular endothelial growth factor
CAM	Chick embryo chorioallantoic membrane
bFGF	basic fibroblast growth factor
PDGF-B	Platelet-derived growth factor-B
VD3	Vitamin D3
NBT	Nitroblue tetrazolium
ATRA	All-*trans*-retinoic acid
TPA	12-*O*-tetradecanoylphorobol-13-acetate
TNFα	Tumor necrosis factor-α

Introduction

Hop is originally a herb (medicinal plant) and has been believed that it had a female hormone (Zenisek and Bedner, 1960; Fenselau and Talalay, 1973). On the other hand, there is a direct relationship between a female hormone (estrogen) and osteoporosis. We thought that there was a possibility to find out an effective compound from hop extract for the treatment of osteoporosis. To estimate the effectiveness of hop extract to osteoporosis, we employed a pit formation assay system (Kitamura *et al.*, 1993) which is a method to estimate the activities of osteoclast cell by counting the number of cavity (pit) on the surface of a dentine slice.

We speculated that the inhibitor, which interferes with the function of osteoclast, will express the inhibitory activity to the bone resorption of osteoclast.

Therefore, we started to screen the inhibitor against osteoclast function (bone resorption) by the pit formation assay.

Hop Extract and Osteoporosis

In the screening assay for the compound to inhibit bone resorption, we found two inhibitors from hop cake (Tobe *et al.*, 1997a). The hop cake (250 g) was extracted with acetone (2 l) to give a syrup (50 g) after the removal of the solvent. These two compounds in the syrup (17.5 g) were purified by Dowex-1 (x4, 200–400 mesh, CH_3COO^- type) column chromatography (stepwise elution with 0.5%, 5%, and 20% acetic acid in 80% methanol) and high performance liquid chromatography (reversed phase column; Chromatorex-ODS DM1020T) with 80% methanol. On the basis of ^{1}H-NMR, ^{13}C-NMR, and mass spectra, we concluded that one of the two inhibitors was to be xanthohumol (XH), and the other one was to be humulone (HU) (Tobe *et al.*, 1997a). The structure of HU is shown in Figure 70.1. The bone resorption inhibitory activities of the two compounds are shown in Table 70.1. The IC_{50} (the concentration of 50% inhibition to bone resorption) value
Figure 70.1   Structure of humulone.

Table 70.1   The bone resorption inhibitory activity of xanthohumol and humulone

Concentration of compound (M)		Number of pits (average ± SD)	Inhibition (%)
Xanthohumol	0	248.3 ± 35.7	–
	10^{-6}	162.7 ± 41.2*	34.5
	10^{-5}	15.8 ± 6.0*	93.6
	10^{-4}	0*	100
Humulone	0	328.0 ± 51.0	–
	10^{-11}	274.3 ± 91.6*	16.4
	10^{-10}	274.3 ± 54.9*	16.4
	10^{-9}	251.5 ± 135.4*	23.3
	10^{-8}	128.5 ± 23.1*	60.8
	10^{-7}	34.5 ± 7.4*	89.5
	10^{-6}	6.5 ± 3.8*	98.0
	10^{-5}	0.3 ± 0.5*	99.9

Notes: Dentin slices (6 mm diameter, 0.15 mm thickness) were placed in each well of a 96-well culture plate (Falcon, Becton Dickinson and Company, Lincoln Park, NJ). One hundred µl of α-MEM (minimum essential medium) containing 5% fetal bovine serum (Flow Laboratories, Scotland) and synthetic rat parathyroid hormone (residues 1–34, Backem, Inc., CA) were added to each well and each slice was overlaid with 100 µl of 1×10^6 mouse bone marrow cells suspension. The cells were then incubated for 3 days at 37°C in a humid atmosphere of 10% CO_2 and 90% air. After incubation, the cells on a slice were removed, and resorbed pits were stained with Coomassie brilliant blue. Bone resorption was assessed by counting the number of pits under a light microscope.

*$p < 0.01$ vs. 0 M ($n = 6$, Bonferroni/Dunn).

of XH and HU were 1.3 µM and 5.9 nM, respectively, in pit formation assay. HU was one of the strongest inhibitors to bone resorption.

HU and COX-2 Gene

The mechanism of the action of HU to bone resorption was unknown. The molecular model of HU was similar to that of prostaglandin (PG). Both HU and PG molecules have a cyclic (ring) structure and side chains in their molecules. We speculated, therefore, that HU might interfere with the cascade pathway of arachidonic acid-PG biosynthesis. On the other hand, it is reported that PGE2 is one of key factors for bone remodeling (Yokota *et al.*, 1986) and that PGE2 produced by osteoblastic cell line (MC3T3E1)

is a chemical mediator to develop and differentiate osteoclast function (Yamamoto *et al.*, 1995, 1998).

Cyclooxygenase-1 (COX-1) and -2 are responsible enzymes for PG biosynthesis. COX-1 is a constitutive enzyme and COX-2 is an inducible enzyme for the biosynthesis of PG. It is reported that COX-2 enzyme is biologically and pathologically more important than COX-1 enzyme (Herschman, 1996; Smith *et al.*, 1996). Therefore, we studied the mechanism of the action of HU to bone resorption with reference of dexamethasone (DEX) in PG biosynthesis (Yamamoto *et al.*, 2000).

We estimated the effects of HU and DEX on tumor necrosis factor-α (TNFα)-mediated COX-2 induction. The results of PGE2 release assay (Figure 70.2a and b), the COX-2 activity assay (Figure 70.2c and d), the COX-2 mRNA assay (Figure 70.2e and f), and the luciferase assay (Figure 70.2g and h) showed that HU inhibited the production of PGE2 and the transcription of COX-2 gene of osteoblast MC3T3E1. As shown in Figure 70.2c and d, the value of IC_{50} of HU and DEX were 30 and 1 nM, respectively. We thought that HU inhibited the osteoclast function (bone resorption) through the inhibition of COX-2 gene expression (transcription) and then PGE2 production.

As shown in Figure 70.3, HU inhibited strongly COX-2 enzyme activity (IC_{50}: 1.6 µM) rather than COX-1 enzyme activity (IC_{50}: 70 µM). HU showed the specific affinity to COX-2 enzyme rather than COX-1 enzyme.

Figure 70.4 showed that both HU and DEX inhibited almost equally the NFκB and NF-IL6 response element activity induced by the addition of TNFα.

As shown in Figure 70.5a, HU inhibited more strongly the PGE2 release from MC3T3E1 cells induced by the addition of TNFα than DEX did. On the other hand, Figure 70.5b showed that DEX reacted strongly to glucocorticoid response element (GRE). But HU did not react strongly to GRE. Therefore, the mechanism of action of HU was different from that of DEX. These data suggested that the HU-dependent suppression of COX-2 induction was mediated by not glucocorticoid response but NFκB and NF-IL6 response element.

HU and Angiogenesis

According to the recent reports, there is a close relationship between COX-2 and angiogenesis (Masferrer *et al.*, 2000). We speculated that an inhibition of COX-2 gene expression might induce the inhibition of angiogenesis.

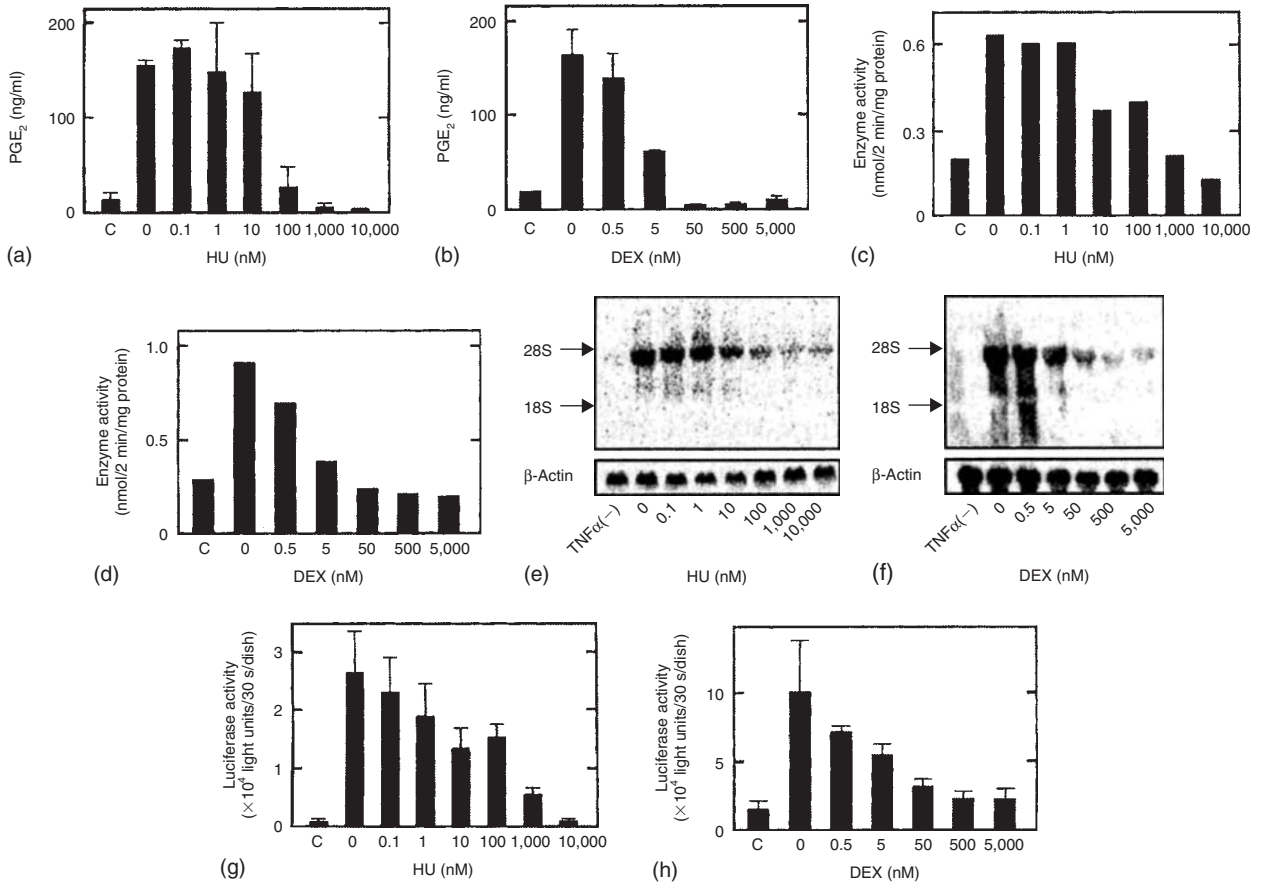
HU showed (Shimamura *et al.*, 2001) the strong *in vivo* antiangiogenic activity, clearly producing an avascular zone in chick embryo chorioallantoic membrane (CAM) (Figure 70.6b). In contrast, no avascular zones were observed in any of the control embryos treated with 0.9% NaCl alone (Figure 70.6a). The inhibitory activity of HU and NS-398 (positive control; an specific inhibitor to COX-2 enzyme) to


Figure 70.2 Effects of HU and DEX on TNFα-mediated COX-2 induction. TNFα was present at a concentration of 10 ng/ml for HU and 20 ng/ml for dexamethasone. HU (a, c, e, and g) or dexamethasone (b, d, f, and h) was added at various concentration. For the PGE2 release assay, 3×10^5 MC3T3-E1 cells were incubated with TNFα for 12 h (a and b). For the COX-2 activity assay, 2.2×10^6 cells were incubated with TNFα for 12 h (c and d). For the COX-2 mRNA assay, 2.2×10^6 cells were incubated with TNFα for 2 h (e and f). Total RNA (10 μg/ml) was applied to Northern blot analysis for COX-2 mRNA assay and β-actin mRNA. For the luciferase assay (g and h), 7.8×10^5 confluent cells were transfected with luciferase plasmid including promoter regions of mouse COX-2 gene. The cells were incubated with TNFα for 12 h. (a), (b), (g) and (h) are means ± SD of triplicate determination. (c), (d), (e) and (f) are typical results of the experiments each repeated three times giving similar results.
Figure 70.3 Effects of HU on COX-1 and -2 activities. The standard COX assays were performed with [1-14C]-arachidonic acid (10 μM) incubated with the COX-1 of sheep seminal vesicle microsome (4.3 μg protein) (closed circle) or the COX-2 of MC3T3-E1 cell lysate (50 μg protein) stimulated by phorbol 12-myristate and A23187 (open circle). HU was added at various concentrations. Data are means ± SD of duplicate determination.

angiogenesis by CAM assay is shown in Figure 70.6c. The dose-dependent inhibition of *in vivo* angiogenesis CAM assay by HU and NS-398 were observed and the value of ED_{50} of HU and NS-398 were 1.5 and 65 μg/CAM, respectively. The inhibitory activity of HU was stronger than that of NS-398 by 40 times.

We tested also an assay of rat lung endothelial cell growth inhibition (Shimamura *et al.*, 2001). Figure 70.7 showed the effect of HU and NS-398 on proliferation of endothelial cells using KOP2.16 (murine endothelial cell line) stimulated by 10 ng/ml basic fibroblast growth factor (bFGF). HU strongly inhibited the proliferation of endothelial cells. The value of ED_{50} of HU and NS-398 were 7 and 100 μM, respectively. The inhibitory activity of HU was stronger than that of NS-398 by 14 times.

Tumor cells are known to produce various factors, such as VEGF (vascular endothelial growth factor), bFGF, and
Figure 70.4 Effect of HU and DEX on NFκB and NF-IL6 response elements as examined by the luciferase analysis. Confluent MC3T3-E1 cells (7.8×10^5) were transfected with luciferase plasmid including NFκB or NF-IL6 response element. The cells were incubated for 12 h in the presence or absence of 10 ng/ml TNFα, 5 μM DEX, or 10 μM HU as indicated. Data are means ± SD of triplicate determination.

PDGF-B which contribute to angiogenesis. To evaluate if HU suppresses the production of VEGF by KOP2.16 endothelial cells or Co26 colon cancer cells which constitutively express COX-2 protein, we measured VEGF in the culture medium of these cells that were treated or not treated with HU. HU at 100 μM substantially inhibited the production of VEGF by KOP2.16 cells (Figure 70.8a) and Co26 cells (Figure 70.8b). The inhibition was more significant in tumor cells than in endothelial cells at 10–100 μM of HU.

HU and Myelogenous Leukemia

HU enhanced effectively the differentiation-inducing action of vitamin D to myelogenous leukemia (Honma *et al.*, 1998).

The active form of vitamin D (VD$_3$; 1α, 25-dihydroxy-vitamin D$_3$) inhibits proliferation and induces differentiation of several leukemia and solid tumor cells (Hozumi, 1983; Koeffler, 1983; Niitsu *et al.*, 1997), but its hypercalcemic effects prevent it from the clinical use (Bikle, 1992). VD$_3$ mobilizes calcium store from bone by inducing the dissolution of bone mineral and matrix. VD$_3$ is a potent stimulator of bone resorption (Raisz *et al.*, 1972; The Southern California Leukemia Group *et al.*, 1985), whereas HU is a potent inhibitor of bone resorption (Tobe *et al.*, 1997a). Then we examined the effect of HU on the differentiation of human monoblastic leukemia U937 cells induced by VD$_3$. As shown in Figure 70.9a, in the presence of VD$_3$ (2 and 4 nM), HU at concentrations up to 2.5 μM induced the nitroblue tetrazolium (NBT)-reducing activity in the U937 cells, and HU effectively enhanced this activity
Figure 70.5 Possible binding of HU and DEX to glucocorticoid receptor. (a) MC3T3-E1 cells (3×10^5) were incubated with TNFα for 12 h in the presence or absence of 5 μM DEX or 10 μM HU. Various concentrations of RU486 were added. Produced PGE2 was measured using radioimmunoassay. Data are means ± SD of triplicate determination. (b) Confluent cells (7.8×10^5) were transfected with luciferase plasmid including two glucocorticoid response elements (GRE) and thymidine kinase gene (tk). The cells were incubated for 12 h in the presence or absence of TNFα, 5 μM DEX, or 10 μM HU. Data are means ± SD of triplicate determinations.

induced by VD$_3$ and the enhancing effect was statistically significant (Figure 70.9b). VD$_3$ induced lysozyme and α-naphthyl acetate esterase activities, other markers of monocytic differentiation, and the combination of VD$_3$ with HU induced these activities more effectively than VD$_3$ alone (Figure 70.9c and d). Morphologically, HU enhanced the monocytic differentiation of U937 cells induced by suboptimal concentration of VD$_3$ (data not shown).

U937 cells are induced to differentiate by TPA (12-*O*-tetradecanoylphorobol-13-acetate), ATRA (all-*trans*-retinoic acid), and TNFα. We examined whether HU enhanced the differentiation of U937 cells induced by these compounds.

(a)   (b)   (c)
Figure 70.6 Inhibitory effect of HU on *in vivo* angiogenesis in CAM. No (a) or 10 µg/ml (b) HU was added to the CAM surfaces of 4-day-old fertilized eggs, and then the eggs were incubated for 46–48 h. HU produced an avascular zone (surrounded by arrows), indicating its antiangiogenic activity. (c) Dose-dependent inhibition of *in vivo* angiogenesis in CAM by HU and NS-398. The antiangiogenic activity was assessed. Values are the means of five experiments. HU potently inhibited angiogenesis in CAM in a dose-dependent manner.
Figure 70.7 Effect of HU on proliferation of endothelial cells. KOP2.16 cells were treated for 48 h with HU or NS-398 at various concentrations indicated. Data are means ± SD from five separate wells. HU potently inhibited the proliferation of endothelial cells.

To access the effect on differentiation, we combined HU with suboptimal concentration of TPA, ATRA, and TNFα. HU also increased the NBT-reducing activity induced by these inducers (Table 70.2).

Other myelomonocytic leukemia cells (erythroid leukemia K562, HEL, and KU812) were induced to differentiation by the addition of VD_3 and this was also enhanced by the addition of HU as shown in Figure 70.10 (the case of K562).

These results indicated that the combination of VD3 derivatives with HU is a promising candidate for differentiation therapy of monocytic leukemia.

HU and Apoptosis

HU induced apoptosis in the promyelocytic leukemia cell line HL-60 in the concentration of 1–100 µg/ml (Tobe

(a)

(b)

Figure 70.8 Effect of HU on production of VEGF by endothelial cells and tumor cells. KOP2.16 cells (a) and Co26 cells (b) were treated for 24 h with HU at various concentrations indicated. VEGF in conditioned medium was assayed by ELIZA. HU suppressed the production of VEGF by endothelial cells and tumor cells.

et al., 1997b). The time-dependent cell death ratio and DNA fragmentation pattern are shown in Figures 70.11 and 70.12, respectively. In the hydrogen peroxide hemolysis test of antioxidants, IC_{50} value of HU and ascorbic acid

Cells were cultured with various concentrations of HU in the presence of 0 (■), 1 (●), 2 (▲), or 4 (◆) nM VD_3 for 6 days.

Table 70.2 Effect of humulone on NBT reduction of U937 cells treated with ATRA, TPA, or TNFα

Treatment	NBT reduction	$(A_{300}\ 10^7\ cells)$
	−Humulone	+Humulone
None	1.2 ± 0.2	1.8 ± 0.2
ATRA	1.6 ± 0.2	3.1 ± 0.4
TPA	1.9 ± 0.3	3.6 ± 0.5
TNFα	1.8 ± 0.2	2.9 ± 0.3

Note: Cells were cultured with 8 nM ATRA, 0.5 ng/ml of TPA, or 1 ng/ml of TNFα in the presence or absence of 2 μM humulone for 5 days. Values are means $\pm$ SD from three separate experiments.

were 2.8×10^{-5} and 1.25×10^{-4} M, respectively. Other antioxidants, quercetin (Takahama, 1988; Whalley *et al.*, 1990) and genistein (Pratt and Watts, 1964; Letan, 1966), showed the apoptosis-inducing activity (Figure 70.13; DNA fragmentation and cell death). We speculated that the apoptosis-inducing activity of HU had a direct correlation with not its inhibitory activity to bone resorption but its antioxidant activity.

Summary Points

- The inhibition of COX-2 gene expression by HU caused the inhibitions of bone resorption and angiogenesis.
- The antioxidant activity of HU induced the apoptosis to the promyelocytic leukemia cell line HL-60.
- The biological activities of HU are useful for our health and the structure of HU presents the idea of the drug design for enzyme inhibitor.

Conclusion

HU had five different biological activities as described below:

1. HU showed the strong inhibitory activity to bone resorption (IC_{50}: 5.9 nM) in pit formation assay. XH had the weaker inhibitory activity (IC_{50}: 1.3 μM). HU might be a candidate for the treatment of osteoporosis.
2. HU inhibited both COX-2 gene transcription (IC_{50}: 5.9 nM) and COX-2 enzyme activity (IC_{50}: 1.6 μM).
Figure 70.10 Effect of HU on induction of erythroid differentiation of K562 cells. Cells were cultured with various concentrations of HU for 4 days. Hemoglobin-producing cells were assayed by benzidine staining. Values are means ± SD from three separate experiments.
Figure 70.11 Growth inhibition of HL-60 by HU. HL-60 cells were incubated with or without HU in the concentration of 1, 10, and 100 g/ml, respectively. The final concentration of EtOH in the culture medium was below 1%. The samples (50 μl) of the culture medium were taken after 0, 2, 4, 6, 8, and 20 h of cultivation and used for counting the viable cell number of HL-60 by trypan blue staining. The four symbols present the viable cell number of HL-60 in the concentrations of 0 (○), 1 (▲), 10 (□), and 100 μg/ml (■).
Figure 70.12 DNA fragmentation pattern of HL-60 by HU. HL-60 cells were treated as described in Figure 70.11. The samples (1 ml) of the culture medium were taken after 0, 2, 4, 6, 8, and 20 h of cultivation and used for the analysis of DNA fragmentation pattern of HL-60. After the samples were treated with RNase A and proteinase K, 10 μl from each sample was applied to 1.5% agarose gel and analyzed. We used λc1857 DNA digested with *Hind*III for DNA size standards.

The inhibition of signal transduction by HU may not involve in a glucocorticoid receptor but may be mediated by the NFκB and NFIL6 response element.

3. HU inhibited angiogenesis in CAM assay (ED$_{50}$: 1.5 μg/CAM). HU also inhibited *in vitro* tube formation of vascular endothelial cells. Moreover it suppressed the proliferation of endothelial cells and the production of VEGF, an angiogenic growth factor, in endothelial and tumor cells. Thus, HU was a potent angiogenic inhibitor both *in vitro* and *in vivo*. HU may be applied clinically as an antiangiogenic agent in the treatment of cancer, rheumatoid arthritis, and diabetic retinopathy.

4. HU enhanced effectively the differentiation-inducing action of vitamin D to myelogenous leukemia cells in
Figure 70.13 DNA fragmentation pattern of HL-60 by ascorbic acid, quercetin, and genistein. HL-60 cells were treated with or without ascorbic acid (100 μg/ml), quercetin (100 μg/ml) and genistein (100 μg/ml), as described in Figure 70.11. The samples (1 ml) of the culture medium were taken after 0, 4, 8, and 20 h of cultivation and used for the analysis of DNA fragmentation pattern of HL-60 as mentioned in Figure 70.12. Asc, ascorbic acid; Qu, Quercetin; Ge, genistein.

the concentration of 0.5–2.5 μM. The combination of VD$_3$ derivatives with HU is a promising candidate for differentiation therapy of monocytic leukemia.

5. HU had the activity to induce apoptosis (DNA fragmentation and cell death) in HL-60 cells in the concentration of 1–100 μg/ml.

We concluded that the primary target molecule of HU was COX-2 gene and that the inhibition of the gene transcription caused the inhibition of bone resorption and angiogenesis. The secondary biological activity of HU was its antioxidant activity, and this activity might induce the apoptosis in HL-60 cells.

Desmethylxanthohumol from Hops, Chemistry and Biological Effects

Reinhard A. Diller and Herbert M. Riepl Institute of Resource and Energy Technology, Technical University of Munich, Straubing, Germany
Oliver Rose, Corazon Frias, Günter Henze and Aram Prokop Department of Pediatric Oncology/Hematology, University Medical Center Charité, Campus Virchow, Berlin, Germany

Abstract

Desmethylxanthohumol is a chalcone-type compound isolated from hops. It is present in extracts in a concentration of about 1/5 of the xanthohumol content. It isomerizes easily in aequous media like beer to a mixture of 6- and 8-prenylnaringenin, a phytoestrogen with hormonal activity. Desmethylxanthohumol is a powerful apoptosis inducing agent in lymphoid leukemic cell assays and it acts as a chemoprotective compound activating oxidation and excretion of harmful xenobiotics.

List of Abbreviations

BJAB	Burkitt-type lymphoma cell line
CAD	Caspase-3-activated DNA fragmenting enzyme
EC_{50}	Half effective dosis
EIMS	Electron impact mass spectroscopy
LDH	Lactate dehydrogenase
MeOH	Methanol
MEM	2-Methoxyethoxymethyl-protecting group
MOM	Methoxymethyl-protecting group
6-PN	6-Prenylnaringenin
8-PN	8-Prenylnaringenin
TNF-α	Tumor necrosis factor
UV–VIS	Spectroscopy with ultraviolet and visible light
λ_{max}	Peak in the UV–VIS spectrum with top most intensity
$\log \varepsilon$	Extinction of the λ_{max}-peak at logarithmic scale

Introduction

Hop is extracted at technical scale with supercritical carbondioxide since nearly 25 years. The knowledge of the cytoprotective effects of hop polyphenoles has triggered some interest how these compounds in beverages possibly can be enriched. It was seen easily that by using carbondioxide extracts of hops as wort, very little of the flavonoid content of the plant is available for the beverage since it is only sparingly soluble in this extractant. This can be overcome by addition of some dried hops. The best known polyphenole from hops is xanthohumol, besides that there are some minor compounds which differ slightly from xanthohumol with respect to their substitutions pattern and properties. Of particular importance due to its relation to hormonal activities of hop and hop containing preparations is desmethylxanthohumol, present in a concentration of 1/5 of the xanthohumol content of a plant.

Chemistry

Desmethylxanthohumol **1** or fully named 1-(2′,4′,6′-trihydroxy-3′(3″-methylbut-2″-enyl) phenyl-3-(4-hydroxyphenyl) prop-2-en-1-one, is one of the five to seven major polyphenoles existent in hop, which are distinguished by the length of their carbon side chains and methylation pattern.

Reactivity

Like xanthohumol, **1** belongs to the chalcone type of chemical compounds which means that there are two phenolic ring moieties (Figure 71.1, **3**, called ring A and B) connected by a three atom-membered carbon chain. This chain is a so-called vinylogous system composed of a ketone group and an adjacent carbon—carbon double bond, usually in the trans configuration. Vinylogous double bonds are very reactive at the β-carbon atom, this site in the molecule is deficient in electron density. Chalcone compounds, which have a suitable heteroatom like oxygen in position (2′) thus can close a ring with the activated carbon—carbon double bond to form a flavanone type of compound. The heterocyclic ring formed like this is saturated with respect to the vinylogous double bond and can decompose under suitable conditions to give back the original chalcone type of molecule. Desmethylxanthohumol differs in its chemical structure from xanthohumol in one particular point, at carbon 6′, where an oxygen is substituted with a methyl group. Xanthohumol **2** itself can thus form only isoxanthohumol **6** because the hydroxyl group at position 6′ is blocked (Figure 71.2).
Figure 71.1 Chemical structure of the title compounds. Xanthohumol (**2**) and desmethylxanthohumol (**1**) are the main flavonoids in hop. Both compounds belong to the chalcone type of natural products characterized by a model structure (**3**).
Figure 71.2 Ring-closure reaction xanthohumol. Solutions of chalcones in water are unstable. They have a tendency to close a ring by virtue of the carbon—carbon double bond, which is electron poor and thus reacts with a nearby 2′-hydroxylgroup. Xanthohumol (**2**) reacts in this manner to give isoxanthohumol (**6**).

In this manner, desmethylxanthohumol **1** can form two isomers due to the possibility of rotation around the carbon bond of the aromatic B ring to the keto-group. By this rotation, either oxygen at 6′or 2′can undergo the vinylogous reaction. These isomers are 6-prenylnaringenin and 8-prenylnaringenin. Principially, two enantiomeric molecules are formed by the ring closure, but the resulting prenylnaringenins are devoid of optical activity.

Physical and chemical data

Desmethylxanthohumol is a yellow powder. Its UV–VIS spectrum shows an absorption at $\lambda_{max} = 366\,nm$ (log ε = 4,591, solv: MeOH). In the infrared spectrum, **1** shows a characteristic carbon–oxygen stretching vibration at $1,623\,cm^{-1}$. Its mass spectrum (electron impact mass spectroscopy, EIMS) has been reported to be $e/m = 340$ (M^+, 100%), 285 (M-$C_4H_7^+$), 26%, 220 (A^+-ring fragment), 13%, 165 (A ring fragment-$C_4H_7^+$), 51%, 120 (B^+-ring fragment), 16%. Nuclear magnetic resonance data (Hänsel and Schulz, 1988; Stevens *et al.*, 1997) can be found in Table 71.1. To determine the concentration of **1** in any solutions, high performance liquid chromatography

(HPLC) analysis using reversed phase columns (C18) is applied, the mobile phases being composed of acetonitrile, another organic solvent and a trace of formic acid. Quantitative assessment by gaschromatography is not considered to be accurate, there is some discrimination and decomposition rendering this method unreliable.

Occurrence in beverages

Desmethylxanthohumol is more soluble in aqueous media than xanthohumol, thus during brewing it is extracted from hops preferably. At the same time, it is isomerized more quickly according to scheme 71.**3**. Following addition of a sample of hop to hot brew, only after 15 min boiling its total content of **1** can be found in solution in form of 8-PN (**4**) and 6-PN (**5**) in a ratio of about 1:4, meaning 6-PN (**5**) is formed preferably (Stevens *et al.*, 1999a). From there on, substances **1**, **4**, **5** disappear from the solution due to absorption on precipitating proteins, carbohydrates or filtering media. Usually, only 10–15% of the original content remain in the beverage amounting to 35–15 µg/l in the form of **4** and **5** (Stevens *et al.*, 1999b) (Figure 71.3).

Table 71.1 Nuclear magnetic resonance data of desmethylxanthohumol

^{1}H-NMR assignment		^{13}C-NMR assignment	
Hydrogen atom no.	NMR-shift (d^6-DMSO, ppm*)	Carbon atom no.	NMR-shift (d^6-DMSO, ppm*)

Note: ^{1}Hydrogen and ^{13}Carbon – Nuclear magnetic resonance-shift data of individual atoms in desmethylxantho-humol **1** in ppm* relative to tetramethylsilane, which is generally acknowlegded to be 0 ppm, calibration against a standard of deuterium containing solvent (d^6-DMSO = deuteriodimethylsulfoxide).
Figure 71.3 Ring-closure reaction of desmethylxanthohumol. Whereas xanthohumol in water only forms isoxanthohumol by a ring-closure reaction, desmethylxanthohumol (**1**) has the possibility to give two compounds because there are two hydroxylgroups. Either hydroxyl group at 2′ can react to give 6-prenylnaringenin (**5**) or hydroxyl group at 6′ reacts to give 8-prenylnaringenin (**4**).

Synthesis

In contrast to xanthohumol, there is a synthesis of **1** (Diller *et al.*, 2005). The key step of the synthesis of prenylated chalcones often relates to the appropriate acetophenone and benzaldehyde for aldol condensation. It is often complicated by interference of the protecting groups with the conditions of the aldol condensation. The lucky use of protecting groups is crucial for the outcome. After checking most of the usual methods without success, the hydroxy-functions of the educts were found to be protected by methoxymethyl-protecting groups (MOM) with advantage, the acid-catalysed deprotection turned out to occur at milder reaction conditions compared to the 2-methoxyethoxymethyl-protecting group (MEM) ethers. The resulting acetophenone was condensed

with a *p*-hydroxybenzaldehyde derivative and deprotected (Figure 71.4).

Biological Activities

Hormonal effects

The chalcone–flavanone system of natural compounds from hops is active toward the estrogenic hormonal system in the human body (Milligan *et al.*, 2000; Zierau *et al.*, 2003). 8-PN is one of the most potent phytoestrogens, due to its activity at estradiol receptors, $EC_{50} = 4.4$ nmol/l compared to estradiol itself (0.82 nmol/l). Information about this issue with prenylated chalcones would become important
Figure 71.4 Synthesis of desmethylxanthohumol via aldol condensation. Many chalcone-type compounds were synthesized according to the scheme of an aldol condensation – reaction of a suitable aldehyde (b) with an acetophenone compound (a) bearing the right assembly of substituents. The problem is that the desired reaction conditions often lead to quite different product because of interference by the hydroxyl-substituents. In the case of desmethylxanthohumol, one hydroxyl group in position 4′ had to be protected as a methoxymethylether. In concentrated alkali in a water/methanol mixture, the desired reaction proceedes sufficiently. Desmethylxanthohumol was obtained finally by removing the protecting group with hydrochloric acid.

in connection with a prospective hormone replacement therapy to counteract osteoporosis. In contrast to 8-PN, desmethylxanthohumol – like xanthohumol – does not activate any estrogen receptors (De Keukeleire *et al.*, 1997; Milligan *et al.*, 2000). If there is any estrogenic activity from beverage preparations containing xanthohumol or desmethylxanthohumol, it may derive solely from an already observed isomerization or from unknown compounds. Concentration of circulating estradiol in the plasma (may amount up to 400 pM in women and 25 pM in men) is tightly regulated at the level of the synthesis of estradiol from androstenedione or testosterone by the enzyme aromatase. At least 8-PN itself, being able to activate estradiole receptors, can interfere substantially with aromatase activity. It is thus acting by a kind of pseudo product inhibition mechanism. Surprisingly, xanthohumol and isoxanthohumol, not being estrogen receptor agonists, inhibited aromatase as well, xanthohumol better than isoxanthohumol. Although for desmethylxanthohumol no data were available, one can assume some inhibition of aromatase which can account for the high aromatase inhibiting properties of some beers (Monteiro *et al.*, 2006).

Cancer protection and cytotoxic activities

Today, cancer is considered as an uncontrolled tissue growth which has two causes: Firstly, it may be induced by mutations or other genetic events resulting in impaired transcription from the DNA to yield ill functioning cell machinery not so severe to lead to cell death. Instead there can be continuous active growth inducing regulatory enzymes. Secondly, it may be caused by growth hormonal influences leading to deregulation at the level of signalization from the cellular environment to the intact cell nucleus. Breast cancer cells, for example, from post menopausal women most likely show hormonal-dependent growth activity. Not only is proliferation greatly induced by estradiol and every agent acting as an estradiol receptor agonist, but these cells

also show very high aromatase activity enabling them to produce estradiol from its source. This type of early neoplastic tissue cells eventually can undergo cell death by so-called induced suicide mechanisms or apoptosis following lack of growth factors (among them – estradiole). Apoptosis is a mechanism for self-digestion of cells after some clearly defined stimuli from inside or outside the cell. It consists of condensation of chromatin, fragmentation of the DNA into small parts of about 180 base pairs, disintegration of the nucleus. Especially, the appearance of an array of small DNA fragments ("DNA ladder") is very characteristic of apoptosis and offers clear means of distinguishing from necrotic cell death by some toxic influence. Apoptosis is the most important mechanism in regulating tissue homeostasis (meaning the equal or nearly equal numbered replacement of cells during existence of an organism, when cells become aged and have to be replaced). Failure of apoptosis is among the most prominent reasons for uncontrolled cell proliferation.

Apoptotic stimuli can be: a lack of growth factors, missing contact to neighbor cells, ill replicated or severely damaged DNA and high or low molecular substances which contact sometimes very specific receptors. Apoptosis is only the last event in a series of signaling/regulating mechanisms. Tumor cells in the progression phase, for example, show uncontrolled cell proliferation, independent of growth factor stimulation, but susceptible to other means of apoptosis induction. This has given insight to the fact that there is more than one simple mechanism leading to apoptotic cell death. Following damage of a site of the DNA, repair/checking mechanisms are activated; especially a protein called P53 is involved, usually committing these cells to programmed cell death or apoptosis. This is called the "intrinsic" way of apoptosis induction. In the system of immune-competent cells (T-lymphocytes, B-cells, etc.), there is a cell surface receptor (Fas-receptor, "death"-receptor) which, upon contact with Fas-ligand protein from the surrounding medium, signalizes the "extrinsic" induction of apoptosis. Another important protein, able to induce apoptosis
Figure 71.5 Decrease of proliferation of BJAB cells under influence of desmethylxanthohumol. Cell density (number of cells $\times 10^5$/ml) at various concentrations of desmethylxanthohumol after 24 h. Beyond a concentration of 75 µM in the culture medium, **1** induces a significant inhibition of proliferation in BJAB cells after 24 h treatment. *Source*: From Diller *et al.* (2005).

Figure 71.6 Viability assessment of BJAB cells after treatment with desmethylxanthohumol by measurement of LDH release. LDH is a cytosolic enzyme liberated only by rupture of the total cell wall. Cell death by apoptosis is not accompanied by disintergration of the cell. The graph indicates only a small effect of about 8% activity from this enzyme, so only very few cells are harmed by unspecific toxicity after treatment over 4 h. This shows that desmethylxanthohumol-induced cell death is a selectively induced process. *Source*: From Diller *et al.* (2005).

by docking to a death receptor is the tumor necrosis factor (TNF-α). Overconcentration of calcium ion or deterioration of cells by heat are additional means of apoptosis induction.

All these signals meet at the level of more central regulating proteins being pro-apoptotic or antiapoptotic. Whereas the cell surface death receptors are often tissue specific, these central regulating proteins are from tissue to tissue uniform. Some proteins of the Bcl-family are antiapoptotic, whereas proteins of the Bax type are pro-apoptotic. Both proteins are located at the surface of the mitochondria or nearby. Bax-proteins can open channels in the mitochondrial membrane; this mitochondrial permeability transition is crucial for apoptosis, since hereby reactive oxygen metabolites and cytochrome c-like proteins with oxidizing properties can be released into the cytosol to do the harmful work characteristic to apoptotic cell death. Bax and Bcl proteins usually form heterodimers, the permeating property of Bax is balanced by Bcl. Disturbing this equilibrium is a main switch of the signaling pathway during the induction of apoptosis.

Both signaling pathways merge at the level of cystein-rich proteolytic enzymes (caspase-3, 6 or 7) whose substrates are the different physiological structural proteins like chromatin that are digested in the process of apoptosis. DNA itself is fragmented by a special protein complex, the caspase-3-activated DNA fragmenting enzyme (CAD). (Hengartner, 2000).

To assess the antiproliferative acitivity of desmethylxanthohumol, the proliferation of BJAB cells, a Burkitt lymphoma cell line from the lineage of B-leucocytes, was measured. We observed a strong inhibition of BJAB cells after 24 h at a concentration of 100 µM (Figure 71.5).

Cell death in experimental systems can occur after two distinct events: cell death due to toxic necrosis or cell death by induction of apoptosis. We were able to show that there is not a significant cytotoxic effect of desmethylxanthohumol due to necrosis. Lactate dehydrogenase (LDH) is an enzyme in the cyclosol. Due to its high molecular weight (140 kDa) it cannot pass the cell membrane. LDH release can only be detected after cell membrane disruption caused by necrotic cell death. The release of LDH was measured 4 h after treatment with desmethylxanthohumol at a concentration of 20, 50 and 100 µM. There was no LDH release detectable after 4 h (Figure 71.6). Therefore, the antiproliferative properties as described above cannot be caused by a general cytotoxicity. Whether there is an apoptotic effect was examined by determination of DNA fragmentation.

The degree of cells undergoing apoptosis was estimated from the percentage of cells with DNA fragments. At a concentration of 100 µM desmethylxanthohumol, a remarkable fraction of cells (35%) in the subG1-phase of the cell division cycle is detected by flow cytometric determination of hypodiploid DNA (Figure 71.7).

At concentrations up to 50 µM desmethylxanthohumol, the amount of apoptotic cells is negligible after treatment for 72 h. In a concentration of 100 µM, desmethylxanthohumol induces apoptosis in BJAB cells. We further investigated the type of apoptotic pathway induced by desmethylxanthohumol. Therefore, we measured the extent of mitochondrial permeability transition. A decrease in the mitochondrial membrane potential indicates that desmethylxanthohumol is able to induce apoptosis via the intrinsic signaling pathway (Figure 71.8).
Figure 71.7 Assessment of cells undergoing apoptotic cell death. Apoptosis is characterized by extensive DNA fragmentation and occurrence of hypodiploid DNA (DNA in subG1-phase of the cell cycle). The latter can be assessed by flow cytometry via propidium iodide-staining. The graph reflects the number of apoptotic cells in relation to the concentration of desmethylxanthohumol. 100 μM is able to induce apoptosis in 36% of all BJAB cells. *Source*: From Diller *et al.* (2005).
Figure 71.8 Assessment of the mitochondrial membrane potential. Mitochondrial membrane potential was determined by staining the cells with 5,5′,6,6′-tetrachloro-1,1′,3,3′-tetraethyl-benzimidazolylcarbocyanin iodide (JC-1) and flow cytometric cell count. The decrease of the mitochondrial membrane potential is induced even at 20 μM desmethylxanthohumol in BJAB Mock cells. Over 40% of all cells have a defect in mitochondrial membrane potential after this treatment. This shows that desmethylxanthohumol most probably is able to induce apoptosis via the mitochondrial-dependent pathway. *Source*: From Diller *et al.* (2005).

It could be demonstrated that there is a clearly shown concentration-dependent decrease in the mitochrondrial membrane potential, enabling oxygen radical species to penetrate into the cytosol and activating the apoptosome.

Anticarcinogenic activity is different from antiproliferative activity since in the latter case an already neoplastic transformed cell line is expected to undergo cell death. Anticarcinogenic activity means an inhibition of the event in a cell system to undergo neoplastic transformation to a fully developed, steadily dividing cancer cell line. An important milestone in this process of transformation is thought to be the presence in the cell of xenobiotics, substances exerting DNA damage. There are mechanisms in the cells to dispose these substances either by immediate expulsion using a transporter system or by the process of reduction, conjugation with glucuronic acid and the final excretion. With this respect, the enzyme quinone reductase has found to be of major importance. Nearly every plant-derived cancer-protective agent has found to be active in this system, either being a mono- or bifunctional inducer of the CYP-Genes encoding for quinone reductases. After Miranda (Miranda *et al.*, 2000) desmethylxanthohumol in a system of quinone reductase from mouse liver cells (Hepa 1c1c7) was able to greatly enhance the activity of quinone reduc-tase, but not so much than xanthohumol itself. Both substances being monofunctional inducers, do not require a functionally intact arylhydrocarbon receptor.

General assessment with respect to human nutrition

Up to the present day, studies of the physiological effects of hop constituents mostly have been done with tissue cultures or in animal studies with mouse models. To assess possible implications on human nutrition, one has to take into consideration the passage of the beverages through the intestinal system. For example, due to its ability easily to isomerize to 8-PN, only desmethylxanthohumol contributes to any hormonal effect of hop, but its concentration relative to xanthohumol is approximately 1/10. It has been shown by Possemiers (Possemiers *et al.*, 2005) that intestinal bacteria can demethylate cyclization products of xanthohumol, means isoxanthohumol to 8-PN. Considering this facts, it can be expected that the total hormonal effect of a hop ingestion will surely increase by such digestional activity.

Summary

Desmethylxanthohumol from hops is protective against mutagenesis by environmental harmful chemical and tumor-like tissue growth. It is unstable in beverages, whereby it contributes more than other compounds to a hormonal effect.

Reproductive and Estrogenic Effects of 8-Prenylnaringenin in Hops

Stuart R. Milligan Division of Reproduction and Endocrinology, School of Biomedical Sciences, King's College London, Guy's Campus, London, UK

Abstract

Historical and anecdotal observations of the estrogenic activity of hops led to the identification of 8-prenylnaringenin (8PN) as one of the most potent phyto-oestrogens. As an estrogen, 8PN has the potential to interact with the estrogen-signaling systems within the body, including the reproductive system. In terms of normal exposure, only those situations in which there is large scale exposure to "raw" hops (e.g. hop workers) are likely to be of significance, with disturbances to menstrual cycles being most likely. There is no evidence, nor reason to suspect, that exposure to 8PN via the most common hop product, namely beer, is of any significance to the fertility of either sex. In terms of the potential exploitation of the estrogenic activity of 8PN, menopausal symptoms seems to offer some promise as a target. Treatment with a weak "natural" estrogen seems to be readily acceptable to many women and uncertainties about efficacy may be masked by strong placebo effects, at least for symptoms like hot flushes. Indeed, the relative weakness of the estrogenic activity of 8PN compared to pharmacological estrogen preparations may be of advantage as this would also reduce the risk of hormone-dependent cancer. However, as treatments for menopausal symptoms typically tend to involve continuous or long-term exposure regimens to otherwise healthy women, all treatments need careful monitoring in terms of both safety and efficacy, not least because other (non-estrogenic) bioactivities of 8PN and associated hop-derived compounds need to be considered.

List of Abbreviations

8PN	8-Prenylnaringenin
ERα	Estrogen receptor alpha
ERβ	Estrogen receptor beta
LH	Luteinizing hormone
SERM	Selective estrogen receptor modulator

Introduction

Over the last two decades there has been increasing scientific and public interest in the reproductive effects of the exposure of humans to compounds in the environment that may interfere with the hormonal control of development. The interest initially developed in relation to compounds with weak estrogenic activity (Routledge and Sumpter, 1996), but further studies soon widened the concept of "endocrine disruption" so that any compound interacting with hormonal signaling systems or interfering with hormonally controlled systems can be labeled as an "endocrine disruptor" (e.g. Zacharewski, 1998).

Reproductive disturbances in wildlife (e.g. feminization of fish downstream from sewage effluents; Sumpter, 1995) raised a general scientific interest. However, the main drive came from the suggestion that the increasing exposure to industrial chemicals with potential endocrine-disrupting activity (e.g. pesticides, phthalates, surfactants) was a cause of the increase in reproductive tract abnormalities in men (Toppari *et al.*, 1996; Sharpe, 2001). These abnormalities include a cluster of conditions under the banner of the "testicular dysgenesis syndrome": reduced sperm counts, increased testicular cancer, cryptorchidism and hypospadias (Skakkebaek *et al.*, 2001; Sharpe and Irvine, 2004). The various phenotypes of this syndrome are thought to derive from disturbances of fetal or early post-natal life, a time when the developing reproductive system is particularly sensitive to perturbations of the hormonal environment.

In seeming contrast to these concerns about the adverse effects of hormonally active, "industrial" chemicals, an alternative focus of interest has come from health beneficial effects attributed to "natural," plant-derived estrogenic compounds (phyto-oestrogens) in food (Adlercreutz, 1990). Phyto-oestrogens have been regularly implicated as protective factors against many of the so-called western diseases, including breast and prostate cancer, and cardiovascular disease in women (e.g. Setchell, 1998). Such potential

beneficial effects have been the rationale for the inclusion of plant extracts rich in phyto-oestrogens in a number of herbal supplements, "health foods" and complementary medicine products (Lee, 2006).

The apparent discrepancy between the potential adverse effects of industrial "endocrine disruptors" and the beneficial attributes of plant oestrogens is counter-intuitive and is due to a number of confounding factors. In part it reflects an unfortunate public perception that industrial chemicals are inherently unnatural and therefore "bad," while plants have "natural compounds." This confusion has been compounded by sometimes over-enthusiastic extrapolation by some scientists of the significance of their field of work and by commercial interests promoting "natural health products." Another complicating factor is that many of the putative hormonal activities of environmental chemicals have been demonstrated *in vitro*. The *in vitro* systems (e.g. effects on cell lines in culture) inevitably tend to focus on the specific effects of single chemicals in a single cell type. These studies are particularly useful in defining the precise cell signaling pathways through which the chemicals can act and in providing a guide to the concentrations that may require to produce any effect. However, trying to extrapolate from *in vitro* results to the whole body situation is notoriously difficult. A mono-culture of identical cells cannot imitate either the complexity of organs or the multifactorial, homeostatic control systems that operate throughout the body. Neither do *in vitro* systems mimic the kinetics of uptake, metabolism, breakdown and excretion. *In vivo* studies in experimental animals can help to bridge the gap in our understanding, but are limited in terms of their experimental design (e.g. the animal and the time of exposure in its life history; the mode, dose and duration of exposure; short or long-term effects evaluated). *In vivo* studies in humans are severely limited both by even more complex ethical and practical considerations. In view of such limitations, the influence of these chemicals on humans remains an area of speculation and sometimes over-hyped debate. The situation is additionally complicated by the fact that the body may be simultaneously exposed to many different endocrine-disrupting chemicals, each operating through different mechanisms in different cell types. For example, oestrogens may act genomically via the two estrogen receptors alpha and beta (ERα and ERβ), and/or non-genomically via cell surface receptors, and/or by modulation of other cell signaling systems, including epigenetic modifications (Crews and McLachlan, 2006).

There is no doubt that many plants provide a source of chemicals with estrogenic activity. The main groups of non-steroidal dietary "phyto-oestrogens" are: isoflavones (e.g. daidzein, genistein), lignans (e.g. secoisolariciresinol, enterodiol, enterolactone), coumestans (e.g. coumestrol) and resorcyclic acid lactones (Dixon, 2004). In addition, Miksicek (1993) originally reported that many of the common plant flavonoids (including some chalcones, flavanones

and flavones) can bind to and activate the estrogen receptor (albeit very weakly). Resveratrol, a phytoalexin found in grapes and red wine was also shown to be a weak agonist for the estrogen receptor (Gehm *et al.*, 1997) and this provided further ammunition for those wishing to attribute health benefits to red wine drinking. Quantitatively, isoflavones (present in legumes, particularly soyabeans) and lignans are the most important dietary phyto-oestrogens (both in terms of magnitude and duration of exposure).

The ability of dietary phyto-oestrogens to affect mammalian reproduction was initially highlighted by the disruption of fertility in ewes grazing on pastures unusually rich in phyto-oestrogens. Similar observations have been made in a number of other farm and animal species exposed to high levels of phyto-oestrogens (Yang and Bittner, 2002), but disturbances to human fertility by normal levels of dietary phyto-oestrogens have not been reported. However, although dietary phyto-oestrogens may have no reproductive effects in humans, there is intense interest in the potential of estrogenic isoflavones to modulate other estrogen-dependent processes, particularly reducing the risk of breast cancer and cardiovascular disease and improving bone health and menopausal symptoms. It is not the place of the current chapter to detail these, but the reader is referred to other literature for current assessments on the role of dietary phyto-oestrogens in health and disease (e.g. cardiovascular disease: Cassidy and Hooper, 2006; breast cancer: Messina *et al.*, 2006; genistein and reproductive health: National Toxicology Program Center For The Evaluation Of Risks To Human Reproduction, 2006; menopausal symptoms: Nedrow *et al.*, 2006). Unfortunately, for those who want a definitive answer, the recurrent take-home message is that more work is needed to define the relative risks and benefits (if any) of dietary phyto-oestrogens to the health of either specific individuals or the general population!

How do hops feature in this context? Circumstantial evidence over many years has linked hops with potential hormonal activity in women, particularly in terms of affecting menstrual cyclicity. However, the scientific literature on the possible hormonal activity of hops ranged from suggestions that they may be one of the richest sources of oestrogens, to the failure to find any evidence of estrogenic activity. The studies eventually led to the identification of one specific chemical, 8-prenylnaringenin (8PN) as the major source of the estrogenic activity of hops. This chapter will review our current understanding of the biological activity of 8PN in terms of its ability to modulate reproductive processes in humans.

The Identification of the Estrogenic Activity of Hops

The use of hops for medicinal purposes dates back centuries and probably reflects the fact that hops are a very rich source of a variety of bioactive chemicals. Although hops

have been used for the treatment of conditions ranging from indigestion to tuberculosis and nervous disorders, a recurring suggestion has been that hops could be used to treat gynecological problems. One early reference cites the following: "Half a dram of the seed in powder take in drink brings down women courses" (Culpepper, 1653; cited by Neve, 1991). Brewery sludge baths were used for many years in Germany, partly for their alleged healing and rejuvenating powers, and partly for the treatment of gynecological disorders (Zenisek and Bednar, 1960). Further observations consistent with some hormonal activity came from reports that changes occurred in the menstrual cycle of women engaged in picking hops. These claims included that menstrual cyclicity was synchronized soon after the start of hop harvesting, and that disturbances of menstrual cyclicity were common (Verzele, 1986). In reply to a query from the present author about the estrogenic activity of hops, Verzele wrote "In my country [Belgium] the notion of the 'hop devil' is well established. People used to gather in September in the hop growing fields for the harvest and the young men and women spent weeks together to do that. Much intercourse went on and these occasions (just like grape picking) were famous for this. The contact of the women with fresh hops … threw off their period and many got unintentionally, unexpectedly pregnant – therefore the term 'hop devil.' Also it seems because women in the hop gardens were unusually receptive to sexual advances" (Verzele, 1992, personal communication). Despite the delightful nature of this communication, it should be remembered that hop pickers were often very poor and suffered many health problems. Since menstrual cycles are notoriously sensitive to nutritional status, energy balance and stress, the causes of any menstrual disturbances in hop pickers must remain speculative. However, reports of modern day workers in hop processing plants suffering disruption of menstrual cyclicity (personal observations) are consistent with the original observations on hop pickers.

The historical reports of reproductive disturbances in female hop pickers were followed by a number of scientific studies on the hormonal activity of hops. Using the sensitive bioassay for oestrogens in rodents, Koch and Heim (1953) reported that a crude extract of hop cones contained estrogenic activity. These authors discovered that the extract of hop cones contained the equivalent of 20–300 μg 17β-oestradiol/g. This is an extraordinarily large amount in relation to other plants. The authors suggested that the high contents of phyto-oestrogens in hops could be of value for medicinal purposes. Zenisek and Bednar (1960) confirmed these findings and suggested that estrogenic activity of hops was much higher than in other plants. They found that the extract rich in the β-bitter acids contained the highest activity. Chury (1960) also reported estrogenic activity in hop extracts when saponified hops were extracted with 95% ethanol. However, in contrast to these positive reports of estrogenic activity, Fenselau and Talalay (1973) found no evidence of such activity in a wide range of hop extracts and hop derivatives (including essential oil fractions, the alpha and beta bitter acids, some commercial extracts and various organic extracts of different varieties of hops from both Europe and the United States). These negative findings were contradicted again by Hesse *et al.* (1981) who used an *in vitro* receptor binding bioassay based on calf uterine estrogen receptors and concluded that hops are one of the richest plant sources of oestrogens. In that study, the estrogenic activity was associated to the lipophilic fractions of hops.

What is the explanation of the apparent inconsistencies in some of the above studies? The *in vivo* assays used by Koch and Heim (1953), Zenisek and Bednar (1960) and Fenselau and Talalay (1973) were based on the stimulation of vaginal cornification or uterine growth in immature or ovariectomized rodents. The ability of these assays to detect weak estrogenic activity is very dependent on the route and frequency of administration of the material; negative results in these assays could easily be explained by an inappropriate treatment regimen. The *in vitro* receptor binding assay (as used by Hesse *et al.*, 1981) detects binding to estrogen receptor but binding activity does not necessarily reflect biological activity. The different investigators also used different hop extracts and the nature of the hop materials were not always adequately identified.

None of these studies had provided clear evidence of the chemical nature and biological activity of the putative estrogen(s). The progress toward its eventual identification has been well described by Chadwick *et al.* (2006). Xanthohumol, a chalcone present in hops at rather high concentrations, was suggested by some (without evidence) to be the active estrogenic compound (Verzele, 1986). Using an *in vitro* assay similar to that of Zenisek and Bednar (1960), Milligan (unpublished observations) was unable to confirm that xanthohumol was estrogenic and was also unable to detect any estrogenic activity in the the β-bitter acid fraction that had been reported as containing high activity by Zenisek and Bednar (1960). Nastainczyk (1972) isolated a hop constituent that could be isomerized into an active estrogen but did not identify it. Hansel and Schulz (1988) concluded that this hop constituent was desmethylxanthohumol and that this was converted into 8PN and 6-prenylnaringenin (6PN). Whilst 6PN was deemed not to have estrogenic activity, the activity of 8PN was not directly studied.

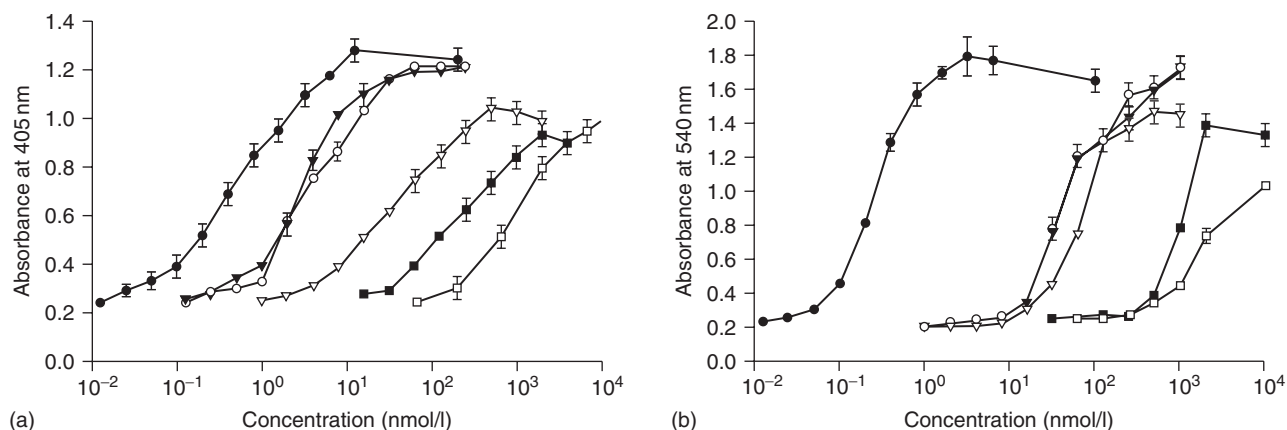
The work that led to the final identification of the chemical nature of the estrogenic activity of hops was initiated by present author following menstrual disturbances in the author's wife when working with hops. A collaboration between the author (with expertise of both *in vivo* and *in vitro* bioassays for oestrogens) and Professor Denis de Keukeleire (with expertise in hop chemistry) was initiated. A bioassay-guided fractionation of hop extracts was undertaken and led to the identification of 8PN as the principle


Figure 72.1 The estrogenic activity of 8PN *in vitro*. The relative estrogenic activity of oestradiol (●), 8PN (semi-synthetic; ○), 8PN (natural; ▼) and other phyto-oestrogens (coumestrol (▽), genistein (■), daidzein (□)) in (a) human Ishikawa Var I cells (a uterine cell line) and (b) a yeast screen bearing the human estrogen receptor. Results are mean + SEM; *n* = 6 wells per point. Where no error bars are visible, the errors were smaller than the symbols. In both assays, 8PN exerts considerably greater bioactivity than the other established phyto-oestrogens. *Source*: From Milligan *et al.* (2002). © Society for Reproduction & Fertility. Reproduced by permission.

hop estrogen. The demonstration that synthetic 8PN also showed strong estrogenic activity confirmed that 8PN was one of the most potent phyto-oestrogens, with an activity far exceeding that of the established soy-derived phyto-oestrogens (Milligan *et al.*, 1999). In an *in vitro* bioassay based on human endometrial cells (Ishikawa Var 1), the EC$_{50}$ for 17β-estradiol, 8PN, coumestrol, genistein and daidzein were 0.8, 4, 30, 200 and 1,500 nM, respectively, while in a yeast screen bearing human estrogen receptors, the results were 0.3, 40, 70, 1,200 and 2,200 nM, respectively (Figure 72.1). The bioactivity was completely blocked in the Ishikawa cells by the anti-estrogen ICI 182,780, confirming that the effects were mediated by estrogen receptors. Subsequently, it was shown that 8PN is able to bind to both ERα and ERβ (Milligan *et al.*, 2000), although Bovee *et al.* (2004) reported that 8PN was relatively more potent with ERα in yeast assays stably expressing the different human estrogen receptors.

Other hop constituents including 6-prenylnaringenin, 6,8-diprenylnaringenin and 8-geranylnaringenin exhibit some oestrogenicity, but their potency is less than 1% of that of 8PN (Milligan *et al.*, 2000). Isoxanthohumol was also weakly active in the Ishikawa cell assay (1% of 8PN) but showed no estrogenic activity in the yeast screen (Figure 72.1). Since it also showed no activity in the receptor binding assay, this was interpreted as suggesting its weak activity reflected metabolic conversion to 8PN in the human cells (Milligan *et al.*, 1999). The importance of this metabolic conversion of isoxanthohumol to 8PN was highlighted again some years later when Possemiers *et al.* (2005, 2006) showed that isoxanthohumol can be converted by intestinal microflora into 8PN, hence providing a much larger potential source of 8PN from beer or hop products than would be suspected by measuring the 8PN content alone (Figure 72.2).
Figure 72.2 Structures of 8PN and related polyphenols. 8PN is the most potent hop estrogen. Isoxanthohumol shows no activity *per se*, but can be metabolized to 8PN. 6-Prenylnaringen shows <1% the estrogenic activity of 8PN. Xanthohumol shows no estrogenic activity.

Potential Sources of 8PN Exposure to Humans

The amount of 8-prenlnaringenin in hop flowers is relatively small but increases during cone development (Stevens *et al.*, 2000). An important route of formation is from the isomerization of desmethylxanthohumol (Stevens *et al.*, 1999; Chadwick *et al.*, 2004). The amount of 8PN in dry hops is in the order of 100 mg.kg^{-1} (Milligan *et al.*, 1999). In the brew kettle, desmethylxanthohumol has a half-life of less than 5 min, isomerizing to 8PN and 6PN (Stevens *et al.*, 1999). Although 8PN levels in beer are relatively low (normally <100 ug/l; Rong *et al.*, 2000; Stevens and Page, 2004; Schaeffer *et al.*, 2005), estimates by Schaeffer *et al.*
Figure 72.3 The stimulatory effects of 8PN in the drinking water on the vaginal epithelium of ovariectomized mice. The vaginal epithelium of mice is very sensitive to oestrogens and responds with cell proliferation. This figure shows the mitotic response of the vaginal luminal epithelium of ovariectomized mice to 8PN or oestradiol (E2) administered for 72 h in drinking water. Data are mean + SEM ($n = 6$ per treatment). Significant differences are denoted by *$p < 0.05$, **$p < 0.005$ (Kruskal–Wallis test on ranks and Dunn's multiple comparison test). *Source*: From Milligan *et al.* (2002). ©Society for Reproduction & Fertility. Reproduced by permission.

(2005) and Possemiers *et al.* (2006) suggested that conversion of isoxanthohumol by intestinal flora might increase 8PN exposure up to 10-fold in some subjects. In this case, exposure levels would be likely to reach 1–2 mg 8PN/day in association with moderate daily beer consumption.

Once formed, important factors influencing the bioavailability and activity of phyto-oestrogens include the route of exposure, the kinetics of absorption and excretion, and metabolic conversions (e.g. Zierau *et al.*, 2005). The pharmacokinetics of a single oral dose of 8PN in post-menopausal women showed that the compound was absorbed rapidly, after which plasma levels remained significantly elevated for many hours, probably reflecting enterohepatic circulation (Rad *et al.*, 2006). There is only a limited amount of data on the routes of metabolism of 8PN by human tissues, but these suggest that it is transformed into a wide variety of metabolites, some of which have very weak estrogenic activity (Nikolic *et al.*, 2004; Zierau *et al.*, 2004). In experimental animals, a variety of estrogenic effects of 8PN on the reproductive tract have been reported after dietary (in food or drinking water) exposure (Milligan *et al.*, 2002; Christoffel *et al.*, 2006). In mice, the minimal effective concentration to stimulate vaginal mitoses (a sensitive index of estrogenic activity) in the drinking water was about 100 µg/ml. This is about 1,000× greater than the levels of 8PN in beer (Figure 72.3).

For most humans, the dietary intake of beer represents the commonest source of 8PN exposure. For a few, the dietary intake of herbal supplements containing hops or hop extracts for the treatment of menopausal symptoms, "breast enlargement" or other "natural therapies" is another possible source. In both situations, the amount of 8PN exposure

will reflect both the amount of 8PN *per se* in the raw product and possible conversion of isoxanthohumol into 8PN (Possemiers *et al.*, 2005, 2006). Individuals working with raw hops would be expected to have the most direct exposure to 8PN, both through transdermal absorption of 8PN and due to inhalation of hop dust.

The Need for Caution in Considering the Reproductive Effects of 8PN

Oestrogens are hormones controlling the development and function of the reproductive system of both sexes. There are many target sites for estrogenic activity, ranging from the reproductive tract and breast, through bone, fat and blood vessels, to the bladder and brain. The physiological significance of estrogenic effects at many of these sites is still unclear. Two estrogen receptors (ERα and ERβ) modulate the effects of the hormones: these receptors have differing affinities for different estrogen, differing tissue and cellular distributions, interact with a large array of different coactivators and corepressors (Kuiper *et al.*, 1997; Xiao *et al.*, 2006). Oestrogens can also act non-genomically. The recognition of such diverse modulators of estrogen action has opened a surprising new dimension in our ignorance of the effects of even the endogenous, potent hormone, 17β-oestradiol (Ciana *et al.*, 2006). In this atmosphere, understanding the molecular mechanisms and activity of the much weaker phyto-oestrogens still seems a long way off.

While much more potent than the traditional soy-based phyto-oestrogens (Milligan *et al.*, 1999, 2002), the bioactivity of 8PN is still relatively weak compared to endogenous oestrogens (e.g. $\sim <1/10–1/100$ that of oestradiol, depending on the assay technique; Milligan *et al.*, 2002). Crucially, the *in vivo* biological activity of weak oestrogens is very dependent on the route of administration and the duration of exposure. This is well illustrated by considering oestriol: a "weak" natural estrogen compared to oestradiol, but considerably more potent than any of the phyto-oestrogens, including 8PN. It was once assumed that oestriol would protect against breast cancer because it appeared to act only weakly in experiments on uterine growth. When its effects were measured 24 h after a single injection, oestriol appeared to have a low potency and a flat dose–response line. This was a misinterpretation: the low apparent potency was not due to a failure of oestriol to stimulate growth but from the failure of a single daily injection to sustain the resulting cells (Martin *et al.*, 1976). Using more a continuous treatment regimen of oestriol, premature cell death was avoided and oestriol produced as much uterine hypertrophy and hyperplasia as oestradiol. These discordant results arising simply from different treatment regimens of a "weak" estrogen should serve as a strong warning to others trying to extrapolate from the results of experiments involving any of the considerably weaker phyto-oestrogens. The issue of how

treatment regimens may affect the responses of different tissues has also been highlighted by the studies of estrogen receptor activation *in vivo* (Ciana *et al.*, 2006). This discussion of the importance of treatment regimens is particularly relevant to the interpretation of the results of the study of Hümpel *et al.* (2005), showing apparent selective effects of 8PN on the bone rather than the uterus and implying a selective estrogen receptor modulator (SERM)-like action of 8PN. However, other studies have certainly shown strong and rapid effects of 8PN on the uterus (Milligan *et al.*, 2002) and the results of Hümpel *et al.* (2005) may simply reflect their particular experimental treatment regimen (single daily injections).

In view of the importance of continuous exposure to weak oestrogens to enhance their estrogenic effects, the potential slow-release reservoir effect provided by intra-intestinal conversion of isoxanthohumol to 8PN (Possemiers *et al.*, 2006) deserves particular emphasis. Such a reservoir effect would be consistent with the observations of Schaefer *et al.* (2005) that urinary 8PN excretion after beer consumption was slower than expected. An additional factor contributing to a more continuous *in vivo* exposure (and hence continuous estrogenic stimulation) would be the enterohepatic circulation (Rad *et al.*, 2006).

A final word of caution concerning 8PN is that, like most compounds, it exhibits a spectrum of different bioactivities (Stevens and Page, 2004; Effenberger *et al.*, 2005; Gerhauser, 2005; Monteiro *et al.*, 2006). It is beyond the scope of this chapter to detail these, but these other potential bioactivities should be considered in any experimental intervention.

8PN and Menstrual Cyclicity

Anecdotal observations about the effects of hop exposure on menstrual cyclicity are detailed above. While the identification of a potent phyto-estrogen in hops (8PN) provides an attractive potential explanation for the cause of such disturbances, there is no direct evidence for this. Dietary phyto-oestrogens (particularly soy-derived) have been implicated in only rather subtle effects on the menstrual cycle and its associated symptoms (Kurzer, 2002; Bryant *et al.*, 2005; Cassidy and Hooper, 2006) but these are not in the same league as the dramatic menstrual disturbances associated with hop exposure.

There are two obvious potential explanations for this difference. The first relates to the potency and method of exposure to phyto-oestrogens. Soy-derived phyto-oestrogens are relatively weak and exposure is via the diet. The impact of dietary phyto-oestrogens is severely modulated by both the kinetics of uptake from the gut and first-pass metabolism by the liver. In contrast, hop workers are likely to have been exposed to 8PN through absorption across the skin (which would be facilitated by the oily nature of hops) and/or

through the lungs (with a very large, thin and well vascularized surface area) after the intake of hop dust. In both cases, the problems of first-pass metabolism would be avoided, resulting in direct exposure of tissues to relatively high levels of 8PN. The potential for 8PN to exert estrogenic effects on the body would be exacerbated by the relatively continuous exposure that hop pickers would have experienced. The importance of such continuous exposure for weak oestrogens to exert their effects is discussed above (see section "The Need for Caution in Considering the Reproductive Effects of 8PN"). Nowadays, premenopausal women are more likely to be exposed to 8PN through "natural" dietary products containing hops, particularly those targeting breast enhancement (see below) and some websites associated with these do warn of possible menstrual problems.

The most likely target sites for the action of 8PN for disrupting menstrual cycles would be either on the hypothalamic-pituitary control of the ovary or directly on the uterus itself. Both acute and chronic effects of weak phyto-oestrogens like 8PN can be envisaged. Milligan *et al.* (2002) reported rapid and dramatic increases in uterine vasculature within 6h of 8PN administration. Experimental studies in primates have shown that treatment with high doses of *Pueraria mirifica* (containing phyto-oestrogens) affected gonadotrophin levels and abolished or increased the length of cycles of monkeys (Trisomboon *et al.*, 2005). Rad *et al.* (2006) reported a small suppression of luteinizing hormone (LH) in post-menopausal women after a single oral dose of 750 mg of 8PN, suggesting an effect on the hypothalamic-pituitary axis. In a long-term study over 3 months, Christoffel *et al.* (2006) showed that 8PN included in the diet of rats (providing them with 70 mg/Kg bw) stimulated uterine growth, specific gene expression in the uterus, and affected serum levels of the pituitary hormones LH and prolactin in a similar manner to oestradiol (Figure 72.4).

The second possible reason why the effects on menstrual cyclicity in hop workers may have been more dramatic than those caused by soy phyto-oestrogens is that the effects in hop workers may not have been due to either 8PN or hops. The menstrual disturbances in hop workers may simply have reflected other lifestyle and nutritional factors associated with their poverty, poor health and lifestyle. In view of the almost complete disappearance of manual hop picking, it is unlikely that this question will ever be answered definitively.

Hops, 8PN and Menopausal Symptoms

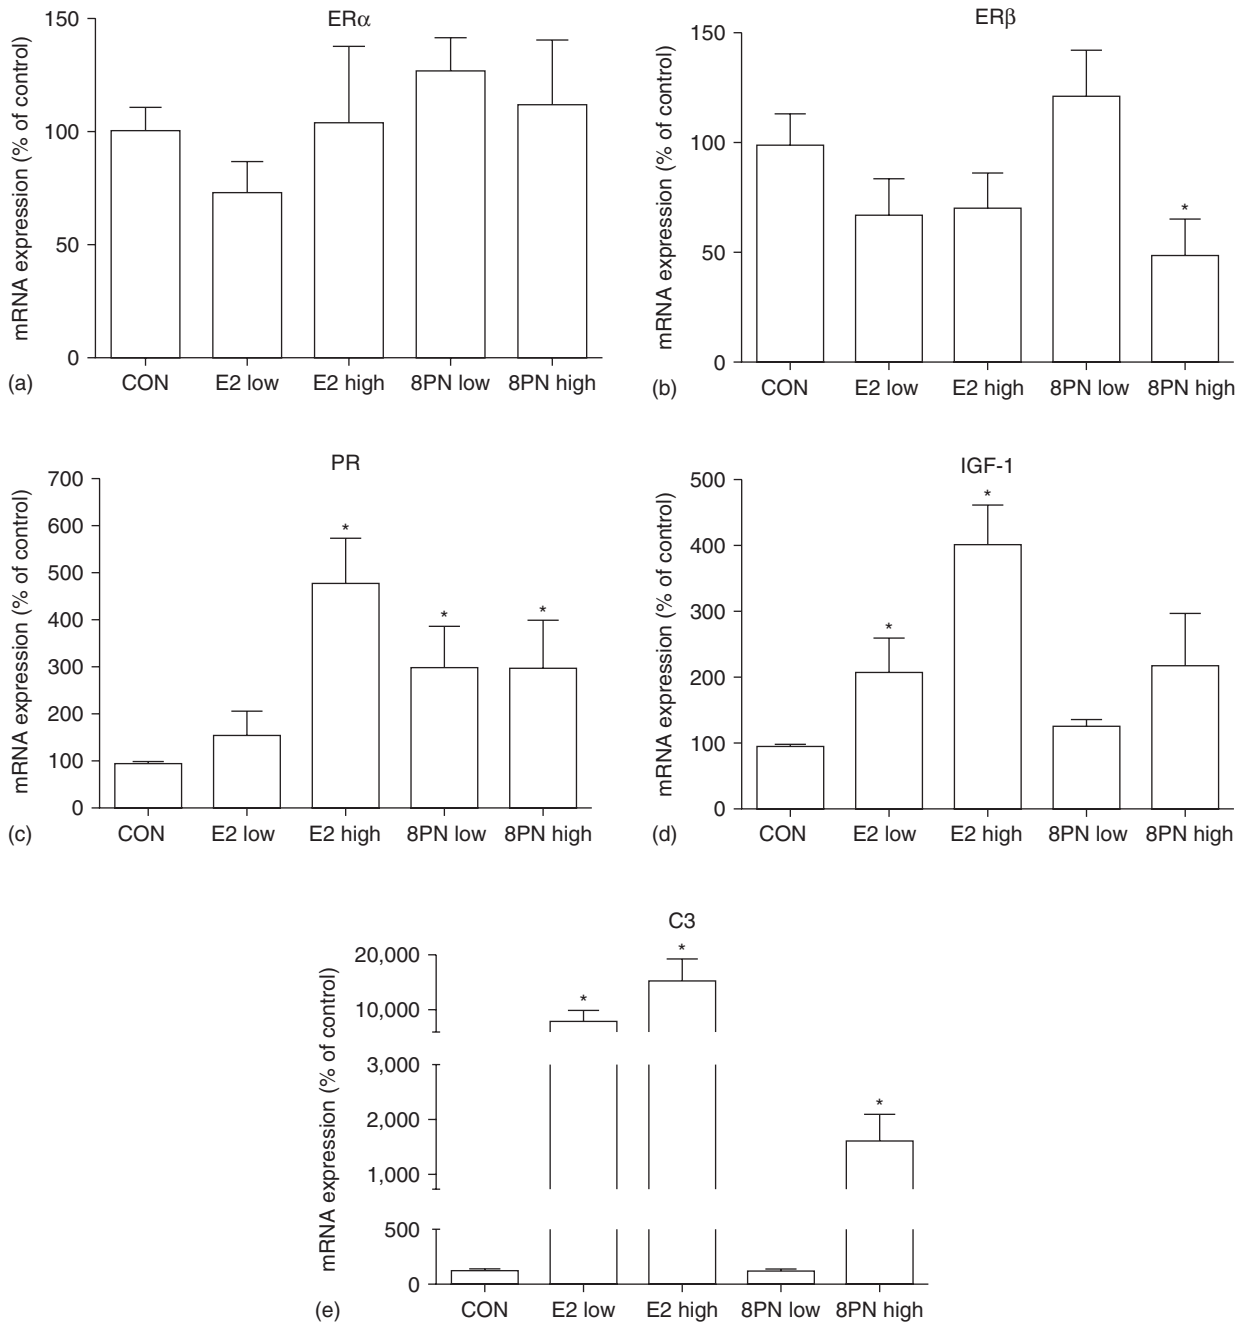
The estrogenic activity of hops in general, and 8PN in particular, has provided a focus for their possible use as a "natural" treatment for post-menopausal symptoms. The menopause is caused by the functional failure of the ovaries in women and is associated with a loss of fertility and a host of symptoms resulting from the sharp decline in circulating estrogen levels. The loss of estrogenic stimulation causes


Figure 72.4   The effects of long-term 8PN exposure via the diet on gene expression in the uterus of ovariectomized rats. The effects of the two dietary doses (6.8 or 68 mg/kg body weight/day) of 17β-oestradiol (E2) and 8PN on uterine ERα (a), ERβ (b), PR (c), IGF-I (d) and complement protein C3 (e) gene expression. Significant effects of the high dose of 8PN were seen on ERβ, PR and C3, similar to those exerted by E2. *p < 0.05 vs. control. *Source*: From Christoffel *et al.* (2006). © Society for Endocrinology. Reproduced by permission.

the reproductive tract to atrophy; the vaginal wall thins and vaginal dryness, itching and painful intercourse are frequent complaints (Suckling *et al.*, 2006). The vaginal environment also becomes less acidic making it more susceptible to infection. The reduction in bone density leading to osteoporosis is a very serious effect of the withdrawal of estrogenic stimulation of bone. Other post-menopausal changes include an

increase in cardiovascular disease, vasomotor changes (especially "hot flushes") and cognitive and psychological function (Morrison *et al.*, 2006). The seriousness and upsetting nature of these symptoms, coupled with the fact that more than a third of a woman's life in Western countries is postmenopausal, has led to the targeted treatment of the estrogen deficiency symptoms. Hormone replacement therapy

with steroids is an extraordinarily effective treatment for osteoporosis and vasomotor problems, but may provide little protective effect against coronary heart disease and athero-sclerosis (Lawlor and Smith, 2006). Recent large scale studies have also identified some risks of hormone replacement therapy to some women, highlighting adverse effects such as breast cancer, stroke and thromboembolism. These have raised concerns and anxiety amongst both patients and practitioners (Chen *et al.*, 2002; Rossouw, 2002; Rossouw *et al.*, 2002; ESHRE Capri Workshop Group, 2006). The recognition of these risks has reinforced the preference of many women to use so-called natural products as alternative therapies for menopausal symptoms, even though these natural products often have no proven effectiveness, contain uncontrolled constituents and may have had no critical safety evaluation. Indeed, there is little evidence from randomized controlled trials that soy protein and isolated isoflavones, or a number of other phyto-estrogen treatments (e.g. red clover, black cohosh), are effective at all (Shanafelt *et al.*, 2002; Krebs *et al.*, 2004).

The high estrogenic activity of hops (compared to many other plants) and 8PN (compared to other phyto-oestrogens) has led to the hope that these may offer better or alternative constituents for "natural" treatments for menopausal symptoms. This hope was reinforced by the report that 8PN may exert greater selectivity toward bone compared to the reproductive tract (Hümpel *et al.*, 2005), raising the possibility that 8PN could provide some of the advantages of estrogen-based hormone replacement therapy but with fewer of the disadvantages (Rad *et al.*, 2006). However, the reader is referred to the section above on "The Need for Caution in Considering the Reproductive Effects of 8PN" for a critical discussion of the interpretation of such results.

Hot flushes

The mechanisms underlying menopausal hot flushes are poorly understood, although it is generally assumed they result from disturbances in thermoregulatory control by the hypothalamus. Hot flushes are a distressing symptom of the menopausal syndrome, affecting over 75% of women, many of whom seek medical treatment (Shanafelt *et al.*, 2002). A number of treatments containing estrogenic isoflavones from soy or red clover have been marketed for treatment of hot flushes and a recent meta-analysis of the published studies found that such supplementation may produce a slight to modest benefit (Howes *et al.*, 2006), albeit with a strong placebo effect as well.

In an inadequately controlled study, a non-standardized hop extract was reported to reduce hot flashes in a small number (25) of menopausal women (Goetz, 1990). After 30 days of treatment with large doses of hops extract (1,600–2,600 mg/day), positive effects were reported. However, the study was not randomized, and the control group was apparently composed of five women who had
Figure 72.5 The effect of a hop extract containing standardized amounts of 8PN on hot flushes in menopausal women. The mean hot flush scores for the three groups of human subjects being given a hop extract containing either 100 or 200 µg 8PN. The scores are shown at the start of treatment (baseline), after 6 weeks, and after 12 weeks. The error bars represent SEM **$p < 0.01$ as compared to placebo. *Source*: From Heyerick *et al.* (2006).

been accidentally treated with a low dose of hops (300 mg), which (since it had no benefit) was considered a placebo. In 17 of the 20 treated subjects, the reduction of hot flush score was better than controls (but neither statistical test nor significance level was stated).

A more rigorous study (randomized, double blind, placebo-controlled) using a hop extract containing defined amounts of 8PN has been undertaken recently (Heyerick *et al.*, 2006). The results suggested that these hop extracts could produce positive benefits in alleviating the range of symptoms contributing to menopausal discomfort (as measured by the Kupperman index). The benefits were particularly evident for hot flushes (Figure 72.5), which were reduced by hop treatment. However, the ability to make firm conclusions is blurred by the known strong placebo effects of menopausal treatments. The potential for the use of 8PN for treating hot flushes is reinforced by the clear demonstration that 8PN reduces the raised skin temperatures in a well-defined experimental animal model of menopausal hot flushes (Bowe *et al.*, 2006) (Figure 72.6).

Vaginal treatment

The loss of estrogenic stimulation to the vagina post-menopausally results in a number of uncomfortable symptoms, as outlined above. These can be readily treated by local administration of oestrogens (e.g. via creams, pessaries, vaginal rings) usually without encountering the side effects and potential risks of systemic estrogen administration (Suckling *et al.*, 2006). There has been one report that good results
Figure 72.6 The effect of 8PN on tail temperature in an animal model of hot flushes. The effects of subcutaneous (sc) administration of 8PN; ●400 μg/kg/day, 8PN and the anti-estrogen ICl 182,780 (▲; 400 μg/kg/day and 200 μg/kg/day, respectively) or peanut oil (■; 1 ml/kg) on tail skin temperature (TST) in the ovariectomized rat. The shaded area from day 4 to 8 indicates period during which treatment was given. The data show the mean changes in TST (±SEM) compared to the mean values on day 1 (△TST). Note that the elevation of temperature caused by ovariectomy (comparable to the hot flush phenomenon in postmenopausal women) is reversed by 8PN. Administration of ICl 182,780 completely blocked the effect of 8PN. *$p < 0.05$ vs. vehicle control on the same day; $n = 7$. *Source*: From Bowe *et al.* (2006). © Society for Endocrinology. Reproduced by permission.

can also be obtained using a vaginal gel containing hop extracts (Morali *et al.*, 2006). The gel contained hyaluronic acid, liposomes, hop extract and Vitamin E and the treatment was well accepted by one hundred post-menopausal women without any obvious adverse side effects. While this may raise hopes that 8PN *per se* may be similarly effective, the study of Morali *et al.* (2006) was not a double blind, placebo-controlled study, did not look at the efficacy of the individual constituents and there was no information provided about the amount of 8PN in the preparation.

Bone and osteoporosis

The control of bone deposition and resorption is complicated, and the reader is referred to other sources for more information on this (e.g. Raisz, 2005; Zallone, 2006). The important effects of oestrogens on bone are particularly clear in relation to the major biological transitions: the growth spurt at puberty and the reduction in bone density that occurs with ovarian failure in the perimenopausal period. These effects of estrogen stimulation and withdrawal are a consequence of reproductive events but are not strictly "reproductive effects" *per se* and are therefore beyond the scope of this chapter. However, in any context in which the risks or benefits of exposure to hop-derived oestrogens and 8PN are being considered, there is obviously a need to take bone effects into account.

As would be expected for an estrogenic compound, there is good evidence that 8PN can mimic oestradiol in terms of effects on bone (Miyamoto *et al.*, 1998). There is also evidence that other, less estrogenic, hop constituents (e.g. 6PN, xanthohumol, isoxanthohumol) can have similar effects on osteoblasts in culture (Effenberger *et al.*, 2005). The significance of understanding the role of oestrogens or phyto-estrogens in bone remodeling is complicated by the involvement of both estrogen receptors (ERα and ERβ) (Silvestri *et al.*, 2006). In view of the fact that one of the drives behind alternative therapies for menopausal symptoms is to find treatments that have selective beneficial effects on bone while reducing inappropriate risks in the reproductive tract and breast ("selective estrogen receptor modulators": SERMs), the findings of Hümpel *et al.* (2005) are of interest. These authors studied the effects of 8PN in the skeleton of female rats following ovariectomy, an animal model of osteoporosis. They found that injections of 8PN protected against the expected ovariectomy-induced bone loss, whilst exhibiting minimal trophic effects on the uterus. However, as already discussed, whether this apparent tissue selectivity is real, or whether it reflects their particular treatment regimen, needs reexamination.

8PN, Hops and Breast Tissue

The breast is an important target site for estrogen action, both in terms of stimulating normal growth and function, and in relation to breast cancer. The main drive to breast growth is the rising levels of circulating ovarian oestrogens at puberty. Local metabolism and synthesis of oestrogens are considered to be important in the pathogenesis and development of hormone-dependent breast cancer (Sasano *et al.*, 2006). The importance of oestrogens in breast cancer is the foundation of concerns about inappropriate exposure of the breast to oestrogens derived from estrogen replacement therapy for menopausal symptoms. The essential role of oestrogens in hormone-dependent breast cancer has led to the use of anti-oestrogens (blocking estrogen action), SERMs and aromatase inhibitors (blocking local synthesis of oestrogens from circulating androgens) in treatment regimens.

As an estrogen-responsive organ, the breast is a potential target site of 8PN. Human breast cancer cells (MCF-7) form the basis of a number of *in vitro* estrogen bioassays and are responsive to 8PN (e.g. Rong *et al.*, 2001; Effenberger *et al.*, 2005; Matsumura *et al.*, 2005; Overk *et al.*, 2005). *In vivo*, Rimoldi *et al.* (2006) showed that 8PN given via the diet (~70 mg/Kg bw/day) stimulated a range of reproductive tissues (uterus, vagina) and the mammary gland in ovariectomized rats.

Hops have been incorporated into a number of herbal preparations that claim the ability to enlarge breasts in women. These have included a variety of imaginatively named products (e.g. Natural Push-Up, 2Enhance, Breast Success and Newbust, amongst many)! The website of one

of these (Natural Push Up, 1999) reported that it was originally developed following reports that cows eating large amounts of brewing waste from "got enormous udders" and observations that women in a small Italian village drinking a local beer that had never been boiled developed "larger and good looking breast" [sic]. Claims for the effectiveness of such herbal breast enlargement preparations have been based partly on their phyto-estrogen content (although these are not necessarily from hops alone). The concentration of 8PN in one type of these breast-enhancing preparations containing hops was found to be ~11 μg/g, producing a daily intake of approximately 130 μg/day (Coldham and Sauer, 2001). This value is less than that found in a liter of some beers. However, the content of 8PN itself is not the only factor to be considered: other phyto-estrogens may be present and other hop prenylflavonoids may be converted to 8PN by gut microflora (Possemiers et al., 2005, 2006). Nevertheless, it should be noted that the same hops-containing supplement studied by Coldham and Sauer (2001) showed no evidence of estrogenic activity in mice following administration either in the feed or by subcutaneous injection of the extract.

The essential question is that, if breast enhancement products do provide 8PN (or other phyto-estrogens), are such products either effective or safe (Milligan, 2002)? In terms of efficacy, no peer-reviewed clinical trials appear to have been published. However, the concern would be that if any such effectiveness were to be shown, real fears over safety issues would then be raised. As noted above, the breast is an important site of hormone-dependent cancer and is very sensitive to oestrogens and inappropriate estrogenic stimulation would be of significant concern. In addition, estrogenic effects would be expected not to be limited to breast tissue alone; this is perhaps consistent with reports of menstrual disturbances associated with taking some of the supplements (see above). Any such disturbance of menstrual cyclicity would raise questions concerning effects on fertility as well as interactions with family planning/contraceptive methods. An additional concern would be that women may inadvertently take such breast enhancement products in the early stages of pregnancy, a time when fetal development is particularly susceptible to perturbations by xenobiotic chemicals (Milligan, 2002).

Are There Any Reproductive Effects of 8PN in Men?

For many years, oestrogens were considered to be primarily "female" hormones, contributing to female health and fertility. However, it is now clear that oestrogens play a variety of important roles in males, including modulating sexual development, the function of the testis, epididymis, brain and bone (Korach et al., 1996; Hess et al., 1997; Luconi et al., 2002). In view of these roles of endogenous oestrogens,

the question arises whether exposure to exogenous environmental or phyto-oestrogens can interfere or modulate estrogen-dependent processes within the body or contribute to the testicular dysgenesis syndrome described earlier (e.g. Skakkebaek et al., 2001; Sharpe and Irvine, 2004). However, there have been no published reports of any effects of either 8PN or hop exposure either in this context or on the fertility and reproductive function of men. Neither are there any documented cases of gynecomastia directly attributable to hop exposure.

Injections of 8PN in mice induce estrogenic responses in the prostate (Hümpel et al., 2005) indicating that this organ is a potential target site in males. While it has been suggested that phyto-oestrogens may offer a protective effect against prostate cancer (Hedelin et al., 2006), there is no epidemiological information available about any association between this condition and exposure to hops. A variety of prenylflavonoids, including 8PN, showed anti-proliferative activity in prostate cancer cells lines, although the effective concentration required for 8PN was high (IC50 ~ 35–40 μM) (Delmulle et al., 2006).

Based on anecdotal observations that many male hop workers seemed to have a preponderance of daughters, a question has been raised concerning whether the expected ~ 50:50 male:female sex ratio of offspring could be affected by exposure to the estrogenic activity of hops (Dr P. Darby, personal communication). There is certainly considerable general academic interest in the control of the sex ratios in a variety of mammalian species, and there is one report of an abnormal sex ratio in a human population possibly associated with pollutant exposure (Mackenzie et al., 2005). However, even if a skewed sex ratio did exist in the offspring of male hop workers, any attribution as to its origin (hops, pesticides, solvents, etc.) would have to remain entirely speculative.

In vitro experimental studies have shown that 8PN can directly affect the function of sperm. A number of reports that spermatozoa may have binding sites or receptors for oestrogens (e.g. Misao et al., 1997; Durkee et al., 1998) and "non-genomic" effects of oestrogens have been reported (Luconi et al., 1999, 2001). Whether such estrogen binding sites play any functional role in the fertilizing ability of sperm was recently investigated by Fraser et al. (2006). At the time of ejaculation, spermatozoa are unable to fertilize an egg (Yanagimachi, 1994) but after some time in an appropriate environment, spermatozoa acquire the capacity to fertilize and are said to be "capacitated" (Chang, 1951; Austin, 1952). Capacitated spermatozoa show hyperactivated motility, can undergo the acrosome reaction (involving the release of enzymes essential for egg penetration) and are able to fertilize an oocyte (Yanagimachi, 1994). Using mouse sperm, Fraser et al. (2006) found that oestradiol, two phyto-oestrogens (genistein and 8PN) and nonylphenol (a weakly active environmental estrogen) were all able to significantly stimulate mammalian sperm capacitation, acrosome reaction and fertilizing ability in vitro. Interestingly, the two

phyto-oestrogens were effective at very low concentrations (1 nM) and were more potent than oestradiol itself. The mechanism(s) mediating such an effect remains unclear and, in the absence of any evidence that male fertility is directly affected *in vivo* by the acute exposure to such xenobiotic compounds, these observations may more reflect our ignorance of normal sperm physiology than imply any *in vivo* effect.

Conclusion

As an estrogenic chemical, 8PN has the potential to interact with the estrogen-signaling systems within the body. Therefore, demonstrations that experimentally administered 8PN can modulate responses in the reproductive tract, breast, bone or any other tissue is not surprising. However, there are two key questions. Firstly, is there any evidence that *normal* exposures to 8PN (either from hops, beer or other hop products) can have effects? Secondly, can the effects of 8PN be exploited for useful treatment of medical conditions in humans?

In terms of normal exposures, only those situations in which there is a large scale exposure to "raw" hops (e.g. hop workers) seem to be of significance, with disturbances to menstrual cycles being the most likely possible effect. There is no evidence, nor reason to suspect, that exposure to 8PN via the most common hop product, namely beer, is of any adverse significance. Any feminization effects of excessive drinking (e.g. in male alcoholics) is due to the effects of alcohol on the liver and steroid metabolism, rather than any hop-derived chemical.

In terms of the potential exploitation of the estrogenic activity of 8PN for use in human treatment, menopausal symptoms seem to offer some promise as a target. Treatment with a weak "natural" estrogen seems to be readily acceptable to many women and uncertainties about efficacy may be masked by strong placebo effects, at least for symptoms like hot flushes. Indeed, the relative weakness of the estrogenic activity of 8PN compared to pharmacological estrogen preparations may be of advantage in that this also minimizes the risks to hormone-dependent cancer. The administration of formulations locally (e.g. intravaginal: Morali *et al.*, 2006; Suckling *et al.*, 2006) may also be particularly useful in avoiding systemic risks. However, as treatments for menopausal symptoms typically tend to involve continuous or long-term exposure regimens to otherwise healthy women, all treatments need careful monitoring in terms of both safety and efficacy, not least because other (non-estrogenic) bioactivities of 8PN and associated hop-derived compounds need to be considered.

Summary Points

- 8PN is a phyto-estrogen with the potential to effect estrogenic responses in human reproductive tissues.

- As a weak estrogen (albeit relatively potent when compared to other, even weaker, phyto-oestrogens), the *in vivo* activity of 8PN is poorly understood.
- It is conceivable that the disturbances to menstrual cyclicity historically reported in hop workers was due to 8PN.
- There is no indication that exposure to 8PN in either hops or beer has any reproductive effect in men.
- The desire for exploitation of 8PN as a "natural" estrogen for the treatment on menopausal symptoms needs to be tempered with caution until clinical trials have justified its efficacy and confirmed its safety.

Regulation of Gene Expression by Hop-Derived 8-Prenylnaringenin

Oliver Zierau and Günter Vollmer Molekulare Zellphysiologie und Endokrinologie, Institut für Zoologie, Technische Universität Dresden, Dresden, Germany

Abstract

Anecdotal stories, structural considerations and findings from *in vitro* assays suggested that 8-prenylnaringenin (8-PN) contained in the female hop (*Humulus lupulus* L.) flowers exhibits a strong estrogenic potency. Estrogens act through the two nuclear receptors estrogen receptor-α and -β (ER-α and -β). Hallmark of estrogen action in target cells or organs is regulation of gene expression. Here we first describe the experimental setup to test for estrogen dependent activation of gene expression *in vitro* and *in vivo*. With these assays we provide several pieces of evidence that 8-PN is a potent ligand for estrogen dependent gene regulation *in vitro* and *in vivo*, particularly on ER-α dependent processes. Based on findings *in vitro* by us and others human exposure to phytoestrogen levels contained in beer apparently does not pose a threat to human health. Whether or not 8-PN represents a natural compound which can be unrestrictedly recommended for pharmacological application particularly in menopausal applications remains to be further elucidated. However, based on the published *in vitro* and *in vivo* biological activities 8-PN has at least to be regarded as an interesting pharmacological lead compound.

List of Abbreviations

8-PN	8-prenylnaringenin
ER	Estrogen receptor
ER-α	Estrogen receptor-α
ER-β	Estrogen receptor-β
AP-1	Activator protein-1
NFκB	Nuclear factor kappa B
ERE	Estrogen responsive element
Nar	Naringenin
6-DMAN	6-Dimethylallylnaringenin
HT	Hormone therapy
PPAR	Peroxisome proliferators-activated receptor

Introduction

Identification of 8-prenylnaringenin

The main focus of this chapter is on putative hormonal activities of substances contained in hops. Since medieval times there are anecdotal stories which point to potential hormonal, particularly estrogenic activities of constituents of the female hop (*Humulus lupulus* L.) flowers. It was reported from Bohemia and Belgium that female hop pickers apparently did not become pregnant in the cropping season. When hops were hand picked, menstrual disturbances amongst women pickers were reportedly common (Verzele, 1986). Other stories followed up by Koch and Heim (1953), who were the first to describe hormonal activities for hops, tell the legend that women who normally live "a distance" from hop gardens regularly begin to menstruate 2 days after arrival to pick hops.

A series of applications published in the scientific literature comprise the use of brewery sludges as baths, cosmetic applications and applications in the folk medicine (for review see Chadwick *et al.*, 2006 and references therein).

The field went ahead when chemical structure of the estrogenic compounds in hops was solved by phytochemical means. Interestingly, almost at the same time the most potent chemical of hops was identified as 8-prenylnaringenin (8-PN) (Milligan *et al.*, 1999) and as isopentenylnaringenin from the Thai medicinal plant *Anaxagorea luzonensis* A. Gray (Annonaceae) (Kitaoka *et al.*, 1998). Soon after discovery it turned out that 8-PN represents the most potent phytoestrogen discovered so far with an IC_{50} value in the nanomolar range (Kitaoka *et al.*, 1998).

Exposure to 8-PN by consumption of beer

The anecdotal tales mentioned above suggest physiological, estrogen-like properties of 8-PN in humans. These

observations pose two important questions: (1) is 8-PN during the brewing process transferred into the beer? and (2) if so, what is the level of human exposure?

Analysis by different analytical protocols revealed that the quantities of 8-PN transferred to beer in the brewing process are low and sometimes undetectable. In selected Belgian beers and other beers of European origin levels between 5 and 20 μg/l were detected (Milligan *et al.*, 1999; Tekel *et al.*, 1999). The overall level apparently is dependent on the brand of beer and the respective brewing process. In this latter study 8-PN content of various North American brands and varieties was compared among each other with imported beers. Except for an American porter (240 μg/l) and a strong ale (110 μg/l) levels of 8-PN were far below 100 μg/l ranging between 1–69 μg/l (Stevens and Page, 2004) with the large majority of beer brands in the range of the Belgian study.

This means exposure by 8-PN through beer consumption is very low even in the beers with the highest content. However, depending on the type of beer isoxanthohumol levels are 5–30 times higher than those of 8-PN (Stevens and Page, 2004). Taking into consideration that isoxanthohumol is readily converted into 8-PN both *in vitro* and by the intestine (Possemiers *et al.*, 2005, 2006), exposure levels could be considerably higher. However, in a worst case consideration and according to the published literature a daily consumption of 1 l of beer by an 80 kg individual would amount to an exposure level of approximately 50 μg/mg/day.

Estrogen receptors

Estrogens and estrogen-like substances act through the two estrogen receptors (ER). Because of their hydrophobic character, estrogens like other steroid hormones are able to enter the cells by diffusion across the plasma membrane into the cell where they encounter their receptors.

Jensen first reported the existence of a protein that mediates the biological effects of estrogen in 1962 (Jensen, 1962). In 1986, two research groups reported the cloning of the first ER (Walter *et al.*, 1985; Greene *et al.*, 1986), which is now called estrogen receptor-α (ER-α). In 1996, a second ER, called estrogen receptor-β (ER-β), was cloned from rat (Kuipper *et al.*, 1996), mouse (Tremblay *et al.*, 1997) and human (Mosselman *et al.*, 1996).

The classical pathway for estrogen action involves the activation of the ERs as transcription factors (see Figure 73.1). After ligand binding, ERs undergo extensive conformational changes, which allow their dissociation from heat shock protein, and the homo- or heterodimerization of ERs (Pettersson and Gustafsson, 2001). Activated dimers diffuse into the nucleus and bind a specific DNA sequence named estrogen response element (ERE), which is located within the promoter region of estrogen target genes, and finally induce gene transcription (Klinge, 2000).
Figure 73.1 Estrogen action through nuclear ER. Estrogens function through genomic and non-genomic pathways. Shown is the "classical" genomic pathway of estrogen action.

Through its binding to ERE, the activated ER complex recruits co-regulators to the promoter through the concerted action of activation function domains. Activated ER complexes bind to the TATA box within the gene promoter, and trigger the expression of specific mRNAs and the subsequent production of proteins that are responsible for the effects of the ligand (Wolffe *et al.*, 1997).

Besides the direct binding of the ER-ligand complex to the ERE sequence, ER-α and -β can also modulate the expression of genes by a tethering mechanism thereby interacting indirectly with DNA. In this way, ER-α and -β act through binding to other DNA-bound transcription factors such as activator protein-1 (AP-1) transcription factors c-fos and c-jun (Paech *et al.*, 1997; Webb *et al.*, 1999), Sp1 (Porter *et al.*, 1997) or nuclear factor kappa B (Nilsson *et al.*, 2001). However, as a functional consequence ERs indirectly regulate the expression of a specific set of genes different from that regulated through ERE dependent mechanisms.

Finally, estrogens and estrogen-like substances act through membrane initiated signalling, also referred to as rapid action (Moriarty *et al.*, 2006). In a rough approximation two main pathways can be discriminated. The first involved recruitment of the nuclear ER to the membrane thereby activating various signal transduction cascades (Song and Santen, 2006), depending on the target cell. Second, the seven transmembrane G-protein coupled receptor GPCR30 for estrogens has been discovered (Rae and Johnson, 2005). Interaction between estrogens and their receptors depend on the number of receptors in the target tissue, the concentration of circulating estrogens and the affinity of estrogenic

compounds to the ER. Generally speaking the affinity of hormone receptors does not change and thus the biological response depends on the number of receptors and the concentration of the estrogenic compounds.

Gene regulation as tool for the assessment of estrogenic activities

Estrogens like other steroid hormones and related molecules can directly regulate gene expression. This means that gene regulation has to be regarded as hallmark of estrogen action. Both *in vitro* and *in vivo* test systems use gene expression analysis as endpoint of estrogen action. This can be done on several levels of complexity.

For pure screening purposes and primary testing for estrogenicity very commonly so-called reporter gene assays are used. For this goal yeast (Routledge and Sumpter, 1996) or mammalian cells (Gagne *et al.*, 1994) are stably or transiently transfected with the respective ER and so-called reporter gene constructs. These reporter gene constructs represent artificial genes consisting either of an extended promoter region of estrogen responsive genes or of naked EREs in a tandem or triple arrangement. Either of these binding sites is capable to control the expression of an easily measurable reporter gene, for example β-galactosidase (Routledge and Sumpter, 1996) or luciferase (Demirpence *et al.*, 1993).

The next level of complexity comprises assays on regulation of endogenous gene expression in estrogen dependent cells in response to treatment with estrogenic compounds. In these assays total RNA, total protein or protein fractions are harvested and analyzed for altered expression levels of specific genes. The steady state mRNA-levels are measured by, for example, Realtime-rt-PCR and the alteration of protein levels by immunobiochemical means, for example Western blots (Strunck *et al.*, 2000).

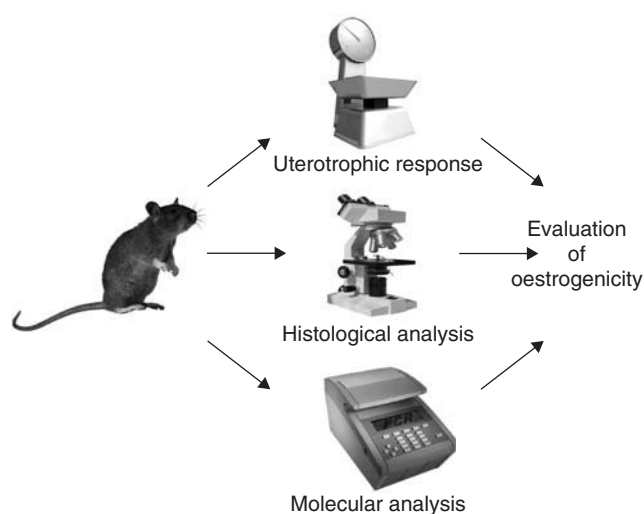
The ultimate level of complexity is the uterotrophic assay in juvenile or adult ovariectomized rodents (Figure 73.2). The classical uterotrophic assay in ovariectomized rats involves castration, so-called ovariectomy, of animals, a period of hormonal decline of 7–10 days and a dose dependent treatment of animals for 3 days in comparison to a carrier treated negative control and a treatment with an appropriate positive control. Following ovariectomy and in response to the hormonal decline the uterus undergoes a reversible regression. If a test compound shows estrogenic activity, the weight loss by regression is counteracted depending on the potency of the estrogen and can be measured as uterine weight gain in comparison to untreated ovariectomized control animals (Owens and Ashby, 2002). The same holds true for the immature or juvenile rat uterotrophic assay, with the only difference, that there is no need of ovariectomy because the animals are not under the influence of endogenous estrogen production.


Figure 73.2 Work flow in the rodent uterotrophic assay. This assay is performed with castrated (ovariectomized) or juvenile female rats. In response to estradiol withdrawal by castration the uterus considerably regresses into an atrophic state. Starting from this situation estrogens reversibly stimulate uterine growth leading to a measurable uterine weight gain. To obtain a higher sensitivity and to assess organ specificity of estrogen action particularly by phytoestrogens, we and others have extended these assays to multiple organ systems and additionally assess histological and molecular endpoints of ER action.

This classical core uterotrophic assay can be modified in its duration (7 h to 3 month; Christoffel *et al.*, 2006) by the source of animals (e.g. transgenic knockout mice) (Hewitt *et al.*, 2003), by increasing the number of organs subjected to investigation (e.g. bone, capillary, pituitary gland and liver), and particularly by increasing the number of assessed morphologic and molecular endpoints (Diel *et al.*, 2002). Our group was one of the first research groups to use gene expression analysis for the assessment of estrogenicity (Diel *et al.*, 2000). This method is superior over others because it not only measures responsiveness but by the usage of pathway specific marker genes also provides clues toward the understanding mechanistic pathways in the hormonal response, for example discrimination between ERE dependent and ERE independent gene regulatory pathways.

Gene Regulation by 8-PN: A Comparative Assessment

Chemical access to test compounds

Although trivial to mention, prerequisite for the molecular characterization of a natural compound is availability of sufficient quantities of test substance. One way to overcome this hurdle is successful chemical synthesis of the compound. Starting from naringenin (Nar) Gester *et al.* were the first to describe a synthetic chemical approach yielding sufficient quantities of the racemic mixture of 8-PN for

biological analysis (Gester *et al.*, 2001). The synthesis strategy consisted of a europium catalyzed Claisen rearrangement reaction yielding in addition to 8-PN significant quantities of 6-Dimethylallylnaringenin (6-DMAN). The latter also represents a natural compound found in the African tree *monotes engleri Gilg* (Seo *et al.*, 1997).

Reporter gene assays

With this tool in hand we could solve several questions: (1) to investigate the relative potency of 8-PN in comparison to estradiol and two structurally related compounds Nar and 6-DMAN (Figure 73.3). (2) To investigate potential preferences of 8-PN for one of the two ERs. Extensive investigations of other xenoestrogens showed that most of the phytoestrogens have a preference for the ER-β, whereas endocrine disruptors are more likely to act through the ER-α. (3) To investigate whether the compounds interact with other nuclear receptor systems and with the endogenous estrogen production.

Using two different reporter gene test system we could clearly confirm previous findings that 8-PN is the most potent ER-α agonist amongst the phytoestrogens known to date, although still some orders of magnitude less potent than estradiol (Table 73.1). In the comparative analysis, however, 8-PN was more potent in the yeast ER assay and in the MCF-7 cells stably transfected with a reporter gene consisting of the Vitellogenin-A2-promoter and the Luciferase reporter (MVLN) test than the parental compound Nar or the other substituted Nar 6-DMAN.

The ER-β activation by 8-PN points toward promoter and/or organ selectivity of the observed effects. Although the activation of ER-β systems requires higher doses of 8-PN, it is still capable to induce ER-β response. Interestingly, the ER-β effect appears to be dependent on the target cells and the promoter constructs used. In bone

cells in combination with a reporter construct in consisting of a minimal promoter (ERE₂) and a reporter gene the overall activity picture for relative potencies of the three Nar
Figure 73.3 Natural occurring Nar. To date at least three Nar from natural sources are known. These comprise Nar from grapefruit (*Citrus grandis*), 8-PN from hops (*Humulus lupulus*) and 6-DMAN from the African tree *Monotes engleri*.

Table 73.1 Relative potency of 8-PN and other Nar in nuclear receptor assays

Test system	Reference hormone	Biological effectiveness (sorted from weakest to strongest effect)
Reporter gene assay ER-α		
Yeast estrogen receptor-α assay	Estradiol	Nar < 6-DMAN < 8-PN < E2
MVLN luciferase assay (ER-α)	Estradiol	Nar < 6-DMAN = 8-PN < E2
Reporter gene assay ER-β		
U2OS transfected by ER-β and (ERE)2-tk-Luc	Estradiol	Nar < 6-DMAN < 8-PN < E2
HEC-1B transfected by ER-β and mC3-tk-Luc	Estradiol	6-DMAN ≤ 8-PN < Nar < E2
Regulation of endogenous gene expression		
AP in endometrial Ishikawa cells (ER-α)	Estradiol	Nar < 6-DMAN < 8-PN < E2
pS2 and PR in MCF-7 cells	Estradiol	Nar < 6-DMAN = 8-PN < E2
Inhibition of yeast androgen receptor assay	Flutamide	Nar < 8-PN ≤ 6-DMAN < Flu

6-DMAN: 6-dimethylallylnaringenin; E2: estradiol; ER-α: estrogen receptor-α; ER-β: estrogen receptor-β; ERE: estrogen responsive element; Flu: Flutamide; Luc: Luciferase; mC3: murine complement C3 promoter; Nar: naringenin; 8-PN: 8-prenylnaringenin; tk: thymidine kinase.

compared is more or less the same as detectable for ER-α, however less potent (Table 73.1). The picture completely changes if the test is performed in HEC-1B human endometrial adenocarcinoma cells and a complex murine complement C3 promoter in front of the luciferase reporter. In this test system 8-PN is by far less effective than Nar or E2 (Table 73.1). These data are in line with a very recent data set on estrogenic activity following subtle side-chain modifications of the 8-position which resulted in very complex functional pattern of function ranging from a full ER-α agonist to pure antagonistic compounds (Roelens et al., 2006).

Endogenous gene expression in target cells

To test for endogenous gene expression in a target cell requires that this particular target cell stably expresses at least one of the ERs and that genes, endogenously regulated by ER are known. For these kinds of assays we used two cell systems representing classical target organs for female sex steroids namely endometrial and breast tissue. We used

the Ishikawa human endometrial adenocarcinoma cell line and human MCF-7 breast cancer cells which both endogenously express ER-α. Representing non-classical target organs we in addition investigated Fe33 rat hepatoma cells, which are stably transfected with the human ER-α and represent a liver model (Diel et al., 1995).

A (semi)quantitative Realtime-rt-PCR of RNA from MCF-7 cells revealed that 8-PN potently stimulates increase of steady state mRNA-levels of the pS2 and the progesterone receptor gene (Figure 73.4; Table 73.2), although at 100-fold higher concentrations as estradiol. This effect was also observable for 6-DMAN (Table 73.1). Likewise both substituted Nar stimulated increase of alkaline phosphatase expression in Ishikawa cells, which was measured on the enzymatic activity level (Wober et al., 2002). These findings clearly validate the findings from reporter gene assays in these more complex test systems (Table 73.2).

An important issue in all gene expression analyses is proof of the receptor mediation of the effect. For this purpose estrogenic effects are counteracted by co-incubation of cells
Figure 73.4 Comparative assessment of regulation of endogenous gene expression in MCF-7 breast cancer cells by 8-PN. This figure shows that 8-PN is capable to induce the estrogen dependent expression of the two marker genes progesterone receptor and pS2 in MCF-7 cells a well-known model cell line for breast tissue. The specificity of this effect is demonstrated by co-incubation of estrogens with the antiestrogen faslodex (ICI 182780) which inhibits estrogen induced gene regulation. E2: estradiol; 8-PN: 8-prenylnaringenin; 6-DMAN: 6-dimethylallylnaringenin; Nar: naringenin. Significance against untreated control $^*p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$; significance of ICI effects amongst treatment groups: $^+p < 0.05$, $^{++}p < 0.01$, $^{+++}p < 0.001$.

with an excess of a pure antiestrogen-like fulvestrant (ICI 182780) (Wakeling and Bowler, 1987, 1992). In all assays co-treatment of cells with an antiestrogen lead to inhibition of estrogen or 8-PN induced gene regulatory responses, as shown for pS2 and progesterone receptor up-regulation in MCF-7 cells (Figure 73.4).

Whereas the findings on regulation of endogenous gene expression in cells representing classical target organs are in line with those obtained in reporter gene assays, the results with hepatic cells deliver another picture. Whereas estradiol up-regulated all genes investigated, unlike in mammary gland derived and in endometrial cells 8-PN did not mimic this estrogenic response (Table 73.2). No effects of 8-PN following treatment of Fe33 cells were detectable for the expression of calcium binding protein 9kD, apolipoprotein A1 and carbonic anhydrase II (Caldarelli et al., 2005), whereas steady state mRNA-levels of insulin-like growth factor binding protein-1 were down-regulated by low doses of 8-PN and up-regulated by high doses of 8-PN. In summary, these findings provide another piece of evidence for an organ selective component of the bioactive function of the pure substance 8-PN.

While 8-PN clearly is estrogenic and activates preferentially ER-α it is questionable whether the estrogenic activity in beer, at least in part attributable to 8-PN, is sufficient to elicit estrogenic effects. One study directly addressed this question. One liter of various varieties of Austrian beers was extracted and the extract subjected to the yeast ER assay. The extracts were capable to induce the reporter gene activity, however, the highest activity corresponded to 43 ng of estradiol. From these low activities measured the authors concluded that there is no hazard for human health from drinking beer (Promberger et al., 2001).

8-prenylnaringenins and other nuclear receptor systems

In other sets of experiments we addressed the question whether 8-PN is capable to induce other nuclear receptors. Some of the xenoestrogens described in the literature also interfere with the androgen receptor signalling pathway (Sohoni and Sumpter, 1998). However, none of the Nar was capable to induce an androgen receptor dependent reporter gene activity comparable to the positive control dihydrotestosterone. Conversely, both substituted Nar, unlike the parental compound Nar inhibited dihydrotestosterone induced reporter gene activity in a yeast androgen receptor assay (Table 73.1). Only for 6-DMAN but not for 8-PN this result could be confirmed in a second independent assay on androgen receptor dependent expression of prostate specific antigen (Zierau et al., 2003).

Very important regarding regulation of general metabolism are "peroxisome proliferator-activated receptor" (PPAR), existing in the three subtypes α,γ,δ with activation of PPAR-γ leading to enhanced insulin sensitivity in type-II diabetes (Knouff and Auwerx, 2004). We tested whether Nar, particularly 8-PN activate PPAR-γ, but no activity was detectable.

In conclusion, these data show that 8-PN is a potent activator of ER-α with a preference for ER-α over ER-β, which is in line with data in the literature (Schaefer et al., 2003). Further, there are first indications that the ER-β response may be tissue selective. Finally, prenylated Nar have also been regarded as week antiandrogens with 6-DMAN being superior over 8-PN regarding this activity.

Gene regulation by 8-PN *in vivo*

As mentioned above 8-PN is a potent *in vitro* activator of ER-α with a clear preference for ER-α over ER-β and therefore theoretically also qualifies for pharmacological application *in vivo*. The first important issue to be investigated *in vivo* is the proof of the principle of the biological activity determined *in vitro*. The *in vivo* effectiveness can be hampered for several reasons; most often this is caused by an insufficient bioavailability.

Phytochemicals, if ingested through an oral route first of all need to be taken up by the intestine and second are subject to massive bioconversion in the liver. Therefore, it is

Table 73.2   Regulation of endogenous gene expression by 8-PN

Cell line	Target organ	Target gene	Estradiol	8-PN
Ishikawa	Endometrium	Alkaline Phosphatase	↑↑	↑↑ (10^{-6}M)
MCF-7	Mammary gland	pS2	↑↑ (10^{-8}M)	↑↑ (10^{-6}M)
		Progesterone receptor	↑↑ (10^{-8}M)	↑↑ (10^{-6}M)
Fe33	Liver	Calcium binding protein 9 KD	↑↑↑ (10^{-8}M)	– (10^{-6}M)
		Insulin-like growth factor binding protein 1	↑↑(10^{-8}M)	↓ (10^{-8}M)/ – (10^{-7}M)/↑ (10^{-6}M)
		Apolipoprotein A1	↑↑ (10^{-8}M)	– (10^{-6}M)
		Carbonic anhydrase II	↑↑ (10^{-8}M)	– (10^{-6}M)

Note: In this table the relative potency of 8-PN in comparison to estradiol is shown for three independent cell culture systems representing three different target organs for estrogens. 8-PN: 8-prenylnaringenin.

important to test whether bioavailable levels of substance are sufficient to induce tissue specific responses. 8-PN for example has been shown to be readily taken up by intestinal mechanisms (Nikolic *et al.*, 2006) and to be subjected to phases I and II mechanisms in the liver (Nikolic *et al.*, 2006) which in other words means that its bioavailability should be reduced significantly by intestinal and hepatic metabolism (Nikolic *et al.*, 2004). On the other hand, two of the most abundant metabolites which are produced by liver microsomal preparations *in vitro*, namely (E)-8-(4″-hydroxyisopentenyl)naringenin and (E)-8-(4″-oxoisopentenyl)naringenin are still quite potent estrogens on inducing reporter gene activation in transactivation assays (Zierau *et al.*, 2004).

As mentioned above, estrogenicity *in vivo* is primarily tested in the uterotrophic assay at pharmacological doses of the tested substance. In a first line of experiments a subcutaneous application route in ovariectomized rodents is taken to achieve significant exposure levels. Following proof of effectiveness usually a second animal study also in ovariectomized rats and mice is performed this time using an oral exposure route. The outcome of this assay shows whether bioavailability of the substance in question is sufficient to evoke responses even after passage of the substance through intestine and liver, including the enterohepatic circulation.

8-PN in a dosage of 10 mg/kg/day given subcutaneously for 3 days is clearly estrogenic *in vivo*. Like estradiol
Figure 73.5   Regulation of uterine gene expression by 8-PN. Here the impact of 8-PN on the expression of rat uterine genes is shown. Complement C3 is up-regulated in response to estradiol (E2; 10 μg/kg/day), whereas clusterin is down-regulated. 8-PN mimics this pattern of regulation although at higher concentrations (10 mg/kg/day). However, its response is stronger than those observable for the isoflavones genistein (Gen) and daidzein (Dai), the latter being completely ineffective. Significance is not given because the results were obtained from two different experiments.

(10 μg/kg/day) 8-PN stimulates increase of uterine wet weight after 3 days of treatment (Diel *et al.*, 2004). In addition, it stimulates the modulation of estrogen responsive genes in the same way as estradiol, meaning, for example, stimulation of proliferation marker, up-regulation of complement C3 and down-regulation of clusterin (Figure 73.5). In a comparison to other phytoestrogens (e.g. genistein and daidzein), 8-PN could be shown to be a lot more potent (Diel *et al.*, 2004).

Menopausal applications of 8-PN

Due to its potent estrogenic profile it has been suggested to use hop extracts and/or 8-PN as an alternative for the classical hormone therapy (HT). HT is very effective in relieving climacteric complaints during postmenopause as well as preventing the long-term consequences of estrogen deficiency such as osteoporosis (Lindsay and Thome, 1990; Skafar *et al.*, 1997). HT replaces the female sex steroid estradiol alone or in combination with the other female sex steroid progestogen. Results from randomized controlled trials (Colditz *et al.*, 1995; Magnusson *et al.*, 1999; Schairer *et al.*, 2000; Beral *et al.*, 2002; Rossouw *et al.*, 2002; Beral, 2003; Chlebowski *et al.*, 2003) showed HT to be associated with an increased risk of endometrial cancer and venous thromboembolism (Ross *et al.*, 2000; Rosendaal *et al.*, 2002). In addition, if HT is started in perimenopause, the risk of developing breast cancer is increased (Aggarwal *et al.*, 2004). Thus, HT is not risk free, and since patients demand for alternative treatments that are free of the potential risks associated with HT, hops extracts and/or 8-PN have been proposed to represent such an alternative treatment regimen.

In perimenopause patients particularly suffer from hot flushes, insomnia and mood disorders. In a very recent animal study it was shown that 8-PN is capable to reverse estrogen deficiency – induce rise in skin temperature (Bowe *et al.*, 2006). Cessation of estrogen production in menopause in addition is accompanied by loss of bone mass and density. In a second study it was shown that 8-PN protects ovariectomized estrogen deficient rats from bone loss, with a minimal stimulation of the uterus (Humpel *et al.*, 2005). In a 3-month study with a threefold higher dose of 8-PN a clear estrogenic response in the uterus could be detected on the level of uterine weight gain and estrogen responsive uterine gene expression (Christoffel *et al.*, 2006). These physiological and molecular observations were further validated by histological means showing an unfavourable impact of 8-PN treatment on uterine and vaginal morphology (Rimoldi *et al.*, 2006).

In a pharmacokinetic study with postmenopausal women it was shown that single doses of up to 750 mg of 8-PN are well tolerated and exert systemic effects as measured by a decrease of luteinizing hormone serum concentrations (Rad *et al.*, 2006). While no further clinical studies have been conducted with pure 8-PN, there is a prospective randomized double blind placebo controlled study with an 8-PN enriched hop extract (MenoHop; 100 or 250 μg 8-PN). This trial showed favorable effects on vasomotor symptoms after 6 but not after 12 weeks of treatment and only for the low dose (Heyerick *et al.*, 2006). No dose response was detectable.

In summary, these data demonstrate that hop extracts and/or 8-PN are capable to alleviate menopausal complaint both in humans and animals. However, concerns come from studies on uterine effects, which clearly showed that 8-PN exerts the undesirable effect of uterine stimulation. One of the authors of the cited papers stated: *Human pharmacologic studies will show whether the stimulatory effect on the uterus that was found . . . . would require the concomitant administration of progestins to prevent endometrial overstimulation* (Christoffel *et al.*, 2006).

Summary Points

- 8-PN is the most potent phytoestrogen identified to date.
- 8-PN represents a highly efficient inductor of ER-α dependent reporter gene activity.
- Unlike other phytoestrogens 8-PN exhibits a clear preference for ER-α over ER-β, a rather unique feature for phytoestrogens.
- The prenylation of the 8-position appears to be particularly important for this feature since substitution of the 6-position also confers to a higher ER-β potency and to antiandrogenicity.
- 8-PN is a potent inducer of ER-α dependent gene regulation in cultured cells from classical target organs for female sex steroids (e.g. endometrium and mammary gland).
- The only cell system investigated so far in which 8-PN just induces a marginal response is a hepatic cell line. This is surprising since liver is believed to express ER-α only.
- 8-PN behaves as an ER-α agonist *in vivo* and induces ER-α dependent gene regulation in all target organs investigated.
- Overall, 8-PN and structural related derivatives represent highly interesting lead compounds for pharmacological applications, including the treatment of menopause associated problems.

Hop-Derived Phytoestrogens Alter Osteoblastic Phenotype and Gene Expression

Katharina E. Effenberger Institute of Tumour Biology, Center of Experimental Medicine, University Medical Center-Hamburg Eppendorf, Hamburg, Germany
Johannes Westendorf Institute of Pharmacology and Toxicology, Center of Experimental Medicine, University Medical Center-Hamburg Eppendorf, Hamburg, Germany

Abstract

Certain plant-derived compounds show selective estrogen receptor modulator (SERM) activity and are therefore considered to have chemopreventive potential or to be an alternative to the conventional hormone replacement therapy. Most of the phytoestrogens identified so far have phenolic structures which are known to be able to bind estrogen receptors (ERs). In addition they have been shown to display desirable effects on hormone-related diseases like osteoporosis or cancer. We tested the effects of the hop-derived prenylflavonoids 8-prenylnaringenin, 6-prenylnaringenin, xanthohumol and isoxanthohumol to modulate markers of differentiation and gene expression in osteoblasts. Additionally, we analyzed the ER-binding affinities of these hop compounds as well as the ER-mediation of their effects. Bone-forming activity and ER-subtype specificity were investigated by measuring alkaline phosphatase (AP) activity in hFOB/ERα cells and regulation of gene transcription for AP, interleukin-6 (IL-6), presenelin-2 (pS2) and von Willebrand Factor (VWF) in U-2 OS/ERα and U-2 OS/ERβ cells.

Our results demonstrate that AP, pS2 and VWF mRNA levels are significantly increased by treatment with the compounds in an estrogen-like manner via both ERα and ERβ, while IL-6 is down-regulated in U-2 OS/ERα cells. Consistently, AP enzymatic activity is up-regulated by all compounds in hFOB/ERα9 cells. Except for 8-PN the hop constituents display an ERβ-preference. Reversal of estrogen-specific AP-induction in Ishikawa cells indicates an ER-regulated mechanism. Finally, the flavonoids display cytotoxic effects only at high concentrations ($\geq 10^{-4}$ M).

In summary, we have demonstrated for the first time that specific phytoestrogen compounds found in hop extracts exert estrogen-like activities on bone metabolism. Beer is the main dietary source of such prenylflavonoids. Regarding a potential for use of beer or isolated prenylflavonoids in osteoporosis-prevention therapy, the dosage and pharmacokinetics of these phytoestrogens will play an important role concerning a desired *in vivo* profile.

List of Abbreviations

AP	Alkaline phosphatase
CFE	Colony-forming efficiency
E$_2$	17β-Estradiol
EE	Ethinyl estradiol
ER	Estrogen receptor
HRT	Hormone replacement therapy
IXH	Isoxanthohumol
6-PN	6-Prenylnaringenin
8-PN	8-Prenylnaringenin
pS2	Presenelin-2
SERM	Selective estrogen receptor modulator
VWF	von Willebrand Factor
XH	Xanthohumol

Introduction

Bone remodeling is a dynamic process which is maintained by a balance between bone formation and bone resorption. It has long been recognized that the acute loss of estrogen at the onset of menopause is responsible for an accelerated bone loss in women, called Type I osteoporosis (Rizzoli and Bonjour, 1997). It is characterized by an imbalance in bone remodeling and leads to an increased fracture risk. Besides estrogen deficiency, there are other important factors which determine the extent of bone loss such as race, genetics and nutrition. The peak bone mass achieved during adolescence also influences the risk of developing osteoporosis during menopause (Bilezikian, 1998).

Hormone replacement therapy (HRT) is currently the most common therapy used for peri- and postmenopausal women to prevent bone loss. However, chronic estrogen therapy provides both benefits and hazards. While there are positive effects on bone, climacteric symptoms and possibly on the cardiovascular system, there are also increased risks of breast and endometrial cancers after a certain period of

application (Grodstein *et al.*, 1997; Rizzoli and Bonjour, 1997; Gustafsson and Warner, 2000). Thus, intensive investigation is currently underway to identify selective estrogen receptor modulators (SERMs) which display the desirable estrogenic effects but lack the undesirable side effects. Several plant-derived compounds, including isoflavones, lignans and coumestans, display SERM activity. Some plant extracts already commonly used against climacteric complaints include soy (*Glycine max* L.), black cohosh (*Cimicifuga racemosa* L.), red clover (*Trifolium pratense* L.) and derivatives of the hop plant (*Humulus lupulus* L.) (Khosla, 2002; Wuttke *et al.*, 2002; Zierau *et al.*, 2002a). The female flowers of the hop plant contain a variety of compounds whose structures have been shown to bind to the estrogen receptors (ERs) α and β such as the flavanones 8-prenylnaringenin (8-PN), 6-prenylnaringenin (6-PN) (Milligan *et al.*, 2000) and the isoflavone xanthohumol (XH), as well as its opened ring form isoxanthohumol (IXH) (Stevens *et al.*, 1999) (Figure 74.1). The hop plant *Humulus lupulus* L. (*Cannabaceae*) has traditionally been used as a sedative and flavoring agent for beer. Beer is the main dietary source of hop prenylflavonoids. Although its estrogenic effects have also been known and investigated (Kumai and Okamoto, 1984; Milligan, *et al.*, 1999; Liu *et al.*, 2001; Milligan *et al.*, 2002; Stevens and Page, 2004), very little is known about the molecular mechanism of action on bone and osteoblastic cell cultures. It is yet to be established if there is a causal link between the action of phytoestrogens and bone mass maintenance in humans. According to Tobe *et al.*, XH, at a concentration of 10^{-5} M, has a strong inhibitory effect on bone resorption, but the mechanism remains unclear. This is not surprising as XH is a precursor of 8-PN (Tobe *et al.*, 1997). 8-PN has been shown to act as an estrogen agonist in bone *in vivo* (Miyamoto *et al.*, 1998). Moreover, in different

tissues 8-PN shows estrogenic effects with an activity about one order of magnitude greater than that of other established plant estrogens (e.g. genistein) (Kitaoka *et al.*, 1998; Milligan *et al.*, 1999, 2002). Genistein, a soybean isoflavone, behaves as a weak estrogen agonist in hFOB/ERα9 and hFOB/ERβ6 cells (Rickard *et al.*, 2003). Since 8-PN, like genistein, binds to both ER isoforms, it might be possible that 8-PN acts in a similar manner to genistein on bone *in vivo* (Morabito *et al.*, 2002; Li and Yu, 2003). Other *in vivo* experiments in ovariectomized rats have shown that certain isoflavones suppress ovariectomy-induced bone resorption in a manner similar to estrogen (Miyamoto *et al.*, 1998).

The action of 17β-estradiol (E_2) in bone occurs via its two receptor subtypes ERα and ERβ (Eriksen *et al.*, 1988; Komm *et al.*, 1988). Both are found in osteoblastic cells *in vivo*. ERα is mainly expressed in cortical bone and therefore responsible for longitudinal growth, whereas ERβ prevails in cancellous bone and may be important for the maintenance of bone substance (Bord *et al.*, 2001). *In vitro* ERα and ERβ are differentially expressed during osteoblast differentiation (Arts *et al.*, 1997). Both receptors exhibit differential ligand-dependent regulation of endogenous genes and markers characteristic for osteoblasts *in vitro* (Kuiper *et al.*, 1997; Waters *et al.*, 2001; Monroe *et al.*, 2003). The variety of target genes as well as the specific effect on gene expression depends on the particular receptor-ligand complex, the ratio of ERα and ERβ, and the steroid receptor coactivators in the specific cell type.

In this study we investigated the effects of several hop-derived compounds on cultured osteoblast-like cells in comparison to E_2. To examine the differential regulation via the two ER isoforms, we compared the responses of normal human fetal osteoblast cells (hFOB) and human osteosarcoma cells (U-2 OS) stably transfected with either ERα or ERβ following treatment with E_2 or the phytoestrogens. In addition, we tested the ER-binding affinity of the hop-derived compounds to the two ER-subtypes in a cell-free system using human recombinant receptor proteins of ERα and ERβ proteins, as well as the ER-mediation of their effects.

The purpose of this study was to investigate the effects of specific hop-derived phytoestrogen compounds on osteoblast-like cell phenotypes and determine if these effects are mediated by either ERα or ERβ (Effenberger *et al.*, 2005). We examined endogenous target gene regulation of four estrogen-regulated genes, alkaline phosphatase (AP), interleukin-6 (IL-6), presenelin-2 (pS2) and von Willebrand Factor (VWF). As AP is an excellent marker of osteoblast function (Waters *et al.*, 2001), we measured its enzymatic activity as well. Furthermore, co-treatment with an antiestrogen demonstrates that these compounds function in an ER-dependent manner. This is the case when induction of estrogen-specific marker AP can be reversed by the antiestrogen.

Regulation of Estrogen-Inducible Gene Expression by Estradiol and Phytoestrogens in U-2 OS/ER Cells

The ER isoforms ERα and ERβ are known to differ in their tissue specificity and response to various ER agonists and antagonists (Paech *et al.*, 1997). To determine the differential gene regulation, we used the human osteosarcoma cell lines U-2 OS/ERα and U-2 OS/ERβ (Monroe *et al.*, 2003). The advantages of these cell lines are that (1) they express comparable ER levels between the two cell lines, (2) the effects observed can directly be ascribed to one receptor subtype and (3) no interactions between the receptor subtypes such as ERα/β heterodimers have to be expected (Pace *et al.*, 1997).

The effects of treatment with the hop compounds (8-PN, 6-PN, XH and IXH) and E_2 on four estrogen-egulated genes AP, IL-6, pS2 and VWF were tested in the U-2 OS/ERα and U-2 OS/ERβ cell lines by semi-quantitative RT-PCR. Two of the genes, AP and IL-6, play an important role in bone metabolism. AP is a bone formation

marker and is up-regulated by E_2 (Riggs and Khosla, 1995; Robinson *et al.*, 1997). In contrast, IL-6 is down-regulated by E_2 and is linked to a decreased bone resorption activity (Qu *et al.*, 1999).

The compound 6-PN increases AP gene expression to the same extent as 10^{-8} M E_2 in the U-2 OS/ERα cells in higher concentrations (Figure 74.2a and b). Interestingly, 8-PN up-regulates AP even stronger than E_2, with a peak induction at $1.0 \mu g/\mu l$. In the U-2 OS/ERβ cells 8-PN has a similarly strong effect as compared to E_2, while 6-PN acts slightly weaker (Figure 74.2c and d). XH and IXH show a weaker effect than estrogen in both cell lines with $1.0 \mu g/ml$ displaying the strongest induction, respectively. Dose dependency is observed for 6-PN, XH and IXH in U-2 OS/ERα cells and for 6-PN in U-2 OS/ERβ cells.

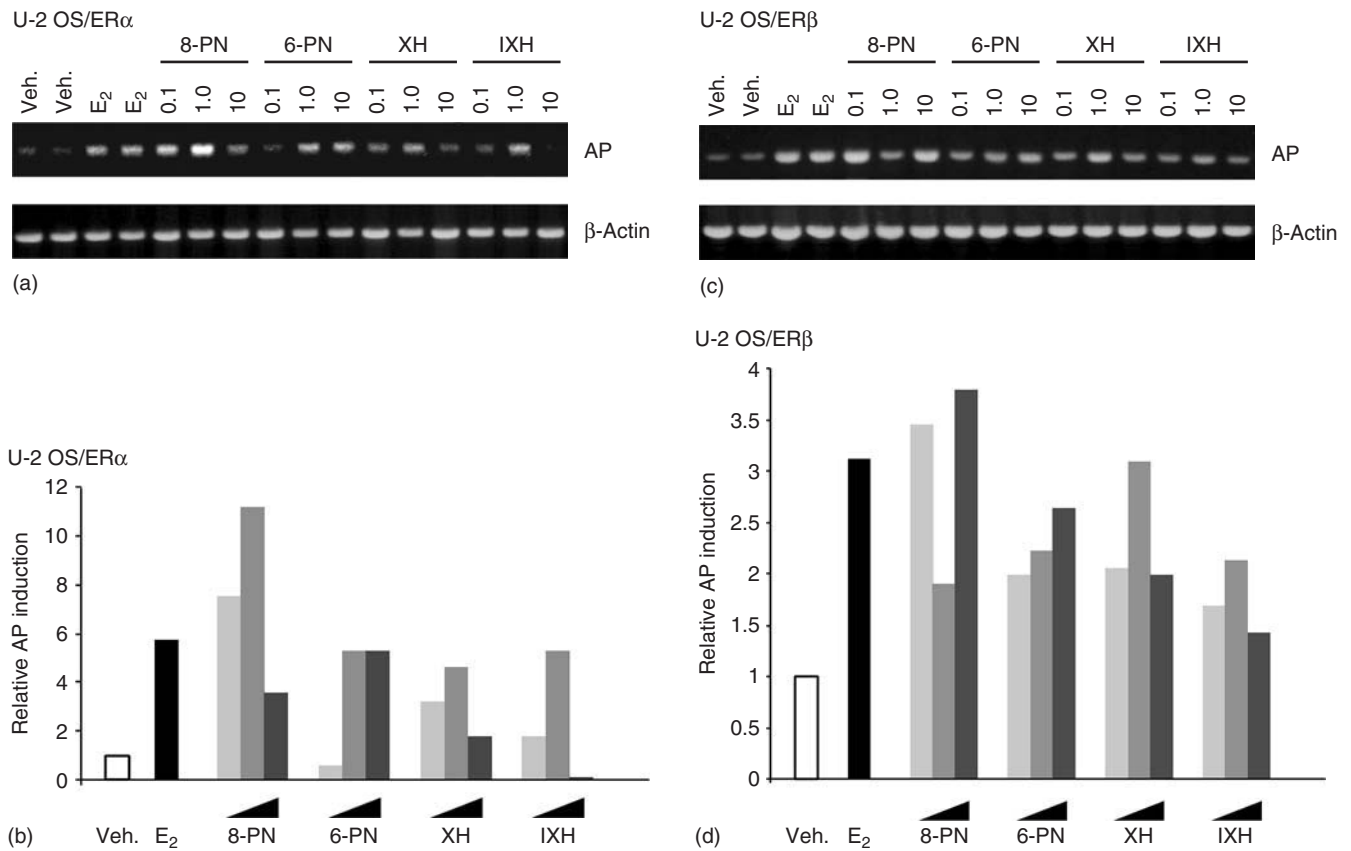
IL-6, a marker of bone resorption, is down-regulated by all test samples in U-2 OS/ERα cells, in certain concentrations to the same extent as estrogen with the exception of IXH which acts slightly weaker. At $10.0 \mu g/ml$, IXH seems to induce IL-6 (Figure 74.3a and b). Here 6-PN


Figure 74.2   Regulation of AP mRNA expression by E_2 and plant-derived compounds. U-2 OS/ERα (a) and U-2 OS/ERβ (c) cells were grown in DMEM/F12 media containing 10% cs-FBS, treated overnight with $1 \mu g/\mu l$ doxycycline to induce ER expression and then treated for an additional 24 h with the indicated compounds in the concentrations 0.1, 1.0 or $10.0 \mu g/ml$ (i.e. 0.5×10^{-6}– 0.5×10^{-4} M) and E_2 10^{-8} M. mRNA was harvested and RT-PCR was performed with cDNA templates using specific primers for human AP. β-actin gene expression serves as a control. Figure (b) (for U-2 OS/ERα) and (d) (for U-2 OS/ERβ) show the quantitated data, which results from densitometry of the bands as bar graphs.

RT-PCR was performed with cDNA from U-2 OS/ERα (a) and U-2 OS/ERβ (c) cells as described in Figure 74.2 using specific primers for human pS2. β-actin gene expression serves as a control. Figure (b) (for U-2 OS/ERα) and (d) (for U-2 OS/ERβ) show the quantitated data, which results from densitometry of the bands as bar graphs.
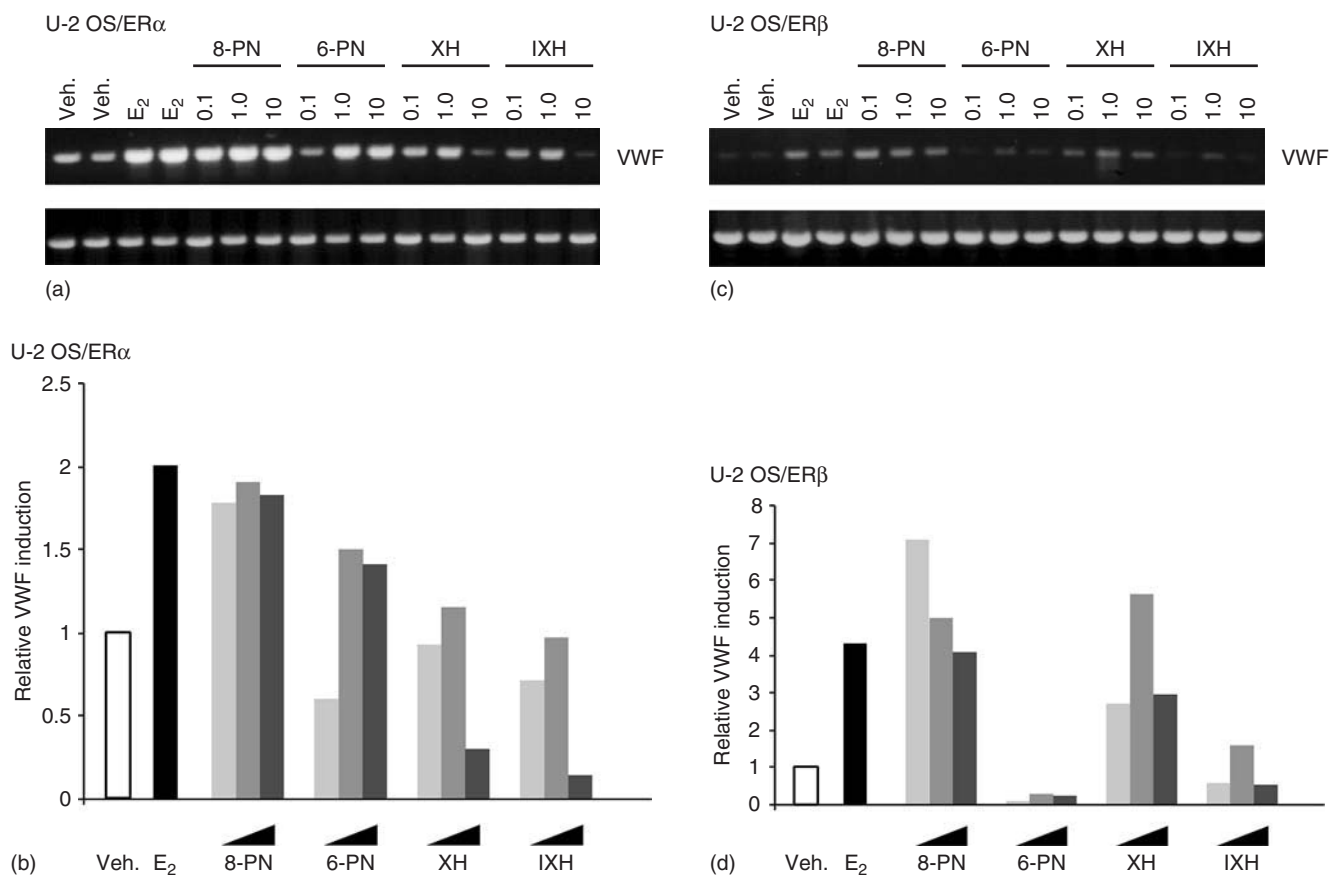

Figure 74.5 Regulation of VWF mRNA expression by E_2 and plant-derived compounds. RT-PCR was performed with cDNA from U-2 OS/ERα (a) and U-2 OS/ERβ (c) cells as described in Figure 74.2 using specific primers for human VWF. β-actin gene expression serves as a control. Figure (b) (for U-2 OS/ERα) and (d) (for U-2 OS/ERβ) show the quantitated data, which results from densitometry of the bands as bar graphs.

displays reverse dose dependency. Surprisingly, IL-6 expression remains unaltered by E^2 and all plant compounds in U-2 OS/ERβ (data not shown). This leads to the assumption that (1) the IL-6 gene in osteoblast-like cells might be ERα-regulated and (2) none of the tested hop constituents or estrogen enhances bone resorption via IL-6 regulation *in vitro*.

Another well-characterized estrogen-regulated gene is pS2. Only the lower doses of 8-PN (0.1 and 1.0 μg/ml) up-regulate pS2 to a similar degree as E_2 in U-2 OS/ERα (Figure 74.4a and b). IXH displays intermediate levels of induction while 6-PN and XH only weakly increase pS2 gene expression. 8-PN and E_2 markedly induce pS2 mRNA levels in U-2 OS/ERβ cells (Figure 74.4c). XH shows a slightly weaker up-regulation with a distinct peak at 1.0 μg/ml, but stronger than 6-PN and IXH. pS2 is a well-characterized estrogen-regulated marker in different cell systems (Brown *et al.*, 1984; Liu *et al.*, 2001; Barkhem *et al.*, 2002) and is over-expressed in certain breast cancers (Nunez *et al.*, 1987). Whether pS2 also plays a role in bone formation is not known. However, because of its robust inducibility by estrogen, we used it for determination of the estrogenicity of the phytoestrogens compared to E^2 in the U-2 OS/ER cell lines.

Finally, recent data demonstrated that the VWF gene is a very sensitive marker for estrogen regulation in the U-2 OS/ER cell lines (Monroe *et al.*, 2003). Therefore, VWF gene regulation was chosen in our study to further investigate the estrogenic effects of the phytoestrogens. In the U-2 OS/ERα cells, VWF is strongly up-regulated to a similar extent as E_2 by 8-PN followed by 6-PN (Figure 74.5a and b). XH and IXH show remarkably weaker effects. Dose dependency is observed for the three latter compounds for 0.1 and 1.0 μg/ml. In U-2 OS/ERβ cells, 8-PN induces VWF gene expression to a higher level than estrogen in a reverse dose-dependent manner (Figure 74.5c and d). XH has a similar effect as E_2 at 1.0 μg/ml, whereas 6-PN and IXH induce VWF gene expression, if at all, to a lesser degree. The VWF gene is a strongly regulated parameter for E_2 and the hop components. VWF is involved in blood clotting as a so-called antihemophilic factor (factor VIIIA) and interacts with factor VIIIC to enhance thrombocyte aggregation at the vascular endothelium. Monroe *et al.* (2003) suggested a possible function in the extracellular matrix of bone as VWF is known to associate with various collagen types during blood clotting (Budde and Schneppenheim, 2001). Collagen is an important constituent of bone extracellular matrix.

In summary, the results of this gene expression profile in the U-2 OS/ER cell lines reveal that the compound 8-PN has the strongest estrogen-like activity of the compounds tested. Furthermore, 8-PN shows potent estrogenic effects in a dose-dependent manner for the regulation of all tested genes. 6-PN, XH and IXH display weaker estrogenic effects than 8-PN. Regarding AP and VWF gene expression, 6-PN induces obviously stronger than XH and IXH.

In some cases a reverse dose dependency, for example 8-PN regulation of VWF in U-2 OS/ERβ, or a decreased effect of the 10.0 μg/ml concentration of the compound, for example XH or IXH in U-2 OS/ERα cells, can be observed while the lower concentrations 0.1 or 1.0 μg/ml show the strongest regulation. This might be due to a nonspecific cytotoxic effect of the higher phytoestrogen concentrations in cell culture as observed for IXH (Miranda *et al.*, 1999). For XH other mechanisms, like tyrosine kinase inhibition, might be crucial (Akiyama *et al.*, 1987; Yamagishi *et al.*, 2001).

We demonstrated for the first time that constituents of the hop plant display positive estrogen-like effects on osteoblast-like cell cultures. In some instances these effects are even stronger than those of E_2. Importantly, they also influence markers of bone metabolism (AP and IL-6) to a similar extent as E_2. The tested compounds can therefore be declared phytoestrogens because they display estrogenic activity in several independent assays.

Regulation of AP Activity by Ethinyl Estradiol and Phytoestrogens in hFOB/ER Cells

For the human fetal osteoblast cell line hFOB/ERα9 the previous statements (2) and (3) made for the U-2 OS/ER cells can be applied, respectively ((2) the effects observed can directly be ascribed to one receptor subtype and (3) no interactions between the receptor subtypes such as ERα/β heterodimers have to be expected). However, ER levels between the two cell lines are considerably different. Whereas hFOB/ERα9 cells express a fairly high level of receptor protein, the level of ERβ expressed in hFOB/ERβ6 is relatively low (Waters *et al.*, 2001). Consistent with this, AP activity was nearly undetectable.

Since AP is both a marker of bone formation and osteoblast differentiation in confluent osteoblast cell cultures (Waters *et al.*, 2001), we tested the effects of the hop compounds on AP activity. Ethinyl estradiol (EE) displays a nearly 5-fold increase in AP activity compared to media in the hFOB/ERα9 cells. All hop compounds or extracts induce the AP enzyme to a lesser extent than EE with AP activity being most strongly induced by 8-PN (Figure 74.6). In the concentrations 0.1 and 1.0 μg/ml 8-PN displays a nearly 3-fold increase compared to media. To a lesser extent XH dose dependently increases AP activity as well. In the concentration 10.0 μg/ml XH displays an approximately
Figure 74.6 Regulation of AP activity by ethinyl estradiol (EE) and plant-derived compounds in hFOB/ERα9 cells. The cells were grown in media containing 10% cs-FBS and treated for 4 days with the indicated compounds (0.1, 1.0 and 10.0 μg/ml) or EE (10^{-8}M). AP activity was determined, normalized for protein content and expressed relative to control (media). The bars represent fold induction of AP ± standard deviation ($n = 8$). At $p < 0.005$ level these data are significantly different (t-test) from the EE control.

2.2-fold stimulation of AP activity compared to media. IXH and 6-PN display no significant effects compared to media.

Consistent with a previous report (Waters *et al.*, 2001), no stimulation of AP activity with EE-treatment is observed after 4 days in the hFOB/ERβ6 cells (data not shown).

Comparing AP gene expression and enzymatic activity we found that they were regulated in the same manner and to a similar extent in the U-2 OS/ER and hFOB/ERα9 cell lines, respectively. 8-PN most effectively up-regulates AP gene expression and activity.

This data demonstrates the consistency and reproducibility of the estrogenic effects of these compounds between different *in vitro* osteoblastic models.

Reversal of Phytoestrogen-Induced AP Up-regulation in Ishikawa Cells

Induction of AP in Ishikawa cells is used as an estrogen-specific marker to analyze the estrogenicity of (plant-derived) compounds (Holinka *et al.*, 1986; Kayisli *et al.*, 2002). To assess whether the observed phytoestrogen effects are tissue specific and ER-mediated, the potent estrogen derivative EE (10^{-9}M) and each compound at the concentration, which showed the strongest AP-induction in this system, were added to the cells together with the ERα-antagonist ICI 182780 (10^{-7}M). Figure 74.7 shows reversal of the inductions for EE as well as for all four hop ingredients. This implies a likely complete ER-mediated mechanism.
Figure 74.7 Reversal of phytoestrogen-induced AP up-regulation in Ishikawa cells. The cells were grown in media containing 10% cs-FBS and treated for 2 days with the indicated compound (μg/ml) or EE (10^{-9} M) with or without ICI182780 (10^{-7} M). AP activity was determined, normalized for protein content and expressed relative to control (media). The y-axis shows the fold activation of AP compared to control. Error bars indicate standard deviation ($n = 4$). Hatched bars display parallel treatment with ICI. The bars represent fold induction of AP ± standard deviation ($n = 4$). At $p < 0.005$ level the data point of each compound/EE for AP activity is significantly different (t-test) from its data resulting from co-treatment with ICI.

Relative Binding Affinities of Estradiol and Phytoestrogens to ERα and ERβ

In addition to these cell culture methods, we tested the ER-binding affinity of the hop compounds to the two ER-subtypes in a cell-free system. To characterize the affinity we calculated the IC_{50}-values for all compounds and E_2 (Figure 74.8; Table 74.1a). The relative binding potency of the phytoestrogens compared to the endogenous ligand is described by dividing the IC_{50} (compound, ERα) through the IC_{50} (E_2, ERα) (Table 74.1b). Further, ER-subtype specificity was determined and expressed by the ratio IC_{50} (compound, ERα) to IC_{50} (compound, ERβ) in Table 74.1c.

We could show that none of the isolated compounds from hops binds as efficiently as E_2. Apart from 8-PN, they display relative affinities of approximately 3 orders of magnitude lower than E_2. 8-PN shows the strongest ER-binding affinity which is only 0.5 orders of magnitude lower compared to E_2. An increased affinity for ERβ, as observed for the well-known phytoestrogen genistein, has been connected with a positive overall action, that is decreased risks of breast and endometrial cancers (Liu *et al.*, 2001; Morito *et al.*, 2001). In our study, 6-PN, XH and IXH, but not 8-PN, reveal a preference for ERβ (Table 74.1c).

Not only the affinity to the ER-subtype, but also the transactivation through the receptor compared to E^2, is important. For 8-PN a remarkable transactivation, even stronger than that of the well-known phytoestrogen genistein but less strong than for E_2, could be shown in reporter gene assays (data not shown; Milligan *et al.*, 2002; Zierau *et al.*, 2002b).

Taken together, 8-PN has to be regarded as a pure estrogen agonist. Shifting of the prenyl group from position 8 to 6 in the flavanone structure (Figure 74.1) goes along with the loss of estrogenic potency. Also ER-binding affinity of 6-PN is tremendously less compared to 8-PN (Milligan *et al.*, 2000).

Cytotoxic Effects of the Phytoestrogens in Cell Culture

To assess the potential toxic effects of the hop compounds and extracts in cell culture, V79 cells were treated with the test compounds and media as a control. The effects of increasing concentrations of the samples on the colony-forming ability were assessed over a 7-day incubation period. The results (Figure 74.9) show that no cells are viable after any treatment with the concentrations 30.0, 100.0 and 300.0 μg/ml. XH is the least cytotoxic treatment. But at a concentration of 10.0 μg/ml, only 65% of the media control colony-forming efficiency (CFE) is kept. XH displays a slight opposite effect at 3.0 μg/ml (120% CFE relative to control).

The highest number of colonies was counted for 1.0 μg/ml 8-PN (130% CFE compared to media control) with a rapid decrease of the colony number down to almost 0% at a concentration of 10.0 μg/ml. For 6-PN, this level is already reached at the concentration of 3.0 μg/ml, whereas 1.0 μg/ml still shows a 10% higher CFE than the control. Interestingly, IXH inhibits colony formation completely in all concentrations tested.

Summary Points

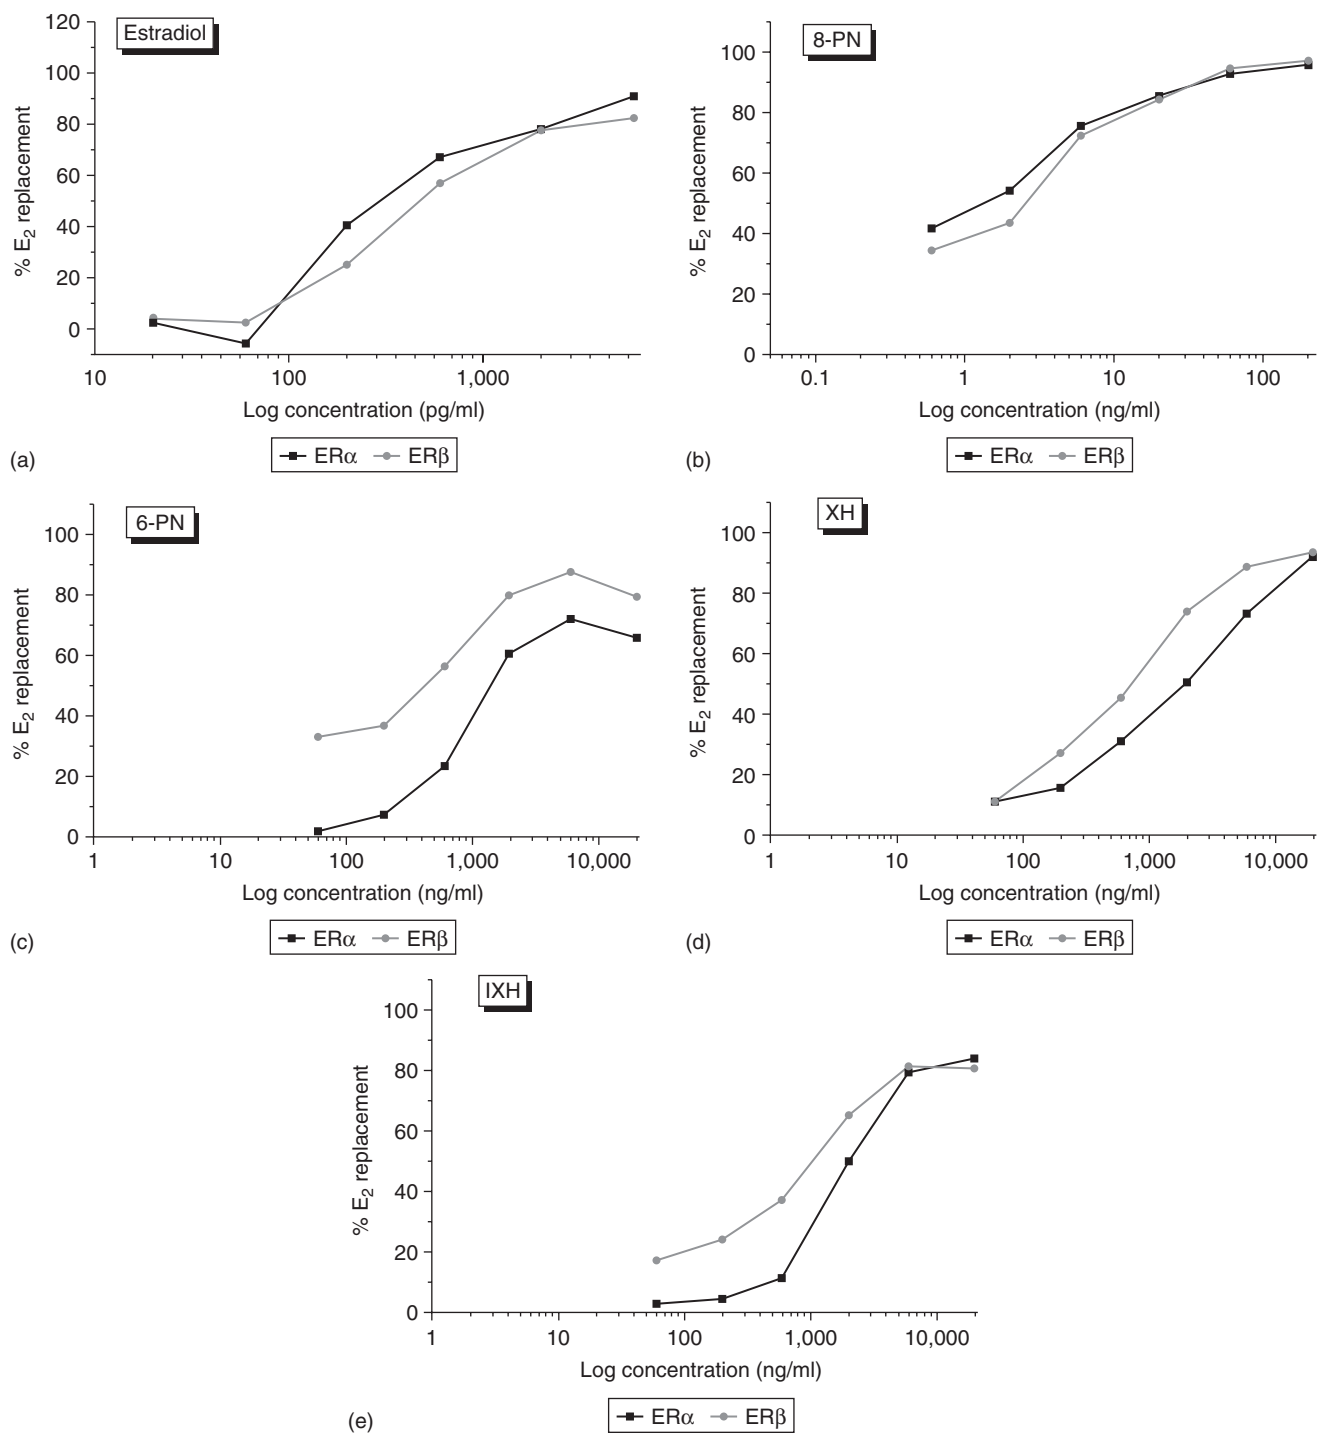
- Loss of estrogen at the onset of menopause results in an increased fracture risk and osteoporosis.
- HRT with E_2 or synthetic estrogens is able to reduce osteoporosis. However, side effects, such as an increased risk of breast and endometrial cancers render this therapy questionable. Alternative treatment schedules are therefore being investigated.
- In this study we investigated isolated components of hops (*Humulus lupulus* L.) concerning their phytoestrogen character: XH, IXH, 8-PN and 6-PN. For these components an estrogenic potency has already been known and partially analyzed.
- To assess the estrogenic effect of the plant-derived compounds vs. estrogen on bone we employed test systems


Figure 74.8   Relative binding affinities of E^2 and phytoestrogens to ERα and ERβ. ERα or ERβ was incubated with the indicated compound ((a)–(e); designated concentrations in µg/ml) or E_2 (Figure 74.9; designated concentrations in pg/ml), DES (1 µM) or solvent as well as ^3H-E_2 (1.2 pM) for 18 h. Any excessive ^3H-E_2 was then bound to HAP. The amount of ^3H-E_2 bound to an ER was determined using a scintillation counter ($n = 3$). Figure (a)–(e) show the replacement of ^3H-E_2 in percent through each compound for ERα (black line with squares) and ERβ (gray line with balls). From these graphs the IC_{50} of each compound was derived.

on the level of enzymatic activity (proteins) and on the level of gene regulation.

- The human osteosarcoma cell lines U2-OS/ERα and U2-OS/ERβ, stably expressing either ERα or ERβ, were assayed for regulation of the bone-specific genes, AP and

IL-6, as well as two other estrogen-regulated genes, pS2 and VWF. These genes are also influenced by the hop components tested in this study.

- Most of the tested phytoestrogens displayed positive profiles in osteoblasts and osteoblast-like cell lines.

Table 74.1 Receptor binding behavior of E^2 and phytoestrogens to ERα and ERβ

(a) IC_{50}-values

Compound	IC_{50} ERα (μg/ml)	IC_{50} ERβ (μg/ml)
Estradiol	0.31×10^{-3}	0.48×10^{-3}
8-PN	1.53×10^{-3}	1.88×10^{-3}
6-PN	1.42	0.42
XH	1.94	0.73
IXH	2.0	1.04

Note: The smaller a compound's IC_{50}-value (μg/ml) the higher receptor's affinity.

(b)   Relative potency of phytoestrogens compared to E^2

Compound	IC_{50} (phytoestrogen, ERα)/IC_{50} (E_2, ERα)	IC_{50} (phytoestrogen, ERβ)/IC_{50} (E_2, ERβ)
Estradiol	1	1
8-PN	4.9	3.9
6-PN	4.6×10^3	0.9×10^3
XH	6.3×10^3	1.5×10^3
IXH	6.5×10^3	2.2×10^3

Note: Dividing the IC_{50} (compound, ERα) through the IC_{50} (E_2, ERα) describes the phytoestrogen's relative potency regarding ER-replacement to the endogenous ligand E_2. Replacement through E_2 is characterized by the number "1". The higher this number the lower the sample's affinity for the ER.

(c)   Receptor-specific affinity: ERα/ERβ

Compound	IC_{50} (ERα)/IC_{50} (ERβ)
Estradiol	0.65
8-PN	0.81
6-PN	3.38
XH	2.66
IXH	1.92

Note: A ratio <1 depicts a stronger affinity for ERα compared to ERβ. An ERβ-preference is described by a ratio >1.

Therefore, a feasible potential of these compounds to effectively prevent osteoporosis *in vivo* might be concluded. This assumption is supported by previous investigations found in the literature (Fanti *et al.*, 1998; Ishimi *et al.*, 1999).

- Regarding the binding affinity to ERα and ERβ, none of the hop components binds as efficiently as E_2. 8-PN shows the strongest ER-binding affinity which is only 0.5 orders of magnitude lower compared to E_2. The other phytoestrogens are 2–3 orders of magnitude less potent.
- An increased relative affinity for ERβ has been connected with a positive overall action, that is bone conserving and decreasing risks of breast and endometrial cancers (Mori *et al.*, 2001; Milligan *et al.*, 2002). In our study, 6-PN, XH and IXH reveal a preference for ERβ.
- Beer is rich in certain flavonoles acting as phytoestrogens; however, the concentrations vary greatly between different brands.
Figure 74.9 Cytotoxicity of hop compounds in V79 hamster fibroblasts. The cells were grown in DMEM/F12 media containing 10% FBS and treated for 7 days with the indicated compounds in the concentrations 1.0, 3.0, 10.0, 30.0, 100.0 and 300.0 μg/ml or media as control in serum-free media. The colony-forming efficiency was determined and expressed relative to control (media). The y-axis shows the factor of viable cells relative to media control. Error bars indicate standard deviation ($n = 3$). No columns are visible at high compound concentrations where no viable cells are left.

- Serum concentrations of phytoestrogens depend on their dietary intake. Pharmacokinetic studies with these compounds will have to be carried out in the future to assess the serum concentrations after supply with beer or as part of a special, balanced diet. The concentrations applied in this study are commonly used to test the *in vitro* activity of phytoestrogens, as for example 8-PN (Kuiper *et al.*, 1998; Milligan *et al.*, 2002; Setchell and Lydeking-Olsen, 2003).
- Despite the observed positive effects on bone, the risk of breast cancer which might be implied in a phytoestrogen intake must be taken into account. So far a good deal of phytoestrogen supplementation of nutrition (in the diet) has been connected with a decreased risk of breast cancer (Ingram *et al.*, 1997) and positive effects on bone. Based on our results (data not shown), certain phytoestrogens consumed in low doses presumably have an enhancing effect on development and promotion of some hormone-dependent breast cancers. In contrast, at high concentrations they act antiestrogenic (e.g. 6-PN, XH, IXH). For other phytoestrogens (e.g. genistein) the opposite is true (Allred *et al.*, 2001; Morito *et al.*, 2001). This means that any recommendation of a phytoestrogen-rich diet or even medical substitution of phytoestrogens should be critically evaluated.

Amounts in Beer

XH	2 mg/l (European lager)–690 mg/l (American porter)
IXH	40 mg/l (European lager)–3,440 mg/l (strong ale)

8-PN	1 mg/l (European lager)–240 mg/l (American porter)
6-PN	–

Stevens and Page (2004)

Antimalarials from Prenylated Chalcone Derivatives of Hops

Sonja Frölich, Carola Schubert and Kristina Jenett-Siems Institut für Pharmazie (Pharmazeutische Biologie), Freie Universität Berlin, Berlin, Germany

Abstract

There is an urgent need to discover new antimalarials, due to the spread of chloroquine resistance and the limited number of available drugs. Chalcones are one of the classes of natural products that are known to possess antiplasmodial properties. Therefore, the *in vitro* antiplasmodial activity of the main hop chalcone xanthohumol and seven derivatives was evaluated against two strains of *Plasmodium falciparum* (poW, Dd2). Four compounds possessed an activity with IC_{50} values below $25\,\mu M$ against either strain. Xanthohumol was most active with IC_{50} values of 8.2 ± 0.3 (poW) and $24.0 \pm 0.8\,\mu M$ (Dd2). In addition, the influence of the compounds on the glutathione-dependent hemin degradation was analyzed to determine its contribution to the antimalarial effect of chalcones.

List of Abbreviations

CQ	Chloroquine
FP	Heme
GSH	Glutathione
GSSG	Glutathione disulfide
Hb	Hemoglobin
HZ	Hemozoin
IC	Inhibitory concentration

Introduction

Malaria still is the most dangerous parasitic disease, afflicting 40% of the world's population with an annual incidence of 300–500 million (Fidock *et al.*, 2005). It is caused by protozoan parasites of the genus *Plasmodium*, of which *P. falciparum* is the most important one, producing the highest mortality with 1–3 million people every year. Most of these victims are children in sub-Saharan Africa. Clinical manifestations include fever, prostration and anemia. Severe disease is characterized by delirium, metabolic acidosis, cerebral malaria and multi-organ system failure, leading to death if not treated. As standard antimalarials (e.g. chloroquine) are loosing efficacy due to spreading resistance of *P. falciparum*, the search for new drugs is increasingly important. New antimalarial drugs have to combine rapid efficacy, low toxicity and low cost. At the moment, artemisinin derivatives are high on the list for chloroquine replacement. However, these drugs have very short half-lives, which make it necessary to combine them with longer-acting drugs. Clearly, additional new drugs are needed.

Chalcones are phenolic secondary plant metabolites derived from the flavonoid pathway but lacking the central heterocyclic ring. Compared to flavonoids, which are nearly ubiquitous occurring plant constituents, chalcones and the closely related dihydrochalcones are much rarer. They are characteristic metabolites of plant families as, for example, Fabaceae, Piperaceae and Cannabaceae. Chalcones/dihydrochalcones are known to possess a variety of biological activities including antiplasmodial activity. Licochalcone A from Chinese licorice roots (*Glycyrrhiza* sp., Fabaceae) (Chen *et al.*, 1994) or the benzylated dihydrochalcone uvaretin from *Uvaria* species (Annonaceae) (Nkunya *et al.*, 1991) have shown *in vitro* IC_{50} values against *P. falciparum* between 4.5 and $0.6\,\mu g/ml$. The former also demonstrated activity against two *Leishmania* species, parasites that cause severe cutaneous and systemic diseases in tropical as well as sub-tropical countries. Li *et al.* (1995) analyzed the structure–activity relationships of a series of semi-synthetic antiplasmodial chalcone derivatives, suggesting them to act as parasitic cysteine protease inhibitors due to certain structural features. A similar study including also an antileishmanial assay has been conducted by Liu *et al.* (2001).

The hop plant, *Humulus lupulus* L., of the family Cannabinaceae is a large, dioecious climber often cultivated. Secretory glands on the surface of the female flowers contain a volatile oil and also a resin consisting of bitter compounds such as humulones and lupulones. In addition, polyphenols like flavonoids and chalcones are present,

especially the prenylated chalcone derivative xanthohumol (Figure 75.1) as a main constituent (Wohlfart, 1993).

In Vitro Antiplasmodial Activity of Hop Chalcones and Semi-synthetic Derivatives

To check the potential antimalarial efficacy of chalcones from hops, the *in vitro* antiplasmodial activity of the main hop chalcone xanthohumol and seven natural or semi-synthetic derivatives against two different strains of *Plasmodium falciparum* has been evaluated (Frölich *et al.*, 2005).
Figure 75.1   Structure of the main hop chalcone xanthohumol (**1**).

The employed bioassay is based on a continuous intra-erythrocytic culture of *P. falciparum*. Normally, two different strains of the parasite are used, one that is sensitive to the standard antimalarial drug chloroquine and another one that is chloroquine- or even multi-resistant. This procedure allows to judge already at this early stage whether an active compound is affected by the same resistance mechanisms as the known antimalarials or not. In this study a West African isolate of *P. falciparum* named poW, which is sensible to chloroquine with an IC_{50} value of 0.01 μM, and the chloroquine-resistant clone Dd2 with a 10-fold higher IC_{50} value were employed. Antiplasmodial activity tests were performed in 96-well culture plates and tritium-labeled hypoxanthin, a metabolite that is essential for the growth of the parasite was used to determine its viability.

Of the eight compounds tested (Figures 75.1 and 75.2), four possessed an activity with IC_{50} values (Figure 75.3) below 25 μM against either strain (Table 75.1; Figure 75.4). The main hop chalcone, xanthohumol (**1**), was most active, revealing IC_{50} values of 8.2 (poW) and 24.0 μM (Dd2), respectively. 2″,3″-Dihydroxanthohumol (**2**) gave an IC_{50} value of 12.9 μM against poW, and also two pyrano-derivatives (**3**, **4**) where the prenyl residue is forming an additional ring possessed antiplasmodial activity
Figure 75.2   Chemical structures of chalcone and flavanone derivatives evaluated.

with IC_{50} values of 16.4 and 23.7 μM (poW), respectively. 6'-Desmethylxanthohumol (**6**) on the other hand displayed only a moderate effect (IC_{50} values: 42.4 μM (poW); 92.1 μM (Dd2)). Compounds **5** (2',4',4-trimethylxanthohumol) and **7** (2',4',4-trimethyl-6'-desmethylxanthohumol) were inactive showing IC_{50} values >100 μM against both strains, whereas the flavanone derivative **8** revealed moderate activity against the multi-resistant clone Dd2 (IC_{50} value 55.3 μM), but no effect against poW (IC_{50} value >100 μM).

This is only the second time that prenylated natural chalcones were proven to possess antiplasmodial properties but in contrast to xanthohumol (**1**) with a prenyl side chain in ring B, the prenyl residue of licochalcone A, which was isolated from Chinese licorice roots, is attached to the ring A of the chalcone skeleton (Chen *et al.*, 1995). Nevertheless, the presence of the double bond in the prenyl side chain is irrelevant for the bioactivity, as indicated by the nearly identical potency of xanthohumol and its 2″,3″-dihydro derivative (**2**). Additionally, the two pyrano-derivatives

3 and **4** where the prenyl residue is cyclized to an additional ring also show antiplasmodial activity. Compared to **1**, desmethylxanthohumol (**6**), which only differs by the lack of the methyl residue at the C-6'-hydroxy group, is four to five times less active. This might be due to its higher hydrophilicity, which makes it more difficult to reach the site of action inside the parasite. Interestingly, the semi-synthetic methylated derivatives **5** and **7** are totally inactive; thus, as synthetic 2',4'-dimethoxychalcones revealed good antiplasmodial activity in an extensive structure–activity relationship study (Liu *et al.*, 2003), especially the methylation of the hydroxy group in position 4 seems to be less favorable.

When comparing these results with those obtained with human cells, *P. falciparum* is slightly more sensitive to xanthohumol (**1**) than are different cancer cell lines and also macrophages (Miranda *et al.*, 1999; Gerhäuser *et al.*, 2002). A real cytotoxic activity can only be observed at 100 μM, though antiproliferative effects become visible at lower concentrations in dependence on the cell line used. In the case of xanthohumol this cytotoxicity is not due to an estrogen-mimicking activity, since in contrast to the flavanone derivative 8-prenylnaringenin, which is also a major constituent of hop cones, xanthohumol does not display estrogenic effects (Milligan *et al.*, 2000). Instead, inhibition of DNA synthesis is discussed. Nevertheless, to develop xanthohumol as a new antiplasmodial lead compound, efforts to separate antiplasmodial and cytotoxic bioactivities have to be undertaken.

Figure 75.3 Growth inhibition of *Plasmodium falciparum* (strain poW) by different concentrations of xanthohumol. The IC_{50} value (concentration of a substance that causes 50% inhibition of a given system) can be calculated from the dose-response curve.

Table 75.1 Antiplasmodial activity

Compound	PoW IC_{50} (μM)	Dd2 IC_{50} (μM)
1 (xanthohumol)	8.2 ± 0.3	24.0 ± 0.8
2	12.9 ± 0.6	17.4 ± 0.6
3	16.4 ± 0.9	10.7 ± 0.3
4	23.7 ± 1.5	35.0 ± 2.9
5	>126	>126
6	42.4 ± 0.3	92.1 ± 2.4
7	>131	>131
8	>147	55.3 ± 2.1
Chloroquine	0.015 ± 0.002	0.14 ± 0.012
Artemisinin	0.003 ± 0.0002	0.015 ± 0.003

Note: IC_{50} values of xanthohumol and chalcone derivatives tested against *Plasmodium falciparum* (strains poW and Dd2, values are given as a mean of three experiments ± standard deviation). Artemisinin and chloroquine are given as references.

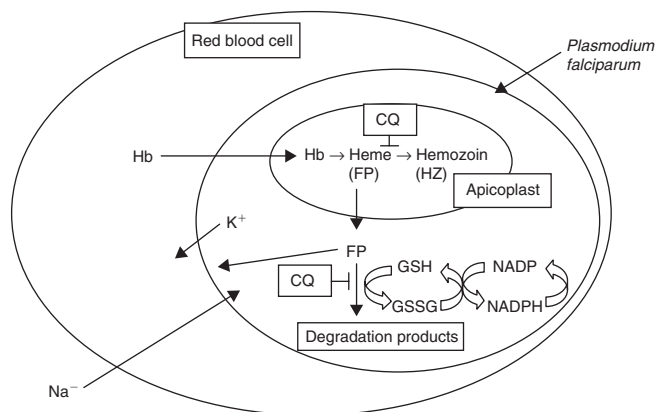
Figure 75.4 Comparison of antiplasmodial activity (IC_{50} value, μM, strain poW of *Plasmodium falciparum*) and influence on hemin degradation (%) of xanthohumol (**1**) and derivatives. Chloroquine is given as reference compound.


Figure 75.5 Heme detoxification and mechanism of action of chloroquine (CQ). When *Plasmodium falciparum* enters human erythrocytes (red blood cells), it feeds from enzymatic degradation of hemoglobin (Hb). Hb is ingested and digested inside the parasite's food vacuole. The by-product of this digestion, toxic heme (FP), is detoxified by forming an insoluble polymer, malaria pigment or hemozoin (HZ). Non-polymerized heme exits the food vacuole into the parasite's cytosol where it is degraded by glutathione (GSH). CQ has been shown to interfere with both detoxification pathways. It accumulates to high levels inside the acid food vacuole where it complexes with heme and prevents its polymerization. Free or complexed heme exits the food vacuole where its GSH-dependent degradation is also inhibited. Heme thus accumulates in membranes and permeabilizes them to cations, thus leading to parasite death. *Source*: Adapted from Ginsburg *et al.* (1998).

Influence of Hop Chalcones on the Glutathione-Dependent Hemin Degradation

When blood stages of the malaria parasite *Plasmodium falciparum* enter human erythrocytes, they feed from enzymatic degradation of hemoglobin. Hemoglobin is ingested from the host cell and is digested inside the parasites food vacuole (Goldberg *et al.*, 1992). The by-product of this digestion is toxic hemin or ferriprotoporphyrin IX, which is detoxified by forming an insoluble polymer, malaria pigment or hemozoin (Bohle *et al.*, 1997). Recently, an alternative heme detoxification mechanism has been described. Non-polymerized heme exits the food vacuole into the parasites cytosol where it is degraded by glutathione (Ginsburg *et al.*, 1998). Quinoline antimalarials like chloroquine have been shown to interfere with both detoxification pathways. Chloroquine accumulates to high levels inside the acid food vacuole where it complexes with heme and prevents its polymerization. Free or complexed heme exits the food vacuole where its glutathione-dependent degradation is also inhibited. Heme thus accumulates in membranes and permeabilizes them to cations, thus leading to parasites death (Ginsburg *et al.*, 1999; Zhang *et al.*, 1999) (Figure 75.5).

To test the ability of compounds to interfere with the parasites heme detoxification pathways, different *in vitro*

Table 75.2 GSH-hemin interaction assay

Compound	% Inhibition of hemin degradation
1 (xanthohumol)	62 ± 6
2	62 ± 7
3	1 ± 0.5
4	68 ± 7
5	7 ± 6
6	36 ± 8
7	1 ± 0.3
8	24 ± 8
Chloroquine	82 ± 3

Note: The effect of chalcone derivatives (11 μM) and chloroquine (11 μM) as reference compound on the interaction of 1 mM GSH with 5.7 μM hemin is given as % inhibition of hemin degradation compared to drug free control. Values are the mean of four assays ± standard deviation.

assays have been developed, thus allowing investigating possible modes of action of antiplasmodial compounds (Basilico *et al.*, 1998; Dorn *et al.*, 1998; Steele *et al.*, 2002). The reaction of hemin with glutathione and the interference of antimalarials can be monitored spectrophotometrically. The broad absorption of hemin is immediately changed to a peak at 364 nm upon addition of glutathione. During 30 min this peak decreases to approximately half without further decrease. Addition of quinoline antimalarials to hemin results first in the alteration of the hemin spectrum due to immediate formation of an alkaloid-hemin-complex and then leads to altered effects of glutathione. In the case of chloroquine the 364 nm peak is not formed and there is little change over 30 min. Based on these findings, Steele (2002) developed a microplate based assay to determine the influence of compounds on heme degradation. Compounds are tested at a concentration of 11 μM in 96-well flat-bottomed plates and are mixed with 5.7 μM hemin and glutathione. The absorbance at 360 nm is measured after 1 and 30 min to determine ΔA_{360} values. The effect of the hemin binding compounds is expressed as the percentage decrease compared with control absorbance.

The exact mechanism of action of antiplasmodial chalcones is not known, though they are often considered to be cysteine protease inhibitors (Li *et al.*, 1995). Nevertheless, natural congeners characterized by a carbonyl moiety in position 9 and a free hydroxy group in position 2 might also be able to form complexes with hemin, thus interfering with its detoxification pathways. Therefore, the influence of compounds **1–8** on the glutathione-dependent hemin degradation was evaluated. In the hemin-degradation assay, compounds **1**, **2** and **4** which also proved to be active in the antiplasmodial bioassay displayed an inhibition >60% at a concentration of 11 μM, compared to 82% for chloroquine (Table 75.2; Figure 75.4), whereas the inactive derivatives **5** and **7** did not inhibit hemin degradation. Compounds **6** and **8** were weakly active, inhibiting hemin degradation by 36% and 24%, respectively, which is also in agreement

with the antiplasmodial findings. However, compound **3** is an exception insofar as it is active against *P. falciparum* but does not inhibit the hemin degradation.

Indeed, those compounds possessing a 2′-methoxy group (**5**, **7**) or a 2′,3′-pyrano ring system (**3**) instead of a free hydroxy group obviously were not able to interact with hemin, stressing the importance of this structural feature for this kind of bioactivity. Desmethylxanthohumol (**6**) and the flavanone derivative **8**, on the other hand, were only weakly active despite their free hydroxy group. In the case of cyclized chalcones such as flavanones and flavones a binding to hemin might not be possible via this structural feature due to less flexibility of the skeleton. Finally, desmethylxanthohumol (**6**) is more easily isomerized to the analogous flavanone derivative in aqueous solutions (Hänsel *et al.*, 1988), thus explaining its poor activity.

These results demonstrate for the first time the ability of chalcone derivatives to interfere with the hemin-degradation process of *P. falciparum*. This effect might contribute to their antiplasmodial activity. Nevertheless, as compound **3** showed inhibition of *P. falciparum* without being able to interact with the GSH-dependent hemin degradation, other modes of action must contribute to the observed antiparasitic activity of hop chalcones. Thus, further studies evaluating their possible inhibition of *P. falciparum* cysteine proteases seem to be worthwhile. Nevertheless, first results in this field indicate that xanthohumol is a poorer inhibitor of parasitic proteases than desmethylxanthohumol (**6**) leading to the assumption that a further up to now unknown mechanism has to be responsible for the antiplasmodial action of xanthohumol.

Is Beer an Antimalarial?

Beer is the most important dietary source of xanthohumol and related derivatives. However, despite the fact that xanthohumol is the major chalcone in hops, it is only a minor compound in beer due to thermal isomerization of chalcones into flavanones during the brewing process. Its content in beer varies between 0 and up to 700 μg/l (Stevens *et al.*, 2004) and may reach 1.2 or 3.4 μM/l in stout and porter beers (Gerhäuser *et al.*, 2005). Therefore, taking into account pharmacokinetic parameters as absorption, distribution and metabolism, it is unlikely that antiplasmodially active blood levels of xanthohumol could be reached by normal beer intake. Nevertheless, this chalcone derivative might be a promising candidate for the development of new antimalarials.

Summary Points

- Due to the spreading resistance of *Plasmodium falciparum* against standard antimalarials, there is an urgent need to discover new lead compounds.
- Xanthohumol, the main chalcone from hops, is active against *P. falciparum in vitro*.

- As a possible mode of action, influence on the glutathione-dependent heme-degradation pathway is discussed.
- Due to its low xanthohumol content, antiplasmodially active blood levels cannot be reached by beer intake.
- Nevertheless, this chalcone derivative might be a promising candidate for the development of new antimalarials.

Acylphloroglucinol Derivatives from Hops as Anti-inflammatory Agents

Hans Becker Pharmakognosie und Analytische Phytochemie, der Universität des Saarlandes, Saarbrücken, Germany
Clarissa Gerhäuser German Cancer Research Center, Chemoprevention, Im Neuenheimer Feld, Heidelberg, Germany
Gregor Bohr Pharmakognosie und Analytische Phytochemie, der Universität des Saarlandes, Saarbrücken, Germany

Abstract

Separation of a polyphenol-enriched fraction of an ethanolic hop extract (*Humulus lupulus* L.) provided four acylphloroglucinol-glucopyranosides (**1**)–(**4**), that is 1-(2-methylpropanoyl) phloroglucinol-glucopyranoside (**1**), 1-(2-methylbutyryl)phloroglucinol-glucopyranoside (**2**), previously known as multifidol-glucoside, 1-(3-methylbutyryl)phloroglucinol-glucopyranoside (**3**), and 5-(2-methylpropanoyl)phloroglucinol-glucopyranoside (**4**). The compounds show a substitution pattern similar to hop bitter acids; therefore we propose the following novel nomenclature: co-multifidol-glucoside for (**1**), ad-multifidol-glucoside for (**2**), and *n*-multifidol-glucoside for (**3**). For compound (**4**), we suggest co-iso-multifidol-glucoside as trivial name. The occurence of these acylphloroglucinol derivatives in beer has not yet been investigated. The compounds were tested for anti-inflammatory potential by inhibition of cyclooxygenase-1 activity. The aglycon (**5**), obtained by acid hydrolysis of (**1**), was equally effective as phloroglucinol with a half-maximal inhibitory concentration (IC_{50}) of 3.8 μM. The inhibitory potential of the glucosides decreased with increasing length of the acyl-side chain (IC_{50} values: (**1**) 23.7, (**2**) 131.3, (**3**) >100 μM). Compound (**4**) with an IC_{50} of 58.7 μM was about 2.5-fold less active than (**1**), indicating that the position of the sugar moiety also influences anti-inflammatory potential.

Introduction

Hops (*Humulus lupulus* L.) is added as a beer ingredient during beer brewing either as hops cones, as an alcoholic or supercritical fluid extract, or as a mixture of bitter acids. When hops cones or an alcoholic extract are added to wort, not only bitter acids, but also a variety of other hops constituents may occur in the end product. Recently, the hops-derived prenylated chalcone xanthohumol and its isomerization product isoxanthohumol were found to exert biological effects indicative of cancer chemopreventive potential in *in vitro* and *in vivo* studies (Gerhauser *et al.*, 2002a; Bertl *et al.*, 2004a, b; Pan *et al.*, 2005; Albini *et al.*, 2006). Other phenolic compounds from beer, such as benzoic and isoferulic acid derivatives, as well as indan and catechin derivatives also showed *in vitro* effects that correlate with cancer chemopreventive activities (Gerhauser *et al.*, 2002b). These results suggested that hops is a source very rich in bioactive phytochemicals.

One of the potential chemopreventive mechanisms of hops constituents is the inhibition of cyclooxygenase (Cox), a key enzyme in inflammatory processes. It is estimated that chronic inflammation and infections contributed to about 18% of all new cancer cases (Oshima *et al.*, 2005). Inflammation is mediated by prostaglandins, that is, hormone-like endogenous substances generated by Cox. The expression of Cox-2, the inducible form of Cox, is often elevated in tumor tissue in comparison to normal tissue. Excessive production of prostaglandins is thought to be a causative factor of cellular injury and may ultimately lead to carcinogenesis, since prostaglandins enhance cell proliferation and stimulate the formation of new blood vessels essential for tumor growth. Consequently, non-steroidal anti-inflammatory drugs like Aspirin® or selective Cox-2 inhibitions (e.g. celecoxib) are regarded as promising chemopreventive agents and inhibitors of tumor promotion (Furstenberger *et al.*, 2006).

The aim of the present study was to fractionate a polyphenol-enriched hop extract to isolate additional pure hops compounds and to test them for their anti-inflammatory activity using microsomes of ram seminal vesicles as a source of Cox-1 activity (Bohr *et al.*, 2005).

Starting Material

Hops is commercially extracted with ethanol. To obtain a fraction rich in bitter acids, the alcoholic extract is evaporated resulting in two phases, a lipophilic phase containing
Figure 76.1 Fractionation scheme: the ethylacetate-extracted portion (G18.2) of an ethanolic hops extract was fractionated by column chromatography using Sephadex LH 20 and isocratic elution with methanol to provide four subfractions G19.1–G19.4.

Figure 76.2 Cox-1 inhibitory effects of the fractions described in Figure 76.1.

bitter acids and a hydrophilic phase containing mostly water-soluble substances. Only about 20% of the latter fraction is used in brewery either to standardize hops extract (lipophilic fraction) for a certain bitter acid content or as addition to wort during the brewing process. The other 80% are used in agriculture as fertilizer because they contain a considerable amount of nitrate. The high nitrate content is the reason why this fraction has no broader use either in the brewing process or for other beverages. Nitrate may be transformed by sublingual or intestinal bacteria to nitrite, which can contribute to the formation of carcinogenic nitrosamines.

The ethanolic hops extract analyzed in this study was derived from the variety "Hallertauer Perle" and provided by Simon H. Steiner, Hopfen GmbH, Mainburg, Germany. The analytical data were as follows: dry weight 55%, nitrate content 56 g/kg, density 1.23 g/ml.

Determination of Cox-1 Activity

Inhibition of Cox-1 activity was measured by monitoring oxygen consumption during the conversion of arachidonic acid to prostaglandins using a Clark-type O_2-electrode (Hansatech Ltd., Kings Lynn, UK) (Jang *et al.*, 1997). The reaction mixture contained approximately 0.2 U Cox-1 in 100 μl microsome fraction derived from ram seminal vesicles as a crude source of Cox-1 (specific activity 0.2–1 U/mg protein). For calculation, the rate of O_2 consumption was compared to a solvent control (100% activity).

Activity-Guided Fractionation

The ethanolic hops extract was partitioned with *n*-hexane to remove lipophilic compounds such as remaining α- and β-bitter acids. The aqueous layer was partitioned with ethylacetate. After drying with Na_2SO_4, the organic layer was concentrated to dryness to provide a powder (G18.2) which yielded 1.3% of the dry weight of the starting aqueous extract. G18.2 was tested for its Cox-1 inhibitory activity. The fraction significantly inhibited Cox-1 activity by 50% at a final test concentration of 40 μg/ml. Further fractionation to identify compounds responsible for the inhibitory effect was done by column chromatography using
Sephadex LH 20 and isocratic elution with methanol. The elution was monitored by thin layer chromatography and high-pressure liquid chromatography (HPLC) coupled with UV spectroscopy.

According to the chromatographic behavior, four subfractions (G19.1–G19.4) were obtained (Figure 76.1) and again tested for Cox-1 inhibitory potential. Good inhibition of Cox-1 activity was achieved with fractions G19.1 and G19.3 (Figure 76.2). Fraction G19.3 was not further investigated in the present study.

G19.1 showed one major and three minor peaks after analytical HPLC separation (Figure 76.3a) and was further subfractionated by semipreparative HPLC (VP 250/10 Nucleodur, 100-5, C 18 ec, Macherey and Nagel, Germany) under isocratic conditions (acetonitrile/water with 0.05% trifluoroacetic acid 25:75) to yield four subfractions G19.1.1–G19.1.4.

Fraction G19.1.2 contained one compound. The structure was elucidated with 1H and 13C NMR spectroscopy as 1-[(2-methylpropanoyl)phloroglucinyl]-β-D-glucopyranoside (**1**) which we named as "*co-multifidol-glucoside*" in comparison to the substitution pattern of hop bitter acids. Subfraction G19.1.3 also provided one pure compound. Structure elucidation identified a homolog of **1**, that is 1-[(2-methylbutyryl)phloroglucinyl]-β-D-glucopyranoside (**2**), which was named "*ad-multifidol-glucoside.*" G19.1.1 and G19.1.4 consisted of a mixture of three respective two compounds with similar UV-spectroscopic properties as G19.1.2 and G19.1.3 (Figure 76.3b). As the amount of these two fractions was too low for isolation and consecutive structure elucidation of pure compounds, we started a second fractionation over Sephadex LH 20 material with 3 g of G18.2. Besides the two already identified compounds, we identified two additional minor phloroglucinol derivatives by further subfractionation using
Figure 76.3 (a) HPLC of fraction G19.1 (also representative for fraction G102.4); structures and descriptions of peaks 1–4 in Figure 76.4. Column: EC250/4 Nucleosil 100-5 C18, Macherey & Nagel, Germany. Solvent A: water + 0.1% trifluoroacetic acid, solvent B: acetonitrile + 0.1% trifluoroacetic acid, gradient 5–95% B in 45 min. (b) UV spectrum of peak 1 with maxima at 225.1 and 286.3 nm.

preparative HPLC: 1-[(3-methylbutyryl)phloroglucinyl]-β-D-glucopyranoside (**3**), named "*n-multifidol-glucoside*," and 5-[(2-methylbutyryl)phloroglucinyl]-β-D-glucopyranoside (**4**), named "*co-iso-multifidol-glucoside*." Whereas **1** and **3** are known compounds of hops, **2** was identified for the first time as a hops component and **4** is a new natural product.

To find structure activity relationships (SARs) we hydrolyzed compound (**1**) to yield the aglycon *co-multifidol* (**5**). Also, we included phloroglucinol (**6**) into our tests (Figure 76.4).

SAR Analyses

The isolated pure compounds as well as aglycon **5** and phloroglucinol (**6**) as a reference were tested for inhibition of Cox-1 activity. Dose–response curves for all compounds are given in Figure 76.5.

Aglycon **5** was equally effective as phloroglucinol (**6**) in inhibiting Cox-1 activity, with half-maximal inhibitory concentrations (IC$_{50}$s) of 4.0 ± 0.2 and $3.9 \pm 0.2\,\mu$M, respectively (summarized in Table 76.1). Addition of a glucose moiety at position C-1 or C-5 to yield the glucosides **1** and **4** significantly reduced the Cox-1 inhibitory potential, and we determined IC$_{50}$ values of 23.7 ± 0.9 and $58.7 \pm 1.1\,\mu$M, respectively. Elongation of the acyl-side chain with a methyl group, as in compound **2** in comparison with compound **1**, further reduced the anti-inflammatory activity (IC$_{50}$ $131.3 \pm 0.2\,\mu$M). Interestingly, with the second purification of compound **2**, the IC$_{50}$ value was decreased to a value as low as $30.3 \pm 0.2\,\mu$M (compound **2a** in Table 76.1). HPLC analyses of the two isolates revealed that compound **2** is not stable under extraction conditions and can lead to the formation of an additional peak, presumably the respective aglycon. Since aglycon **5** is about 6- and 15-fold more active than the glucosides **1** and **4**, we assume that impurities due to aglycon formation are responsible for the observed lower IC$_{50}$ value. In contrast, derivative **3** was basically inactive with only 12% inhibition at a $100\,\mu$M concentration (IC$_{50} > 100\,\mu$M).

From these data we concluded that:

(i) Phloroglucinol (**6**) is a good Cox-1 inhibitor.
(ii) Substitution with the short 2-methylpropanoyl moiety at position C-2 as in aglycon **5** does not reduce the inhibitory potential.
(iii) Addition of a sugar moiety in position C-1 reduces the IC$_{50}$ value of **5** about 6-fold.
(iv) Glycosylation at position C-5 reduces the inhibitory potential more than addition of a sugar moiety at position C-1.
(v) Modifications of the acyl-side chain severely lower Cox-1 inhibitory potential.
(vi) For SAR analyses, stability and purity of the compounds have to be carefully monitored.

Outlook

The isolated phloroglucinol derivatives from hops showed a fairly good inhibition of Cox-1 activity. However, due to the relative high amount of nitrate, the native extract cannot be used in significant amounts for the production of beer or other beverages. The nitrate content can be considerably reduced either by dialysis or by adsorption chromatography (Bohr and Becker, unpublished results). Such extracts with low nitrate content might contribute to taste and stability of beer as well as possess physiological effects if added in sufficient amounts. Until now it has not yet been tested if the above described phloroglucinol derivatives are present in beers that are either flavored with hop cones or with alcoholic extracts thereof.
Figure 76.4 Chemical structures of compounds **1–6**. **1**: 1-[(2-methylpropanoyl)phloroglucinyl]-β-D-glucopyranoside = co-multifidol-glucoside; **2**: 1-[(2-methylbutyryl)phloroglucinyl]-β-D-glucopyranoside = ad-multifidol-glucoside; **3**: 1-[(3-methylbutyryl)phloroglucinyl]-β-D-glucopyranoside = n-multifidol-glucoside; **4**: 5-[(2-methylbutyryl)phloroglucinyl]-β-D-glucopyranoside = co-iso-multifidol-glucoside; **5**: (2-methylpropanoyl)phloroglucinol = co-multifidol; **6**: phloroglucinol.
Figure 76.5 Dose-dependent inhibition of Cox-1 activity by acyl-phloroglucinol derivatives **1** (▼); **2** (■); **3** (□); **4** (◇); **5** (●) in comparison with phloroglucinol (**6**) (△); see Figure 76.4 for structures.

Table 76.1 Summary of Cox-1 inhibitory potential of isolated pure compounds in comparison with phloroglucinol

Compound	% inhibition at 100 µM	IC_{50} (µM)*
(**1**) Co-multifidol-glucoside (G19.1.2. = G102.4.2)	78	23.7 ± 0.9
(**2**) Ad-multifidol-glucoside (G19.1.3)	46	131.3 ± 0.2
(**2a**) Ad-multifidol-glucoside (G102.4.3 with impurities of aglycon)	71	30.3 ± 0.2
(**3**) n-multifidol-glucoside (G102.4.4N)	12	>100
(**4**) Co-iso-multifidol-glucoside (G102.4.5)	61	58.8 ± 1.1
(**5**) Co-multifidol (G112.1.4)	92	4.0 ± 0.2
(**6**) Phloroglucinol	90	3.9 ± 0.2

*IC_{50}: concentration required to inhibit the activity of Cox-1 by 50%.

Summary Points

- Alcoholic hop extracts contain four multifidol-glucosides (acyl substituted phloroglucinol glucosides).
- The acyl-side chains are the same as found in hop bitter acids (humulones). Accordingly, the compounds were named with the prefix n-, co- and ad-.
- Phloroglucinol, the tested aglycon co-iso-multifidol (**5**) as well as one multifidol-glucoside (**1**) show fairly good anti-inflammatory (Cox-1 inhibitory) activity.
- A broader application of the alcoholic hops extract in brewery as well as in other areas of food industry may be obtained if the nitrate content of extract is reduced by adsorption chromatography or dialysis.

Hops Derived Inhibitors of Nitric Oxide

Hajime Nozawa, Feng Zhao and Keiji Kondo Central Laboratories for Frontier Technology, Research Section for Applied Food Science, Kirin Holdings Co., Ltd., Takasaki, Gunma, Japan

Abstract

Nitric oxide (NO) plays an important role in many inflammatory responses and is also involved in carcinogenesis. In this chapter, the inhibitory effect of extracts from *Humulus lupulus* L. on both the production of NO and the expression of inducible NO synthase (iNOS) in mouse macrophage RAW 264.7 cells is discussed. The production of NO was induced by a combination of lipopolysaccharide (LPS) and IFN-γ, and determined by Griess assay. The expression of iNOS was detected by Western blotting. The LPS/IFN-γ-induced production of NO and expression of iNOS were significantly inhibited by the ethyl acetate soluble fraction of *Humulus lupulus* L. Through bioactivity-guided fractionation, humulene, five chalcones, 2,2-di-(3-methyl-2-butyleyl)-4,5-dihydroxy-cyclopent-4-en-1,3-dione, lupulone and three of its derivatives were isolated from the ethyl acetate soluble fraction. The chalcones, including xanthohumol, significantly inhibited the production of NO by suppressing the expression of iNOS and it is suggested that the double bond in α and β position of chalcones structure is important for the inhibitory activity of iNOS expression, by the comparison of the activities of these compounds and their chemical structures.

List of Abbreviations

Inos	Inducible nitric oxide synthase
NO	Nitric oxide
LPS	Lipopolysaccharide
DMSO	Dimethyl sulfoxide
NF-kB	Nuclear factor-kB

Introduction

Hops, the female inflorescences of the hop plant (*Humulus lupulus* L.), are widely used in the brewing industry to add bitterness and aroma to beer. Hop cones are also used in folk medicine as a tranquilizer or bitter stomachic. In the 1950s and 1960s, some papers reported the existence of substances with estrogen-like activity in hop cones (Chury, 1960; Bednar and Zenisek, 1961), and Kumai and his colleagues discovered that gonadotropin inhibitors were contained in hop cones (Kumai and Okamoto, 1984). Recently, some flavanones and chalcones with prenyl or geranyl groups have been identified in hops and beers, and their biological activities such as the inhibition of bone resorption (Tobe *et al.*, 1997), inhibition of diacylglycerol acyltransferase (Tabata *et al.*, 1997) and antimicrobial activities (Haas and Barsoumian, 1994) have been reported. Moreover, some constituents of hops have been reported to inhibit the growth of breast cancer cells in a dose-dependent manner (Miranda *et al.*, 1999). So, because of their potential anticancer properties, active agents from hops have received much recent attention. Xanthohumol, the principal flavonoid in hops, was reported to inhibit the proliferation of human breast cancer MCF-7 cells, colon cancer HT-29 cells and ovarian cancer A-2780 cells *in vitro* (Miranda *et al.*, 1999). Xanthohumol has also been shown to inhibit the ethoxyresorufin *O*-deethylase activity of recombinant human CYP1A1 and CYP1B1, and the acetanilide 4-hydroxylase activity of CYP1A2 (Miranda *et al.*, 2000). These findings suggest that further investigations on the biological activities of hops and on the active agents in this plant may be beneficial.

Nitric oxide (NO) is a gaseous free radical that is released by a family of enzymes, including a constitutive NO synthase and an inducible one (iNOS) (Vanvaskas and Schmidt, 1997). The excessive and prolonged NO generation mediated by iNOS has attracted attention because of its relevance to epithelial carcinogenesis (Tsuji *et al.*, 1996; Xie *et al.*, 1997). It has been reported that NO is also involved in the production of vascular epidermal growth factor (Xiong *et al.*, 1998), the overexpression of which induces angiogenesis and vascular hyperpermeability, and accelerates tumor development (Larcher *et al.*, 1998).

Nuclear factor-kB (NF-kB) and MAP kinase (including Erk1/2, SAPK/JNK, p. 38) are important regulators of iNOS expression in lipopolysaccharide (LPS)-induced macrophages (Bhat *et al.*, 1998; Pahl, 1999).

In this chapter, search for inhibitors of NO production in *Humulus lupulus* L. by activity-guiding fractionation and purification were performed, using an LPS/IFN-γ-induced NO production test in mouse macrophage RAW 264.7 cells. As a result, we have identified several compounds to be potent inhibitors of both the production of NO and the expression of iNOS.

Inhibitory Effects of the Ethyl Acetate Fraction, the *n*-Butanol Fraction and the Aqueous Fraction of Hops on NO Production Induced by LPS/IFN-γ in RAW 264.7 Cells

The hops CAS pellet (2.5 kg) was extracted with ethyl acetate to obtain a dark green extract (PEE, 329.17 g). The pellet was then extracted with 80% acetone (3 l × three times), and the extract obtained was suspended in water and partitioned with *n*-butanol. Evaporation of the solvent yielded the *n*-butanol fraction (PEB, 84.19 g) and the aqueous fraction (PEW, 282.52 g).

RAW 264.7 cells were treated with LPS (100 ng/ml), IFN-γ (100 units/ml) and test samples dissolved in dimethyl sulfoxide (DMSO) (final DMSO concentration 0.2%, v/v). The levels of NO_2^- in the supernatant were measured by Griess assay after 16 h of incubation at 37°C. The inhibitory rate on NO production induced by LPS/IFN-γ was calculated by the NO_2^- levels as follows: Inhibitory rate (%) = 100 × (LPS/IFN−LPS/IFN/sample)/(LPS/IFN-untreated). Cytotoxicity was measured by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. The percentage of suppression was calculated by comparing the absorbance of sample-treated cells with that of non-treated cells. The ethyl acetate soluble fraction, the *n*-butanol soluble fraction and the aqueous fraction of *Humuslupulus* L. were tested for their inhibitory activities on the production of NO induced by LPS/IFN-γ. As shown in Figure 77.1, the ethyl acetate fraction exhibited the strongest inhibitory activity on NO production. The *n*-butanol fraction also inhibited NO production induced by LPS/IFN-γ; however, the aqueous fraction showed no inhibitory activity. These assay results suggested that the inhibitory agents in *Humuslupulus* L. are low-polarity constituents.

Mechanistic Examination for Inhibitory Effect of the Ethyl Acetate Fraction of Hops on NO Production

Inhibitors of NO production by macrophages act mainly through two mechanisms: the inhibition of iNOS expression and the inhibition of enzyme activity. Therefore, we
Figure 77.1 Inhibitory effects of the ethyl acetate fraction, the *n*-butanol fraction and the aqueous fraction of *Humulus lupulus* L. on NO production induced by LPS/IFN-γ. RAW 264.7 cells were treated with LPS/IFN-γ alone or together with the fractions at the concentrations indicated. After 16 h incubation, the supernatants were tested by Griess assay and the inhibitory rates were calculated. The experiment was performed independently twice and the data are expressed as mean ± SD values. An MTT assay was performed simultaneously, and the cell viabilities were more than 95%, except for 100 µg/ml PEE (6.4%) and for 50 µg/ml PEE (11.1%).

examined the effect of the ethyl acetate fraction on iNOS protein expression by Western blotting. Cells were treated with LPS/IFN-γ alone or together with different doses of the ethyl acetate fraction. The treated and untreated cells were then collected and tested for their iNOS protein levels by Western blotting analysis. The results of Western blotting are shown in Figure 77.2. Although iNOS protein was undetectable in the untreated cells, it was significantly induced in cells stimulated with LPS/IFN-γ. Treatment with the ethyl acetate fraction inhibited the LPS/IFN-γ-induced iNOS protein expression in a dose-dependent manner. The results suggested that the ethyl acetate fraction of *Humulus lupulus* L. strongly inhibits the production of NO induced by LPS/IFN-γ by suppressing the expression of the iNOS protein.

Isolation and Characterization of Hops Derived Inhibitors for NO Production

Then the further bioassay-based fractionation has been performed: 262.7 g of the PEE fraction was separated by a silica gel column chromatography eluted with a hexane-ethyl acetate gradient (0→100%) of increasing polarity to give 15 fractions: PEE-1 (1.9 g), PEE-2 (5.1 g), PEE-3 (41.8 g), PEE-4 (19.1 g), PEE-5 (8.6 g), PEE-6 (39.1 g), PEE-7 (22.8 g), PEE-8 (13.6 g), PEE-9 (8.1 g), PEE-10 (33.1 g), PEE-11 (18.1 g), PEE-12 (21.6 g), PEE-13 (7.4 g), PEE-14 (5.2 g), PEE-15 (4.3 g). Fraction 1 inhibited NO production but concomitant cytotoxicity was observed.
Figure 77.2 Inhibitory effects of the ethyl acetate fraction of *Humulus lupulus* L. on the iNOS expression induced by LPS/IFN-γ. Confluent RAW 264.7 cells were stimulated by the indicated conditions. The cells were collected and proteins were extracted, then, 10 µg of protein were separated on 7.5% SDS/PAGE and tested by Western blotting. The arrow signal indicates the 136 kDa iNOS-specific band.

Figure 77.3 Inhibitory effects of the subfractions 1–15 of the ethyl acetate fraction of *Humulus lupulus* L. on the NO production induced by LPS/IFN-γ. RAW 264.7 cells were treated with LPS/IFN-γ alone or together with each fraction at a concentration of 10 µg/ml. After 16 h incubation, the supernatants were tested by Griess assay and the inhibitory rates were calculated. The experiment was performed independently in duplicate twice and the data are expressed as mean ± SD values. An MTT assay was performed simultaneously, and the solid line indicates the relative cell viability values.

Among the other fractions, fractions 9–11 also showed strong inhibitory activities with no cytotoxic effects. The inhibitory effects of other fractions were much weaker, especially the last four fractions (12–15), which contained the high-polarity constituents (Figure 77.3).

Fraction PEE-1 was separated by normal-phase silica gel column chromatography to obtain compound 1. Fraction PEE-9 was separated by a combination of normal-phase silica gel column chromatography, Sephadex LH-20 column chromatography and high-pressure liquid chromatography (HPLC) to obtain compound 2. Fraction PEE-10 was separated by a combination of normal-phase silica gel column chromatography, Sephadex LH-20 column chromatography and HPLC to obtain compounds 8–11. Fraction PEE-11 was separated by a combination of normal-phase silica gel column chromatography, Sephadex LH-20 column chromatography and HPLC to obtain compounds 3–7. Their chemical structures were determined by a combination of UV, IR, MS and NMR as shown in Figure 77.4. Chemical structures of known compounds 1 (humulene), 3 (xanthohumol), 4 (xanthohumol D), 5 (dihydroxanthohumol), 6 (xanthohumol B) and 8 (lupulone) were determined by comparison with the published data (Stevens *et al.*, 1997, 2000). Compound 2 was first isolated from a natural source, although its chemical synthesis has been reported. We consider it to be a type of biosynthesis product in *Humulus lupulus* L. Other structures were determined by a combination of UV, IR, MS and NMR spectral data (^{1}H-NMR, ^{13}C-NMR, HMBC, HMQC, ^{1}H-^{1}H COSY). Compound 7 is a new chalcone, an oxidation product of compound 3 (xanthohumol). So far, there has been no report of its isolation. Compounds 9–11 are derivatives of compound 8 (lupulone, a main β acid in hops), and are likely to be formed during the process of its oxidation.

Inhibitory Effects of Compounds 1–11 on the Production of NO Induced by LPS/INF-γ

The inhibitory activities of these isolated compounds were evaluated. Most of them exhibited significant inhibitory effects on the production of NO induced by LPS/IFN-γ.

As shown in Table 77.1, the five chalcones (compounds 3–7) strongly inhibited NO production at low concentrations without showing cytotoxic effects. The inhibitory activities of chalcones (compounds 3–7) were much stronger than those of lupulone and its derivatives (compounds 8–11), suggesting that chalcones are the main inhibitors of NO production found in *Humulus lupulus* L. By comparing the inhibitory activities of these compounds and their chemical structures, we identified some interesting features that may affect the level of activity. Among the isolated chalcones, compound 5, which has no double bond between α and β position, inhibited NO production much more weakly than the other four compounds (3, 4, 6 and 7). This suggests that the double bond may be important for the inhibitory activity of chalcones. Compounds 4, 6 and 7 have the same backbone structure as xanthohumol (compound 3), but differ in the prenyl side chain. The inhibitory activities of these compounds are almost the same, which indicates that the prenyl chain is not necessary for inhibiting NO production. Compounds 9–11 are oxidative derivatives of lupulone (compound 8), with oxidation at different side-chain positions of lupulone. These compounds exhibited either much weaker inhibitory activities on NO production than lupulone (compound 9) or false inhibitions with strong cytotoxicity (compounds 10 and 11), meaning that oxidation may reduce the inhibitory activity of lupulone on NO production.

Inhibitory Effects of Compounds 1–8 on the Expression of iNOS Induced by LPS/IFN-γ

The effects of these isolated compounds on the expression of iNOS were also examined by Western blotting.
Figure 77.4   Chemical structures of compounds isolated from the ethyl acetate fraction of hops.

As shown in Figure 77.5, RAW 264.7 cells were treated with LPS/IFN-γ alone or together with isolated compounds 1–8 at 5 μg/ml, a concentration at which no cytotoxicity was observed. Compounds 3, 4, 6 and 7, which significantly inhibited NO production at 5 μg/ml, completely suppressed the expression of iNOS induced by LPS/IFN-γ. Other compounds (compounds 1, 2 and 8) did not inhibit iNOS expression at this concentration, whereas

compound 5 slightly suppressed iNOS expression. Taken together, these results suggest that the chalcones, the main inhibitory agents of NO production in hops, inhibit NO production by suppressing the expression of iNOS protein induced by LPS/IFN-γ.

Macrophages play major roles in inflammation and host defense mechanisms against bacterial and viral infections (Adam and Hamilton, 1984). During acute and

The experiment was done independently twice and a representative result is shown. The arrow signal indicates the 136 kDa iNOS-specific band.

chronic inflammation, excessive production of NO may cause severe injury to host cells and tissues (Knowles and Moncada, 1994). iNOS, the enzyme responsible for the synthesis of NO in macrophages, is not expressed under normal conditions but is strongly induced upon exposure to LPS/IFN-γ. Through bioactivity-guided fractionation, we purified several NO production inhibitors from the ethyl acetate fraction of *Humulus lupulus* L. and compared their activities against their chemical structures. Xanthohumol (compound 3) and several other chalcones were found to be the major inhibitory constituents of hops. It has been recently reported that xanthohumol is the potent inducer of quinone reductase via activation of nrf2 by the reaction of its double bond between α and β position with Keap1 protein using matrix-assisted laser desorption time-of-flight mass spectrometry (Liu *et al.*, 2005). It is suggested from our results that xanthohumol and related chalcones might interact with the regulator for the iNOS expression.

Summary Points

- The ethyl acetate soluble fraction of hops (*Humulus lupulus* L.) inhibited LPS/IFN-γ-induced production of NO.
- The ethyl acetate soluble fraction of hops inhibited the expression of iNOS by Western blotting analysis.
- Eleven compounds (humulene, five chalcones, 2,2-di-(3-methyl-2-butyleyl)-4,5-dihydroxy-cyclopent-4-en-1,3-dione, lupulone and three of its derivatives) have been isolated from the ethyl acetate soluble fraction of hops.
- The chalcones, including xanthohumol, significantly inhibited the production of NO by suppressing the expression of iNOS and it is suggested that the double bond in α and β position of chalcones structure is important for the inhibitory activity of iNOS expression.

Non-specific Hydroxyl Radical Scavenging Properties of Melanoidins from Beer

Francisco J. Morales Instituto del Frío, Consejo Superior de Investigaciones Científicas, Madrid, Spain

Abstract

Melanoidins are widely distributed in western-countries diet, due to home or industrial processing of foods. In the past, melanoidins were considered as inert, brown-colored polymeric food constituents. However, recent research into their nutritional, physiological and functional properties has suggested that they have antioxidant properties. This chapter described the non-specific hydroxyl radical scavenging properties of melanoidins isolated from different styles of beer. During beer processing, melanoidins are formed mainly during kilning in a different yield according to the raw material and technological conditions applied. Melanoidins from pilsener beer, Belgium Abbeys style beer and dry-stout beer have shown hydroxyl radical scavenging properties in different extent. Beer melanoidins inhibit the 2-deoxy-D-ribose degradation competitively, showing that they are scavengers of hydroxyl radicals. Brewery companies should put more attention on those newly formed compounds since they may balance the overall antioxidant activity due to the loss of naturally occurring antioxidant substances.

List of Abbreviations

ESR	Electron spin resonance spectroscopy
LC	Liquid chromatography
TCA	Trichloroacetic acid
TBA	2-Thiobarbituric acid
DR	2-Deoxy-D-ribose
MR	Maillard reaction
MRP	Maillard reaction products
DPPH	2,2-Diphenyl-1-picrylhydrazyl
DMPD	*N,N*-Dimethyl-*p*-phenylenediamine
ABTS	2,2′-Azobis(3-ethylbenzothiazoline-6-sulfonic acid)
ROS	Reactive oxygen species
DTPA	Diethylenetriaminepentaacetic acid
Trolox	6-Hydroxy-2,5,7,8-tetramethylchroman-2-Carboxulic acid
CL	Chemiluminescence
DMPO	5,5-Dimethyl-1-pyrroline-*N*-oxide

Introduction

The beer production is an extremely complicated process since many variables are taking place and the chemistry and biochemistry involved in are highly complex. The compositions and concentrations of reducing substances are constantly changing throughout the process as well as raw material and treatment applied is a source of variation as well. Slight changes in structure, or even conformational changes, can alter the antioxidant activity of a compound. In this sense, the brewing industry is concerned with the stability of the beer under shelf-life. In recent years, there has been a general trend toward minimizing the use of added antioxidants in food in general and in beer production in particular (Pokorný, 1991). It is therefore desirable to prevent oxidation by maximizing the natural occurring reducing agent present in the raw materials and hence in the wort, as well as retaining newly formed heat-induced compounds which offer an overall reducing effect in the beer to increase its stability during storage (Galic *et al.*, 1994). This issue is greatly recognized by consumers and administrative bodies to keep the natural properties of this beverage.

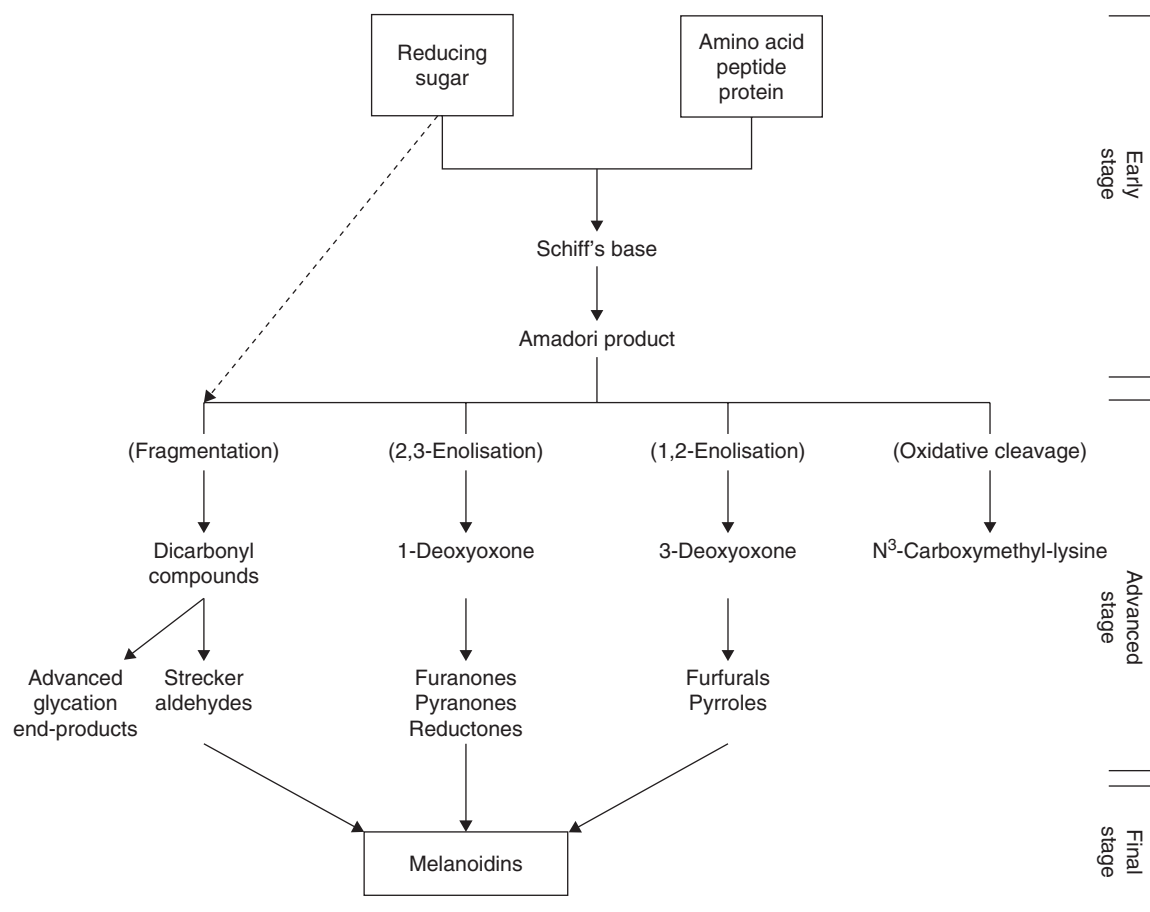
But not only shelf-life is partly affected by the antioxidative status of the beer, it is known that antioxidants activity in beer plays a crucial role in providing flavor stability to beer (Bamforth *et al.*, 1993). Antioxidants formed during brewing are capable of delaying, retarding or preventing oxidation processes caused by activated or radical species and they are therefore thought to have a significant effect in malting and brewing as inhibitors of oxidative damage (Araki *et al.*, 1999). Furthermore, compounds with antioxidant activity play a crucial role maintaining the flavor stability of beer during storage by reducing the rate of lipid oxidation and thereby preventing the production of stale flavor compounds (Walters *et al.*, 1997; Goupy *et al.*, 1999). These components can inhibit lipoxygenase activity during malting and mashing and limit auto-oxidation during brewing and beer storage. Then protection of the natural polyphenols antioxidants of barley and the production of new antioxidants during malting are of great interest (Maillard and Berset, 1995).


Figure 78.1 Schematic overview of the MR.

Formation of stable antioxidant compounds in beer is important from a technological point of view but from a health point of view as well. Beer is a low-alcohol beverage brewed from natural ingredients which may be involved in the prevention of cardiovascular and carcinogenesis diseases (Henderson *et al.*, 2000; Bamforth, 2002). One mechanism through which it may contribute to positive health effects is related to its antioxidant properties (Arimoto-Kobayashi *et al.*, 1999; Ghiselli *et al.*, 2000; Rivero *et al.*, 2005). An increase in plasma antioxidant capacity has been reported to occur following the consumption of certain types of beer and this increase can be associated with levels in plasma flavonoids in humans (Ghiselli *et al.*, 2000).

As reviewed by Chandra (2002), several reducing agents that are known to be important in malting and brewing include melanoidins and reductones, phenolics substances, thiols, non-fermentable reducing sugars and carotenoids and vitamins. Of these, melanoidins (formed during kilning throughout Maillard reaction (MR)) and polyphenols (natural from the barley, malt and hops) are the most significant sources of natural antioxidants in beer. On the other hand, a mixture of different types of antioxidants, which work

via different mechanism, can often display a synergistic effect, for instance, a peroxide decomposer and a free radical inhibitor. The content of melanoidins and polyphenols in beer is largely influenced by the genetic factor of its raw materials and therefore by the environmental conditions in which they grow and it is also influenced by the technological brewing factors (Nicoli *et al.*, 1999; Lugasi, 2003).

Melanoidins are formed in the malt by both the thermal degradation of sugars and by the MR. MR occurs during heating of many foods of a typical Western diet which are heat processed and the resulting products have a direct impact on the organoleptic properties of the product (Ames, 2003). The MR is a complex network of reactions and is summarized in Figure 78.1. The initial stage involves the condensation of a carbonyl group, mostly form a reducing sugar, with a free amino group such as the epsilon amino group of lysine residue within peptides or proteins. This results in the formation of an unstable Schiff base, which spontaneously rearranges to form the more stable Amadori rearrangement product. Several Amadori products could be formed depending on the reactants taking place in the rearrangement, for instance, fructosyllysine is formed when

initial sugar is glucose and amino group is lysine. Later, Amadori products can be degraded by several pathways, leading the formation of reductones and furfurals. These compounds can react further to give colored, low molecular mass products and melanoidins. On the other hand, Amadori products can also fragment to form various dicarbonyl compounds which are more reactive compounds and can lead to the formation of compounds that contribute to flavor such as Strecker aldehydes, pyrazines, thiophenes and furans. In the final stage of the MR, melanoidins are formed from reactive compounds formed in previous stages. Then melanoidins are formed by cyclizations, dehydrations, retro-aldolizations, rearrangements, isomerizations and condensations of MR products, but none of them has been fully characterized. This final stage is not well characterized from a chemical and structural point of view yet.

During the brewing process, melanoidins are provided mainly from the malt, although they are also formed during mashing and wort boiling. It is known that MR products act as scavengers for reactive oxygen species (ROS) such as superoxide, peroxide and hydroxyl radicals. Melanoidins mainly consisted of compounds formed from carbohydrates and their degradation products. Besides proteins, other food constituents were incorporated in the melanoidin structure as well, such as lipid oxidation products and phenolics compounds in the case of beer and coffee as well. On the other hand, melanoidins comprise a substantial proportion of several food products apart from beer, such as coffee, roasted malt, breakfast cereals and bread, and are widely consumed with dietary components. In addition, melanoidins possess antioxidant activity (Manzocco et al., 2001), are responsible for the development of color in heat-processed food products (Rizzi, 1997), may contribute to food texture and are likely to play a role in the binding of nutritionally important metals (O'Brien and Morrissey, 1997), potentially undesirable dietary compounds (Yen and Hsieh, 1994) and flavor compounds (Hofmann and Schieberle, 2002).

Concerning the natural phenolics substances present in the malt, they act as radical scavengers and are highly effective in inhibiting non-enzymatic lipid peroxidation as stated for a large number of studies. About 70–80% of the polyphenols in wort are malt-derived and 20–30% are from the hops (Chandra, 2002). Polyphenols are the most important antioxidant in pilsener malts; however, in dark malts MR products seem to be the major antioxidants. The most abundant polyphenols in malt are (+)-catechin, (−)-epicatechin, (+)-gallocatechin, ferulic acid, p-coumaric acid and vanillic acid (McMurrough et al., 1983). Traditionally, the use of colored malt is known to improve the stability of the finished beer, and it has also been shown that higher colored beers retain a greater reducing power during storage (Chapon et al., 1971; Coghe and Delvaux, 2002). The final beer produced has a reducing power mainly dependent on melanoidin compounds and simple and polymerized polyphenols. It is likely that the polyphenols from these two sources are different, and

the specific properties are highly dependent on the degree of polymerization. Furthermore, correlations between levels of (+)-catechin or ferulic acid and antioxidant activity are poor, suggesting that other components, for example, polyphenols oligomers and MR products also contribute to the total antioxidant activity of beer (Woffenden et al., 2002). An obvious effect will be a decrease in reducing power as oxidation gradually occurs over time. Oxygen in the headspace will therefore cause a problem during beer storage.

Kilning is the most important stage of malt production with regard to the formation of antioxidants since majority of reducing power come from the kilned malt. In fact, germination releases reducing sugars and amino acids. During the first step of kilning, the water at the surface layers of the grain is removed (the humidity falls from 0.45 to 0.12 g/g) and the MR is initiated. By altering the drying phase in a kiln or in a roasting cylinder, a wide assortment of dark specialty malts can be produced ranging in color from 5 to 1,600 European Brewery Convention (EBC) units. The final step of kilning (curing) involved temperatures up to 95°C causing the development of color, flavor and aroma (Woffenden et al., 2002). Pale and larger malts are produced by kilning at 50–85°C over 28–32 h, but temperatures of 80–100°C are applied for up to 170 min for caramel malt production (Blenkinsop, 1991). Finally, classical colored malts are roasted at temperatures up to 240°C. Apart from the MR caramelization of sugars can also occur during the last stages of kilning, catalyzed by the low concentration of organic acids (Karakus, 1975). In general, pale malts contribute less reducing power to the wort and beer than higher color malts. Kilning involves drying of the malt for up to 30 h and results in a stable product that can be readily handled, stored and milled. The reducing power is associated with the higher temperatures involved in the production of color compounds, including both melanoidin and phenolics species (Woffenden et al., 2002). As results of the higher temperatures applied for the production of dark specialty malts, higher levels of antioxidants (reductones and melanoidins) are formed during the MR. Consequently, beers with dark malts normally have a longer shelf-life than pale beers (Cantrell and Griggs, 1996).

Isolation of Water-Soluble Melanoidins from Commercial Beer Samples

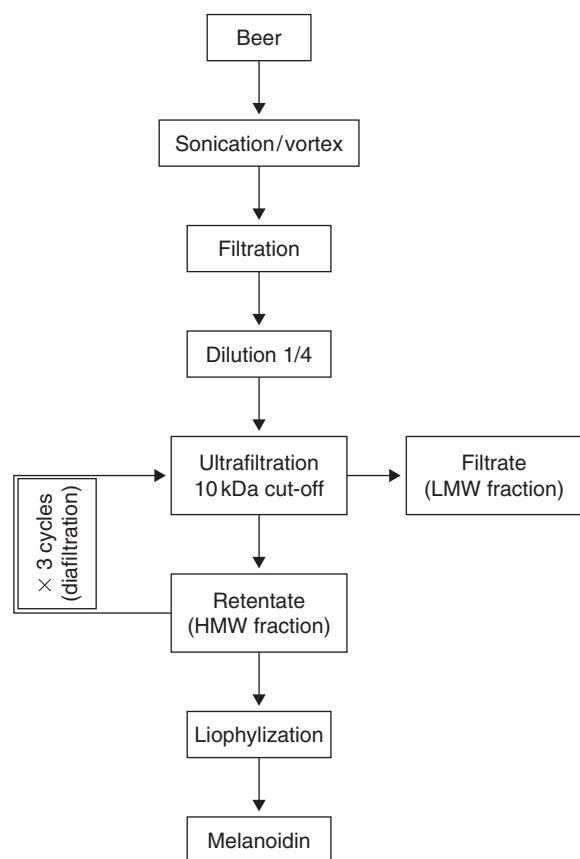
There are several procedures to isolate the water-soluble high molecular weight (HMW) fraction from beer, named melanoidin. Dialysis has been widely used but some drawbacks concerning potential contamination and structural changes on the melanoidin have arisen since procedure usually takes 3 or 4 days. It is expected further that condensation of polymers structures during the dialysis and final structures could be different to the initial ones. High performance gel filtration chromatography is an efficient approach but the reduced amount of recovered melanoidin


Figure 78.2 Flow diagram for isolation of soluble melanoidin fraction from beer.

is the limiting factor. Lately, ultrafiltration has been used by applying membranes with different cut-off, and provides a reliable and smart procedure for isolation in short time. A scheme of the procedure is depicted in Figure 78.2. Ultrafiltration combined a cost-effective, low time-consuming procedure with higher recoveries. Then, after sonication and appropriate dilution beer samples are subjected to ultrafiltration using an Amicon ultrafiltration cell model 8400 (Amicon, Beverly, MA, USA), equipped with a 10,000 Da nominal molecular mass cut-off membrane. The retentate was filled up to 200 ml with water and washed again. This washing procedure is repeated at least three times to ensure the absence of low molecular weight material (LMW). The HMW fraction corresponding to melanoidins can be freeze-dried and stored in a dessicator until analysis. Isolated beer melanoidins could be reanalyzed by gel filtration chromatography in absence of LMW compounds as described by Morales *et al.* (2005).

Antioxidant Activity of Maillard Reaction Products (MRP)

Most of the antioxidant properties of MR products have been evaluated on single model systems (sugar – amino

acids) and latter on the different fractions according to their molecular weight. The main factors affecting the formation of antioxidant compounds are known to be pH (Lingnert and Eriksson, 1981), nature and molar ration of reactants (Kawashima *et al.*, 1977), water activity (Eichner, 1981) and temperature and heating time (Lingnert and Eriksson, 1980). But it is important to assess specific antioxidative activity of fractions of MRP for evaluating use in potential food processing strategies (Jing and Kitts, 2000). Several authors suggested that HMW fraction ($\geqslant$10 kDa, melanoidins) were responsible for the antioxidative efficiency of MR mixtures in water-soluble (Morales and Babbel, 2002) and water-insoluble matrices (Wagner *et al.*, 2002). Melanoidins, polymeric high molecular mass fraction of MRP, have traditionally been skipped from these studies since melanoidins have been considered as inert materials, associated to the concept of fiber.

Antioxidant activity of MRP from synthetic and food melanoidins, including beer, has been mainly related to determining peroxyl radical scavenging activity (Morales and Jiménez-Pérez, 2004) or quenching specific stable radicals, such as 2,2-diphenyl-1-picrylhydrazyl (DPPH) (Morales and Jiménez-Pérez, 2001) or *N,N*-dimethyl-*p*-phenylenediamine (DMPD) (Morales and Babbel, 2002). Few studies have reported the affinity of different model MRP to specifically scavenge hydroxyl radicals *in vitro* (Wijewickreme *et al.*, 1999). Since significant quantities of melanoidins enter in the human gut on daily basis (Ames *et al.*, 1999), it is important to assess the implication of these compounds on the overall antioxidant activity of foods. Studies focused on the antioxidant activity of melanoidins, and more specifically on the radical scavenging properties, are scarce in the literature. Furthermore, the effects of ROS and free radicals in producing tissue damage in human disorders are becoming increasingly well recognized. Active oxygen as superoxide ($O_2^{\bullet2}$), hydrogen peroxide (H_2O_2) or hydroxyl radical ($^\bullet OH$) is a by-product of normal metabolism. It represents a potential toxic hazard to various biological molecules leading to tissue damage, cell injury or death (i.e. Yen and Chung, 1999). Hydroxyl radicals are short-lived, extremely reactive molecules that react by H-abstraction, electron addition or electron transfer with most organic compounds in a diffusion-limited reaction and thus cause the breakdown of essential cell constituents such as DNA, membrane lipids or cell wall polymers. Formation of $^\bullet OH$ or highly oxidizing species from H_2O_2 has been associated with transition metal ions such as iron and copper and reducing agents (at low concentrations) such as $O_2^{\bullet2}$ and ascorbate. The damage induced by free radicals is often prevented by scavengers. The antioxidant activity of plasma has been shown to increase after consumption of foods high in antioxidants (Temple, 2000). Thus, phytochemicals may combat oxidative stress in the human body by maintaining a balance between oxidants and antioxidants (Temple, 2000). This is particularly important because under severe oxidative stress excessive

formation of ROS and free radicals can damage biomolecules, such as DNA, proteins, lipids and carbohydrates, and lead to numerous disease conditions (Halliwell, 1996).

Methods for Assessing the Protective Effect of Molecules Toward Hydroxyl Radicals

In the past decades, scientific literature collected a huge number of procedures to assess the antioxidant activity of food constituents. Methods based on stable radicals have been criticized because these stable radicals are foreign to biological systems, in contrast to the short-lived radicals, like the hydroxyl and peroxyl radicals occurring as reaction intermediates in oxidative processes (Becker et $al.$, 2004). In general, $^{\bullet}$OH generation has three model systems, including ultraviolet photolysis of hydrogen peroxide, γ-irradiation of water (Tteiner and Babbs, 1990) and via chemical reactions. Fenton reaction is often used to generate $^{\bullet}$OH (Lloyd et $al.$, 1997). The hydroxyl radical is widely accepted to be generated when hydrogen peroxide reacts with Fe(II) (Fenton reaction).

$$Fe^{2+} + 2H_2O_2 \rightarrow Fe^{3+} + {}^{\bullet}OH + OH^-$$
There are several approaches for the detecting hydroxyl radicals or assessing the scavenging properties of substances toward hydroxyl radicals. One of these methods is the electron spin resonance spectroscopy (ESR), which measures the electron paramagnetic resonance spectrum of a spin adduct derivative after trapping (Geoffroy et $al.$, 2000; Domingues et $al.$, 2001; Mizuta et $al.$, 2002). But this method cannot be directly employed to acquire quantitative estimate of $^{\bullet}$OH production because the $^{\bullet}$OH adduct is a short-lived radical. Spin-traps are special designed molecules, which react readily with highly reactive radicals forming relatively stable spin-adducts. In the FRBR-assay (Fenton Reaction Based Radical assay), detection of hydroxyl radicals after reaction with the spin-trap 5,5-dimethyl-1-pyrroline-N-oxide (DMPO). But, the expensive instruments make it unsuitable for routine analysis.

Other approaches imply chemiluminescence (CL) (Parejo et $al.$, 2000; Tsai et $al.$, 2001), ultraviolet–visible and fluorescence spectrophotometry (Joseph et $al.$, 2001; Yang and Guo, 2001) or electrochemical detection (Zou et $al.$, 2002). Aromatic hydroxylation has also been applied, in which the hydroxylated products generated from the reaction of hydroxyl radicals with aromatic compounds, such as phenol, benzoic acid or salicylic acid (SA), are separated by gas chromatography or liquid chromatography (LC) by using different detectors (Coudara et $al.$, 1995; Vanhees et $al.$, 2001; Jurva et $al.$, 2002) but it presents some drawbacks (Li et $al.$, 1997). Methanesulfinic acid has also been adopted for determination of hydroxyl radicals by a spectrophotometric method (Babbs and Griffin, 1989) and LC (Fukui et $al.$, 1993). However, methanesulfinic acid is only an intermediate

product, which also reacted rapidly with hydroxyl radicals leading to methanesulfonic acid and sulfate formation. Another highly sensitive method based on methyl radicals reacting with a fluorescamine-derivatized nitroxide forming a stable omethylhydroxylamine has been developed for the determination of hydroxyl radicals in biological systems (Li et $al.$, 1997). Another widely used approach in the reactions with SA to produce 2,3-dihydroxy benzoic acid (2,3-DHBA) and 2,5-dihydroxy-benzoic acid (2,5-DHBA). DHBA, as the probe of $^{\bullet}$OH, can be determined by LC.

Non-site-Specific Hydroxyl Radical ($^{\bullet}$OH) Scavenging Activity Assay

As described previously, hydroxyl radicals are easily generated by the Fenton reaction. However, the Fe(II)/H_2O_2 mixture has disadvantages in a scavenging assay because many antioxidants are also metal chelators. When the sample is mixed with Fe(II), it may alter the activity of Fe(II) by chelation. As a result, it is impossible to distinguish if the antioxidants are simply good metal chelators or $^{\bullet}$OH scavengers. The generation of radicals is not affected by iron chelators, such as diethylenetriaminepentaacetic acid (DTPA) or ethylenediaminetetraacetic acid (EDTA), bathophenanthroline disulfonic acid, phytic acid and bathocuprione disulfonic acid. EDTA prevent the uncontrolled generation of $^{\bullet}$OH and potential reducing effect of target substances is minimized.

Non-site-specific $^{\bullet}$OH radical scavenging activity of melanoidins can be measured according to the well-characterized method of Halliwell et $al.$ (1987). Hydroxyl radical formation in a Fenton drive system in the absence or presence of melanoidins is evaluated by both time-course as to determine rate constants. Reaction mixture at a final volume of 1 ml contains 0.249 mM 2-deoxy-D-ribose (DR), 1 mM H_2O_2, 100 μM FeCl$_3$, 104 μM EDTA, 100 μM ascorbic acid, in 10 Mm NaH$_2$PO$_4$–NaHPO$_4$ buffer (pH 7.4). Solution containing EDTA and FeCl$_3$ is premixed the day before. All the solutions should be made up before use in de-aerated water. Several concentrations of melanoidins or reference antioxidant (trolox or chlorogenic acid) are tested in a final volume of 50 μl. Then reaction is initiated after the addition of hydrogen peroxide. Reaction media is incubated in a water bath at 37°C up to 120 min. The reaction is stopped by adding 100 μl of 28% (w/v) cold trichloroacetic acid (TCA) once incubation time is reached. The development of the chromogen is achieved by heating the reaction vessel in a boiling bath for 30 min before addition of 2-thiobarbituric acid (TBA) solution (1% w/v in 0.05 M NaOH). After cooling, the chromogen is determined spectrophotometrically at 532 nm against a blank containing phosphate buffer. The scavenger (melanoidin or reference antioxidant) rate constant (k_S) is determined from the plot $1/A$ vs. concentration of the scavenger (mg/ml), being A the absorbance at 532 nm of the experiment. Halliwell et $al.$ (1987) proposed the reference value of 3.1×10^9/M/s

(0.0231 × 109 l/g/s) for the second rate constant of the reaction of DR with $^{\bullet}$OH (k_{DR}), same value is applied for beer.

Hydroxyl Radical Scavenging Properties of Melanoidins from Beer

Hydroxyl radicals are formed in the mix by the Fenton reaction and are detected by their ability to degrade DR into fragments that on heating with TBA at low pH form a pink chromogen. TBA-adducts gave a maximum of absorbance at 532 nm which is named as positive control (Figure 78.3). The extent of the reaction can be determined by measuring the rate of inhibition of DR oxidation in the presence of the antioxidant molecule. Addition of hydroxyl radical scavengers competes with DR for hydroxyl radicals and diminishes chromogen formation at a defined time of reaction (Figure 78.3). Then, it is able to calculate a percentage of inhibition of the target molecule on the hydroxyl radicals. This approach cannot be directly applied when the aim is to evaluate the hydroxyl scavenging properties of different complex systems, where different molecules are expected. It is necessary to gain insight on the hydroxyl radical scavenging activity through a period of time.

Three widely distributed commercial brands of beer in Europe with different elaboration procedures were analyzed. A Pilsener style beer from a Spanish brewery, Abbeys style beer from a Belgian brewery, and a dry-stout beer from an Irish brewery were studied. Melanoidins isolated from these beers are used for assessing the antiradical activity. Table 78.1 shows the yield of melanoidin obtained from each sample.

Color is a classical attribute of melanoidins. Isolated melanoidins show an apparent absorbity (l/g/cm) of 0.014, 0.064 and 0.294 for pilsener, Abbey and dry-stout beers, respectively. The contribution of the color at the experimental conditions is always lower than 0.035 absorbance units at 532 nm. On the other hand, TBA reactive substances are not formed during the treatment of melanoidins in the absence of DR or are negligible to the contribution of the intrinsic color on the overall measurement at 532 nm at the range studied (Figure 78.3). The non-specific hydroxyl scavenging activities of melanoidins and reference material through a period of time are evaluated. The presence of EDTA–Fe(III) enhances the generation of hydroxyl radicals since keep it from attacking DR. Therefore, hydroxyl radicals generated attack DR in a non-site-specific manner (Halliwell *et al.*, 1987). Most of the melanoidins exerted inhibition effects on hydroxyl radical formation during the first part of the incubation period (up to 40 min) presumably due to the presence of residues acting as nucleophilic, and decreasing the activity after that. The hydroxyl radical scavenging activity is lost after 2 h of reaction for most of beer melanoidins. Trolox is able to keep the antiradical activity for at least 90 min. On the other hand, the efficiency to scavenge hydroxyl radical is significantly lower for melanoidins as compared with trolox (Table 78.2).

Figure 78.3 Classical spectrophotometric profile of a beer melanoidin sample after 30 min of reaction at 37°C with 0.337 mM deoxyribose. Deoxyribose positive control (absence of melanoidin, solid bold line), in the presence of beer melanoidin (solid line), blank assay (absence of deoxyribose, dotted line) and negative control (absence of both melanoidin and deoxyribose, bold dotted line).

Table 78.1 Melanoidin content from three beer styles

Beer style	Melanoidin content (g/l)
Dry-stout beer	2.18
Abbeys style beer	2.36
Pilsener beer	1.63

Table 78.2 Rates of percentage of inhibition of the deoxyribose degradation by hydroxyl radicals in the presence of melanoidins (1 mg/ml) from three beer styles and coffee brew and trolox as reference material (0.05 mg/ml)

Melanoidin	Incubation time (min)						
	10	20	30	40	60	90	120
Pilsener beer	35.4	26.3	21.0	17.8	4.9	0.0	0.0
Abbey beer	33.2	29.4	24.6	23.1	10.6	2.1	0.0
Dry-stout beer	41.9	38.2	34.2	34.7	34.8	7.7	1.1
Coffee brew	24.2	29.0	28.4	26.8	23.5	8.7	0.4
Trolox	*81.9*	*81.4*	*81.8*	*83.1*	*79.6*	*84.8*	*71.9*

Since melanoidin structure is unknown, studies concerning the structure–activity relationships of melanoidins are limited (Jing and Kitts, 2000). Different hypotheses have been formulated on the structural backbone of these model melanoidins. A first hypothesis states that a melanoidin skeleton is constituted mainly from sugar degradation products, polymerized through aldol type condensations and probably branched via amino compounds (Yaylayan and Kaminsky, 1998; Cämmerer and Kroh, 1995). It was shown that, under water-free MR conditions, significant amounts of carbohydrates are incorporated as side chains, with an intact glycosidic bond, into the melanoidin skeleton (Cämmerer et al., 2002). Tressl et al. (1998) proposed a complex macromolecular structure consisting of repeating units of furans and pyrroles, linked by polycondensation reactions. Hofmann (1998) identified low molecular weight chromophores and postulated the generation of melanoidin-type colorants by a crosslinking reaction between these LMW substances and non-colored HMW biopolymers, such as proteins.

It could be plausible that the antiradical effects of MRP could be correlated to their iron-chelating properties (Yoshimura et al., 1997). Then it could be deactivated in iron Fenton-type reactions by chelating the iron and form an inactive complex with the melanoidin. It is known that melanoidins are able to quelate iron (Morales et al., 2005), but this ability is drastically reduced in the presence of ascorbic acid. In the presence of ascorbic acid most of the iron was released from the melanoidin structure. Furthermore, EDTA eliminates the iron-chelating effects that may interfere with the accurate determination of hydroxyl radical scavenging activity in the system. On the other hand, ascorbic acid greatly increases the rate of $^\bullet$OH generation by reducing iron and maintaining a supply of Fe^{2+}–EDTA quelate. Furthermore, the effect of melanoidins in the speciation of the iron during the time of incubation is not clear. Additional experiments are necessary to gain more insight on the iron-reducing ability of the beer melanoidins. The presence of the ascorbic acid ensures the rapid turn-over of Fe(II), if necessary. The ability of beer melanoidins to reduce Fe(III) at the reaction vessel concentrations is investigated by applying the ferrozine method. This effect imparts the pro-oxidant activity when catalytic transition metal ions are present. This fact is important to be evaluated when non-site-specific hydroxyl radicals scavenging ability assay is applied. Ferrozine was used to measure the levels of iron reduction in that it forms a stable complex with Fe(II) that can be measured by its absorbance at 562 nm. Beer melanoidins do not exert a change in the iron speciation for 2 h of incubation at 37°C in the reaction vessel (Morales, 2005).

A kinetic approach could be applied to assess the hydroxyl radical scavenging properties of beer melanoidins. The second order rate constants are obtained by competition kinetic method with DR whose product can be monitored (λ_{max} at 532 nm, ε of 153,000 l/mol/cm) (Gutteridge, 1981). Previously, it was confirmed that melanoidin did not scavenge hydrogen peroxide, and the intrinsic color did not show interferences with the DR assay at the concentration range tested (1.5–50 μg/ml in the reaction vessel). In agreement with Halliwell et al. (1987), the rate constant for the reaction of scavengers with hydroxyl radical can be determined based on the following equation:

$$1/A = 1/A_0(1 + k_M[M]/k_{DR}[DR])$$

where A is the absorbance in the presence of melanoidin (M) at concentration [M] and A_0 the absorbance in the absence of a scavenger; rate constants of reactions in the presence (k_M) or absence of melanoidin (k_{DR}), [DR] is the concentration of deoxyribose used in the experiment. A scheme of the competitive reactions involved is represented in Figure 78.3. It was represented by $1/A$ against melanoidin concentration to calculate the constant rates from the slope (Figure 78.4). The rate constant (k_M) was determined from the slope of the curve. Higher slope is related to a higher competition toward $^\bullet$OH radicals, meaning a higher antihydroxyl radical activity (Figure 78.5).
Figure 78.4 Scheme of the main chain reaction and rate constants involved in the competitive deoxyribose test for assessing hydroxyl radical scavenging properties of beer melanoidins.
Figure 78.5 Competition curves of melanoidins (mg/ml) from Pilsener beer (◆), Abbey style beer (□) and dry-stout beer (■). Reaction was carried out in phosphate buffer (pH 7.4) at 37°C for 30 min. Data average of two independent assays.

Table 78.3   Second order rate constants (k_M) for trolox, melanoidins from beer and coffee brew determined by the competitive assay of the deoxyribose method

Melanoidin	Range	A_0	r	$k_M \times 10^6$	$SD \times 10^6$
Pilsener beer	2.0–10.0	0.627	0.997	3.02	0.33
Abbey beer	2.0–10.0	0.794	0.998	10.52	0.01
Dry-stout beer	2.0–10.0	0.635	0.996	7.22	0.35
Coffee brew	0.4–2.0	0.821	0.996	13.00	0.01
Trolox	*0.005–0.50*	*2,062*	*0.963*	*2,491.07*	*46.58*
Figure 78.6   Relationship between color (apparent absorbity, l/g/cm, □) and hydroxyl radical scavenging properties (k_M, l/g/s, ■) for melanoidins isolated from Pilsener, Abbeys and dry-stout beer.

Based on the competition principle, the second order rate constants of OH radical of melanoidins are summarized in Table 78.3. Beer melanoidins are found to inhibit the DR degradation competitively, showing that they are scavengers of •OH radicals. The efficiency to scavenge hydroxyl radicals could be applied for classification of the melanoidins reactivity. Traditional approaches did not give clear results where indirect methods are useful to get knowledge on the functional residues attached to the melanoidin skeleton. At present, the mechanism by which OH radicals react with melanoidins is not documented.

As previously mentioned, color is the most relevant external characteristic of the melanoidins. Many previous investigations tried to find a correlation between the browning and the antioxidant properties of several processed food (i.e. Anese *et al.*, 1999; Manzocco and Nicoli, 2003). It is noticed that a lack of correlation between beer melanoidins and color, meaning that chromophore residues linked to the melanoidin skeleton are not the main responsible for the hydroxyl scavenging properties of the melanoidins (Figure 78.6). These findings lead to the conclusion that both non-specific hydroxyl radical scavenging properties of beer melanoidins and the color increase with heating time to a maximum level, after which point antioxidant activity decreases while color levels off, in agreement as

described by Samaras *et al.* (2005) for malt model systems. Thermally induced compounds produced at higher temperatures and/or long heating times may contribute to color development, but not to antioxidant activity. Also, some thermally induced compounds possessing antioxidant activity may degrade on prolonged heating. Manzocco and Nicoli (2003) stated that correlation of antioxidant activity and color is expected in food and model systems where MR is the sole or prevalent driving force, and content of thermolabile naturally occurring antioxidant is low. In a previous work, evaluating the antiperoxyl activity of melanoidins in watery fluids, a correlation with color melanoidins in watery fluids was found (Morales and Jiménez-Pérez, 2004). It could be plausible to state that residues involved in the scavenging of hydroxyl radicals by beer melanoidins are not necessarily colored.

Summarizing, many compounds are formed with antioxidant activity during the beer production process. Researchers and brewery companies should put much attention on the potential antioxidant activity of newly formed compounds since reduction of antioxidant activity due to loss of natural antioxidant compounds from malt at least could be balanced. Levels of phenolics compounds in malt do not explain the overall antioxidant activity in malts and beer. This effect is more pronounced in beer processed with severely roasted malts. Hence, it should be plausible that MRP and melanoidins should be taken into account to understand the overall antioxidant activity of beers. Future studies should be addressed to gain more insight on the structural characterization of melanoidins from beer as well as to clarify the main LMW substances involved in their formation during kilning. It has been reported that beer melanoidins protect against oxidation induced by hydroxyl radicals which is important for protecting beer against oxidation and therefore for beneficial health implications. In that sense, brewery companies could get more precise information to drive the process to obtain melanoidins with higher protective effect against different radical species.

Summary Points

- During brewery process a myriad of new compounds are formed and some of them exert a significant antiradical activity.

- Melanoidins are colored polymeric material newly formed at the final stage of the MR during kilning.
- Beer melanoidins exert hydroxyl radical scavenging properties *in vitro* as recorded by the DR test. Different brewing process may be classified according to their potential antiradical activity.
- Hydroxyl radical scavenging activity of beer melanoidins is not related to their color, meaning that colored structures are not involved in such antioxidant effect.

Anti-obesity Effects of a Dietary Isomerized Hop Extract Containing Isohumulones Generated via Peroxisome Proliferators-Activated Receptors

Hiroaki Yajima Central Laboratories for Frontier Technology, Kirin Holdings Co., Ltd., Yokohama, Japan

Abstract

Isomerized hop extract (IHE), which consists mainly of isohumulones and is required in the beer-brewing process, was investigated for its effects on diet-induced obesity. Supplementation of high fat-containing chow with IHE reduced body weight gain and improved glucose tolerance in C57BL/6N and KK-A^y mice. Reduced weight gain was also observed in C57BL/6N mice fed a standard diet containing IHE. IHE may induce its effects by inhibiting fat absorption through the intestines, and peroxisome proliferator-activated receptors (PPARs) may also be involved. Isohumulones activated PPARs α and γ. Diabetic KK-A^y mice treated with isohumulones showed reduced plasma glucose, triacylglycerol, and free fatty acid levels. Isohumulone treatment did not cause significant weight gain, though treatment with the PPARγ agonist pioglitazone did. C57BL/6N mice fed a high fat diet and treated with isohumulones showed improved glucose tolerance, reduced insulin resistance, increased liver fatty acid oxidation, and decreased hypertrophic adipocyte size. A study of diabetes patients suggested that IHE significantly decreased blood glucose and hemoglobin A1c levels. These results suggest that isohumulones can modulate insulin sensitivity in mice on a high fat diet that develop insulin resistance and in patients with type 2 diabetes.

Introduction

Obesity has been described as "a product of free society in which a multitude of food choices and job opportunities are available" (Grundy, 2004). It is also well recognized that obesity extracts social costs. Obesity, the abnormal excessive growth of adipose tissue and accumulation of abdominal fat, results from the combined effects of excess energy intake and reduced energy expenditure (Spiegelman and Flier, 2001). It is also known to be an underlying risk factor for cardiovascular disease (CVD). Obesity raises the risk

for CVD because of its association with other risk factors such as hypertension, hyperglycemia, hypercholesterolemia (major risk factors) and atherogenic dyslipidemia, insulin resistance, proinflammatory state, and prothrombotic state (emerging risk factors). The majority of obese persons who develop CVD have a cluster of major and emerging risk factors known as "metabolic syndrome" (National Cholesterol Education Program (NCEP) Expert Panel on Detection, 2002; Grundy, 2004). It has been suggested that the increasing prevalence of obesity is mainly responsible for the rising prevalence of metabolic syndrome in the United States and worldwide (Ford et al., 2002).

The Adult Treatment Panel III (ATP III) stated that the root causes of metabolic syndrome were overweight or obese status, physical inactivity, and genetic factors. The specific factors considered to be important included abdominal obesity, hypertension, glucose intolerance, and other conditions related to metabolic syndrome (Expert Panel on Detection, 2001; Reaven, 2006). In fact, it was reported that the components of metabolic syndrome occur more commonly in obese persons, but this relationship is not due to obesity itself. Rather, obesity increases the likelihood that a person will become insulin resistant (Abbasi et al., 2002; McLaughlin et al., 2003). Also, adiposity is only one of the variables determining whether a person is sufficiently insulin resistant to develop an adverse clinical outcome, and defects in insulin metabolism play a fundamental role in the development of CVD risk factors (metabolic syndrome) (Reaven, 2006). Therefore, we should pay attention to insulin resistance as an obesity-related CVD risk factor. Insulin resistance is defined as reduced insulin action in peripheral tissues such as skeletal muscle, adipose tissue, and liver. It is closely associated with type 2 diabetes (Pi-Sunyer, 2002).

While extensive research has gone into developing anti-obesity drugs (Schwartz et al., 2000), the abilities of various factors present in foods derived from plant sources

to ameliorate obesity, such as caffeine in oolong tea and capsiate in sweet pepper, have also been investigated (Han *et al.*, 1999; Ohnuki *et al.*, 2001; Birketvedt *et al.*, 2002). Furthermore, attention has recently been focused on the potential use of constituents in plants and other foods for the treatment of diabetic symptoms (Fujita *et al.*, 2001). The treatment of type 2 diabetes with herbal plants, which was carried out generations ago in Europe, may have provided some benefit because they contained compounds that stimulated the activity of PPARs α and γ (Swanston-Flatt *et al.*, 1989; Takahashi *et al.*, 2002).

The transcriptional factor PPARγ is highly expressed in adipocytes, where it regulates genes responsible for growth and differentiation following its activation by both natural and synthetic ligands. Activation of PPARγ was shown not only to stimulate the differentiation of adipocytes but also to induce their apoptotic death, thereby preventing adipocyte hypertrophy (Yamauchi *et al.*, 2001). PPARα, another nuclear fatty acid receptor that is widely expressed in liver, muscle, kidney, and intestine, mediates the expression of genes involved in lipid metabolism. Activators of PPARα, such as fibrates, lower circulating lipid levels and are commonly used to treat hypertriglyceridemia and other dyslipidemic states. Abnormalities in fatty acid metabolism underlie the development of insulin resistance and alterations in glucose metabolism. Recent studies have suggested that the activation of PPARα helped to modulate insulin resistance that was triggered by the oversupply and accumulation of lipid (Guerre-Millo *et al.*, 2000; Ye *et al.*, 2001). It has also been reported that several novel compounds that act as co-ligands for PPARs α and γ can improve insulin sensitivity and correct diabetic dyslipidemia in obese diabetic animals (Ljung *et al.*, 2002; Ye *et al.*, 2003).

Hops, the female inflorescences of the hop plant (*Humulus lupulus* L.), are used as a preservative and flavoring agent in the beer-brewing process. Humulones, also called α acids, are the primary compounds responsible for imparting the bitter taste to hops. They have been shown to suppress the expression of cyclooxygenase-2 (COX-2), a key enzyme that is involved in inflammation and carcinogenesis, and that has been shown to inhibit angiogenesis (Shimamura *et al.*, 2001). During the beer-brewing process, humulones are converted to isohumulones, also called iso-α-acids, which are the actual compounds responsible for imparting the bitter taste to beer. The physiological effects of isohumulones, other than their anti-bacterial properties, have not been as fully investigated as those of humulones (Simpson and Smith, 1992). Isohumulones are composed primarily of isohumulone, isocohumulone, and isoadhumulone, and they exist in beer at concentrations of 20–40 ppm. Isomerized hop extract (IHE), which consists primarily of isohumulones, is made by extracting α acids from the other components in hops, and then heating them in an alkaline environment to induce isomerization.

Prevention of Diet-Induced Obesity by IHE

IHE (ISOHOPCO2N) was purchased from Botanix Limited. The purity of isohumulones in IHE is 79% and its isohumulone:isocohumulone:isoadhumulone ratio is 37:48:15. Male KK-A^y mice and female C57BL/6N mice were maintained on either a standard (AIN93G (Reeves *et al.*, 1993)) or high fat (60% of total calories (Ikemoto *et al.*, 1996)) diet, with or without added IHE.

Six C57BL/6N mice (three mice/cage) that were placed on the *ad libitum* diets described above had their average energy intake measured daily during the course of the study. Body weight gain in C57BL/6N mice fed a high fat diet containing 0.2% or 0.6% IHE was significantly reduced in a dose-dependent manner compared to mice fed a high fat diet without IHE (control group) (Figure 79.1a). Specifically, the body weights of mice fed a diet containing 0.2% or 0.6% IHE were reduced by 14.1% and 22.0%, respectively, compared to control animals after 6 weeks of feeding. No significant differences in energy intake were demonstrable between the groups (Table 79.1). Similarly, there were no significant differences in the weights of their heart, spleen, or liver. However, ingestion of IHE prevented the weight gain in subcutaneous, retroperitoneal, and parametrial adipose tissues and in the kidney in a dose-dependent manner (Table 79.1). Feeding C57BL/6N mice an AIN93G standard diet containing 0.2% or 0.6% IHE for 5 weeks resulted in body weights that were reduced by 9.9% and 13.1%, respectively, compared to the control group (Figure 79.1b). On the other hand, feeding these mice a high fat diet containing 0.2% or 0.6% IHE for 5 weeks resulted in body weights that were reduced by 14.0% and 21.3%, respectively, compared to the control group. Note that these reductions were greater than those seen in mice fed standard chow, and the differences measured for the animals fed 0.6% IHE-containing chow reached statistical significance.

Six KK-A^y mice (one mouse/cage) were fed restricted diets. Specifically, these mice received either 4.5 g of a high fat diet or 5.0 g of a normal (AIN) diet, with or without added IHE. These dietary amounts represent the maximum amount of chow that the animals were able to consume during a 24-h period. When 6-week-old KK-A^y mice were fed a high fat diet containing 0.2% and 1.2% IHE for 5 weeks, their body weights were reduced by 9.7% and 10.9% compared to controls, respectively (Figure 79.1c). Administration of IHE to their diet did not affect body weight gain in KK-A^y mice that were fed the normal AIN93G chow (Figure 79.1d).

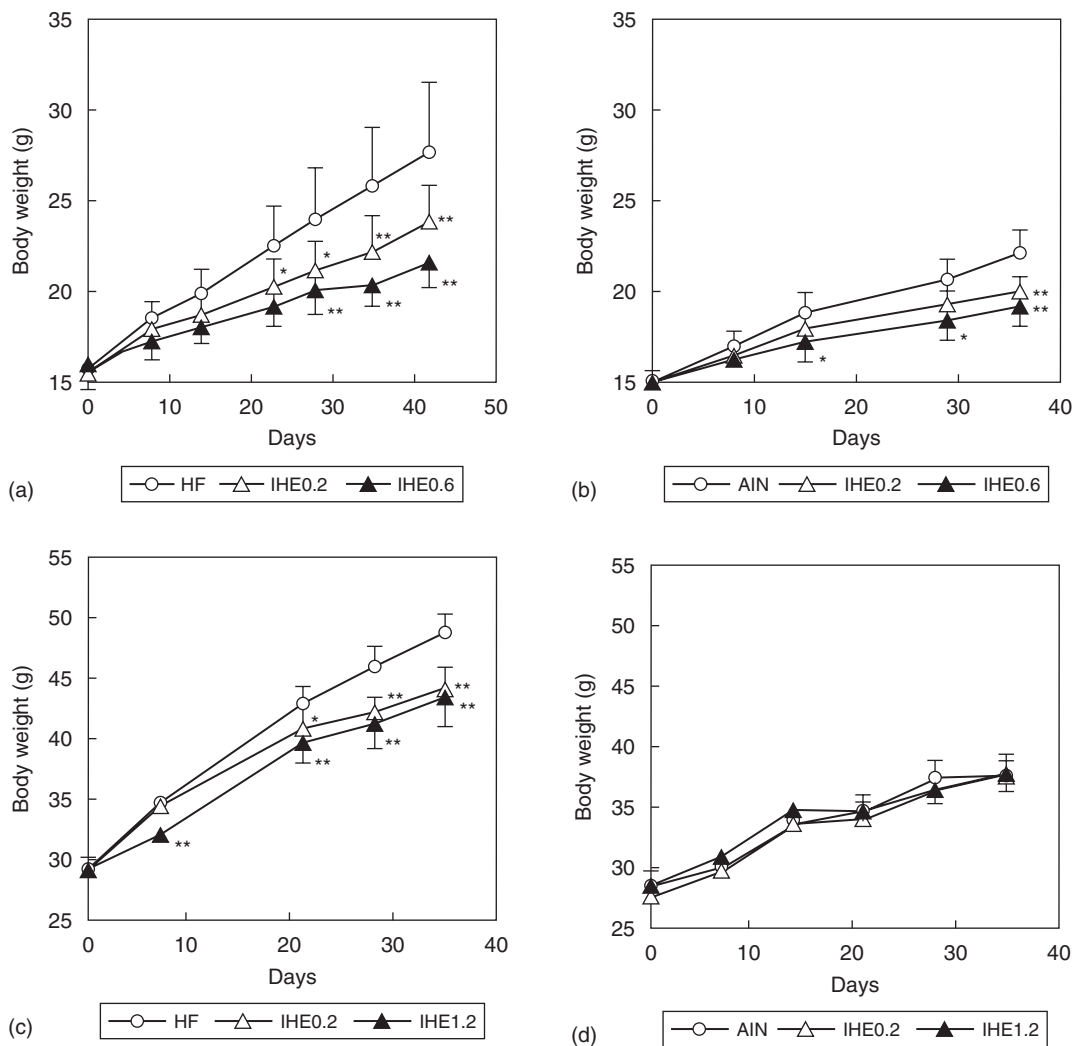
These results showed that body weight gain in most of the groups fed a diet supplemented with IHE was reduced in a dose-dependent manner compared to control animals; this effect was more marked in animals fed a high


Figure 79.1   Effects of IHE on body weight in C57BL/6N and KK-A^y mice. Female C57BL/6N mice ($n = 6$, 3 mice/cage) were fed a high fat (a) or standard diet (b) that was supplemented with 0.2% or 0.6% (w/w) IHE. Male KK-A^y mice ($n = 6$, 1 mouse/cage) were fed a high fat (c) or standard diet (d) that was supplemented with either 0.2% or 1.2% IHE. The data represent the mean ± SD for 6–8 mice. *$p < 0.05$, **$p < 0.01$ for the high fat diet-fed group vs. the IHE-supplemented group on the same day.

Table 79.1   Tissue weights and energy intake of C57BL/6N mice fed a standard (AIN93G) diet or a high fat diet with or without IHE

	AIN control	HF	IHE0.2	IHE0.6
Heart (g)	0.13 ± 0.02	0.12 ± 0.02	0.12 ± 0.01	0.10 ± 0.01
Spleen (g)	0.076 ± 0.01	0.065 ± 0.01	0.071 ± 0.01	0.065 ± 0.008
Kidney (g)	0.24 ± 0.02	0.27 ± 0.01	0.25 ± 0.02*	0.24 ± 0.03**
Liver (g)	1.1 ± 0.08	1.0 ± 0.1	0.90 ± 0.4	0.95 ± 0.07
Adipose tissue (g)				
Subcutaneous	0.32 ± 0.1	1.9 ± 0.9	1.4 ± 0.4	0.87 ± 0.28**
Retroperitoneal	0.092 ± 0.03	0.44 ± 0.2	0.29 ± 0.1*	0.17 ± 0.06**
Parametrial	0.060 ± 0.03	0.37 ± 0.2	0.20 ± 0.07*	0.13 ± 0.04**
Energy intake (kJ/day)		38.8 ± 1.7	40.6 ± 1.3	38.1 ± 2.9

Notes: IHE was mixed with a high fat diet at 0.2 or 0.6 % (w/w). Tissue weights were measured after 6 weeks of feeding. Energy intake was measured daily during the course of the study. Results are represented as the means ± SD for six mice.

*$p < 0.05$ for the high fat diet-fed group vs. the IHE supplemented group.
**$p < 0.01$ for the high fat diet-fed group vs. the IHE supplemented group.

fat diet. The fact that there were no differences in food intake in C57BL/6N mice that were fed the various diets suggests that IHE had a direct effect in preventing body weight gain. The body weight-lowering effect of IHE was confirmed in genetically obese KK-A^y mice that were kept on a calorie-restricted diet. It is noteworthy that the body weight-lowering effect of IHE was not observed when KK-A^y mice were fed a regular diet. Although the results of studies involving female C57BL/6N and male KK-A^y mice are shown here, the weight-lowering effect of IHE was also observed in male C57BL/6N and female KK-A^y mice (data not shown), suggesting that the effects of IHE are sex-independent.

Adipose tissue mass in C57BL/6N and KK-A^y mice was significantly reduced by IHE supplementation in a dose-dependent manner. The reduction in kidney weight observed in IHE-supplemented C57BL/6N mice was likely due to the normalization of kidney hypertrophy that had been induced by the high fat diet, since the kidney weight in mice fed 0.6% IHE was almost the same as that found in mice fed the standard diet. A decrease in the weight of subcutaneous and epididymal adipose tissues, as well as the liver and kidney, was observed in the IHE diet-supplemented KK-A^y mice (Table 79.2). The mean weights of the liver and kidney in animals fed chow supplemented with 1.2% IHE were nearly identical to those of mice fed the AIN93G diet (liver; 2.5 ± 0.25 (g), and kidney; 0.52 ± 0.04 (g)), suggesting that the weights of the liver and kidney in animals fed IHE-containing high fat diet were normal. The concentration of triacylglycerols in the liver of IHE diet-supplemented animals was similarly reduced in a dose-dependent manner (Table 79.2).

Inhibition of Intestinal Dietary Fat Absorption by IHE

Supplementation of the diet of Wistar rats with IHE significantly increased the lipid content of their feces compared to control rats fed the high fat diet alone. There was no significant difference in the total weight of feces produced by the two groups (Figure 79.2a).

The serial changes in plasma triacylglycerol levels of rats after oral administration of lipid emulsion are shown in Figure 79.2b. Plasma triacylglycerol levels in rats treated with IHE (100 and 150 mg/kg body weight) were significantly reduced compared to rats treated with vehicle at all time points up through 5 h after administration. At 2 h

Table 79.2 Tissue weights and liver triacylglycerol content of KK-A^y mice fed a high fat diet with or without IHE

	HF	IHE0.2	IHE1.2
Liver (g)	3.9 ± 0.3	$3.3 \pm 0.3**$	$2.6 \pm 0.3**$
Liver triacylglycerol (mmol/g liver)	0.21 ± 0.03	0.20 ± 0.05	$0.10 \pm 0.02**$
Kidney (g)	0.72 ± 0.05	$0.58 \pm 0.06**$	$0.52 \pm 0.06**$

Epididymal	2.0 ± 0.2	2.0 ± 0.2	0.9 ± 0.3

Notes: IHE was mixed with the diet at 0.2% and 1.2% (w/w). Tissue weight was determined after 5 weeks of feeding. Results are represented as the means $\pm$ SD for six mice.

**p < 0.01 for the high fat diet-fed group vs. the IHE supplemented group.

Figure 79.2 Effects of IHE on intestinal lipid absorption. (a) Fecal lipid content of Wistar rats. Feces of the rats fed a high fat diet with or without IHE were collected and weighed four times every 24 h from day 12 to day 15. They were then lyophilized and their lipids extracted and quantified gravimetrically. *p < 0.05 for the high fat diet-fed group vs. the IHE-supplemented group. (b) Wistar rats were orally administered lipid emulsion containing IHE at a concentration of 50, 100, or 150 mg/kg body weight. Plasma triacylglycerol (TG) levels were quantified at the indicated times after administration of lipid emulsion. The data represent the mean $\pm$ SD for six rats. **p < 0.01 for the high fat diet-fed group vs. the IHE-supplemented group at each indicated time. (c) Effect of IHE on pancreatic lipase activity. *In vitro* pancreatic triacylglycerol lipase activity was determined in the absence or presence of IHE. The inhibitory effect of IHE on pancreatic lipase was expressed as the relative percent suppression of enzymatic activity. The data represent the mean $\pm$ SD from three independent experiments.

after administration, the elevation in plasma triacylglycerol levels was suppressed by IHE in a dose-dependent manner; peak levels in rats treated with 50, 100, and 150 mg/kg IHE were reduced to 67.9%, 36.4%, and 20.1%, respectively, of the values seen in control animals. As shown in Figure 79.2c, IHE also inhibited pancreatic triacylglycerol lipase activity, which plays a crucial role in intestinal lipid absorption, in a dose-dependent manner; lipase activity was suppressed by about 50% in the presence of 0.5 g/l of IHE.

These results might suggest that inhibition of lipase activity by IHE contributed to the reduction in plasma triacylglycerols in these animals. The inhibitory effect of IHE on lipid absorption may have accounted for our data showing that the reduction in body weight gain induced by IHE in mice fed a high fat diet was greater than that seen in animals fed a standard diet. It has been reported that teasaponin, an inhibitor of pancreatic lipase activity that was isolated from oolong tea, suppressed the increase in body weight of mice fed a high fat diet (Han et al., 2001). Accordingly, it is likely that the inhibition of intestinal lipid absorption by IHE was responsible to some extent for the effect of IHE in reducing body weight gain.

Modulation of Lipid Metabolism by IHE

Quantitative RT-PCR analysis of the mRNAs for the acyl-CoA oxidase (ACO), medium-chain acyl-CoA dehydrogenase (MCAD), and diacylglycerol O-acyltransferase 2 (DGAT2) genes in the liver of KK-A^y mice fed a standard diet with or without IHE was performed. Treatment of mice with IHE significantly increased the mRNA levels of the ACO and MCAD genes while significantly reducing the expression of the DGAT2 gene (Table 79.3).

Table 79.3 Effect of IHE on the expression of genes involved in fatty acid metabolism

	Control	IHE
Acyl-CoA oxidase	1.00 ± 0.11	1.55 ± 0.15*
Medium-chain acyl-CoA dehydrogenase	1.00 ± 0.21	1.31 ± 0.16**
Diacylglycerol acyltransferase	1.00 ± 0.16	0.720 ± 0.068*

Notes: Total RNA was isolated from KK-A^y mice fed a diet with or without 1.2% IHE. The RNA was subjected to quantitative RT-PCR to measure the mRNA levels of the indicated genes. Results are expressed as relative expression levels normalized to the expression of the control group (mean ± SD, $n = 6$).

*$p < 0.01$ for the standard diet-fed group (control) vs. the IHE supplemented group.
**$p < 0.05$ for the standard diet-fed group (control) vs. the IHE supplemented group.

ACO and MCAD are known to be regulated by PPARα and to be involved in β-oxidation in the liver (Schoonjans et al., 1996). In contrast, the DGAT2 gene plays a vital role in the production of triacylglycerol (Meegalla et al., 2002; Waterman and Zammit, 2002). These results suggest that IHE might accelerate lipid oxidation, while at the same time it suppresses triacylglycerol biosynthesis. This effect of IHE on lipid metabolism may be related to its effect on reducing body weight gain.

Activation of PPARs by IHE and the Active Ingredient Contained in IHE

The peroxisome proliferator-activated receptors (PPARs) are nuclear fatty acid receptors that have been implicated in obesity-related metabolic diseases such as insulin resistant-type 2 diabetes, hyperlipidemia, and coronary artery disease. To evaluate the ability of IHE to transactivate PPARs, reporter assays were performed.

An increase in luciferase activity was observed following the addition of IHE to HepG2 cells that were transfected with PPARα. The addition of 50 μg/ml of IHE significantly increased luciferase activity compared to the vehicle control, and this increase was smaller than that seen when 1 μM fenofibrate, a specific agonist for PPARα, was added to the cells. IHE also increased luciferase activity in CV-1 cells transfected with PPARγ. The effect of 50 μg/ml of IHE was almost the same as that of 1 μM pioglitazone, a specific agonist for PPARγ (Figure 79.3a).

Purification of the active component that induces PPAR-mediated transcription, resulted in the identification of isohumulones. Isohumulones, also called iso-α-acids, are the compounds that impart a bitter flavor to beer. Figure 79.4 shows the chemical structure of three major homologs of isohumulones, that is isohumulone, isocohumulone, and isoadhumulone. The effects of isohumulones and IHE on PPARs α and γ were evaluated in transient co-transfection assays.

A dose-dependent increase in luciferase activity was observed following the addition of isohumulones to cells transfected with PPARγ. The addition of either 10 μM isohumulone, isocohumulone, or isoadhumulone induced a 3.8-, 3.5-, and 2.8-fold increase in luciferase activity, respectively, compared to the vehicle control (Figure 79.3b). These activities were almost the same as those seen when 1 μM pioglitazone, a specific agonist of PPARγ, was added to the cells. Isohumulone and isocohumulone also activated the PPARα construct in a dose-dependent manner; 10 μM isohumulone and isocohumulone increased luciferase activity by about 3.2- and 1.9-fold, respectively, compared to the vehicle control (Figure 79.3c). Isoadhumulone had no effect on PPARα, suggesting that the side-chain of isohumulone may be involved in the activation of the PPARα receptor. The activity of isohumulone at 30 μM was almost the same as that of 3 μM fenofibrate, a PPARα-selective agonist.

(b)

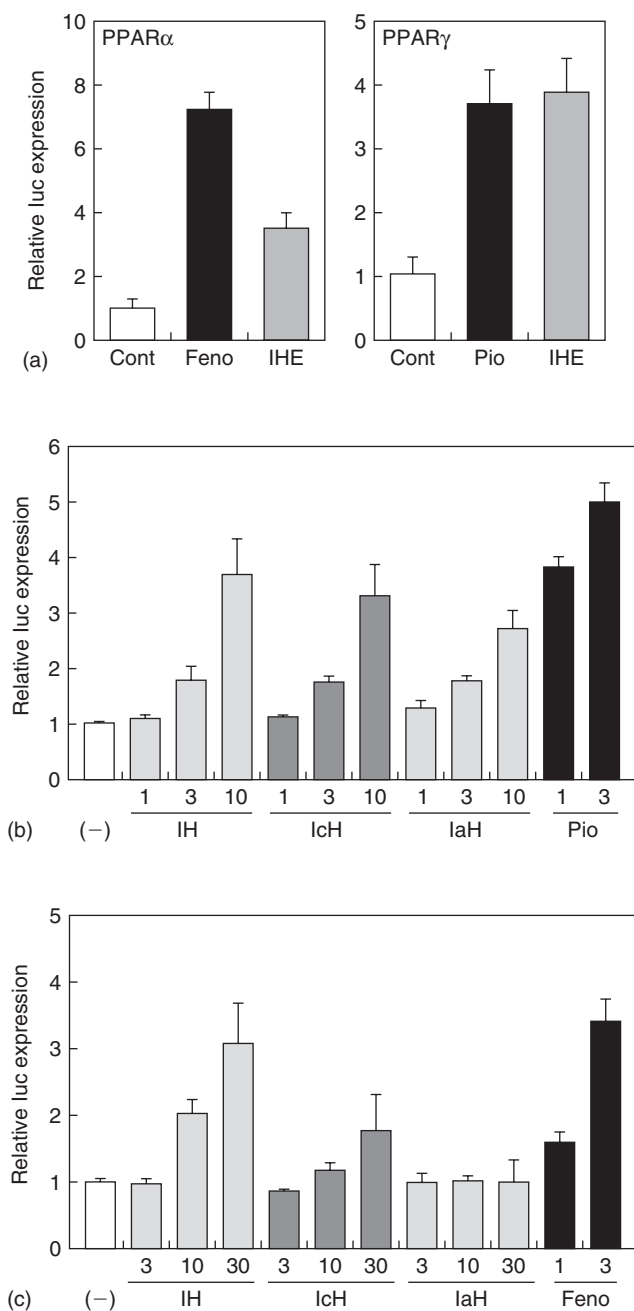
(c)


Figure 79.3 Transactivation of PPARs by IHE and isohumulones. (a) IHE activated transcription mediated by PPARs α and γ. Details of the assay are described below. (b) Activation of PPARγ by isohumulones. CV-1 cells were co-transfected with a luciferase reporter plasmid, pG5 luc (Promega), containing five copies of GAL4 UAS in the promoter region and an expression vector for the human PPARγ ligand-binding domain fused to the GAL4 DNA binding domain (DBD). Results show the relative luciferase expression levels normalized with the protein concentration of the cell lysates. (c) Activation of PPARα by isohumulones. HepG2 cells were co-transfected with pG5 luc and an expression vector for the human PPARα coding region fused to the GAL4 DBD. Isohumulone (IH), isocohumulone (IcH), and isoadhumulone (IaH) at the indicated concentrations were added to the transfected cells. Pioglitazone (Pio) and fenofibrate (Feno) were used as positive controls for PPARs γ and α transactivation, respectively.
Figure 79.4 Structure of isohumulone. (R: –CH$_3$CH(CH$_3$)$_2$; 2-(3-methylbutanoyl)-5-(3-methyl-2-butenyl)-3,4-dihydroxy-4-(4-methyl-3-pentenoyl)-2-cyclopentenone), isocohumulone (R: –CH(CH$_3$)$_2$; 2-(2-methylpropanoyl)-5-(3-methyl-2-butenyl)-3,4-dihydroxy-4-(4-methyl-3-pentenoyl)-2-cyclopentenone), and isoadhumulone (R: –CH(CH$_3$)C$_2$H$_5$; 2-(2-methylbutanoyl)-5-(3-methyl-2-butenyl)-3,4-dihydroxy-4-(4-methyl-3-pentenoyl)-2-cyclopentenone).

These results indicate that isohumulones activated transcription that was mediated by PPARs α and γ, suggesting that isohumulones may modulate reactions that are regulated by these transcriptional activators. Metabolic syndrome, which is particularly relevant to insulin resistance, is characterized by glucose intolerance, hyperinsulinemia, dyslipidemia, and hypertension, and is frequently associated with visceral obesity. Pharmacological treatment of this syndrome aims to reduce insulin resistance and other risk factors by modulating PPARs. Fibrate drugs, which act as ligands for PPARα, and thiazolidinedione drugs, which are ligands for PPARγ, are often used to treat hyperlipidemia and hyperglycemia, respectively. Combination therapy using these medications is an attractive option for the treatment of obese, type 2 diabetics. Compounds that have dual agonistic activity on both of these receptors have been shown to reverse symptoms of insulin sensitivity and dyslipidemia in obese diabetic animals (Murakami *et al.*, 1998; Ljung *et al.*, 2002). Therefore, amelioration of hyperglycemia and hyperlipidemia by activating PPARs with isohumulones should be possible.

Isohumulones Reduce Insulin Resistance and Prevent the Development of Diabetes in Mice

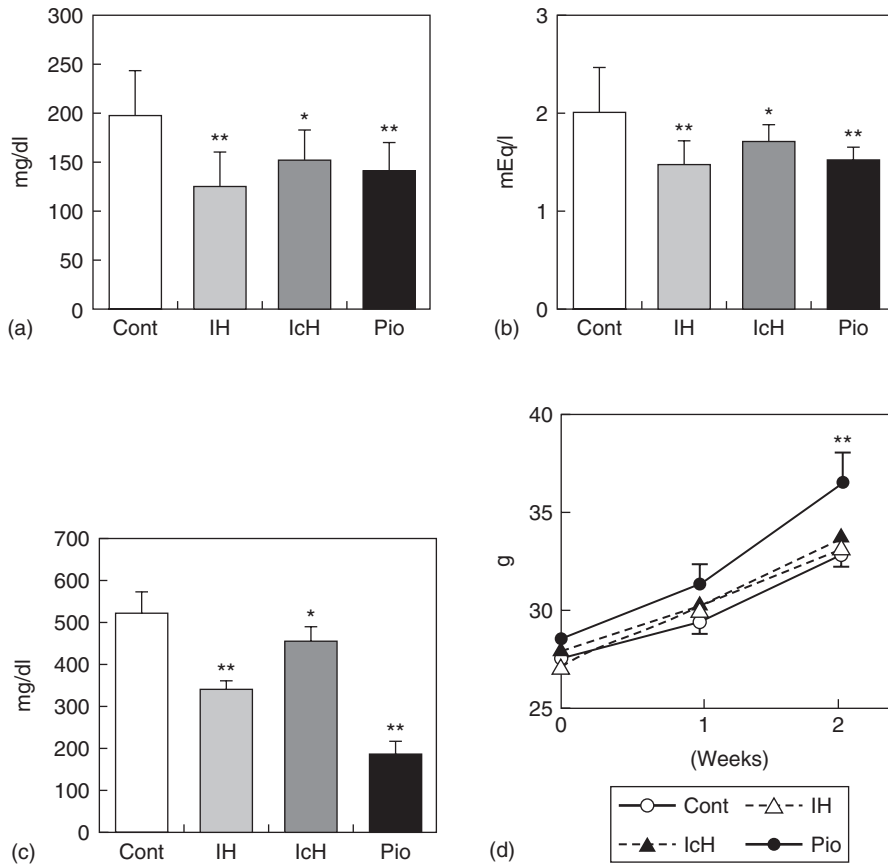
Treatment of KK-A^y mice with isohumulones for 2 weeks significantly lowered their plasma triacylglycerol (62.6% for isohumulone, 76.4% for isocohumulone, respectively) and free fatty acid (FFA) (73.1% for isohumulone, 84.8% for isocohumulone, respectively) levels. These reductions were comparable to those seen in 0.05% pioglitazone-treated mice (60.5% and 69.9%, respectively) (Figure 79.5a and b). The non-fasting plasma glucose levels of isohumulones-treated mice were also reduced to 65.3% of controls for isohumulone and 87.1% of controls for isocohumulone, although these levels were higher than those seen in animals fed pioglitazone (35.1%) (Figure 79.5c). There was


Figure 79.5 Isohumulone and isocohumulone prevented the development of diabetes in KK-A^y mice. Male KK-A^y mice were fed either a standard diet or a diet containing 0.18% isohumulone (IH), 0.18% isocohumulone (IcH), or 0.05% pioglitazone (Pio) for two weeks. Fasting blood samples were collected and plasma triacylglycerol and FFA levels were measured (a, b). Non-fasting plasma glucose levels were also determined (c), and body weights were measured weekly (d). Data are the means ± SD for six mice per group. *$p < 0.05$, **$p < 0.01$ vs. control.

a significant difference in body weight gain between these groups in spite of their equivalent caloric intake. Thus, pioglitazone induced a 10% increase in body weight, while isohumulones did not induce an increase in body weight compared to the control group (Figure 79.5d). As described above, IHE did not affect body weight gain in KK-A^y mice fed a normal diet. Therefore, the influence of isohumulones on body weight gain in mice seemed to be similar to that of IHE. These results suggest that isohumulones ameliorate the pathology of genetically diabetic KK-A^y mice without affecting body weight gain, whereas body weight increased after treatment with pioglitazone, an anti-diabetic PPARγ agonist.

Female C57BL/6N mice were fed a high fat diet for 12 weeks. During their last 14 days on the diet, they were orally administered isocohumulone. Oral glucose tolerance tests (OGTTs) and insulin tolerance tests (ITTs) were performed on their 10th and 14th day of isocohumulone treatment, respectively.

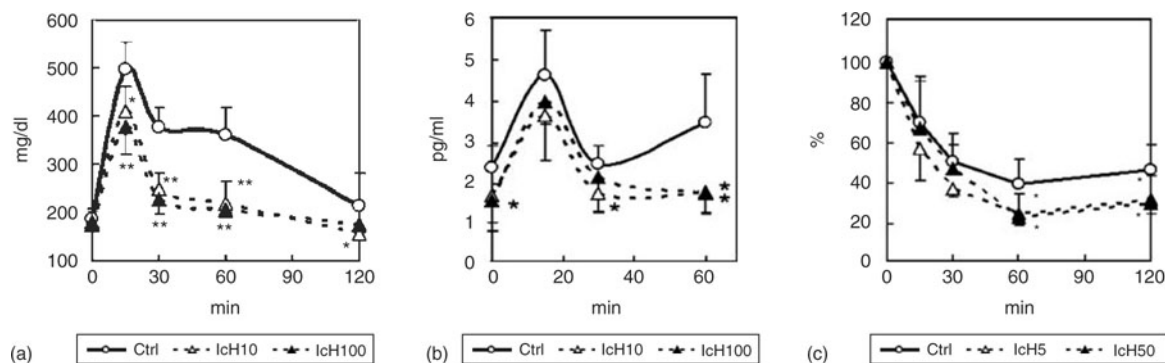
After glucose loading, plasma glucose levels in the mice treated with isocohumulone at 10 and 100 mg/kg/day were significantly reduced compared to mice treated with vehicle at all time points, except for the mouse treated with 100 mg/kg of isocohumulone at 120 min (Figure 79.6a). Fasting plasma insulin levels were significantly reduced in animals treated with 100 mg/kg isocohumulone (2,396 ± 520 and 1,605 ± 570 (pg/ml) for vehicle-treated and 100 mg isocohumulone-treated mice, respectively). Plasma insulin levels during the OGTT were also reduced in the isocohumulone-treated animals (Figure 79.6b). The insulin resistance indices (IR, (Mondon et al., 1981)) of mice treated with isocohumulone (1,094.4 ± 259.2 and 1,034.0 ± 259.2 for 10 mg isocohumulone-treated and 100 mg isocohumulone-treated mice, respectively) were significantly ($p < 0.01$ using the Dunnett's test) lower than that of the control group (2,217.3 ± 792.9), indicating that isocohumulone improved insulin sensitivity in mice fed a high fat diet. Modulation of insulin sensitivity was also observed after treatment with isohumulone; a significant decrease in IR was observed in the group receiving 100 mg/kg of isohumulone (1,240.2 ± 259.5, $p < 0.01$ using the Dunnett's test, data not shown). Results of the ITT showed a greater


Figure 79.6 Isocohumulone ameliorated insulin resistance in high fat diet-fed C57BL/6N mice. Female C57BL/6N mice were fed a high fat diet for 10 weeks. For glucose tolerance testing, isocohumulone (IcH) was orally administered to mice at a dose of 10 or 100 mg/kg body weight for 14 days. Control mice received buffer alone. The mice were then subjected to an OGTT. For oral glucose testing, D-glucose (1 g/kg body weight) was administered by stomach tube after an overnight fast. Blood samples were collected from the orbital sinus before and 15, 30, 60, and 120 min after delivery of the glucose load, under light anesthesia. Control mice received buffer alone. (a) Plasma glucose and (b) insulin concentrations were plotted on the graph (mean $\pm$ SD, n = 5–6). For insulin tolerance testing, high fat diet-fed mice were administered IcH at a dose of 5 or 50 mg/kg body weight for 10 days. For insulin tolerance testing, human insulin was injected intraperitoneally (0.75 U/kg body weight) into non-fasted animals. Blood samples were collected from the tail vein before and 15, 30, and 60 min after insulin injection and blood glucose levels were determined. Blood glucose concentrations during the ITT were plotted on the graph (mean $\pm$ SD, n = 6) (c). *$p < 0.05$ and **$p < 0.01$ for vehicle vs. treatment with IcH at each indicated time.

glucose-lowering effect in mice treated with isocohumulone for 10 days than in vehicle-treated animals (Figure 79.6c). Plasma glucose levels in mice treated with 5 or 50 mg/kg of isocohumulone were significantly reduced to 76.8% and 69.3% of controls after 60 min and to 82.8% and 69.3% of controls after 120 min. These results indicated that insulin resistance and glucose intolerance in obese mice fed a high fat diet improved after short-term oral administration of isohumulones.

Effect of Isohumulones on Liver and White Adipose Tissue of Mice

Quantitative real time RT-PCR analysis of the mRNAs for ACO and fatty acid translocase/CD36 (FAT) genes in the liver of KK-A^y mice treated with isohumulone, isocohumulone, or pioglitazone was performed (Figure 79.7a). ACO and FAT, whose expression levels are regulated by PPARα, are involved in peroxisomal β-oxidation of fatty acids and in the uptake of long-chain fatty acids through the cell membrane, respectively (Motojima *et al.*, 1998; Memon *et al.*, 2000).

Treatment of mice with isohumulone, isocohumulone, or pioglitazone increased ACO and its mRNA levels by 1.6-, 1.7-, and 2.7-fold, and FAT mRNA levels by 2.9-, 3.3-, and 2.8-fold, compared to the control mice, respectively. The significant increase in ACO and FAT mRNA levels in the pioglitazone-treated mice was likely due to activation of PPARα by pioglitazone. An increase in the activity of ACO was observed in the liver of C57BL/6N mice treated with isohumulone or isocohumulone (Figure 79.7b). These results indicated that the effect of isohumulones on liver was similar to that of IHE.

Isohumulones treatment unexpectedly resulted in only a fairly small increase in the expression of PPARγ-regulated adipocyte differentiation related protein (adipocyte-ADRP/aP2) and lipoprotein lipase (LPL) genes. These proteins are involved in lipid uptake and storage in the white adipose tissue (WAT) (Tontonoz *et al.*, 1994) of KK-A^y mice; only the LPL mRNA level in the mice treated with isocohumulone increased significantly, by 1.2-fold, although treatment with pioglitazone did increase the aP2 and LPL mRNA levels by 2- and 1.7-fold, respectively (Figure 79.7c). Histological analysis of subcutaneous WAT of the high fat diet-fed C57BL/6N mice treated with isohumulone, isocohumulone, or pioglitazone for 10 days revealed an increase in the number of small adipocytes after treatment with all three of these compounds compared to vehicle-treated mice (Figure 79.7d). These results suggested that isohumulones affect WAT as well as liver.

The Effects of Oral Isohumulones in Type 2 Diabetics: A Placebo-Controlled Pilot Study

The ethics committee of KIRIN Brewery Co., Ltd. approved this study, and it complied with the principles outlined in the Declaration of Helsinki. Written informed consent was obtained from all subjects. Twenty volunteers with mild, type 2 diabetes (both males and females) were included in this study. Ten men and 10 women were randomized into one of two groups receiving either placebo or a capsule containing 100 mg of IHE.

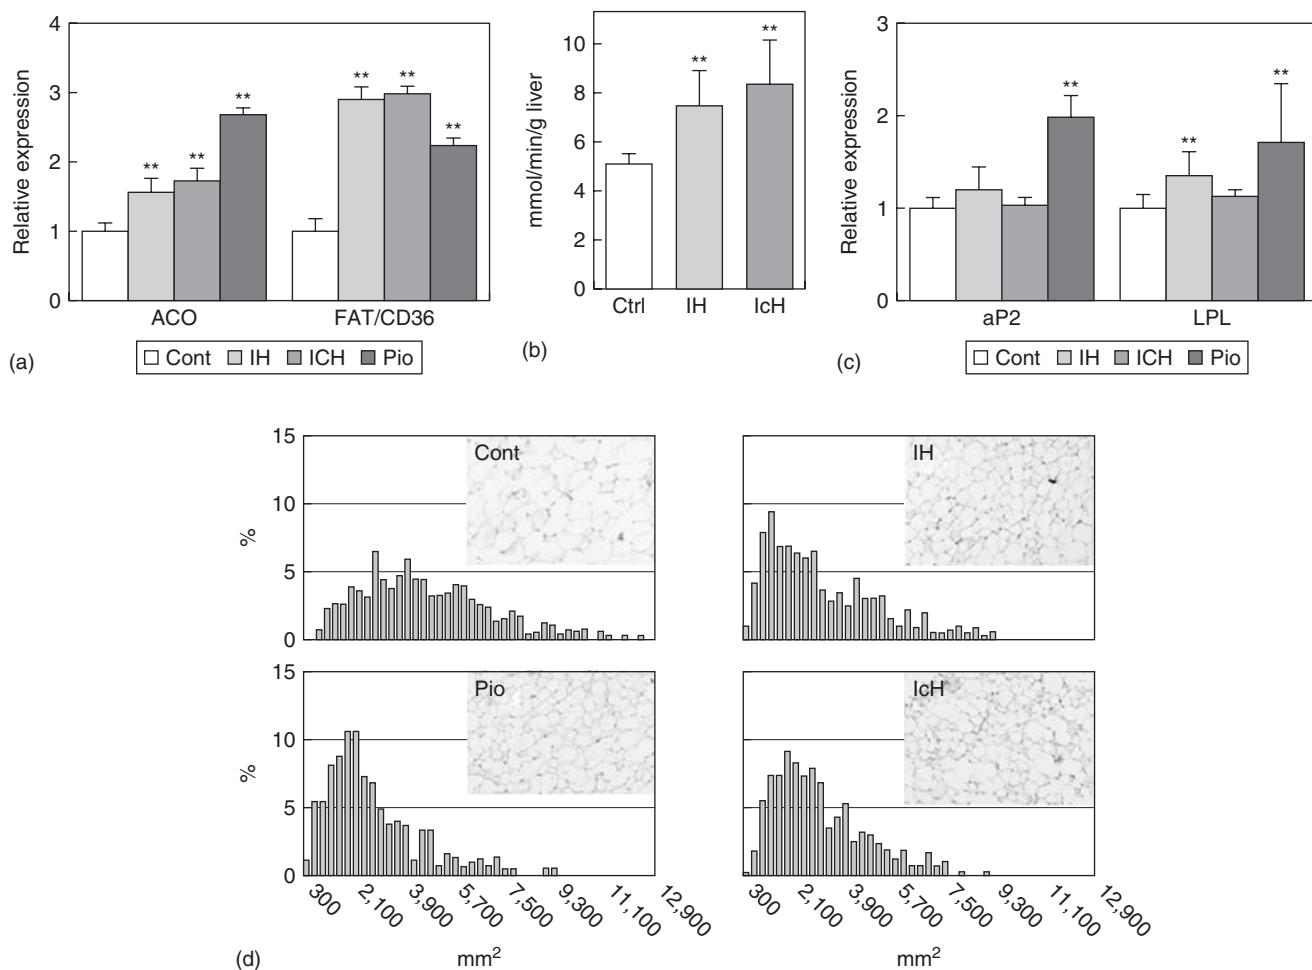
Supplementation of 10 mild diabetic patients with IHE over 8 weeks resulted in a significant reduction in their


Figure 79.7 Effects of isohumulone and isocohumulone on liver and WAT. (a and c) Total RNA was isolated from liver and subcutaneous adipose tissue of KK-A^y mice fed diets containing 0.18% isohumulone (IH), 0.18% isocohumulone (IcH), or 0.05% pioglitazone (pio). Quantitative RT-PCR was performed to measure the mRNA levels of liver ACO and FAT (a), and aP2 and LPL in WAT (c). Results are presented as relative expression levels normalized to the expression level in the control group (mean ± SD, $n = 6$). (b) ACO activity in the liver of C57BL/6N mice treated with IH or IcH at 100 mg/kg weight for 6 days. Six-week-old female C57BL/6N mice fed a standard diet were orally administered isohumulone or isocohumulone for 6 days. Their livers were then isolated and homogenized. The homogenates were centrifuged and their supernatants were used as an enzyme source. Data are presented as the amount of hydrogen peroxide produced by oxidation of palmitoyl-CoA in the homogenates. ** $p < 0.01$ vs. control. (d) Histological analysis and cell-size distribution of subcutaneous WAT in C57BL/6N mice. High fat diet-fed mice were orally administered vehicle (Cont), IH or IcH (100 mg/kg weight), or pioglitazone (Pio) (10 mg/kg weight) for 2 weeks. Their subcutaneous WAT was removed and fixed in 4% paraformaldehyde in phosphate-buffered saline (PBS). Fixed specimens were dehydrated, embedded in tissue-freezing medium, and frozen in liquid nitrogen. Sections (14 μm) were cut and stained with hematoxylin and eosin. More than 200 cells/mouse in each group were analyzed. Bar indicates 100 μm.

blood glucose and hemoglobin A1c levels by 10.1% and 6.4%, respectively; interestingly, a weak but significant reduction in blood glucose levels (7.3%) was also observed in the placebo control group. Furthermore, significant reductions in systolic blood pressure and blood levels of GPT, GOT, and γGPT were observed in the IHE-treated group (7.2%, 33.4%, 21.3%, and 25.6% reduction, respectively) (Table 79.4). These results indicated that isohumulones modulated insulin sensitivity in type 2 diabetic patients. Interestingly, in this latter study the patients also showed significant reductions in systolic blood pressure

and in the levels of serum markers of liver disorder. The amount of daily isohumulone intake from IHE was about 80 mg, which is approximately the amount of IHE present in 20 l of beer. Since this study was preliminary and the minimum effective dose of isohumulones has not yet been determined, we do not recommend attempting to obtain therapeutic doses of isohumulones by drinking sufficient quantities of beer. However, these results indicate that isohumulones in beer are worth investigating further as therapeutic agents for the treatment of metabolic syndrome associated with insulin resistance.

Table 79.4   Results of the placebo-controlled pilot study of the effects of hop extract in type 2 diabetic patients

	IHE		Placebo	
	0 Week	8 Weeks	0 Week	8 Weeks
Blood glucose (mg/dl)	127.1 ± 10.9	$114.3 \pm 10.4^*$	130.5 ± 12.0	$122.3 \pm 8.37^{**}$
HbA1c (%)	7.14 ± 0.36	$6.68 \pm 0.68^*$	7.00 ± 0.38	6.76 ± 0.65
Systolic blood				
Pressure (mmHg)	137.1 ± 13.6	$128.6 \pm 15.5^*$	129.0 ± 16.4	127.5 ± 15.3
GPT (IU/l)	40.8 ± 26	$27.2 \pm 11.0^*$	25.4 ± 18.0	24.8 ± 23
GOT (IU/l)	28.6 ± 13	$22.5 \pm 6.30^{**}$	25.7 ± 10.0	27.0 ± 16
γGTP (IU/l)	48.1 ± 41	$35.8 \pm 26.0^{**}$	75.3 ± 91.0	78.3 ± 110

Notes: Twenty volunteers with mild, type 2 diabetes (both males and females) were included in this study. The subjects were between 45 and 65 years of age (mean=53 years) and had fasting blood glucose and hemoglobin A1c levels between 110 and 140 (mg/dl) and 6.4 and 8.0 (%), respectively. IHE containing isohumulones at a purity of 79% was used in this study. The subjects were randomized to one of two groups that received either a placebo or a capsule containing 100 mg of IHE (equivalent to about 80 mg of isohumulones) twice a day for 12 weeks. Laboratory tests were performed every 4 weeks for 12 weeks. Data are indicated as the means $\pm$ SD.

$^*p < 0.01$ vs. 0 week of each group.
$^{**}p < 0.05$ vs. 0 week of each group.

Summary Points

- IHE, which consists mainly of isohumulones and is a required component of the beer-brewing process, showed an inhibitory effect on diet-induced obesity in mice.
- Inhibition of intestinal lipid adsorption by IHE was responsible to some extent for the effect of IHE in reducing body weight gain.
- Isohumulones improve insulin sensitivity and prevent the development of diabetes in mice.
- IHE and isohumulones modulate lipid metabolism, accelerate lipid oxidation, and suppress triacylglycerol biosynthesis.
- The modulatory effect of IHE and isohumulones on lipid metabolism via nuclear receptor peroxisome PPARs may also, at least in part, be responsible for its beneficial effects on body weight gain.

Moderate Beer Consumption: Effects on Silicon Intake and Bone Health

Ravin Jugdaohsingh & Jonathan J. Powell MRC Human Nutrition Research, Elsie Widdowson Laboratory, Fulbourn Road, Cambridge, UK

Abstract

Accumulated evidence suggests that dietary silicon (Si) is beneficial for bone and connective tissue health and that higher intakes of dietary Si are associated with higher bone mineral density (BMD) (a proxy for bone health). A major source of Si is whole grain cereals and their products, such as beer, which is brewed from macerated, malted whole grain barley. Beer is a top contributor to Si intake in men and is a source of highly bioavailable Si. Beer also has a modest alcohol content. It is well established that moderate ingestion of alcoholic beverages is associated with increased BMD but mechanisms are unknown. In a recent extensive review (Jugdaohsingh *et al.*, 2006) we have made a case for ethanol and Si as the two major constituents of alcoholic beverages that can positively influence BMD; the latter being nearly beer-specific. Indeed in a recent report, we showed that the association between moderate beer ingestion and BMD was significantly reduced when a correction was made for Si (Tucker *et al.*, 2004). This was not seen with the other types of alcoholic beverages (wine and liquor). In more recent detailed analyses (Tucker *et al.*, 2007 unpublished data) we confirmed these findings and showed that while the major positive effect of moderate beer ingestion on BMD is an ethanol effect, some could be attributed to Si. Thus *moderate* beer ingestion (1–4 UK units/day) could be advantageous to bone health by providing both an anti-resorptive and an anabolic component, namely ethanol and silicon, respectively.

APOSS	Aberdeen Prospective Osteoporosis Screening Study
BMD	Bone mineral density
Si	Silicon
HRT	Hormone replacement therapy

Introduction

Silicon (Si) is a major, naturally occurring element in animal diets, including the human diet (Powell *et al.*, 2005). Accumulating evidence over the last 30 years strongly suggests that dietary Si is beneficial to bone and connective tissue health (Sripanyakorn *et al.*, 2005) and, with our collaborators, we recently reported strong positive associations between dietary Si intake and bone mineral density (BMD) in US and UK cohorts (Jugdaohsingh *et al.*, 2004; Macdonald *et al.*, 2005). BMD, at the population level, is a proxy for functional bone health. A major source of dietary Si is whole grain cereals and their products including beer which is a macerated product of malted whole grain barley (Sripanyakorn *et al.*, 2004; Powell *et al.*, 2005), and beer is a top contributor to dietary Si intake in men (Jugdaohsingh *et al.*, 2002, 2004). Women drink much less beer so it's not a major contributor to Si intake in this population. Beer is also a source of alcohol (ethanol), and alcohol consumption *per se* strongly influences BMD and bone health (Jugdaohsingh *et al.*, 2006). In a preliminary analysis (global linear regression) we recently reported that Si intake from beer ingestion may explain some of the positive association between moderate beer ingestion and BMD (Jugdaohsingh *et al.*, 2004). In a more recent detailed analysis (Tucker *et al.*, 2007 unpublished data) we dissected out and compared the individual effects of the alcoholic beverages (beer, wine and spirits) on BMD and determined the contribution of Si to these associations. These results support our previous published findings of a contributory effect of Si from beer ingestion on BMD although the effect (attributable benefit) is small compared to that derived from the moderate ethanol ingestion (Jugdaohsingh *et al.*, 2004). Nonetheless, this was not seen with the other types of alcoholic beverages (wine and liquor) that have lower levels of Si and this is the first time that the effect of a non-ethanol component has been shown to contribute to the health benefit of moderate ingestion

of alcoholic beverages. This chapter summaries these findings and, prior to this, gives a brief overview/description of what Si is and its effects on BMD and bone health.

What Is Si?

Silicon, a non-metallic element with an atomic weight of 28, is the second most abundant element of the Earth's crust after oxygen (Sjöberg, 1996). It is also one of the most abundant trace elements in the human body, found at similar levels to selenium and zinc (Dobbie and Smith, 1982; Geigy Scientific Tables, 1984). Although widely distributed in the environment, Si is rarely found in its free form as it readily reacts with oxygen and water to form insoluble oxides (e.g. quartz, cristobalite and tridymite) and silicates (e.g. Ca, Mg, Al silicates), respectively, which at 92%, are the most common minerals on Earth (Klein, 1993). Biological and chemical weathering of these minerals leaches/releases soluble silicates or "silicic acids" into soil solutions, and natural water bodies, where Si is present in the latter at concentrations between 1 and 15 mg/l in the form of orthosilicic acid $[Si(OH)_4]$ (Farmer, 1986). Orthosilicic acid is a weak diprotic acid and the most stable Si species in aqueous solutions at low ($\leq$2 mM) total Si concentrations (Iler, 1979; Glasser and Lachowski, 1980; Glasser, 1982). However, at concentrations above 2 mM and around neutral pH, orthosilicic acid polymerizes to form a range of silica species from soluble dimers through aquated oligomers, polymers and colloids to solid phase silica, reducing the solubility and hence bioavailability of Si (Iler, 1979; Glasser and Lachowski, 1980; Glasser, 1982; Sjöberg, 1996; Taylor et al., 1997). Silicon is also present in silicones, which are synthetic (i.e. man-made) "organo-silicon" compounds, but these are rarely found in the diet or in nature in general.

Silicon, as orthosilicic acid, is neutrally charged at physiological pHs and is relatively chemically inert. Thus, until recently, it was suggested not to take part in any biochemical reactions/interactions in higher animals, even though it is known to be actively taken up and transported by some primitive organisms and plants to form elaborate silica exoskeletons and biogenic silica, respectively the formation of which is assisted and controlled by proteins and polysaccharides (Cha et al., 1999; Kröger et al., 1999; Perry and Keeling-Tucker, 2000). Recently, however, Kinrade et al. (1999, 2004) reported that $Si(OH)_4$ interacts readily with alkyl diols of sugars to form five- and six-coordinate Si complexes suggesting that interactions with organic bio-molecules is at least possible. Functional, biological binding sites for Si (orthosilicic acid) still remain elusive, however.

Where Is Si Found?

Humans are exposed to numerous sources of silica/Si including dust, pharmaceuticals, supplements, cosmetics and medical implants and devices. However, the major and most important source of exposure for the majority of the population is the diet, and typical Si intakes are 20–50 mg/day in Western countries (Pennington, 1991; National Academy of Science, 2001; Jugdaohsingh et al., 2002; McNaughton et al., 2005). Intakes in males (33.1 $\pm$ 19.4 mg/d) is higher than in females (25.0 $\pm$ 11.4 mg/d), which is mainly due to higher intake of beer in males (Pennington, 1991; Jugdaohsingh et al., 2002, 2004; Sripanyakorn et al., 2005); beer is a high natural source of Si (see below). Intake also decreases significantly with age in adults (0.1 mg for every additional year) (National Academy of Science, 2001; Jugdaohsingh et al., 2002).

Food sources

Silicon is taken up and actively accumulated by some plants and deposited as solid amorphous silica (phytoliths) in the cell lumen and walls (Sangster and Hodson, 1986; Epstein, 1999). As such, plant-based foods tend to have higher levels of Si (1–23 mg/100 g) compared to foods of animal origin, which contain very little Si (<1 mg/100 g; Powell et al., 2005; Table 80.1). Amongst plant-based foods, un-refined ("whole") cereal grains (oats, barley, wheat) and grasses (e.g. rice) have the highest Si levels (mean 8 $\pm$ 6 mg/100 g; Powell et al., 2005). Up to 50% of the Si is present in the hulls and husks, which is lost in the refined/processed food. However, grain products such as breakfast cereals, flour and bread, biscuit, rice, pasta, cake and pastry, etc. are still high dietary sources of Si (Pennington, 1991; Jugdaohsingh et al., 2002; Powell et al., 2005). Naturally high levels of Si are also present in some vegetables, namely beans, spinach and root vegetables and some herbs (mean 1.79 $\pm$ 2.42 mg/100 g; Pennington, 1991; Powell et al., 2005). Fruits generally contain low levels of Si except for bananas and dried fruits and nuts (mean 1.34 $\pm$ 1.30 mg/100 g; Powell et al., 2005). However, very little Si is digested in the gut and made available from bananas (<2%; Jugdaohsingh et al., 2002). As already stated earlier, animal and dairy products are low in Si (Powell et al., 2005). Slightly higher levels of Si may be present in offals and the less popular eaten parts (Pennington, 1991) presumably due to the presence of large vessels, since Si is suggested to contribute to the integrity of blood vessels such as the aortic wall lining (the tunica intima) (Loeper et al., 1979).

Silicon-containing additives, typically silicates, are added to manufactured and processed foods as anti-caking agents, hygroscopic agent, emulsifiers, thickeners, stabilizers, coating agent and anti-foaming agents; for example, in beverage mixes, salad dressings, snack foods and sugar substitutes (Anonymous, 1974; Villota and Hawkes, 1986; Hanssen and Marsden, 1987). As noted earlier, solid phase silicates are thought to be inert and generally not absorbed in the gastrointestinal tract (see below), and, under UK regulations, solid phase silicate additives are added at less than

Table 80.1   Silicon in the diet

Food Groups	Si (mg/100g)			Si (mg/portion)

Wines	0.68–2.31	1.35	3	1.69 (125 g)
Port/sherries	1.24–1.26	0.13	2	0.62–0.63 (50 g)
Liquor/spirits	0.06–0.20	0.13	1	0.052 (40 g)

Note: Mean silicon (Si) levels (mg/100 g and mg/portion) in the different food groups and in non-alcoholic and alcoholic beverages. Plant-based foods, in particular whole grain cereals and products (including beer), are high sources of dietary Si, while dairy and animal products contain negligible levels. For each food group the range, mean level and number of foods analyzed are given. Mean portion sizes are given in parentheses. Table is adapted from Powell *et al.* (2005). *N*: number of samples. TDS: sample from the Food Standard Agency Total Diet Study.

2% weight of the food (Anonymous, 1974; Dobbie and Smith, 1982).

Drinking water

Silicon in drinking water is derived from the weathering of rocks and soil minerals and since different types of minerals weather at different rates, the concentration of Si in drinking water is dependent on the surrounding geology (Farmer, 1986). Concentration ranges between 0.2 and 14 mg/l in tap water, although the majority tends to be at the lower/mid-end (2–6 mg/l) (Dobbie and Smith, 1982; Birchall and Chappell, 1989; Roberts and Williams, 1990; Parry *et al.*, 1998; Powell *et al.*, 2005). Concentrations in mineral waters are typically higher, especially those from volcanic sources, such as Volvic (16 mg/l), Spritzer (30 mg/l) and Fiji (40 mg/l) mineral waters, from France, Malaysia and Fiji, respectively (Jugdaohsingh *et al.*, 2006 unpublished

data). Silicon levels in tea, coffee, squash, etc. are derived from the water used to prepare these beverages and potentially also from the silicate additives that are present in instant tea and coffee (Powell *et al.*, 2005).

Beer and other alcoholic beverages

Whole grain barley and hops are used in making beer and the maceration (mashing) process breaks down the phytolithic silica in the husks, etc. into soluble forms, so this beverage is high in Si (see Chapter 46; also: Pennington, 1991; Bellia *et al.*, 1994; Sripanyakorn *et al.*, 2004; Powell *et al.*, 2005; Table 80.1). We previously reported a mean (±SD) concentration of 19.2 ± 6.6 mg Si/l beer (Sripanyakorn *et al.*, 2004). Not surprisingly, therefore, beer can be a major contributor to Si intake in the Western diet, especially for men who consume considerably more beer than women (Pennington, 1991; Jugdaohsingh *et al.*, 2002; Sripanyakorn

et al., 2004; Powell *et al.*, 2005), contributing, on average, between 11% and 24% of total daily Si intake (Jugdaohsingh *et al.*, 2002, 2004). The consumption of beer in the United Kingdom was 173 pints per capita in 2004 (http://www.kirin.co.jp/english/ir/news_release051215_4.html), confirming beer as a significant dietary source of Si in the UK diet.

In contrast, levels of Si in wines are more varied and can be as high as some beers (see Chapter 46; Powell *et al.*, 2005; Table 80.1). Silicon levels in liquors/spirits is much lower being 1.3 ± 0.04 mg/l (Jugdaohsingh *et al.*, 2004).

Silicon Metabolism

Absorption

Recent studies have increased our understanding of the bioavailability of Si from food and other sources, but the mechanism(s) of absorption of Si from the gastrointestinal tract is/are yet to be established (Calomme *et al.*, 1998; Reffitt *et al.*, 1999; Van Dyck *et al.*, 1999; Jugdaohsingh *et al.*, 2002; Sripanyakorn *et al.*, 2004, 2005; Sripanyakorn *et al.*, 2005 unpublished data). Uptake from the gastrointestinal tract is primarily dependent on the speciation of Si, and soluble orthosilicic acid $[Si(OH)_4]$ is the most bioavailable and readily absorbable species (Yokoi and Enomoto, 1979; Calomme *et al.*, 1998; Reffitt *et al.*, 1999; Van Dyck *et al.*, 1999; Jugdaohsingh *et al.*, 2002; Sripanyakorn *et al.*, 2004, 2005; Sripanyakorn *et al.*, 2005 unpublished data). Thus, drinking water, beer and other fluids/beverages can provide the most readily bioavailable source of Si in the diet, which, coupled with the fact that fluid ingestion can account for $\leq 20\%$ of the total dietary intake of Si (Bellia *et al.*, 1994), makes these sources significant contributors to bio-active Si exposure (Reffitt *et al.*, 1999; Jugdaohsingh *et al.*, 2002). At least 55% of Si in beer is absorbed and

much is then rapidly excreted in urine within 6–8 h of ingestion (Bellia *et al.*, 1994; Sripanyakorn *et al.*, 2004) (Figure 80.1). Absorption and excretion profiles were similar or slightly higher than for orthosilicic acid (Sripanyakorn *et al.*, 2004) (Figure 80.1a and b) suggesting that beer alcohol must only minimally affect the metabolism of Si and confirming that Si is present in beer as absorbable and bioactive orthosilicic acid (Sripanyakorn *et al.*, 2004).

Silicon is also readily absorbed from food sources (mean 41% of ingested dose) suggesting that much phytolithic silica is broken down to soluble species (e.g. orthosilicic acid) in the gastrointestinal tract, prior to absorption (Reffitt *et al.*, 1999; Jugdaohsingh *et al.*, 2002).

Excretion

The main route of elimination/excretion of absorbed Si is via the kidneys into urine (Berlyne *et al.*, 1986; Reffitt *et al.*, 1999). Indeed, renal function appears to be a good determinant of plasma Si concentration (Hosokawa and Yoshida, 1990; Roberts and Williams, 1990; D'Haese *et al.*, 1995; Sanz-Medel *et al.*, 1996; Parry *et al.*, 1998). Silicon is not associated with plasma proteins and thus it is readily filtered by the renal glomerulus (Adler and Berlyne, 1986; D'Haese *et al.*, 1995), and eliminated with little tubular reabsorption. Hence, urinary Si excretion is a good proxy for absorption, or of gastrointestinal uptake into serum (Reffitt *et al.*, 1999) and this is commonly used/exploited in Si absorption studies to study the bioavailability of Si from Si-containing foods and compounds.

Tissue Distribution, Function and Essentiality

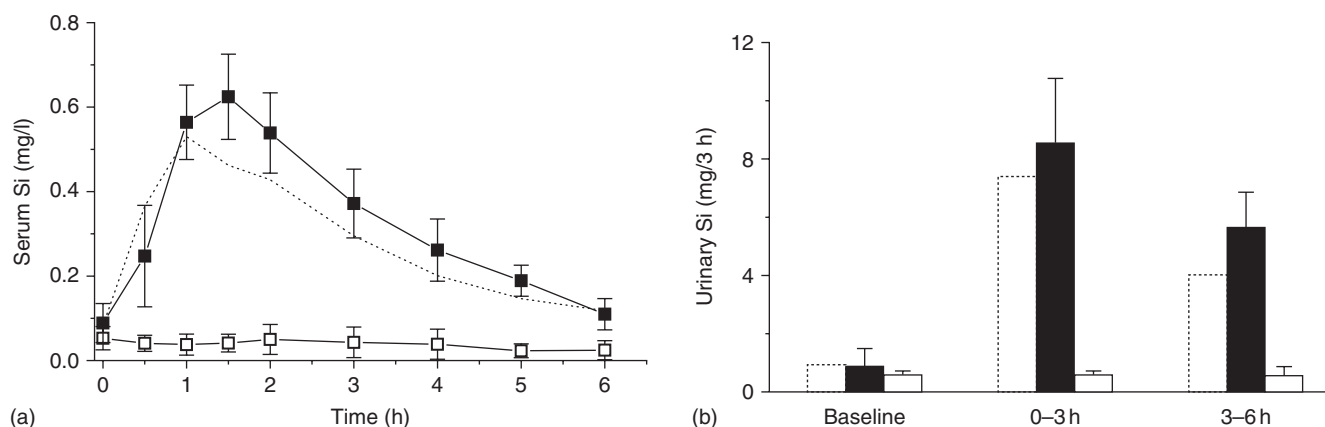
Some absorbed Si is retained by the body and all tissues contain some Si, but highest levels are found in bone and


Figure 80.1 Bioavailability of silicon from beer. (a) Mean ($\pm$ SD) serum silicon (Si) and (b) urinary Si excretion (mg/3 h), in eight subjects following the ingestion of 600 ml beer containing 22.5 mg Si and 4.6% alcohol (■—■, *black bars*), and 600 ml solution containing 4.6% ethanol and negligible amounts of Si <0.02 mg (□—□, *white bars*). For comparison, the absorption and urinary excretion profiles for orthosilicic acid are shown (*dotted line*). The results suggest that Si in beer is highly bioavailable. Further, speciation studies confirmed that Si is present as orthosilicic acid in beer (Sripanyakorn *et al.*, 2004).

other connective tissues, such as skin, nail, trachea, tendons and aorta and very much less (10- to 20-fold less) in soft tissues (Le Vier, 1975; Carlisle, 1986; Jugdaohsingh *et al.*, 2006 unpublished data). Silicon is suggested to be integrally bound to connective tissues and their components and to play an important structural role (Schwarz, 1973) as Si deprivation has detrimental effects on these tissues (Carlisle, 1972; Schwarz and Milne, 1972), as is also speculated to occur with normal aging with the decline in tissue Si levels (McCarty, 1997). *Vice versa*, increasing Si intake has been reported to have beneficial effects on these tissues, *especially* bone where much of current work has concentrated (Loeper *et al.*, 1979; Schiano *et al.*, 1979; Eisinger and Clairet, 1993; Hott *et al.*, 1993; Lassus, 1993, 1997; Rico *et al.*, 2000; Jugdaohsingh *et al.*, 2004; Barel *et al.*, 2005; Spector *et al.*, 2005; Calomme *et al.*, 2006). The potential importance of Si in bone health is thus discussed below.

Dietary Si and Bone

Mounting evidence over the last 30 years strongly supports a biological role for Si in bone and connective tissue health. This includes cellular, animal and human studies (see Sripanyakorn *et al.*, 2005 for a review of the evidence). Recent studies have shown that dietary Si, as soluble orthosilicic acid, has anabolic effects on human osteoblast-like cells and in animal models of post-menopausal osteoporosis (Hott *et al.*, 1993; Rico *et al.*, 2000; Calomme *et al.*, 2006). Increased type I collagen synthesis, osteocalcin secretion and alkaline phosphatase activity have been reported in human osteoblast-like cells (Reffitt *et al.*, 2003; Arumugam *et al.*, 2006). In animal studies, supplemental Si not only inhibits bone loss but also increases BMD above controls, suggesting Si may have both anti-resorptive and anabolic properties (Hott *et al.*, 1993; Rico *et al.*, 2000).

There are few studies of Si in humans, but these have also shown that supplemental Si has both anti-resorptive and anabolic properties (Schiano *et al.*, 1979; Eisinger and Clairet, 1993; Spector *et al.*, 2005). Additionally, in a recent cross-sectional study in the Framingham Offspring Cohort we reported that dietary Si intake was positively and significantly associated with BMD in pre-menopausal women, less so in men and not at all in post-menopausal women (Jugdaohsingh *et al.*, 2004). Large differences in BMD, up to 10%, were observed between the highest (>40 mg/d) and lowest (<14 mg/d) Si intake categories in men and pre-menopausal women with similar results obtained using a linear regression model. These results, in pre- and post-menopausal women, we recently confirmed in a cohort of the UK population (Macdonald *et al.*, 2005). Using the APOSS (Aberdeen Prospective Osteoporosis Screening Study) cohort we similarly showed that dietary Si intake was significantly positively associated with BMD at the hip and spine of pre-menopausal women. We also showed a similar correlation in post-menopausal women

but only in those currently on hormone replacement therapy (HRT) (Macdonald *et al.*, 2005). A weaker (non-significant) correlation was found in past-HRT users and no correlation in those who had never taken HRT. These two studies strongly suggest that higher intake of dietary Si is associated with higher BMD, a marker of bone strength and bone quality, and also suggests a potential interaction between Si and hormonal status.

Altogether, the accumulated evidence suggests that Si plays an important role in bone health. However, although a number of possible mechanisms have been proposed the exact role/biochemical function of Si remains unknown.

Beer Ingestion and Bone Health

Moderate alcohol consumption (up to 14 g alcohol/d (1 serving/d) for women and up to 28 g/d (2 servings/d) men) seems to be beneficial to health *per se*, in contrast to excessive alcohol consumption/alcohol abuse that is associated with increased risk of morbidity and mortality (De Loromier, 2000). Thus moderate consumption of alcoholic beverages is associated with higher BMD, especially in post-menopausal and elderly women (Jugdaohsingh *et al.*, 2006); differences in BMD of 1–16% have been reported between drinkers and abstainers/minimal drinkers, with highest BMD in moderate drinkers (Feskanich *et al.*, 1999; Rapuri *et al.*, 2000; Tunner and Sibonga, 2001; Williams *et al.*, 2004; see also Jugdaohsingh *et al.*, 2006 for a review of current evidence). There are, however, few studies in men and pre-menopausal women and previous studies have used simple linear regression models to test for association when the relationship between alcohol consumption and health status is described as "J" or "U" shaped. In addition many have inconsistently adjusted for potential confounders of BMD. Hence there is still a need for well-controlled, robust studies, and the individual effects of the different classes of alcoholic beverages (beer, wine, liquor) on BMD has also not been studied or dissected out.

We have recently studied the effects of the different classes of alcoholic beverages (beer, wine and spirits) on BMD in men, pre- and post-menopausal women of the Framingham Osteoporosis cohort, using both continuous and categorical analyses with adjustment for all known potential confounding factors of BMD (Tucker *et al.*, 2004; Tucker *et al.*, 2006 unpublished data). From these analyses, linear regression analysis showed that alcohol intake was positively associated with adjusted BMD at the hip sites and lumbar spine in men and women. Categorical analysis by alcohol intake supported these findings, and showed differences in BMD of 4–6% at the trochanter between those ingesting moderate amounts of alcohol and abstainers/non-drinkers (Tucker *et al.*, 2007 unpublished data). Differences existed between men, pre- and post-menopausal women and between the different classes of alcoholic beverages. For men, associations (with BMD) for beer intake

was > liquor > wine intake, while for post-menopausal women associations for wine intake ≥ beer = liquor. Our findings thus support current evidence that moderate consumption of alcohol may be beneficial to bone health, but also suggest that the different types of alcoholic beverages may have different effects on BMD and gender, that the other (non-alcoholic) components of the beverage may have additional/contributory effect on the association between alcohol intake and BMD. We have investigated one such component, namely Si, which is found almost exclusively in beer, compared to the other alcoholic beverages (see below).

Beer Silicon and Bone

The mechanism of action of moderate alcohol consumption on BMD is less clear. Although in our recent review (Jugdaohsingh et al., 2006) a case was made for the acute suppression of bone resorption as the primary effect of moderate ethanol ingestion, the effect of minerals/nutrients obtained from moderate alcohol consumption has not been well studied. Indeed, as noted above these non-alcohol constituents may contribute to the effect/association between alcohol intake and BMD. Since beer is a major source of bioavailable Si, we have investigated whether the contribution of Si from beer ingestion could contribute to the positive effects of moderate alcohol consumption on bone. Firstly, one 300–574 ml size serving of beer would contribute between 3.8 and 16 mg Si/day (or 2–9 mg/d absorbed if bioavailability is taken into consideration), which could be enough to detect an association with BMD based on Si intake and BMD data (Jugdaohsingh et al., 2004). Indeed, an increase in Si intake of 5–6 mg/d was associated with a 2–5% increase in BMD at the Trochanter in men and pre-menopausal women, respectively. Secondly, in previous work, we looked at the association between beer intake and BMD, with and without correcting for Si intake. Correcting for the Si contribution from beer attenuated the positive association and reduced or negated the significance between beer intake and BMD (Jugdaohsingh et al., 2004). Similar investigations on the intake of non-beer alcohols showed no effect of Si correction on the alcohol-BMD association, due to the small contribution of Si intake from non-beer alcohols (Jugdaohsingh et al., 2004). Thus these findings suggest that the Si component of beer may explain/contribute to some of the positive effects of moderate alcohol consumption on bone. However, as noted previously, these findings are based on basic regression models as an initial "global overview" and further, more detailed studies are required using categorical data to really dissect out the role of Si vs. that of ethanol and/or other components in the association of the intakes of different alcoholic beverages with bone health.

We recently completed these detailed analyses, that is, using both linear and categorical analysis of alcohol intake (Tucker et al., 2006 unpublished data). We confirmed our previous findings, including that adjustment for Si intake reduces the magnitude and significance of the association between beer intake and BMD in men and pre-menopausal women but not post-menopausal women (Tucker et al., 2006 unpublished data). Further, categorical analysis in men indicated that some of the effects for moderate beer consumption on BMD may be attributed to Si intake from beer ingestion. As previously reported, adjustment for Si intake had no effect on the associations between wine or liquor intake and BMD as expected since wine and liquor are lesser and negligible sources of dietary Si, respectively (Powell et al., 2005). These results suggest that the main effect of moderate alcohol consumption on BMD is an ethanol effect, which is suggested to act on bone resorption (Rapuri et al., 2000; Tunner and Sibonga, 2001; Jugdaohsingh et al., 2006). However, these results also provide some evidence for a non-ethanol, bone active component in beer, namely Si. This is the first time a non-ethanol effect has been dissected out and reported. The Si effect is moderate and observed at the higher intake categories and in contrast to ethanol, Si is more likely to act on bone formation (Jugdaohsingh et al., 2004; Sripanyakorn et al., 2005). Thus moderate beer ingestion may not only inhibit bone resorption but also increase bone formation which could make beer unique amongst the other alcoholic beverages.

Summary Points

- Dietary Si is a major component of the daily diet; 20–50 mg/d in the Western diet.
- Higher intake of dietary Si is associated with higher BMD (a marker of bone strength and bone quality) in men, pre- and post-menopausal women on HRT.
- Major sources of dietary Si are whole grain cereals and their products including beer, a macerated product of whole grain barley.
- Beer is a top contributor to daily Si intake in men, who are typically beer drinkers and beer is one of the most highly bioavailable source of Si.
- *Moderate* ingestion of beer, up to 1 serving/d (or 14 g alcohol) for women and up to 2 servings/d (28 g alcohol) for men, is associated with increased BMD; an increase of 4–6% at the trochanter compared to abstainers (non-drinkers).
- This effect is mainly an alcohol (ethanol) effect, but at least a small proportion of the increased BMD in men, at the trochanter, could be attributed to Si intake from beer ingestion.
- Moderate ingestion of beer may provide both an anti-resorptive and an anabolic component, namely ethanol and Si, respectively.

Biolabeling of Xanthohumol in Hop Cones (*Humulus Lupulus* L., Cannabaceae) with Stable and Radioactive Precursors for Biosynthetic and Metabolic Studies

Hans Becker and Stefanie Berwanger Pharmakognosie und Analytische Phytochemie der Universität des Saarlandes, Saarbrücken, Germany
Norbert Frank German Cancer Research Center (DKFZ) Chemoprevention, Im Neuenheimer Feld, Heidelberg, Germany

Abstract

The biosynthesis of xanthohumol (Xn), a prenylated chalcone from hop cones has been studied by feeding ^{13}C labeled precursors to hop cuttings. Feeding of [ring-^{13}C6] phenylalanine resulted in incorporation of the B-ring of the chalcone. [1-^{13}C] acetate and [2-^{13}C] malonate were incorporated in the A-ring according to the established biosynthesis of chalcones. The biosynthetic pathway of the prenyl side chain was attributed to the deoxyxylulose or methylerythrothiol (MEP) pathway. Uniform labeled ^{13}C-glucose (2.5%) led to a 9-fold increase of ^{13}C abundance of every carbon atom of the molecule. These results prompted us to perform labeling studies with radioactive ^{14}C-glucose which resulted in Xn with a specific activity of up to 318 μCi/mmol. The radioactive Xn can be used for distribution and metabolic studies in experimental animals.

Introduction

According to the "German Reinheitsgebot," beer is exclusively made from water, malt and hops. Hops is used for more than 500 years in brewery due to its bitter acids which are located in specific glands of the female hops cones and which contribute to the bitter taste and to the stability of beer.

Besides these bitter acids, hops – and therefore even beer – contains other compounds, from which in recent years mainly the phenolic compounds have attracted attention because of their interesting physiological properties. Thus Gerhäuser *et al.* (2002a) isolated 51 compounds from unstabilized beer and tested them for potential cancer chemopreventive activities. Some of these compounds showed inhibitory effects on enzymes involved in carcinogen metabolism (inhibition of phase 1 cytochrome P450 1 A activity),

induction of NAD(P)H:quinone oxidoreductase as well as anti-inflammatory properties (inhibition of lipopolysaccharide-mediated induction of inducible nitric oxide synthase, inhibition of cyclooxygenase 1). Among these phenolic compounds xanthohumol (Xn) has shown the most outstanding activities and was therefore chosen for further detailed tests on its chemopreventive potential (Gerhäuser *et al.*, 2002b).

Besides the above-mentioned activities Xn is able to scavenge reactive oxygen species, including hydroxyl- and peroxyl radicals and to inhibit superoxide anion radical production. It demonstrates anti-inflammatory properties not only by inhibition of cyclooxygenase-1 but also by inhibition of cyclooxygenase-2 activity and it shows anti-estrogenic potential. Antiproliferative mechanisms of Xn to prevent carcinogenesis in the progression phase include inhibition of DNA synthesis and induction of cell cycle arrest in S phase, apoptosis and cell differentiation. Xn at nanomolecular concentrations prevents carcinogen-induced preneoplastic lesions in mouse mammary gland organ culture. The anti-infective potential of Xn in comparison with other hop constituents and Xn-metabolites was summarized by Gerhäuser (2005).

Xn belongs to a group of prenylated chalcones and flavanones which are located in the glands of the female cones as well as the bitter acids (Stevens *et al.*, 1997). The amount of Xn in hop cones differs between the various varieties. It ranges from 0.23% (Hersbrucker Spalt) to 0.95% (Hallertauer Taurus) (Biendl, 2002/2003).

During the brewing process most of Xn is transformed into the flavanon iso-xanthohumol. Following only relative small amounts of Xn can be detected in beer. According to Stevens *et al.* (1999), American beers contain between 0.005 mg/l (wheaten beer) and 0.69 mg/l (porter). We analyzed

German beers with Xn ranging from 0.05 to 0.16 mg/l (Cernko and Becker, unpublished results).

Due to the promising results regarding the chemopreventive potential of Xn, new brewing techniques have been developed to increase the yield of Xn in beer recently (Wunderlich *et al.*, 2005). With these techniques and depending on the addition of roasted malt or special Xn-enriched roasted malt extracts, dark beers with more than 10 mg Xn/l were achieved.

Metabolites of Xn have been identified through transformation with rat liver microsomes (Yilmazer *et al.*, 2001) and in rat feces (Nookandeh *et al.*, 2004). *In vivo* tissue distribution and the bioavailability of Xn have still to be clarified for its future commercial or therapeutic use.

For bioavailability studies, radiolabeled compounds have been widely used (Vitrac *et al.*, 2003) because these compounds and their metabolites can be easily traced *in vivo*. Since no chemical synthesis of Xn has been published so far, biolabeling seemed to be an appropriate method for obtaining [13]C- and ^{14}C labeled Xn. The biolabeling method uses the plant metabolism for the incorporation of isotope into the respective natural compound by feeding labeled biosynthetic precursors of this compound to the plant. The choice of a suitable isotope depends on its stability in the molecule and on the commercial availability (and its price) of precursor compounds.

For tracing a radiolabeled compound and its metabolites *in vivo*, it is important to know the labeling position within the molecule as even fragments of the molecule could be included into radiodetection. It is not possible to precisely determine the incorporation pattern and ratio of ^{14}C into the molecules for each carbon. However by using the stable isotope ^{13}C, distinct labeling patterns can be obtained, as this isotope can easily be detected and quantified by using quantitative ^{13}C-NMR-technique. Therefore such experiments, using ^{13}C labeled precursors, are mainly carried out for biosynthesis studies, because the fate of a labeled precursor during plant metabolism can be easily traced.

To clarify the labeling positions and ratios in Xn for further ^{14}C experiments and to clarify the hitherto unknown biosynthesis of the prenyl side chain of Xn, we carried out experiments by feeding ^{13}C labeled potential known biosynthetic precursors (Berwanger *et al.*, 2005a) to hops. Studies on biosynthesis of bitter acids in hops were carried out by this method by Goese *et al.* (1999).

Biosynthesis of Xn

It is quite sure that the chalcone moiety is synthesized by a combination of the phenylpropane pathway (ring B) and the acetate/malonate pathway (ring A) (Heller and Forkmann, 1968). The prenyl side chain may be formed either by the classical acetate-mevalonate pathway or by the deoxyxylulose/methylerythrothiol (MEP) pathway (Eisenreich *et al.*, 1998; Rohmer, 1999). Direct labeled

precursors to distinguish between the two pathways for the prenyl side chain were not available. Glucose is a universal nutrient for plants. For biosynthetic studies either uniform or 1-^{13}C labeled glucose was used in *in vitro* cultures (e.g. Adam *et al.*, 1998), *in vitro* crown plantlets (Umlauf *et al.*, 2004) or in cuttings from plants (e.g. Goese *et al.*, 1999). To distinguish between the two alternative pathways [1-^{13}C] glucose or uniform labeled [U-^{13}C] glucose has been successfully applied in various cases (Adam *et al.*, 1998; Eisenreich *et al.*, 1998). Whereas the classical mevalonate pathway leads to a symmetric labeling of the prenyl side chain (C-2″, C 4″, C-5″), the MEP-pathway will lead to the labeling of C-1″ and C-5″ (see Figure 81.1). With the latter precursor also a labeling of the two ring systems in specific positions and the connecting C-3 unit is expected.

Selection of potential precursors

To label specifically the B-ring ^{13}C labeled phenylalanine seemed to be a suitable precursor. It was expected that the amino acid is metabolized by phenylalanine-ammonium-lyase (Pal) to cinnamic acid, followed by hydroxylation in para position to *p*-coumaric acid. The activated form of this acid (*p*-coumaroyl-CoA) should then condensate successively with three molecules of acetate via malonate to yield the A-ring of Xn. 1-^{13}C-acetate or 2-^{13}C-malonate were the respective precursors which were commercially available.

Furthermore we fed glucose as general metabolite either as [U-^{13}C] glucose or as [1-^{13}C] glucose. The labeling pattern with [1-^{13}C] glucose should allow elucidation of the biosynthetic origin of the prenyl side chain. Incorporation was detected by means of quantitative ^{1}H and ^{13}C NMR spectrometry (Braun *et al.*, 1996).

Feeding conditions ^{13}C-experiments

For our feeding experiments a similar setup was used as described by Goese *et al.* (1999). Hop sprouts were obtained from a hop variety rich in Xn (Hallertauer Taurus). Fifteen short sprouts of approximately 2 cm containing 2–3 cones were cut from the plant using a razor blade. Their stems were immediately immersed into one of the following solutions in Gamborg B5 medium (Gamborg *et al.*, 1968):

0.5% [ring – [13]C6] phenylalanine
0.5% [2-^{13}C] acetate
0.5% [2-^{13}C] malonate
1% [1-^{13}C] glucose
2.5% [U-13C] glucose

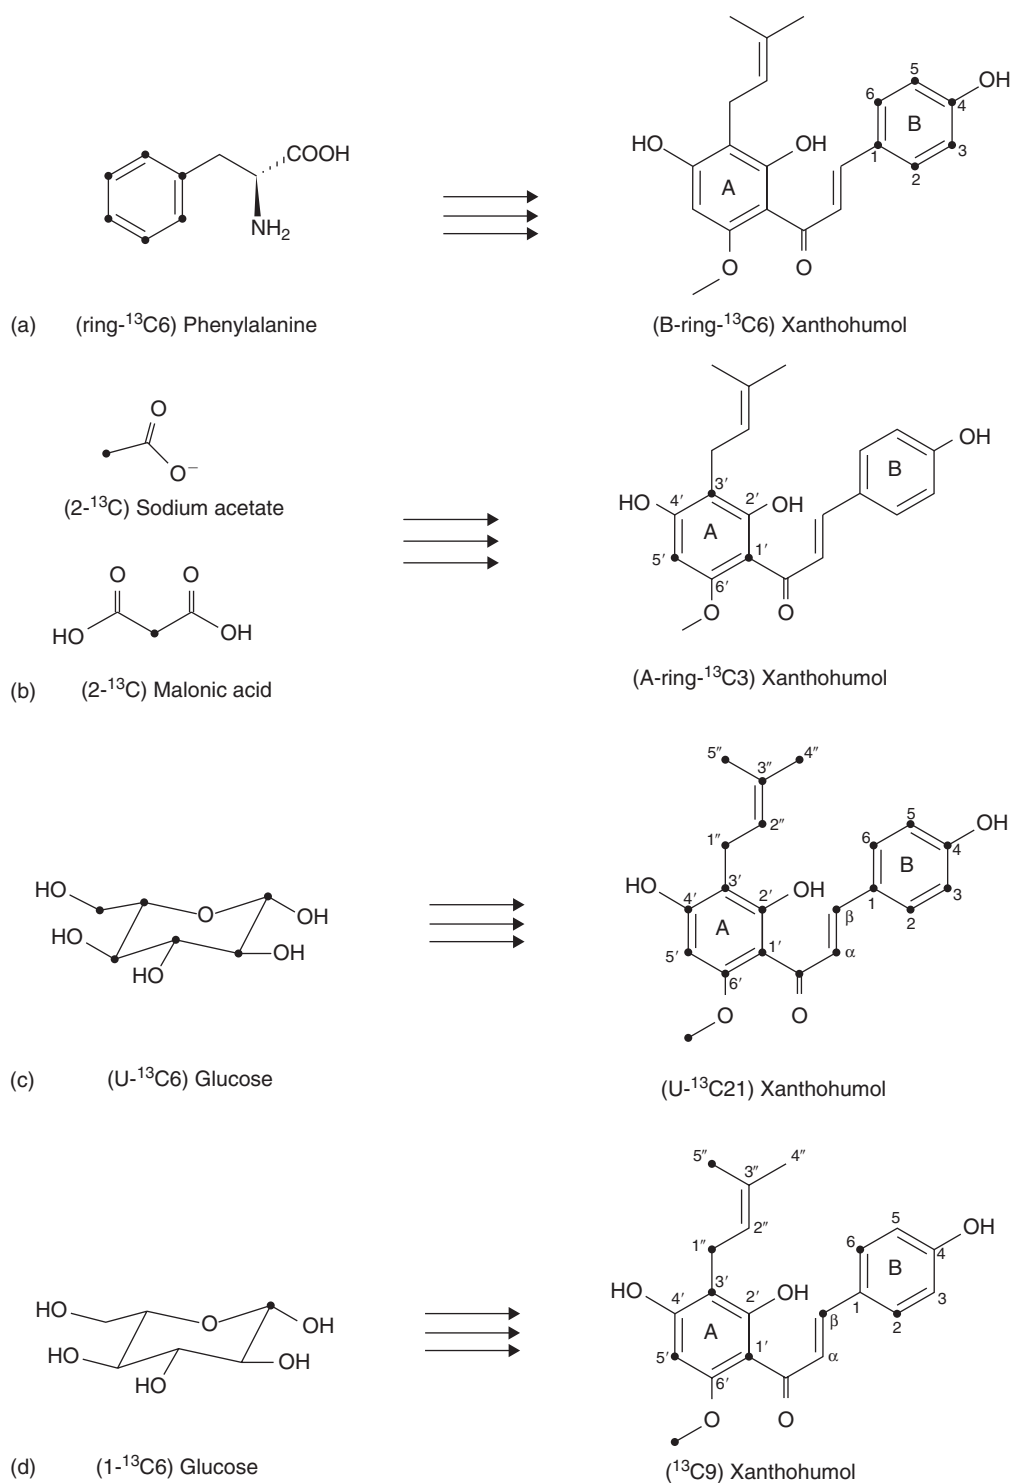
The stems were left for 6–11 days until wilting occurred. The cones were then cut, dried at 40°C and stored at −20°C until further use.


Figure 81.1 Labeling pattern of xanthohumol with ^{13}C precursors: (a) incorporation of [ring [13]C6]phenylalanine; (b) incorporation of [2-^{13}C] acetate or [2-[13]malonate]; (c) incorporation of [U-[13]C6]glucose; (d) incorporation of [1-^{13}C]glucose. • = labeled carbon.

Isolation of Xn

The hop cones were minced and extracted with hot methanol under reflux for 1 h. After cooling, the extract was filtered and evaporated to dryness. Fractionation and isolation of Xn was achieved by column chromatography with a modified method according to Gardner (1972). About 1 g of the extract were applied to a small column (8 cm length,

2 cm i.d.) filled with a mixture (1/1) of kieselgur and poly-vinylpyrrolidone. Elution was by a gradient of 100% methanol to methanol/ethylacetate −0.1% formic acid (water saturated) 60:40. Fractions were monitored by thin layer- and high-performance-liquid-chromatography.

NMR-spectroscopy

NMR spectra were recorded in CDCl$_3$/CD$_3$OD (92:8, v/v), [^{1}H-NMR (500 MHz), ^{13}C-NMR (125 MHz)] relative to CDCl$_3$ at δ$_H$ = 7.24, δ$_C$ = 77.0 using a Bruker DRX spectrometer. ^{13}C measurements were recorded with the inverse gated decoupling pulse sequence in the presence of 0.1 M Cr(acac)$_3$ (Braun *et al.*, 1996). For integration the signal-to-noise ratio was at least 40:1.

Incorporation of ^{13}C

The results of the experiments for the incorporation of ^{13}C labeled precursors for the chalcone core were in full agreement with the established data (Heller and Forkmann, 1968) (see Figure 81.1).

[2-^{13}C] acetate and [2-^{13}C] malonate led to a significant labeling of the expected positions C-1′, C-3′ and C-5′ in ring A. The presence of ^{13}C in these positions was at least 1.6-fold compared to the natural 1.11% of this isotope. [Ring-^{13}C$_6$] phenylalanine was nearly uniformly incorporated into ring B whereas the other carbon atoms seemed not to be affected.

The feeding of [1-^{13}C] glucose resulted in the enrichment of ^{13}C into the positions C-1″ and C-5″ thus proving that the MEP-pathway is active in the biosynthesis of the prenyl side chain. This is in agreement with hop bitter acids where the prenyl side chain is formed in the same way (Goese *et al.*, 1999).

In addition to the above-described experiments we carried out labeling with uniform labeled glucose ([U-^{13}C$_6$] glucose), which led to a 9-fold enrichment in nearly every carbon atom of the Xn-skeleton (Berwanger *et al.*, 2005a) (see Table 81.1).

Radioactive labeling of Xn

On the basis of these results it was possible to perform experiments (Berwanger *et al.*, 2005b) with uniform labeled radioactive glucose ([U-^{14}C$_6$]glucose) by feeding a solution containing 55 mCi [U-^{14}C$_6$]glucose to hop cones. This incorporation experiment resulted in radioactive Xanthohumol with a high specific activity of 318 μCi/mmol.

The experimental design was the same as for ^{13}C incubation. We conducted two different feeding experiments: (1) the total amount of radioactive glucose was fed on the first day of incubation and (2) the same amount was fed successively over 4 days. In both experiments 40 mg radiolabeled Xn of high chemical purity was isolated. The specific activity of Xn in the two experiments differed by a factor of 6. Whereas in experiment (1) the specific activity

was 318 μCi/mmol, it was only 53.1 μCi/mmol in experiment (2). This big variation in ^{14}C incorporation may be explained by decreasing activity of the enzymes involved in the biosynthesis of secondary metabolites and/or by a reduction of the transport of the precursors.

Outlook

The resulting radioactive Xn can be used for bioavailability and distribution studies (Frank *et al.*, unpublished results) that are urgently needed to determine the target organs for its chemopreventive effects. Moreover future studies could be done *in vitro* and *in vivo* with specifically labeled B-ring Xn or A-ring Xn or even side chain labeled Xn by using the respective radiolabeled precursors.

The high efficacy of isotope incorporation and the easily feasibility of the incubation, is the main advantage of this biolabeling method. A further positive point of this method is the concurrently labeling of other pharmacologically interesting hop compounds, such as bitter acids and the phytoestrogen 8-prenylnaringenin, which could also be used for pharmacological *in vitro* tests or *in vivo* distribution studies.

Summary Points

- Xanthohumol shows various effects related to chemoprevention.
- Biosynthesis of xanthohumol was elucidated by feeding ^{13}C labeled precursors to hop cones, such as [ring-[13]C$_6$] phenylalanine, [2-^{13}C] acetate, [2-^{13}C] malonate, [1-^{13}C] glucose, [U-^{13}C] glucose.
- The labeling pattern of the chalcone skeleton proved the well-established biosynthetic pathway. The biosynthesis of the prenyl side chain was attributed to the deoxyxylulose/methylerythrothiol pathway.
- Radioactive xanthohumol is obtained by feeding uniform labeled ^{14}C-glucose.
- Radioactive xanthohumol can be used for bioavailability and distribution studies.
- Feeding ^{14}C-glucose leads to other labeled hop compounds (e.g. 8-prenylnaringenin).

Epicatechin and Its Role in Protection of LDL and of Vascular Endothelium

Tankred Schewe Institute of Biochemistry and Molecular Biology I, Heinrich Heine University of Duesseldorf, Duesseldorf, Germany
Helmut Sies Institut fuer Biochemie und Molekularbiologie I, Duesseldorf, Germany

Abstract

(−)-Epicatechin is a dietary polyphenol exerting beneficial effects on the cardiovascular system as judged from epidemiological and clinical studies. Cocoa products, red wine as well as green and black tea are most prominent sources for (−)-epicatechin and related flavan-3-ols. The possible contribution of beer still remains to be substantiated. Comparison of the uptake and elimination kinetics as well as of plasma peak concentrations revealed that among dietary flavan-3-ols, (−)-epicatechin exhibits sufficient bioavailability. The catechol arrangement of the B ring in flavan-3-ols accounts for radical-scavenging, reducing and metal ion-chelating properties *in vitro*, which may play a protective role in the gastrointestinal tract, whereas for the metabolites in blood plasma these properties are largely lost if this grouping is blocked through glucuronidation and/or methylation. This fact may explain why flavan-3-ols and other flavonoids show strong anti-oxidant activities *in vitro* such as inhibition of low-density lipo-protein (LDL) oxidation, whereas the corresponding activities *in vivo* or *ex vivo* are only moderate. Flavan-3-ols serve anti-oxidant functions in a broader sense suppressing reactions of prooxidant enzymes such as myeloperoxidase, lipoxygenases and NADPH oxidases. High flavan-3-ol intake through a model meal or beverage gives rise to anti-atherosclerotic, anti-inflammatory and anti-platelet activities *in vivo* as well as improvement of endothelial function of arterial vessels, and lowering of blood pressure. Part of these actions is closely connected with modulation of nitric oxide metabolism of vascular endothelium. *In vitro*, (−)-epicatechin protects vascular endothelial cells against a number of cytotoxic and proapoptotic actions of oxLDL. Mechanistically, the protective actions involve prevention and scavenging of superoxide anion radical, peroxynitrite and nitrogen dioxide radical, collectively leading to elevation of bioavailability and bioactivity of nitric oxide and, in turn, to improvement of endothelial function.

List of Abbreviations

CVD	Cardiovascular diseases
FMD	Flow-mediated dilation
HPLC	High-performance liquid chromatography
HDL	High-density lipoprotein
LDL	Low-density lipoprotein
oxLDL	Oxidatively modified low-density lipoprotein
MPO	Myeloperoxidase
eNOS	Endothelial nitric oxide synthase
iNOS	Inducible nitric oxide synthase

Introduction

Epidemiological evidence accumulated showing that consumption of red wine, tea and cocoa products is inversely associated with the risk of cardiovascular diseases (CVD) and cardiac death, which is attributed to a high content of flavonoids and other dietary polyphenols (Maron, 2004; Buijsse *et al.*, 2006). Among flavonoids, (−)-epicatechin has found particular interest, because its bioavailability surpasses that of structurally related compounds such as (+)-catechin, (−)-catechin and other flavan-3-ols (Manach and Donovan, 2004; Donovan *et al.*, 2006, and references therein). Moreover, protective actions of (−)-epicatechin on the cardiovascular system are substantiated by a number of *in vivo* and *in vitro* studies. A recent study suggested that the *in vivo* effects are largely mediated by (−)-epicatechin (Schroeter *et al.*, 2006). (−)-Epicatechin also occurs in beer. Most knowledge on absorption, pharmacokinetics and biological activities of (−)-epicatechin and related polyphenols *in vivo* comes from studies with humans consuming red wine, tea or high-flavanol cocoa products.

Chemistry

(−)-Epicatechin is the prototype of flavan-3-ols (also termed catechins), a major subgroup of flavonoids of plant origin (besides flavonols, flavones, flavanones, isoflavones and anthocyanins). Further congeners are among others, the epimer (+)-catechin as well as (−)-epicatechin gallate, (−)-epigallocatechin and (−)-epigallocatechin gallate. Natural mixtures of flavan-3-ols contain not only monomeric compounds but also oligomers, the procyanidins, consisting of 2–10 monomer units linked through C—C bridges between the flavan ring systems. The catechol arrangement at the B ring is a crucial structural feature of flavan-3-ols, which determines several chemical properties such as reductant and free radical-scavenging activities and chelation of transition metal ions. (−)-Epicatechin monomer contains a total of five hydroxyl groups, which lend the lipophilic flavan system sufficient hydrophilicity as reflected by an octanol–water partition coefficient of 1.5 (Schroeder *et al.*, 2003), thus rendering the molecule soluble in both lipophilic and aqueous environment, and hence passively permeable through biomembranes. Unlike the flavonol quercetin, having the same number and positions of hydroxyl groups, in (−)-epicatechin the double bond systems of the three rings (A, B and C) are not conjugated with each other, which gives rise to distinct chemical and biological properties. Most importantly, (−)-epicatechin exhibits less prooxidant and cytotoxic properties at high concentrations than quercetin. The high degree of conjugation of the double bonds enables quercetin to be oxidized to an array of quinoid oxidation products, so-called quinone methides (Awad *et al.*, 2002), which cannot be expected to such an extent with (−)-epicatechin or related flavan-3-ols.

The chemical structures of some monomeric and oligomeric flavan-3-ols are shown in Figure 82.1. For details as to chemistry of flavonoids and related polyphenols the reader may refer to the respective monograph by Haslam (1998).

Absorption, Biotransformation and Biological Kinetics

Monomeric (−)-epicatechin is satisfactorily absorbed from the small intestine. Dependent on ingested dose and food source of flavan-3-ols (red wine, green or black tea or cocoa products in most studies) total plasma concentrations including conjugated metabolites between 0.2 and 6 μM have been reported (Manach and Donovan, 2004, and references therein). The peak level is usually reached 1–2 h after intake (Schroeter *et al.*, 2006). Its epimer (+)-catechin, although contained in most dietary sources in comparable amounts, gives rise to much lower plasma levels (∼0.1 μM) than (−)-epicatechin, possibly owing to faster metabolism, so that its bioavailability is considerably lower (Holt *et al.*, 2002). The same is true for galloylated flavan-3-ols, which exhibit faster renal elimination. In plasma, however, they are conjugated to a lesser extent than (−)-epicatechin. Procyanidins are not absorbed, except for possible trace amounts of the dimers procyanidin B$_1$ and B$_2$ (Holt *et al.*, 2002). The half-lives of monomeric flavan-3-ols range between 1.5–7 h and are shorter than that of the flavonol quercetin (for review, see Manach and Donovan, 2004).
Figure 82.1 Major flavan-3-ols identified in beer (Weiß and Hofmann, 2006; modified). **I**, (+)-catechin; **II**, (−)-epicatechin; **III**, epicatechin(4β→8)-epicatechin (procyanidin B$_2$); **IV**, [epicatechin(4β→8)]$_2$-epicatechin (procyanidin C$_1$); **V**, epicatechin(4β→6)-epicatechin (procyanidin B$_5$). The stereochemistry in **III**, **IV** and **V** was not considered. The Arabic numerals in **I** designate the positions of OH groups.

While food rich in protein and lipid does not seemingly influence the absorption and elimination of flavan-3-ols, bread and sugar-containing test meals enhance the bioavailability of (−)-epicatechin and (+)-catechin to 140% of controls, which is thought to be due to decrease in elimination half-life (Schramm *et al.*, 2003). An opposite effect has been postulated for ethanol, which accelerates the urinary excretion of flavan-3-ols by virtue of its diuretic action (Donovan *et al.*, 2002). This effect of ethanol should be kept in mind in evaluating beer as source of flavan-3-ols. Thus, the (−)-epicatechin content of beer has been reported to be only about one-fourth of that of red wine (de Pascual-Teresa *et al.*, 2000), whereas the ethanol contents of the two beverages are comparable.

In human plasma the following (−)-epicatechin metabolites occurring 1 h after administration were identified in the order of decreasing average levels: epicatechin-3′-glucuronide > epicatechin > 4′-*O*-methyl-epicatechin-3′-glucuronide > 3′-*O*-methyl-epicatechin ≈ 4′-*O*-methyl-epicatechin-5- (or 7)-glucuronide, indicating that upon absorption a sizeable amount of (−)-epicatechin is conjugated involving both glucuronidation at B and A rings and selective methylation of 3′-OH or 4′-OH of the catechol arrangement of the B ring (Natsume *et al.*, 2003). Except for nonmetabolized epicatechin and 3′-*O*-methyl-epicatechin, these compounds were also isolated from human urine (Natsume *et al.*, 2003), so that the metabolic fate of 3′-*O*-methyl-epicatechin remained unexplored. Sulfated metabolites were also reported.

The metabolic profile of (−)-epicatechin metabolites is possibly not limited to conjugative metabolism, but may also include oxidative conversions, which were not addressed so far. Oxidative conversions of flavonoids are known, however, for galangin, kaempferide and isoflavones via cytochrome P450 catalysis (Walle, 2004). Moreover, flavonoids are prone to non-enzymatic oxidations by reactive oxygen species, which are expected to be favored under pathophysiologic conditions.

A considerable part of dietary (−)-epicatechin is not absorbed as unchanged molecule, but is metabolized by the microflora of the large intestine yielding a number of absorbable phenolic acids such as 4-hydroxybenzoic, 3,4-dihydroxybenzoic, 3-methoxy-4-hydroxybenzoic and 3-methoxy-4-hydroxyhippuric acids as well as di-hydroxylated phenylvalerolactone, which were detected in human plasma in conjugated form (Rechner *et al.*, 2002; Rios *et al.*, 2003; Manach and Donovan, 2004). The total amount of these microbial metabolites in urine accounts for as much as 15% of the ingested dose. Procyanidins are also metabolized via this route yielding other phenolic acids. The efficiency of the intestinal microbial breakdown of procyanidins, however, decreases with increasing oligomer size, which may be due to some antibacterial activity of larger oligomers.

The fact that a number of dietary polyphenols, such as procyanidins and anthocyanins, among the compounds occurring in beer, are not or only poorly absorbed does not rule out beneficial biological actions for the human organism. In addition to serve as substrates for microbial conversions, they may also directly act in the gastrointestinal tract. Besides protection against development of gastrointestinal tumors such as colon cancer, they are capable of reducing and, thus, of detoxifying food-derived hydroperoxides, which are sometimes abundant in high-fat meals. By this mode, dietary polyphenols are expected to counteract postprandial oxidative stress (for review, see Sies *et al.*, 2005b).

An incomplete or retarded absorption of certain flavan-3-ols from the gastrointestinal tract may also be advantageous for their modulating effects on water and chloride secretion by the small intestine as suggested from mild inhibitory effects of cocoa flavan-3-ols on forskolin-stimulated cystic fibrosis transmembrane conductance regulator activity (Schuier *et al.*, 2005). This action may plausibly explain the known capability of cocoa products of alleviating diarrhea.

Flavan-3-ol content of beer

Data as for the content of (−)-epicatechin, (+)-catechin and total flavan-3-ols in beer (Table 82.1) vary by two orders of magnitude. Arts *et al.* (2000) detected sizeable amounts in various sorts of green tea, black tea and red wine as well as low amounts in white wine and chocolate milk, but failed to detect them in lager beer (Heineken), possibly owing to a too high detection limit of their analytical method. By contrast, de Pascual-Teresa *et al.* (2000) analyzed a broad array of Spanish foodstuffs and beverages and presented a complete pattern of flavan-3-ols of beer without specifying the sort of beer; the content of (−)-epicatechin was found to be 1.8 ± 0.6 mg/l and that of total flavan-3-ols 6.4 ± 1.9 mg/l, which is in fair agreement with recently reported data, where the high-performance liquid chromatography (HPLC) method was evaluated by recovery experiments, revealing recovery rate of >90% (Kusche, 2005).

De Pascual-Teresa *et al.* (2000) also reported that soluble cocoa, red wine and green tea have 3.3-, 4.2- and 69-fold, respectively, higher contents of (−)-epicatechin than beer.

Table 82.1 Content of flavan-3-ols in beer[1]

(−)-Epicatechin	(+)-Catechin (mg/l)	Total flavan-3-ols	Reference
<0.5	<1	<2	Arts *et al.* (2000)
1.8	7.3	6.4	de Pascual-Teresa *et al.* (2000)
132	–	–	Gorinstein *et al.* (1997a)
1.2	5.8	–	Kusche (2005)
11.1	60.5	–	Weiß and Hofmann (2006)

[1] Unpublished data for lager beer (mg/l): Epicatechin 0.6, catechin 1.8, dimer procyanidin B3 1.5, dimer gallocatechin–catechin 1.8, kindly provided by Dr. A. Scalbert, Unité de Nutrition Humaine, INRA, Centre de Recherche de Clermont-Ferrand/Theix, France (personal communication, with permission).

On the other hand, beer surpassed white wine and coffee 3-fold. Moreover, hardly any flavanols were found in vegetables, which usually contain, however, other polyphenols.

Gorinstein et al. reported an (−)-epicatechin content of 132 ± 2.5 mg/l in a special sort of beer and achieved in their clinical studies with this beer beneficial effects on some blood parameters (Gorinstein et al., 1997a, b). In a variety of clinical studies using cocoa or chocolate, relevant beneficial effects were achieved with an intake of at least 40 mg (−)-epicatechin or 140 mg total flavan-3-ols, respectively (Ding et al., 2006; Engler et al., 2006, and references therein). Such an intake can be regarded as clue to evaluate whether a special sort or brand of beer may have a flavan-3-ol-related health benefit.

The phenolic constituents of beer including flavonoids originate from barley or wheat malt (70–80%) and hop (20–30%). The flavan-3-ol content of malts varies depending on barley cultivar and growing area. The flavan-3-ols of beer contribute to bitter-astringent taste of the beverage.

In general, the flavan-3-ol content of beverages and foodstuffs strongly depends on the source variety, stage of ripeness, post-harvesting conservation, and processing as well as on origin of the sample. The behavior of flavan-3-ols during beer processing has recently been studied in detail (Kusche, 2005). While the mashing program had no or only slight influence, the oxygen-sensitivity of beer polyphenols turned out to be strongly temperature-dependent. The sensitivity to heat increased in the order (+)-catechin < procyanidin B_3 < prodelphinidin B_3 (Kusche, 2005). Interestingly, (−)-epicatechin was not detected during the mashing process; it was formed, however, through depolymerization of procyanidins during wort boiling (Kusche, 2005).

Collectively, a conclusive appraisal of the (−)-epicatechin content of beer is not possible until a systematic study with a large variety of sorts and brands of beer using an evaluated analytical method will have been conducted.

Although in beer the content of (+)-catechin is at least four times higher than that of (−)-epicatechin, the following sections focus on (−)-epicatechin, since in human blood plasma (−)-epicatechin and its metabolites predominate due to a better bioavailability (Manach and Donovan, 2004, and references therein).

Flavan-3-ols and antioxidant capacity

Flavanols and other dietary polyphenols are capable of reducing oxidants and of scavenging injurious radicals in vitro. This capacity can be quantified in complex mixtures by various methodological approaches. The antioxidant capacity of a beverage is a useful parameter to evaluate both stability during storage and the protectant action against dietary oxidants during the gastrointestinal passage. For example, it has been estimated that 500 ml of beer has the same antioxidant capacity as 150 ml of red wine (Paganga et al., 1999), which may roughly correlate with the (−)-epicatechin content of these beverages. The antioxidant capacity of red wine per serving is topped by cocoa drink (Lee et al., 2003).

Estimation of the total antioxidant capacity of blood plasma upon intake of a polyphenol-rich diet, although assessed in numerous studies, does not provide useful information, since secondary metabolic effects by other plant constituents are mirrored rather than direct polyphenol effects (Lotito and Frei, 2006). The antioxidant capacity of plasma is mainly determined by endogenous antioxidants such as urate, which occurs in the millimolar range, whereas the plasma level of flavan-3-ols barely exceeds micromolar concentrations. By contrast, the plasma level of α-tocopherol (vitamin E) is a relevant parameter for the antioxidant function of plasma, because this natural antioxidant accumulates in plasma lipoproteins rendering them more resistant to oxidative modification (see below).

By virtue of their antioxidant capacity, flavan-3-ols are capable of counteracting oxidative stress. Oxidative stress has been defined as a shift in the balance between prooxidant and antioxidant processes of the organism toward prooxidants (Sies, 1985).

Flavan-3-ols and cardiovascular diseases (CVD)

CVD are prominent causes of death in industrial countries. The risk of CVD is strongly influenced by aspects of individual lifestyle, including nutrition. Epidemiological prospective cohort studies revealed that a general high intake of flavonoids from fruits, vegetables, tea, red wine and cocoa products is associated with a lowered risk of CVD mortality (Huxley and Neil, 2003, and references therein). The more specific contribution of flavan-3-ols, an important subgroup of flavonoids, to this health benefit is documented by respective studies on the intake of dark chocolate and other cocoa products, one of their most prominent dietary source. A recent meta-analysis of literature data revealed an inverse correlation between chocolate consumption and CVD mortality (Ding et al., 2006). This conclusion is convincingly supported by a 15-year follow-up study on a cohort of 470 elderly men, in which high cocoa intake was significantly correlated with both lowered blood pressure and diminished CVD mortality (Buijsse et al., 2006). It must be kept in mind, however, that this correlation is an association and does not prove cause–effect relationship, because it may also reflect a more general lifestyle favorable for cardiovascular health.

Although such extensive in vivo studies as with cocoa products were not conducted with beer, intake of beer may also be beneficial for cardiovascular health. Daily intake of 330 ml Israeli Maccabee beer by patients with coronary artery disease and atherosclerosis led to a significant increase in HDL cholesterol and plasma α-tocopherol as compared with a corresponding control group without intake of any

alcoholic beverage (Gorinstein, 1997b). These changes are generally viewed as beneficial for cardiovascular health (see next sections), although in this study an improvement of other clinical parameters reflecting cardiovascular functions more directly was not observed.

Human studies on intake of high-flavanol cocoa products as well as respective *in vitro* investigations revealed antioxidant, anti-platelet and anti-inflammatory activities as well as improvement of endothelial function of blood vessels and lowering of blood pressure (Keen *et al.*, 2005; Engler *et al.*, 2006; Ding *et al.*, 2006, and references therein). Since (−)-epicatechin isolated from cocoa polyphenols produced similar biological responses (Schroeter *et al.*, 2006), this compound is concluded to play a key role. Its mode of action seems to involve more than one mechanism.

Epicatechin and plasma lipoproteins

Plasma lipoproteins play a pivotal role in atherosclerosis and, consequently, in CVD. While low-density lipoprotein (LDL) favors the development of atherosclerotic lesions, high-density lipoproteins (HDL) are protective against it, so that the LDL/HDL ratio of plasma is a determinant for the risk of CVD. This ratio appears to be favorably lowered by (−)-epicatechin and related flavan-3-ols by 2 ways: (i) elevation of HDL as measured as HDL cholesterol (Gorinstein, 1997b; Wan *et al.*, 2001; Mursu *et al.*, 2004), (ii) lowering of LDL through up-regulation of hepatic LDL receptor (Bursill *et al.*, 2007).

Recent atherosclerosis research revealed that biochemical modification of LDL, affecting its composition and, in turn, receptor affinities, greatly enhances the injurious potential of LDL in the pathogenesis of LDL in various disease states. Thus, the "oxidation hypothesis of atherosclerosis" predicts that the proatherogenic and proinflammatory role of LDL is mediated by oxidative modification of LDL. While cells take up native LDL via the well-regulated LDL receptor, thus preventing deleterious consequences, oxidized LDL (oxidatively modified low-density lipoprotein, oxLDL) is avidly taken up by vascular endothelial cells, macrophages and other cells via so-called scavenger receptors. In response to this oxLDL-mediated pathway, the cells are damaged by several ways. The impact of LDL oxidation implies the following sites of pharmacological or dietary intervention to counteract atherosclerosis and endothelial dysfunction: (i) generation of oxLDL, (ii) interaction of oxLDL with vascular endothelial cells. Recent research from this laboratory has provided ample evidence that (−)-epicatechin blocks both consecutive steps of this scenario (Steffen *et al.*, 2006a).

Impact of LDL Oxidation in Jeopardizing Cardiovascular Health: oxLDL   The pathophysiologic role of oxidative modifications of LDL has been suggested from observations that oxLDL species are detectable in early and advanced atherogenic lesions in the arterial wall,

whereas no such species occur in uninvolved areas of the same blood vessels. In these lesions, a cascade of events is initiated by oxLDL leading to vascular dysfunction and progression of the lesion and finally to plaque rupture and occlusion of the vessel, a key process responsible for myocardial infarction.

OxLDL is used in the literature as collective term for chemically modified species of LDL particles, which are heterogeneous in composition and biological activities. The modifications can include the lipid moiety and/or apoB-100, the protein component of LDL. Modification of the lipid moiety is brought about by lipid peroxidation and gives rise to a number of biologically active lipid oxidation products such as free and esterified polyunsaturated hydro(pero)xy fatty acids, oxygenated products of cholesterol and its esters (oxysterols), lysophospholipids, platelet-activating factor-like phospholipid cleavage products, F_2-isoprostanes and various aldehydes. Lipid-derived oxidation products are believed to contribute to proinflammatory events in the subendothelial space of arterial vessels such as activating expression of adhesion molecules, apoptosis of endothelial cells, recruitment and differentiation of monocytes and fibrous plaque formation. Modification of the protein moiety preferably includes oxidation-sensitive amino acid residues such as lysine, arginine, tyrosine, tryptophan, threonine and methionine. Oxidation of lysines or their masking by aldehydes (e.g. by malondialdehyde and 2-hydroxynonenal, which originate from lipid peroxidation) via Schiff base formation leads to loss of positive charges of the apoprotein, which renders the whole oxLDL particle more negative as detectable by electrophoresis.

A mildly oxidized form of oxLDL, "LDL-minus," becomes detectable in plasma about 2 h after intake of a fat and carbohydrate-rich, but polyphenol-poor meal (Ursini and Sevanian, 2002). This phenomenon, a consequence of postprandial oxidative stress (Sies *et al.*, 2005b), is due to a high oxidant load from the gastrointestinal tract to the blood plasma, which cannot be sufficiently compensated by the endogenous antioxidant systems of the organism.

Other pathways to generate oxLDL species *in vivo* are difficult to define, but may be a consequence of systemic or local oxidative stress. Local injury of the endothelium of the wall of arterial vessels facilitates LDL oxidation. Such loci enable both LDL and inflammatory cells such as monocytes to enter the subendothelial space of the vessel, where the monocytes differentiate to macrophages, and a cocktail of oxidants are released from activated inflammatory cells that promote LDL oxidation and other prooxidant and proinflammatory responses ("response-to-injury hypothesis of atherosclerosis").

Employing an enzyme-linked immunoassay on aldehyde-modified oxLDL, the plasma level of oxLDL was found to strongly correlate with coronary artery disease (Holvoet *et al.*, 1998). It turned out to be a prognostic biomarker of subclinical atherosclerosis development (Wallenfeldt *et al.*,

2004). Elevated plasma levels of oxLDL are predictive for a future coronary heart disease event such as myocardial infarction (Meisinger *et al.*, 2005; Johnston *et al.*, 2006). Similar conclusions have been drawn for the plasma level of myeloperoxidase (MPO) (Brennan *et al.*, 2003), a prooxidant enzyme that is recruited in atherosclerotic lesions and capable of modifying LDL (Schewe and Sies, 2005, and references therein). No studies were conducted until now to address the effect of dietary intake of flavan-3-ols on these parameters.

LDL oxidation *in vivo* can be mimicked in a number of *in vitro* models. A most common model is Cu^{2+}-catalyzed LDL oxidation owing to its methodological simplicity, although it does not reflect the *in vivo* situation, because plasma does not contain free Cu^{2+} ions. Modification of LDL by a reaction system MPO/H_2O_2/nitrite is preferable (Kostyuk *et al.*, 2003; Kraemer *et al.*, 2004, Schewe and Sies, 2005; Steffen *et al.*, 2006a), because it may mirror the *in vivo* process of LDL oxidation more closely. A number of other *in vitro* models can also be applied. They include spontaneous autoxidation (storage under air) as well as enzymatic (MPO, 15-lipoxygenase), non-enzymatic (transition metal ions, free radical-generating compounds, irradiation plus photosensitizers) and cellular reactions (vascular endothelial cells, macrophages). The oxLDL preparations thus obtained differ with respect to both chemical composition and biological activities, which needs to be considered when data are evaluated.

Epicatechin Protects Against LDL Oxidation Strongly *In Vitro*, but Only Marginally *Ex Vivo* While no data are available as to the effect of (−)-epicatechin on LDL oxidation *in vivo*, a universal protection against LDL oxidation *in vitro* is well documented (Table 82.2). Notably, all LDL oxidation systems, so far tested, proved to be inhibited by micromolar concentration of (−)-epicatechin or other flavonoids. As an example, the time-course of Cu^{2+}-elicited LDL oxidation is shown in Figure 82.2. (−)-Epicatechin increases dose-dependently the lag phase without affecting the propagation phase, thus shifting the time-curve to the right. In contrast, with lipid peroxidation of LDL catalyzed by the reaction system MPO/H_2O_2/nitrite, both lag phase and propagation phase are affected by (−)-epicatechin (Kraemer *et al.*, 2004). Interestingly, the MPO/nitrite system also evokes protein tyrosine nitration of LDL, forming 3-nitrotyrosine. This reaction may contribute to formation and progression of atherosclerotic lesions, since both MPO-derived products and 3-nitrotyrosine are accumulated in such lesions (Daugherty *et al.*, 1994; Leeuwenburgh *et al.*, 1997). An alternative route to protein-bound 3-nitrotyrosine is the reaction with peroxynitrite (Ischiropoulos, 2003). Peroxynitrite, formed in a diffusion-controlled reaction from nitric oxide (•NO) and superoxide anion radical ($O_2^{•−}$), is both strong oxidant and nitrating agent. (−)-Epicatechin is known to protect against oxidant and nitrating reactions of peroxynitrite (Schroeder *et al.*, 2001; Wippel *et al.*, 2004). Since (−)-epicatechin in micromolar concentrations does not only abrogate MPO-catalyzed lipid peroxidation, but also tyrosine-protein nitration as well as chloride-dependent increase in relative electrophoretic mobility by MPO (Steffen *et al.*, 2006a), we conclude that this dietary polyphenol is a potent protectant against MPO-mediated proatherogenic modifications of both lipid and protein moieties of LDL *in vitro*. This quality may be one way by which (−)-epicatechin or its metabolites could limit oxidative modification of LDL *in vivo*.

A number of studies addressed the susceptibility of LDL to oxidation *ex vivo* (Table 82.3). The protective effects

Table 82.2　Effect of (−)-epicatechin on LDL modification *in vitro*

Oxidant system	Parameter	Effect	Effective concentration (μM)	Reference
MPO/nitrite	Conjugated dienes in lipids	Prolongation of lag phase	0.5–5	Kraemer *et al.* (2004)

Peroxynitrite	Protein tyrosine nitration	Inhibition	0.1–3	Kraemer *et al.* (2004)

of flavan-3-ol intake, however, although being statistically significant in the majority of these studies, are rather marginal. Thus, extension of the length of the lag phase of LDL oxidation by as low as 8–15% cannot be regarded as relevant protection. It must be emphasized, however, that most previous studies employed Cu^{2+} oxidation, the biological relevance of which for the *in vivo* process is questionable. Further efforts are needed, therefore, to substantiate a role of LDL protection *in vivo*, including *ex vivo* susceptibility of LDL to MPO-elicited or cell-mediated modifications as well as measurement of oxLDL levels in plasma.

Epicatechin Protects Against oxLDL-Mediated Damage to Vascular Endothelial Cells As stated above, interaction of oxLDL with vascular endothelial cells is a key event leading to atherosclerotic lesions of arterial vessels, thus favoring CVD. Using cultured endothelial cells, this process can be studied *in vitro*. As numerous investigators have shown, oxLDL is highly toxic toward various endothelial cell lines. Notably, we have demonstrated that MPO/H_2O_2/nitrite-oxLDL is more cytotoxic than Cu^{2+}-oxLDL despite a lower extent of lipid peroxidation (Steffen *et al.*, 2005). Distinct patterns of oxysterols were recently identified as reason for this difference (Steffen *et al.*, 2006b). Since pure oxysterols or defined mixtures mimicked the behavior of oxLDL preparations, it may be concluded that oxysterols, in particular 7β-hydroxycholesterol, contribute to a sizeable part to the cytotoxicity of oxLDL. Another oxysterol, 7-ketocholesterol, attenuated the injurious effects of 7β-hydroxycholesterol (Steffen *et al.*, 2006b). As expected, formation of oxysterols during LDL oxidation was dose-dependently inhibited by (−)-epicatechin (Steffen *et al.*, 2006b).

The damage to vascular endothelial cells by oxLDL is complex and involves several targets, all of them being protected by (−)-epicatechin (Table 82.4). A key event of this multiple damage could be oxLDL-elicited activation of the endothelial nicotinamide adenine dinucleotide phosphate (NADPH) oxidase generating $O_2^{\bullet-}$, thus provoking

Figure 82.2 Dose-dependent effect of (−)-epicatechin on Cu^{2+}-catalyzed LDL oxidation. The time-course of conjugated dienes absorbing at 234 nm is shown in the absence (control) and presence of increasing concentrations of (−)-epicatechin. At reaction start the basal absorbance was adjusted to zero. The presence of conjugated dienes is a structural feature of peroxidized polyunsaturated fatty acids. Therefore, their concentration in LDL mirrors the degree of lipid peroxidation of LDL. As seen, the start of lipid peroxidation is strongly retarded (lag phase). During the lag phase LDL is protected by endogenous antioxidants such as vitamin E present in LDL. At the end of the lag phase vitamin E and other protectant compounds are destroyed by the Cu^{2+}-treatment, so that lipid peroxidation starts and continues with nearly linear rate (propagation phase). The reaction ceases, when all accessible polyenoic fatty acid residues of LDL lipids are peroxidized (termination phase). (−)-Epicatechin and related polyphenols selectively prolong the lag phase without affecting propagation and termination phases. This effect may be due to refilling of antioxidative capacity of LDL.

Table 82.3 Inhibition of LDL oxidation *ex vivo* upon intake of flavanol-rich food

Flavanol source	LDL oxidation catalyst	Parameter	Effect	Reference
Green and black tea extracts	Cu^{2+}	Conjugated dienes, lag phase	No effect	van het Hof *et al.* (1997)

		Conjugated dienes, lag phase	Prolongation by 15% (p < 0.05)	

[a]AMVN, 2,2′-azobis(4-methoxy-2,4-dimethylvaleronitrile), an inducer of free radical-mediated oxidations.
[b]TBARS, thiobarbituric acid-reactive substances, an indirect measure for peroxidized polyenoic fatty acids.

oxidative stress. This assumption was corroborated through detection of oxLDL-induced, 2-deoxyglucose-sensitive $O_2^{\bullet-}$ generation in endothelial cells, which was inhibited by apocynin, a known NADPH oxidase inhibitor (Steffen *et al.*, 2007a). 2-Deoxyglucose blocks the oxidative pentose-phosphate pathway of glucose metabolism, a major source of NADPH generation. Notably, $O_2^{\bullet-}$ generation was also suppressed by (−)-epicatechin (Steffen *et al.*, 2007a), which may explain the universal protectant action of this polyphenol on endothelial cells. Some protectant actions required pretreatment of the cells with (−)-epicatechin. Therefore, it is conceivable that metabolites rather than the parent compound constitute the active agent(s). Murine aortic endothelial cells have been observed to accumulate (−)-epicatechin from the medium within 10 min followed by sizeable conversion of it after 1 h. The putative conversion products and their biological activities remain to be identified. (−)-Epicatechin (Cos *et al.*, 1998) as well as its plasma metabolites (Harada *et al.*, 1999) are known to scavenge $O_2^{\bullet-}$, which may additionally contribute to the counteraction of NADPH oxidase activation and to attenuate $O_2^{\bullet-}$ generation via pathways other than NADPH oxidase in endothelial cells. Taken together, these data argue in favor of NADPH oxidase as a prominent site of endothelium-protectant action of flavan-3-ols and/or their metabolites (see "Note" on page 812).

Epicatechin and bioavailability of nitric oxide

Structural and functional intactness of the endothelium of vascular walls is an important prerequisite for cardiovascular health. Thus, its ability to dilate enables an adequate transport of oxygen through blood stream via arterial conduit vessels and capillaries to organs and tissues, including heart and brain. An important mediator for endothelial dilation is $^\bullet$NO, which is formed in endothelial cells through an L-arginine pathway by endothelial NO synthase (eNOS). $^\bullet$NO is cofactor for soluble guanylate cyclase in smooth muscle cells forming cyclic guanosine monophosphate (cGMP) that in turn regulates smooth muscle tone by dilating the vessel. Besides this signal function, $^\bullet$NO at low concentration possesses antioxidant, anti-inflammatory and cytoprotective properties, making it a protectant for endothelial cells. Among others it inhibits LDL oxidation. This dual function requires the maintenance and functional adaptation of an adequate steady-state level of bioavailable $^\bullet$NO. Although being chemically relatively stable, $^\bullet$NO is short-lived in biological systems, mainly due to reactions with other molecules or oxidations. The steady-state level of $^\bullet$NO is lowered under conditions of oxidative stress, since more $^\bullet$NO is consumed due to a higher oxidant load. For review of the role of $^\bullet$NO for protection of the arterial wall against atherosclerosis the reader is referred to Napoli *et al.* (2006).

The crucial role of the bioavailability of $^\bullet$NO for vascular function has been demonstrated by measurement of flow-mediated dilation (FMD). With this method the dilation of the brachial conduit artery is measured *in vivo* after transient ischemia provoked by a cuff (Kelm, 2002). The FMD is mediated through the L-arginine/$^\bullet$NO pathway as evident from the effect of eNOS inhibitors. This response is markedly diminished with individuals at risk for CVD, a phenomenon known as endothelial dysfunction. Several studies demonstrated marked improvement of FMD 2 h after intake of a high-flavan-3-ol cocoa beverage or chocolate, but not of low-flavan-3-ol control diet (Heiss *et al.*, 2003; Schroeter *et al.*, 2006, and references therein). Elevation of FMD unequivocally coincided with an increase in plasma nitroso compounds and with the

Table 82.4 Adverse actions of MPO/H_2O_2/nitrite-oxLDL on endothelial cell lines

Target of damage	Cell line	Assay	Protection by (−)-epicatechin

maximum of plasma metabolites of (−)-epicatechin. These observations show that (−)-epicatechin ameliorates the bioavailability and bioactivity of •NO *in vivo*.

The effect of (−)-epicatechin on •NO metabolism was also studied with endothelial cells *in vitro* (see "Note" on page 812). Exposure of endothelial cells to MPO/H$_2$O$_2$/nitrite-oxLDL caused down-regulation of eNOS protein, which was prevented by pretreatment with (−)-epicatechin (Steffen *et al.*, 2005). This effect of (−)-epicatechin was brought about by suppression of the proteasomal degradation of eNOS protein, although proteasome activity of a cell-free system was not inhibited (Steffen *et al.*, 2007a). Notably, down-regulation by oxLDL of eNOS protein was accompanied by up-regulation of inducible •NO synthase (iNOS), an isoform of eNOS, the induction of which is paralleled, however, by proinflammatory events, so that through the iNOS pathway preferably peroxynitrite rather than bioavailable •NO is generated. (−)-Epicatechin partially suppressed both oxLDL-mediated up-regulation of iNOS protein and iNOS-dependent •NO formation and strongly abrogated the formation of nitrated and carbonylated proteins in endothelial cells, which were shown to be to a large part mediated by iNOS (Steffen *et al.*, 2007a). Notably, (−)-epicatechin significantly elevated the nitrite/nitrate ratio of the secondary oxidation products of •NO (Steffen *et al.*, 2007a), which may reflect a suppression of injurious peroxynitrite formation (see below). Since nitrate may be regarded as indicator of intermittent peroxynitrite formation (see next section), it appears that (−)-epicatechin "tames" the iNOS by converting it from deleterious to beneficial.

Molecular mechanisms of epicatechin

Previous investigators supposed that (−)-epicatechin and related dietary polyphenols would simply act as general antioxidant. If this assumption would be true, antioxidant vitamins such as vitamins C and E should exert similar effects. We have shown, however, that antioxidant vitamins do not share a number of protective actions of (−)-epicatechin (Steffen *et al.*, 2006a). Thus, MPO/H$_2$O$_2$/nitrite-elicited lipid peroxidation of LDL is strongly inhibited by (−)-epicatechin, but only weakly by vitamin E, another radical chain-breaking natural antioxidant. This type of lipid peroxidation involves the nitrogen dioxide radical (•NO$_2$) to start free radical chain reaction. Flavan-3-ols appear to possess high affinity to scavenge this short-lived radical, which is apparently not sufficiently accessible to vitamin E.

A general antioxidant activity would imply inhibition of lipid peroxidation *in vivo*. F$_2$-isoprostanes are a reliable parameter of *in vivo* lipid peroxidation, but upon intake of high-flavanol-cocoa products neither sizeable lowering of the plasma level (Wiswedel *et al.*, 2004) nor any effect on urinary excretion of F$_2$-isoprostanes (Mathur *et al.*, 2002) were observed. As already mentioned, lipid peroxidation of LDL *ex vivo* is only marginally affected under these conditions as

well (Table 82.3). These observations are in sharp contrast to the potent inhibition of several types of LDL oxidation *in vitro* (Table 82.2). A plausible explanation for this discrepancy may be the chemical nature of the plasma metabolites of (−)-epicatechin, which are predominantly glucuronidated or methylated at the 3′ or 4′ hydroxyls of the catechol arrangement in the B ring (Natsume *et al.*, 2003), whereas the free radical-scavenging action requires a free catechol grouping. Indeed, flavonoid metabolites having a partially blocked catechol exhibit a strongly diminished antioxidant activity toward free radicals.

(−)-Epicatechin has antioxidant activity in a broader sense, which is reflected by the fact that reactions of prooxidant enzymes are also suppressed, even though they do not implicate free radicals. Thus, 5- and 15-lipoxygenase activities are inhibited by flavan-3-ols and other flavonoids directly at the enzyme level (Sies *et al.*, 2005a, and references therein). Since these lipoxygenases are involved in both inflammation and atherogenesis, a contribution of these enzyme inhibitions may be plausible. Here again, however, lipoxygenase inhibition requires a free catechol arrangement, and evidence for its occurrence *in vivo* is still lacking.

The flavonoid inhibition of NADPH oxidase, another prooxidant enzyme system important for oxidative stress, has already been reported for the leukocyte enzyme in older work (Tauber *et al.*, 1984) and was now demonstrated also for the endothelial enzyme (Steffen *et al.*, 2007a, b; 2008). Recent work on the mode of action of epicatechin and its methyl ethers on endothelial NADPH oxidase (see "Note" on page 812) make this target as prominent site of the action of epicatechin *in vivo* probable. It may afford a plausible explanation for the protection of the vascular endothelium by dietary flavan-3-ols, as substantiated by recent *in vivo* data. Through blockage of NADPH oxidase-mediated O$_2$•$^-$ formation, generation of secondary reactive oxygen species such as H$_2$O$_2$ and •OH radical is prevented. Elimination of O$_2$•$^-$ generation also preserves bioavailable •NO by shutting down the formation of peroxynitrite. By this mode, flavan-3-ols or their metabolites may sustain an adequate steady-state level of bioactive •NO necessary for both function as well as antioxidant and anti-inflammatory defense reactions of the vascular endothelium.

Summary Points

- Epicatechin belongs to the group of micronutrients thought to provide health benefit by preventing or alleviating CVD.
- Epicatechin is absorbed from the intestine as well as bioavailable and bioactive in humans.
- Cocoa, dark chocolate, red wine and tea are major known sources of epicatechin and related compounds, whereas beer as a source of flavonoids was studied less extensively.

- In addition to general antioxidant activities, recent studies reveal a modulation of the metabolism of nitric oxide and reactive nitrogen species, which results in preservation and improvement of endothelial function of arterial vessels.
- Metabolic conversion products of epicatechin such as methylated and glucuronidated species may contribute to the protectant action on the vascular endothelium.

Note

Recently, new aspects on the mode of action of (−)-epicatechin on endothelial NADPH oxidase were revealed (Steffen *et al.*, 2007b, 2008). Vascular endothelial cells convert (−)-epicatechin or the plasma metabolite (−)-epicatechin glucuronide to 3′- and 4′-*O*-methyl epicatechin via catechol-*O*-methyltransferase (COMT). These methyl ethers act as inhibitors of endothelial NADPH oxidase. This, in turn, spares •NO from its reaction with the superoxide anion radical, so that there is an elevation in the cellular level of •NO, as actually observed.

Isohumulones from Beer Modulate Blood Lipid Status

Aruto Yoshida Central Laboratories for Frontier Technology, Kirin Brewery Co., Ltd., Yokohama, Japan

Abstract

Isohumulones, which impart bitter flavor and an antibacterial property to beers, are generated from humulones (also known as alpha acids) in the hop plant (*Humulus lupulus* L.) during the brewing process. The three major types of isohumulones are isohumulone, isocohumulone, and isoadhumulone, all of which are structurally related. The presence of isohumulones has long been noted in beers, but their physiologic actions remained curiously obscure. However, their unexpected pleiotropic effects on glucose and lipid metabolism in the body have recently been uncovered due to the availability of isomerized hop extract (IHE) that primarily contains isohumulones. Oral administration of IHE or isohumulones to mice results in significantly decreased blood triglyceride and non-esterified free fatty acid (NEFA) levels, adipose tissue weight, and hepatic cholesterol content. Microarray analysis and quantitative real time PCR (QPCR) have indicated that IHE dose-dependently upregulated the expression of hepatic genes involved in microsomal co-oxidation and peroxisomal and mitochondrial β-oxidation. These effects are very similar to those that follow administration of hypolipidemic drugs with the potential of activating the peroxisome proliferator-activated receptor α (PPARα). Moreover, these effects are not seen in PPARα-deficient mice. An *in vitro* reporter assay also indicates the activation of PPARα by isohumulone and isocohumulone. These observations strongly suggest that isohumulones upregulate the expression of key genes in hepatic fatty acid oxidation, and that they ameliorate blood and hepatic lipid profiles through activation of PPARα. This review focuses primarily on the effects of isohumulones on lipid metabolism through PPARα activation. Several PPARα independent functions are also described. These physiologic actions of isohumulones may be potentially therapeutic for the prevention of dyslipidemia in metabolic syndrome and alcoholic fatty liver disease.

List of Abbreviations

3KT	3-Ketoacyl-CoA thiolase
ACO	Acyl-CoA oxidase
ACSL	Long-chain fatty acid CoA ligase
ApoCIII	Apolipoprotein CIII
CACT	Carnitine/acylcarnitine translocase
CAT	Carnitine acetyltransferase
Chol	Cholesterol
CPT2	Carnitine palmitoyltransferase 2
CTL	Control
Cyp	Cytochrome P450
DCI	Mitochondrial delta3-delta2-enoyl-CoA isomerase
DGAT2	Diacylglycerol acyltransferase 2
FABP	Fatty acid binding protein
FF	Fenofibrate
FLD	Fatty liver disease
HDL	High-density lipoprotein
IHE	Isomerized hop extracts
LCFA	Long-chain fatty acid
L-PBE	Peroxisomal enoyl-CoA hydratase/L-3-hydroxyacyl-CoA dehydrogenase bifunctional enzyme
LPL	Lipoprotein lipase
LDL	Low-density lipoprotein
MCFA	Medium-chain fatty acid
NAFLD	Non-alcoholic fatty liver disease
NEFA	Non-esterified free fatty acid
PECI	Delta3-delta2-enoyl-CoA isomerase
PPAR	Peroxisome proliferator-activated receptor
QPCR	Quantitative real time PCR
RXR	Retinoid X receptor
SCFA	Short-chain fatty acid
VLCFA	Very long-chain fatty acid
VLDL	Very-low density lipoprotein

Introduction

The recent increased consumption of foods containing high levels of sugar and saturated fats, in conjunction with reduced physical activity, have caused an explosive increase in the incidence of obesity worldwide. There has also been a

proportionate increase in obesity-associated metabolic disorders, including type 2 diabetes, dyslipidemia (high triglycerides and low high-density lipoprotein (HDL)-lipoproteins), hypertension, and non-alcoholic fatty liver disease (NAFLD) accompanied by insulin resistance. Thus, the prevention of this medical sequela is a very serious issue. Accordingly, improved food choices offer a promising approach to solve obesity-related health problems (Kopelman, 2000; Evans *et al.*, 2004). Accumulating evidence has demonstrated that peroxisome proliferator-activated receptors (PPARs) are potential molecular targets for drugs to treat metabolic syndrome. PPARs are members of the nuclear receptor superfamily of ligand-inducible transcription factors. They play a central role in carbohydrate and lipid metabolism and inflammation. PPARα is a target of hypolipidemic drugs, fibrates, and PPARγ is a target of insulin-sensitizing antidiabetic drugs, thiazolidinediones (Evans *et al.*, 2004). Recently, a report suggested that isohumulones, which are the bitter compounds in beer, activate both PPARα and PPARγ *in vitro* and that they also ameliorate insulin resistance, hyperglycemia, and dyslipidemia in diabetic mice (Yajima *et al.*, 2004). This is the first observation relating to the physiologic effect of isohumulones, which have long been known to be a component of beer. Several latest studies have also supported the possibility that isohumulones may be potentially therapeutic for the prevention of dyslipidemia in metabolic syndromes and fatty liver diseases (FLD) (Miura *et al.*, 2005; Shimura *et al.*, 2005; Yajima *et al.*, 2005). This review primarily discusses recent progress of the effects of isohumulones on lipid metabolism through PPARα activation.

Metabolic Syndrome and PPARα

Obesity and metabolic syndrome

Since the 1980s, increased consumption of more energy-dense, nutrient-poor foods with high levels of sugar and saturated fats, combined with reduced physical activity, have caused an explosive increase in the obese population. Nowadays, the obesity epidemic is not restricted to industrialized societies such as North America, Western Europe, and Japan. Obesity is growing at a much faster rate in developing countries than in the developed world. The World Health Organization recently announced that obesity has reached epidemic proportions globally. More than 1 billion adults are overweight, of which at least 300 million are clinically obese. Along with the increase in obesity and overweight status, there has been a proportionate increase in obesity-associated metabolic disorders, including type 2 diabetes, dyslipidemia (high triglycerides and low HDL-lipoproteins), and hypertension. This dangerous cluster of chronic diseases accompanied by insulin resistance is correctively referred to as metabolic syndrome, or syndrome X (Kopelman, 2000; Evans *et al.*, 2004). Recently, obesity and obesity-associated FLD have become global health

problems, and NAFLD, defined as a significant accumulation of fat in the liver without alcohol consumption, is also considered one aspect of metabolic syndrome (Bugianesi *et al.*, 2005; Hamaguchi *et al.*, 2005). This medical sequela is currently one of the most serious global threats that reduces the overall quality of life. Effective weight management for people at risk of developing obesity involves a range of long-term strategies including prevention, weight maintenance, and management of co-morbidities. Several public health efforts to diminish food portion sizes, improve food choices, and increase physical activity represent promising approaches to solve this global problem.

Roles of PPARα in lipid metabolism

PPARs are members of the nuclear receptor superfamily of ligand-inducible transcription factors. They form a heterodimer complex with retinoid X receptors (RXRs). Since PPARs bind to a diverse set of saturated and unsaturated fatty acids, and their eicosanoid derivatives generated from dietary fat or cellular metabolism function as natural ligands, they seem to play a role as lipid sensors for modulating lipid metabolism, storage, and transport in the body (Kersten *et al.*, 2000; Kliewer *et al.*, 2001; Evans *et al.*, 2004). In contrast to other nuclear receptors, the ligand binding domain of PPARs accommodates a wide range of structurally diverse ligands. Ligand binding triggers a conformational change of the PPAR/RXR complex, recruits transcriptional regulators and basal transcriptional machinery, and results in activation of a series of target gene expressions (Xu *et al.*, 2001). So far, three PPAR isotypes, α, δ, and γ, have been found in mammals. Their possible roles in the regulation of glucose homeostasis and inflammation, as well as lipid and lipoprotein metabolism, have been indicated. Accumulating evidence has also intimated a possible link between these PPARs and metabolic syndrome (Evans *et al.*, 2004).

PPARα is highly expressed in liver and to a lesser extent in heart, skeletal muscles, and kidneys. This expression profile is considerably different from the patterns that PPARγ is primarily expressed in adipose tissue and PPARδ is present throughout the body. Consistent with their expression profiles, each PPAR plays a unique role in the regulation of energy metabolism. During prolonged fasting, the expression of hepatic PPARα is increased, and fatty acids released from adipose tissues are transported into the liver. As a result, the activation of PPARα by fatty acids promotes lipid utilization as an energy source instead of carbohydrate and protein (Kersten *et al.*, 2000; Duval *et al.*, 2002; Lefebvre *et al.*, 2006). This PPARα mediated regulation is a critical response during fasting, as indicated by the fact that PPARα-deficient mice display severe hypoglycemia, hypoketonemia, hyperlipemia, and fatty liver. These conditions are likely due to reduced capacity for hepatic fatty acid oxidation, which generates acetyl-CoA that is required

for gluconeogenesis and ketogenesis on demand (Lee *et al.*, 1995; Kersten *et al.*, 1999; Leone *et al.*, 1999).

As well, PPARα is an important therapeutic target for hypolipidemic drugs, and a class of synthetic PPARα agonists such as fibrates (fenofibrate, benzafibrate, and ciprofibrate, gemfibrozil, among others) has been developed (Kersten *et al.*, 2000; Kliewer *et al.*, 2001). In a variety of mice models, these drugs commonly decrease triglyceride and increase HDL-cholesterol level in the blood, accompanying enhanced hepatic fatty acid oxidation systems including microsomal ω-oxidation and peroxisomal and mitochondrial β-oxidations (Schoonjans *et al.*, 1996; Kersten *et al.*, 2000; Reddy and Hashimoto, 2001; Ferre, 2004; Lefebvre *et al.*, 2006). In addition, fibrates may improve adiposity, hepatic and muscle steatosis, as well as insulin sensitivity (Guerre-Millo *et al.*, 2000; Chou *et al.*, 2002; Ip *et al.*, 2003; Kim *et al.*, 2003; Ide *et al.*, 2004; Tsuchida *et al.*, 2005; Haluzik *et al.*, 2006). Although PPARα activation leads to peroxisome proliferation, hepatomegaly, and hepatocarcinoma in rodents, these are not observed in humans. A recent study with PPARα-humanized mice demonstrated that species specific effects are due to structural differences between the receptors. Furthermore, the control of lipid metabolic pathways is separable from cell proliferation pathways (Lee *et al.*, 1995; Cheung *et al.*, 2004). Accordingly, several fibrate drugs have shown potent hypotriglycemic efficacy in hyperlipemic subjects without serious side effects, resulting in a subsequent reduction of cardiovascular morbidity (Staels *et al.*, 1998; Guay, 2002; Staels and Fruchart, 2005). Some clinical studies have suggested that fibrates may also improve insulin sensitivity in type 2 diabetic patients (Ferrari *et al.*, 1977; Murakami *et al.*, 1984; Kobayashi *et al.*, 1988; Haluzik and Haluzik, 2006).

Effects of Isohumulones Intake

Isohumulones

The hop plant (*Humulus lupulus* L.) has been used in brewing over the centuries to impart bitterness and aroma to beers. The bitter taste of beer is largely due to the presence of isohumulones (also known as iso-alpha acids), which are generated from humulones (also known as alpha acids) that exist within lupulin glands in hop cones. Although humulones in themselves are not particularly bitter and are poorly soluble, they are converted into the bitter-tasting and more soluble isohumulones by an isomerization reaction that occurs during the process of boiling wort in the brew (Malowicki and Shellhammer, 2005). Wort is an aqueous solution containing primarily hops and fermentable sugars (e.g. glucose, maltose, maltotriose) obtained by enzymatic hydrolysis of starch from malt, or from other sources such as wheat, corn, and rice. The three major compounds of isohumulones, isohumulone, isocohumulone, and isoadhumulone, are all structurally related. They are derived from humulone, cohumulone, and adhumulone, respectively (Figure 83.1a). The concentration of isohumulones in beers is generally up to 100 mg/l, and they are responsible for 70% of the observed sensory bitterness in beers (Techakriengkrai *et al.*, 2004). In traditional brewing, whole hops are added to wort; however, many brewers have taken to use hop pellets or hop extract to increase brewing efficiency. Also, isomerized hop extract (IHE), which primarily contains isohumulones, is sometimes used in the post-fermentation adjustment of beer bitterness.

The use of hops is also important for keeping beers in a bacteriostatic condition. While humulones show remarkable antibacterial properties against Gram-positive bacteria such as *Bacillus subtilis* and *Staphylococcus aureus*, isohumulones have
Figure 83.1 Structures of hop-derived compounds (a) and representative PPARα agonists (b). Humulones are converted into isohumulones during the process of boiling wort in the brewing.

much weaker effects under neutral pH condition (Teuber, 1970). Nevertheless, isohumulone seems to still be crucial for the prevention of the major beer spoiler lactic bacteria, since it exhibits 20 times greater antibacterial activity against *Lactobacillus brevis* than humulone under low pH condition, as is observed in beers (Simpson and Smith, 1992). However, neither isohumulones nor humulones substantially inhibit growth of Gram-negative bacteria. Although the presence of isohumulones in beer has long been noted, their physiologic actions have remained obscure. This might be due to the relatively low stability and limited commercial availability of purified isohumulone, isocohumulone, and isoadhumulone. However, their unexpected pleiotropic effects on the body have recently been uncovered due to the availability of IHE, which is used for beer manufacturing (Yajima *et al.*, 2004; Miura *et al.*, 2005; Shimura *et al.*, 2005; Yajima *et al.*, 2005). In particular, the aqueous type of IHE, such as ISOHOP CON2 (Botanix Ltd., UK), is superior in terms of purity, stability, and usability compared to the viscous kettle type. ISOHOP CON2 is a solution that is standardized to 30% w/w isohumulones. It is produced from a supercritical CO_2 hop extract and is isomerized under alkaline conditions in an all aqueous process. The purity of the isohumulones is approximately 80% and its isohumulone:isocohumulone:isoadhumulone ratio is 37:48:15. Several reports have shown good agreement regarding the physiologic effects of IHE and the purified isohumulones (Yajima *et al.*, 2004; Miura *et al.*, 2005).

Activation of PPARα *in vitro* reporter assay

An *in vitro* reporter assay is often used to evaluate the transient transcriptional activation of PPARs by ligands (Lehmann *et al.*, 1997). Interestingly, isohumulone dose-dependently activates PPARα in assays using a human hepatocellular carcinoma line, HepG2, and its specific activity is approximately one-tenth that of a PPARα agonist, fenofibrate (FF) (Yajima *et al.*, 2004). The crystal structure of the PPARα protein shows that it has a relatively large binding pocket that can accommodate diverse fatty acids and fibrates (Xu *et al.*, 2001). However, curiously, isohumulone has no marked similarity to these molecules (Figure 83.1a and b). This may suggest that isohumulone is a structurally unique PPARα agonist and that it may have potential as a candidate for a new lead compound for therapeutics. Also, isohumulones have drawn attention as food-derived PPARα activators, since few dietary factors having this activity other than lipids have been reported, to our knowledge (Rimando *et al.*, 2005). It is interesting that structural differences in the side chain of isohumulones affect the ligand binding and/or transactivation of PPARα. The activity of isocohumulone is approximately 10-fold lower than that of isohumulone, and isoadhumulone has no effect. This result is in stark contrast to the fact that all three isohumulones equivalently activate

PPARγ, and that none of them activates PPARδ (Yajima *et al.*, 2004). However, this may not be so surprising, because the three PPAR subtypes show distinct selectivity against synthetic ligands, although there is a 60–70% sequence identity between their ligand binding domains. In particular, PPARδ has a narrower ligand binding domain that only accepts a limited set of ligands (Xu *et al.*, 2001). Further study will be necessary to elucidate why PPARα accepts the relatively long side chain of isohumulone but not the branching methyl group at the base of isocohumulone and isoadhumulone (Figure 83.1a).

Effects on body and tissue weights

Supplement of IHE in the diet dose-dependently suppresses body weight gain in the absence of a remarkable change of food intake in mice (Miura *et al.*, 2005; Shimura *et al.*, 2005; Yajima *et al.*, 2005). In male C57BL/6N mice, consumption of a basic diet containing 1% IHE suppresses body weight gain within 1 week, regardless of cholesterol content in the diet (Shimura *et al.*, 2005) (Figure 83.2a), whereas such an inhibition is only observed with a high-fat diet in male obese KK-A^y mice (Yajima *et al.*, 2005). In female C57BL/6N mice, 1% IHE significantly suppresses body weight gain within 2 weeks under cholesterol supplemented or atherogenic (high-fat and high-cholesterol) diet conditions (Figure 83.2b) while such an inhibition is not detected within 1 week when mice are placed on a chow diet (Miura *et al.*, 2005). Additionally, the preventive effect is observed even in 0.2% IHE within 3 weeks under high-fat diet conditions (Yajima *et al.*, 2005). Taken together, these data indicate that the inhibition of body weight gain by IHE is more distinct under high-fat diet and longer feeding conditions. It is noteworthy that the same repression is also observed in mice fed purified isohumulones (Figure 83.2b) (Miura *et al.*, 2005).

Although several reports have shown that a PPARα agonist, FF, inhibits body weight gain in male mice fed a high-fat diet (Guerre-Millo *et al.*, 2000; Yoon *et al.*, 2002; Jeong *et al.*, 2004), such an inhibition is not observed in female mice (Yoon *et al.*, 2002; Yoon *et al.*, 2003). Also, another PPARα agonist, WY-14,643, shows no obvious antiobesity effect even in male mice when they consume comparable amounts of diets (Ide *et al.*, 2004; Tsuchida *et al.*, 2005). Thus, it is likely that the effect of PPARα activation on body weight is not so significant, and it might require certain conditions such as a high-fat diet, long feeding periods, and/or genetically manipulated mice. In contrast, IHE shows a relatively clear suppression of body weight gain within a few weeks for both genders of mice. Since IHE induces less hepatic PPARα activation than FF *in vivo* (Shimura *et al.*, 2005) and represses the body weight gain even in PPARα-deficient mice (Figure 83.2c), the phenomenon is probably due to some other mechanisms.

Short-term supplementation of 1% IHE increases the relative liver weight in both male and female C57BL/6N mice (Figure 83.3a and b), which is reminiscent of the rodent specific hepatomegaly that has been reported as a result of PPARα activation (Akiyama *et al.*, 2001; Cheung *et al.*, 2004). The fact that the phenomenon disappears in PPARα-deficient mice suggests the involvement of PPARα (Figure 83.3c). However, it is curious that long-term feeding of 0.2% IHE in a high-fat diet rather decreases liver weight in obese mice (Yajima *et al.*, 2005). Since FF increases liver weight in mice fed a high-fat diet (Jeong *et al.*, 2004), the effect might be PPARα independent and related to hepatic lipid content, as described below. Interestingly, IHE significantly reduces the weights of subcutaneous, retroperitoneal, and parametrial adipose tissues in female C57BL/6N mice and the weights of subcutaneous

and epididymal adipose tissues in male KK-*A*[y] mice (Yajima *et al.*, 2005). These results are very similar to recent observations that FF (Guerre-Millo *et al.*, 2000; Haluzik *et al.*, 2006) and WY-14,643 (Tsuchida *et al.*, 2005) remarkably reduce the weights of various adipose tissues, suggesting the importance of PPARα activation. In addition, IHE tends to slightly decrease kidney weight in both male and female mice under high-fat diet conditions, although the basis for this effect is still unclear (Miura *et al.*, 2005; Yajima *et al.*, 2005). No significant change is detected in the weights of heart and spleen (Yajima *et al.*, 2005).

Effects on blood and hepatic lipids

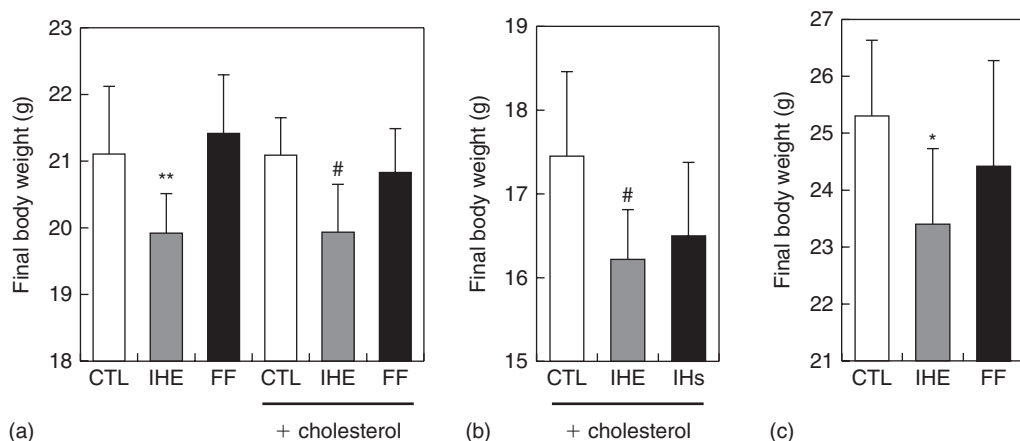
Numerous studies have demonstrated that PPARα agonists decrease blood triglyceride and non-esterified free fatty


Figure 83.2 The effect of 1% isomerized hop extract (IHE), 0.05% fenofibrate (FF), or 0.3% isohumulones (IHs) intake for 1 week on final body weight in male C57BL/6N mice (a), in female C57BL/6N mice (b), and in male PPARα-deficient mice (c). Two types of basic diets (i.e. AIN-76A or AIN-76A + cholesterol (Chol)) were used. The results are expressed as the mean ± SD. *p < 0.05 and **p < 0.01 vs. AIN-76A diet; #p < 0.05 vs. AIN-76A + Chol diet. *Source*: Miura *et al.* (2005), Shimura *et al.* (2005).
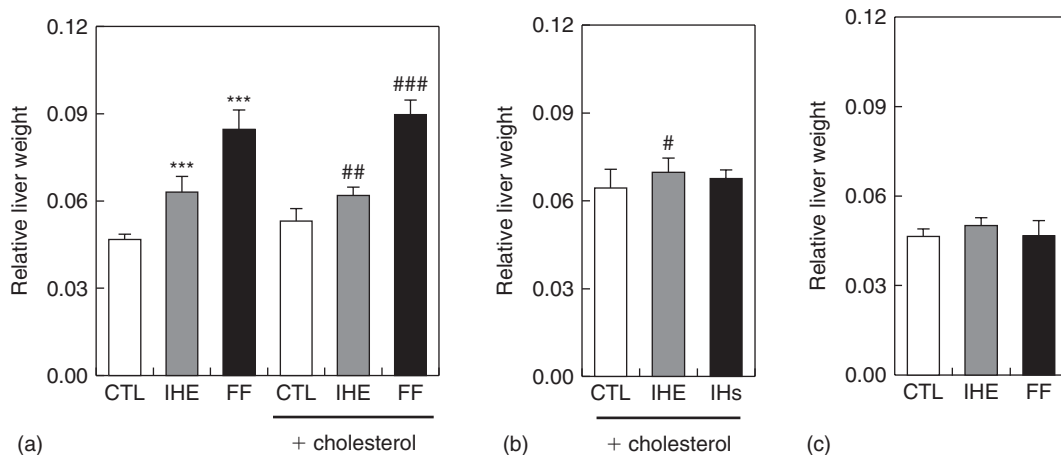

Figure 83.3 The effect of 1% isomerized hop extract (IHE), 0.05% fenofibrate (FF), or 0.3% isohumulones (IHs) intake for 1 week on relative liver weight in male C57BL/6N mice (a), in female C57BL/6N mice (b), and in male PPARα-deficient mice (c). Two types of basic diets (i.e. AIN-76A or AIN-76A + cholesterol (Chol)) were used. Relative tissue weight was calculated by dividing tissue weight (g) by body weight (g). The results are expressed as the mean ± SD. ***p < 0.0001 vs. AIN-76A diet; #p < 0.05, ##p < 0.001, and ###p < 0.0001 vs. AIN-76A + Chol diet. *Source*: Miura *et al.* (2005), Shimura *et al.* (2005) .
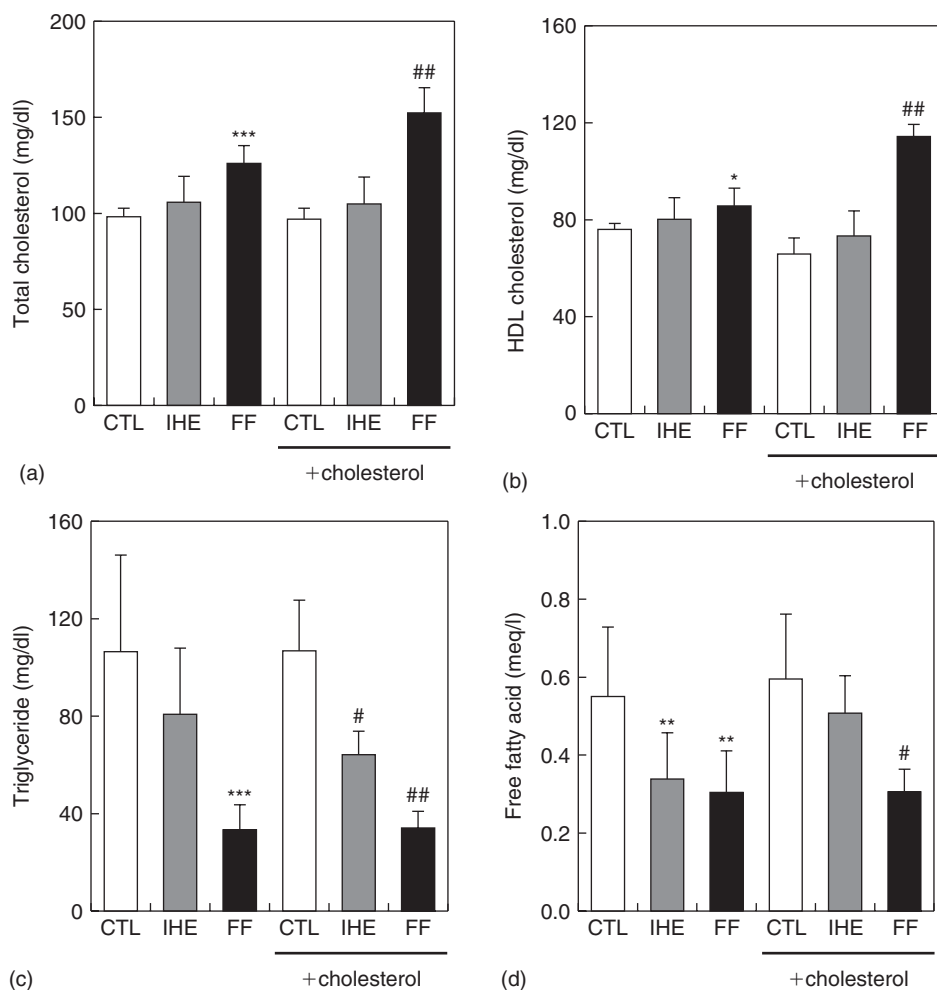

Figure 83.4 The effects of 1% isomerized hop extract (IHE) or 0.05% fenofibrate (FF) intake for 1 week on plasma total cholesterol (a), HDL-cholesterol (b), triglyceride (c), and NEFA (d) levels in male C57BL/6N mice. Two types of basic diets (i.e. AIN-76A and AIN-76A + cholesterol (Chol)) were used. The results are expressed as the mean ± SD. *$p < 0.05$, **$p < 0.01$, and ***$p < 0.0001$ vs. AIN-76A diet; #$p < 0.01$ and ##$p < 0.0001$ vs. AIN-76A + Chol diet. *Source*: Shimura *et al*. (2005).

acid (NEFA) levels and increase HDL-cholesterol levels in rodents (Olivier *et al.*, 1988; Schoonjans *et al.*, 1996; Kersten *et al.*, 2000; Tsuchida *et al.*, 2005; Lefebvre *et al.*, 2006). Likewise, 1% IHE significantly decreases blood triglyceride level both in male (Figure 83.4c) and female mice (Miura *et al.*, 2005) within a few weeks, even when they are fed a standard diet. IHE also lowers NEFA in male mice (Figure 83.4d), regardless of whether or not the diet is supplemented with cholesterol. It is important to note that purified isohumulone and isocohumulone also reduce blood triglyceride and NEFA in male KK-*A^y* mice, and that the former shows a slightly stronger effect than the latter, consistent with their observed potency in PPARα activation in an *in vitro* reporter assay (Yajima *et al.*, 2005). While IHE slightly but insignificantly increases blood total and HDL-cholesterol levels in male mice fed a normal diet (Figure 83.4a and b), these parameters are more apparent when female mice are fed an atherogenic diet (Miura *et al.*, 2005). The plasma

cholesterol profile analyzed by gel filtration chromatography has clearly indicated that the major contributor to increased total cholesterol is the rise in the number of HDL but not low-density lipoprotein (LDL) particles (Miura *et al.*, 2005). The fact that none of these alterations in blood lipid profile by IHE is observed in PPARα-deficient mice (Figure 83.5) indicates that they depend on PPARα activation.

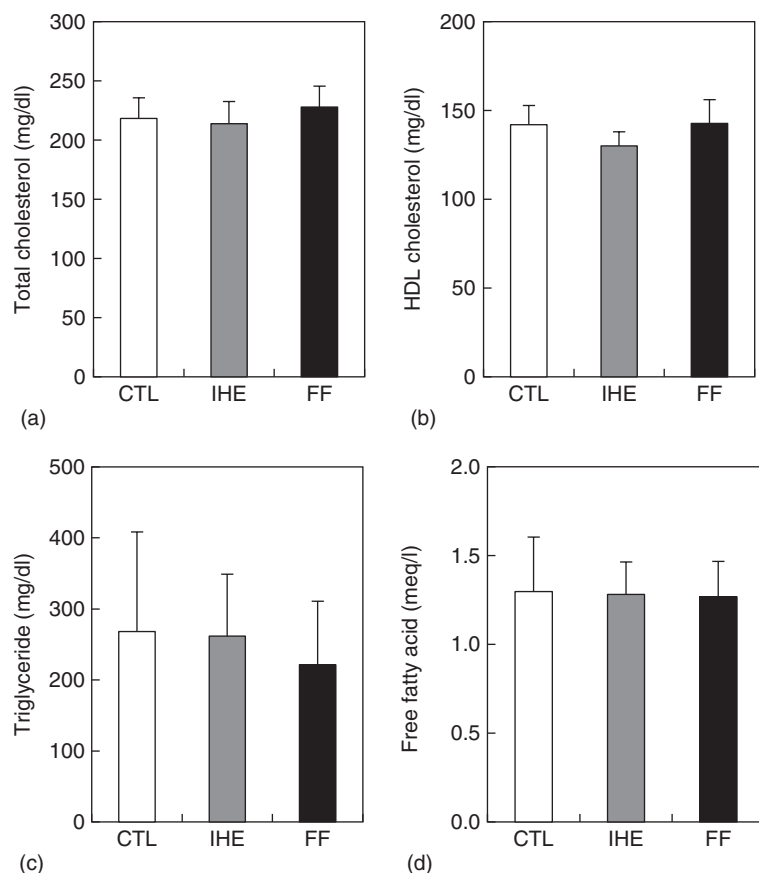
The mice fed 1% IHE or a corresponding amount of isohumulones for 1 week show a significant decrease of cholesterol content in the liver. This is especially apparent in a cholesterol supplemented diet, and a similar effect is also observed for FF (Figure 83.6a) (Miura *et al.*, 2005). While there have been few reports on the action of PPARα agonists in hepatic cholesterol metabolism, a recent study has demonstrated that WY-14,643 lowers hepatic cholesterol levels, with a corresponding decrease in cholesterogenic carbon flux in mice; a similar reduction is not observed in PPARα-deficient mice (Knight *et al.*, 2005).


Figure 83.5 The effects of 1% isomerized hop extract (IHE) or 0.05% fenofibrate (FF) intake for 1 week on plasma total cholesterol (a), HDL-cholesterol (b), triglyceride (c), and NEFA (d) levels in male PPARα-deficient mice. AIN-76A was used as a basic diet. The results are expressed as the mean ± SD. *Source*: Shimura *et al*. (2005).
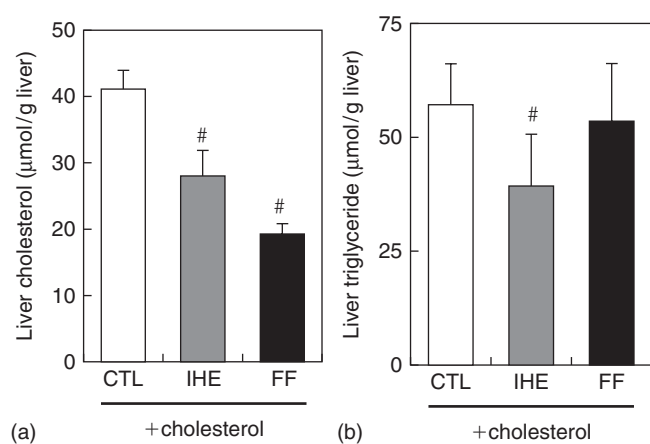

Figure 83.6 The effects of 1% isomerized hop extract (IHE) or 0.05% fenofibrate (FF) intake for 2 weeks on hepatic cholesterol (a) and triglyceride (b) contents in female C57BL/6N mice. AIN-76A + cholesterol (Chol) was used as a basic diet. The results are expressed as the mean ± SD. [#]$p < 0.05$ vs. AIN-76A + Chol diet. *Source*: Miura *et al*. (2005).

Thus, the decrease of hepatic cholesterol by isohumulones appears to be PPARα dependent. In contrast, IHE as well as isohumulones also reduces hepatic triglyceride, whereas such an effect is not observed for FF under the same conditions (Figure 83.6b). This suggests that isohumulones may have a unique and PPARα independent influence on triglyceride metabolism in the liver. The reason for this is currently unknown; however, it may be related to the significant decrease of diacylglycerol acyltransferase 2 (DGAT2) expression in the liver, which has been noted in male KK-A^y mice fed with IHE (Yajima *et al*., 2005). Recent reports have demonstrated that the mice overexpressing hepatic DGAT2 exhibit a marked increase in hepatic triglyceride content (Yamazaki *et al*., 2005) and that obese mice showing reduced hepatic DGAT2 expression following treatment with an antisense oligonucleotide show a significant reduction of triglyceride in the liver (Yu *et al*., 2005).

Effects of hepatic gene expression and lipid metabolism

Alteration of hepatic gene expression in male C57BL/6N mice fed with diets containing either 1% IHE or 0.05% FF for 1 week has been analyzed by cDNA microarray and quantitative real time PCR (QPCR) (Shimura *et al*., 2005). As shown in Table 83.1, IHE and FF specifically increase

Note: Male C57BL/6N mice at 6 weeks of age were fed basic diets containing either 1% IHE or 0.05% FF for 1 week. Two types of basic diets, AIN-76A and AIN-76A + 0.2% Cholesterol (Chol), were used. The pooled RNA from the liver of six mice was used to determine the expression of each gene by QPCR.

Source: Shimura *et al*. (2005).
Figure 83.7 Dose-dependent induction of representative PPARα target genes in liver by isomerized hop extract (IHE). Male C57BL/6N mice were fed AIN-76A containing 0%, 0.03%, 0.3%, or 1% IHE for 1 week. The relative expression level of each gene was determined by QPCR. The results are expressed as the mean ± SD. *p < 0.05 and †p < 0.0001 vs. control diet (Shimura et al., 2005). Cyp: cytochrome P450.

Figure 83.8 Gender differences in isomerized hop extract (IHE)-induced hepatic gene expression. Male and female C57BL/6N mice were fed AIN-76A containing 1% IHE for 1 week. The pooled RNA from six mice was used to determine the relative expression level of each gene by QPCR (Shimura et al., 2005). Cyp: cytochrome P450.

the expression of approximately 20 and 100 genes among the 8,245 genes analyzed, respectively. These numbers are not significantly affected by supplementation of the diet with 0.2% cholesterol, as cholesterol alone does not significantly affect hepatic gene expression. The annotated genes upregulated more than 2-fold by FF are listed in Table 83.1, and the precise quantification of the selected genes by QPCR is shown in Table 83.2. The fold change values between the microarray analysis and QPCR correlate highly ($R^2 = 0.94$), indicating high reliability of the transcriptional profiles. FF greatly increases the expression of genes involved in microsomal co-oxidation and peroxisomal and mitochondrial β-oxidation, which is a common feature induced by several different PPARα activators (Cherkaoui-Malki et al., 2001; Yamazaki et al., 2002; Frederiksen et al., 2004). Likewise, but to a lesser extent, IHE upregulates most of these target genes of PPARα as follows (Tables 83.1 and 83.2). Both FF and IHE induce Cyp4a14 most strikingly (171.4- and 46.5-fold, respectively), and also significantly upregulate the other two members of the Cyp4a family (Cyp4a10 and Cyp4a12), suggesting an enhancement of microsomal ω-oxidation. In addition, they significantly increase a series of enzymes including peroxisomal enoyl-CoA hydratase/L-3-hydroxyacyl-CoA dehydrogenase bifunctional enzyme (L-PBE), acyl-CoA oxidase (ACO), 3-ketoacyl-CoA thiolase (3KT), and delta3-delta2-enoyl-CoA isomerase (PECI), which are involved in peroxisomal β-oxidation. It should be noted that increased enzymatic activity of ACO has also been reported in male C57BL/6N mice administered 100 mg/kg body weight of isohumulone or isocohumulone for 6 days (Yajima et al., 2004). In contrast to these drastic changes in microsomal ω-oxidation
and peroxisomal β-oxidation, elevations in the expression of genes involved in mitochondrial β-oxidation are small. Thus, FF clearly induces carnitine acetyltransferase (CAT), carnitine/acylcarnitine translocase (CACT), carnitine palmitoyltransferase 2 (CPT2), and mitochondrial delta3-delta2-enoyl-CoA isomerase (DCI) in the range from 2.4- to 3.4-fold, while the values for IHE range from 1.4- to 2.4-fold (Table 83.2). Additionally, IHE and FF weakly induce the expression of several long-chain fatty acid CoA ligases, ACSL1, 4, and 5, which are required for the activation of fatty acids to metabolize compounds in the two β-oxidation systems described above (Reddy and Hashimoto, 2001; Coleman et al., 2002). It is noteworthy that FF and IHE significantly increase the expression of lipoprotein lipase (LPL) and reduce the expression of apolipoprotein CIII (ApoCIII), which is involved in triglyceride hydrolysis (Table 83.2).

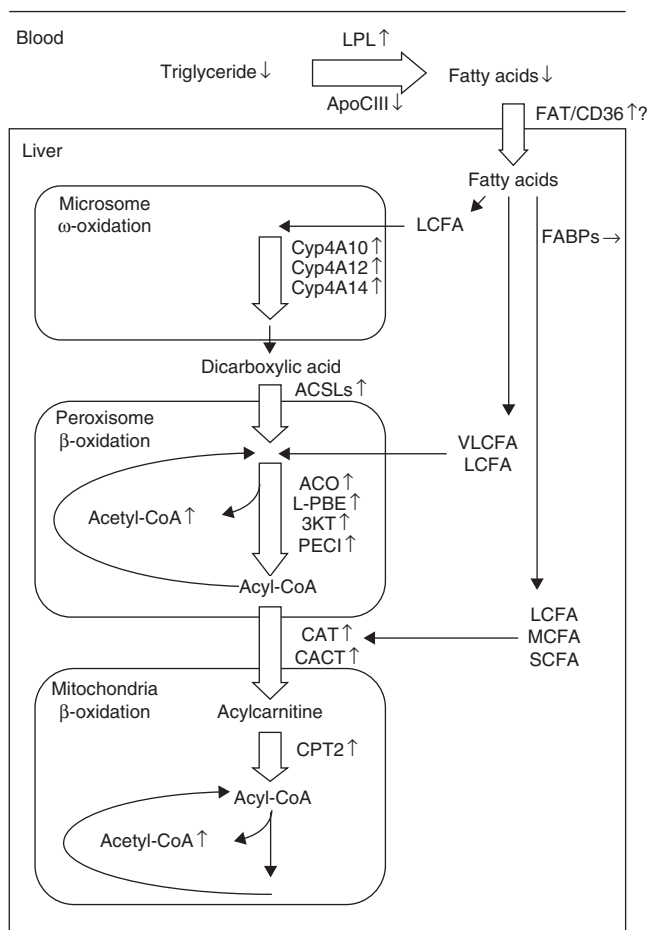
The expression levels of representative hepatic genes (i.e. Cyp4a10, Cyp4a14, ACO, L-PBE, and CAT) increase in a dose-dependent fashion in response to IHE feeding (Figure 83.7). Statistically significant inductions for all of these genes are detected in male mice within 1 week at an IHE concentration of 0.3%. A comparable hepatic gene induction in fatty acid oxidation is also observed in female C57BL/6N mice (Figure 83.8). However, the induction of Cyp4a10 and Cyp4a14 genes in males is significantly higher than for female mice fed with IHE as well as FF. A similar gender specific high induction of the hepatic Cyp4 family by clofibrate has been also observed in rats (Sundseth and Waxman, 1992), but not all peroxisome proliferators induce increased gene expression of this gene family in males (Bell et al., 1993). Additionally, the LPL


Figure 83.9 Schematic representation of hepatic lipid metabolism altered by isomerized hop extract (IHE) intake in C57BL/6 mice. Enhanced lipid hydrolysis and fatty acid oxidation pathways are indicated by thick arrows. The regulation of representative PPARα target genes is indicated with small arrows (Shimura *et al.*, 2005). Cyp: cytochrome P450; DGAT2: diacylglycerol acyltransferase 2; FABP: fatty acid binding protein; LCFA: long-chain fatty acid; MCFA: medium-chain fatty acid; SCFA: short-chain fatty acid; VLCFA: very long-chain fatty acid.

gene is induced to a greater extent in male than in female mice, which may be related to the greater reduction of blood triglyceride level in males (Figure 83.8).

Again, the genes significantly induced by IHE as well as by FF are mainly involved in microsomal ω-oxidation and peroxisomal and mitochondrial β-oxidation. These are typical hepatic PPARα target genes, and their induction for the most part is not seen in PPARα-deficient mice (Table 83.2). Thus, the results strongly indicate the alteration of gene expressions is mediated through PPARα activation (Lee *et al.*, 1995; Akiyama *et al.*, 2001; Reddy and Hashimoto, 2001).

Although IHE and FF induce most of the PPARα target genes in a similar manner, there are several exceptions. Distinct differences are found in the genes of the fatty acid

binding protein (FABP) family, which is thought to bind to and transport fatty acids to various sites within the cell. FF increases the expression of FABP1, 2, and 4 (most notably FABP4), but IHE does not (Table 83.2). Since FABP1 is abundantly expressed in liver, it seems to be the most important member for hepatic lipid metabolism. However, FABP1-deficient mice show no significant change in serum and tissue lipid profiles and fatty acid distribution within hepatic complex lipid species. Rather, the increasing of hepatic triglyceride in respond to fasting is suppressed in the deficient mice (Newberry *et al.*, 2003). Therefore, a lack of induction of the FABP family by IHE might not have a significant impact on blood lipids. Instead, this phenomenon may be related to the lower hepatic triglyceride content in IHE fed mice, which is not observed for FF (Miura *et al.*, 2005). A recent report illustrates that the induction of FABP1 by PPARα agonists is markedly repressed by the expression of COUP-TFII through its binding to a complex of PPARα/RXRα (Spann *et al.*, 2006). Thus, isohumulones may specifically affect the recruitment of other transcriptional regulators. A similar different regulation mechanism for the human apolipoprotein A-I gene has been also observed when comparing effects of FF and gemfibrozil, which is due to a differential recruitment of coactivators to the promoters (Duez *et al.*, 2005).

In accordance with the changes in hepatic gene expression, the decreased blood triglyceride and NEFA and the increased blood HDL-cholesterol in response to IHE and FF are almost completely abolished in PPARα-deficient mice (Figure 83.5). Accordingly, these physiologic changes appear to be consequence of PPARα-dependent enhancement of lipolysis and fatty acids catabolism in liver (Figure 83.9). Since LPL hydrolyzes the triglyceride moiety of chylomicrons and very-low density lipoprotein (VLDL) particles, and ApoCIII effectively inhibits this hydrolysis, the upregulation of LPL and the downregulation of ApoCIII contribute to the reduction of blood triglyceride level cooperatively (Schoonjans *et al.*, 1996). The released fatty acids seem to be converted into acyl-CoA derivatives by the increased ACSLs, and they are further effectively degraded by coordination of three enhanced fatty acid oxidation systems as follows (Reddy and Hashimoto, 2001). The enzymes of the Cyp4a family are rate limiting in ω-oxidation, and they metabolize long-chain fatty acids to dicarboxylic acids. Although ω-oxidation is a minor pathway of fatty acid metabolism, significant amounts of dicarboxylic acids are generated under conditions of fatty acid overload in obesity and diabetes (Sanders *et al.*, 2005). In the peroxisomal β-oxidation pathway, ACO (Fan *et al.*, 1996), L-PBE (Qi *et al.*, 1999), 3KT (Chevillard *et al.*, 2004), and PECI (Geisbrecht *et al.*, 1999) preferentially degrade straight very long- and long-chain fatty acids in addition to dicarboxylic acids from the microsome. This reaction is likely to become more important during periods of increased influx of fatty acids into liver, since ACO-deficient mice exhibit severe microvesicular hepatic

steatosis (Fan *et al.*, 1996). The acyl-CoAs with appropriately shortened chains in peroxisomes are then transported to mitochondria to complete their oxidation. Mitochondrial β-oxidation is the major process for degradation of short-, medium-, and long-chain fatty acids to generate energy. This results in shortening of fatty acids into acetyl-CoA subunits, which then either condense into ketone bodies or enter the tricarboxylic acid cycle for further oxidation to water and carbon dioxide. CAT, CACT, and CPT2 are involved in the rate-limiting carnitine shuttle system for the entry of fatty acids into mitochondria. CAT prefers short- and medium-chain acyl groups and catalyzes the reversible exchange of acyl groups between carnitine and coenzyme A. This enzyme may also be important for fatty acid transport processes from the peroxisome to mitochondria (Hsiao *et al.*, 2006). The resulting acylcarnitines are translocated into the mitochondrial matrix through CACT, and they are then converted back to the acyl-CoA by the action of CPT2 for the following β-oxidation (Longo *et al.*, 2006).

Prospective effects on health

Several recent reports have demonstrated that isohumulones upregulate the expression of key genes in hepatic fatty acid oxidation and ameliorate blood and hepatic lipid profiles through the activation of PPARα (Yajima *et al.*, 2004; Miura *et al.*, 2005; Shimura *et al.*, 2005). These results conjure up the image of their similar efficacy to the PPARα agonists, fibrates. Fibrates have been used as hypolipidemic drugs for several decades, and their safety and efficacy in patients have been extensively demonstrated (Staels *et al.*, 1998; Guay, 2002; Staels and Fruchart, 2005). Several clinical trials further indicate that fibrates reduce the progression of coronary atherosclerosis (Ericsson *et al.*, 1997; Frick *et al.*, 1997; Anonymous 2001) and the primary and secondary incidence of coronary heart disease (Frick *et al.*, 1987; Rubins *et al.*, 1997; Anonymous, 2000). Also, several lines of evidence suggest that fibrates reverse endothelial dysfunction, which is closely related to atherosclerosis and hypertension, in patients with type 2 diabetes (Evans *et al.*, 2000; Avogaro *et al.*, 2001; Playford *et al.*, 2002) and hypertriglyceridemia (Capell *et al.*, 2003). These results illustrate the fact that PPARα agonists are particularly useful to treat atherogenic dyslipidemia of prediabetic individuals and diabetic patients, who often also exhibit insulin resistance and obesity and are highly susceptible to cardiovascular morbidity. Accordingly, isohumulones may provide an alternative for the prevention and amelioration of dyslipidemia and endothelial dysfunction in metabolic syndrome. Indeed, a preliminary pilot study with mild type 2 diabetic subjects suggests a hypotensive effect of isohumulones (Yajima *et al.*, 2004)

The lipid-lowering action of isohumulones through activation of PPARα may also be good news for the prevention of FLD. In the past, excessive alcohol consumption accounted for the majority of FLD cases, but in recent years obesity-associated FLD has attracted considerable attention. Although FLD is now clinically categorized into two broad entities, alcoholic FLD and non-alcoholic FLD, both commonly encompass a morphological spectrum consisting of hepatic steatosis and steatohepatitis, which have an inherent propensity to progress toward the development of cirrhosis and hepatocellular carcinoma. In mice, chronic ethanol feeding deteriorates hepatic fatty acid degradation and promotes an accumulation of hepatic lipids with an accompanying increase of blood triglyceride and NEFA. This appears to include decreased DNA binding of PPARα in the liver, which is mainly caused by acetaldehyde generated during ethanol metabolism (Galli *et al.*, 2001; Fischer *et al.*, 2003). Treatment with a PPARα agonist, WY-14,643, significantly improves the DNA binding activity of PPARα and ethanol-induced steatosis, resulting in decreasing hepatic and blood triglyceride levels and blood NEFA levels in mice (Fischer *et al.*, 2003). Similarly, the PPARα agonists FF (Tsutsumi and Takase, 2001) and clofibrate (Nanji *et al.*, 2004) also ameliorate ethanol-induced steatosis in rats. In addition to these effects of fibrates on alcoholic FLD, several reports have shown that WY-14,643 reduces hepatic triglyceride accumulation, with a significant decrease of blood triglyceride levels, in different types of non-alcoholic FLD mouse models (Chou *et al.*, 2002; Ip *et al.*, 2003; Kim *et al.*, 2003; Ide *et al.*, 2004). Thus, isohumulones may play a role in protecting against the development of alcoholic and non-alcoholic FLD.

Isohumulones are only a few of the food-derived PPAR activators, and their presence has long been noted in beer. Our results suggest that they might be beneficial, not to mention cost effective, for the prevention and/or treatment of cardiovascular disease and FLD. However, further human study is necessary to confirm their potential benefits, since the effects shown so far are mostly based on animal studies. Simple arithmetic based on short-term animal studies indicates that we would need to drink more than 5 l/kg body weight of beer daily to obtain the optimal effects of these compounds (Miura *et al.*, 2005). However, a preliminary pilot study with mild type 2 diabetic subjects suggests that the daily intake of approximately 50 mg of isohumulones, which is generally contained in less than two litters of beer, may contribute to the prevention of hypertension. (Yajima *et al.*, 2004). Thus, it appears to be important to evaluate the possible utility of isohumulones from beer for prevention of metabolic syndrome by epidemiological studies. Further investigations will unravel whether the original idea of our mediaeval ancestors to use the hop plant in the production of beer actually has great medical merit.

Summary Points

- The major bitter compounds in beers are isohumulone, isocohumulone, and isoadhumulone, all of which are

produced from the hop plant (*Humulus lupulus* L.) during the beer-making process.

- Isohumulone and isocohumulone activate PPARα in an *in vitro* reporter assay, while isoadhumulone does not.
- Supplementation with isohumulones suppresses body weight gain without an effect on food intake through a PPARα independent mechanism.
- Supplementation with isohumulones increases liver weight and decreases adipose tissue weight.
- Supplementation with isohumulones decreases triglyceride and NEFA and increases HDL-cholesterol in blood through the activation of PPARα.
- Supplementation with isohumulones decreases hepatic triglyceride and cholesterol contents.
- Supplementation with isohumulones dose-dependently induces hepatic gene expression mainly of proteins that are involved in fatty acid oxidation in a PPARα-dependent manner.
- Although the effects of isohumulones are generally observed both in male and female, subtle differences are detected in the biochemical parameters and gene expressions.
- Animal studies suggest a possibility that isohumulones provide an alternative for the prevention and amelioration of dyslipidemia in metabolic syndrome, whereas further human study is needed.

Flavonoids in Beer and Their Potential Benefit on the Risk of Cardiovascular Disease

C-Y. Oliver Chen. and Jeffrey B. Blumberg Antioxidants Research Laboratory, Jean Mayer USDA Human Nutrition Research Center on Aging, Tufts University, Boston, MA, USA

Abstract

Beer is a popular alcoholic beverage and its consumption is characterized by a U- or J-shaped relation to the risk of cardiovascular disease (CVD). In addition to the ability of ethanol to elevate high-density lipoprotein–cholesterol, other constituents of beer, including flavonoids, may also contribute to its association with a reduced risk of CVD among moderate drinkers. Flavonoids are ubiquitous in plant-based foods and an integral part of any diet that includes fruits, vegetables, whole grains and/or beverages derived from them. Six classes of flavonoids, including 31 specific compounds, have been characterized in beer with a wide range of concentration, from 0.001 to 20 mg/l, likely due to variations in the barley and hops, brewing and stabilization processes, and duration of storage. The principal flavonoids in beer are isoxanthohumol, catechin, catechin gallate, epicatechin gallate, kaempferol, quercetin, procyanidin B3, and prodelphidins B3 and B9. Flavonoid intake has been demonstrated to impact an array of biochemical and functional actions in animal models and human studies that are associated with ameliorating CVD risk, such as reducing angiogenesis, cholesterol, inflammation, oxidative stress, and thrombogensis as well as promoting vascular reactivity. Nonetheless, definitive studies on the direct contribution of flavonoids to the benefit of moderate beer consumption on CVD remain to be undertaken.

Introduction

Alcoholic beverages, including beers, spirits, and wines, have been consumed for millennia and are an integral part of the daily diet among people in several societies. Average daily intake of beer in the USA is 227 ml per person (USDA, 2004), equivalent to 4% of energy intake (at 5% ethanol content) in a 2,000 kcal diet. While alcoholic beverages are consumed for pleasure and relaxation, observational studies reveal a U- or J-shaped relationship between their intake and overall morbidity and mortality (Camargo *et al.*, 1997; Keil *et al.*, 1997; Gaziano *et al.*, 2000; Gronbaek,

2006). These data suggest this potential health benefit is obtained at light to moderate consumption, that is, 10–19 and <10 g alcohol/day for men and women, respectively (Moore and Pearson, 1986; Fuchs *et al.*, 1995; Kannel and Ellison, 1996; Hendriks and van Tol, 2005; Mukamal *et al.*, 2006). While this health benefit appears independent of the type of alcoholic beverage, several reports have focused particularly on the value of red wine (Rimm *et al.*, 1996; Cleophas, 1999). In trying to elucidate the mechanism of action of alcoholic beverages on CVD risk, most attention has been directed to the ability of ethanol to elevate high-density lipoprotein (HDL)-cholesterol. However, other constituents may also contribute to reducing the incidence of CVD among drinkers either independently from or in a complementary manner to ethanol (Pace-Asciak *et al.*, 1995; Gasbarrini *et al.*, 1998; Serafini *et al.*, 1998). This chapter reviews the basis for a potential contribution of beer flavonoids to reduced CVD risk.

Beer Consumption and Risk of CVD

CVD, including coronary heart disease, cerebrovascular disease, and peripheral artery disease, is the leading cause of morbidity and mortality in the industrialized world (World Health Organization, 2006). The pathogenesis of CVD involves injury to vascular endothelial cells, stimulation of inflammatory responses, adhesion of lymphocytes to vessel walls and migration into the intima, oxidation of LDL, formation of lipid-laden foam cells, development of plaque, and thrombosis (De Caterina *et al.*, 2006). Numerous risk factors of CVD have been identified (Table 84.1). Most of these factors are modifiable through lifestyle changes and pharmacotherapy, except age, male sex, and ethnicity/genetics (Scott, 2004).

Importantly, the impact of drinking alcoholic beverages on CVD risk can be positive or negative depending on amount and pattern of consumption (Hendriks and

Table 84.1 Risk factors of CVD[a]

Modifiable risk factors	Impact of moderate consumption of alcoholic beverages
Clinical and lifestyle risk factors	
Visceral obesity	?[b]
Hypertension	↑
Smoking	–[d]
Excessive alcohol intake	–[d]
Physical inactivity	–[d]
Dietary patterns high in saturated fats and cholesterol; low in fruits, vegetables, soluble fiber, and whole grains	–[d]
Psychosocial stress	?[c]
Biochemical risk factors	
Dyslipidemia (high triglycerides and LDL-cholesterol; low HDL cholesterol)	↓
Lipoprotein(a)	–[d]
Hyperglycemia	–[d]
Platelet aggregation	↓
Oxidative stress	↓
Chronic inflammation	↓
Hyperhomocysteinemia	↓
Endothelial dysfunction	↓

[b] Heavy drinking can substantially increase caloric intake but the impact of moderate intakes is not clear.
[c] Heavy drinking is associated with mood and anxiety disorders but the impact of moderate consumption is less well characterized but often considered a relaxant.
[d] No association.

van Tol, 2005). Regular and moderate consumption of alcoholic beverages can ameliorate some CVD risk factors such as elevating HDL-C via reducing hepatic lipase and increasing lipoprotein lipase and lecithin:cholesterol acyltransferase activity (Gaziano *et al.*, 1993; Hendriks and van Tol, 2005). In addition, ethanol can improve antioxidant capacity by raising HDL paraoxonase 1 activity (Van der Gaag *et al.*, 1999; Sierksma *et al.*, 2002a); promote vascular reactivity via increasing nitric oxide availability (Puddey *et al.*, 2001); decrease platelet aggregation by lowering the concentration of fibrinogen (Dimmitt *et al.*, 1998; Sierksma *et al.*, 2002b; De Lange *et al.*, 2003); and blunt inflammation (Sierksma *et al.*, 2002b). In contrast, heavy drinking can elevate blood pressure and psychosocial stresses as well as promote visceral obesity, thereby contributing to the development of metabolic syndrome, diabetes, and CVD.

While ethanol is the principal ingredient shared among beer, wine, and spirits, their impact on CVD risk may vary substantially due to quantity and quality of phytochemicals. Some observational studies indicate a significant inverse relationship between CVD and red wine consumption

but weak or null associations with beer and spirits (Truelsen *et al.*, 1998; Gronbaek, 1999; Di Castelnuovo *et al.*, 2002; Ruf, 2003). However, other larger cohort studies demonstrate comparable protection from beer, wine, and spirits (Rimm *et al.*, 1991; Keil *et al.*, 1997). The conflicts between these reports can be attributed to unknown confounding factors as well as to established factors such as socioeconomic status (Nielsen *et al.*, 2004). When examining only beer consumption among Czech men, Bobak *et al.* (2000) found that 4–9 l/week was associated with the lowest risk of CVD. In a study of 312 patients with clinically stable, angiographically confirmed coronary heart disease and 479 healthy controls, Brenner *et al.* (2001) found an odds ratio (OR) of 0.55 (95% confidence interval (CI) = 0.37–0.83) for coronary heart disease in drinkers compared with non-drinkers, with particularly strong reduction among participants drinking predominantly beer. In a prospective study of 24,523 Danish participants, Gronbaek *et al.* (2000) found that for coronary heart disease OR were 0.78 (95% CI = 0.67–0.91), 0.74 (0.63–0.86), and 0.97 (0.83–1.12) for beer, wine, and spirits drinkers with alcohol intake at 1–7 drinks/week compared with non-drinkers. A health benefit from moderate consumption of beer has also been suggested by a clinical trial in which 330 ml/day for 30 days was found to lower thrombogenic activity in 28 coronary heart disease patients (Gorinstein *et al.*, 1997). In addition to its alcohol content, beer may possess other bioactive constituents, particularly flavonoids, derived from its two principal plant ingredients, barely and hops (Gronbaek, 2006).

Nomenclature and Chemistry of Flavonoids

Flavonoids, a subfamily of polyphenols, are secondary metabolites involved in plant growth, reproduction, protection against pathogens and predators, and seed germination (Treutter, 2005). They are products of the shikimate pathway from phenylalanine and the acetate pathway (Aherne and O'Brien, 2002). The shared structure defining flavonoids is a diphenylpropane (C6-C3-C6) consisting of three phenolic rings (Figure 84.1). The A ring is usually derived from resorcinol or phloroglucinol synthesized via the acetate pathway and the B ring is derived from the shikimate pathway. Flavonoids are typically divided into eight subclasses: anthocyanin, chalcone, dihydroflavonol, flavan-3-ol (or catechin), flavanone, flavone, flavonol, and isoflavone based on the connection position of the B and C rings as well as the degree of oxidation and hydroxylation of the C ring. The majority of plant flavonoids have a conjugated moiety linked to the hydroxyl group via glycosylation, malonylation, methylation, and/or sulfation, with glucoside as the most frequently occurring form (Bravo, 1998).
Figure 84.1   Molecular structures of typical flavonoids.

Dietary Sources of Flavonoids

Flavonoids are ubiquitous in common plant foods, for example, with the flavonols quercetin, kaempferol, and myricetin found in onions, curly kale, leeks, broccoli, blueberries, red wine, and tea; the flavones, apigenin and luteolin, found in parsley, celery, and cereals; the flavanones naringenin, hesperetin, and eriodictyol found in tomatoes, mint, grapefruit, oranges, and lemons; the isoflavones genistein, daidzein, and glycetin found in soy foods; the flavan-3-ols catechin and epicatechin found in green tea, red wine, and cocoa; the anthocyanins cyanidin and malvidin found in red wine, grapes, beans, onions, and berries (Manach *et al.*, 2004). Their distribution in plants is dependent in part on the degree of accessibility of the plant's parts to light and other environmental stresses (Aherne and O'Brien, 2002); thus, most flavonoids tend to be prevalent and most concentrated in the outer parts of plants, for example, leaves, flowers, and the skin or peel of fruit (Aherne and O'Brien, 2002). Although flavonoids are an integral part of our daily diet, intakes have not been accurately or fully determined for nutrient databases because of the several thousand individual flavonoids present and their marked variation due to the impact of environmental, seasonal, agricultural production, and other factors, including differences between varietals of the same species. Nevertheless, daily average intakes have been estimated to range between 14 and 72 mg/day, though individual differences may be substantially less or greater (Graf *et al.*, 2005; USDA, 2006).

Flavonoids in Beer

Beer is produced in a simple fermentation process using barley (*Hordeum vulgare* L.), dried flowers of hops (*Humulus lupulus* L.), water, and yeast. In addition to being rich in amino acids, peptides, and B vitamins, beer contains

phenolic acids and flavonoids derived principally from barley and hops, with most of these compounds from barley (Boivin *et al.*, 1993). Barley contains flavanols, flavonols, and proanthocyanidins with total polyphenols at 1.2–1.5 g/kg (Madigan *et al.*, 1994) (Table 84.2). Hops, added to

Table 84.2   Maximum possible concentrations of flavonoids in beers, determined by HPLC[a]

Flavonoid	Beer (mg/l)	Hop (mg/kg)	Barley (mg/kg)
Chalcone			
Xanthohumol	≤1.2	4,800

[a] Achilli *et al.* (1993); Andersen *et al.* (2000); Arts *et al.* (2000); Clarke *et al.* (2004); Cortacero-Ramírez *et al.* (2004); de Pascual-Teresa *et al.* (2000); Garcíía *et al.* (2004); Gerhauser (2005); Goupy *et al.* (1999); Hertog *et al.* (1993b); Jandera *et al.* (2005); Lapcik *et al.* (1998); Li and Deinzer (2006); Madigan *et al.* (1994); McMurrough (1981); McMurrough and Baertt (1994); Milligan *et al.* (1999); Stevens *et al.* (1999); Tekel̀ *et al.* (1999); USDA (2006).

enhance bitterness and flavor to beer, contain polyphenols at 3–6% dry weight comprised largely of proanthocyanidins, flavanols, and flavonols (De Keukeleire *et al.*, 1999). Large variations in the flavonoid composition and content of both barley and hops are due to plant varieties, methods of cultivation and harvesting, and degree of aging. Tedesco *et al.* (2005) and Vinson *et al.* (2003) determined the range of total phenolics in commercially available beers from 187 to 2,504 μmol/l (32–426 mg/l) using the Folin–Ciocalteu assay. The rank of total phenolic content among different types of beers was ales > lagers > low calorie > nonalcoholic (Vinson *et al.*, 2003).

Using a more specific HPLC determination of phenolic compounds, individual flavonoids in beer have been identified and quantitated, including those from the anthocyanin, chalcone, flavonol, flavan-3-ol, procyanidin, and isoflavone classes (Table 84.2). The concentration of individual flavonoids is expressed according to their possible maximum value because of relatively large variations in reported concentrations of individual flavonoid among beers analyzed by laboratories in different countries. The major reported flavonoids are catechin, catechin gallate, epicatechin gallate, isoxanthohumol, kaempferol, quercetin, procyanidin B3, and prodelphidin B3 and B9 (see structures in Figure 84.2). Interestingly, flavones, isoflavones, and catechin gallate have not been identified in barely or hops. These flavonoids

may be created during brewing process from related compounds, for example, xanthohumol, a prenylflavonoid chalcone found in hops. Xanthohumol may be converted into isoxanthohumol via thermal isomerization (Stevens and Page, 2004). There are not only four prenylflavonoids in beer, principally isoxanthohumol, but also 6-prenylnaringenin, 6-granylnaringenin, and 8-prenylnaringenin (8-PN) (Stevens and Page, 2004). Although 8-PN is a negligible component of beer at 0.24 mg/l, it appears beer is a unique dietary source of this flavonoid. While isoflavones are found principally in soy foods, genistein, biochanin A, daidzein, and formononetin are found as well in beer (Lapcik *et al.*, 1998). The natural concentration of flavonoids in freshly brewed beer is reduced through the use of polyvinylpolypyrrolidone (a stabilizer) which adsorbs flavanols and tannins as well as through subsequent filtration steps employed to prevent haze formation (McMurrough *et al.*, 1995). Further, flavonoid content declines during the storage of beer through conversion to tannoids (flavonoid polymers) (McMurrough and O'Rourke, 1997).

Although their calculations must be considered as a rough estimate, Vinson *et al.* (2003) have estimated total phenol intake from beer at 42 mg catechin equivalents/day/person, based on the average consumption of beer at 225 ml/day and 64 mg catechin from a serving (341 ml or 12 oz.). Flavonoid intake from consumption of red wine has been
Figure 84.2 Structures of major beer flavonoids.

estimated at 21 mg/day (Vinson and Hontz, 1995; Vinson, 1998). Thus, depending on one's dietary pattern, consumption of beer or wine can contribute significantly to flavonoid intake.

Absorption and Metabolism of Flavonoids

Flavonoids are absorbed throughout the gastrointestinal tract and excreted in the feces or urine (Figure 84.3). The site and rate of absorption depend in part on the specific flavonoid and its conjugation with sugar, degree of polymerization, and solubility (Bravo, 1998; Scalbert and Williamson, 2002). Sugar moieties are generally cleaved by lactase phlorizin hydrolase or β-glucosidase prior to absorption. In the colon, flavonoids can be degraded into phenolic acids by gut microflora (Bravo, 1998). Flavonoids can enter enterocytes via active transportation (Walle, 2004). Once absorbed, glucuronide, sulfate, and/or methyl groups are added to hydroxyl moieties via phase II pathways in enterocytes, liver, and kidney (Manach et al., 2004). Subsequently, flavonoid metabolites are transported to extrahepatic tissues and eventually to the kidneys where they are excreted in the urine or incorporated into bile and recycled to the gut and eventually excreted in the feces (Bravo, 1998). The maximum concentration of most flavonoids in human plasma is reached 1–6 h after ingestion. The elimination half-life of most flavonoids ranges from 1 to 18 h depending on the flavonoid class and specific compound (Manach

et al., 2005b). The acute bioavailability and kinetics of flavan-3-ols, flavones, flavonols, and isoflavones have been partly characterized though little information is available regarding these parameters during chronic consumption or their interactions with other food components (Manach et al., 2005b). Much less is known about the bioavailability of proanthocyanidins though it has been suggested little can be absorbed as the intact parent form and, thus, their bioactivity may be a result of the phenolic acids absorbed after their breakdown by gut microflora (Gonthier et al., 2003). Xanthohumol, a prenylchalcone present in hops, has been detected in rat plasma in the form of two monoglucuronides with a maximum concentration reached 4 h after ingestion (Yilmazer et al., 2001). The bioavailability of isoxanthohumol and 8-prenylnaringenin has not been characterized.

Mechanisms of Beer Flavonoids in CVD Reduction

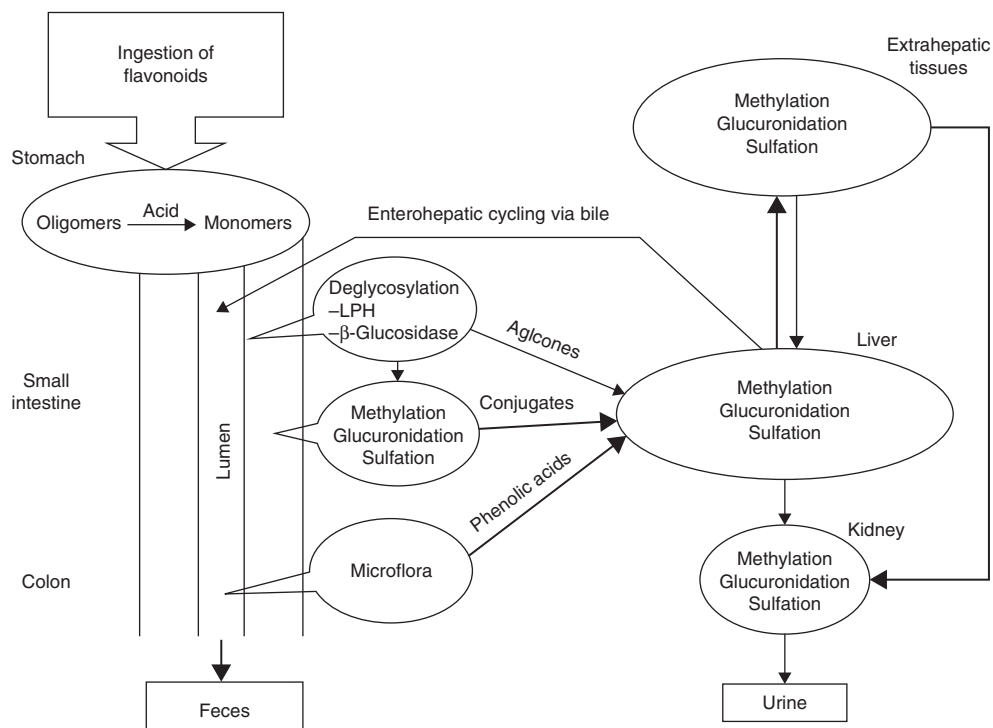
As noted, ethanol is generally considered the most significant contributor in alcoholic beverages to the reduction in CVD risk via increasing HDL-C and fibrinolysis and decreasing platelet aggregation. Nonetheless, due to a relevant array of bioactivities, flavonoids have also been suggested to contribute to this benefit of moderate drinking (Langer et al., 1992; Renaud and Ruf, 1996; Dimmitt et al., 1998; Mann and Folts, 2004). Observational data from the Zutphen Elderly Study (Hertog et al., 1993a; Keli


Figure 84.3   Absorption, metabolism, and excretion of flavonoids. LPH, lactase phlorizin hydrolase.

et al., 1996), Rotterdam Study (Geleijnse *et al.*, 1999), and Iowa Study (Yochum *et al.*, 1999) suggest flavonoid intake reduces CVD risk. While direct evidence regarding the impact of beer flavonoids on health remains to be determined, flavonoids present in beer have been shown to have anti-inflammatory, antioxidant, and hypocholesterolemic actions as well as work to maintain homeostasis and endothelial function via several different pathways important to the pathogenesis of chronic disease (Figure 84.4).

Anti-inflammatory activity

Atherosclerosis is substantially a chronic inflammatory response to injured endothelium (Ross, 1999; Libby, 2002). C-reactive protein (CRP), an acute-phase protein and useful biomarker of inflammation, has been established as a significant predictive factor of CVD (Ridker *et al.*, 2001; Albert *et al.*, 2003). Indeed, the relationship between CRP and consumption of alcohol is consistent with the U-shaped relation between CVD risk and drinking (Imhof *et al.*, 2001; Stewart *et al.*, 2002; Albert *et al.*, 2003; Volpato *et al.*, 2004). Sierksma *et al.* (2002b) conducted a cross-over trial in 10 men and 9 women providing 4 and 3 glasses of beer with dinner daily (providing 40 and 30 g ethanol/day, respectively) for 3 weeks and found a 35% reduction in

plasma CRP compared to a similar intervention with non-alcohol beer. While this study did not evaluate flavonoid intake or status, flavonoids have been shown to reduce biomarkers of inflammation, including CRP, tumor necrosis factor-α, monocyte chemoattractant protein, and nuclear factor-κB. For example, Estruch *et al.* (2004) found that 30 g ethanol from flavonoid-rich red wine daily for 28 days decreased CRP by 21% as compared to an equivalent amount of ethanol from gin in 40 healthy men (mean age = 37.6 years). However, results from other human studies with flavonoid-rich foods indicate equivocal or null outcomes regarding CRP (de Maat *et al.*, 2000; Mathur *et al.*, 2002; Fukino *et al.*, 2005). Thus, additional studies are warranted with particular attention provided to the flavonoid composition and content of both the beer and other foods in the diet.

Antioxidant activity

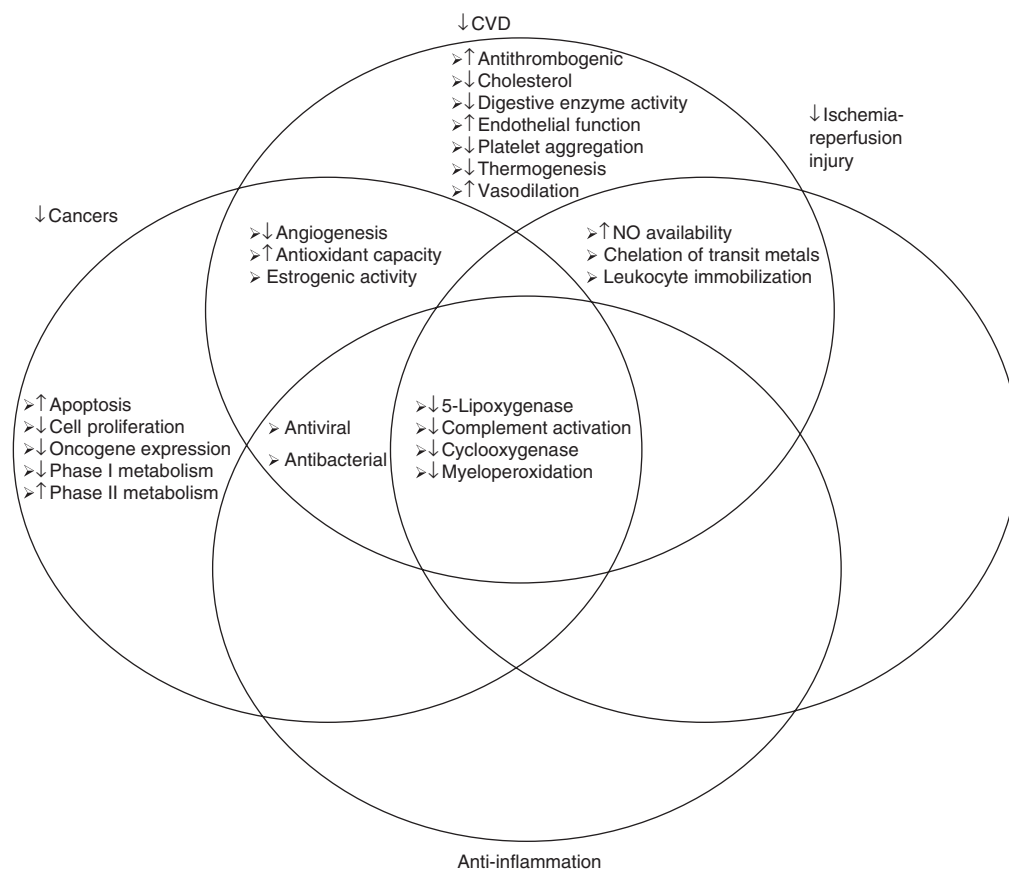
Reactive oxygen species generated during normal aerobic metabolism can damage DNA, lipids, and proteins if not adequately protected by the antioxidant defense network. Low-density lipoproteins (LDL) are particularly susceptible to free radical attack. Oxidized LDL contributes to atherogenesis by promoting inflammation, stimulating


Figure 84.4 Putative preventive mechanisms of flavonoids against chronic disease.

smooth muscle cell proliferation, impairing endothelial function, and provoking platelet aggregation (Esper *et al.*, 2006). Flavonoids, including those from beer, may act to increase the resistance of LDL to oxidation by scavenging both reactive oxygen and nitrogen species, chelating transition minerals like copper and iron, and up-regulating endogenous antioxidant defenses (Torel and Cillard, 1986; Robak and Gryglewski, 1988; Hu *et al.*, 1995; Nijveldt *et al.*, 2001). While there are no reports examining the effect of beer flavonoids on biomarkers of oxidative stress *in vivo*, Vinson *et al.* (2003) and Miranda *et al.* (2000) found LDL resistance against oxidation was enhanced *in vitro* by beer with its potency greater than α-tocopherol but less than quercetin.

The antioxidant capacity of beer against lipoprotein oxidation has been examined in animal models. Even though ethanol can act as a pro-oxidant via action on hepatic cytochrome P450-2E1 (Nagy, 2004), Gasbarrini *et al.* (1998) reported that chronic beer consumption increased lipoprotein resistance against oxidation *ex vivo* in rats. In another rat study, Gasowski *et al.* (2004) found an inverse association between the antioxidant capacity of beer and the reduction of plasma malondialdehyde, a biomarker of lipid peroxidation. Using hamsters, Vinson *et al.* (2003) found that lager or dark beer containing 2% ethanol enhanced lipoprotein resistance against *ex vivo* oxidation by ≥1-fold as compared to ethanol only. This experimental evidence implicates flavonoids and/or other phenolic compounds as contributors to the antioxidant actions of beer.

Several assays have been employed to evaluate the "total antioxidant capacity" of foods and beverages, including the oxygen radical absorbance capacity (ORAC), total reactive antioxidant potential (TRAP), trolox equivalent antioxidant capacity (TEAC), and ferric reducing antioxidant power (FRAP) assays. Using the TEAC assay assays, Gasowski *et al.* (2004) reported the antioxidant capacity of four beers (from Bulgaria, Czech Republic, Israel, and the Netherlands) ranged from 1.65 to 2.07 mmol Trolox equivalents/l. Using the FRAP assay, Tedesco *et al.* (2005) determined the antioxidant capacity of 48 commercial beers without ethanol ranged from 112.2 to 637.5 μmol quercetin equivalents/l. The antioxidant capacity of beer is attributed to its polyphenol content due to its strong correlation with H-donating capacity (Lugasi, 2003). In addition to acting as an antioxidant in simple chemical reactions *in vitro*, constituents in beer have been shown to increase total antioxidant capacity in plasma. Using the TRAP assay, Ghiselli *et al.* (2000) found a bolus of 500 ml beer (4.5% ethanol) elevated total plasma antioxidant capacity by 17% in healthy adults but the same volume of dealcoholized beer or 4.5% ethanol were without an effect on this parameter. In contrast, Van der Gaag *et al.* (2000) found no effect of beer (40 g alcohol/day) consumed for 3 weeks on total antioxidant capacity in 11 healthy, non-smoking middle-aged men with the TEAC assay; however, this

outcome may have been confounded by a 15% reduction in plasma concentrations of vitamin C and β-carotene (but not other carotenoids, vitamin E, or glutathione). Further study of the kinetics of beer flavonoids under acute and chronic conditions of intake would help resolve the discrepancy among these studies.

Red wine appears to have the highest polyphenol content of alcoholic beverages, about 8-fold greater than that of beer (Gorinstein *et al.*, 1998a; Lugasi, 2003). However, lyophilized dry substances from 6 ml beer and 2 ml red wine had comparable efficacy inhibiting lipid peroxide formation by 50% in rats, suggesting the bioavailability and/or bioactivity of antioxidants from beer might be more potent than those from red wine (Gorinstein *et al.*, 1998b). Again, more studies directly examining beer flavonoids *in vivo* are necessary to clarify their actions and putative health benefits.

Cholesterol lowering activity

Dyslipidemia, that is, elevated total cholesterol (TC), triglyceride (TG), and LDL-C and/or low HDL-C, is a significant CVD risk factor. Evidence from animal models, observational studies, and clinical trials indicate that flavonoids derived from tea, virgin olive oil, cocoa, soybean, and red clover possess hypocholesterolemic activity due to their inhibition of cholesterol and fatty acid absorption, apoB-100 production, and very low-density lipoprotein (VLDL) secretion (Zern and Fernandez, 2005). Thus, the flavan-3-ols, flavanones, and isoflavones in beer share the capacity for this action, though consideration must be given to their content per serving with regard to achieving a similar magnitude of effect (Zern and Fernandez, 2005; Manach *et al.*, 2005a). Nonetheless, beer flavonoids may act in an additive or synergistic manner with ethanol to improve lipid profiles. While there is no direct evidence demonstrating a hypocholesterolemic action of beer *in vivo*, dried beer substances (6 ml beer equivalent/day), including flavonoids, phenolic acids, minerals, vitamins, and amino acids, fed to rats fed a diet containing 5% sunflower oil and 1% cod liver oil decreased TC, TG, and LDL-C (Gorinstein *et al.*, 1998a). The magnitude of improvement in lipid profiles was comparable to rats fed 2 ml red wine dried substances. A beneficial effect of ethanol-free beer constituents on cholesterol metabolism and accumulation in aorta was observed in a study using LDLr−/− apoB100/100 mice (Degrace *et al.*, 2006). Using hamsters, an animal model in which cholesterol metabolism is similar to that of humans, Vinson *et al.* (2003) also found that constituents other than ethanol in lager and dark beer decreased TC by 57% and 70% and TG by 76% and 51%, respectively, as well as inhibited atherosclerotic foam cell formation by 62% and 71%. However, null results were observed in apoE−/− mice fed ethanol, mild beer, dark beer, or ethanol-free beer (Escola-Gil *et al.*, 2004). The influence of genomics on flavonoid action remains to be determined.

Hemostasis and endothelial function

Vascular hemostasis involves a delicate balance between the formation and degradation of blood clots within an interacting network of coagulation factors and vessel walls (Lefevre *et al.*, 2004). Impaired hemostasis is associated with increased risk of CVD (Willoughby *et al.*, 2002). The effect of alcoholic beverages on hemostasis may partially explain the U- or J-shaped relation between moderate drinking and CVD. Hendricks *et al.* (1994) found that moderate consumption of beer, wine, or spirits (40 g alcohol/day) with dinner for 4 days temporarily increased plasminogen activator inhibitor activity, in a manner sufficient to increase fibrinolysis. Similarly, Gorinstein *et al.* (1997) provided 22 patients with coronary artery disease with 330 ml beer (20 g alcohol) daily for 30 days and found a decrease in thrombogenic activity. As noted above, these studies do not demonstrate a specific effect of beer flavonoids but such results are consistent with reports of other interventions with flavonoids showing improved hemostasis, including increased bleeding time and reduced platelet aggregation (Freedman *et al.*, 2001; Murphy *et al.*, 2003; Hubbard *et al.*, 2004).

Endothelial cells serve not only as a physical barrier between blood and smooth muscles in the vessel wall but participate dynamically in both anti- and pro-atherogenic actions, including the regulation of vasomotor tone, adhesion and aggregation of platelets, adhesion and migration of monocytes, and proliferation of smooth muscle cells (Esper *et al.*, 2006). Endothelial dysfunction predisposed by smoking, hypercholesterolemia, hypertension, diabetes, and/or hyperhomocystinemia plays a critical role in the development of atherosclerosis (Ross, 1999; Kinlay and Ganz, 2000). Endothelial function can be assessed using a non-invasive measure of flow-mediated dilation (FMD) in the brachial artery. FMD is regulated substantially by nitric oxide (NO) release following the endothelial response to sheer stress and consequent relaxation of the underlying smooth muscle (Kinlay and Ganz, 2000). Moderate intake of alcoholic beverages may enhance this vascular reactivity due to the effect of ethanol to increase NO production as well as HDL-C (Puddey *et al.*, 2001). The increase of FMD induced by both red wine and alcohol-free red wine suggests that flavonoids can directly improve endothelial function (Karatzi *et al.*, 2004, 2005). Other flavonoid-rich foods, including grape juice, black tea, soy, and cocoa, have also shown a beneficial effect on endothelial function in healthy adults and/or patients with coronary heart disease (Manach *et al.*, 2005a). While beer flavonoids may also act in a similar manner, studies have yet to test this hypothesis.

Summary Points

- Flavonoids possess a variety of biological actions, particularly as demonstrated *in vitro* and in short-term studies *in vivo*. However, their bioactivity in humans remains to be fully examined, particularly in "real-life" conditions with a mixed diet of foods and beverages consumed in usual amounts.
- Consumption of beer and other alcoholic beverages in excess is associated with increases in blood pressure and psychosocial stress which are risk factors for CVD.
- Beer consumption in moderation appears to reduce CVD risk via the beneficial action of ethanol and perhaps other constituents, particularly flavonoids, on hemostasis, inflammation, oxidative stress, and/or vascular reactivity.
- Beer has been characterized as containing 31 flavonoids derived principally from barley and hops. Major beer flavonoids are isoxanthohumol, catechin, catechin gallate, epicatechin gallate, kaempferol, quercetin, procyanidin B3, and prodelphinidins B3 and B9.
- The concentrations of flavonoids in beer vary widely from 0.001 to 20 mg/l depending on the plant ingredients, brewing techniques, stabilization process, and duration of storage.
- Beer consumption has been associated with an increase in HDL-C. In addition to this action of ethanol, beer flavonoids may contribute independently or in conjunction with ethanol to an improved lipid profile and an associated reduction in atherogenesis.
- Acute, moderate beer consumption can increase total antioxidant capacity in plasma, an effect attributed to its polyphenol content. Dry matter from red wine and beer has a comparative ratio of antioxidant potency *in vitro* of 1:3.

Vasoactivity of Flavonols, Flavones and Catechins

Owen L. Woodman School of Medical Sciences, RMIT University, Victoria, Australia

Abstract

Flavonols, flavones and catechins are three families amongst the very large group of biologically active plant-derived compounds known as flavonoids. These compounds have in common that they are all vasoactive and antioxidant, and through these actions it has been proposed that they may offer protection against cardiovascular disease. Each of these compounds is found in significant levels in barley and hops, the two important plant ingredients in beer, and therefore beer is one of the dietary sources of these flavonoids. The flavonols and flavones cause purely vasorelaxation *in vitro*, whereas catechins can cause contraction or relaxation depending on the individual compound and the concentration. By contrast, all of these compounds are reported to improve endothelium-dependent dilation in humans that may result from their common ability to preserve nitric oxide (NO) activity. This arises from the antioxidant actions of these flavonoids resulting in reduced inactivation of NO by the superoxide anion. Oxidant stress is an important contributor to the pathogenesis of cardiovascular disease and this chapter will review the growing evidence that flavonols, flavones and catechins through their direct and indirect actions on the vasculature are able to prevent the development of hypertension and ischemia/reperfusion injury.

List of Abbreviations

ACE	Angiotensin converting enzyme
DNA	Deoxyribonucleic acid
ECg	Epicatechin gallate
eNOS	Endothelial nitric oxide synthase
HUVEC	Human umbilical vein endothelial cell
LDL	Low-density lipoprotein
NO	Nitric oxide
SOD	Superoxide dismutase
TUNEL	Terminal deoxynucleotidyl transferase mediated dUTP nick end labeling
ACh	Acetylcholine
DiOHF	3′,4′-dihydroxy flavonol
EC	Epicatechin
EGC	Epigallocatechin
EGCg	Epigallocatechin gallate
MDA	Malondialdehyde
SHR	Spontaneously hypertensive rat
TBARS	Thiobarbituric acid-reactive substances

Introduction

The flavonoids are a large group of plant-derived compounds that are known to exhibit biological effects, including lowering plasma levels of low-density lipoproteins (LDLs), inhibiting platelet aggregation and reducing cell proliferation. In addition, many flavonoids have been reported to modulate vascular tone and to exert antioxidant activity. Flavonoids are based on the structure of 2-phenyl-benzopyrone, differing from one another in the orientation of hydroxylation or methylation, the position of the benzenoid substituent, the degree of unsaturation and the types of sugar attached. Of the many classes of flavonoids of particular interest to this review are the flavonols, flavones and catechins (which are also referred to as flavanols or flavan-3-ols). Flavones and flavonols are structurally very similar with a 2,3-double bond conjugated with the 4-oxo group in ring C, with flavonols having an extra hydroxyl substitution at the carbon 3 position (Figure 85.1). By contrast, the catechins lack the double bond in the middle ring (Figure 85.2). Flavonoids are ubiquitous to green plant cells, including in barley and hops, leading to their ingestion through the consumption of beer in addition to many other foodstuffs. The phenolic content of beer depends on both the raw materials and the brewing process (Vinson *et al.*, 2003).

Fitzpatrick *et al.* (1993) demonstrated that wine and grape products such as quercetin and tannic acid cause endothelium-dependent relaxation in rat thoracic aorta and there have been several subsequent reports of the pharmacological actions of flavonoids on vascular smooth muscle tone. Duarte *et al.* (1993b) compared the relaxant effects of examples of compounds from the different structural subgroups of flavonoids. They reported that the order of potency for relaxation was flavonols > flavones > catechins. In addition these three groups of compounds exert significant antioxidant activity through a variety of mechanisms. This review

will focus on the direct vascular actions of these three groups of flavonoids including the ability of these polyphenols to preserve endothelial function as a result of their antioxidant effects, potentially offering protection against cardiovascular disease. In particular the evidence that flavonols, flavones and catechins may offer protection against hypertension and ischemia/reperfusion injury is explored.

Quantity of Flavones, Flavonols and Catechins in Beer

The two important plant ingredients in beer, barley and hops, both act as sources of the flavonoids and other polyphenolic compounds found in beer. Barley is a particularly good source of the catechins, epicatechin and epigallocatechin (EGC) but flavonols have also been identified (Goupy *et al.*, 1999), as have flavones (Markham and Mitchell, 2003). Hops also provides a source of both flavonols and flavones that are then found in beer (Stevens *et al.*, 2002). Vinson (1998) suggested that the most common phenols found in beer are "flavonols, phenolic acids, catechins, procyanidins and tannins" but there are only a few reports of quantitative analysis of distinct phenols found in beer. McMurrough *et al.* (1996) reported that a lager beer contained 56 mg/l of total polyphenols with flavonols contributing 19.5 mg/l. After examination of nine non-alcoholic beers from Spain, Alonso Garcia *et al.* (2004) reported that the total polyphenol content ranged from 0.8 to 8.6 mg/l with catechin contributing 0–4.5 mg/l and EC 0–0.22 mg/l. There was no detectable level of the flavonol quercetin. In an analysis of the catechin content of a variety of Spanish foodstuffs, De Pascual-Teresa *et al.* (2000) reported that a beer had a total flavonol content of 6.4 mg/l including catechin (7.3 mg/l), EC (1.8 mg/l) and gallocatechin (3.1 mg/l).

Vinson *et al.* (2003) have made an estimate of the average phenol intake from beer compared to wine in the United States based on consumption statistics for the year 2000 provided by the US Department of Agriculture. They

Catechins	R_1	R_2
Catechin	H	OH
Gallocatechin	OH	OH
Catechin gallate	H	GA
Gallocatechin gallate	OH	GA

Epicatechins	R_1	R_2

concluded that if lager beer were consumed, containing 677 μM phenols, at the average volume of 225 ml/day the phenol intake, expressed as catechin equivalents, would be 42 mg/day. This is twice the amount of phenol obtained from the average of 20.7 ml of red and white wine per day based on a phenol concentration of 3,397 μM (Vinson, 1998). Thus, whilst wine is often referred to as an important source of cardioprotective flavonols, in societies where beer is more widely consumed than wine, it too should be recognized as an important source of flavonoids together with other beverages such as tea, in addition to foodstuffs, particularly fruits and vegetables.

Vascular Activity of Flavonols and Flavones

The observations of the vascular effects of extracts of wine, fruit and vegetables have provoked considerable interest in the potential activity of flavones and flavonols. Particular attention has been paid to quercetin, the most abundant of the naturally occurring flavonols. Several studies have demonstrated relaxant effects of quercetin, predominantly in rat isolated aorta (Duarte *et al.*, 1993a, b; Fitzpatrick *et al.*, 1993; Chen and Pace-Asciak, 1996; Flesch *et al.*, 1998; Chan *et al.*, 2000; Perez-Vizcaino *et al.*, 2002) also in coronary arteries from rabbits (Rendig *et al.*, 2001) and pigs (Taubert *et al.*, 2002). Although one of the initial studies indicated that the mechanism of quercetin-induced relaxation involved the release of a dilator from the endothelium, the same study also reported the contrary finding that the responses were unaffected by inhibition of nitric oxide synthase (NOS) (Fitzpatrick *et al.*, 1993). A number of subsequent studies reported that quercetin acted in an endothelium-dependent manner (Duarte *et al.*, 1993a, b; Flesch *et al.*, 1998; Perez-Vizcaino *et al.*, 2002), whereas in our laboratory removal of the endothelium decreased the sensitivity to quercetin without altering the maximum relaxation (Chan *et al.*, 2000). Chen and Pace-Asciak (1996) also noted that whilst low concentrations of quercetin acted in an endothelium-dependent manner, higher concentrations caused relaxation in the absence of the endothelium. Furthermore inhibition of NOS reversed relaxation in response to low but not high concentrations of quercetin. Taking into account all of these observations it appears that quercetin predominantly acts by direct relaxation of vascular smooth muscle and in addition it stimulates the release of endothelium-derived NO. Similar observations have been made with other flavonols such as leukocyanidol, fisetin, galangin and 3′,4′-dihydroxy flavonol (DiOHF) (Andriambeloson *et al.*, 1997; Chan *et al.*, 2000; Morello *et al.*, 2006).

Flavonols differ from flavones by the presence of a hydroxyl group at the 3 position of the C ring (Figure 85.1). It appears that it is this structural feature that leads to the endothelium-dependent component of flavonol-induced relaxation. The ability of flavonols to acutely stimulate the

release of endothelium-derived NO is supported by the studies of Taubert *et al.* (2002) who measured NO release from porcine coronary arteries in response to 28 phenols commonly occurring in plant foods. The flavonols quercetin, myricetin and fisetin were very effective stimulants of NO release, whereas the flavones apigenin, luteolin and naringenin caused much less effect (Taubert *et al.*, 2002). Flavones, without the hydroxyl substitution at the 3 position, are most commonly reported to act in an entirely endothelium-independent manner (Duarte *et al.*, 1993b; Herrera *et al.*, 1996; Chan *et al.*, 2000; Ajay *et al.*, 2003) although apigenin has been reported to show some sensitivity to NOS inhibition (Zhang *et al.*, 2002).

Of the flavonoids studied, flavonols and flavones appear to demonstrate the greatest level of vasorelaxant (Duarte *et al.*, 1993a) and antioxidant activity (Rice-Evans *et al.*, 1996; Pietta, 2000). The extra hydroxyl group present in the flavonols at the C_3 position (Figure 85.1) is important for vascular activity as they are more potent vasodilators than flavones (Duarte *et al.*, 1993a). The pattern of substitution of hydroxyl groups on the A and B rings of these compounds also influences activity, particularly substitution on the B ring, as flavonols with a $C_{2',4'}$ diOH or $C_{3',4',5'}$ triOH orientation are weak vasodilators (Herrera *et al.*, 1996), while a catechol group, comprising OH groups at $C_{3'}$ and $C_{4'}$, is associated with strong vasorelaxant activity (Herrera *et al.*, 1996). In contrast, OH substitution on the A ring reduces the relaxant actions of flavonols (Chan *et al.*, 2000). Similar to vascular activity, the antioxidant activity of flavones is enhanced by the C_3 OH group, indicating that flavonols are better antioxidants than the flavones (Figure 85.1) (Cao and Li, 2004; Kim and Lee, 2004). On ring B, the presence of a catechol group is reported to be a major determinant for high radical scavenging activity (Burda and Oleszek, 2001; Kim and Lee, 2004), and an additional OH at $C_{5'}$ results in even higher activity (Cos *et al.*, 1998).

In studies from our laboratory the flavonols 3′-hydroxyflavonol, DiOHF and 7,4′-dihydroxy flavonol tended to be more potent at causing vasodilation than DiOHF, consistent with the observations of Duarte *et al.* (1993b) who reported that flavonols, with the additional OH substitution at the C_3 position of the C ring, are the more potent vasodilators of the two groups. Although the B ring catechol group has been proposed as an important determinant for vasodilator activity (Herrera *et al.*, 1996), we found that, DiOHF was equally potent at impairing Ca^{2+}-contraction and less potent at impairing PE-contraction than 3′-hydroxyflavonol. This suggests that the $C_{3'}$ OH group on the B ring could be the main determinant for maximal vascular activity, while the presence of an additional OH group at C_4 results in unchanged or even lessened activity. The higher potencies observed in flavonols and flavones with the $C_{3'}$ OH group (Duarte *et al.*, 1993a) further support this proposition. The $C_{4'}$ OH group may be less important than the $C_{3'}$ OH as 7,4′-dihydroxy flavonol

tended to be less active than 3′-hydroxyflavonol at reducing vascular tone, although the reduced activity may also be due to the C_7 OH, which has been previously proposed to be associated with lessened activity (Chan et al., 2000). Duarte et al. (1993b) demonstrated that flavonols were more active vasodilators than flavones; however, this may only be true for flavonols with other substitutions on the A or B ring, as flavonol with only the C_3 OH group and unsubstituted flavone were equally weak at reducing vascular tone (Woodman et al., 2005). Moreover results of this study indicate that although substituted flavonols are more potent than flavones, it appears that the C_3 OH alone contributes little to activity. However the C_3 OH group may aid in the ability of OH substitutions on the A and B rings to increase vascular activity of the flavonol. The substitution of methoxy groups at positions C_3' and C_4' on the B ring abolished the high vascular activity of the catechol group, as 3′,4′-dimethoxyflavonol was observed to exhibit very weak vascular activity (Woodman et al., 2005). A limitation to our understanding of structure–activity relationships is that there are relatively few flavonols and flavones available with three or less hydroxyl substitutions or substitutions other than hydroxy or methoxy. Synthesis of flavonols and flavones with a wider variety of substitutions would facilitate the further investigation of the vascular structure–activity relationships of these compounds.

The mechanism of the endothelium-independent component of flavone- and flavonol-induced relaxation remains uncertain. Mechanisms that have been proposed include an inhibitory effect on protein kinase C, which is involved in contraction (Duarte et al., 1993a), or in the activity of phosphodiesterases, which inactivate cyclic nucleotides that are involved in relaxation (Herrera et al., 1996). Alternatively, flavonols and flavones may interfere with the utilization of calcium in the contractile process in vascular smooth muscle cells that may involve a reduced influx of extracellular calcium (Duarte et al., 1994) and impairment of release of intracellular calcium stores (Chan et al., 2000). There is also some evidence of the involvement of calcium-activated and ATP-sensitive potassium channels in flavone and flavonol-induced relaxation (Calderone et al., 2004).

Vascular Activity of Catechins

There have been several reports of the vasoactivity of the catechins, predominantly in rat isolated aorta, but the mechanism of their vascular effects remains uncertain. The most common catechins are shown in Figure 85.2. Of the eight most common catechins, EC, epicatechin gallate (ECg), EGC and epigallocatechin gallate (EGCg) are the compounds most frequently investigated in regard to their vascular activity. In contrast to the flavones and flavonols, which universally cause vascular relaxation, those catechins that possess vascular activity have been observed to induce both contraction and relaxation which is related to both structure and concentration.

The earliest reports of the vascular activity of catechins were that they were relaxants (Andriambeloson et al., 1997; Huang et al., 1998, 1999; Chen et al., 2000, 2001) which generally acted in an endothelium-independent manner (Andriambeloson et al., 1997, 1998; Chen et al., 2002) although it was also reported that the relaxation could be partially inhibited by endothelium removal, inhibition of endothelial NOS (eNOS) with L-NAME and by iberiotoxin, an inhibitor of large conductance, calcium-activated potassium channels. In all of these studies, rat aorta was employed for the assays.

Subsequently Sanae et al. (2002) in a more thorough investigation of the structure–activity relationships of all of the eight common catechins shown in Figure 85.2 reported that, in rat aortae precontracted with phenylephrine, EGC and EGCg enhanced phenylephrine-induced contraction at low concentrations that did not on their own cause any effect. Relaxation was only observed at the high concentrations of $100\,\mu M$. The contraction appeared to arise due to the impairment of the activity of endothelium-derived NO as contraction was abolished by endothelium removal and EGC and EGCg both inhibited relaxant responses to acetylcholine (ACh). Removing the endothelium did not affect the EGCg-induced relaxation and enhanced the relaxation to EGC (Sanae et al., 2002).

Later studies confirmed the biphasic responses to EGCg (Shen et al., 2003; Lorenz et al., 2004; Alvarez et al., 2006). In our laboratory we compared the responses to catechin, EC, ECg, EGC and EGCg in rat isolated carotid artery rings (Figure 85.3). Catechin and EC had no effect in the
Figure 85.3 Vascular actions of catechins. Cumulative concentration–response curves to catechin, EC, EGC, ECg and EGCg in rat carotid artery rings. The artery rings were contracted with phenylephrine to produce approximately 50% of their maximal tone before addition of the catechins. Only EGCg showed significant relaxation at the highest concentration although EGC also showed reversal of previous contraction at that concentration. Data is shown as mean ± SEM, n = 6–9. Source: Lee and Woodman (unpublished observations).

submaximally constricted rat aorta, whereas ECg and EGC caused only contraction. EGCg caused concentration-dependent contraction at concentrations up to $10\,\mu M$ but this was reversed at higher concentrations with a marked relaxation at the highest concentration tested $(100\,\mu M)$. The mechanism of contraction remains uncertain with a variety of mechanisms proposed such as release of H_2O_2 (Shen *et al.*, 2003) and promotion of calcium entry (Alvarez-Castro *et al.*, 2004). The role of the endothelium in the relaxant responses is not clear as there are reports supporting (Chen *et al.*, 2002; Lorenz *et al.*, 2004) and opposing (Alvarez-Castro *et al.*, 2004) a role of the endothelium. Lorenz *et al.* (2004) provided evidence that EGCg was able to increase eNOS activity when bovine aortic endothelial cells were exposed to the catechin for 15 min, but the level of eNOS protein expression was not affected by catechin treatment for 72 h. Anter *et al.* (2004, 2005) also reported that polyphenols derived from black tea acutely enhanced eNOS activity. Unfortunately the contents of the black tea polyphenols were not identified but it is likely that catechins were the major components of the extract.

Preservation of Endothelial Function by Flavones, Flavonols and Catechins

In addition to direct relaxation of vascular smooth muscle, an important action of the flavonols and flavones may be their ability to enhance responses to other vasodilator stimuli. There is epidemiological evidence that the consumption of polyphenols, in particular flavonols, flavones and catechins, in foods and beverages offers protection against cardiovascular disease (Arts and Hollman, 2005; Stangl *et al.*, 2006). The mechanisms of any beneficial effects of dietary polyphenols on the cardiovascular system are uncertain but are the focus of considerable interest. In particular, a number of studies have investigated the possibility that flavones, flavonols and catechins may increase the bioactivity of endothelium-derived NO.

Maintenance of release of endothelium-derived NO is critical for normal cardiovascular function. Endothelium-derived NO, in addition to acting as a vasodilator contributing to the local regulation of blood flow, is a potent inhibitor of platelet aggregation and platelet adhesion to endothelial cells (Tziros and Freedman, 2006). In addition, NO inhibits the expression of surface adhesion molecules that promote leukocyte adhesion to endothelial cells and migration into the vascular wall (Kubes *et al.*, 1991).

There is a range of mechanisms by which the bioactivity of endothelium-derived NO might be increased (Figure 85.4), for example, an increase in synthesis resulting from an increase in expression of eNOS. Alternatively interventions that attenuate the rate of inactivation of NO, for example by reducing the interaction with superoxide anions, would also increase NO activity. Considerable attention has been paid to the possible antioxidant activity of flavones and flavonols (Cos *et al.*, 1998; De Groot and Rauen, 1998; Vinson, 1998). Several mechanisms of flavonoid antioxidant activity have been reported including suppression of synthesis of reactive oxygen species
Figure 85.4 Sites of action of flavonols and catechins. Diagram illustrating possible sites at which flavonols and catechins may act to enhance the release or activity of endothelium-derived NO. The release of NO can be increased by increasing the expression or activity of eNOS. Alternatively the bioactivity of NO once released may be increased by reducing the interaction with superoxide anions (O_2^-). There is evidence that flavonols and catechins may inhibit the activity of two important enzymatic sources of superoxide, that is xanthine oxidase and NADPH oxidase. In addition they may act as radical scavengers directly inactivating superoxide.

(ROS) by inhibiting enzymes such as xanthine oxidase and NADPH oxidase or by chelating trace metals that play an important role in oxygen metabolism (Pietta, 2000). Structure–activity studies of flavones and flavonols indicate that the presence of a 3-hydroxyl group in the heterocyclic ring and a catechol group in ring B favors antioxidant activity (Pietta, 2000). Furthermore the structural features of the flavonols that result in their effective scavenging of superoxide also favor their ability to attenuate the toxic effects of peroxynitrite (Santos and Mira, 2004). Endothelium-derived NO rapidly reacts with superoxide anions (rate constant $2 \times 10^{10} M^{-1} s^{-1}$) to form peroxynitrite (Kissner et al., 1997), which then reduces the relaxant activity of NO. Superoxide dismutase (SOD) also reacts rapidly with superoxide (rate constant $1–2 \times 10^{10} M^{-1} s^{-1}$) and in so doing enhances NO bioavailability (Ferrer-Sueta et al., 2002) and may enhance endothelium-dependent relaxation (Jackson et al., 1998). We have demonstrated that flavonols with demonstrated antioxidant activity, such as DiOHF, are able to mimic the actions of SOD and significantly improve endothelium-dependent dilation in the presence of oxidant stress (Figure 85.5) (Chan et al., 2003; Woodman et al., 2005). Similarly,

Girard et al. (1995) demonstrated the ability of a synthetic flavone to preserve endothelium-dependent relaxation in the presence of oxidant stress caused by pyrogallol. However antioxidant capacity alone does not guarantee the ability to enhance endothelium-dependent relaxation. For example, the well-known antioxidant ascorbic acid does not enhance endothelium-dependent relaxation in arteries when endogenous superoxide levels are elevated by inhibiting the activity of endogenous SOD (Jackson et al., 1998). This is probably due to the relatively slow rate of reaction between ascorbic acid and superoxide anions (rate constant $2 \times 10^{5} M^{-1} s^{-1}$) (Gotoh and Niki, 1992). Butkovic et al. (2004) also investigated the effect of flavonoid structure on the reaction rate with superoxide and concluded that flavonols such as kaempferol and quercetin reacted very rapidly with free radicals. Thus it is likely that flavones and flavonols have the potential to promote vascular NO activity by attenuating the interaction with superoxide.

The antioxidant activity of flavonols and flavones may also be important in contributing to an anti-apoptotic action (Pryor et al., 2006). Apoptosis was induced in human umbilical vein endothelial cells (HUVECs) by incubation with oxidized LDL. The flavonols quercetin and myricetin effectively attenuated lipid peroxidation and decreased deoxyribonucleic acid fragmentation measured by terminal deoxynucleotidyl transferase mediated dUTP nick end labeling staining. Apoptosis in HUVECs exposed to oxidized LDL was confirmed by increased expression of Bax and activated caspase-3 and decreased levels of Bcl-2, whereas the flavonols attenuated the changes in these markers of apoptosis. The flavones luteolin and apigenin, which demonstrated less antioxidant activity than the flavonols, were also less effective in preserving cell viability in the presence of oxidant stress (Jeong et al., 2005).

There is also some limited direct evidence that flavonols can increase NO synthesis. Benito et al. (2002) supplemented the diet of rats with quercetin for 10 days and then demonstrated an increase in eNOS activity in the aorta together with elevated levels of cGMP. This elevation of NO synthesis was not accompanied by any change in eNOS protein expression. Wallerath et al. (2005) also reported that several flavonols did not affect the expression of eNOS protein or mRNA in human endothelial cells and that quercetin decreased the level of eNOS protein. Taken together with the functional data, indicating the involvement of endothelium-derived NO in flavonol-induced relaxation, it appears that a non-genomic activation of eNOS is most likely to contribute to the vascular actions of flavonols.

Catechins also efficiently scavenge a variety of ROS and nitrogen species such as superoxide, NO and peroxynitrite (Jovanovic and Simic, 2000; Paquay et al., 2000; Boveris et al., 2002; Stangl et al., 2006). Of the catechins the ability to scavenge superoxide is favored by the presence of a gallate group, that is, EGCg, gallocatechin gallate and ECg

Figure 85.5 Flavonol protection against oxidant stress. Concentration–response curves to ACh in the absence or presence of pyrogallol ($2 \times 10^{-5} M$) in endothelium-intact rat aortic rings. Pyrogallol auto-oxidizes to generate superoxide resulting in impaired endothelium-dependent relaxation. 7,4'-dihydroxy flavonol (7,4'DiOHF) was able to acutely enhance endothelium-dependent relaxation in the presence of the oxidant stress indicating an ability to rapidly scavenge superoxide anions. Data is shown as mean ± SEM, $n = 6$. *Source*: Modified from Woodman et al. (2005).

(Nakagawa and Yokozawa, 2002) and by the catechol group on the B ring (Figure 85.2). In addition to radical scavenging, catechins can chelate metal ions thereby reducing the generation of oxygen radicals (Guo *et al.*, 1996; Seeram *et al.*, 2002). There do not appear to be any reports that the ability to scavenge superoxide is able to preserve endothelium-dependent relaxation in the presence of oxidant stress. Catechins have, however, been reported to exert a number of effects linked to their antioxidant activity that are likely to result in preservation or improvement of endothelial function. EC, EGCg and catechin have all been reported to protect endothelial cells from injury caused by exposure to oxidized LDL (Jeong *et al.*, 2005; Steffen *et al.*, 2006) and EC was demonstrated to inhibit the oxidation of LDL (Kostyuk *et al.*, 2003).

Flavonols and Flavones in Hypertension

An increase in total peripheral resistance resulting from both structural and functional changes in the arterioles is a characteristic of hypertension, and endothelial dysfunction is an important contributor to the increase in arteriolar tone. This may involve impaired release of NO (Yang and Kaye, 2006) and/or a decrease in NO bioavailability due to increased inactivation by superoxide anions (Paravicini and Touyz, 2006). As flavones and flavonols both enhance NO activity and exert antioxidant effects, they are logical candidates for investigation for the treatment or prevention of hypertension. The efficacy of the flavonol quercetin has been investigated in a variety of models of hypertension in rats (Table 85.1). Duarte and colleagues reported that quercetin reduces systolic blood pressure in spontaneously hypertensive rats (Duarte *et al.*, 2001; Sanchez *et al.*, 2006) as well as in rats where hypertension is induced by NOS inhibition (Duarte *et al.*, 2002), DOCA salt (Galisteo *et al.*, 2004) or impaired renal perfusion (Garcia-Saura *et al.*, 2005). In each of these studies, together with that by another research group (Jalili *et al.*, 2006), quercetin failed to alter arterial pressure in normotensive control animals. There is clear evidence that the antihypertensive actions of quercetin are associated with an improvement in endothelial function together with a reduction in oxidant stress. Quercetin treatment improves endothelium-dependent relaxation in aortae from hypertensive rats without affecting endothelium-independent relaxation (Duarte *et al.*, 2001, 2002; Ajay *et al.*, 2003, 2006; Galisteo *et al.*, 2004; Garcia-Saura *et al.*, 2005; Sanchez *et al.*, 2006). In addition quercetin exerts a number of actions suggesting that antioxidant activity may contribute to the antihypertensive outcomes. Several studies report that quercetin lowers biomarkers of oxidant stress such as urinary isoprostane, plasma malondialdehyde, and plasma and liver thiobarbituric acid-reactive substances (Duarte *et al.*, 2001; Galisteo *et al.*, 2004; Garcia-Saura *et al.*, 2005; Jalili *et al.*, 2006). Sanchez

et al. (2006) also demonstrated that the significantly greater superoxide generation by aortae from spontaneously hypertensive rats, in comparison to normotensive Wistar–Kyoto controls, was lowered by quercetin treatment, an effect that was accompanied by a decreased expression of the NADPH oxidase subunit p47^{phox}. There is considerable evidence supporting a critical role for NADPH oxidase-derived ROS in hypertension (Paravicini and Touyz, 2006). This is the first evidence that quercetin might target an important mechanism in the pathogenesis of hypertension.

Despite these positive findings with quercetin, there is an absence of human intervention studies using flavonols to test their potential antihypertensive activity. Whilst two studies report that quercetin did not alter arterial pressure, in both cases the subjects had normal blood pressure and, given the observation that quercetin does not affect arterial pressure in normotensive rats, the outcome of those studies is predictable. The efficacy of quercetin as an antihypertensive in humans awaits an intervention trial using a suitable group of hypertensive subjects.

Catechins as Antihypertensives

Although the antihypertensive actions of flavonols are well established in animal models there has been very little investigation of catechins. Negishi *et al.* (2004) examined the effects of mixed polyphenols derived from green or black tea in spontaneously hypertensive stroke prone rats. The treatments were provided in the rats drinking water and the green tea polyphenols were predominantly catechins (3.5 g/l) but there were also flavonols (0.5 g/l) and polymetric flavonoids (1 g/l). The rats consuming the green tea polyphenols for 3 weeks achieved a plasma total catechin concentration of 200 nM and had significantly lower systolic and diastolic blood pressures compared to controls. A possible mechanism for this antihypertensive action includes inhibition of angiotensin converting enzyme (ACE). Actis-Goretta *et al.* (2003) demonstrated that EC caused concentration-dependent inhibition of rabbit lung ACE. Further investigation indicated that EGC was the most active ACE inhibitor of the catechins tested and that the flavonols quercetin and kaempferol did not share the ability to inhibit the enzyme activity (Actis-Goretta *et al.*, 2006). Further investigation of the mechanism of the antihypertensive actions of the catechins is clearly warranted.

In clinical studies the potential antihypertensive actions of catechins have been investigated by the inclusion of catechin-rich dark chocolate or cocoa in the diet. There have been mixed outcomes in healthy, normotensive subjects where decreases in arterial pressure were reported in two studies from the same group of researchers (Grassi *et al.*, 2005a, b), whereas others reported no change in arterial pressure (Fisher *et al.*, 2003; Engler *et al.*, 2004; Fisher and Hollenberg, 2006). It should be noted that, even in the

Table 85.1 Studies that have investigated the antihypertensive actions of quercetin and flavone

Treatment	Model of hypertension	Biomarkers significantly affected	Biomarkers not significantly affected	Reference
Quercetin (10 mg/kg/day, oral, 5 weeks)	Spontaneously hypertensive rat	SBP, DBP, HR[a] LV weight index[b] Kidney weight index[c] Endothelium-dependent relaxation (ACh) of aorta Urinary isoprostane Plasma MDA[d]	Endothelium-independent relaxation (SNP) Aortic constriction to noradrenaline or KCl	Duarte et al. (2001)
Quercetin (5 or 10 mg/kg/day, oral, 6 weeks)	NOS inhibition (l-NAME 75 mg/100 ml drinking water)	SBP LV weight index Kidney weight index Proteinuria	Endothelium-dependent relaxation (ACh) of aorta Endothelium-independent relaxation (SNP) Aortic constriction to noradrenaline or KCl	Duarte et al. (2002)
Quercetin (10 mg/kg/day, oral, 5 weeks)	Uninephrectomy and DOCA salt (12.5 mg/week sc, 5 weeks)	SBP Endothelium-dependent relaxation (ACh) of aorta Heart and plasma TBARS		Galisteo et al. (2004)
Quercetin (10 mg/kg/day, oral, 4 weeks)	Spontaneously hypertensive rat	SBP Endothelium-dependent relaxation (ACh) of aorta	Endothelium-independent relaxation (SNP)	Ajay and Mustafa (2005)
Flavone (10 mg/kg/day, oral, 4 weeks)	Spontaneously hypertensive rat	SBP Endothelium-dependent relaxation (ACh) of aorta Endothelium-independent relaxation (SNP)		Ajay and Mustafa (2005)
Quercetin (10 mg/kg/day, oral, 5 weeks)	Two-kidney, one clip Goldblatt rats	SBP Proteinuria Endothelium-dependent relaxation (ACh) of aorta Plasma TBARS Liver glutathione peroxidase	Endothelium-independent relaxation (SNP) Aortic constriction to noradrenaline or KCl	Garcia-Saura et al. (2005)
Quercetin (10 mg/kg/day, oral, 13 weeks)	Spontaneously hypertensive rat	SBP, mean AP, HR LV weight index Endothelium-dependent relaxation (ACh) of aorta eNOS activity, protein expression of eNOS and caveolin-1 aortic superoxide p47^{phox} expression	Kidney weight index Endothelium-independent relaxation (SNP) TXB$_2$ synthesized by aorta	Sanchez et al. (2006)
Quercetin (1.5 g/kg chow)	Abdominal aortic constriction in rats	SBP, DBP Heart weight index Aortic hypertrophy Endothelium-dependent relaxation (ACh) of aorta Liver TBARS	Endothelium-dependent relaxation (ACh) of mesenteric and coronary arteries Endothelium-independent relaxation (SNP) Aortic constriction to noradrenaline or potassium chloride	Jalili et al. (2006)

Notes: The flavonol quercetin has been demonstrated to reduce arterial pressure, and to exert a number of other beneficial cardiovascular outcomes, in a variety of rat models of hypertension. Flavone has also shown a similar decrease in SBP in spontaneously hypertensive rats.

[a] SBP, systolic blood pressure; DBP, diastolic blood pressure; HR, heart rate.
[b] Left ventricle to body weight ratio.
[c] Kidney to body weight ratio.
[d] Malondialdehyde.

latter studies where there was no significant change in arterial pressure, there was an improvement in endothelium-dependent dilation. In another study, a range of doses (90–400 mg) of EGCg were administered to normotensive men and it was found that there was a significant elevation of diastolic pressure in the following 24 h (Berube-Parent *et al.*, 2005). However the catechin was given in combination with caffeine that may have caused the pressor effect. Grassi *et al.* (2005b) also reported that the intake of 88 mg catechins per day for 15 days decreased systolic and diastolic pressure in patients with essential hypertension, once again accompanied by an improvement in endothelial function. The results of these clinical studies using mixed catechins contained in foodstuffs suggest that the further investigation of individual catechins is warranted in animal studies to investigate mechanism of action and structure–activity relationships.

Prevention of Injury Due to Ischemia and Reperfusion

As described earlier there is considerable epidemiological evidence that dietary intake of flavonols, flavones and catechins may reduce the incidence of cardiovascular disease. The dilator actions of these compounds may contribute to their protective effects as well as their antioxidant activity (Vinson, 1998). ROS such as the free radicals superoxide anion (O_2^-) and hydroxyl radical (OH^-) and non-radicals hydrogen peroxide (H_2O_2), peroxynitrite ($ONOO^-$) and hypochlorous acid (HOCl) all contribute to oxidant stress. NO reacts very rapidly with superoxide anion to produce peroxynitrite anion. Thus ROS can disturb endothelial function by enhancing degradation of NO and in addition by oxidizing lipids, in particular LDL, resulting in impaired endothelium-dependent relaxation (Cominacini *et al.*, 2000). In a number of disease states, such as atherosclerosis, hypertension and diabetes, the impairment of endothelium-dependent relaxation has been associated with enhanced degradation of NO by ROS (Cai and Harrison, 2000).

In addition to the contribution of long-term oxidant stress to chronic disease such as hypertension and atherosclerosis, an acute exacerbation in the generation of ROS is important in reperfusion injury of organs after a period of ischemia. There is a well-established link between reperfusion injury and the generation of oxygen radicals (Becker, 2004), and there are many studies demonstrating that oxygen radical scavengers reduce cardiac injury (Sobey and Woodman, 1993). In experimental animals inhibition of the effects of ROS has also proved to be an effective means of preserving coronary vasodilator capacity after ischemia and reperfusion. For example, treatment with the xanthine oxidase inhibitor, allopurinol preserves endothelium-dependent vasodilation *in vivo* and *in vitro* (Sobey and Woodman, 1993). There is also clinical evidence that

antioxidants improve outcomes after ischemia and reperfusion. Antioxidants administered in the period immediately after myocardial infarction reduce infarct size and cardiac events (Tribble, 1999; Becker, 2004). In addition ascorbate, α-tocopherol and other antioxidants given before and continued after coronary angioplasty reduce the incidence of restenosis (Tribble, 1999).

Although there has been only limited investigation of the anti-ischemic actions of flavonols the observations have been consistently positive. There are several reports that flavonols and flavones are able to improve cardiac function after ischemia and reperfusion of rabbit and rat isolated hearts (Rump *et al.*, 1994; Schussler *et al.*, 1995; Lebeau *et al.*, 2001; Brookes *et al.*, 2002) as well as reducing ischemia–reperfusion injury to other organs such as kidney (Inal *et al.*, 2002; Singh *et al.*, 2004) and stomach (Mojzis *et al.*, 2001). In addition daflon a purified micronized flavonoid fraction containing 90% diosmin (flavone) and 10% hesperidin (flavanone) improved microvascular function after ischemia and reperfusion in the hamster cheek pouch (Bouskela *et al.*, 1997). The protective actions of daflon may be due to inhibition of expression of leukocyte adhesion molecules (Korthuis and Gute, 1999) and subsequently reduced adhesion of leukocytes to endothelial cells (Bouskela *et al.*, 1999).

We have investigated the protective action of DiOHF on vascular dysfunction caused by ischemia and reperfusion (Chan *et al.*, 2003). DiOHF was administered at one of two times, either prior to ischemia or during ischemia but before reperfusion. ACh- and sodium nitroprusside (SNP)-induced vasodilation was then assessed in the previously ischemic and reperfused rat hindquarters. Similar to SOD, DiOHF administered before ischemia or before reperfusion significantly enhanced vasodilation to both ACh and SNP in rats subjected to ischemia–reperfusion. Thus, we demonstrated that the synthetic flavonol DiOHF preserves vasodilator reactivity normally impaired by ischemia and reperfusion of the hindquarters vasculature. This indicates that DiOHF, like SOD, reduces vascular plugging caused by ischemia and reperfusion and, thus, preserves vasodilator reserve. We have also demonstrated that DiOHF is able to reduce infarct size after myocardial ischemia and reperfusion in anesthetized sheep (Wang *et al.*, 2004). DiOHF also reduced superoxide generation by myocardium in the ischemic zone, increased levels of NO metabolites in the venous outflow and improved coronary blood flow on reperfusion. Thus it appears that the antioxidant activity of this synthetic flavonol does result in improved endothelial function after ischemia and reperfusion in addition to the reduction in infarct size suggesting that it has clinical potential for improving recovery from myocardial infarction and other ischemic syndromes.

Recently considerable attention has been paid to the potential for flavones and flavonols to protect neurones against injury resulting from ischemia of the brain. There is

now an established association between brain injury caused by ischemic or hemorrhagic stroke and the presence of oxidant stress. Acute brain injury increases the levels of excitotoxic amino acid neurotransmitters, such as glutamate, which in turn stimulate the generation of ROS. This suggests that antioxidants should prevent propagation of tissue injury, improve survival and reduce morbidity after stroke. Unfortunately, whilst a few antioxidants have shown efficacy in animal models of cerebral ischemia, none are yet to demonstrate a positive outcome in large scale clinical trials (Gilgun-Sherki et al., 2002). Thus a number of groups have targeted flavonoids toward this elusive goal. Both flavones and flavonols have demonstrated neuroprotection in a variety of models of ischemic brain injury. When injury was induced by permanent occlusion of the middle cerebral artery in rats, infarct size was reduced by nictoflorin, a rutinoside of the flavonol kaempferol (Li et al., 2006), or the flavone wogonin (Cho and Lee, 2004). Infarct size after transient ischemia–reperfusion is also reduced by quercetin (Cho et al., 2006), morin (Gottlieb et al., 2006) or wogonin (Lee et al., 2003). In addition amentoflavone reduces infarct size in a rat model of hypoxic-ischemic brain injury where rat pups at post-natal day 7 had one common carotid artery ligated and were then exposed to 8% oxygen for 2.5 h (Shin et al., 2006). In addition to their antioxidant activity there is evidence that the flavones and flavonols exert other protective actions such as preventing the activation of the apoptotic protein caspase-3 (Kang et al., 2004; Shin et al., 2006) or inhibiting matrix metalloproteinases (Cho et al., 2006).

There has been even less investigation of the ability of catechins to prevent ischemic injury despite some promising observations. Chan et al. (1996) reported that catechin possesses significant antioxidant activity, an effect that was confirmed to occur in vivo with a mixture of catechins (Maffei Facino et al., 1999). The antioxidant action of this catechin preparation was suggested to explain its ability to reduce ischemia-induced damage of rat isolated hearts (Maffei Facino et al., 1999). Similarly catechin treatment was found to reduce injury to subsequent renal ischemia and reperfusion. The protective actions of catechin were associated with reduced oxidant injury and maintenance of the activity of renal antioxidant enzymes (Singh et al., 2005). EGCg (Fiorini et al., 2005) and mixed catechins extracted from green tea (Muia et al., 2005) have also been reported to attenuate ischemia–reperfusion injury of the liver and gastrointestinal tract, respectively.

Sutherland et al. (2006) have recently reviewed the evidence that catechins may also prevent ischemic damage to the brain. EGCg is reported to be protective against injury caused by transient or permanent cerebral ischemia (Lee et al., 2000, 2003; Nagai et al., 2002; Choi et al., 2004; Rahman et al., 2005; Sutherland et al., 2005). There have been both positive (Matsuoka et al., 1995; Inanami et al., 1998) and negative (Dajas et al., 2003; Rivera et al., 2004) outcomes with catechin. Protection has been associated with antioxidant activity in some studies (Inanami et al., 1998; Choi et al., 2004) but other actions of catechins such as an inhibition of calcium entry to nerve cells (Sutherland et al., 2006) and inhibition of the expression of pro-apoptotic genes (Mandel and Youdim, 2004) have also been implicated.

Thus flavonols, flavones and catechins have all demonstrated some capacity to attenuate ischemia/reperfusion injury. Although it is often suggested that it is their antioxidant activity that leads to the beneficial effects, the precise mechanism of action is yet to be determined. In particular, it is not known whether their vascular actions might also contribute to their efficacy. A possible argument against that hypothesis is the similar protective capacities of the flavonols and catechins despite the limited vasodilator actions of the catechins. The earlier failure to demonstrate efficacy of antioxidants in clinical trials, after positive outcomes from animal experiments, means that any interpretation of the possible benefits of these agents needs to be cautious.

Summary Points

- Flavonols, flavones and catechins are found in significant levels in beer as well as other beverages, fruits and vegetables.
- Flavonols and flavones are able to exert direct relaxant effects that are predominantly endothelium-independent. By contrast, catechins show quite variable vascular effects ranging from no effect to pure constriction to constriction at low doses and vasodilation at high doses.
- Through their antioxidant activity flavonols, flavones and catechins are all able to improve endothelial function by protecting endothelium-derived NO from inactivation by ROS.
- Animal studies suggest that these compounds can protect against hypertension and ischemia/reperfusion injury. While the antioxidant activity of these flavonoids contributes to those benefits, the mechanism of action remains to be fully elucidated.
- Animal studies support the epidemiological evidence that flavonols, flavones and catechins may be useful in the prevention or treatment of cardiovascular disease but this needs to be supported by further clinical trials.

The Anti-invasive and Proapoptotic Effect of Xanthohumol: Potential Use in Cancer

Barbara Vanhoecke and Marc Bracke Laboratory of Experimental Cancer Research, Department of Radiotherapy and Nuclear Medicine, Ghent University Hospital, Ghent, Belgium
Jerina Boelens, Sofie Lust and Fritz Offner Department of Hematology, Ghent University Hospital, Ghent, Belgium

Abstract

In recent years, a lot of attention has been paid to phytochemicals such as flavonoids with anticancer effects since they may interact with cellular signaling pathways controlling proliferation, differentiation, apoptosis and invasion. Invasion is the hallmark of malignancy, and the search for anti-invasive agents remains a challenge. A number of studies reported a promising role for xanthohumol (X) as a chemopreventive agent, since it can modulate the carcinogen metabolism and act by cytotoxic/-static mechanisms. Recently, X was investigated for its anti-invasive activity on human breast cancer cell lines and shown to inhibit the invasion of breast cancer cells in different invasion assays. One of the possible mechanisms of the anti-invasive effect of X includes the involvement of the E-cadherin/catenin invasion-suppressor complex. Another mechanism by which X influences the invasive behavior is by reducing the number of invasive cells (i.e. by promoting cell death). Recent data demonstrate that X induces a specific stress reaction (i.e. endoplasmic reticulum stress) followed by the unfolded protein response and programmed cell death (apoptosis). In this overview, we highlight the effect of X on invasion and survival of breast cancer cells and the mechanisms associated with these effects.

List of Abbreviations

8PN	8-Prenylnaringenin
APAF-1	Apoptotic protease activating factor 1
ATF6	Activating transcription factor 6
BiP	B-cell immunoglobulin heavy-chain binding protein
bZIP	Basic leucine zipper
CHI	Chick heart invasion assay
CHOP	C/EBP homologous protein-10, also known as GADD153
CI	Collagen invasion assay
CNX	Calnexin
COX	Cyclooxygenase
CRT	Calreticulin
cyt c	Cytochrome c
ECM	Extracellular matrix
eIF2α	α Subunit of eukaryotic translation initiation factor 2
ER	Endoplasmic reticulum
ERAD	Endoplasmic reticulum-associated degradation
ERSE	Endoplasmic reticulum-stress-responsive element
FAA	Fast aggregation assay
GRP	Glucose-regulated protein
IRE1	Inositol-requiring enzyme 1
NO	Nitrogen oxide
PCD	Programmed cell death
PDI	Protein-disulphide isomerase
PERK	Doublestranded RNA-activated protein kinase-like ER kinase
PG	Prostaglandin
PHF	Precultured heart fragment
PPI	Peptidyl–prolyl isomerases
QR	Quinone reductase
ROS	Reactive oxygen species
S1P	Site-1 protease
S2P	Site-2 protease
TF	Transcription factor
UPR	Unfolded protein response
UPRE	Unfolded protein response-responsive element
X	Xanthohumol
XBP1	X-box-binding protein 1

Introduction

A typical Asian diet contains approximately 150–200 mg flavonoids per day. These compounds are of particular interest, since they may interact with cellular signaling

pathways controlling proliferation, differentiation, apoptosis and invasion of cancer cells. Moreover, flavonoids have different targets in the cancer cell, in the normal host cell or in the extracellular matrix (ECM). This review focuses on the anticancer effect of the prenylated chalcone, xanthohumol (X). From a medical point of view, the prenylated flavonoids are most notable since they add unique health-beneficial properties to beer (Gerhäuser et al., 2002). Prenylated flavonoids can be divided into two major groups: prenylated chalcones and prenylated flavanones. The most abundant prenylated flavonoid in the hop cones is X, which generally accounts for ca. 90% of the prenylated flavonoids in the hop plant (Stevens et al., 1997). The structure of X was already described in 1957 as 6′-O-methyl-3′-prenylchalconaringenin (Verzele et al., 1957). However, only during the last decade, X has gained attention as a promising cancer chemopreventive agent.

Recent studies reported that X can inhibit carcinogenesis at the initiation, promotion and progression stages of cancer. Consistent with its anti-initiating potential, X efficiently modulates the carcinogen metabolism at the level of carcinogen activation by CYP450 enzymes and at the level of detoxification by Phase II detoxifying enzymes like quinone reductase (QR) (Miranda et al., 2000; Gerhäuser et al., 2002). In addition, it contributes to the prevention of oxidative damage by scavenging reactive oxygen species (ROS) and nitrogen oxide (NO) production (Miranda et al., 2000; Gerhäuser et al., 2002; Zhao et al., 2003). In the present review, we will note that X can also induce ROS formation (oxidative stress) which is associated with endoplasmic reticulum (ER) stress that ultimately results in selective cancer cell death.

Potential anticancer-promoting mechanisms include anti-inflammatory properties by inhibition of cyclooxygenase (COX) activity and anti-estrogenic activities. Excessive production of prostaglandins (PGs), endogenous mediators of inflammation, is associated with carcinogenesis. PGs are thought to stimulate proliferation and promote angiogenesis, essential for tumor growth (Subbaramaiah et al., 1997). X was characterized as an effective anti-inflammatory agent by inhibiting the activity of COX-1 and COX-2 (Chi et al., 2001; Gerhäuser et al., 2002). Similar to PGs, hormones like estradiol are regarded as endogenous tumor promotors, stimulate tumor growth via interaction with estrogen receptors, and increase the risk for breast and uterine cancer (Reid et al., 1996). X was identified as an anti-estrogen without intrinsic estrogenic potential, as demonstrated by the dose-dependent inhibition of estrogen-mediated induction of alkaline phosphatase activity and by a weak inhibition of cell growth in a human endometrial cell bio-assay for estrogenic activity (Gerhäuser et al., 2002).

The progression phase of cancer cells is characterized by an uncontrolled cell proliferation independent of hormonal or growth factor stimulation. During this phase, important mechanisms regulating tissue homeostasis, such as apoptosis and terminal cell differentiation, are impaired (King and Cidlowski, 1995; Compagni and Christofori, 2000). X appeared to be the most effective anti-proliferative agent of six prenylated hop flavonoids in human breast cancer (MCF-7), colon cancer (HT-29) and ovarian cancer (A-2780) cells in vitro (Miranda et al., 1999). Furthermore, X was found to inhibit DNA polymerase that can initiate de novo DNA synthesis (Gerhäuser et al., 2002). Inhibition of DNA synthesis may be one of the mechanisms by which X exerts its anti-proliferative effect in cancer cells. However, additional mechanisms have been proposed. For example, X may cause growth arrest at more than one stage of the cell cycle (Miranda et al., 1999). Gerhäuser et al. (2002) found that X causes a significant dose-dependent accumulation of breast cancer cells in the S-phase of the cell cycle and induces apoptosis of cancer cells after 48 h. In addition, X has been demonstrated to induce terminal differentiation in human promyelocytic leukemia cells (Gerhäuser et al., 2002). In this review, the mechanisms associated with the proapoptotic effect of X will be described in detail.

Invasion and Progression

During the progression phase of cancer, new clones of cancer cells with increased proliferative capacity, invasiveness and metastatic potential arise and increase the malignancy of the disease. Invasion and metastasis are multistep processes (Figure 86.1) and result from the cross-talk between cancer cells and the microenvironmental elements of the host, that is, the ECM, fibroblastic cells (myofibroblasts), lymphocytes, macrophages, dentritic cells and endothelial cells. Paget's "seed and soil hypothesis" according to which the microenvironment of each organ (the soil) influences the survival and growth of the cancer cells (the seed) is still valid today (Paget, 1889). It implicates the destructive entry of the cancer cells into normal tissue by attachment to the ECM, proteolysis of these components, loss of cell–cell contacts, and subsequent migration through the ECM (Liotta and Kohn, 2001; Friedl, 2004). After survival in the circulation and arrest of metastatic cells in the vasculature, degradation of the basement membrane surrounding the blood vessels and extravasation occur. Survival and growth of the cancer cells at the site of extravasation results from interactions with the host cells and the ECM including activities like cell–cell adhesion, cell–matrix adhesion, proteolysis and motility. Like growth, survival and angiogenesis, invasion is the result of a balance between stimulatory and inhibitory factors.

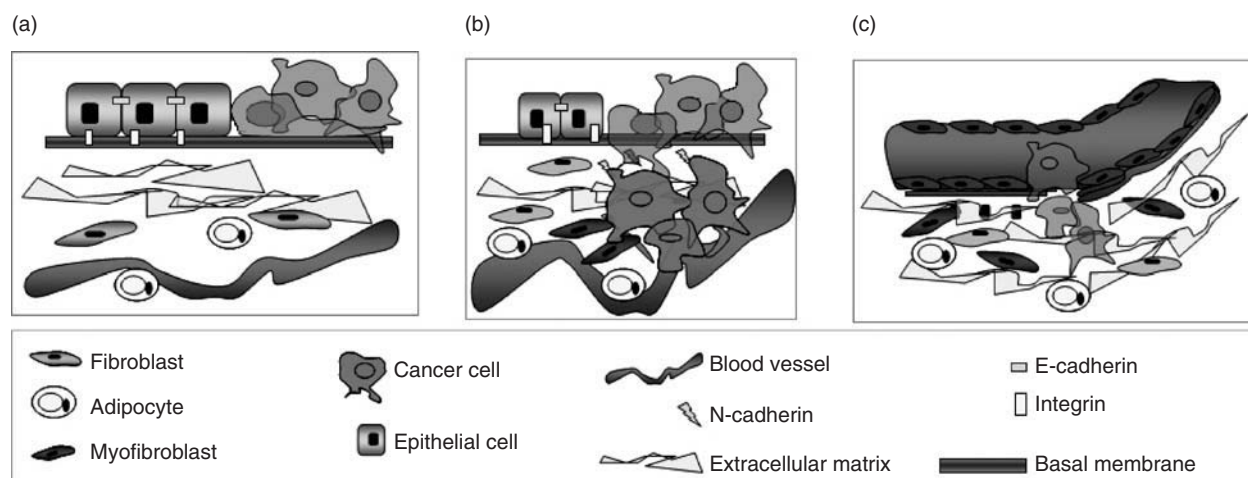
Cellular activities associated with the invasive phenotype comprise cell–cell adhesion, cell–matrix adhesion, ectopic survival, migration and proteolysis. Based on previous reports that flavonoids possess potential anti-invasive properties in vitro (Bracke et al., 1994, 1996; Rong et al., 2001), the effect of X on cancer cell invasion has recently been


Figure 86.1 The multistep process of cancer: (a) During tumor progression, a series of cumulative genomic alterations modulate the transition from a normal to a malignant state. (b) During the multistep invasion process of metastasis, cancer cells invade from the primary tumor tissue through the basement membrane into the surrounding tissue. (c) They can enter the blood circulation (intravasation) (b) so that they can reach distant organs where they can form secondary tumors (metastasis) after extravasation, survival and growth. A continuous molecular cross-talk between tumor cells, host and environmental factors has an impact on a series of cellular activities such as growth, differentiation, ECM production and degradation, invasion, ectopic survival and metastasis. The success of the invasive process depends how cells interact with one another and with the other elements of the ecosystem.

investigated. By using the chick heart invasion assay (CHI) (Figure 86.2a), proven to be a valuable tool for evaluation of invasion (Bracke *et al.*, 2001), evidence was provided that X inhibits invasion of breast cancer cells into normal chick heart tissue (Vanhoecke *et al.*, 2005). This anti-invasive effect was confirmed in another invasion assay (i.e. the collagen invasion assay, CI) (Bracke *et al.*, 2001) (Figure 86.2b). Collagen type I is the most abundant protein in humans and the fibers are extremely stable structures. During cancer invasion, the rates of collagen type I and of other ECM elements degradation are accelerated. Native collagen type I is degraded by matrix-metalloproteinases which are zinc-dependent endopeptidases expressed at low levels in normal adult tissues and upregulated during normal and pathological remodeling processes, embryonic development, inflammation, tumor invasion and metastasis (Birkedal-Hansen, 1995; Egeblad and Werb, 2002). Pericellular breakdown of ECM components generates localized matrix defects and remodeling along migration tracks. However, cancer cells do not always rely on proteolytic matrix remodeling for migration, but rather acquire a shape change to allow gliding and squeezing through gaps and trails present in connective tissues (Friedl and Wolf, 2003). To invade the surrounding tissue and to metastasize at the secondary site, cancer cells must cross the ECM barrier which comprises the basement membrane and the interstitial stroma. Collagen type IV, laminin, entactin and heparan sulfate proteoglycans are the major constituents of the basement membrane while collagen type I and III, elastin, vitronectin, proteoglycans and glycoproteins are the major constituents of the interstitial stroma.

Effect of X on Invasion of Breast Cancer Cells

To screen a potential anti-invasive effect of X, three cell lines derived from human mammary carcinomas (MCF-7/6, MCF-7/AZ and T47-D) were used. These cell lines were selected because they have retained many morphological and biochemical characteristics of their mammary origin, such as the expression of the estrogen receptor α (Bracke *et al.*, 1991) and their striking differences in invasive properties in the CHI model (Vanhoecke *et al.*, 2005). MCF-7/6 cells spontaneously invade into the chick heart tissue, whereas MCF-7/AZ and T47-D formed a non-invasive multilayered epithelium covering the heart fragments. Earlier studies also demonstrated the existence of invasive and non-invasive variants of the MCF-7 cell population (Rong *et al.*, 2001).

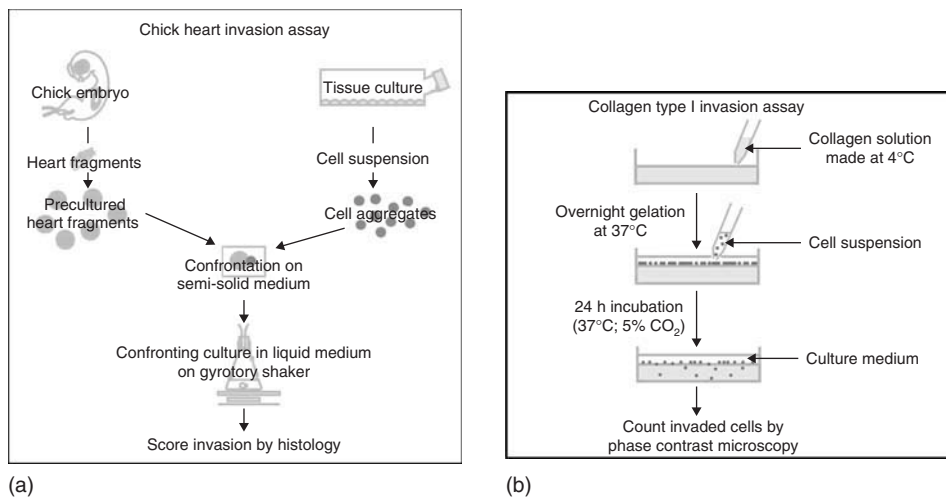
The effect of X on invasion of MCF-7/6 cells into chick heart fragments was examined during 8 days of treatment using varying concentrations (0.1, 1, 5, 10, 20, 50 and 100 μM); 5 μM X inhibited invasion of MCF-7/6 cells completely, and the effect could be described as Grade I. Immunohistochemical staining with 5D10, a specific antibody against the MCF-7 cells, confirmed that no cancer cells had invaded the chick heart (Figure 86.2c right panel), in contrast to the untreated cells (Figure 86.2c left panel). Lower concentrations (<1 μM) only partially inhibited invasion whereas higher concentrations (10, 20, 50 and 100 μM) were toxic both for MCF-7/6 cells and the chick heart tissue. The anti-invasive effect was not due to irreversible cytotoxicity or increased resistance of the chick


Figure 86.2 The effect of X on invasion: (a) Chick heart invasion assay. In CHI, heart tissue fragments are dissected from 9-day-old chicken embryos and precultured to obtain living spheroids with a standard diameter of 0.4 mm. These precultured heart fragments (PHFs) are mainly composed by cardiomyocytes, but fibroblasts and endothelial cells are present as well. The ECM contains laminin, fibronectin, collagen type IV and collagen type I. These PHFs are confronted with standard volume aggregates (diameter 0.2 mm) of invasive test cells, such as human MCF-7/6 breast cancer cells (Soule *et al.*, 1973). The aggregates become attached to PHFs by incubation on a semi-solid agar bed overnight and are then transferred as individual pairs into mini-Erlenmeyer flasks for suspension culture in liquid medium. After 8 days of incubation on a gyratory shaker, the cultures are fixed and imbedded for histology. After serial sectioning and staining of the sections with hematoxylin–eosin, the interaction of the cancer cells with the PHF can be reconstructed tri-dimensionally from microscopic analysis of all sections. Although automated image analysis systems are available, the results can be classified along a 5-grades objective scale: Grade 0: Only PHF is found. No confronting cells can be observed. Grade I: The confronting test cells are attached to the PHF and do not occupy the heart tissue. Grade II: Occupation of the PHF is limited to the outer fibroblast-like and myoblast cell layers. Grade III: The confronting cells have occupied the PHF, but have left more than half of the original amount of heart tissue intact. Grade IV: The confronting cells have occupied more than half of the original volume of the PHF. The assay has proven to be relevant to cancer invasion in cancer patients for multiple reasons: Invasion is progressive in time and space as it is in natural tumors, the histological pattern of invasion resembles the one observed in the tumor of origin, and the assay discriminates between benign (non-invasive) and malignant (invasive) tumors. However, the assay does not cover all aspects of invasion, as it does not take into account the contribution of immune cells. (b) Collagen invasion assay. Collagen gels, with a minimum thickness of 250 μm, are prepared in a 6-well plate (Nunc, Roskilde, Denmark), from a collagen type I solution (Upstate Biotechnology, Lake Pacid, NY), and polymerized overnight at 37°C. Cancer cells are incubated on top of these collagen gels for 24 h at 37°C in presence or absence of a test compound. The number of cells penetrating into the gel or remaining at the surface can be counted using an inverted-microscope controlled by a computer program. Invasion indices (%) are ratios between the number of invaded cells inside the collagen gel and the total number of cells, counted in at least 12 microscopic fields and determined with a computer-assisted-inverted-microscope (Bracke *et al.*, 2001; Vakaet *et al.*, 1991). (c) Light micrographs of sections from 8-days-old confronting cultures of PHFs and MCF-7/6 cells. Untreated confrontations (left panel) are compared with confrontations treated with 5 μM X (right panel). MCF-7/6 cells were stained immunohistochemically with the monoclonal antibody 5D10 and appear dark. Scale bar = 50 μm. (d) Detailed morphological analysis of the confronting cultures revealed a selective effect of X on the MCF-7/6 cells. Nuclear pyknosis (arrowheads, black) and vacuolization (arrows, white) could be observed in the MCF-7/6 cells but not in the heart cells. Scale bar = 50 μm. (e) Effect of X on invasion of T47-D cells into collagen type I gel. Cells were treated with varying concentrations for 24 h. Results are presented as percentage (%) of invasion (percentage of penetrating cells divided by the total number of cells; mean ± standard deviation). The % of invasion of X-treated T47-D cells is compared with the % of invasion of solvent-treated cells (unt). Asterisks: ρ value $\leq$ 0.001.

heart tissue against the invasive behavior of the MCF-7/6. Moreover, the effect of X appeared to be selective for the cancer cells as signs of nuclear pyknosis and vacuolization were present in the MCF-7/6 cells but not in the chick heart cells (Figure 86.2d).

Furthermore, the CI assay was performed to evaluate if the anti-invasive effect of X was restricted to MCF-7/6 cells. Invasiveness of MCF-7/6, MCF-7/AZ and T47-D cells was assessed and MCF-7/6 and MCF-7/AZ cells were considered non-invasive (1–2%) whereas T47-D strongly invaded the collagen gel (10–15%). Consequently, T47-D cells were chosen to test varying X concentrations (5, 10 and 30 μM) and a significant concentration-dependent anti-invasive effect could be observed after 24 h (Figure 86.2e).

An anti-invasive effect can be based either on a reduction of the number of invasive cancer cells, on a decreased invasiveness per cell or on an increased resistance toward invasion (Parmar *et al.*, 1997). However, a number of data suggested that the target of X resides in the cancer cells. Morphological analysis of the confronting cultures and growth assays with aggregates and cell cultures, clearly depicted a cytotoxic effect of X on the cancer cells while normal cells remained unaffected. Therefore, X could target specific activities implicated in breast cancer progression, like cell–cell adhesion *via* the E-cadherin/catenin complex, as reported for other flavonoids like 8-prenylnaringenin (8PN) (Rong *et al.*, 2001), genistein and daidzein (Maubach *et al.*, 2003). Cell–cell adhesion has a critical role in morphogenesis, establishment of tissue architecture, cell–cell communication and normal cell growth and ensures tissue integrity. During malignant transformation and invasion of epithelial tumors, cell–cell adhesion is often disrupted. The prototype of homotypic cell–cell adhesion (this is between cells of the same type) is the invasion-suppressor molecule E-cadherin, the major cadherin present in polarized epithelial cells (Bracke *et al.*, 1996; Mareel *et al.*, 1997). Cadherins form a family of cell-surface glycoproteins that function in promoting calcium-dependent cell–cell adhesion and serve as the transmembrane components of adherens junctions. Cell–cell adhesions are formed through the stable calcium-dependent binding of a dimer of another cell. Intracellularly, the E-cadherin molecule is attached to the actin cytoskeleton via the catenins that interact with transmembrane or cytoplasmic proteins (Figure 86.3). Disruption of the E-cadherin/catenin complex or one of its components may therefore promote invasion and is a common feature of carcinoma cells. Yet, mutations of the genes of these molecules are rare in human cancer. Therefore, agents that influence positively or negatively E-cadherin-mediated cellular responses, may stimulate or inhibit invasion. As the complex appears to be amenable to hormonal modulation by (anti-)estrogens, resulting in the upregulation of E-cadherin expression (Blaschuk and Farookhi, 1989) or function in mammary cancer cells (Bracke *et al.*, 1994),
Figure 86.3 The E-cadherin/catenin complex (simplified scheme): E-cadherin is a calcium-dependent transmembrane protein involved in adhesion junctions of epithelial cells. It typically connects epithelial cells, reducing their invasion potential. (a) Its extracellular domain mediates homophilic interaction with E-cadherin expressed by adjacent cells. The association of E-cadherin cytoplasmic domain to cytoplasmic proteins called catenins is necessary for strong cell adhesion. E-cadherin C-terminus interacts directly with β-catenin (β-CTN/PLAKO), which in turn binds α-catenin (α-CTN) and α-actinin to provide a link between E-cadherin and the actin cytoskeleton. p120ctn is a catenin which binds directly to the juxtamembrane region of E-cadherin (B). *Abbreviation list*: CTN, catenin.

Rong *et al.* (2001) evaluated if the hop phytoestrogen 8PN was able to influence the cell–cell aggregation of MCF-7/6 cells, which have a defective E-cadherin/catenin complex. Indeed, they found that aggregates treated with 8PN were larger than their untreated counterparts and that increased cell–cell adhesion and cell number contributed to this phenomenon. In parallel, our group showed that X stimulates cell–cell adhesion in an E-cadherin-mediated manner in an aggregation assay (Figure 86.4a). The assay is based on the preparation of a single-cell suspension in E-cadherin-saving conditions followed by quantification of cell aggregation in a calcium-containing medium (Boterberg *et al.*, 2001). Subsequently, the suspension was treated with varying X concentrations for 30 min at 4°C and incubated at 37°C for 30 min under continuous shaking, while untreated cells were incubated with 0.1% EtOH. Cells were fixed in 2.5% paraformaldehyde at the start of the incubation and after 30 min and the particle size distribution was measured with a Coulter Particle Size Counter LS 200 (Coulter Company, Miami, FL, USA). Thus, using human MCF-7/6 breast cancer cells with a functionally defective E-cadherin/catenin complex, we demonstrated that X was able to stimulate aggregation of MCF-7/6 cells in suspension thereby restoring the function of the complex (Figure 86.4b) (Vanhoecke *et al.*, 2005). The implication of E-cadherin was indicated by a neutralizing monoclonal antibody, MB2, which functionally blocks the molecule. Co-treatment with X and MB2 during
Figure 86.4   The effect of X on cell–cell adhesion: (a) The aggregation assay is based on the preparation of a single-cell suspension in E-cadherin-saving conditions followed by quantification of cell aggregation in a calcium-containing medium. The suspension is treated with the test compound for 30 min at 4°C and incubated at 37°C for 30 min under continuous shaking. Cells are fixed in 2.5% paraformaldehyde at the start of the incubation (N_0) and after 30 min (N_{30}) and the particle size distribution is measured with a Coulter Particle Size Counter LS 200 (Coulter Company, Miami, FL, USA). (b) Breast cancer cells (MCF-7/6) were pretreated for 24 h with varying X concentrations followed by trypsinization in E-cadherin-saving conditions to preserve E-cadherin-mediated cell–cell adhesion during the assay. In the presence of a calcium-containing aggregation buffer, cells were allowed to aggregate for 30 min in the presence or the absence of varying X concentrations. The initial mean particle diameter of the MCF-7/6 cells at time zero was 27.65 µm for solvent-treated cells (T_0 untreated) and 30.27 µm for the 5 µM X-treated cells (T_0 5 µM X), indicating suspensions of single cells or cell doublets in both conditions. After 30 min, the mean particle diameter shifted toward 177.4 µm for solvent-treated cells indicating aggregates of around 6 cells (T_{30} untreated). However, for X-treated cells aggregates of around 11 cells were formed and the mean particle diameter shifted toward 328.2 µm (T_{30} 5 µM X). The implication of E-cadherin was indicated by a neutralizing monoclonal antibody, MB2, which functionally blocks the molecule. Co-treatment with X and MB2 (T_{30} 5 µM X + MB2) during aggregation completely abrogated the effect of 5 µM X (T_{30} 5 µM X). *Abbreviation list*: MB2, monoclonal antibody 2.

aggregation completely abrogated the effect of X. However, the molecular mechanisms underlying this stimulated E-cadherin-mediated cell–cell adhesion have not yet been unraveled.

Recently, Albini *et al.* (2006) showed that X inhibited proliferation of both endothelial and KS-IMM tumor cells and strongly reduced their invasion in different *in vitro* invasion models. Moreover, they demonstrated that X was able to reduce solid tumor growth and angiogenesis *in vivo*. These observations suggest that X interferes with the molecular mechanisms of migration and survival as was evidenced by the inhibitory effects of X on NF-κB and Akt pathways both involved in the regulation of invasion, migratory and prosurvival signaling pathways.

Apart from its effect on cell–cell adhesion, X might also influence factors like cytokines and growth factors present in the microenvironment of the confronting cultures that

are associated with cancer cell invasion (Rolland *et al.*, 1980; Rozic *et al.*, 2001; Wülfing *et al.*, 2003). Indeed, X has been reported to reduce inflammation by inhibiting the activity of COXs and the production of PGs via this route (Gerhaüser *et al.*, 2002), and may, directly or indirectly, affect the invasive potential of the cancer cells.

ER Stress, Survival and Apoptosis

In eukaryotic cells, the ER is the principal site for folding and maturation of transmembrane, secretory and ER-resident proteins. Functions of the ER are affected by various intracellular and extracellular stimuli, which include inhibition of glycosylation, reduction of disulfide bonds, calcium depletion from the ER lumen, impairment of protein transport to the Golgi and expression of mutated proteins in the ER.
Figure 86.5 ER functions under non-stress conditions. (a) Proteins that are destined for synthesis in the ER are recognized, through signal peptides, by the signal recognition particle (SRP), which associates with the ribosome. The complex diffuses to the translocon, where the SRP docks with the SRP receptor (SR). GRP78 is the chaperone responsible for maintaining the permeability barrier of the ER translocon, the proteinaceous channel in the ER-membrane to which a nascent peptide is transferred for folding and assembly in the ER, during the early stages of protein translocation. Once the nascent peptide chains reach a length of 70 amino acids, GRP78 is released from the translocon, opening the channel to allow translocation of the protein into the luminal space. (b) As the nascent peptide is entering the ER, it is often modified by addition of *N*-linked glycans before folding. In the extremely crowded, calcium-rich, oxidizing environment of the ER lumen, resident chaperones like GRP78, GRP94, GRP170, CNX, CRT, PDI and ER-degradation-enhancing α-mannosidase-like protein (EDEM) serve to facilitate proper folding of the nascent protein by preventing its aggregation, monitoring the processing of the highly branched glycans, and forming disulfide bonds to stabilize the folded protein. (c) Once correctly folded and modified, the protein will exit the ER through coat protein (COP) II-coated vesicles and move to the Golgi apparatus through the secretory pathway. (d) Misfolded proteins can associate with CNX, PDI and EDEM (e) for retrotranslocation to the cytosol, ubiquitination and digestion by the proteasome via a process called the ERAD. (f) Perturbations that alter the ER homeostasis disrupt folding, and lead to the accumulation of unfolded proteins and protein aggregates, which are detrimental to cell survival. As a consequence, the cell has evolved an adaptive coordinated response to limit further accumulation of unfolded proteins in the ER. This signaling pathway is termed as the UPR and is associated with the activation of three ER-stress transducers, namely the PERK, the IRE1 and ATF6. GRP78 is the master regulator of the activation of the ER-stress transducers. In non-stress conditions, the ER-stress sensors are associated with GRP78, which keeps them in their inactive state. (g) The functions of the ER can be affected by various extracellular stimuli, so called ER stress. ER stress can be induced by agents that interfere with protein glycosylation (i.e. glucose starvation, tunicamycin, calcium balance (i.e. thapsigargin), disulfide bond formation (i.e. dithiotreitol (DTT)), and/or by a general protein overload of the ER (i.e. viral and non-viral oncogenesis). *Abbreviation list*: pATF6, cleaved ATF6.

Under ER stress, unfolded/misfolded proteins accumulate in the ER lumen, which induces conflicting cellular activities: survival and apoptosis. To cope with this stress, cells activate intracellular signaling pathways such as the unfolded protein response (UPR) and the ER-associated degradation (ERAD). However, under conditions of severe ER stress or when the UPR has been compromised, the cell may be incapable of maintaining ER homeostasis, which may eventually activate programmed cell death (PCD) pathways.

To assist in the folding of nascent polypeptides and to prevent aggregation of folding intermediates, the ER contains a high concentration of chaperones including the glucose-regulated proteins (GRPs), calnexin (CNX), calreticulin (CRT), peptidyl–prolyl isomerases (PPI), and protein-disulphide isomerase (PDI) (Gething and Sambrook, 1992). In addition to their role in folding, some of these chaperones act as a quality control system to ensure that only correctly folded proteins proceed to the Golgi apparatus for further processing and secretion (Kuznetsov *et al.*, 1997; Ellgaard *et al.*, 1999) (Figure 86.5). Of particular interest is the chaperone GRP78, which has been characterized in B-cells as part of the immunoglobulin secretory machinery and is also known as B-cell immunoglobulin heavy-chain binding protein (BiP), due to its association with incompletely assembled subunits of antibody
Figure 86.6 ER functions under stress conditions. (a) On accumulation of unfolded proteins in the ER lumen, GRP78 releases from PERK is activated to phosphorylate eIF2 on the α-subunit at Ser51. As phosphorylation of eIF2α reduces the functional level of eIF2α, the general rate of translation initiation is reduced. (b) In parallel, IRE1 dimerizes and activates its endoribonuclease activity after its release from GRP78. It splices its substrate XBP1 mRNA to remove a small intron, which changes the translational reading frame of XBP1 to yield a potent transcriptional activator that activates the transcription of responsive genes, including XBP1, ER chaperones and folding enzymes. (c) At the same time, ATF6 moves to the Golgi compartment, where it is cleaved by the S1P and S2P to yield a cytosolic fragment. This p50ATF6 fragment (pATF6) migrates to the nucleus to activate the transcription of responsive genes, including XBP1, ER chaperones and folding enzymes. *Abbreviation list*: XBP1(u), X-box-binding protein 1 (unspliced); XBP1(s), X-box-binding protein 1 (spliced).

molecules (Haas and Wabl, 1983; Bole *et al.*, 1986). GRP78 resides primarily within the ER (Munro and Pelham, 1986; Haas, 1994; Little *et al.*, 1994) and although it is constitutively expressed, its expression is enhanced up to 20-fold in cells under a variety of stressful conditions or agents that interfere with protein glycosylation, folding, transport, and disrupt calcium homeostasis (Lee, 1992; Li *et al.*, 1993).

The functions of the ER can be affected by various intra- or extracellular stimuli. Agents that interfere with protein glycosylation, calcium balance, disulfide bond formation and/or by a general protein overload of the ER are well-known inducers of ER stress (Kaufman, 1999; Pahl, 1999; Lee, 2001), therefore disrupt folding and lead to the accumulation of unfolded proteins and protein aggregates. As a consequence, the cell has evolved an adaptive coordinated response to limit further accumulation of unfolded proteins in the ER which are detrimental for cell survival. This signaling pathway is termed as the UPR and consists of three different mechanisms: (1) translational attenuation to further limit the synthesis of misfolded proteins (Harding *et al.*, 1999); (2) transcriptional activation of genes encoding ER-resident chaperones (Gething and Sambrook, 1992) and (3) ERAD, which serves to reduce the stress and

thereby restores the folding capacity by directing misfolded proteins in the ER back into the cytosol for degradation by the 26S proteasome (reviewed by Meusser *et al.*, 2005). This integrated intracellular signaling pathway transmits information about the protein folding status in the ER lumen to the cytoplasm and the nucleus via the activation of three ER-stress sensor molecules namely the doublestranded RNA-activated protein kinase-like ER kinase (PERK), the inositol-requiring enzyme 1 (IRE1) and activating transcription factor 6 (ATF6) (Figure 86.6).

PERK is an ER-resident transmembrane serine/threonine protein kinase, which consists of an ER luminal stress-sensing domain, a transmembrane domain, and a cytosolic domain with kinase activity that phosphorylates the α subunit of eukaryotic translation initiation factor 2 (eIF2α) in response to ER stress (Shi *et al.*, 1998; Harding *et al.*, 1999; Liu *et al.*, 2000). Phosphorylation of eIF2α reduces formation of translation initiation complexes and thus translation.

IRE1 is an ER-transmembrane glycoprotein consisting of a *N*-terminal ER luminal stress-sensing domain, a transmembrane domain, and a cytosolic domain with both serine/threonine kinase and *C*-terminal endoribonuclease activities (Tirasophon *et al.*, 1998; Wang *et al.*, 1998). ER stress initiates its dimerization and autophosphorylation
Figure 86.7   ER stress and apoptosis (simplified scheme): (a) Activation of PERK can result in the preferential translation of selective mRNAs under ER stress. Translational upregulation of ATF4 yields a potent transcriptional activator that activates the transcription of responsive genes, including CHOP. CHOP can also be induced by activation of ATF6 and IRE1. Upregulation of CHOP results in the downregulation of the anti-apoptotic proteins bcl-2 and bcl-xL and in ROS accumulation. The disturbed balance between proapoptotic proteins, for example, bad, bak and bax, and the anti-apoptotic bcl-2 proteins and the increase in oxidative stress activate the intrinsic apoptotic pathway. (b) By sequestering IRE1, TNF-receptor-activating factor 2 (TRAF2) promotes clustering of and release from ER-localized procaspase-12/-4 upon ER stress. Procaspase-12/-4 is then converted to caspase-12/-4 which initiates a caspase cascade through cleavage of procaspase-9 and -3. This pathway is independent of APAF-1 and mitochondrial cyt c release. (c) Furthermore, procaspase-12 can be activated by caspase-7 after its relocation from the cytosol to the ER. (d) Calcium released from the ER is rapidly taken up by the mitochondria, where it may lead to collapse of the inner membrane potential, cytochrome (cyt c) release and subsequent initiation of the caspase cascade.

to activate its kinase and RNase activities. The splicing of its substrate, the mRNA of X-box-binding protein 1 (XBP1), a basic leucine zipper (bZIP)-containing transcription factor (TF), removes a 26-nucleotide intron leading to a potent TF that binds to the unfolded protein response-responsive element (UPRE) and ER-stress-responsive element (ERSE) sequence of many ER stress and UPR-target genes (Yoshida et al., 2001; Lee et al., 2002).

p90/p110ATF6 is an ER-resident ATF consisting of a cytosolic *N*-terminal (bZIP) domain, a transmembrane domain and a *C*-terminal ER luminal stress-sensing domain (Haze et al., 1999). Upon ER stress, ATF6 transits to the Golgi compartment where it is cleaved by Golgi site-1 and site-2 proteases (S1P and S2P) to generate a fragment, namely p50ATF6 (Brown and Goldstein, 1997; Yoshida et al., 1998; Haze et al., 1999; Kaufman, 1999; Li et al., 2000; Wang, 2000; Ye et al., 2000; Sakai and Rawson, 2001). p50ATF6 then translocates to the nucleus where it binds to the ERSE of target genes.

GRP78 is the master regulator of the activation of the ER-stress sensors. Under normal conditions, GRP78

serves as a negative regulator of IRE1, PERK and ATF6. However, upon ER stress, GRP78 releases from the transducers and binds to unfolded proteins. GRP78 release from IRE1 and PERK permits their homodimerization and activation (Bertolotti et al., 2000; Liu et al., 2000). GRP78 release from ATF6 permits its transport to the Golgi compartment (Ye et al., 2000; Shen et al., 2005).

For many years, two major pathways of PCD were believed to induce apoptosis namely the intrinsic pathway, which is mainly controlled at the level of the mitochondria, and the extrinsic pathway, which is regulated by binding of specific death ligands to their receptors on the cell surface. However, a number of recent studies have now provided convincing evidence that PCD cascades can be initiated also at other sites within the cell, in particular, organelles such as the ER and the Golgi apparatus. Indeed, although the UPR is a cytoprotective response, prolonged ER stress can activate PCD through mitochondria-dependent or mitochondria-independent pathways (Rao et al., 2002; Breckenridge et al., 2003) (Figure 86.7). While attenuating global protein synthesis, phosphorylation

of eIF2α by PERK promotes preferential translation of ATF4 mRNA, which results in transcriptional induction of a proapoptotic protein, namely CHOP (C/EBP homologous protein-10, also known as GADD153) (Wang et al., 1998; Harding et al., 2000). CHOP is able to transcriptionally downregulate the levels of the anti-apoptotic bcl-2 and upregulate DR5, a ember of the death receptor protein family (Yamaguchi and Wang, 2004). In addition, CHOP leads to a depletion of the cellular glutathione levels (Marciniak et al., 2004) and it increases the levels of ROS in the cell (McCullough et al., 2001). This results in leakage of mitochondrial cytochrome c (cyt c), activation of cytosolic apoptotic protease activating factor 1 (APAF-1), and stimulation of caspase-9 and -3.

ER stress can also activate general regulators of apoptosis, including the bcl-2 and caspase families of proteins. Several BH3-only proapoptotic members of the bcl-2 family, including bim (Morishima et al., 2004), bik (Germain et al., 2002, 2005; Mathai et al., 2002, 2005), PUMA (Reimertz et al., 2003; Li et al., 2006), bax and bak (Nutt et al., 2002a, b; Scorrano et al., 2003; Zong et al., 2003; Oakes et al., 2005) can be involved. Accumulation of these proapoptotic members may antagonize ER-membrane-resident anti-apoptotic members such as bcl-xL and bcl-2, resulting in structural changes of the ER, ER calcium release and/or caspase-12 activation (Breckenridge et al., 2003; Zong et al., 2003). Caspases are required for apoptosis, and certain members of this family of cysteine proteinases associate with the ER-like caspase-12/-4. Although caspase-12 may play an important role during ER stress-induced apoptosis, it has recently been shown that its expression is not required for apoptosis, as cells lacking caspase-12 were not protected from apoptosis after treatment with ER-stress agents (Obeng and Boise, 2005). Procaspase-12 can also be cleaved by caspase-7. Rao et al. (2002) demonstrated that ER stress induces translocation of cytosolic caspase-7 to the ER surface followed by cleavage of procaspase-12.

Also stress-activated protein kinases such as JNK and p38MAPK can be activated during ER stress through signaling from the ER-stress transducers to the cell nucleus (Urano et al., 2000) and are involved during apoptosis.

The ability of the cell to detoxify ROS and thus oxidative stress is crucial for homeostasis and survival. Indeed, free radical production has been implied in development of cancer, progression of neurodegenerative diseases and in ageing processes (Hayes and Pulford, 1995; Richter et al., 1995; Hayes et al., 1999). Intracellular glutathione levels serve as buffer of oxidative stress and reduced glutathione plays an active role in removal of toxic compounds via binding and promoting ROS export (Richter et al., 1995). ER stress can induce oxidative stress due to the formation of ROS (Rushmore et al., 1991). The cellular response to ROS is the induction of genes that encode proteins that function as antioxidants and enzymes involved in glutathione biosynthesis (Rushmore et al., 1991; Hayes and Pulford, 1995; Hayes et al., 1999).

Effect of X on Survival of Breast Cancer Cells

Chemical ER-stress inducers like tunicamycin, thapsigargin and brefeldin A are well reported to induce cell death via a disturbance of the ER homeostasis. Recently, our laboratory discovered that X induces ER stress and apoptosis in various human breast cancer cell lines but not in human primary normal breast epithelial cells (unpublished data). In T47-D breast cancer cells, X stimulates the transcription (evidenced by quantitative RT-PCR) and translation (evidenced by Western blotting) of the ER chaperone GRP78, the marker for ER stress. During the X-induced ER stress, the ER-stress transducers PERK, IRE1 and ATF6 are activated. X stimulated the phosphorylation of eIF2α, the splicing of XBP1 and the cleavage of ATF6. Furthermore, sustained ER stress eventually resulted in apoptotic events like activation of caspase-9 and -3, downregulation of expression of anti-apoptotic proteins bcl-xL and mcl-1, upregulation of the proapoptotic CHOP and ATF4, accumulation of ROS and stimulated poly(ADP)ribose-polymerase (PARP) cleavage, a marker of late apoptosis (Figure 86.8). Interestingly, susceptibility to the X-induced apoptosis appeared to correlate with the GRP78 expression levels as MCF-7/6 cells in which GRP78 expression levels were unaltered after treatment with X, were shown to be most sensitive to apoptosis.

Thus – and in contrast to what is published about the molecular mechanisms of flavonoid-induced apoptosis – the proapoptotic effect of X appeared to be associated with a chronic stress condition in the cancer cells. In that respect, we note that flavonoids can initiate, apart from an oxidative stress response, an ER-stress response, that ultimately results in apoptosis and cell death. As the ER-stress response is characterized by an upregulation of the ER-stress chaperone, GRP78 and based on the observations that X induced in some, but not all, breast cancer cell lines GRP78 upregulation, it is interesting to unravel the role of this chaperone in the resistance of breast cancer cells to X.

In conclusion, X has multiple effects on human breast cancer cells *in vitro*. It elicits both a direct and an indirect effect on invasion through a stimulation of the E-cadherin-mediated cell–cell adhesion and a decrease in the number of invasive cells by promoting a chronic stress condition and PCD (Scheme 86.1). Agents that inhibit cancer cell invasion by selective killing of cancer cells, inhibiting their growth or stimulating cell–cell adhesion between cancer
Figure 86.8 Signaling pathways involved during X-induced ER stress and apoptosis (a) X induces ER stress which triggers the UPR. All three ER-stress sensor molecules IRE1, PERK and ATF6 are involved. Activation of PERK results in the phosphorylation of eIF2α (not shown), the activation of IRE1 in the spicing of XBP1 (XBP1(S)), and the activation of ATF6 in a 50kD cleavage fragment, pATF6. (b) Activation of the UPR results in the translational upregulation of ATF4 which yields the potent proapoptotic protein CHOP, and in oxidative stress through the accumulation of ROS. (c). The X-induced sustained ER-stress is followed by the activation of the intrinsic apoptotic pathway, accompanied by the activation of caspase-9, caspase-3 and the cleavage of the nuclear protein PARP. ER-associated caspases (caspase-4/-12 and -7) are not involved. (d).
Scheme 86.1

cells should be considered as potential therapeutic drugs in cancer.

Summary Points

- X inhibits invasion of human breast cancer cells.
- X stimulates E-cadherin-mediated cell–cell adhesion.
- X induces a chronic stress response in the cell, namely ER-stress.
- ER-stress induces a specific response, namely the UPR.
- Sustained ER-stress results in the activation of the intrinsic apoptotic pathway and cell death.
- Therefore, X induces ER-stress and cell death by activation of the UPR and apoptosis of human breast cancer cells.

Anti-cancer Property of Epicatechin Gallate in Colon Cancer Cells

Seung Joon Baek and Seong-Ho Lee Laboratory of Environmental Carcinogenesis, Department of Pathobiology, College of Veterinary Medicine, University of Tennessee, Knoxville, TN, USA

Abstract

There is persuasive epidemiological and experimental evidence that dietary polyphenolic plant-derived compounds have anti-cancer activity. Many laboratories, including ours, have reported such an effect in cancers of the gastrointestinal tract, lung, skin, prostate, and breast. The catechins are a group of polyphenols found in many beverages, including beer. While the preponderance of the data strongly indicates significant anti-tumorigenic benefits from catechins, the potential molecular mechanisms involved remain obscure. Although most studies are from epigallocatechin gallate (EGCG), much effort has recently been paid to epicatechin gallate (ECG) regarding the identification of its biological properties, including anti-cancer activity. ECG has been shown to alter the expression of several genes that are involved in apoptosis, cell cycle arrest, and angiogenesis. For examples, non-steroidal anti-inflammatory drug-activated gene and activating transcription factor 3 are induced, whereas basic fibroblast growth factor is down-regulated in the presence of ECG. Thrombospondin, an anti-angiogenic factor, is also increased by ECG treatment in human colorectal cancer. Several biological activities of ECG have been described and discussed. Therefore, this chapter attempts to highlight the biological activities of ECG in human colorectal cancer, and emphasize the pro-apoptosis and anti-angiogenesis that may play a role in chemopreventive activity of ECG.

Introduction

During the last half century, extensive research has identified various dietary compounds found in vegetables, fruits, and beverages, compounds that can potentially be used not only for the prevention of cancer but also for other diseases. Beer, a low-alcohol beverage, is one of the most commonly consumed alcoholic beverages in the world. It has not only plenty of nutrients, but also beneficial non-nutrient compounds such as phenolic acids, flavonoids, chalcones, proanthocyanidins, and catechins (Gerhauser, 2005). Although heavy alcohol consumption is one of the leading causes of

preventable death related to coronary heart and liver disease, low or moderate alcohol consumption was associated with a beneficial effect on cancer-related mortality in middle age (35–69), compared with non-drinking and heavy drinking groups (Thun *et al.*, 1997). Epidemiological studies also suggested that moderate consumption of alcoholic beverages including beer is significantly associated with a reduction in coronary heart disease mortality (Rimm *et al.*, 1991; Gronbaek *et al.*, 1995). It has also been known that drinking beer can significantly decrease cholesterol and triglyceride level, and inhibit atherosclerosis compared to a control group that drinks 2% alcohol only (Vinson *et al.*, 2003). The protective effects of beer may be the result of non-alcoholic phenolic compounds abundantly present in beer. Furthermore, several animal studies examined beer's antioxidative and anti-tumorigenic properties in liver and colorectal carcinogenesis. Intake of beer significantly increased antioxidant capacity of plasma, for example, as a protective agent against the oxidation of ascorbic acid and unsaturated fatty acids (Pulido *et al.*, 2003; Gasowski *et al.*, 2004). Beer consumption decreased liver DNA adducts, induced by several heterocyclic amines (Arimoto-Kobayashi *et al.*, 1999) and reduced the incidence of dimethylhydrazine- or azoxymethane-induced colonic carcinogenesis (Nelson and Samelson, 1985; Nozawa *et al.*, 2004). Moderate beer intake was also associated with higher bone mineral density in postmenopausal elderly women (Rapuri *et al.*, 2000) and lowered the risk of type-2 diabetes (Conigrave *et al.*, 2001) as well as dementia (Ruitenberg *et al.*, 2002). Thus, non-nutrient components found specifically in beer, rather than the alcohol, may play an important role in beer's beneficial effects on several diseases.

Beer has a complex mixture of polyphenols ranging from 150 to 300 mg/l in concentration (Bendelow, 1977). Since the average per capita consumption of beer in the United States in 2004 was 224 ml/day (USDA, 2005), we can assume a consumption of 34–67 mg/day of polyphenolic compounds. Polyphenols in beers are present in the malt (70–80%) and hops (20–30%) used to make beer, and have an impact on the quality of flavor, colloidal

stability, and haze formation by oxidative polymerization (Gerhauser, 2005; Lopez and Edens, 2005). Because phenolic compounds can act as antioxidants in the human body, polyphenols in beer appear to be responsible for the benefits of beer. Among the numerous polyphenols isolated from unstabilized beer, total catechins, which have been detected in concentrations of <15 mg/l, account for approximately 70% of the polyphenolic compounds of beer (Gerhauser *et al.*, 2002). The major catechin substances are epicatechin (EC), epicatechin gallate (ECG), epigallocatechin (EGC), and epigallocatechin gallate (EGCG). Catechin gallates such as ECG and EGCG are esters of a catechin and gallic acid (GA). Although ECG is not the major catechin in beer, it shows a strong biological activity in several aspects, including apoptosis, transport, and growth inhibition in colorectal cancer cells (Okabe *et al.*, 1997; Vaidyanathan and Walle, 2003; Baek *et al.*, 2004a). However, ECG has not been studied in detail regarding how this compound affects several disease statuses. Several studies have shown that EGCG induces apoptosis in cancer cells, but little effort has been directed at evaluating the induction of apoptosis by ECG. Thus, the precise molecular mechanisms by which the other ester forms of ECG-induced anti-cancer activity remain to be elucidated. This chapter will provide the value of ECG present in beer as an antioxidant and potential cancer chemopreventive agent and its application in cancer prevention.

Biological Activities of ECG in General

ECG [(−)-epicatechin-3-gallate] is a 3-gallate ester form of (−)-epicatechin, as shown in Figure 87.1. The health benefits of ECG are mainly attributable to its antioxidant properties and contribution to the reduced risk of cancer, obesity, and cardiovascular disease as well as to its anti-hypertensive effect, antibacterial and antiviral activity, ultraviolet protection to skin, and neuroprotective power (Zaveri, 2006).

Kinetic analysis of the antioxidation process demonstrates that ECG is a strong antioxidant for microsomal peroxidation and synergizes the effect of endogenous alpha-tocopherol (Cai *et al.*, 2002). As an alpha-tocopheroxyl radical scavenger, ECG was the most effective catechin among the catechins tested, including EGCG, EC, EGC, and GA (Liu *et al.*, 2000). In addition to its antioxidant effects, ECG is studied for its effect on cellular and molecular targets in signal transduction pathways associated with cell death and survival in cancer chemoprevention. Studies in animal models of carcinogenesis clearly demonstrate anti-cancer activities against various tumor models. As summarized in Table 87.1, ECG inhibits the growth of tumors in the colon (Hong *et al.*, 2001; Weyant *et al.*, 2001; Baek *et al.*, 2004a), breast (Liao *et al.*, 1995; Bigelow and Cardelli, 2006), prostate (Ahmad *et al.*, 1997; Chung *et al.*, 2001), head and neck (Lim *et al.*, 2006), lung (Yang *et al.*, 1998), and skin (Ahmad *et al.*, 1997; Huang *et al.*, 2005). Intake of

catechin-rich green tea prevented an increase in body weight in an obese animal model (Kao *et al.*, 2000) and inhibited adipocyte proliferation (Hung *et al.*, 2005; Wu *et al.*, 2005). ECG also inhibited development of insulin resistance and hyperglycemia (Wu *et al.*, 2004), as well as coronary artery disease and atherogenesis (Miura *et al.*, 2000). ECG inhibited fatty acid synthase, which is a potential therapeutic target of obesity (Tian, 2006; Zhang

et al., 2006). In addition, ECG protected the development of diabetes by suppression of oxidative stress (Rizvi *et al.*, 2005), and directly inhibited synthesis of new blood vessels by inhibition of matrix metalloproteinases and vascular cell adhesion molecules, the physiological activators of angiogenesis (Ludwig *et al.*, 2004; El Bedoui *et al.*, 2005), and inhibited the growth of vascular smooth muscle cells, which play an important role in the development of proliferative cardiovascular diseases (Sachinidis *et al.*, 2002). ECG showed anti-helicobacter pylori activity as effective as the EGCG effect (Yanagawa *et al.*, 2003). In addition, age-associated diseases such as Parkinson's disease (Nie *et al.*, 2002; Mandel *et al.*, 2004) were inhibited by ECG intake. Therefore, the multiple biological pathways involved in human diseases could be modulated by ECG and further represent an important target of chemoprevention research.

ECG-Induced Apoptosis in Colorectal Cancer

Cancer is second only to heart disease as the leading cause of death in the United States, and colorectal cancer is one of the most prevalent causes of cancer-related mortality in the Western world. Further development of therapeutic and preventative means of controlling this disease are clearly needed, particularly as they pertain to gastrointestinal cancer (Lamprecht and Lipkin, 2003). Since colorectal cancer progresses for 10–40 years, several approaches could attack this heterogeneous disease (Figure 87.2). Among these, prevention studies are the most promising from the public health point of view. Chemoprevention is one of the most rapidly growing fields, and apoptosis induction is a target of this chemoprevention research.

Apoptosis can be induced by a wide variety of physical, chemical, and biological stimuli, and two very distinct apoptotic pathways have been identified: the death receptor pathway involving activation of caspase-8, and the mitochondrial pathway involving caspase-9. These two independent apoptotic pathways converge on the activation of downstream caspase-7, -6, and -3, key proteins that mediate apoptosis. Cellular stress, including that generated by many chemotherapeutic agents, stimulates the p53/p73/p14^{ARF} pathway, which is thought to act by increasing expression of pro-apoptotic proteins such as Bcl-2 family members Bax, Bak, and Bcl-XS. These in turn, stimulate mitochondrial release of cytochrome c, which causes Apaf1 to bind to procaspase-9 and activate this apoptotic pathway. To date, there have been few reports on whether ECG affects apoptosis in colon cancer cells by modifying expression of key regulatory proteins, or whether apoptosis occurs through caspase-8 and/or mitochondria (caspase-9)-dependent mechanisms in colorectal cancer cells.

The similarity of the biochemical events during apoptosis is reflected by a high uniformity of morphological
Figure 87.2 Schematic diagram of colorectal tumorigenesis.

changes in many situations of naturally occurring or experimentally induced cell death. As shown in Figure 87.3, ECG obviously increases apoptosis in human colorectal cancer cells as assessed by cell morphology. ECG-treated HCT-116 cell culture contained many cells with condensed DNA and fragmented apoptotic bodies, whereas treatment with vehicle or 50 μM EGCG did not produce the same observations. In addition to changing morphology and biochemical pathways, there have also been reports that several apoptotic-related genes at the molecular levels are affected by ECG. In this section, we focus on two apoptosis-related genes, NAG-1 and ATF3, which are induced by ECG.

NAG-1

NAG-1 (non-steroidal anti-inflammatory drug-activated gene-1) was identified by PCR-based subtractive hybridization from an NSAID-induced library in cyclooxygenase (COX)-negative cells as a divergent member of the TGF-β superfamily (Baek *et al.*, 2001). The induction of NAG-1 by NSAIDs is an important COX-independent mechanism by which some of these proven anti-inflammatory compounds mediate their effects (Baek *et al.*, 2002b). NAG-1 protein has broad activity in inflammation, cancer, and differentiation. Although the molecular mechanisms responsible for these functions have yet to be determined in detail, experimental evidence suggests that NAG-1 may share at least some of the common functions of TGF-β superfamily cytokines (Baek and Eling, 2006). It is highly expressed in mature intestinal epithelial cells, but is significantly reduced in human colorectal carcinoma samples and neoplastic intestinal polyps of *Min* mice (Kim *et al.*, 2002). In addition, it has been reported that NAG-1 overexpression from a recombinant adenoviral vector results in up to an 80% reduction of MDA-MB-468 and MCF-7 breast cancer cell viability (Li *et al.*, 2000), and treatment of prostate cancer cells with purified NAG-1 induces apoptosis (Liu *et al.*, 2003).

To obtain further support for *in vitro* results, we have made a transgenic mouse (NAG-Tg) that expressed the human form of NAG-1 in all tissues, including the intestinal tract, and then investigated intestinal tumor development. The transgenic mice appeared to be normal but were smaller in weight (Baek *et al.*, 2006). The mice were either treated with a carcinogen that induces intestinal tumors or a genetic mutation that results in intestinal tumors was
Figure 87.3 ECG induces apoptosis in HCT-116 cells. Representative photomicrographs of cytospin preparations from HCT-116 cell cultures treated with vehicle (0.2% DMSO), EGCG (50 μM), or ECG (50 μM) for 48 h. Mitotic figures were obvious in vehicle (arrow) and EGCG-treated cells (inserted), but not apparent in ECG-treated cells. In contrast, ECG-treated cells (arrow) more often had morphologic features of apoptosis, with condensation of nuclear chromatin and cytoplasmic structure, and fragmentation into smaller, discrete bodies. Wright-Giemsa stain, 600×.

introduced into the NAG-Tg mice. Compared to control mice, the NAG-Tg mice had a greater than 50% reduction in intestinal cancer, confirming the tumor suppression activity of NAG-1. These data support the evidence that NAG-1 is linked to apoptosis and that its reduced expression may enhance tumorigenesis.

NAG-1 expression is up-regulated in a prostaglandin-independent manner in human colorectal cancer cells by several NSAIDs (Baek *et al.*, 2002b), as well as by anti-tumorigenic compounds such as resveratrol (Baek *et al.*, 2002a), genistein (Wilson *et al.*, 2003), ECG (Baek *et al.*, 2004a), indole-3-carbinol (Lee *et al.*, 2005), PPARγ ligands (Baek *et al.*, 2004b; Yamaguchi *et al.*, 2006a), horehound extracts (Yamaguchi *et al.*, 2006b), 5F-203 (Monks *et al.*, 2003), and retinoid 6-[3-(1-adamantyl)-4-hydroxyphenyl]-2-naphthalene carboxylic acid (AHPN) (Newman *et al.*, 2003). While some dietary compounds, including resveratrol and genistein, induce NAG-1 expression through the p53 tumor suppressor protein, NSAIDs, ECG, and indole-3-carbinol induce NAG-1 in a p53-independent manner. Thus, several pathways are involved in NAG-1 expression. ECG seems to be one of the strongest NAG-1 inducers among the other catechins. Unlike EGCG, ECG induces NAG-1 expression in a p53-independent manner. Therefore, ECG induces NAG-1 expression in cells lacking p53, and a NAG-1 promoter that lacks the p53 binding site is activated in the presence of ECG (Baek *et al.*, 2004a). Furthermore, p53 protein expression is not induced by ECG. Since most of colorectal cancer cells were mutated in a p53 locus, any compound like ECG that does not mediate p53 expression will be beneficial.

ATF3

ATF3 (activating transcription factor) is designated as a stress-inducible gene and several genes have been implicated as the targets of ATF3. The ATF3 homodimer functions as a repressor for most of the target genes such as gadd153/Chop10, E-selectin, and phosphoenolpyruvate carboxylase (Chen *et al.*, 1996; Hai and Hartman, 2001). However, the heterodimeric complex of ATF3 with c-Jun, for instance, has been demonstrated to function as a transcriptional activator (Hai and Hartman, 2001). ATF3 binds to the AP-1 family, and its transcriptional activity differs according to its counterpart. ATF3, in combination with c-Jun, activates specific promoters containing AP-1 and CRE sites, but in contrast, ATF3 in combination with JunB potently represses activation of these promoters (Hsu *et al.*, 1992). In addition, Hai and colleagues proposed mechanisms by which ATF3 can perform the opposite functions of gene repression or activation (Chen *et al.*, 1994). The functional consequence of ATF3 thus varies in stress signals and cell types. ATF3 is induced by camptothecin and etoposide, agents known to induce apoptosis (Hai *et al.*, 1999; Hai and Hartman, 2001). Furthermore, ATF3 is highly expressed after sulindac sulfide treatment and may also play

an important role in sulindac sulfide-induced apoptosis and anti-tumorigenic activity (Iizaka *et al.*, 2002). Tetracycline-inducible overexpression of ATF3 suppresses cell growth and slows cell cycle progression from the G_1 to the S phase (Fan *et al.*, 2002).

ATF3 has been postulated to be a tumor suppressor gene because it coordinates the expression of genes that may be linked to cancer (Fawcett *et al.*, 1999). Moreover, the expression of ATF3 was repressed in human colorectal tumors compared to normal adjacent tissue (Bottone *et al.*, 2003). Interestingly, it has been reported that both ATF3 and NAG-1 were co-induced by treatment with the 5F-203 anti-tumorigenic compound (Monks *et al.*, 2003) and sulindac (Iizaka *et al.*, 2002). We also found that ATF3 expression is induced by ECG or indole-3-carbinol treatment, supporting the concept that ATF3 expression has a role in compound-induced apoptosis (Baek *et al.*, 2004a; Lee *et al.*, 2005). However, the exact molecular mechanisms of ATF3 action and gene regulation in carcinogenesis need to be elucidated further.

Down-regulation of β-catenin signaling

Many signaling pathways play a pivotal role in colorectal tumorigenesis. Specifically, the Wnt/β-catenin signaling pathway is important in development and tumorigenesis (Polakis, 2000; Widelitz *et al.*, 2000). In an unstimulated cell, most of the endogenous β-catenin interacts with adenomatous polyposis coli (APC), glycogen synthase kinase (GSK)-3β, casein kinase 1α, axin, or the closely related factor conductin/Axil, and is found at epithelial cell adherens junctions, where it interacts with E-cadherin and α-catenin to help mediate cell adhesion. However, binding of the Wnt ligand to its receptor complex triggers a series of events that ultimately disrupt the β-catenin/APC/Axin/GSK3β complex. This, in turn, results in the nuclear accumulation of β-catenin and to the increased transcription of Wnt-β-catenin target genes. In the nucleus, β-catenin acts as a transcriptional activator in conjunction with the LEF/TCF DNA binding proteins. The transcription of Wnt-β-catenin target genes is further modulated by a variety of different co-activators and co-repressors that have been identified in the past decade. Among the target genes of the β-catenin/TCF complex, several cell growth related genes have been identified, including cyclin D1 (Shtutman *et al.*, 1999; Tetsu and McCormick, 1999), c-myc (He *et al.*, 1998), and PPAR-δ (He *et al.*, 1999). Indeed, ECG down-regulates cyclin D1 expression by the suppression of β-catenin signaling (Lim *et al.*, 2006). Like other polyphenols that suppress the β-catenin signaling pathway, the inhibition of β-catenin signaling by ECG should be considered as a molecular target in colorectal cancer. Although the exact mechanisms have not been elucidated, down-regulation of β-catenin signaling plays an important role in chemopreventive compound-induced anti-cancer activity.

ECG-Induced Anti-angiogenesis

Angiogenesis, the generation of new capillaries by sprouting of pre-existing microvessels, is a tightly regulated process that is restricted to a few conditions, including normal reproductive function and wound healing (Whisenant and Bergsland, 2005). However, aberrant angiogenesis is a crucial factor in the pathogenesis of numerous diseases, including cancer. In this section, we will focus on the alteration of pro-angiogenesis factor bFGF and anti-angiogenesis factor TSP-1, mediated by ECG treatment.

TSP-1

Thrombospondin-1 (TSP-1) is an extracellular glycoprotein first recognized as an inhibitor of angiogenesis more than a decade ago. Since then, much has been learned about its ability to regulate vascular growth in several angiogenesis models, functional domains have been identified, and mechanisms of action determined. TSP-1 is a potent inhibitor of angiogenesis and effectively inhibits a wide variety of angiogenic stimuli, including VEGF, proteins that act via tyrosine kinase receptors, G proteins, serine/threonine kinase receptors and lipids. To examine other potential pathways by which ECG induces anti-tumorigenic activity, we performed superarray analysis to characterize the mRNA expression profile of cancer-related genes in HCT-116 cells. After incubation with or without $50\,\mu M$ ECG, cellular RNA was extracted, and cancer-related gene expression was analyzed using Superarray[TM] membranes. TSP-1 is a gene that was up-regulated >3.0-fold by ECG (Table 87.2). Oligonucleotide primers were designed for TSP1, and RT-PCR was performed. TSP1 transcription was markedly up-regulated with ECG treatment, whereas the levels of transcription of GAPDH were not affected. We then performed Western analysis to confirm that ECG induces TSP1 protein expression. TSP-1 is induced by ECG treatment as early as 1 h after treatment, with increased expression following 24–48 h of treatment. Taken together, these results showed that ECG may alter several genes in HCT-116 cells, including TSP1, which probably account for apoptotic and/or anti-tumorigenic activities.

TSP-1 is an inhibitor of invasion but also an inhibitor of angiogenesis and its suppression is crucial for the angiogenic switch in many tumor models. The cellular mechanism is not well known, but TSP-1 can inhibit endothelial cell growth via the apoptotic pathway (Hamano *et al.*, 2004). TSP-1 inhibits the activity of matrix metalloproteinase-9, which causes a release of vascular endothelial growth factor (VEGF) sequestered in the extracellular matrix, thereby increasing invasion potential (Rodriguez-Manzaneque *et al.*, 2001). Moreover, TSP-1 can promote secretion of PAI-1, which was shown to inhibit the invasiveness of human lung carcinoma cells (Albo *et al.*, 1999). Thus, ECG induces TSP-1, followed by the induction of anti-tumorigenic activity mediated by anti-angiogenesis.

Table 87.2 ECG altered gene expression in human colorectal cancer cells

Gene name	Description	GeneBank	Up/down
Bcl-x	Bcl2-like 1	NM_138578	Up
CDC25A	Cell division cycle 25A	NM_001789	Up
E-Cadherin	E-Cadherin	NM_004360	Up
IFNA1	Interferon α 1	NM_024013	Up
IL-8	Interleukin 8	NM_000584	Up
IKBA/MAD-3	NF-κB inhibitor, α	NM_020529	Up
uPA	Plasminogen activator, urokinase	NM_002658	Up
uPAR	Plasminogen activator, urokinase receptor	NM_002659	Up
DNA-PK	Protein kinase	NM_006904	Up
PAI-1	Plasminogen activator inhibitor type 1	NM_000602	Up
TSP1	Thrombospondin 1	NM_003246	Up
TIMP1	Tissue inhibitor of metalloproteinase 1	NM_003254	Up
TNFA	Tumor necrosis factor	NM_000594	Up
Apaf-1	Apoptotic protease activating factor	NM_001160	Down
RB1	Retinoblastoma 1	NM_000321	Down

Note: HCT-116 cells were seeded into plates 100 mm in diameter. Once they reached 60–80% confluency, vehicle or 50 μM ECG was added and treated for 24 h. Total RNA was extracted and cDNA was labeled from 5 μg of total RNA in a reverse-transcription (RT) reaction with biotin-16-dUTP (Roche Diagnostics GmbH). RT reaction was performed using MMLV reverse transcriptase (Promega, WI). The labeled cDNA was hybridized to GEArray Q Series Human Cancer PathwayFinder Gene Array (HS-006, SuperArray Bioscience) overnight at 60°C. The membrane used in the present study contained 96 genes that were closely related to cancer, in addition to four positive control genes (glyceraldehyde-3-phosphate dehydrogenase, cyclophillin A, ribosomal protein L13A, and β-actin) and one negative control (pUC18). The list of genes identified by up- and down-regulation by ECG, compared to the vehicle treated samples, is shown.

bFGF

Basic fibroblast growth factor (bFGF, also known as FGF-2) is a well-documented angiogenic growth factor that induces endothelial cell replication, migration, and extracellular proteolysis (Chen *et al.*, 2004). The bFGF protein is produced by several normal, tumor, and endothelial cells, and has autocrine activities in angiogenesis and may promote angiogenesis both by a direct effect on endothelial cells and indirectly by the up-regulation of VEGF in endothelial cells. Thus, bFGF and VEGF have a synergistic effect in the induction of angiogenesis both *in vitro* and *in vivo*. Basic FGF belongs to the FGF superfamily, which contains at least 20 distinct FGFs (Dow and deVere White, 2000). Four different bFGF polypeptides of 18–24.2 kDa can be formed from one *fgf-2* gene. The bFGF peptide does not code for a signal sequence required for vectorial translocation into endoplasmic

reticulum and can be released through a yet unknown mechanism of exocytosis independent of the ER-Golgi pathway. Mechanical damage such as wounding has also been proposed as one mechanism for release of biologically active bFGF from endothelial cells. In the extracellular matrix and on the cell surface, bFGF is bound to heparan-like glycosaminoglycans (HLGAGs). The association to HLGAGs may afford bFGF protection from proteolysis, besides creating a localized and persistent reservoir of the growth factor. Like VEGF, bFGF also inhibits apoptosis of endothelial cells, and it is a well-characterized fibroblast growth factor that induces mitogenic and chemotactic activity and differentiation of some other cell types of mesodermal and neuroectodermal origin.

Our recent results with human colorectal cancer cells indicated that either ECG or EGCG treatment suppressed bFGF expression at both transcriptional and translational levels (unpublished results). While transcriptional regulation by ECG is not clear, ECG clearly suppressed bFGF protein expression via degradation. ECG activates ubiquitinase-dependent protein degradation in human colorectal cancer cells, followed by the selective degradation of bFGF. It has been demonstrated that ester bond-containing polyphenols such as EGCG and ECG potently and specifically inhibit the chemotrypsin-like activity of the proteasome *in vitro* (Wan *et al.*, 2005). However, our data suggest that ECG promotes proteasome machinery and facilitates protein degradation. Therefore, the precise mechanisms by which catechins affect protein degradation need to be elucidated.

Concluding Remarks

The appropriate use of a chemopreventive agent that includes catechins ultimately depends on the understanding of catechin's mechanism of action at all levels. Based on such knowledge, the trend in the field of chemoprevention has been to develop new agents based on their mechanism of action. With the rapid progress in molecular medicine and development of the state-of-the-art technologies applied to biomedical research in general, we are now better aware of the intracellular events associated with chemopreventive compounds. Despite this progress, the identification of molecular and cellular targets of chemopreventive phytochemicals remains still incomplete. In this regard, catechins, especially EGCG and ECG, have received much attention by the pharmacological and nutritional scientists, who demonstrated that cancer chemoprevention by catechins, can be achieved by signaling transduction blockade.

Most results regarding catechin effects on chemopreventive activity are from EGCG. Few studies were performed using ECG, although ECG has been shown to be more potent in some aspects. ECG is a strong apoptosis inducer, and NAG-1/ATF3 expressor in HCT-116 cells, compared to other catechins. ECG also suppresses bFGF as illustrated in Figure 87.4. In this chapter, we have further shown that EGCG and ECG may affect different mechanisms regarding

Molecular targets of ECG
Figure 87.4 Schematic diagram of molecular targets of ECG. ECG enhances pro-apoptotic protein and anti-angiogenic protein, but suppresses angiogenic protein.

chemopreventive activity. Although ECG differs from EGCG only by the lack of one hydroxyl group on the B-ring, ECG is more biologically active than EGCG in some aspects. Although further studies are required to recommend using ECG as a supplementary compound, ECG could be a potential agent for the chemoprevention of colorectal cancer.

Use of Quercetin in Prostate Cancer Cell

Charles Y. F. Young Department of Urology, Mayo Clinic/Foundation, Rochester, MN, USA

Abstract

The anti-cancer activity of beers is believed residing in its non-alcoholic portion containing phyto-polyphenols that comes from the raw materials including hops and malt, used for making beers. Although a recent study indicated that beers and red wines may have a trend of reduction of prostate cancer risk, more studies with a large population are required to demonstrate its potency. Quercetin, a major polyphenol existing in many fruits and vegetables, is one of the polyphenols found in beers that shows anti-prostate cancer activities in cell culture and animal models. In addition to its strong antioxidant/detoxification activities, quercetin can derail cell cycle progression by causing various cell phase arrests, therefore exhibiting anti-proliferative activities and inducing apoptosis. Alterations in expression levels or activities of a number of cell cycle regulatory related genes including Cdc2/Cdk-1, cyclin B1, phosphorylated pRb and p21 were observed by quercetin treatment. Similarly, the expression or activities of apoptotic-related proteins like anti-apoptotic proteins Bcl-2 and Bcl-X-L and pro-apoptotic proteins Bax and caspase-3 are also found to be changed by quercetin. Quercetin may also affect a number of signaling molecules or transcription factors including the androgen receptor, the signal transducer and activator of transcription 3 (STAT3), c-Jun, Sp1, etc. in prostate cancer cells in response to stimulation by hormones or growth factors/cytokines. Finally, it has been shown in several studies that a combining use of quercetin with other agents (e.g. ellagic acid, tamoxifen, etc.) may enhance the anti-prostate cancer effects of quercetin.

List of Abbreviations

ACF	Aberrant crypt foci
AR	Androgen receptor
ARE	Androgen responsive element
CYP	Cytochrome P450 enzyme
FAS	Fatty acid synthase
GSP	Glutathione *S*-transferase
HSP70	Heat shock protein 70
IGFs	Insulin-like growth factors
IGFBP-3	IGF binding protein-3
IL-6	Interleukin 6
IP3	Inositol 1, 4, 5-triphosphate
QR	Quinone reductase
STAT3	The signal transducer and activator of transcription 3
SULT	Sulfotransferase
UGT	Uridine diphosphate-glucuronyltransferase
VEGF	Vascular endothelial growth factor

Introduction

It is well established the seriousness of alcohol abuse to the health of individuals (Fothergill and Ensminger, 2006). It has been a long time that there was a suspicion that use of alcoholic beverages may have a positive impact on prostate cancer risk. However, many recent studies (Jain *et al.*, 1998; Sesso *et al.*, 2001; Albertsen and Gronbaek, 2002; Platz *et al.*, 2004; Chang *et al.*, 2005; Schoonen *et al.*, 2005) seem to indicate that alcohol intake from beer, wine or liquor may not be a strong contributor to prostate cancer risk, except possibly in men who drink large quantities. For example, a large prospective cohort study of 47,843 US men with 2,497 men developing prostate cancer revealed no positive association between alcohol consumption and cancer risk (Platz *et al.*, 2004). Another relative large cohort study also showed no association of neither amount nor type of alcohol consumed with the risk of prostate cancer (Albertsen and Gronbaek, 2002). A Harvard Alumni Health study showed only liquor, but not wine or beer, consumption was positively associated with prostate cancer (Sesso *et al.*, 2001). On the other hand, it was suggested that drinking red wine may relatively reduce prostate cancer risk (Schoonen *et al.*, 2005). Interestingly, another study showed that beer may have trends to decrease risk of prostate cancer (Jain *et al.*, 1998). Clearly more in-depth studies will be required to clarify the issue. Regardless, excessive alcohol consumption can seriously damage general health of individuals and should be avoided.

Recently, an animal study (Nozawa *et al.*, 2004) demonstrated that azoxymethane (AOM)-induced colonic
Figure 88.1　Chemical structures of quercetin and some derivatives.

carcinogenesis in male Fischer 344 rats can be repressed by intake of beer. This investigation showed that freeze-dried beer, but not alcohol can significantly inhibit the formation of aberrant crypt foci (ACF), suggesting that non-alcohol components of beer could be responsible for the inhibition. A long-term (42 weeks) of beer intake decreased tumor incidence by 22% and decreased the number of neoplastic lesions by 44%. In an *in vitro* study (Tedesco *et al.*, 2005), the authors selected a particular brand of beer containing high antioxidant polyphenols for investigating cell prolif-eration effects of lyophilized beer materials in comparison with that from another brand of beer with low polyphenol contents on a leukemia cell line, HL-60. The lyophilized beer material containing high polyphenol content showed much higher anti-proliferation effect than that from low polyphenol containing beer. The important point is that these studies seem to suggest that certain non-alcoholic components, perhaps particularly polyphenols, in beer may have chemopreventive effects and that intake of beer might contribute to a reduction in the risk of cancer development. Again, more *in vitro* and human clinical studies may be required to further investigate any chemopreventive effects of beer on cancers.

It has been shown that a main type of substances in beer presenting potential anti-cancer activities is plant pheno-lics (Gorinstein *et al.*, 2000; Gerhauser, 2005; Nardini *et al.*, 2006). These plant phenolics or polyphenols possess antioxidant properties which are thought to have anti-

cancer activity. Paganga *et al.* (1999) estimated that the antioxidant activities of plant polyphenols in 500 ml beer are equivalent to 4 apples, 2 cups of tea or 500 g of fresh onion. The beer phenolics are mainly from hop (20–30%) and malt (70–80%), the two major raw materials for mak-ing beer. One of the major forms of poly-phenols in beer is quercetin and its glycosyl-derivatives (Figure 88.1 and Table 88.1).

Quercetin Actions in Prostate Cancer Cells

Prostate cancer is among the top cancer killers for men in several western or highly industrialized countries, such as United States, United Kingdom, etc. It has been suggested that the much higher rates of prostate cancer incidents in these countries than that in those less-developed countries may be largely attributable to life styles, especially diets (Kamangar *et al.*, 2006; Klein, 2006). In general agree-ment, prostate cancer is one of cancer types most suitable for chemoprevention modalities, in part, because it requires decades to develop or progress (Kamangar *et al.*, 2006; Klein, 2006).

Structure of quercetin

Quercetin is one of the most abundant flavonoids present in various fruits, vegetables and beverages (Aherne and

O'Brien, 2002; Mertens-Talcott *et al.*, 2003; Erlund, 2004; Manach *et al.*, 2004) (Tables 88.2 and 88.3). The basic nucleus structure of flavonoids consists of two benzene rings (A and B) connected by an oxygen containing pyrene ring (C). With a various substitution pattern in these three rings it forms a large numbers of subgroups. Basically, flavonoids can be divided into several classes (e.g. anthocyanidins, flavanols/catechins, flavones, flavonols, flavanones and isoflavones, etc.) depending on oxidation levels on the C-ring. Quercetin belongs to a class of flavonoids, called flavonols, which carry a carbonyl group on C-4 (4-oxo) of the C-ring. So far quercetin is one of the most commonly investigated plant phenolics for its biological functions, maybe because it possesses much higher anti-radical activities toward hydroxyl radical, peroxyl and superoxide anion than many other flavonoids (Morel *et al.*, 1993; Skibola and Smith, 2000). Interestingly, quercetin also exists in many different glycosidic forms in their natural sources. The glycoside moiety is linked through hydroxyl group at C3 position of the C-ring as seen in the examples of Figure 88.1. Some examples (Sagesser and Deinzer, 1996; Aherne and O'Brien, 2002; Mertens-Talcott *et al.*, 2003; Manach *et al.*, 2004; Chen *et al.*, 2005; Lee *et al.*, 2005) (Table 88.1) of quercetin glycosides are quercetin-3-rhamnoglucoside (or rutin) in black tea, guercetin-4′-glucoside and guercetin-3, 4′-glucoside in onion, quercetin galactoside in apples, and quercetin arabinosides in berries. The glycoside moieties may facilitate absorption in human intestine.

Anti-carcinogenesis of quercetin by antioxidative/detoxification effects

Oxidative stress can cause cellular damage at protein, lipid and DNA levels. Accumulative damages of those cellular components may be linked to cancer development. It has been proposed that certain reactive oxygen species may be related to prostate cancer development in that male hormones/androgens are shown to be an important agent to produce such oxygen species in the prostate (Ripple *et al.*, 1997, 1999). Note, androgens via the nuclear androgen receptor (AR) are absolutely required for development and maintenance of normal human and rodent prostates. In addition, oxidative species such as reactive oxygen, nitrogen and lipid species as well as other environmental reactive agents derived from consumption of red meat, fats/oils and exposures to pollutants may be more or less

contributed to prostate cancer development (Hsieh and Albertsen, 2003; Kamangar *et al.*, 2006; Colli and Colli, 2006; Klein, 2006; Moon *et al.*, 2006; Rodriguez *et al.*, 2006). Quercetin has been shown as one of the strong anti-oxidants *in vitro* (Morel *et al.*, 1993; Skibola and Smith, 2000). Potentially it might act as a scavenger to remove some reactive oxygen species generated by androgens or other sources. However, whether quercetin could actually exert its antioxidative activities effectively in the body remains elusive.

Quercetin could act at least two ways to ward off reactive oxidants (Nagata *et al.*, 1999; Aherne and O'Brien, 2002; Mertens-Talcott *et al.*, 2003; Erlund, 2004; Manach *et al.*, 2004; Moon *et al.*, 2006). In principle, the phenolic group of polyphenols including quercetin can accept an electron from or be oxidized by radicals to form a more stable, less reactive phenoxyl radical, and thus disrupting further chain oxidative reactions. Secondly quercetin can be an effective phase II detoxifying enzyme inducer or a direct phase I enzyme inhibitor to indirectly reduce formation of carcinogens activated by endogenous metabolism pathways (Nagata *et al.*, 1999; Aherne and O'Brien, 2002; Mertens-Talcott *et al.*, 2003; Erlund, 2004; Manach *et al.*, 2004; Moon *et al.*, 2006). For example, it was reported that quercetin can inhibit human cytochrome CYP1 enzymes (a phase I enzyme) at 50% inhibition concentration of 4.1 uM in a prostate cancer cell (Chaudhary and Willett, 2006). The CYP1B1 enzyme can metabolize polycyclic aromatic hydrocarbons to active carcinogenic metabolites (Chaudhary and Willett, 2006). Sun *et al.* (1998) found that several flavonoids including quercetin can induce activity of a phase II enzyme, UDP-glucuronyltransferase (UGT), in a human prostate cancer cell line, whose enzyme activity can enhance the removal of androgens like testosterone from body, implying that the flavonoids tested may be used to modulate hormone metabolism and therefore for prevention or treatment of prostate cancer. Table 88.4 lists some examples of phase I and II enzymes that can be affected by quercetin in both non-prostate and prostate tissues or *in vitro* cell culture conditions. It is assumed that the detoxifying effects of those phase I and II enzymes outside of the prostate (e.g. liver) may benefit in protecting from prostate cancer formation. However, whether all of these enzymes are expressed and can be affected by quercetin in the prostate remains to be further studied.

Anti-androgen receptor effects

As mentioned above, androgens are not only important to the normal prostate but also implicated in the development and progression of prostate cancer (Scher *et al.*, 2004; Dehm and Tindall, 2005). The androgen action is mediated by a specific nuclear receptor protein or AR. In fact, the AR is a member of nuclear receptor superfamily of transcription factors (Scher *et al.*, 2004; Dehm and Tindall,

Table 88.4 Known effects of quercetin on expression or activities of phase I and II enzymes

Enzyme	effect	References
Phase I		
CYP1A1	Increases mRNA expression	Ciolino *et al.* (1999)
CYP1A2	Inhibitor	Tsyrlov *et al.* (1994)
CYP3A4	Inhibitor	Obach (2000)
Phase II		
UGT	Increases enzyme activity	van der Logt *et al.* (2003)
UGT1A1	Increases enzyme activity	Williams *et al.* (2002)
GSTP1-1	Inhibitor	van Zanden *et al.* (2003)
QR	Increases enzyme activity	Uda *et al.* (1997); Valerio *et al.* (2001)
SULT1A1	Inhibitor	Mesia-Vela and Kauffman (2003)
SULT1E1	Inhibitor	Schrag *et al.* (2004)

Notes: Related to carcinogenesis, although phase I enzymes can activate procarcinogens and phase II enzymes are used to detoxify potential carcinogens, either one can sometimes also do opposite actions, depending on substrates and varying conditions.
CYP, cytochrome P450 enzymes; UGT, uridine diphosphate-glucuronyltransferase; GSP, glutathione S-transferase; QR, quinone reductase; SULT, sulfotransferase.

2005), and is activated by androgens to regulate gene expression and proliferation of prostatic cells. Upon androgen binding, the AR will be translocated from cytoplasm to nucleus and then binds a specific DNA sequence, termed androgen responsive element or ARE, in the promoter area of androgen target/regulated genes. Activated AR may undergo some chemical modification such as phosphorylation and acetylation and recruit other non-DNA-binding proteins named co-activators to enhance gene transcription. Androgen deprivation or ablation can cause prostate epithelial apoptosis, therefore prostate regression, and is the basis for androgen or hormonal therapy of prostate cancer (Scher *et al.*, 2004; Dehm and Tindall, 2005). As aforementioned, androgens via the receptor may enhance oxidation stress which would increase genomic mutation rates. Properly modulating androgen actions in the prostate might be an effective means to prevent prostate cancer development and progression.

Like several other dietary factors (Ren *et al.*, 2000; Bektic *et al.*, 2004; Cho *et al.*, 2004; Dong *et al.*, 2004; Gao *et al.*, 2004; Lee *et al.*, 2004; Jiang *et al.*, 2006; Morris *et al.*, 2006), quercetin has been shown to exhibit activity of inhibiting the expression and function of the AR in prostate cancer cells (Xing *et al.*, 2001; Morris *et al.*, 2006). Further, the functional repression of the AR by quercetin is due to prolonged overexpression of c-Jun which has been shown to be able to physically interact with the AR (Yuan *et al.*, 2004, 2005). c-Jun is a transcription factor but acts as a co-repressor of the AR in quercetin-treated

prostate cancer cells. Further studies (Palapattu *et al.*, 2005) showed that quercetin can reduce phosphorylation of the AR and increase interaction of AR with Sp1, the latter is another transcription factor, but in this case acting as a co-activator to enhance AR's function. The repression effect of quercetin could be due to the combination of hypo-phosphorylation and increased interactions of AR with c-Jun and Sp1 (published data). More in-depth studies will be needed to understand how quercetin could facilitate the formation of the above protein complex to inhibit AR action in prostate cancer cells.

Anti-inflammatory effects

This section will only focus on the relevance in prostate cancer. The recent realization of association of inflammatory lesions with prostatic cancerous tissues suggests the potential involvement of local inflammation in prostate carcinogenesis (Ho *et al.*, 2004; Hodge *et al.*, 2005; Mauri *et al.*, 2005; Palapattu *et al.*, 2005). It has been shown that quercetin has anti-inflammation effects (Di Carlo *et al.*, 1999). Whether this effect has any influence on repressing prostate carcinogenesis is not clear at present time. Preliminary studies seemed to indicate the possibility, because inflammation-related factors can be produced in infiltrated immune cells as well as prostate cells (Shariat *et al.*, 2001; Lee *et al.*, 2003; Sivashanmugam *et al.*, 2004; Hodge *et al.*, 2005; Mauri *et al.*, 2005; Zhu *et al.*, 2006). These factors may modify endocrine response and enhance prostate cell proliferation. For instance, pro-inflammatory cytokine factors including interleukin 6 (IL-6) may be overexpressed in pre-cancerous and cancerous areas of the prostate and stimulate prostate cell proliferation and increase immune cell filtration. Interestingly, IL-6 and other cytokines may activate AR without the presence of or at very low concentrations of androgens. This could provide an additional way to enhance AR functions (e.g. cell proliferation and oxidative stress). Preliminary data shown in Figures 88.2 and 88.3 indicate that quercetin may be able to inhibit IL-6 mediated activities (e.g. AR activation without androgens) in prostate cancer cells. Moreover, it has been shown that quercetin can inhibit NO production in prostate cancer cells. NO may be related to induction of inflammation (Kampa *et al.*, 2000). Interestingly, quercetin has been suggested to treat prostatitis, an inflammatory form of the prostate (Shoskes and Manickam, 2003).

Effects on cell proliferation, cell cycle and apoptosis

A major hallmark of cancer cells is their deregulated cell cycle compared to a stringent cell cycle control of their normal counterparts (Hermeking and Benzinger, 2006). Basically, cancer cells will allow themselves to proliferate continuously if nutrients and space are not restricted, which is mainly because of aberrant expression of extracellular factors
Figure 88.2 Quercetin inhibits activation of STAT3 stimulated by interleukin 6 (IL-6) in human prostate cancer cell line, LNCaP. LNCaP cells were treated with or without IL-6 (50 ng/ml) ± quercetin (50 uM) for 15 min or 2.5 h. Thirty microgram proteins from cell extracts prepared from the above cells were used for immunoblotting analysis for phosphorylated STAT3 and total STAT3 with specific antibodies. Phosphorylated STAT3 represents the activation of STAT3 by IL-6. This study shows that IL6 activates STAT3 by inducing phosphorylation of STAT3 but not changing the levels of STAT3 after short incubation of cells with IL-6. Quercetin can inhibit phosphorylation of STAT3. Tubulin was used as internal controls for equal loading.
Figure 88.3 Quercetin inhibits IL-6 induced AR activation of luciferase reporter expression via the prostate-specific antigen (PSA) promoter in a transfection assay. IL-6 activates STAT3 which in turn interacts and activates the AR. The expression of PSA is mediated via AR activated by androgens or IL6. In this figure, LNCaP cells that express AR were used for transfection with a PSA promoter-luciferase plasmid construct (1 μg) and then treated with (+) or without (−) IL6 (50 ng/ml) ± quercetin (50 uM) overnight. Cell extracts were prepared for luciferase and protein assays. Luciferase activities were normalized with protein contents and used to present AR function activated by IL-6 which can be inhibited by quercetin.

(e.g. growth factors) and/or intracellular factors (e.g. cyclins, cyclin-dependent kinases and kinase inhibitors, etc.) related to regulation of the cell cycle in cancer cells or tissues.

Quercetin may inhibit cancer cell proliferation by stalling cell cycle progression at particular stages of the cell cycle,

which may result in cell death or apoptosis, depending on cell types or concentrations of quercetin used. For instance, quercetin at 100 uM can induce G0/G1 phase arrest of bladder cancer cell and subsequently apoptosis (Ma *et al.*, 2006). Interestingly, this study showed that quercetin may possess anti-DNA methyltransferase activity, and, therefore, re-activate the expression of tumor suppressors. However, quercetin can cause G2/M phase arrest in human PC-3 prostate cancer cells followed by apoptosis (Vijayababu *et al.*, 2005). The induced apoptosis could be related to inhibition of multiple intracellular signaling pathways involving tyrosine kinase activity (Wang *et al.*, 2003). Also, substantial decrease in the expression of cell cycle related proteins such as Cdc2/Cdk-1, cyclin B1 and phosphorylated pRb and increase in p21 were observed (Vijayababu *et al.*, 2005). Quercetin may inhibit PC-3 cell proliferation by reducing insulin-like growth factors (IGFs) and IGF binding protein-3 (IGFBP-3) secretion (Vijayababu *et al.*, 2006a) or reducing the expression of ErbB-2 and ErbB-3 to prevent proliferative stimulation by transforming growth factor alpha and epidermal growth factor (Huynh *et al.*, 2003). It was reported (Vijayababu *et al.*, 2006b) that quercetin can downregulate matrix metalloproteinases 2 and 9 proteins expression in PC-3 cells, which may reduce cell migration and metastasis ability. In addition, anti-apoptotic proteins like Bcl-2 and Bcl-X-L were significantly decreased and pro-apoptotic proteins Bax and caspase-3 were increased. Quercetin induced G2/M phase arrest can be seen in another prostate cancer cell line, LNCaP (Shenouda *et al.*, 2004). Another study (Knowles *et al.*, 2000) reported that quercetin at 25 uM blocks PC-3 cells at G2/M transition, but at 100 uM it causes an increase in S-phase, whereas neither concentration induces apoptosis. The discrepancy between this latter study and the above study regarding the detection of apoptosis in the same cell line is not clear.

Furthermore, it was suggested (Brusselmans *et al.*, 2005) that in both prostate and breast cancer cells, fatty acid synthesis by fatty acid synthase (FAS) inhibited by flavonoids including quercetin may play a critical role of inducing apoptosis. This notion seems to be supported by reversal of apoptosis by addition of palmitate, the end product of FAS.

Synergistic effects with other chemical or physical factors

Obviously when consuming quercetin-containing foods and/or beverages, inevitably many phytochemicals possessing anti-cancer activities would be partaken with quercetin. However, there are only few studies showing some phytochemicals can synergistically enhance anti-carcinogenesis activities of quercetin. For example, ellagic acid, a type of flavonoids, can synergistically increase anti-proliferation ability of quercetin at low concentrations in human leukemia cells (Mertens-Talcott *et al.*, 2005). This study indicated that ellagic acid can enhance expression of tumor suppressors like p21waf1/cip1 and p53 as well as signaling molecules, MAP kinases induced by quercetin. The same group of the authors (Mertens-Talcott and Percival, 2005) demonstrated that when quercetin and another flavonoid, resveratrol, work together, they can induce transient cell cycle arrest and largely increase apoptosis of human leukemia cells. Other study (Chen *et al.*, 2005) showed that quercetin can act synergistically with vitamins C and E to block oxidation of low-density lipoprotein.

It has been realized that combination chemotherapy is increasingly practiced for more effective treatment of advanced prostate cancers. Synergistic effects of a combining use of quercetin and other agents have been studied to explore therapeutic potentials in treating prostate cancer. An early study (Li *et al.*, 1999) showed that quercetin and a synthetic drug called ribavirin in combination can produce a synergistic anti-proliferative action against myeloma 8,226 cell line and ovarian carcinoma OVCAR-5 cell line due to the synergistic reduction of an oncogenic signal transduction (i.e. IP3 concentration). Another intriguing observation is that Fujita *et al.* (2004) reported that a combination of quercetin and heat treatment can increase cytotoxic effect in a lymphoid cell line. In xenograft mouse model, Asea *et al.* (2001) demonstrated that quercetin can dramatically enhance the effects of hyperthermia on inhibiting tumor growth of two human prostate cancer cell lines, PC-3 and DU145. Another *in vitro* study (Nakanoma *et al.*, 2001) using human prostate cancer lines JCA-1 and LNCaP showed that quercetin can reduce heat shock protein 70 (HSP70) induced by heat shock treatment and increase cell number in G1 phase. The authors concluded that quercetin can enhance heat shock-induced apoptosis in both JCA-I and LNcap cells. Further study (Jones *et al.*, 2004) concluded that indeed HSP70 plays a role in protection of prostate tumor cells from apoptosis because depletion of HSP70 by using anti-sense oligonucleotide approach can induce cell apoptosis without any additional treatments. This probably explains why quercetin treatment can synergistically enhance apoptosis of human prostate cancer cells treating with heat shock *in vitro* or a hyperthermia procedure to xenograft models.

Furthermore, a human prostate cancer CWR22-xenograft model was used to determine therapeutic efficacy of tamoxifen (a synthetic non-steroidal antiestrogen), quercetin or a combined tamoxifen and quercetin for 28 days (Ma *et al.*, 2004a). The results showed either tamoxifen or quercetin alone only exhibited a moderate anti-tumor growth effect, whereas the combined tamoxifen and quercetin showed synergistic reduction of tumor weight and volume. The authors showed that angiogenesis-related molecular events including the vascular endothelial growth factor (VEGF) and microvessel density in tumor areas are largely reduced, suggesting quercetin may potentiate the

tamoxifen effects on repressing tumor angiogenesis. Owing to low potency of quercetin for treating prostate cancer, Paliwal *et al.* (2005) showed if prostate and skin cancer cells pre-treated with low-frequency ultrasound (20 kHz, 2 W cm^{-2}, 60 s) can exhibit strong cytotoxicity in the presence of quercetin. Interestingly the combined effects only affect cancer cells but not their normal counterparts. However, at present time, there is no clear explanation of how ultrasound selectively sensitizes cancer cells to amplify cytotoxic effects of quercetin.

Recently a 5 reductase inhibitor finastride, which can reduce androgen concentrations in the prostate, has been shown to be possibly used in humans for preventing prostate cancer (Zeliadt *et al.*, 2005). In animal model, male rats received finasteride showed lower serum androgen and prostate weight, whereas in quercetin treated male rats, serum androgen levels were increased and prostate weight was also slightly increased (Ma *et al.*, 2004b). However, co-administration of quercetin and finasteride reduced prostate weight much higher than finasteride alone. It was shown that quercetin enhances finasteride to cause a wide range of changes in cell cycle regulatory proteins including lower levels of cyclin D1, CDK-4, cdc-2, and phospho-cdc-2 at tyrosine 15, phospho-MEK1/2, phospho-MAP kinase, phospho-pRb and higher levels of tumor suppressors p53, and p15, p21 and p27 when compared to non-treated prostate. The authors concluded that quercetin synergizes with finasteride to reduce the wet prostate weight through a cell cycle-related pathway. This study seems to warrant future investigations to test if quercetin may be used in combination with finasteride for effective prevention or even treatment of prostate cancer.

Quercetin in human or animal studies

Results from numerous *in vitro* studies strongly suggest quercetin exerts anti-cancer activities. Animal model data seem to support the notion that quercetin possesses anti-carcinogenesis activities in some studies but are not confirmed by others. A recent study (Volate *et al.*, 2005) showed that quercetin (being the most potent one among the tested) and other flavonoids can reduce formation of ACF in an AOM-induced rat colon cancer model. However, an earlier study (Femia *et al.*, 2003) using onion or tomatoes fortified with quercetin glycosides did not show any obvious anti-carcinogenesis effects. Another earlier study (Mahmoud *et al.*, 2000) used C57BL/6J-Min/+(Min/+) mice bearing a germline mutation in the Apc gene and capable of spontaneously developing numerous intestinal adenomas by 15 weeks of age to investigate anti-tumor efficacy of quercetin. This study also failed to show anti-cancer effect of quercetin. On the other hand, Verma *et al.* (1988) were able to demonstrate that quercetin can inhibit both the incidence and the number of palpable rat mammary tumors in both 7,12-dimethylbenz(a)anthracene (DMBA)- and *N*-nitrosomethylurea-induced mammary cancer in female Sprague-Dawley rats. Moreover, Jin *et al.* (2006) in a very recent report showed that quercetin can effectively repress formation of lung cancer induced by benzo[a]pyrene in mice. Yuan *et al.* (2006) reported that liposomal quercetin can effectively inhibit growth of several types of tumor in mouse models. Asea *et al.* (2001) showed that quercetin can significantly inhibit the growth of human prostate cancer cells in athymic mice.

Similar to animal models, human studies of quercetin effects on cancer development are also relatively scarce and results are not necessarily consistent. Recently Neuhouser (2004) comprehensively reviewed data from 4 cohort studies and 6 case-control studies focusing on dietary flavonoids and cancer risk. The author concluded that the most consistent results from those studies was that high intake of dietary flavonoids especially quercetin may reduce lung cancer risk. Some of the studies described in this report also found no association of quercetin and the risk of prostate cancer. In an average of 6.1 year follow-up of the alpha-tocopherol, beta-carotene cancer prevention (ATBC) cohort study of 27,100 Finnish male smokers, intake of flavonols and flavones was reported (Hirvonen *et al.*, 2001) to be inversely associated with the risk of lung cancer but not with other cancers including prostate cancer. Another Finnish study (Knekt *et al.*, 2002) investigating flavonoid intake and the risk of chronic diseases of 10,054 men and women showed that men with higher quercetin intakes has a lower lung cancer risk. These above studies seem to confirm the earlier study that high intakes of quercetin-containing foods might lower the risk of lung cancer. However, Spanish studies (Garcia-Closas *et al.*, 1998; Garcia-Closas *et al.*, 1999) showed that quercetin does not reduce lung cancer risk in women but does have a trend to reduce gastric cancer risk. A recent study (Adebamowo *et al.*, 2005) reported that no overall association between intake of flavonols including quercetin and risk of breast cancer is found. Interestingly, a case-control study (McCann *et al.*, 2005) of diet and prostate cancer in Western New York involving 433 men with primary, histologically confirmed prostate cancer and 538 population-based controls, frequency matched to cases on age and county of residence was conducted. When compared with men in the lowest quartile of intake, reduced risks were observed for men in the highest quartile of intake of quercetin as well as several other phytochemicals studied.

Clearly the above studies are not sufficient to conclude whether quercetin can effectively reduce prostate cancer risk. Incorporating the measurements of bioavailable quercetin in the study subjects into designs of the future epidemiologic studies may be helpful in the evaluation (Lambert *et al.*, 2005). Intervention study could also be useful to determine the efficacy of quercetin in prostate cancer prevention.

Concluding Remarks

Non-alcoholic portion of beers has been shown to have anti-cancer activities on human cancer cells in culture vessels and chemical-induced tumor in laboratory animal models. A human survey study seemed to suggest that drinking beer and some wines may have trends to reduce prostate cancer risk; of course, more studies will be required to verify that in the near future. Quercetin is a major antioxidant polyphenolic molecule found in many vegetables and fruits as well as in beers and red wines. It has been shown that quercetin possesses anti-prostate cancer cells activities for example, proliferation inhibition, apoptosis, anti-androgen receptor and inhibiting other growth regulatory related cellular factors in prostate cancer cell culture and/or animal systems. However, whether quercetin can really reduce human prostate cancer risk remains to be rigorously studied.

Beer and Prevention of Heterocyclic Amine-Induced DNA Adducts and O^6-methylguanine

Sakae Arimoto-Kobayashi Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama University, Okayama, Japan

Abstract

Non-volatile dissolved materials in beer amount to as much as about 5% (w/w) on freeze-drying of beer samples. These dissolved components should be taken into account for any study of the biological effects of beer. We have described here inhibitory effects of beer on the formation of O^6-methylguanine (O^6-meG) by N-methyl-N'-nitro-N-nitrosoguanidine (MNNG) in the DNA of Salmonella YG7108 when beer was added to bacteria in the presence of MNNG. We have also evaluated the *in vivo* effects of beer components on the formation of DNA adducts by Trp-P-2, MeIQx and PhIP under conditions reflecting human dietary habits. The protective effects were found in liver and lung, the target organ for MeIQx tumorigenesis in mice, with a drinking solution containing beer components and also by adding beer components to the diet to simulate intake of food additives. We also investigated the inhibitory effects of a solution of beer components on DNA damage in mice liver with single and continuous administration of Trp-P-2. Furthermore, we evaluated the *in vivo* protective effect of beer samples in relation to PhIP-induced DNA adduct formation in the colon (the target organ associated with PhIP tumorigenesis) and other important organs (liver, lung and kidney) of mice fed with a beer solution or by the addition of beer components to the diet.

List of Abbreviations

CMBA	2-Chloro-4-methylthiobutanoic acid
EROD	7-Ethylresorufin O-deethylase
MeIQx	2-Amino-3,8-dimethylimidazo[4,5-f]quinoxaline
MROD	7-Methoxyresorufin O-demethylase
MNNG	N-methyl-N'-nitro-N-nitrosoguanidine
O^6-meG	O^6-methylguanine
PhIP	2-Amino-1-methyl-6-phenylimidazo[4,5-b]pyridine
RAL	relative adduct labeling
Trp-P-2	3-Amino-1-methyl-5H-pyrido[4,3-b]indole
Trp-P-2(NHOH)	3-Hydroxyamino-1-methyl-5H-pyrido[4,3-b]indole

Introduction

Antimutagenic and anticarcinogenic effects of dietary components are being studied extensively (IARC, 1996; Ohigashi *et al.*, 1997; World Cancer Research Fund, 1997). Many epidemiological studies have demonstrated reduced mortality from coronary heart diseases among moderate alcohol consumers in comparison to abstainers (Rimm *et al.*, 1991). On the other hand, there is evidence that alcohol itself increases the risk of mouth, esophageal and primary liver cancers (World Cancer Research Fund, 1997). There are conflicting reports concerning the relationship between beer consumption and the risk of cancer. For example, Riboli *et al.* (1991) did not find an association between beer consumption and colon cancer, whereas Kato *et al.* (1990) have shown that beer drinkers have an increased risk to colorectal cancer. Swanson *et al.* (1993) suggested an inverse association between moderate beer consumption and endometrial cancer. However, Potter *et al.* (1992) suggested a relationship between beer consumption and lung cancer. Non-volatile dissolved materials in beer amount to as much as about 5% (w/w) on freeze-drying of beer samples, as shown in our previous report (Arimoto-Kobayashi *et al.*, 1999). Therefore, these dissolved components should be taken into account for any study of the biological effects of beer.

The carcinogenicity and anticarcinogenicity of dietary components is currently receiving a great deal of attention (Dashwood, 2002; Knasmuller, 2002). Heterocyclic amines, including 2-amino-3,8-dimethylimidazo[4,5-f]quinoxaline (MeIQx), 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP) and 3-amino-1-methyl-5H-pyrido[4,3-b]indole (Trp-P-2), which have been identified as potent mutagens and carcinogens in rodents, are produced in foods during the

process of cooking (Felton *et al.*, 2000; Sugimura, 2000). Since humans are frequently exposed to cooked-food carcinogens such as heterocyclic amines, these compounds are suspected of being human carcinogens (Sugimura, 2000). Epidemiological studies have established an apparent association between the consumption of well-cooked red meat and certain types of cancer. Ohgaki *et al.* (2000) showed that Trp-P-2 at 0.02% in the diet induced a high incidence of hepatocellular tumors in female CDF1 mice, and that mice fed MeIQx at 0.06% in the diet developed liver tumor, lymphoma and leukemia in males and liver and lung tumors in females. Mice fed with PhIP at 0.04% in the diet had a higher incidence of lymphoma and leukemia than control mice, and rats fed with PhIP at 0.00125–0.01% in the diet developed colon and prostate carcinomas in males, while mammary gland carcinomas appeared in females.

We have previously investigated the inhibitory effects of beer on bacterial mutagenicity of preactivated heterocyclic amines (3-hydroxyamino-1-methyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-2(NHOH)) and 2-hydroxyamino-6-methyldipyrido [1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1(NHOH)) (Arimoto-Kobayashi *et al.*, 1999)), 2-chloro-4-methylthiobutanoic acid (CMBA) (Kimura *et al.*, 1999) and *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG) (Yoshikawa *et al.*, 2002). Beer also inhibited the mutagenicity of Trp-P-2, IQ, MeIQx and PhIP in the presence of metabolic activation (Arimoto-Kobayashi *et al.*, 2006). Beer prevented radiation-induced chromosome aberrations in human lymphocytes (Monobe *et al.*, 2003), and genotoxicity of PhIP in V79 cells measured by the comet assay (Edenharder *et al.*, 2002).

We have also isolated and identified pseudouridine from beer as an antimutagenic substance against MNNG (Yoshikawa *et al.*, 2002), and glycine betaine, a compound present in beer and known to be distributed widely in plants and animals, which inhibits CMBA, the sanma-fish mutagen (Kimura *et al.*, 1999) (Figure 89.1). Pseudouridine and glycine betaine did not inhibit the mutagenicity of heterocyclic amines. There must therefore be another component(s) in beer that is responsible for the antimutagenicity toward heterocyclic amines.

We have described here an investigation of the effects of beer on the formation of O^6-methylguanine (O^6-meG) by MNNG in the DNA of Salmonella YG7108 when beer was added to bacteria in the presence of MNNG. We have also evaluated the *in vivo* effects of beer components on the formation of DNA adducts by Trp-P-2, MeIQx and PhIP under conditions reflecting human dietary habits. The protective effects were studied in liver and lung, the target organ for MeIQx tumorigenesis in mice, with a drinking solution containing beer components and also by adding beer components to the diet to simulate intake of food additives. We also investigated the effects of a solution of beer components on DNA damage in mice liver with single and continuous administration of Trp-P-2. Furthermore,
Figure 89.1 Structures of mutagen and corresponding antimutagenic compounds in beer.

we evaluated the *in vivo* protective effect of beer samples in relation to PhIP-induced DNA adduct formation in the colon (the target organ associated with PhIP tumorigenesis) and other important organs (liver, lung and kidney) of mice fed with a beer solution or by the addition of beer components to the diet.

Materials and Animals

MNNG (CAS 70-25-7), Trp-P-2 (CAS 62450-07-1), MeIQx (77500-04-0) and PhIP (CAS 105650-23-5) were obtained from Wako Chemicals (Osaka, Japan). O^6-meG was obtained from Sigma (St. Louis, MO). The diet for mice (MF powder) was purchased from Oriental Yeast (Tokyo, Japan). *Salmonella typhimurium* TA100 was a gift from Dr. B.N. Ames of the University of California, Berkeley, and strain YG7108 was provided by Dr. Yamada of the National Institute of Public Health, Tokyo (Yamada *et al.*, 1995). CDF1 mice (male, 6-weeks old) and C57BL/6N mice (male, 6-weeks old) were obtained from Charles River Japan (Atsugi, Japan) and housed one or two mice per cage with access to food and water *ad libitum*, unless indicated otherwise.

All experiments were carried out in accordance with the Safety Guidelines of Okayama University and the Japanese
Figure 89.2   Inhibitory effects of beer on the formation of *O*⁶-meG in DNA of *S. typhimurium* YG7108 treated with MNNG. Government Management Law for toxic chemicals (No. 303). Animal experiments were carried out in accordance with the Guidelines for Animal Experiments at Okayama University Advanced Science Research Center, Japanese Government Animal Protection and Management Law (No. 105), and Japanese Government Notification on Feeding and Safekeeping of Animals (No. 6). Statistical analyses were performed using ANOVA analysis and the unpaired Student's t-test with KaleidaGraph (Sydney Software, Reading, PA, USA). Results were considered significant at $p < 0.05$.

Preparation of Beer Samples

Two different samples of beer (beer-A and beer-B) produced in Japan were examined. Beer-A was a stout beer and beer-B was a lager beer, both of which were purchased in local stores in Okayama. Beer samples were freeze-dried to remove ethanol, unless indicated otherwise. The solid obtained was dissolved in a volume of water representing a fifth, a half or an equal volume of the original sample, designated as "beer solution (×5)," "beer solution (×2)" and "beer solution (×1)," respectively. "μL eq." represents the amount of beer equivalent to a corresponding volume of beer.

Effects of Beer on the Formation of *O*⁶-meG in DNA from *S. typhimurium* YG7108 Treated with MNNG

An overnight culture of *S. typhimurium* YG7108 (50 ml) was mixed with MNNG (final concentration, 0.014 mM) and beer (beer-A, 0–50 ml) in 0.07 M Na-phosphate (pH 7).

The beer used was not freeze-dried, but an original sample. Total volume was 350 ml. The concentration of beer in the reaction mixture was 0%, 2.85% (10 ml of beer in 350 ml of mixture) and 14.3% (50 ml of beer in 350 ml of mixture). The possibility of any effects due to ethanol was eliminated by inclusion of ethanol to a fixed concentration (1.1%) in these treatments. The mixture was incubated for 30 min at 37°C with continuous mechanical shaking. The treated bacteria were then collected by centrifugation at 500 rpm for 10 min at 4°C. The genomic DNA of Salmonella was prepared using a previously described method (Wilson, 1997). The DNA obtained was dissolved in 0.1 ml of 0.1 N HCl and heated at 70°C for 30 min. The mixture was then cooled in ice before the addition of ethanol (2 volume). Precipitates were removed from the mixture by centrifugation and the supernatant obtained was concentrated under a reduced pressure. The residue was dissolved in 0.05 ml water and analyzed using high performance liquid chromatography (HPLC) on a Waters system (USA) coupled to a fluorescence detector (Arimoto-Kobayashi *et al.*, 1997). HPLC was performed with an ODS-80Ts column (4.6 × 250 mm; Tosoh, Japan): column temperature 40°C; eluent 0.1 M NH₄OAc (pH 5.0)–methanol (95:5); flow rate 0.8 ml/min; fluorescence (287 nm excitation and 362 nm emission) of *O*⁶-meG and 247 nm absorbance of dG were detected.

As shown in Figure 89.2, the beer sample (beer-A) inhibited *O*⁶-meG formation by MNNG in the DNA of *S. typhimurium* YG7108. The decrease in *O*⁶-meG was dependent on the dose of beer. Beer-A (original, not freeze-dried) showed inhibition of MNNG mutagenicity in the Ames test using *S. typhimurium* TA100 (Figure 89.2). The

concentration of beer in this experiment, 50 ml of beer in 350 ml of the reaction mixture (i.e. 14.3%), corresponds to 0.1 ml of beer in 0.7 ml of the preincubation mixture of the Ames assay described in Figure 89.3, in which the mutagenicity of MNNG was decreased to 16.4%. The decrease in the formation of O^6-meG to 16% by this beer concentration was consistent with the decreased level of mutagenicity.

Beer-A inhibited the MNNG-mediated methylation of guanine residues in the DNA of *S. typhimurium* (Figure 89.2). It is likely that the inhibitory effect of beer upon the mutagenicity of MNNG is a result of this suppression of alkylation of DNA.

Effects of a Beer Solution on Formation of Trp-P-2-DNA Adducts in Mice

Experiment 1 (single administration of Trp-P-2 with gavage, and beer-A components in drink for 4 days)

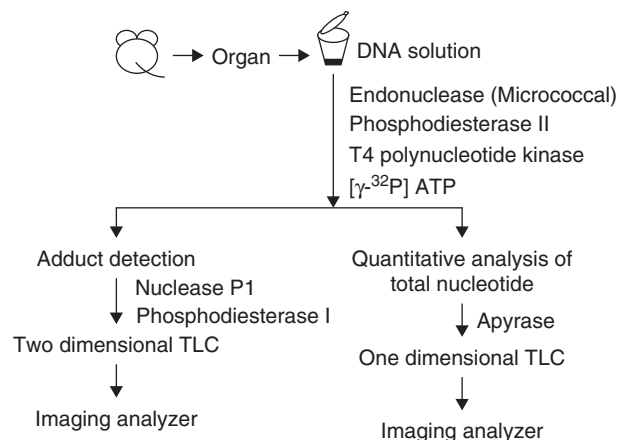
The effects of a beer solution (beer-A) on Trp-P-2-DNA adducts were investigated with CDF_1 mice. Mice were divided into five groups, each composed of three mice kept in a cage. Treatments were started from 3 p.m. of day 1. They were given normal food and a drinking solution consisting of either plain water (group 1), the "beer solution (×2)" (group 2), the "beer solution (×1)" (group 3), or the "beer solution (×2)" (group 4), all of which were provided *ad libitum*. After 72 h, an aqueous solution of Trp-P-2 (30 mg/kg b.w.) was administered orally to each animal of groups 1–3. The volume of the Trp-P-2 solution was about 0.2 ml. One mouse was used as a no-treatment control, fed only a normal diet with plain water, and was given no Trp-P-2. After an additional 24 h of feeding with the beer solutions, the animals were sacrificed and their livers were removed for analysis. DNA was isolated from the liver by phenol extraction and analyzed by the ^{32}P-postlabeling method using the intensification protocol described previously (Sugiyama *et al.*, 1996). Briefly, as detailed in Figure 89.3, the DNA was digested with micrococcal nuclease and spleen phosphodiesterase, and the digest was then labeled with ^{32}P under adduct-intensification conditions (Ochiai *et al.*, 1993) using T4 polynucleotide kinase and [γ-^{32}P]ATP. The labeled mixture was further digested with nuclease P1 and phosphodiesterase I. The digest was subjected to ODS-TLC (thin-layer chromatography), contact-transferred to polyethyleneimine cellulose TLC (Randerath *et al.*, 1984) and the plate was developed four times, as described elsewhere (Sugiyama *et al.*, 1996). The radio activities of adduct spots were analyzed using a Bio-Imaging Analyzer (BAS 2000, Fuji Photo Film, Tokyo) with an exposure time of 2 h. The adduct level was determined with relative adduct labeling (RAL) (Randerath *et al.*, 1985), namely, "RAL in the modified adduct-intensification


Figure 89.3 Brief scheme of the ^{32}P-postlabeling methods.

method" = [(count rate in adduct nucleotides)/(count rate in total nucleotides)] × (IF)−1, where IF (intensification factor) is the value obtained in a Trp-P-2-only experiment, such that IF = [RAL in the modified adduct-intensification method]/[RAL in the modified standard method]. The detection limit was 1.0 adduct/10^7 nucleotides.

Experiment 2 (single administration of Trp-P-2, and beer-A components in the diet for 4 days)

The effects of beer-A (original, not freeze-dried) and beer-A solution (×5) on Trp-P-2-DNA adducts were also investigated with C57BL/6N mice. Trp-P-2 (30 mg/kg) was given to mice by gastric intubation in a single dose dissolved in sterile water on day 3. For controls, solvent (water) was given to mice not receiving Trp-P-2 by intubation (group 4). A diet mixed with water or a beer sample was given to mice for 3 days. A diet mixed with water and Trp-P-2 was given to mice in group 1, while a diet mixed with beer-A (original, not freeze-dried) and Trp-P-2 was given to mice in group 2. Group-3 mice received a diet mixed with beer-A solution (×5) and Trp-P-2, and mice in group 4 were given a diet mixed with water alone. Mice were sacrificed on day 4.

Experiment 3 (continuous feeding with Trp-P-2 in the diet for 3 days, and beer-A components in a diet paste for 5 days)

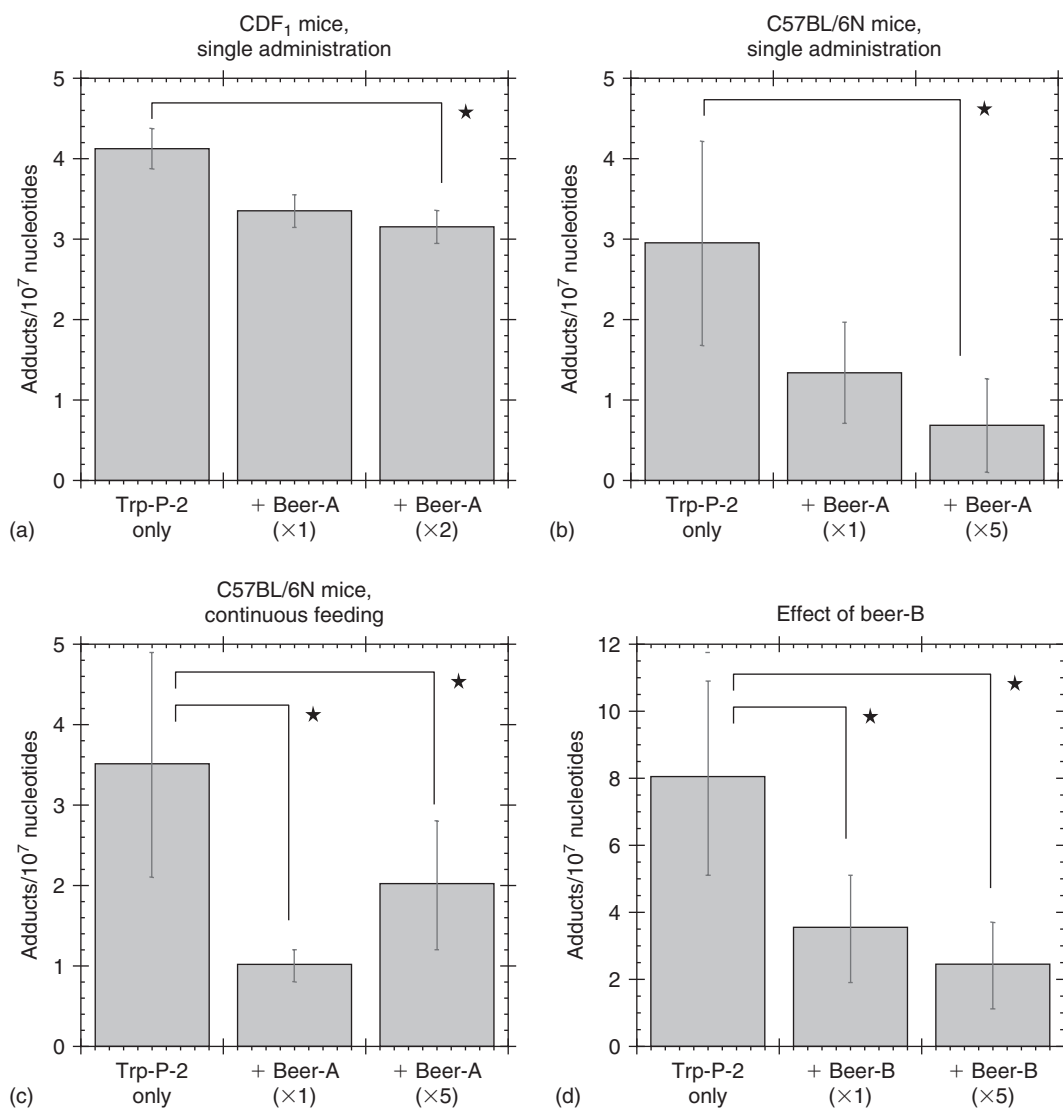
Trp-P-2 and beer solution-A were mixed with an equal weight of the control diet (MF powder, Oriental Yeast, Tokyo, Japan) to form a paste, which was given to C57BL/6N mice for 5 days. The total amount of Trp-P-2 given was 30 mg/kg. Diets mixed with either water (groups 1 and 4), beer-A solution (×1) (group 2) or beer-A solution (×5) (group 3) were given to mice for 2 days. Diets mixed with Trp-P-2 (group 1), Trp-P-2 and beer-A solution


Figure 89.4 Inhibitory effects of a beer solution on DNA adduct formation in mice fed Trp-P-2. Formation of Trp-P-2-DNA adduct in the liver in mice treated with (a) single administration of Trp-P-2 with gavage, and beer-A components in drink for 4 days, (b) single administration of Trp-P-2, and beer-A components in the diet for 4 days, (c) continuous feeding with Trp-P-2 in the diet for 3 days, and beer-A components in a diet paste for 5 days, (d) continuous feeding with Trp-P-2 in the diet for 3 days, and beer-B components in a diet paste for 5 days (Arimoto-Kobayashi *et al.*, 1999, 2005). *Significantly different at p < 0.05.

(×1) (group 2), Trp-p-2 and beer-A solution (×5) (group 3) or water only (group 4) were given for 5 days. Mice were sacrificed on day 8.

Experiment 4 (continuous feeding with Trp-P-2 in the diet for 3 days, and beer-B components in a diet paste for 5 days)

Beer-B solution was given to C57BL/6N mice. The concentration of Trp-P-2 in the diet was 0.005%. A diet mixed with beer-B solution was given for 2 days, and then a diet containing Trp-P-2 with beer solution was given for 3 days. Mice were sacrificed on day 5. Other procedures were similar to those of Experiment 3. Providing 0.005% of Trp-P-2

in the diet for 3 days was equivalent to the administration of a total of 25 mg/kg body weight.

As shown in Figure 89.4a, adduct formation in the liver DNA of CDF1 mice given Trp-P-2 on day 3 decreased significantly by the continuous administration of twice the concentrated beer (freeze-dried beer-A) constituents for 4 days, compared with that of mice given Trp-P-2 without beer (Experiment 1, Figure 89.4a). No adducts were observed in the tested organs of mice fed on a control diet (group 4; data not shown).

Reproducibility of the protective effect with another mouse strain (C57BL/6N) was investigated, and results revealed that adduct formation in the liver DNA of mice given Trp-P-2 with a single administration on day 3 also

decreased significantly by the continuous administration of beer-A solution (×5) in the diet for 4 days, compared with that of mice given Trp-P-2 without a beer solution (Experiment 2, Figure 89.4b). Formation of DNA adducts in liver DNA in C57BL mice receiving administration of Trp-P-2 at 0.005% in the diet was observed with an amount of Trp-P-2 that was lower than that recorded for carcinogenicity in CDF$_1$ mice. Adducts of Trp-P-2 produced in the liver DNA of mice that were continuously given Trp-P-2 in the diet for 5 days decreased following the addition of beer-A solution (×1) and beer-A solution (×5) in the form of a diet paste (Experiment 3, Figure 89.4c). Reproducibility of the protective effect of beer constituents in another kind of beer sample, the lager type, was investigated with beer-B solution (Experiments 4, Figure 89.4d). Adduct formation in liver DNA of mice fed Trp-P-2 for 5 days decreased significantly with addition of beer-B solution (×1) and beer-B solution (×5) in the diet, compared to that of mice fed with Trp-P-2-only.

Trp-P-2 in the diet induced a high incidence of hepatocellular tumors in female CDF$_1$ mice. Previously, we reported that beer samples inhibited the mutagenicity of both Trp-P-2 and Trp-P-2(NHOH) in the Ames test. We also observed in an earlier study that a direct-acting mutagenicity emerges in the serum of mice that have been administered Trp-P-2 intravenously, and that this direct-acting mutagenicity persists for a period of 0.5–6h after the administration (Aji *et al.*, 1994). Trp-P-2(NHOH) is known to be a primary metabolite of Trp-P-2 (Ishii *et al.*, 1980). Since Trp-P-2 itself is an indirect mutagen, the direct activity detected in the serum has been ascribed to the presence of Trp-P-2(NHOH), the metabolically activated form of Trp-P-2. The present study demonstrated that the administration of freeze-dried beer in drinking water and in the diet inhibited Trp-P-2-DNA adduct formation in the liver. The antimutagenic and Trp-P-2(NHOH)-degrading component(s) of beer may work after being absorbed through the digestive tract.

The genotoxicity of Trp-P-2 in mice also depends on the induction of phase I cytochrome P450 (CYP) enzymes and phase II enzymes. We have already demonstrated that Trp-P-2(NHOH) production from Trp-P-2 through *in vitro* metabolic activation was inhibited by the presence of beer components (Arimoto-Kobayashi *et al.*, 2005). The suppression of the metabolic conversion from Trp-P-2 to Trp-P-2(NHOH) indicated that the antimutagenic effects of beer components on Trp-P-2 were linked with the inhibition of metabolic activation. Therefore, the results suggest that steps involved in the activation of Trp-P-2 and binding of Trp-P-2(NHOH) to DNA are the targets of the antimutagenicity of beer (Figure 89.5).

DNA adduct formation in the livers of mice receiving a single administration (*p.o.*) or continuous supply of Trp-P-2 was significantly inhibited by the addition of beer-A solution to the diet (Experiments 2 and 3, Figure 89.4b and c).
Figure 89.5   Scheme of the antigenotoxic mechanisms of beer components on Trp-P-2-DNA adduct formation.

It is interesting that beer inhibited DNA adduct formation in the target organ of Trp-P-2 tumorigenesis, the liver. This observation suggests that protective effects can also be anticipated in humans when beer components are consumed on a daily basis with occasional or periodic intake of fried fish and meats. Both stout-type beer (beer-A) and lager-type beer (beer-B) solutions inhibited DNA adduct formation by Trp-P-2 *in vivo* (Experiment 4, Figure 89.4d). The effects of both types of beer components (beer-A and beer-B solutions) were similar in relation to the preventive effects on DNA adduct formation by Trp-P-2. The results suggest that antigenotoxic components might be present in beer.

Effects of a Beer Solution on Formation of MeIQx-DNA Adducts in Mice

Experiment 5 (beer-A components in drink for 5 days, and MeIQx in a diet paste for 3 days)

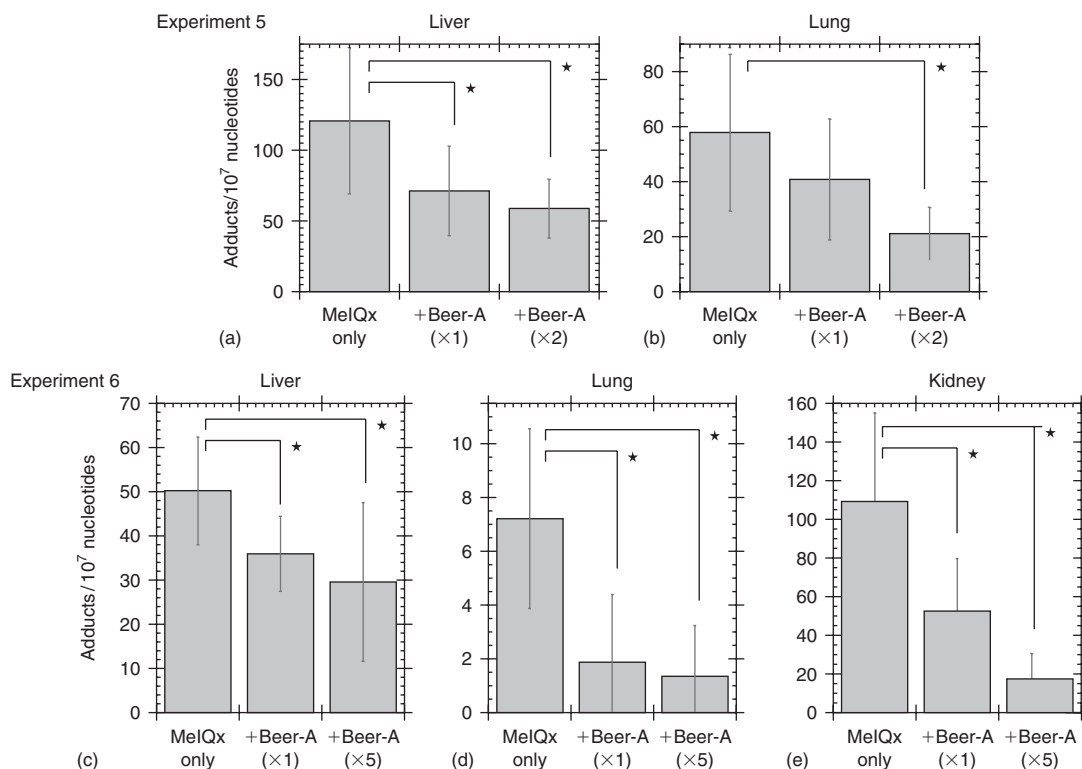
For an investigation of the influence of beer on MeIQx-DNA adducts, beer-A solution was given to C57BL/6N mice as a replacement for drinking water for 5 days, and a diet containing MeIQx (0.005%) was given for the subsequent 3 days. MeIQx was dissolved and mixed with diet powder to form a diet paste. Four groups of mice received the diet paste mixture with either MeIQx (group 1), MeIQx and beer-A solution (×1) in water (group 2), MeIQx and beer-A solution (×2) in water (group 3) or the paste alone as a control (group 4). The calorie content of the diet was adjusted with maltose. Mice were sacrificed on day 6 by cervical dislocation. Tissues were collected, washed with ice-cold KCl (0.15 M), and frozen in liquid nitrogen. Samples were stored at −80°C until use. The amount of heterocyclic amine-DNA adduct in the DNA of treated mouse tissue was determined using the modified adduct-intensification analysis in the ^{32}P-postlabeling method, as described above.


Figure 89.6   Inhibitory effects of a beer solution on DNA adduct formation in mice fed MeIQx. Formation of MeIQx-DNA adduct in (a, c) liver, (b, d) lungs and (e) kidney in mice treated with (a, b) beer-A components in drink for 5 days, and MeIQx in a diet paste for 3 days or (c–e) beer-A components in the diet for 5 days and MeIQx in the diet for 3 days (Arimoto-Kobayashi *et al.*, 2005). *Significantly different at $p < 0.05$.

Experiment 6 (beer-A components in the diet for 5 days and MeIQx in the diet for 3 days)

Beer solution-A and a MeIQx solution (final level of 0.005%) were mixed with an equal weight of powdered diet to form a paste, which was given to C57BL/6N mice. Mice received a control diet mixed with water for 2 days (groups 1 and 4), a diet mixed with beer-A solution (×1) (group 2), or a diet mixed with beer-A solution (×2) (group 3). Then, the mice were given a diet mixed with MeIQx (group 1), beer-A solution (×1) and MeIQx (group 2), beer-A solution (×2) and MeIQx (group 3) or a control diet (group 4), for 3 days. Mice were sacrificed on day 6. Other procedures were similar to those used for Experiment 5.

As shown in Figure 89.6, DNA adducts of MeIQx were formed in the liver, lung and kidney of mice given MeIQx at 0.005% in the diet (Experiments 5 and 6). No adducts were observed in the tested organs of mice fed a control diet (group 4) (Figure 89.7). The addition of beer-A solution to the drinking water significantly decreased the formation of DNA adducts in the liver and lung of mice given MeIQx in the diet, compared with that of mice given MeIQx without a beer solution (Experiment 5). The amounts of DNA

adducts in the liver, lung and kidney of mice given MeIQx in the diet also decreased significantly when beer-A solution (×1) and (×5) were added to the diet (Experiment 6). Typical examples of MeIQx adduct spots on a PEI sheet are shown in Figure 89.7. The intensity of MeIQx adduct spots obtained from the liver of a mouse given MeIQx and beer in the diet was lower than that obtained for a mouse given MeIQx alone (Experiment 6).

The effects of a beer solution in the form of a drinking beverage were investigated because of its relevance to the human situation. The presence of beer-A solution in drinking water decreased the level of DNA adduct formation in the liver and lung of mice fed with MeIQx (0.005%) in the diet (Figure 89.6a and b). The addition of beer-A solution in the diet to mimic intake of food additives also decreased DNA adduct formation in the liver, lung and kidney of mice given MeIQx in the diet (Figure 89.6c–e). Ohgaki *et al.* (2000) showed that mice fed MeIQx at 0.06% in the diet developed liver tumors, lymphomas and leukemia in males, and liver and lung tumors in females. The results of our investigation suggest that beer components both in drinking water and in the diet could suppress DNA adducts of MeIQx in target organs of tumorigenesis (liver and lung) and in a non-target organ (kidney).
Figure 89.7 Inhibitory effects of a beer solution on DNA adduct formation in the liver in mice fed MelQx detected by ^{32}P-postlabeling. Examples of MelQx adduct spots on a PEI sheet. A spot of MelQx-DNA adduct is marked by a circle.

Effects of a Beer Solution on Formation of PhIP-DNA Adducts in Mice

Experiment 7 (beer-A components in drink for 5 days and PhIP in the diet for 3 days)

C57BL/6N mice were housed singly or in pairs in a cage with access to food and water *ad libitum*. The diet was prepared by mixing 3 g of feed with 3 ml of 0.005% PhIP solution or 3 ml of water (for the control diet) to form a diet paste (final weight, 6 g). The calorie content of the diet was adjusted using maltose. Investigations concerning the influence of beer on PhIP-induced DNA adduct formation involved continuously providing beer-A components (beer-A solution) to mice instead of drinking water for 5 days. Diet paste (6 g) carrying 0.005% PhIP was given for three subsequent days at 3 p.m. Four groups of mice received a diet mixed with either PhIP (group 1), PhIP in the diet and a beer-A solution (×1) in water (group 2), PhIP in the diet and a beer-A solution (×2) in water (group 3) or a control diet (group 4). Mice were sacrificed on day 6 by cervical dislocation. Tissues were excised, washed with ice-cold 0.15 M KCl, frozen in liquid nitrogen, and then stored at −80°C until use. The amount of PhIP-DNA adducts in treated mouse tissue was determined using a modified adduct-intensification analysis of the ^{32}P-postlabeling method (Fukutome *et al.*, 1994). Each detection and quantitative analysis of PhIP-DNA adducts was carried out in triplicate and the reproducibility was confirmed.

Experiment 8 (beer-A components in diet for 5 days and PhIP in diet for 3 days)

C57BL/6N mice were fed with a paste formed by mixing beer-A components (beer-A solution) and 0.005% PhIP with an equal weight of the control diet (powder). For 2 days, mice received a control diet mixed with either water (groups 1 and 4), the beer-A solution (×1) (group 2) or the beer-A solution (×5) (group 3). For the subsequent 3 days, mice were given a diet mixed with PhIP (group 1), the beer-A solution (×1) and PhIP (group 1), the beer-A solution (×5) and PhIP (group 3) or a control diet (group 4). Mice were sacrificed on day 6. Subsequent procedures were similar to those outlined for Experiment 7.

As shown in Figures 89.8 and 9, PhIP-induced DNA adducts were formed in the colon, liver, lung and kidney of mice given 0.005% PhIP in the diet. No adducts were observed in the tested organs of mice fed a control diet (group 4; data not shown). The formation of DNA adducts in the colon and lungs of mice given PhIP in the diet decreased significantly with administration of drinking beer-A solution (×2) *ad libitum*, compared with mice given PhIP without beer-A solution (Figure 89.8). Beer-A solution (×1) and (×5) administered in the diet also significantly decreased the amount of DNA adducts in the liver and lung of mice given PhIP in the diet (Figure 89.9).

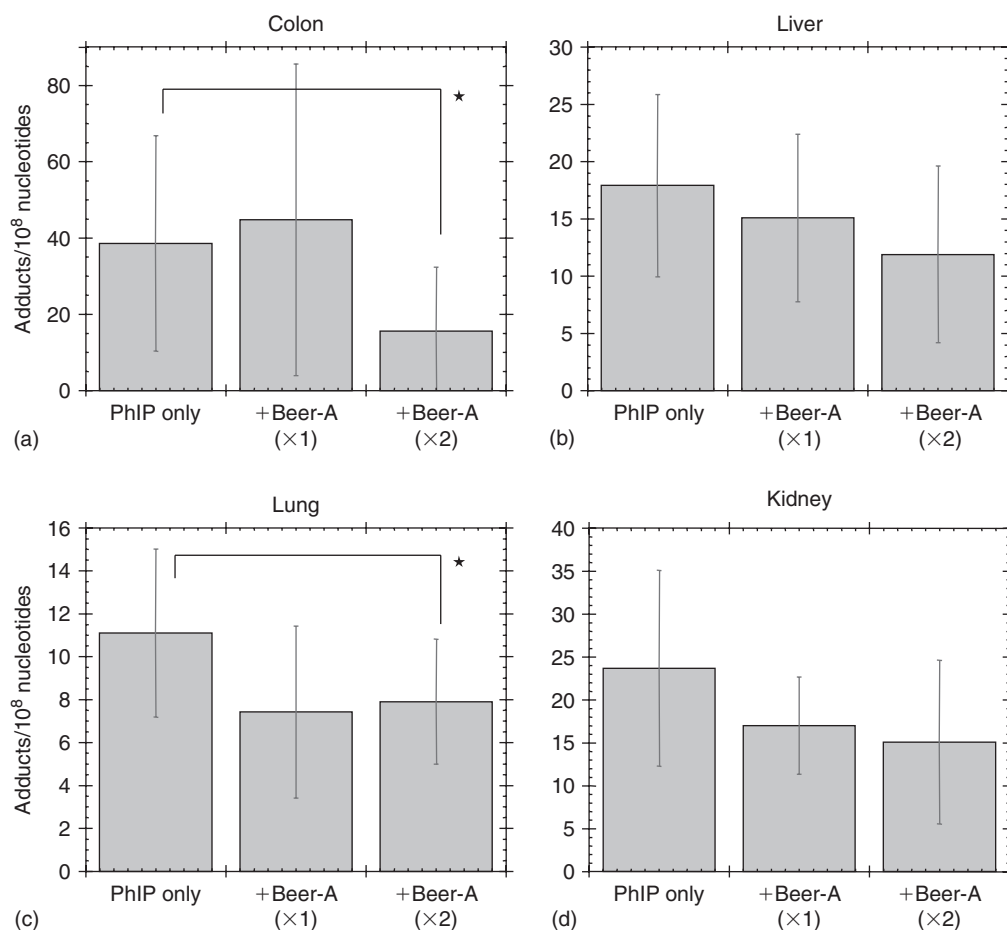
Beer-A solution in drinking water decreased the amount of DNA adducts formed in the colon and lung of mice fed with PhIP (Figure 89.8). This result suggested that beer components in drinking water could suppress the formation of PhIP-DNA adducts in target organs (colon) associated with carcinogenesis in male rats. The addition of beer-A solution in the diet also decreased the amount of DNA adducts formed in the liver and lung of mice given PhIP; however, this effect was not observed for the colon (Figure 89.9). The observed differences in the suppression of DNA adduct formation in the liver and colon between Experiments 7 and 8 could be explained by the differences in feeding method employed in each experiment. It is known that enterohepatic circulation is important for PhIP metabolism. Watkins *et al.* (1991) reported that fecal excretion was the major route of elimination of PhIP, and suggested biliary excretion of PhIP. Buonarati *et al.* (1992) reported that urinary and fecal excretion over 24 h accounted for 16% and 42–56% of the dose, respectively, in mice administered [^{14}C]PhIP (i.p.). This suggested that colon cells had been exposed to PhIP for over 24 h following administration. The diet paste given to mice in Experiment 8 was completely eaten by 9 a.m. the following day. Mice in Experiment 7 were given beer-A solution throughout the experimental period as drinking water, while mice in Experiment 8 received a diet mixed with beer-A solution between 3 p.m. and 9 a.m. the following day, but then received a diet mixture without beer-A solution from 9 a.m. to 3 p.m. The continuous presence of beer components


Figure 89.8 Effects of a beer solution in the drinking water on DNA adduct formation in mice fed PhIP. Formation of PhIP-DNA adduct in (a) colon, (b) liver, (c) lungs and (d) kidney in mice treated with beer-A components in drink for 5 days and PhIP in the diet for 3 days (Arimoto-Kobayashi *et al.*, 2006). * Significantly different at $p < 0.05$.

throughout an experimental period might be more effective in providing protection against PhIP-induced DNA damage in the colon. In contrast, administration of beer with PhIP in the diet might be more effective in suppressing the activation of PhIP by CYP enzymes during the first pass through the liver of mice.

Results obtained from the Ames test showed that certain beer samples could inhibit the mutagenicity of heterocyclic amines (PhIP, MeIQx, IQ and Trp-P-2) that were present in cooked food (Arimoto-Kobayashi *et al.*, 2006). The present study revealed that the amount of DNA adducts in mice fed with MeIQx and PhIP decreased significantly with administration of beer-A solution mixed in drinking water, as well as in the diet (Figures 89.6–9). A common mechanism concerning the inhibitory effect of components in beer-A toward mutagenicity in the Ames test and DNA adduct formation induced by PhIP and MeIQx might be involved. The metabolism of mutagens represents one protection mechanism associated with the use of certain chemopreventive agents (Nelson *et al.*, 2001; Walters *et al.*, 2004). PhIP was metabolically activated by CYP1A1, CYP1A2 and CYP1B1 through a process involving *N*-hydroxylation

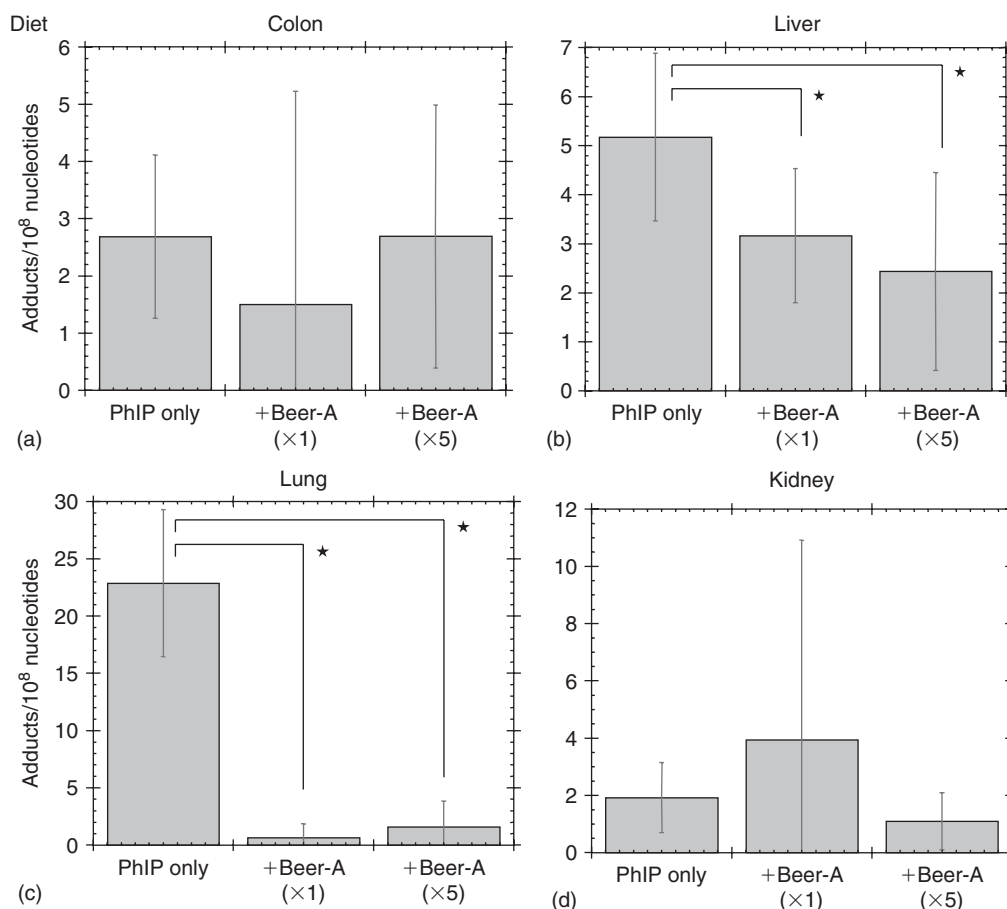
(Boobis *et al.*, 1994; Hammons *et al.*, 1997). The CYP1A2-catalyzed *N*-hydroxylation pathway was shown to account for 70% of the overall elimination of a PhIP dose ingested by human volunteers, and 91% of ingested MeIQx (Boobis *et al.*, 1994). Relative enzyme activity in the presence of beer has been demonstrated (Arimoto-Kobayashi *et al.*, 2006). 7-Methoxyresorufin *O*-demethylase (MROD) activity was significantly inhibited by the presence of beer solutions (beer-A and -B). The amount of beer sample needed for a 50% inhibition (IC_{50}) of demethylase activity was approximately 60 and 200 μl eq./ml for beer-A and -B, respectively. 7-Ethylresorufin *O*-deethylase (EROD) activity was slightly enhanced by the presence of a small amount of beer solution, and was then inhibited. The differences were significant at $p < 0.05$. The amount of beer solution needed for 50% inhibition (IC_{50}) values of deethylase activity were 80 and 200 μl eq./ml for beer-A and beer-B, respectively. Suppression of CYP1A2 and CYP1A1 activities suggested that the antimutagenicity observed with the Ames test was related to the inhibition of metabolic activation. The inhibition of DNA adduct formation might also be linked with the inhibition of metabolic activation.


Figure 89.9 Effects of a beer solution mixed in the diet on DNA adduct formation in mice fed with PhIP. Formation of PhIP-DNA adduct in (a) colon, (b) liver, (c) lungs and (d) kidney in mice treated with beer-A components in diet for 5 days and PhIP in diet for 3 days (Arimoto-Kobayashi *et al.*, 2006). *Significantly different at p < 0.05.

Components from hops could be responsible for the inhibition of CYP enzymes by beer. For example, 8-prenylnaringenin and xanthohumol from hops inhibited the mutagenic activation of CYP1A2-mediated IQ (Miranda *et al.*, 2000). Although an antimutagenic effect against heterocyclic amines remains to be determined, it is assumed that beer components have at least one target associated with the observed antimutagenicity, namely, the inhibition of the activity of CYP enzyme activities for PhIP. The formation of DNA adducts and associated genetic changes play critical roles in processes involved in carcinogenesis (Nagao *et al.*, 2001). The results of the present study have provided candidates that might act as potential modulators of heterocyclic amine-induced carcinogenesis. Due to the wide-spread consumption of beer in human populations, its potential protective effects against mutagens are worthy of further investigation.

Summary Points

- Beer inhibits the formation of O^6-meG by MNNG in the DNA of Salmonella YG7108 when beer was added to bacteria in the presence of MNNG.

- Beer components inhibit the formation of DNA adducts in mice fed with Trp-P-2, MeIQx and PhIP under conditions reflecting human dietary habits, that is, with a drinking solution containing beer components and also by adding beer components to the diet to simulate intake of food additives.
- Inhibitory effects of a solution of beer components were found on DNA damage in mice liver with single and continuous administration of Trp-P-2.
- The *in vivo* protective effect of beer samples were found in relation to PhIP-induced DNA adduct formation in the colon (the target organ associated with PhIP tumorigenesis) and other important organs (liver, lung and kidney) of mice fed with a beer solution or by the addition of beer components to the diet.

Techniques for Assessing Anti-cancer Effects of Beer

Clarissa Gerhäuser German Cancer Research Center, Division Toxicology and Cancer Risk Factors, Workgroup Chemoprevention, Heidelberg, Germany

Abstract

The development of cancer (carcinogenesis) is a multi-stage process which is generally divided into initiation, promotion and progression phases. Carcinogenesis offers a variety of targets for intervention at every stage. These include modulation of xenobiotics metabolism, antioxidant and radical-scavenging activity, anti-mutagenic, anti-inflammatory and anti-hormonal mechanisms, anti-proliferative activities, induction of terminal cell differentiation and apoptosis (programmed cell death) as well as inhibition of angiogenesis. For each of these mechanisms, *in vitro* test systems have been described that allow the identification of potential anti-cancer activity. This chapter will give a brief overview of the mechanisms and describe the basic principle of the test systems, as well as instrumental requirements.

Introduction: Carcinogenesis and Targets for Anti-cancer Activity

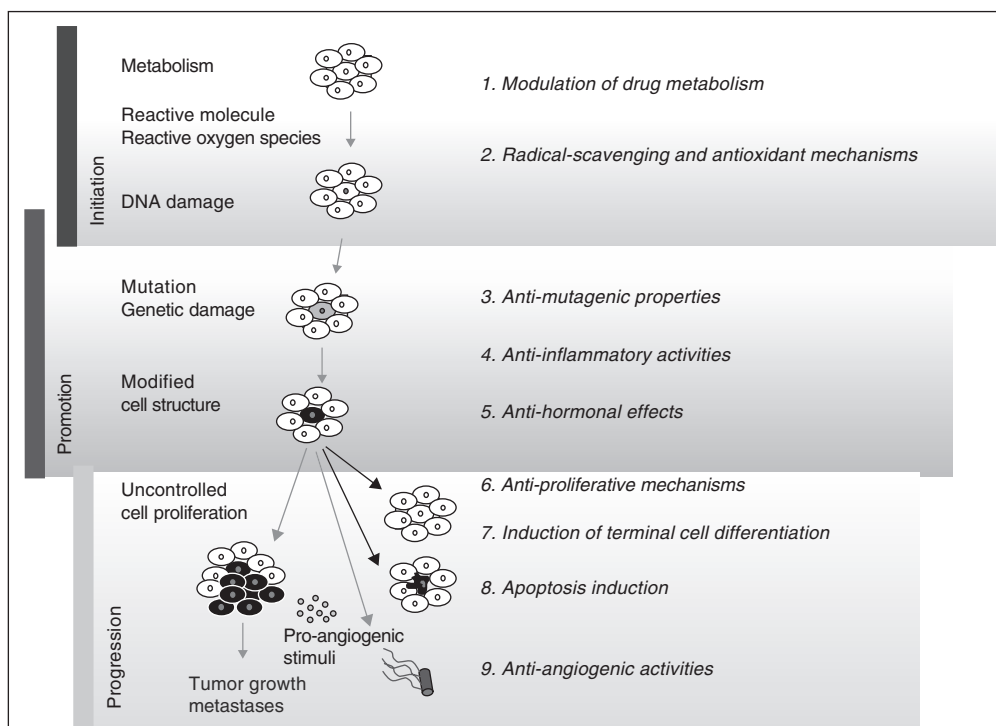
The development of cancer is a multi-stage process which is generally divided into initiation, promotion and progression phases, as depicted in Scheme 90.1. Carcinogenesis can be regarded as an accumulation of genetic or biochemical cell damage which offers a variety of targets for chemopreventive agents to prevent or inhibit the slow progression from early genetic lesions to tumor development (Hanahan and Weinberg, 2000). During the initiation phase, a carcinogen, either directly or after metabolic activation to a reactive molecule, interacts with intracellular macromolecules (DNA, proteins). This may cause DNA damage, which, if not repaired, can result in mutations and genetic damage. These mutations eventually lead to an altered expression of oncogenes and tumor suppressor genes or, for example continuous activation of protein kinases during the promotion phase, and finally result in modified cell structure, uncontrolled cell proliferation, tumor growth and metastases (De Flora and Ferguson, 2005). This cascade of events offers a variety of targets for chemopreventive intervention at every stage.

As indicated in Scheme 90.1, well-established molecular mechanisms of chemoprevention include modulation of xenobiotics metabolism, antioxidant and radical-scavenging activity, anti-mutagenic, anti-inflammatory and anti-hormonal mechanisms, anti-proliferative activities, induction of terminal cell differentiation and apoptosis (programmed cell death) as well as inhibition of angiogenesis, the tumor-induced formation of new blood vessels (De Flora and Ferguson, 2005; Aggarwal and Shishodia, 2006).

Techniques

For the mechanisms and targets described above, various *in vitro* methods have been described which are suitable to assess anti-cancer effects of beer and beer-derived constituents.

Modulation of xenobiotics metabolism

Compounds effective at the initiation stage of carcinogenesis are described as blocking agents; that is, they block carcinogen interaction with DNA. An important mechanism of blocking agents is the modulation of xenobiotics metabolism, that is inhibition of metabolic activation of carcinogens by phase 1 cytochrome P450 (CYP) enzymes, and induction of phase 2 drug-detoxification enzymes to enhance excretion of reactive metabolites (Kohle and Bock, 2006). Phase 1 enzymes such as Cyp1A1, CYP1A2, CYP1B1, CYP2E1 and CYP3A4 activate xenobiotics by addition of functional groups which render these compounds more water-soluble (Nebert and Dalton, 2006). Then, phase 2 enzymes like glutathione *S*-transferase, *N*-acetyl transferase, sulfotransferases or UDP-glucuronosyl transferase conjugate the activated compounds to endogenous ligands, thus facilitating their excretion in the form of these conjugates. Although phase 1 enzymatic activity may be required for complete detoxification, it frequently contributes to the activation of carcinogens (Table 90.1). Moreover, the activity of phase 1 enzymes is often induced by carcinogens and xenobiotics *via* the action of the so-called aryl hydrocarbon (A*h*) receptor, which binds these compounds and stimulates the expression of several phase 1 and phase 2 enzymes (Bock and Kohle, 2006; Brauze *et al.*, 2006). Consequently, inhibition of the


Scheme 90.1 Carcinogenesis (left) and mechanisms of anti-cancer activity (right).

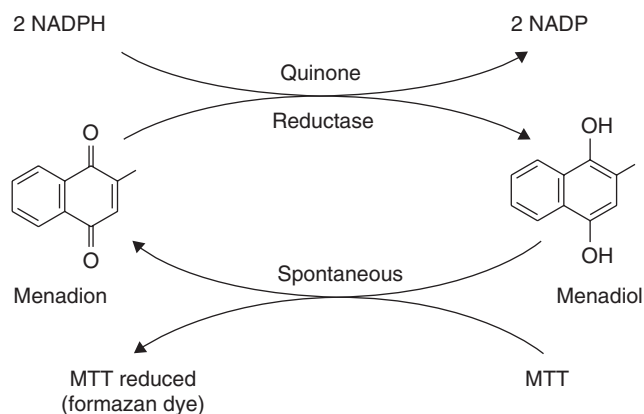
[c]Gerhauser *et al.* (2003).

enhanced activity of phase 1 enzymes concomitantly with induction of detoxifying phase 2 enzymes is considered a logical strategy in chemoprevention (Moon *et al.*, 2006). Agents that selectively induce phase 2 enzymes are so-called monofunctional inducers, whereas less desirable bifunctional inducers lead to simultaneous induction of phase 1 and phase 2 enzyme activities (Kohle and Bock, 2006).

Methods for the Determination of Phase 1 Enzyme Activities   Phase 1 enzymes are often monooxygenases and dealkylate or hydroxylate their substrates to render them more hydrophilic.

A standard substrate for various phase 1 enzymes is 7-ethoxyresorufin, which is de-ethylated by 7-ethoxyresorufin *O*-deethylase (EROD) activity to form 7-hydroxyresorufin. To determine inhibition of the activity of phase 1 enzymes, substrate conversion is monitored fluorimetrically or by high-performance liquid chromatography (HPLC). Suitable enzyme sources are liver microsomes or S9 supernatants of liver homogenates prepared from rodents pretreated with an enzyme inducer such as Aroclor 1254, homogenates from cultured H4IIE rat hepatoma cells induced with 10 µM β-naphthoflavone for 38 h (for Cyp1A activity), or microsomes of insect cells expressing human recombinant enzymes (supersomes), respectively. Enzymes are incubated with suitable substrates and the rate of product formation is monitored over a period of time with linear enzyme kinetics, as summarized in Table 90.1 (Henderson *et al.*, 2000; Gerhauser *et al.*, 2003). Beer constituents have been shown to inhibit the activities of CYP1A1, CYP1A2 and CYP1B1, whereas potential to inhibit CYP2E1 and CYP3A4 was negligible (Henderson *et al.*, 2000; Gerhauser *et al.*, 2003).

Methods to Measure Phase 2 Enzyme Induction   For the identification of inducers of phase 2 enzymes, Prochaska and Santamaria, (1988) have developed a rapid and direct assay of NAD(P)H:(quinone-acceptor) oxidoreductase (QR; EC 1.6.99.2) activity in cultured Hepa1c1c7 murine hepatoma cells. QR catalyzes the two-electron reduction of menadione (2-methyl-1,4-naphthoquinone) to menadiol by NADPH. In parallel, MTT [3-(4,-5-dimethylthiazo-2-yl)-2,5-diphenyltetrazolium bromide] is reduced non-enzymatically by menadiol, resulting in the formation of a blue formazan which can be quantitated on a microtiter plate absorbance reader (Scheme 90.2).

Although QR does not catalyze a conjugation reaction, it is induced coordinately with other phase 2 enzymes and therefore used as a marker enzyme (Kohle and Bock, 2006). Use of the BP[r]c1 cell line, a mutant of Hepa1c1c7 cells defective in A*h* receptor-mediated induction, allows the distinction of mono- and bifunctional enzyme inducers (Seidel and Denison, 1999). Prenylated chalcones and flavanones from hop and beer have been shown to induce QR activity in Hepa1c1c7 cells (Miranda *et al.*, 2000a; Gerhauser *et al.*, 2002a).


Scheme 90.2   Determination of NAD(P)H:quinone reductase activity according to Prochaska and Santamaria (1988).

Antioxidant activity

Generally, in a healthy organism several physiological processes lead to the formation of reactive oxygen species (ROS) (Valko *et al.*, 2007). Insufficient oxygen consumption in mitochondria during fat metabolism (lipid peroxidation) might result in the production of ROS. Also, manifestation of oxidative stress (e.g. by immune diseases, chronic inflammation and infection) disturbs the intracellular homeostasis of pro- and antioxidants. Overproduction of ROS leads to the formation of highly reactive oxidation products, activation of carcinogens, formation of oxidized DNA bases and DNA strand breaks. These then cause mistakes during DNA replication and genetic alterations, increased transformation frequencies, induced transcription of redox-regulated proteins and ultimately result in enhanced cell proliferation and tumor promotion/progression (Valko *et al.*, 2007).

In a biological system there are multiple free radical and oxidant sources (e.g. $O_2^{\bullet-}$, $^1O_2$, $HO^\bullet$, $NO^\bullet$, $ONOO^-$, $HOCl$, $RO(O)^\bullet$, $LO(O)^\bullet$) which are controlled by at least four general sources of antioxidants: (i) enzymes, such as superoxide dismutase, glutathione peroxidase and catalase; (ii) large proteins including albumin and ferritin; (iii) small molecules (glutathione, ascorbic acid, tocopherol, carotenoids, (poly)phenols) and (iv) some hormones (estrogen, angiotensin, melatonin, etc.) (Prior *et al.*, 2005). Assays to determine antioxidant capacity (AOC) are manifold. Since both oxidants and antioxidants have different chemical and physical characteristics, no single assay will accurately reflect all antioxidants and all radical sources in a complex biological system.

Techniques to Assess AOC   Prior *et al.* (2005) and Huang *et al.* (2005) have recently reviewed and evaluated the most common techniques to assess antioxidant activities and have described the chemistry behind these assays. Methods distinguish between hydrogen atom transfer (HAT) and single electron transfer (SET) reactions. HAT-based

methods measure the classical ability of an antioxidant to quench free radicals by hydrogen donation, whereas SET-based methods detect the ability of a potential antioxidant to transfer one electron to reduce another compound.

- HAT-based reactions:
$$X^{\bullet} + AH \rightarrow XH + A^{\bullet}$$
with $X^{\bullet}$ (free radical) and AH (any H donor)

HAT reactions are solvent- and pH-independent and rapid. However, the presence of reducing agents such as metals can disturb the reaction.

- SET-based reactions:

$$X^{\bullet} + AH \rightarrow X^{-} + AH^{\bullet+}$$
$$AH^{\bullet+} + H_2O \rightarrow A + H_3O^{+}$$
$$X^{-} + H_3O^{+} \rightarrow XH + H_2O$$
$$M(III) + AH \rightarrow AH^{+} + M(II) \qquad \text{with M (metal)}$$
Reactivity in SET methods is based on deprotonation and ionization potential of the reactive functional group; therefore, SET methods are pH-dependent. Notably, SET-methods are very sensitive to ascorbic acid and uric acid, which maintain the plasma redox potential (Prior *et al.*, 2005).

The most common methods for the assessment of AOC, including a categorization of the simplicity of the assay, instrumentation required, biological relevance, mechanisms, endpoints, quantitation method as well as whether the assay is suitable to measure lipophilic and hydrophilic antioxidants are summarized in Table 90.2 (adapted from Prior *et al.*, 2005).

AOC methods using HAT reaction mechanisms include the oxygen radical absorbance capacity (ORAC) assay, the total radical-trapping antioxidant parameter (TRAP) assay, the total oxygen scavenging capacity (TOSC) assay, and low-density lipoprotein (LDL) oxidation. The ferric reducing antioxidant power (FRAP) assay and copper reduction assay (CUPRAC) belong to the SET-based methods, whereas the trolox equivalent antioxidant capacity (TEAC) and the 2,2-diphenyl-1-picrylhydrazyl (DPPH) assay utilize both HAT- and SET mechanisms.

For a description of the test systems as well as advantages/disadvantages of each system refer to Prior *et al.* (2005). The authors recommend to use a combination of the ORAC assay (modified with fluorescein instead of the originally descried β-phycoerythrin) based on a HAT-mechanism and the TEAC assay as a SET-based method together with the Folin–Ciocalteu (FC) assay, which is commonly used as a measure of total phenolics in natural products. The FC assay may be regarded as an oxidation/reduction reaction and thus represents another simple, sensitive and precise method to determine AOC (improved modification of Singelton and Rossi (1965) with gallic acid as a reference standard).

Numerous studies have investigated the AOC of beer and beer constituents using the test systems described above or modification thereof. It is generally accepted that the AOC of beer correlates with its polyphenol content (Lugasi and Hovari, 2003).

Anti-mutagenic potential

Several activated carcinogens and ROS lead to DNA damage, which will result in mutations if not repaired. A well-established test system to detect mutagens is the Ames

[d]OD: optical density.

assay, initially described by Ames *et al.* (1973a, b). The test uses various *Salmonella typhimurium* strains as sensitive indicators for DNA damage caused by structurally diverse mutagens, and mammalian liver extracts for metabolic conversion of carcinogens to their active mutagenic forms. The Ames assay has been utilized to demonstrate anti-mutagenic activity of beer and prenylflavonoids from hops against the food-derived mutagenic heterocyclic amine 2-amino-1-methyl-6-phenylimidazole[4,5-*b*]pyridine (PhIP) (Miranda *et al.*, 2000b; Arimoto-Kobayashi *et al.*, 2006) and other heterocyclic amines (Arimoto-Kobayashi *et al.*, 1999). Anti-mutagenic potential was partly attributed to the inhibition of metabolic activation of these mutagens.

To counteract mutagenic and lethal effects of DNA damage, healthy organisms have developed DNA repair pathways (Salles *et al.*, 1999). The two most important processes are the nucleotide excision repair (NER) and the base excision repair (BER) pathway. *In vitro* eukaryotic DNA excision repair assays have been described (Salles *et al.*, 1995), but so far, not effects of beer on DNA repair have been reported.

Anti-inflammatory mechanisms

It is assumed that up to 18% of all cancer cases are related to chronic inflammatory processes as for example chronic gastritis, esophagitis, pancreatitis, ulcerative colitis and Crohn's disease (Ohshima *et al.*, 2005).
Scheme 90.3 Formation of prostaglandin PGE$_2$ from arachidonic acid by cyclooxygenases.

Inhibition of Cyclooxygenases Excessive production of prostaglandins, that is hormone-like endogenous mediators of inflammation, is thought to be a causative factor of cellular injury and may ultimately lead to carcinogenesis. Cyclooxygenase (Cox) 1 and 2 enzymes play a substantial role in the biosynthesis of prostaglandins from arachidonic acid as depicted in Scheme 90.3. Cox enzymes contain two catalytic sites, the Cox site, which exists as a long hydrophobic channel within the core of the protein, and a peroxidase site containing a heme moiety.

Since prostaglandin levels are often elevated in tumor tissue in comparison to normal tissue, and Cox-2 activity is inducible during the development of tumor cells, inhibitors of the arachidonic acid cascade are regarded as promising chemopreventive agents.

Methods to Detect Anti-inflammatory Activity Various test systems have been developed to identify anti-inflammatory agents. These systems are based on (i) the measurement of oxygen consumption, which occurs during the first step of Cox activity, (ii) monitoring direct binding of the inhibitor to the enzyme, or (iii) the quantification of arachidonic acid and the resulting prostaglandin metabolites (summarized in Table 90.3).

Enzyme sources for Cox-1 are sheep seminal vesicles or bovine aortic endothelial cells (BAECs), whereas Cox-2 can be enriched from sheep placental cotyledons or phorbol myristate acetate (PMA) treated BAECs. Alternatively, both human enzymes are commercially available as recombinant proteins expressed and purified from insect cells or *E. coli.*

Inhibition of Inducible Nitric Oxide Synthase Nitric oxide (NO) is an important signaling molecule and is involved in the immune defense against pathogens and certain tumor cells. Chronic inflammation and infection, however, result in the induction of the inducible form of NO synthase (iNOS) and consequently, in an overproduction of NO. Long-term elevated levels of NO have been linked to early steps in carcinogenesis *via* nitrosative desamination of DNA bases, accumulation of reactive nitrogen oxide species, DNA adduct formation and consequent DNA damage (Ohshima *et al.*, 2005; Lechner *et al.*, 2005).

Assay to Determine iNOS Acitivity To identify inhibitors of iNOS induction, the murine macrophage cell line Raw 264.7 can be utilized and stimulated with bacterial lipopolysaccharides (LPS) to mimic a state of infection and inflammation. Raw cells are plated in 96 well plates and incubated overnight. Cells are then treated with test compounds and stimulated with LPS for 24 h to induce iNOS. NO production is determined via quantification of nitrite levels in cell culture supernatants according to the Griess reaction. Briefly, 100-µl aliquots of cell culture supernatants are incubated with an equal volume of Griess reagent (1% sulfanilamide/ 0.1% naphthylethylene diamine dihydrochloride/2.5%

Table 90.3 Summary of test systems for the detection of cyclooxygenase inhibitors

Assay	Cox-1/Cox-2	Simplicity	Throughput	Instrumentation required	Endpoint	Reference
Cyclooxygenase reaction						
Oxygen consumption	Cox-1/Cox-2	+++	−	Clark-type electrode	Slope of O_2 consumption	Jang and Pezzuto (1997)
Ultrafiltration LC-MS	Cox-2	−	−−	HPLC-MS	Ligand binding[a]	Nikolic *et al.* (2000)
Metabolite production						
Radiodetection	Cox-1/Cox-2	++	+	HPLC with radiodetector	Detection of radiolabeled PGE_2	Redl *et al.* (1994)
Bovine aortic coronary endothelial cell assay	Cox-1/Cox-2[b]	−	+	Cell culture HPLC-DAD	UV-detection of 6-keto $PGF_1\alpha$ and 12-HHT[c]	Dannhardt and Ulbrich (2001)
ELISA[d]	Cox-1/Cox-2	+++	+++	Microplate reader	PGE_2 quantification	Cuendet *et al.* (2006)

[a] Allows immediate identification of known enzyme ligands.
[b] Cox-2 after stimulation.
[c] 12-HHT: 12-L-hydroxy-5,8,10-heptadecatrienoic acid, derived non-enzymatically/enzymatically from PGH_2.
[d] Kits and enzyme sources commercially available (compare Reininger and Bauer, 2006).

H_3PO_4) at room temperature for 10 min. The absorbance at 550 nm is determined in a microplate reader, and nitrite levels are quantified in comparison with a nitrite standard curve (Heiss *et al.*, 2001). Using this model, inhibitors of NO production have been identified in hops (Zhao *et al.*, 2003, 2005) and beer (Gerhauser *et al.*, 2002b).

Anti-hormonal effects

Similar to prostaglandins, hormones like estradiol are regarded as endogenous tumor promoters, stimulate cell growth via interaction with estrogen receptors, and increase the risk for breast and uterine cancer (Yager and Davidson, 2006). In addition, estrogen metabolites may directly react with DNA to form adducts. Release of these adducts from DNA and repair of the resulting damage may lead to DNA mutations that can initiate various types of hormone-related cancers. Hops has repeatedly been reported to possess estrogenic properties. Therefore, evaluation of estrogenic and potential anti-estrogenic properties of hops and beer is important.

Measurement of Estrogenic and Anti-estrogenic Properties Estrogenic and anti-estrogenic effects can be determined at several levels: (i) interaction with the estrogen receptors α and β; (ii) estrogen-induced gene transcription; (iii) estrogen-induced enzyme activity and (iv) estrogen-induced cell proliferation in estrogen-responsive mammary cancer cell lines (overview of test systems in Table 90.4). All systems can be used to detect estrogenic effects, but also to measure anti-estrogenic properties, when test compounds are applied simultaneously with estrogens. Indirectly, anti-estrogenic effects can be achieved by inhibition of aromatase (CYP 19), which converts male testosterone into female estrogen.

To monitor the relevance of *in vitro* findings, the uterotrophic assay is a generally accepted short-term *in vivo* screening assay for estrogenicity or anti-estrogenicity. Immature prepubertal or adult ovariectomized female rats or mice are used. Administration of an estrogenic compound will lead primarily to an increase in the uterine weight besides effects on other estrogen-dependent parameters. Anti-estrogenic compounds diminish this estrogen-dependent weight increase (Kanno *et al.*, 2001).

Anti-proliferative activity

The survival of multicellular organisms involves a balance between cell proliferation and cell death. Overexpression of hormone/growth factors and their receptors might present a growth advantage to pre-neoplastic cells. Also, continuous accumulation of genetic damage and mutations during carcinogenesis can result in uncontrolled cell proliferation and cell growth.

Test to Determine Anti-proliferative Activity A simple test system to monitor the effects of test compounds on proliferation of cultured cancer cells is the sulforhodamine B (SRB) assay, developed by Skehan *et al.* (1990). The SRB assay is based on the ability of the protein dye SRB to bind

Table 90.4 Summary of *in vitro* test systems to determine estrogenic and anti-estrogenic activity

Assay	Material	Instrumentation required	Reference
Direct estrogenic and anti-estrogenic activity			
Estrogen receptor (ER) binding assay	Human recombinant ER-α/-β combined with use of fluorescent non-steroidal estrogen	Fluorescence polarization instrument	Bolger *et al*. (1998)
Yeast ER cytosensor assay	Yeast strains expressing human ER-α, -β or both, and ER-controlled yeast enhanced green fluorescence protein	Microplate fluorescence reader	Bovee *et al*. (2004a, b)
MVLN assay	Bioluminescent MCF-7-derived cell line, expressing ER-controlled firefly luciferase	Luminescence reader or photon-counting camera	Pons *et al*. (1990); Demirpence *et al*. (1993)
Ishikawa Var-1 bioassay	Human endometrial cell line with estrogen-dependent alkaline phosphatase activity	Microplate photometer	Littlefield *et al*. (1990); Markiewicz *et al*. (1992)
Proliferation of MCF-7 cells	Human hormone-dependent breast cancer cell line expressing functional ER	Microplate photometer	Katzenellenbogen *et al*. (1987); Skehan *et al*. (1990)
Indirect anti-estrogenic activity			
Aromatase inhibition	Human recombinant CYP19 (aromatase) and *O*-benzylfluorescein benzyl ester as a substrate	Microplate fluorescence reader	Stresser *et al*. (2000)

electrostatically and pH-dependent to protein basic amino acid residues of trichloroacetic acid-fixed cells. Under mild basic conditions the dye can be extracted from cells and quantified by photometric or fluorescent determination. The assay is non-destructive and fixed/stained cells are indefinitely stable. These practical advances make the SRB assay an appropriate and sensitive tool to measure drug-induced inhibition of cell proliferation even at large-scale application. Miranda *et al.* (1999) have used this model to detect anti-proliferative and cytotoxic activity of several hop flavonoids.

Induction of cell differentiation

Differentiation refers to the ability of cancer cells to escape from uncontrolled cell proliferation and to revert to their normal counterparts. Its induction represents an important non-cytotoxic therapy for leukemia, and also breast, prostate and other solid malignancies.

Cell System to Monitor Differentiation-Inducing Capacity Terminal differentiation of human promyelocytic leukemia (HL-60) cells can be induced by a variety of chemical agents (Suh *et al.*, 1995). This process can be monitored by the generation of functionally mature granulocytes and monocytes/macrophages. HL-60 cells undergo growth arrest while they terminally differentiate. Consequently, cell proliferation and an arrest of cell growth are determined by cell counting. Differentiation along the granulocytic lineage is based on the ability of phagocytic cells to generate superoxide upon stimulation with PMA, which is detectable by reduction of nitroblue tetrazolium (NBT). NBT-positive cells are counted as a marker for differentiation.

Induction of differentiation to monocytes/macrophages is determined by evaluation of the expression of non-specific/specific acid esterase by cell staining (Suh *et al.*, 1995).

Induction of apoptosis

Apoptosis (programmed cell death) is a genetically controlled response for cells to commit suicide. Apoptosis represents an innate cellular defense mechanism against carcinogen-induced cellular damage by inhibiting survival and growth of altered cells and removing them at different stages of carcinogenesis. Accordingly, deregulation of apoptosis has been implicated in the onset and progression of cancer. Apoptotic cells are characterized by specific morphological and biochemical changes. The morphological features of apoptosis consist of chromatin condensation, cell shrinkage and membrane blebbing, which can be clearly observed by light microscopy. The biochemical changes during apoptosis induction include (i) the appearance of phosphatidylserine on the cell membrane surface, (ii) increased mitochondrial membrane permeability, (iii) activation of caspases, (iv) DNA fragmentation and (v) protein cleavage at specific locations.

Methods to Detect Induction of Apoptosis Based on these characteristics of apoptotic cells, multiple methods have been described to detect the induction of apoptosis.

Basically all methods have some limitations and are not completely specific and quantitative (Sgonc and Gruber, 1998; Hall, 1999).

(i) Phosphatidylserine is normally situated on the inner surface of the cytoplasmic membrane. During apoptosis, phosphatidylserine is translocated to the outer surface. Annexin V, a highly conserved 35 kDa protein, has a high affinity to phosphatidylserine and can be used, as a fluorescent conjugate, to detect phosphatidylserine externalization by flow cytometry or fluorescent microscopy.

(ii) Breakdown of the mitochondrial transmembrane potential can be measured by fluorochromes that are sensitive to the electrochemical potential within the mitochondria, such as JC-1. These changes can be detected by flow cytometry or fluorescent microscopy.

(iii) The caspases are a group of aspartic acid-specific cysteine proteases which are activated during apoptosis. These unique proteases, which are synthesized as inactive pro-forms, are involved in the initiation and execution of apoptosis once activated by proteolytic cleavage. Caspase assays are based on the measurement of caspase processing to an active enzyme (detected by Western blotting) and of their proteolytic activity using suitable peptide substrates which yield fluorescent or colored products after cleavage. A number of commercial kits and reagents are available to assess apoptosis based on caspase function.

(iv) During the execution phase of apoptosis, nucleases are activated which cleave DNA into 180–200 bp increments. This DNA fragmentation (DNA laddering) can be detected by gel electrophoresis. At the single cell level, the TUNEL (TdT-mediated dUTP nick-end labeling) assay measures the fragmented DNA of apoptotic cells by catalytically incorporating fluorescein-12-dUTP(a) at 3′-OH DNA ends using the enzyme "terminal deoxynucleotidyl transferase." The fluorescein-12-dUTP-labeled DNA can then be visualized directly by fluorescence microscopy or quantified by flow cytometry. Alternatively, biotinylated nucleotides can be incorporated and detected via streptavidin-coupled horseradish peroxidase with suitable colorimetric substrates. DNA fragmentation is also detectable by flow cytometry after propidium iodine staining of fixed cells via the occurrence of a subG1 peak in cell cycle analyses.

(v) Poly(ADP-ribose)polymerase (PARP) is a zinc-dependent eukaryotic DNA-binding protein that specifically recognizes DNA-strand breaks produced during apoptosis induction. The 113 kD protein serves as a substrate for effector caspases and is cleaved during apoptosis into 89-kD and 24-kD fragments, which can be detected by Western blotting as specific markers of apoptosis.

For more in-depth mechanistic evaluation of apoptosis induction, changes in the expression and phosphorylation of pro- and anti-apoptotic proteins can be detected by Western blotting. Some relevant mechanisms observed during the induction of apoptosis by dietary factors have been summarized by Khan *et al.* (2007).

Inhibition of angiogenesis

Angiogenesis – the formation of new blood vessels from already established vessels – plays an essential role in tumor survival and growth. Without adequate blood supply, a tumor cannot grow beyond a critical size of $1–2\,mm^2$ due to lack of oxygen and nutrients (Carmeliet, 2000). The process of angiogenesis is regulated by various factors and includes multiple steps, which may be targets for anti-angiogenic agents, such as (i) production of growth factors, (ii) activation of endothelial cells, (iii) production of lytic enzymes to digest the basement membrane and extracellular matrix, (iv) endothelial cell migration, proliferation and tube formation.

Test Systems for Anti-angiogenic Activity   Current test systems for anti-angiogenic research have been summarized by Auerbach *et al.* (2003). Cell-based systems using endothelial cells only investigate single steps of angiogenesis, for example proliferation, migration or differentiation to microtubules.
Scheme 90.4   Scheme of the human *in vitro* anti-angiogenesis assay. Superficial arterial or venular vessels are pulled from human placentas and immersed immediately in tissue culture medium. Fragments of $1–2\,mm^2$ are prepared by cutting, placed in the eight center wells of a 24-well plate and embedded in 1-ml fibrin gel. The gel is overlaid with 1 ml medium containing the test compound at one test concentration (three wells), a solvent control (three wells) and a positive control inhibitor at a concentration giving 40–60% inhibition of vessel growth (two wells). Medium is changed twice weekly. Experiments are terminated after 21 days, when microvessel density reaches a plateau phase. Microvessel density is quantified by acquisition of standardized digital images and densitometric evaluation. Details are described in Bertl *et al.* (2004, 2006).

Therefore, these assays are useful only for mechanistic elucidation. The chorio-allantoic membrane (CAM) assay is an *in vivo* assay using fertilized chicken eggs. Test compounds are placed on carriers, and inhibitory potential can be assessed either on normal CAM vasculature or on growth factor-induced angiogenesis. The rabbit cornea assay is an animal model for angiogenesis. Since all these assays have some limitations for screening, we have developed a human *in vitro* anti-angiogenic model, which covers a broad range of angiogenic key steps, starting from the production of growth factors up to endothelial cell proliferation, migration and tube formation (Bertl *et al.*, 2004, 2006). The main principle of the test is described in Scheme 90.4.

The model has been used to investigate anti-angiogenic activity of several potential cancer chemopreventive agents, including isoxanthohumol (Bertl *et al.*, 2004). Recently, humulone as well as xanthohumol have been described as anti-angiogenic agents (Shimamura *et al.*, 2001; Gerhauser, 2005; Albini *et al.*, 2006).

Summary Points

- Cancer is a complex process that offers various targets for inhibition.
- Multiple test systems have been developed that are suitable to detect anti-cancer agents. These are either simple chemical or biochemical (enzyme) models or involve the *in vitro* culture of primary cells, cancer cell lines, or tissues. Short-term *in vivo* models allow, for example the detection of anti-estrogenic agents.
- Mechanisms of anti-cancer agents include modulation of xenobiotics metabolism, anti-oxidant and radical-scavenging activity, anti-mutagenic, anti-inflammatory and anti-hormonal mechanisms, anti-proliferative activities, induction of terminal cell differentiation and apoptosis (programmed cell death) as well as inhibition of angiogenesis.
- Care should be taken when selecting a test system for a certain mechanism, for example antioxidant activity, since these models are often not equally relevant for the human situation.
- When a potential anti-cancer agent has been identified, proof of anti-cancer efficacy (either preventive or therapeutic) can only be obtained in suitable animal models, which reflect parameters such as absorption, bioavailability, tissue distribution, metabolism and excretion and monitor whether a compound or extract is truly capable to reduce cancer burden *in vivo*. These models are however not included in this chapter.

The Evaluation of Beer Aging

María Purificación Hernández-Artiga and Dolores Bellido-Milla Department of
Analytical Chemistry, Faculty of Sciences, University of Cádiz, Cádiz, Spain

Abstract

Beer contains certain components, which act as protective
agents in relation to consumers' health, such as antioxidants,
which decrease over time. The shelf life of package beer is
determined to a large extent by the appearance of haze or dete-
rioration of the flavor. A comprehensive understanding of the
mechanisms involved in beer instability has yet to be achieved.
The raw materials are considered the main source of haze pre-
cursors, although the brewing process also has effects. Flavor
stability depends on the oxygen content of the packaged beer,
which gives rise to active oxygen species. The process of beer
aging in the package is discussed with the aim of evaluating
the various methods found in the literature for the detection
of beer aging. These methods have been classified according to
the methodology used, as follows: methodologies to measure
one compound or groups of similar compounds, methodolo-
gies to detect the time elapsed for appearance of OH$^{\bullet}$ radicals,
simulations adding exogenous free radicals to beer, and other
methods related to the general properties of sensory analysis
and sensors. Correlations between sensory analysis and chemi-
cal analysis are emphasized. Attention is given to controversial
opinions of authors in relation to compounds with antioxi-
dant properties which retard beer aging. The complexity of
the mechanisms and the amount of compounds involved in
beer aging is pointed out. The methods that follow the evolu-
tion of general properties are considered more closely related
to beer aging than those following a single compound. A sec-
ondary aim is to shed light on a more holistic understanding
of beer aging, the mechanisms of which are at present only
poorly understood.

List of Abbreviations

ABTS	2,2′-Azino-bis(3-ethylbenzothiazoline-6-sulfonic acid)
CEAC	Vitamin C equivalent antioxidant capacity
EN	Electronic nose
ESR	Electron spin resonance
FID	Flame ionization detector
GC	Gas chromatography
HPLC	High performance liquid chromatography
MEK	Methyl ethyl ketone
MRP	Maillard reaction product
MS	Mass spectrometry
SPE	Solid phase extraction
TAA	Total antioxidant activity
TEAC	Trolox equivalent antioxidant capacity
UV–Vis	Ultraviolet–visible

Introduction

Besides their gustatory and nutritional properties, beers
contain some components that have been recognized in epi-
demiological studies as acting as protective agents. This is the
case of natural antioxidants (Nicoli *et al.*, 1997). It has been
reported that the intake of beer significantly increases plasma
antioxidant capacity, since beer is able to transfer its phenolic
compounds to body fluids (Montanari *et al.*, 1999). It is
well known that many antioxidants are lost during storage,
producing beer aging. These compounds can also react with
other beer components, which make beer aging a compli-
cated process involving many components and mechanisms,
which at present are not very well understood.

It is not clear whether Maillard reaction products (MRPs)
exhibit predominantly mutagenic or antimutagenic activity.
The antimutagenic activity has been attributed to the fact
that certain MRPs can act as antioxidants (i.e., chain break-
ers) oxygen scavengers and metal chelating agents (Nicoli
et al., 1997).

In epidemiological studies with Spanish people groups,
it has been found an inadequate intake of riboflavin and
niacin (B vitamins) that can be normalized along with min-
erals and proteins by moderate beer consumption (Serra-
Majen and Aranceta, 2003; Bamforth, 2004).

Chemical methods to evaluate antioxidant capacity
provide information on beer stability, but they may not

be correlated with the health effects, which are evaluated by biological methods. The information obtained by both methods is required (Gonzalez-San José *et al.*, 2001).

Maturation (commercial aging) at the final stage in the brewery followed by filtration is carried out to develop desirable flavors and aromas and to diminish off-flavors. It also allows time for proteins and polyphenols to precipitate, which contribute to a haze in the final beer if not removed. In spite of this, the finished beer continues changing and a new period of aging starts. Compared to most other alcoholic beverages, beer is unique because it is unstable when in the final package (Stewart, 2004). The shelf life of packaged beer is essentially determined by either the appearance of haze (colloidal instability) or deterioration of the flavor. Both of these phenomena are the result of non-biological oxidation processes that involve active oxygen species (Andersen *et al.*, 2000). This implies a wide range of complex chemical processes, including proteins, carbohydrates, polyphenols, metal ions, thiols, sulfur dioxide and carbonyl compounds. However, in spite of the scientific progress in this field during the last decades, a complete understanding of the mechanisms involved in beer instability is still lacking.

When beer is stored for an extended time period, permanent haze is formed. Although the brewing process does affect colloidal stability, raw materials are considered the source of haze precursors. The colloidal instability of beer is mainly caused by the formation of insoluble complexes between proteins and oxidized polyphenols (Andersen *et al.*, 2000). Therefore, the balance between these two groups of compounds largely dictates colloidal stability (Andersen *et al.*, 2000). Haze formation is increased mainly by storage temperature and the presence of oxygen (closely related to flavor instability). Iron at trace levels indirectly promotes the haze formation due to its catalytic role in oxidation reactions. The movement of beer accelerates haze formation (due to the rapid interaction of colloids) and light encourages oxidation and haze formation (Stewart, 2004).

The flavor stability depends on the oxygen content of the packaged beer. It is critical that the oxygen level in beer be as low as possible immediately prior to packaging (less than 100 mg/l) and that oxygen accumulation during filling is minimized. The oxidative reaction of beer has been recognized as the most important cause of the staling of flavor development. Molecular oxygen, O_2, is itself relatively unreactive (Bamforth and Parsons, 1985), but the activated forms of oxygen (O_2^-, O_2^{2-}, H_2O_2, $OH^{\cdot}$), which are called "active oxygen" species in beer oxidation, have been indicated to participate in the aging process (Uchida and Ono, 1996) (Figure 91.1).

The oxidation reactions involve Fenton reactions, which are dependent on oxygen and iron or copper ions, and minimizing these contents in the packaged beer has a positive effect on flavor stability (Andersen *et al.*, 2000). However, it is now clear that flavor stability is in fact influenced by all stages of the brewing process. In many foods, staling is
Figure 91.1 Reactive oxygen species. Schematic showing generation from molecular oxygen. The hydroxyl radical ($OH^{\cdot}$) and hydroperoxyl (OOH) are considered to be the most reactive.
Figure 91.2 The Dalgliesh plot. Changes in various flavors in beer as the beer is stored over time.

caused by the appearance of various unwanted unsaturated carbonyl compounds. The same is true in beer staling (Bamforth, 2000). The actual compounds responsible for stale flavor vary during prolonged storage, as evidenced by the changes in the flavor profile of beers (Figure 91.2).

It is known that the development of certain carbonyl compounds (oxidation products) plays an essential role in the loss of taste stability (Varmuza *et al.*, 2002). The compounds causing the "sweetish, leathery character" of very old beers have not been identified. However, there is evidence that the "papery cardboard character" of 2–4-month-old beer is due to unsaturated aldehydes. The most flavor-active is *trans*-2-nonenal, with a very low stale flavor threshold. Other aldehydes such as nonadienal, decadienal and undecadienal, may also exceed threshold levels (Stewart, 2004). Other

compounds have been found to increase in concentration during beer aging and include: β-damascenona, methional dimetyltrisulfide (Chevance *et al.*, 2002; Guido *et al.*, 2004) and furfuryl ethyl ether (Vanderhaegen, 2004). It is known that beer flavor stability is determined by the endogenous antioxidant activity of beer itself, which is affected by each step in the brewing process (Uchida and Ono, 1996). Beers contain compounds with antioxidant properties such as reducing sugars, sulfur dioxide, phenolic compounds, vitamins and MRPs. A considerable number of phenolic compounds may act as antioxidants, with mechanisms involving both free radical scavenging and metal chelation (Fantozzi *et al.*, 1998). The beer phenolic compound content described in the bibliography oscillates between 50 and 350 mg/l. On the other hand, the role of phenols as antioxidants is controversial. In fact, contradictory results have been reported on the effectiveness of some phenolic compounds as potential antioxidants, pointed out the sulfite as relevant antioxidant in beer (Kaneda and Takashio, 1996; Uchida and Ono, 1996; Foster *et al.*, 1999).

Methods to Evaluate Beer Aging

Although off-flavors are easily identifiable by sensory analysts trained in the assessment of beer flavor, there is a definite requirement for analytical methods that may detect the specific compounds responsible for these flavors and thereby enable quantitative determination of beer staling. It is possible to find in the literature numerous methodologies to evaluate beer aging; they refer mainly to flavor instability, which has become the most important factor in determining the shelf life of packaged beer (Uchida and Ono, 1996). We can classify them as follows:

(a) Methodologies to measure one compound or groups of similar compounds.
(b) Methodologies to detect the time elapsed for the appearance of OH radicals.
(c) Simulations adding an exogenous free radical to beer.
(d) Other methods related to a variety of general properties.
(e) Sensory analysis and sensors (electronic nose (EN) and electronic tongue).

Methodologies to measure one compound or groups of similar compounds

There are numerous studies indicating that volatile long-chain unsaturated aldehydes are the main compounds responsible of the initial stale flavor of beer.

E-2-nonenal is believed to be the major source of the "cardboard" character of (appearing in) stale beer. Simultaneous determination of *E*-2-nonenal and β-damascenone by reverse phase liquid chromatography with UV detection is reported (Guido *et al.*, 2004). This entails steam distillation, passage of the distillate through a C_{18} solid phase extraction (SPE) column, and analysis by high performance liquid chromatography (HPLC) with UV detection. The results were confirmed by gas chromatography with a mass spectrometry detector (GC–MS). *E*-2-nonenal at 0.06–0.07 μg/l in fresh beer and 0.16–0.20 μg/l in aged beer. β-damascenone was found at 1.8 μg/l in fresh beer and at 2.8–2.9 μg/l in aged beers. Both compounds are proposed as markers of beer aging.

The increase of β-damascenone content during aging has been reported in commercial Belgian beers (Chevance *et al.*, 2002). The methodology used consists of an extraction; passage through a resin and injection in a gas chromatographer with a flame ionization detector (FID) and olfactometry detector. In fresh commercial beers, β-damascenone was detected below 25 ng/g and in aged beers up to 210 ng/g.

Furfuryl ethyl ether, detected by gas chromatography, has also been proposed as a marker of aging (Vanderhaegen, 2003, 2004). Concentrations between 76 and 216.7 μg/l were found in 4-year-old aged beers. It is concluded that the aging of ale beers differs significantly from that of lager beers.

Dimetyltrisulfide is a key flavor in beers; the detection of precursors of this compound has also been investigated (Gijs *et al.*, 2000) by means of extractions followed by gas chromatography.

Chromatographic techniques (GC–MS after steam distillation and HPLC) have been used to determine aldehydes, ketones and esters relevant in beer aging, both in fresh beers and in artificially aged samples (Varmuza *et al.*, 2002). A chemometric evaluation shows that the concentration profiles in artificially aged beer samples are clearly distinguishable from those of fresh samples.

The behavior of sulfites in beers during fermentation and storage after packaging was studied using HPLC with a fluorescence detector to determine aldehyde–bisulfite adducts. Acetaldehyde–bisulfite and free sulfite decreased during beer storage, indicating that they are oxidized by free radical reactions during beer storage and inhibit the oxidation of the other beer components. They proposed that the contribution of sulfite to beer flavor stability is not based on a masking effect on stale flavor through adduct formation, but rather on an antioxidative action, a radical scavenging action (Kaneda and Takashio, 1996).

A method for the evaluation of beer aging measuring acetaldehyde and sulfite voltammetric peaks is reported. The ratio of acetaldehyde and SO_2 currents correlates well with those given by an expert sensory panel (Guido *et al.*, 2003). These results are supported by the theory of an adduct acetaldehyde – SO_2 formation with a high constant (compared with other carbonyl compounds – SO_2), and furthermore, acetaldehyde is the main component of the carbonyl compounds in beers. These adducts are not flavor actives. Other authors had previously accepted the mechanism of

the adduct formation (Illet *et al.*, 1996) as responsible for the SO_2 contribution to beer stability.

In a review (Illet, 1995) of sulfur dioxide in beers the methods to determine SO_2 have been presented based on a variety of methodologies. They are classified as follows: distillation followed by titration, iodometric titration with visual or electronic end point determination, ultraviolet–visible (UV–Vis) spectrophotometry (based on the reaction between SO_2, *p*-rosaniline and formaldehyde or on the reaction with the tetradichloromercurate (II) ion or on the use of dithiobis(2-nitrobenzoic acid) after distillation), selective electrodes, enzymic determination, chromatographic methods (gas chromatography, ion chromatography, ion exclusion and high performance liquid chromatography). The total concentration of SO_2 typically ranges from 1 to 30 mg/l.

Methodologies to detect the time elapsed for the appearance of OH• radicals

Partially reduced forms of oxygen (notably superoxide and hydroxyl radicals) are the responsible species that cause flavor instability due to oxidation. Free radicals were observed after a definite period during an oxidative forcing test. The detected free radicals were identified as hydroxyl radicals (OH•) using a spin trapping method with electron spin resonance (ESR) spectroscopy (Uchida and Ono, 1996). It was found that the OH• was not always generated just after starting the forcing test, but was generated after a definite time period the authors called the "lag time" of OH•-radical generation. The lag time was considered to be related to the endogenous antioxidant activity of beer. Beer itself has endogenous antioxidant activity to prevent free radical generation and free radicals are generated only after the antioxidants in beer are deactivated. The effect of the catalytic role of the ferrous ion was investigated and it was concluded that it contributes to the generation of free radicals. The same authors demonstrated that the method to detect the endogenous antioxidant activity by ESR exhibited a good correlation with sensory analysis by experimental panelists (Uchida *et al.*, 1996).

A number of potential antioxidants have been evaluated for their effect on the formation of radicals in beer using the ESR lag phase method (Andersen *et al.*, 2000). Sulfite was found to be the only one able to delay radical formation, whereas phenolic compounds had no effect. Ascorbate, cystein and cysteamin were, on the other hand, found to be prooxidants which reduce iron and copper ions to Fe(II) and Cu(I) that catalyze free radical formation. Other authors (Foster *et al.*, 1999) obtained similar results studying flavor stability using ESR to detect free radicals, which support the theory that phenolic compounds do not contribute to the antioxidant capacity but SO_2 does increase the lag time.

In terms of the sulfite contribution to beer stabilization, two mechanisms have been proposed (Kamiura and Kaneda, 1993). First, sulfite inhibits beer oxidation during storage by acting as an antioxidant. Second, sulfite masks staling flavors via adduct formation between aldehydes and bisulfite.

The results obtained using ESR support the first mechanism (Uchida and Ono, 1996; Foster *et al.*, 1999; Andersen *et al.*, 2000), since the sulfite inhibits the generation of radicals, it extends the lag time and retards beer flavor staling. These results are supported by the ones obtained by HPLC with fluorescence detection (Kaneda and Takashio, 1996), which indicated sulfite has an extremely poor reactivity with *trans*-2-nonenal (responsible for the cardboard flavor with a very low threshold). Furthermore, in the same article it is reported that acetaldehyde bisulfite and free sulfite decrease during beer storage, indicating they are oxidized by free radical reactions during beer storage and inhibit the oxidation of other components.

Simulations adding an exogenous free radical to beer

These simulations are based on the determination of the total antioxidant activity (TAA) by measuring the capacity of beer to capture free radicals. It is possible to measure all of the antioxidant components known in a sample individually, but this is time-consuming and expensive. In addition, since there seems to be cooperation between antioxidants during oxidative stress, examining one in isolation may not accurately reflect their combined activity (Cano *et al.*, 1998). Interest has, therefore, been focused by many researchers on the measurement of TAA. Beer generally contains a range of antioxidants, the most important of which are the polyphenols, phenolic acids, sulfur dioxide, reducing sugars, vitamins and products of the Maillard reaction.

The methods used to determine the total antioxidant capacity are based on the addition of an exogenous free radical and measurement of the decrease in absorbance (by UV–Vis spectrophotometry) produced by the addition of beer.

Method of the 2,2-Diphenyl-1-picryl Hydrazyl Radical (Kaneda *et al.*, 1995)   This method is limited by low reproducibility when it is applied to beers.

Method of the *N,N*-dimethyl-*p*-phenylenediamine (Gonzalez-San José *et al.*, 2001)   This method has previously been applied to wine. The corresponding cation radical is obtained by oxidation with Fe(III) chloride at pH 5.25. The absorbance is measured by UV–Vis spectrophotometry at 505 nm. A small volume of beer is added and the absorbance decreases due to free radical scavenging capacity of the sample is measured. The absorbance difference is related to the antioxidant capacity. It is expressed as TEAC (trolox equivalent antioxidant capacity) using a calibration

curve plotted with different amounts of trolox or as CEAC (vitamin C equivalent antioxidant capacity). It is a rapid, reproducible and inexpensive method. It was applied to 80 commercial beers grouped in four types: lager, stout, alcohol-free and special (fruit, wheat and ecological). Beers containing red fruits exhibited the maximum activity. The values obtained were between 2–56 mg CEAC and 20–190 mg TEAC (in a package of 333 ml). These ranges were similar in the four types.

Method of the 2,2′-Azino-bis(3-ethylbenzothiazoline-6-sulfonic acid)   Recently, the 2,2′-Azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) ABTS method (Millar *et al.*, 1993) was presented as an excellent tool for determining the antioxidant activity of plant materials and beverages (Arnao *et al.*, 1996; Cano *et al.*, 1998; Cano-Lario *et al.*, 1998). The procedure to determine the antioxidant capacity is as follows: The ABTS$^{\bullet+}$ is prepared by enzymatic oxidation of ABTS with H_2O_2 and peroxidase. It (shows) displays the spectrum that can be observed in Figure 91.3.

One hundred microliters of distilled water are added to 2.5 ml of ABTS$^{\bullet+}$ and the absorbance is measured by UV–Vis spectrophotometry at 414 nm. Subsequently, 100 µl of beer is added into the spectrophotometer cuvette that contains 2.5 ml of ABTS$^{\bullet+}$ and the new absorbance is measured. The absorbance difference is recorded. This is called the "end point" method (Cano *et al.*, 1998). Another strategy with ABTS has been described for citric fruit juices and is known as "lag time." This is based on the addition of the antioxidant to the ABTS peroxidase/H_2O_2 system to retard the formation of the ABTS$^{\bullet+}$ (Arnao *et al.*, 1996). This method is longer and prone to interference, which affects radical formation compared to the end point method.

The authors applied to beers the described "end point method" (Oñate-Jaén *et al.*, 2006) and found that the absorbance difference was not stable and the absorbance value for ABTS$^{\bullet+}$ plus beer continues slowly decreasing for approximately 30 min, after which a tendency to stabilize was observed. The correlation coefficient between the absorbance decrease at $t = 0$ (measured immediately after mixing) and the absorbance decrease at $t = 90$ min was $r = 0.938$, therefore, the absorbance decrease at $t = 0$ was proposed as a measure of the antioxidant capacity of beer. Furthermore, this measurement of the immediate absorbance decrease represents the group of beer antioxidants acting with a rapid mechanism when free radicals are formed naturally in this beverage. The slow antioxidants are of less interest since a slow radical scavenger reaction allows the oxidation of the beer compounds. This method provides a rank order of antioxidant capacity.

The quantitative evaluation using ascorbic acid or trolox proposed by some authors was considered troublesome and unnecessary. Therefore, the authors propose this precise methodology as an index to compare the antioxidant capacity of beers that really is related to the taste and stability of this beverage, since it represents antioxidants with rapid kinetics.
Figure 91.3   UV–Vis spectrum of the ABTS and ABTS$^{\bullet+}$. The ABTS$^{\bullet+}$ absorbance measured at $\lambda_{max} = 414$ nm.

Other methods related to general properties

Many of the carbonyl compounds that play an essential role in the loss of taste stability exhibit a characteristic absorption in the UV region 240–310 nm. The absorption integral for this region has been successfully used as an easy parameter for characterizing the quality and aging status of beer (Klein *et al.*, 2000). The same authors had found that this values correlates well with furanic aldehydes.

A simple and direct method to evaluate beer aging based on liquid–liquid extraction and UV–Vis spectrophotometric measurement has been developed (Oñate-Jaén *et al.*, 2006). The procedure is as follows: 20 ml of fresh beer after being degasified was extracted with methyl ethyl ketone (MEK) after 5 min shaking. The organic phase spectrum was registered and it showed a broad band with a maximum at $\lambda = 333$ nm. It is shown in Figure 91.4.

As is well known, beers develop compounds that end up producing haze since the colloidal stability is broken down; therefore, the extraction with a solvent of low polarity can isolate the compounds with low solubility in the aqueous medium of beer. A search of the literature was used to identify the groups of compounds extracted with MEK. Hydroxycinnamic derivatives (phenolic compounds) were found to exhibit a very similar band with a maximum around 330 nm (Maillard *et al.*, 1996). In a previous work (Bellido-Milla *et al.*, 2004), the authors identified phenolic acid in beers by UV–Vis spectrophotometry at 333 nm with a previous extraction or separation by high pressure liquid chromatography. Reports were also found on methods able to identify MRPs in the extract, since soluble premelanoidins absorb between 320 and 350 nm (Morales and Jimenez-Pérez, 2001), MRPs of low polarity are also found at 334.4 nm (Billaud *et al.*, 2004) by HPLC with UV–Vis spectrophotometry detector.
Figure 91.4 UV–Vis spectrum of the MEK extract for pilsner beer.

Certain experiments, heating and measuring the antioxidant capacity of beers before and after extraction with EMK have confirmed the presence of both groups of compounds in the extract. The ABTS method and the extraction method were checked for a group of beers (control) and for the same beers after natural and forced aging. The forced aging test at 60°C is carried out to save analytical time, since qualitatively similar results have been found compared to natural aging (Uchida and Ono, 1996) (when higher temperatures are used the changes undergone are not comparable to a natural aging). The results are shown in Table 91.1.

In all cases, the values were observed to diminish with aging. Pilsner beer in both aging methods exhibits a higher decrease, probably due to the traditional brewing process without additives by which it is obtained. A similar behavior for natural and forced aging (60°C) has been observed by other authors when ESR is used (Uchida *et al.*, 1996). The decrease of absorbance for EMK extract might be due to the transformation of the extracted compounds (mainly polyphenols) by aging.

In order to study the utility of the two methods mentioned above, 34 beers were analyzed. They were obtained

from local stores and represent the types of beers readily available to consumers. The antioxidant capacity and the absorbance of the EMK extract were obtained in fresh and aged beers (60°C) during a week. The correlation coefficient (r) between both groups of data for the 34 fresh beers is 0.896. This allows predicting the antioxidant capacity by means of the mathematical model A = 0.234 + 0.424 E. Therefore, with a simple extraction and a measurement by UV–Vis spectrophotometry the antioxidant capacity can be predicted avoiding the use of an organic reagent and the development of the corresponding free radical. The correlation coefficients between fresh and aged beers for the antioxidant capacity and the EMK extract are 0.939 and 0.995, respectively. It means that it is possible to predict the antioxidant capacity for aged beers from fresh beers.

With the aim of differentiating groups of beers the analysis of variance was applied to the results obtained from the 34 beer samples analyzed. Statistically significant differences were found between ecological and non-ecological beers. Lager and weizen were also differentiated from stout beers.

Reductones are a type of antioxidants which can bind oxygen or be oxidized in the presence of oxygen and transition metals acting as prooxidants. They are powerful reducing agents. Different types of reductones have a considerable influence on the stability of beers. An automated voltammetric method for the determination of the reducing power of beer has been reported (Sobiech *et al.*, 1998). The reductones are determined indirectly using the redox dyestuff 2,6-dichlorophenol-indophenol. Its reduced form is electrochemically reoxidized. The highest reductone contents were observed with dark beers. This is due to a higher melanoidin content (MRP) resulting from the higher kilning temperature. This is the reason for the persistent flavor stability of dark beer. The values of strongly hopped pilsner beers were considerably higher than those of conventional pale lager beers, as hop bitter acids and hop polyphenols can also react as reductones. The lowest values were obtained for alcohol-free beers. It is possible to take the different reactivity of reductones into consideration. A "reductone distribution" with repeated measurement at several reaction times could be achieved. This would extend the

Table 91.1 Results of natural and forced aging

	EMK extract absorbance			Absorbance decrease of ABTS$^{\bullet+}$		
Beers	Control beer	Natural aging	Forced aging	Control beer	Natural aging	Forced aging
Carlsberg	0.840	0.766	0.783	0.580	0.493	0.346

range of possible applications of the method, as reductones of different reactivity can have a different influence on the stability of beer. The authors propose future investigations about the correlation of reductone content and composition with colloidal and flavor stability.

Chemiluminiscence has been reported to be observed during beer storage, probably due to MRPs (Morales and Jimenez-Pérez, 2001). The changes produced patterns during beer storage that show a good correlation with the degree of stale flavor in panel scores. The deterioration rates of beers might be assessable by measuring the chemiluminiscence. However, the precision needed for the accurate prediction of beer flavor stability is as yet a subject of research (Kaneda et al., 1990, 1991, 1994).

Sensory analysis and sensors

It is quite possible for a beer to have physical and chemical properties well within generally accepted levels and yet be completely unacceptable in taste. Sensory data are therefore also necessary to complement the chemical analysis. In order to obtain this data, the use of a highly trained sensory panel is necessary. The members of this panel are trained in identifying the various characteristics associated with the aroma, taste, mouth feel and aftertaste of the product (McKellar et al., 2002). The major problems with flavor components typically found in beer arise primarily as a result of flavor instability during storage. Perhaps, the best known tool for sensory beer flavor detection is the construction of the beer flavor wheel (Hughes and Baxter, 2001), which brings together the main descriptors associated with taste and odors for many beers produced commercially. It can be seen in Figure 91.5.

A modification has been suggested to incorporate aspects of texture and mouth feel (Hughes and Baxter, 2001). Reliable and statistically well-founded tests are available which can provide authoritative and semiquantitative information that can be applied to make decisions about beer quality (Bamforth, 1998). These methods can be divided into difference tests and descriptive tests. For the descriptive tests a wide terminology is used. The individual attributes are scored by the tasters (usually from 0 to 10). It takes real ability to be able to separate out the various terms and recognize them individually. Once the scoring is completed, the findings may be reported in the form of a spider diagram (Figure 91.6).

A spindle represents each flavor. The shape is characteristic of a product. This test is usually applied to fresh beers but they could be used also to detect beer aging due to sensory changes in beer flavor during the aging process.

The determination of foodstuff quality is usually carried out with the help of sample preparation and rather complex and expensive instrumentation. These types of analysis may ultimately be profound and reliable but the procedures can hardly be done rapidly and, moreover, on-site
Figure 91.5 The meilgaard beer flavor wheel. Sensory assessment of beer.

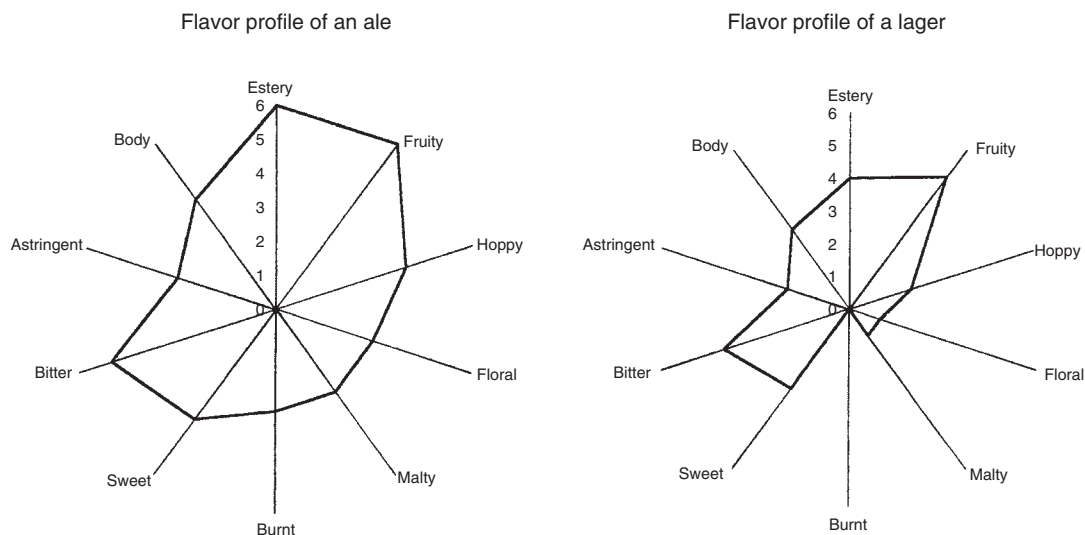
or on-line. For quality control it is necessary to monitor the evolution of a group of certain components that accurately reflect the process of aging and spoilage. These components can be numerous or unknown and the problem appear to be quite difficult. Besides, it is very complex at present to compare the results of instrumental analysis to biological sensing. One of the promising directions of development of different analytical methods implies the use of artificial sensors combined with advanced statistical methods. Electronic nose, devices constructed according to the principles of the human olfactory system, based on sensor arrays and application of pattern recognition tools are at present capable of distinguishing between very complex and rather similar gas mixtures, such as the odors of certain beverages, sometimes even odors containing up to several hundreds of components (Legin et al., 1997). The EN is one of the most promising techniques for rapid analysis of volatiles. Generally, it consists of a semiselective metal oxide sensor array that reacts with volatile chemicals in the sample headspace. Data are analyzed using computer based pattern recognition algorithms. The result is a "fingerprint" characteristic of the headspace volatiles, which allows qualitative comparisons. EN systems have recently been applied to the analysis of beer. Instruments based on ion-conducting polymer sensors have been applied to the differentiation of beers brands, identification of hops and monitoring of fermentation. Recently, a sensor was used to establish the influence of aging time in the brewery (maturation) and on the development of the aroma characteristics of beer (McKellar et al., 2002). The results were


Figure 91.6   The spider diagram. The flavor of beer represented by spider diagram. Each flavor term is represented by a spindle.

compared to data obtained from a trained sensory panel and by headspace analysis with GC–MS. The EN was able to distinguish finished beer made after different periods of maturation, while the sensory panel was not. The results suggest that the EN can complement traditional chemical and sensory approaches to the optimization of beer maturation (McKellar *et al.*, 2002).

However, there is too little evidence that gas phase composition is always perceptibly dependent on the evolution of the liquid phase composition. There is not sufficiently clear reasons to assume that all changes taking place in liquid are reflected adequately by the detectable changes in the gas phase and hence by EN output. The development and evolution of a set of devices for liquids has been reported (Legin *et al.*, 1997). It is based on a wide range of potentiometric chemical sensors and methods of complex signal processing. Such a system mimics significantly the organization (but not the actual appearance) of human sense and, also using the analogy with the EN can be called a prototype of electronic tongue. It has been used to distinguish between different sorts of the same type of beverages (tea, coffee, juice, soft drinks and beers) and to monitor the aging process of juice.

The application of an EN or electronic tongue to follow beer aging in the package was not found upon literature search, but it could be an appropriate tool to study beer staling.

Conclusions

There are a great number of published methods for evaluating the process of beer aging based on different instrumental techniques. The aging process is closely related to the antioxidant capacity. The retarding role of sulfite in

the beer aging process is more relevant than the role of polyphenols. The sulfite acts as an antioxidant by radical scavenging rather than adduct formation, which mask flavor staling. The amount of O_2 present when beer is in its final package is an important factor in that an increase in O_2 gives rise to a more rapid aging through the formation of active oxygen species. Since sensory analysis obviously has the final word, more research needs to be conducted on the development and application of sensors (EN and electronic tongue) to beer aging, since such technologies appear to hold the greatest promise to imitate the detection of flavors by the actual consumers.

Summary Points

- The beer aging mainly depends on the raw materials, the oxygen present and the brewing process. So, polyphenols and proteins form insoluble complexes that provoke colloidal instability in the final beer. Also, the active oxygen species act in non-biological oxidation process, they increase the haze formation (colloidal instability) and they are the most important cause of the staling of flavor development (flavor instability). On the other hand, the flavor instability is determined by endogenous antioxidant activity of beer itself, which is affected by each step in the brewing process.
- Two different methodologies are available for evaluating beer aging. The first requires analytical methods to detect the compounds responsible for these flavors and enable quantitative determination. The second implies trained sensory panel to assess the beer flavor.
- Chromatographic techniques have been used to determine aldehydes, ketones and esters relevant in beer aging. Some of these compounds are responsible for the initial

stale flavor of beer ("sweetish leathery character" and "papery cardboard character").

- ESR spectroscopy technique have been utilized to detect and to identify the free radicals coming from active oxygen species. These free radicals are responsible for flavor instability due to oxidation of beer. The results obtained with ESR have proved that the SO_2 is the only one able to delay the radical formation.

- The measurement of the capacity of beer constituents to capture free radicals is recognized as TAA. The UV–Vis spectrophotometry is the technique more widely applied to determine the TAA through the addition of an exogenous free radical and measurement of the decrease in absorbance. This methodology evaluates the cooperation among endogenous antioxidants of beer during oxidative stress.

- The reductones (a type of antioxidants) have been determined indirectly by voltammetric methods. With this methodology it is possible to evaluate the reducing power of different type of beers. The changes observed during beer storage have been assessable by chemiluminiscence. These changes produced patterns that show a good correlation with the degree of stale flavor in panel scores.

- Sensory analysis performed by trained sensory panel, is necessary to complete the data obtained by analytical methods. The results of sensory analysis provide semiquantitative information about beer quality. The methodology is based on difference and descriptive tests and the testers score the individual attributes of beers.

- The development of artificial sensors, such as EN and electronic tongue, is a promising direction to evaluate the process of aging and spoilage of beers. The advantages of this methodology are the rapidity (analysis on-site or on-line), the accurate analysis for quality control, and the inexpensive and simple instrumentation and in the present, these sensors are the complement to the traditional chemical and sensory analysis.

Use of Electrospray Ionization Mass Spectrometry to Fingerprint Beer

Rodrigo R. Catharino Thomson Mass Spectrometry Laboratory, Institute of Chemistry, State University of Campinas, UNICAMP, Campinas, SP, Brazil
Alexandra C.H.F. Sawaya Program for Post-graduate Studies in Pharmacy, Bandeirante University of São Paulo, UNIBAN, São Paulo, SP, Brazil
Marcos N. Eberlin Thomson Mass Spectrometry Laboratory, Institute of Chemistry, State University of Campinas, UNICAMP, Campinas, SP, Brazil

Abstract

Mass spectrometry constitutes one of the most encompassing instrumental techniques in science, widely applied in the fields of chemistry, biology, medical science and technology. Direct insertion electrospray ionization mass spectrometry (ESI-MS) is a fast and sensitive method which differentiates diverse types of beer, in both positive and negative ion modes, characterizing their main constituents. Although the basic ingredients of beer (water, malt, hops and yeast) have not changed much since the dark ages, variations in these ingredients and in the manufacturing process result in diverse types of beer. The spectra or fingerprints of each type of beer permit not only the separation of samples according to their main characteristics, but also further information through the ESI-MS/MS fragmentation of the diagnostic ions of each type, adding another dimension to the analytical results. Fast and characteristic beer fingerprint mass spectra were obtained by ESI-MS in both the negative and positive modes. A total of 29 samples of ale produced in Brazil and other countries were divided into three groups by visual analysis of the positive [ESI(+)-MS] and negative [ESI(−)-MS] mode fingerprints as well as by chemometric analysis of the data. Many of the marker ions in both modes were found to be simple sugars and oligosaccharides, although their intensities varied depending on the type of ale (pale colored, dark colored and sweetened). This shows that direct infusion ESI-MS could distinguish between samples of ale with different compositions and is promising as a fast and efficient method of beer characterization.

List of Abbreviations

APCI	Atmospheric pressure chemical ionization
CO	Carbon monoxide
CO_2	Carbon dioxide
CI	Chemical ionization
CID	Collision-induced dissociation
D	Dark beer
DIOS	Desorption ionization on silicon
EI	Electron ionization
ESI	Electrospray ionization
ESI-MS	Electrospray ionization mass spectrometry
ESI-MS/MS	Electrospray ionization with sequential (tandem) mass spectrometry
ESI(+)-MS	Positive ion mode electrospray ionization mass spectrometry
ESI(−)-MS	Negative ion mode electrospray ionization mass spectrometry
FAB	Fast atom bombardment
GABA	δ-Aminobutyric acid
H_2O	Water
ICP–AES	Inductively coupled plasma atomic emission spectrometry
IEM	Ion evaporation model
M	Malt beer
MALDI	Matrix assisted laser desorption ionization
MS	Mass spectrometry
$[M + H]^+$	Protonated molecule
$[M − H]^-$	Deprotonated molecule
$[M + K]^+$	Potassium adduct of a molecule
$[M + Na]^+$	Sodium adduct of molecule
m/z	Mass to charge ratio
NH_3	Ammonia
P	Pale beer
PCA	Principal component analysis
RCM	Residual charge model
TOF	Time of flight

Introduction

Recent advances in instrumentation and development of new and revolutionary techniques have revitalized mass spectrometry (MS) which constitutes one of the most

encompassing instrumental techniques in science, widely applied in the fields of chemistry, biology, medical science and technology. Opening new horizons and ample perspectives for future development, MS has consolidated its position as an extremely versatile and essential scientific tool for both fundamental and applied research. In the field of beverages, MS has been increasingly applied with excellent results for complex compositions such as beer.

Direct insertion electrospray ionization mass spectrometry (ESI-MS) is a fast and sensitive method which differentiates diverse types of beer, characterizing their main constituents. The spectra or fingerprints of each type of beer permit not only the separation of samples according to their main characteristics, but also further information through the ESI-MS/MS fragmentation of the diagnostic ions of each type, adding another dimension to the analytical results. As ESI-MS shows such great potential for the analysis of different types of beer, it can be applied to both research and development as well as quality control during the manufacturing procedure and in the final product.

Manufacturing and Composition of Beer

Beer is an aqueous solution of complex composition containing CO_2, ethyl alcohol, several inorganic salts and multiple organic compounds. Inorganic salts come primarily from the brewing grains (such as barley and other cereals) and water. The mineral composition of water in natural reservoirs depends on the minerals found in the region. In areas where rocks are harder, water will not penetrate through them into the soil, therefore will be "softer" with a lower concentration of dissolved salts. Many of the organic compounds come from the brewing materials but others are by-products of yeast metabolism and are responsible for most of the flavor characteristics that are so unique to beer.

The most important stages of beer processing are malting, brewing and fermentation, followed by maturation, filtering and bottling (Hardwick, 1995). During the malting and mashing procedures that produce the wort, polysaccharides and starches from the cereals are hydrolyzed to low molecular weight sugars (such as glucose, sucrose and maltose) as well as malt oligosaccharides (consisting of 3–10 glucose units). Most of the low molecular weight sugars are converted into alcohol during the fermentation process, whereas maltotetraose and higher oligosaccharides are not fermented by most yeast strains (Berlitz et al., 2004; Mauri et al., 2004).

Beers throughout the world have distinctive tastes, although brewed from similar materials, their uniqueness comes from the mineral content of the water used, small variations in the ingredients employed and differences in the brewing methods. In a strict sense, there are two classical beer styles, ales and lagers. Ales are fermented using *Saccharomyces cerevisiae* in a process frequently denominated "high fermentation" at temperatures normally between 16°C and 24°C. Lagers are fermented using a different species of yeast and at lower temperatures (Berlitz et al., 2004). Commercially available brands of beer in Brazil are produced exclusively by the high fermentation process, therefore are all ales. Three different types can be found: pale colored ales, dark colored ales and sweetened dark-colored ales known as malt beer.

At the present time, beer is produced in modern high technology equipment, although many traditional artisan concepts are taught in renowned beer master courses. The use of modern analytical techniques, which are fast and efficient, will permit the optimization of the manufacturing process, resulting in a higher quality product.

Chemical Characterization of Beer

The characterization of beer samples according to their mineral content has been carried out using inductively coupled plasma atomic emission spectrometry (ICP–AES) in 32 samples of lager, dark and low alcoholic content beers (Alcázar et al., 2002). Several papers relate the identification of classes of compounds in beer by ESI-MS associated with liquid chromatography (Hofte et al., 1998; Degelmann et al., 1999; Whittle et al., 1999) and capillary electrophoresis (Klampfl et al., 2002). Recently, the sugars in beer were analyzed directly by ESI-MS, without previous chromatographic separation (Mauri et al., 2004).

ESI is a soft and wide-ranging ionization technique that has revolutionized the way the molecules are ionized and transferred to mass spectrometers for mass and property measurements as well as structural characterization. ESI has therefore greatly expanded the applicability of MS to a variety of new classes of molecules with thermal instability, high polarity and mass (Cole, 1997). Although ESI mass (and tandem or sequential mass) spectrometry has been most successfully applied to the analysis of biomolecules (Kotiaho et al., 2000; Cooks et al., 2001; Rioli et al., 2003), ESI-MS has also been proven to be a powerful technique for the structural characterization of organic, inorganic and organometallic compounds. Direct infusion ESI-MS has also been applied as a fast fingerprint method for complex mixtures such as plant extracts, propolis and wine (Catharino et al., 2006). ESI, with direct sample introduction, is also a convenient technique for the direct introduction of beer into a mass spectrometer, as most molecules bearing acidic or basic sites will be detected and MS/MS with collision-induced dissociation (CID) of ionized molecules can be used for structural elucidation studies.

Mass Spectrometry

According to John B. Fenn, Nobel prize winner in 2002 and pioneer in the use of ESI-MS for biological molecules, MS is "The art of measuring atoms and molecules to
Figure 92.1 Schematic drawing of an electrospray ionization, triple quadrupole, mass spectrometer. Samples are introduced via the capillary, where molecules are ionized and transferred to the gas state through the electrospray process, which are attracted into the mass spectrometer through a difference in potential. The nitrogen gas between the orifice and nozzle prevents the entrance of neutral molecules into the mass analyzer (Q1). To obtain the dissociation patterns of marker compounds, these are mass selected in Q1, dissociated by collision against a gas in Q2 and the fragments analyzed in a second mass analyzer (Q3).

determine their molecular mass. This mass information is often sufficient, frequently necessary and always useful for determining the identity and structure of a compound. To carry out this art, a charge is added to sample of interest (analyte). The trajectory of the resultant ion is then measured under vacuum, under diverse electronic and magnetic fields. In this way, the basic condition for this method is the transformation of molecules into ions. The ionization of low molecular weight compounds is rapidly carried out in the gas phase by the collision of the neutral molecules with electrons, photons or other ions. In the last years, various researchers have made efforts toward producing ions from high molecular weight compounds (>1000 Da) which are too complex to be vaporized without decomposing."

Mass spectrometers have been described as the smallest scales in the world, not due to the size of the equipment, but due to the fact that it "weighs" molecules. For the last decade, mass spectrometry has gone through great technological advances, permitting its application to the analysis of proteins, peptides, carbohydrates, DNA, drugs and several other relevant biological molecules. Using ionization sources such as electrospray ionization (ESI) and matrix assisted laser desorption ionization (MALDI), mass spectrometry has become an irreplaceable tool in biological

science, for example. Mass spectrometers determine molecular weight of ions by measuring their mass to charge ratio (m/z). The same basic components are found in practically all mass spectrometers (Figure 92.1). After introducing the sample, ions are formed by the loss or gain of an electric charge, when parting from a neutral molecule. Once the ions are formed, they are directed toward a mass analyzer (molecular scale), by a difference in potential, where they are separated according to their m/z relation and finally detected (Siuzdak, 2005).

There are different kinds of ionization sources, such as electron ionization (EI), chemical ionization (CI), fast atom bombardment (FAB), matrix assisted laser desorption ionization (MALDI), desorption ionization on silicon (DIOS), atmospheric pressure chemical ionization (APCI) and electrospray ionization (ESI), used in the following study.

Electrospray ionization mass spectrometry

The principle of ESI-MS is the transference of ions existing in solution directly to the gas phase, in a mild manner. This versatility has significantly increased the number of substances that can be analyzed by mass spectrometry, permitting polypeptides, which would be instable in the analytic

conditions necessary for EI or CI, to be analyzed without decomposing. ESI involves forming an electrolytic spray of a solution, which produces electrically charged droplets, from which the ions are then liberated. The structure of an ESI source is quite simple, compared to other sources for mass spectrometry. A source of high voltage (1.0–7.0 kV) in contact with a solution containing polar substances is necessary. This solution is pumped through a micro-capillary (i.e. 50 to 100 μm) at a flow rate of 1–20 μl/min, or less (at flow rates of less than 1 μl/min, it is usually called nanoelectrospray). When a positive potential is applied to the solution, the positively charged ions tend to move away, toward a less positively charged region, that is, toward the counter electrode. Therefore, the droplet formed at the tip of the capillary is enriched with cations. As the charge density increases in the droplet, the electric field formed between the capillary and the counter electrode causes a deformation of the droplet in contact with the capillary tip. The droplet becomes cone shaped and called a Taylor cone. This cone-shaped droplet remains "stuck" to the tip of the capillary until the charge density and the repulsion between the ions present in the droplet overcome the surface tension, resulting in small, highly charged droplets breaking away from the tip of the capillary. The frequency of this process depends on the magnitude of the electric field, the surface tension of the liquid and the conductivity of the solution (Cole, 1997).

As reported above, electrospray can generate ionic species through an electrolytic process, similar to an electrolytic cell with two electrodes. The metal capillary, or a metallic wire in contact with the solution, is one of the electrodes of the cell, which can be considered the work electrode, because the main reactions which alter the initial chemical system occur on its surface. The second electrode is the counter electrode, which is usually earthed. Due to the difference of potential applied and the closeness of these two electrodes, there is a high electric field in this region, resulting in the Taylor cone. The electrospray system functions as a special type of electrolytic cell, because movement of ions between electrodes does not happen without interruption in the solution, as in conventional cells, but part of it happens in the gas phase (Cole, 1997).

After the highly charged droplets are liberated from the Taylor cone and pass through the region between the tip of the capillary and the counter electrode, they go through dessolvation. The mass of solvent in the droplets is reduced by evaporation, aided by a flow of inert dessolvation gas, normally nitrogen, at a temperature between 30°C and 100°C. As the amount of solvent in the droplet decreases, the charge density increases to the point where the repulsion between ions overcomes the surface tension and smaller droplets are formed. This process is known as Columbic explosions and is illustrated in Figure 92.2. The maximum charge, Q, which a drop with a ray of R can maintain before fragmenting into smaller droplets is given by equation 92.1:

$$Q = 8\pi(\varepsilon_0 \gamma R^3)^{1/2} \qquad (92.1)$$

where ε_0 is the permissiveness in space and γ is the surface tension of the drop. This deduction was proposed by Lord Rayleigh and is known as the Rayleigh limit. The dessolvation process has been studied by various groups, for example, Tang and co-workers observed that the droplets do not necessarily have to reach the Rayleigh limit to break up (Russel, 1994). Rupture actually occurs at around 80% of the limit, resulting in droplets with 2–3% of the mass of
Figure 92.2   Schematic drawing of the Taylor cone on the tip of the capillary (ESI source) and the Columbic explosions forming smaller droplets. The accumulated charges on the tip of the capillary result in the Taylor cone, and the expulsion of small, highly charged droplets, which through Columbic explosions form even smaller droplets.

the original drop, but containing 10–18% of the original charge. In this way, the droplets formed are much smaller but have a much higher *m/z*.

Two models of mechanisms for the final transfer of the ions to the gas phase have been proposed. One was proposed by Dole in 1968 and named the residual charge model (RCM), and depends on the formation of extremely small charged droplets, generated by successive Columbic explosions, containing only one ion. When the solvent evaporates, the ion will be left alone in the gas phase. The other mechanism, proposed by Thomson and Iribarne, named the ion evaporation model (IEM), suggests that the emission of ions occurs directly from these small, highly charged droplets, from which the ions are ejected due to the electrostatic repulsion between ions of the same charge.

After they are formed, the ions reach the sampling cone, which has a very small orifice with a diameter of $1\,\mu$m, and then pass into a low pressure area. At the atmospheric pressure/vacuum interface, a series of pumps and optical lenses lead the ions to the mass analyzer. The region between the sampling cone, the skimmer and the lenses or hexapoles is very important for, in this area, CID can occur. The ions formed by electrospray are present, along with the drying gas (nitrogen). There is a difference of potential which accelerates these ions, leading to a physical collision with the drying gas. Therefore, if a solvated ion enters this area, it can collide and fragment. The CID process is interesting in fragmentation studies, but it can make visualization of the species that were in the original solution difficult. To minimize the CID effect, the difference in potential between sampling cone and the skimmer must be reduced.

The CID process used in tandem or sequential mass spectrometry (MS/MS) has an important role in the structural determination of ions and the analysis of complex mixtures. Used together with ionization such as FAB, MALDI and ESI, which generate ions with high molecular mass but with little or no fragmentation, the activation and dissociation of the molecules by CID furnish fragmentation patterns that give important structural information about the ions, frequently necessary for their identification and characterization. The CID process can be considered as a two-step process: activation through collision, where a fraction of the kinetic energy of the ion (M_1) is transferred to its internal energy, followed by the uni-molecular dissociation of the internally excited ion. This process is illustrated in equations 92.2 and 92.3.

$$M_1^+ + M_2 \rightarrow M_1^{+*} + M_2 \qquad (92.2)$$

$$M_1^{+*} \rightarrow M_3^+ + M_4 \qquad (92.3)$$
Raftery and Geczy (2002) used the technique of low energy CID together with ESI and MALDI for the study of polypeptides with cross-linking bonds with protonated sulfonamides, proving, through the observed dissociations, the formation of sulfonamide links through the oxidative processes which resulted between thiols and amines, which can both stabilize or modify the function of the protein. Williams *et al.* (2003) used CID in a high precision ESI–TOF system for the sequencing of a mixture of peptides. Biological molecules have been successfully analyzed through electrospray systems and (MS/MS) (Cooks *et al.*, 2001; Koch *et al.*, 2002; Rioli *et al.*, 2003). This system permits molecules, such as peptides for example, which would not be stable in EI or CI conditions, to be analyzed without decomposing. ESI-MS has also been applied to the identification and structural characterization of organic (Eberlin *et al.*, 2003), inorganic and organometallic compounds, precursors of nanomaterials and identification of nanoclusters (Gaumet and Strouse, 2000).

A series of electrochemical processes occur during ESI, the importance of these processes in relation to this ionization source and the advances toward a better understanding of the process were the subjects of discussions between researchers such as la Mora, Fenn, Cole, Enke, Berkel and Martinez-Sanchez (Cole, 2000; de la Mora *et al.*, 2000). For an ion accelerated by a voltage *V*, the resulting speed of *v* relates to its mass/charge (*m/z*) ratio. In time of flight (TOF) mass analyzers, ions are separated according to their TOF and the mass/charge ratio is determined by measuring the time taken to complete a given distance (*L*) to the detector. These variables are correlated in equation 92.4:

$$m/z = 2eEs(t/L)^2 \qquad (92.4)$$

where *E* is the extraction pulse, *s* is the length of the tube on which *E* is applied, *t* is the TOF measured for the ion. In this way, all the ions receive the same initial kinetic energy through the extraction pulse (*E*) and then fly along the tube with length (*L*) where they are separated according to their *m/z*, as the lighter ions take less time to reach the end. One advantage of TOF mass analyzers is their sensitivity, resulting from two instrumental characteristics: high transmission rates – due to the lack of ray defining fends and separation of ions by TOF – which, differently form spatial separation, does not direct some of the ions away from the detector. In view of the advances in the data acquisition instruments, it is possible to acquire spectra referring to the total mass range analyzed. The resolution of the TOF mass analyzers can be increased by the use of reflectrons or ion mirrors, with the function of compensating for differences in the initial kinetic energy of identical ions. After passing through the tube, the ions go into a retardation field, defined by a series of grids and they are turned back into the tube. The principle behind the reflectron is that the ions with the greatest kinetic energy will penetrate more deeply in this retardment field, taking more

time to return to the tube, whereas those with less energy (but the same mass) will penetrate less, and finally both will reach the detector simultaneously. The reflectron results in a loss of signal due to the grid, therefore gridless reflectrons are being developed.

Fingerprinting samples with a complex composition

The ease with which ESI-MS provides spectra of samples with a complex composition in a short time (few minutes) in an ample *m/z* range, where each spectrum has unique characteristics, permits the use of ESI-MS as a fingerprinting technique. ESI-MS has been used as fingerprinting system for: the analysis of molecular species of triacylglycerols extracted from lipids (Hans and Gross, 2001), the analysis and characterization of 52 synthetic substances with the application of principal component analysis (PCA) to determine the differences and similarities within the compounds used in the pharmaceutical industry (Schoonjans *et al.*, 2002), the analysis of ethanolic extracts of different types of propolis from different geographic regions, providing spectra containing diagnostic ions for each type (Sawaya *et al.*, 2004), the analysis of subproducts resulting from the chlorine added to potable water (Zhang *et al.*, 2004), proof of authenticity and origin of whisky samples, being able to prove if a sample is false or authentic in a matter of minutes (Möller *et al.*, 2005) and in the analysis of different samples of beer, separating them into classes, identifying the diagnostic ions for each type, with MS/MS analysis of the characteristic ions adding a further dimension to the fingerprints obtained (Araújo *et al.*, 2005).

Mass Spectrometry Fingerprinting of Beer

The advantages offered by ESI-MS permit this technique to be used in different areas, including analysis of beer, as reported above. This was the first study where the ESI-MS fingerprints of different types of beer, the classification of the samples according to their main diagnostic ions and the study of these diagnostic ions were carried out. The following procedure was standardized: 10 ml of the beer sample was placed in a 100 ml beaker and placed in an ultrasonic bath, to de-gas the sample, with minimum loss of volatile substances. The choice of this procedure was based on the reproducibility of the ESI-MS fingerprints obtained, considering the quantity and the intensity of the ions. A solution can contain ions resulting from dissolution (of salts, for example), by adding a proton ($[M + H]^+$) or subtracting a proton ($[M - H]^-$) from a neural molecule, or by forming complexes with cations, anions, acidic or basic compounds of a wide variety of molecular masses. A Q-TOF mass spectrometer (Micromass, Manchester, UK) was used for fingerprint ESI-MS analysis. The conditions used were: source temperature 100°C, capillary voltage 3.0 kV and cone voltage used 40 V. An aliquot of 250 µl of each de-gassed beer sample was diluted in a flask with a 1:1 solution of water:methanol to a final volume of 1.0 ml. In positive mode analysis [ESI(+)-MS] 2 µl of formic acid was added to each sample and in negative mode analysis [ESI(−)-MS] 2 µl of ammonium hydroxide solution were added. The samples were infused at a flow rate of 15 µl/min using a syringe pump (Harvard Apparatus). Mass spectra were acquired over a *m/z* range of 50–1000.

Although beer has a complex composition, direct insertion ESI-MS, without previous chromatographic separation, proved to be a convenient technique for the analysis of beer. In beer, many molecules possess acidic or basic sites, can be observed in the fingerprint as a singly charged ion of the monoprotonated $[M + H]^+$ or deprotonated $[M - H]^-$ form. Several different makes and varieties of beer were selected and analyzed, to obtain fingerprints in both the positive and negative ion modes, containing a set of diagnostic ions which are characteristic for each type of beer. The variability observed in the diagnostic ions results from variations in the raw materials used as well as the fabrication process. The storage conditions and the age of the beverage can also influence the composition of the samples, that is, the presence absence of determined substances; therefore, the Brazilian samples of beer were analyzed within 1 or 2 months of fabrication, which is the normal shelf life of beer in supermarkets. The samples of beer from other countries were between 4 and 6 months old (Araújo *et al.*, 2005). The type of beer, brand name and place of origin of the beer samples can be seen in Table 92.1.

The visual analysis of the fingerprints obtained by ESI-MS in both the positive [ESI(+)-MS] and negative ion [ESI(−)-MS] modes, and the observation of the most intense ions, permits the division of these beer samples into three distinct groups, corresponding to three well-defined beer types, being: P = pale (lager, pilsner, draft); D = dark (bock, stout, dunkel) and M = malt (malt beer).

Positive ion mode fingerprints

In the positive ion mode fingerprints, substances can be observed as protonated neutral molecules, or adducts of cations found in the solution. Figure 92.3a shows a typical ESI(+)-MS fingerprint for a pale (P) beer with intense ions observed in the *m/z* range from 70 to 705. Several similarities can be observed with Figure 92.3c, presenting a typical fingerprint for dark (D) beer; however, some ions are absent or present with different intensities. As to Figure 92.3b, presenting a typical fingerprint of malt beer, no ions can be observed in the region above *m/z* 400. This type of beer is known for its sweet taste, resulting from the addition of sugar and caramel, which give the beer its dark color and reduce the bitter taste of hops.

Table 92.1 Origin, brand name and abbreviation used for the samples of beer analyzed

Origin	Brand name	Abbreviation
Brazil	Schincariol	P1

To derive more information from the fingerprints, the most intense ions were fragmented by CID. The resulting MS/MS fragmentation patterns were analyzed and compared with standards and data in literature, resulting in the identification of diagnostic ions such as sugars and maltose oligomers, among others. Therefore, in Figure 92.3a, the fingerprint of pale beer, the ions of m/z 365, 527 and 689 are the sodium adducts $[M + Na]^+$ of maltose, maltotriose and maltotetraose, respectively, whereas m/z 381, 543 and 705 are the potassium adducts $[M + K]^+$ of the same carbohydrates. Similar to the pale (P) beers, the dark (D) beers also present the potassium adducts of these carbohydrates. It is interesting to note that in the dark beers, only the potassium adducts (m/z 381, 543 and 705) are clearly visible in the fingerprint, and the sodium adducts are practically imperceptible. This demonstrates the capacity of ESI-MS fingerprinting to show the concentration ratio of $[K^+]/[Na^+]$ in D and P type beers. Dark beers have a more intense ion of m/z 219 (which is the potassium adduct of glucose) in their fingerprints than in pale beer. For malt (M) beer fingerprints the most intense ions are m/z 203, 219, which the MS/MS fragmentation patterns show to

be the sodium and potassium adducts of glucose, respectively, and a potassium adduct of a dimer of glucose at m/z 399. The potassium and sodium adducts of the other malt oligosaccharides are not observed in the fingerprint of malt beer. Considering that malt beer differs from pale beer mainly in respect to the addition of sugar and caramel at the end of the manufacturing process, clearly the presence of large amounts of glucose inhibits the detection of the other malt oligosaccharides due to matrix suppression. In ESI-MS, matrix suppression results from the presence of more and less polar substances in the same droplet. This suppression can occur as the result of competition between different components to become ionized, competition to reach the surface of the droplet, differences in the polarity of the compounds resulting in different solvation effects, among others (Annesley, 2003).

Other ions present in the fingerprints are m/z 163 and 325, referent to anhydrohexose and a potassium adduct of a dimer of anhydrohexose, respectively. Ions of m/z 116 and 118 are present in all spectra, and for the dark beers m/z 116 is the base peak (the most intense ion present). According to their MS/MS and searches in the NIST database, compared to substances known to be present in beer, m/z 116 is probably the protonated amino acid, proline, and m/z 118 a protonated amino acid with the formula $C_5H_{11}NO_2$ (2-amino-3-methylbutanoic acid). The MS/MS of the intense ion of m/z 104 shows neutral losses that may correspond to NH_3, H_2O, CO and CO_2, and typical fragmentation may be attributed to GABA, δ-aminobutyric acid.

Negative ion mode fingerprints

The presence of ions in the negative mode fingerprints is due to the abstraction of protons from neutral molecules with the aid of ammonium hydroxide, as well as adducts of the neutral molecules with anions present in solution. The negative ion mode [ESI(−)-MS] fingerprints show a large variety of ions, which was to be expected, given the low pH value of this beverage. Acid compounds ionize preferably in the negative ion mode. As observed previously in relation to the positive ion mode fingerprints, the ESI(−)-MS fingerprints separate the samples into three groups, which correspond to the main types of beer. Figure 92.4a shows a fingerprint of a typical pale (P) beer sample. The most intense ions appear in the m/z range between 75 and 925. The most intense ions of m/z 161, 179, 341, 503, 665 and 827 correspond to the deprotonated forms of anhydrohexose, glucose, maltose, maltotriose, maltotetraose and maltopentaose (respectively) as determined by their MS/MS. Pairs of anions of m/z 377 and 379, 539 and 541, 701 and 703 are the chloride adducts of maltose, maltotriose, and maltotetraose (typical isotopic pattern of 3:1 between $_{35}Cl$ and $_{37}Cl$). Other intense ions present in the fingerprint that are characteristic of pale beer are m/z 439 (adduct of m/z
Figure 92.3 Positive ion mode electrospray mass spectrometry fingerprints of beer. *Source*: Adapted from Araújo *et al.* (2005). ESI(+)-MS mass spectra characteristic of (a) pale colored ale, (b) malt beer and (c) dark colored ale. Differences in the presence and intensity of the positively charged ions observed in the fingerprints are the result of differences in composition between these types of beer.

ESI(–)-MS mass spectra characteristic of (a) pale colored ale, (b) malt beer and (c) dark colored ale. Differences in the presence and intensity of the negatively charged ions observed in the fingerprints are the result of differences in composition between these types of beer.
Figure 92.5 Statistical grouping of beer samples according to their positive ion mode fingerprints. *Source*: Adapted from Araújo *et al.* (2005). Scores of principal component analysis of the positive ion mode fingerprints ions of the 29 samples of beer (for abbreviations see Table 92.1). Samples were clearly grouped according to their type (P = pale, M = malt beer, D = dark).

259 with glucose), *m/z* 601 (adduct of *m/z* 259 with maltose) and *m/z* 763 (adduct of *m/z* 259 with maltotriose). *m/z* 259 itself is an adduct of *m/z* 79 with maltose.

Figure 92.4b shows the typical ESI(−)-MS fingerprint of malt beer (M). As noted before, the addition of caramel during the manufacturing process of this type of beer makes the ion of *m/z* 179 (deprotonated glucose) the base peak of the fingerprint, followed by the chloride adducts of glucose at *m/z* 215 and 217. The ion of *m/z* 359 appears only in fingerprints of malt beer and is the dimer of deprotonated glucose. Once again, the effect of matrix suppression in relation to the ions corresponding to the other oligosaccharides can be observed.

The fingerprint of a typical sample of dark (D) beer can be observed in Figure 92.4c, which is quite similar to that of pale beer (Figure 92.4a), with the high mass ions in lesser intensity and the pair of ions of *m/z* 161 and 179, standing out. As with pale beer, *m/z* 161 corresponds to deprotonated anhydrohexose and *m/z* 179 to deprotonated glucose. Other characteristic ions for this dark beer are *m/z* 255 and 683, the latter is the dimer of deprotonated maltose (Araújo *et al.*, 2005).

Statistical Analysis of Results

Simple sugars and oligosaccharides stand out in the positive and negative fingerprints of beer, while the relative intensity of marker ions varies according to the type of ale analyzed. This variability made the grouping of samples according to their composition possible in both ion modes, as well as other characteristic ions, mainly in the lower mass range

of 50–200. Statistical analysis of results by PCA permitted the clear grouping of samples according to the results in both the negative and positive ion modes. Data matrixes were constructed using the information of the mass spectra obtained in both ESI(+)-MS and ESI(−)-MS modes. The groups formed by the 20 major peaks of each of the 29 samples analyzed were the variables. The exploratory data analysis was applied to the data matrix constituted by the 29 samples (as the rows) and this group of variables (as the columns). Einsight and Pirouette, both from Infometrix (Seattle, WA), were used to perform the PCA using Mean Center as data pre-treatment.

Figure 92.5 shows a scatter plot of PC1 and PC2 from the data matrix obtained from positive mode fingerprints. In this case, PC1 has 42% and PC2 has 27% of the variance. The pale colored ales are placed on the right side of the figure while the dark colored ales and Malzbier are divided in two groups on the left side. For the pale ales the variables that characterize them are the ions of *m/z* 70, 118, 206, 258 and 325. For malt beer the most influent variables are the ions of *m/z* 70, 203 and 219. For dark colored ales the most important ions are *m/z* 116, 381 and 399. Most of these ions stand out in the positive mode fingerprints and have already been discussed.

In the negative mode, chemometric analysis also divides the samples in three groups (Figure 92.6); PC1 has 57% and PC2 has 17% of the variance in the original data matrix. The pale colored ales are on the right side of the figure but divided into two subgroups. Most Brazilian samples (P1, P2, P3, P4, P5, P11, P12) are in one while the foreign samples and one Brazilian sample (P6) are in another. The
Figure 92.6 Statistical grouping of beer samples according to their negative ion mode fingerprints. *Source*: Adapted from Araújo *et al.* (2005). Scores of principal component analysis of the negative ion mode fingerprints ions of the 29 samples of beer (for abbreviations see Table 92.1). Samples were clearly grouped according to their type (P = pale, M = malt beer, D = dark).

ions that have the most influence on the grouping of these samples are the ions of *m/z* 79, 97, 101, 128, 133, 161, 191, 259, 341 and 363. The samples of dark ales and malt beer are found on the left side of the figure and the most influent ions for dark ales are *m/z* 59, 161, 221, 341 and 377. For malt beer, the most important ions are *m/z* 89, 179, 215, 217 and 277.

Simple sugars and oligosaccharides stand out in the positive and negative fingerprints of beer, while the relative intensity of marker ions varies according to the type of ale analyzed. This variability made the grouping of samples according to their composition possible in both positive and negative ion modes.

The results obtained showed that ESI-MS fingerprinting, both in the negative and positive ion modes, is a fast, robust and selective method for high throughput screening of beer samples. PCA was a useful tool for the grouping of samples and the identification of marker ions for each type of sample. Further studies are being undertaken to identify other beer components that influence the taste and odor of this beverage.

Acknowledgment

Summary Points

- Mass spectrometry constitutes one of the most encompassing instrumental techniques in science, widely applied in the fields of chemistry, biology, medical science and technology.
- A brief review of the theoretical basis of mass spectrometry and ESI is presented.
- Direct insertion ESI-MS is a fast and sensitive method which differentiates diverse types of beer, characterizing their main constituents.
- Further information about the composition and type of beer can be obtained through the ESI-MS/MS fragmentation of the diagnostic ions of each sample.
- A total of 29 samples of ale produced in Brazil and other countries were divided into three groups by visual analysis of the positive [ESI(+)-MS] and negative [ESI(−)-MS] mode fingerprints as well as by chemometric analysis of the data.
- Many of the marker ions in both modes were found to be simple sugars and oligosaccharides, although their intensities varied depending on the type of ale (pale colored, dark colored and sweetened).
- A statistical analysis of results, PCA, confirmed the visual evaluation of the MS beer fingerprints obtained.

Methods for the Characterization of Beer by Nuclear Magnetic Resonance Spectroscopy

A.M. Gil Department of Chemistry-CICECO, University of Aveiro, Campus de Santiago, 3810-193 Aveiro, Portugal
J. Rodrigues Department of Chemistry-CICECO, University of Aveiro, Campus de Santiago, 3810-193 Aveiro, Portugal

Abstract

The use of high-resolution nuclear magnetic resonance (NMR) spectroscopy in the characterization of beer is described, making reference to site-specific natural fractionation (SNIF) NMR methods, NMR characterization of beer extracts and, finally, of whole beer. Qualitative analysis of specific components in beer usually requires the tandem use of NMR and other analytical techniques for sample extraction/concentration and complementary characterization. For whole beer, a range of newly developed NMR-based methods have been applied, showing promise in widening the range of detectable compounds and lowering detection limits. NMR quantitative analysis has also been applied successfully for specific compound families in beer extracts and in whole beer. Practical applications accommodating large sample numbers require the use of multivariate analysis and the existing applications of this strategy are reviewed.

List of Abbreviations

Ala	Alanine
DOSY	Diffusion ordered spectroscopy
GABA	γ-Aminobutyric acid
His	Histidine
HPAEC-PAD	High-performance anion-exchange chromatography with pulsed amperometric detection
Ile	Isoleucine
IRMS	Isotopic ratio mass spectrometry
LC	Liquid chromatography
Leu	Leucine
MALDI-TOF MS	Matrix-assisted laser desorption/ionization-time of flight mass spectrometry
M_r	Molecular mass
MS	Mass spectrometry
NMR	Nuclear magnetic resonance
PCA	Principal component analysis
Phe	Phenylalanine
PLS	Partial least squares
Pro	Proline
RT	Retention time
SNIF	Site-specific natural fractionation
TOCSY	Total correlation spectroscopy
Tyr	Tyrosine
Un.	Unassigned
Val	Valine

Introduction

The characterization of the chemical composition of beer and its relation to quality is of great importance for efficient quality control and to improve the properties of the final product. The complex chemical composition of beer depends on many factors including water quality, malt, hop, yeasts and the precise recipe and timing of the brewing process. An adequate characterization of chemical composition might, thus, give important indications about the nature and history of the beer sample and have significant implications for the quality control of the product.

Nuclear magnetic resonance (NMR) spectroscopy is a technique of increasing promise in the chemical characterization of complex mixtures such as beer, wine, fruit juices and many other foodstuffs. NMR is based on the magnetic moments of some atomic nuclei (e.g. the nuclei of ^{1}H, ^{13}C, ^{15}N) which enable them to reorient when exposed to a fixed external magnetic field and absorb radiofrequency energy (Table 93.1). The exact value of the radiofrequency absorbed is exquisitely dependent on the chemical environment of the nucleus in a molecule, so that each compound gives, in the case of proton (^{1}H) NMR, a well-defined set of ^{1}H absorption peaks. In addition, the intensity of each absorption peak reflects the number of nuclei therefore

Table 93.1 Summary of principles and some applications of NMR spectroscopy

Principle	NMR is based on the magnetic moments (μ) of some atomic nuclei (e.g. the nuclei of ^1H, ^{13}C, ^{15}N) which enable them to reorient when exposed to a fixed external magnetic field (B_0) and absorb radiofrequency energy. The exact value of energy absorbed depends on the chemical environment of the nucleus in a molecule, hence, each compound gives, in the case of proton (^1H) NMR, a well-defined set of ^1H absorption peaks.
Some applications	• Determination of chemical structure and quantitation of compounds in solution. • Determination of secondary and tertiary structures of proteins in solution. • Determination of chemical structure and molecular interactions in the solid state. • Determination of overall compositional profile in complex mixtures. • Determination of product origin for quality control.

enabling quantitative as well as qualitative studies. The principles and methods of NMR spectroscopy are described in detail in several publications (Harris, 1983; Derome, 1987).

NMR-based methods have long been recognized as valuable in the monitoring of quality of many alcoholic drinks and beverages. The first applications involved the use of site-specific natural isotope fractionation (SNIF) NMR. This technique measures the isotopic ratios, for example D/H or $^{12}C/^{13}C$ of ethanol by NMR (Cordella *et al.*, 2002). These ratios are very sensitive to many aspects of the history of the drink: geographical origin, specific materials and methods employed. An alternative approach is the recording of high-resolution NMR spectra of abundant nuclei such as ^1H, a method which has the ability of simultaneously detecting several families of compounds over a wide range of concentrations ($> \mu$molar). This has, traditionally, been applied to the detection of particular compounds or families of compounds in concentrated food extracts, however, an increasing number of applications for the direct analysis of foods has been noted in the last few years. Requiring minimal or no sample preparation, a direct high-resolution NMR spectrum of a complex mixture such as beer or wine presents the challenge of interpretation of multiple compound profiles in one spectrum. Spectral assignment normally relies on the so-called bidimensional (or 2D) NMR methods to disentangle spectral information to some extent but, when

the analysis of large sample numbers is considered, the use of multivariate analysis methods is required. Indeed, the richness of information made available in direct 1D and 2D NMR spectra of a mixture poses the problem of extensive signal overlap and, hence, great difficulty in extracting fully detailed compositional information, particularly for a large number of samples. The tandem use of NMR and multivariate analysis methods such as principal component analysis (PCA) or partial least squares (PLS) regression enables large sample groups to be tackled and meaningful compositional variations to be detected. This approach has been the basis of numerous NMR-based methods for classification and origin determination of foods (Belton *et al.*, 1998; Sacchi *et al.*, 1998; Le Gall *et al.*, 2001; Brescia *et al.*, 2002; Charlton *et al.*, 2002; Košir and Kidrič, 2002; Brescia *et al.*, 2003; Duarte *et al.*, 2004), providing the possibility of pinpointing specific compounds responsible for the occurrence and/or intensity of a particular property of the final product.

NMR Applications to the Study of Beer

SNIF NMR of beer

Isotopic ratios such as D/H, $^{12}C/^{13}C$, $^{16}O/^{18}O$ found in naturally occurring molecules are not constant and depend on biochemical pathways and reaction mechanisms. In food science, this has been exploited to assign the origin of food components and, hence, detect food adulteration (Rossmann, 2001). This strategy is now routinely applied in the wine industry, mainly with basis on D/H measurements by ^2H NMR and often used in tandem with other methods (e.g. isotopic ratio mass spectrometry (IRMS)). In the case of beer, a limited number of applications have been carried out, to our knowledge. ^2H NMR has been applied to beer to determine the origin of malt from several grain species (Martin *et al.*, 1985). Also, the D/H ratio of the methylene group in beer ethanol and the $^{16}O/^{18}O$ ratio of beer water have been suggested to correlate to regional origin. The D/H and ^{13}C abundance values have been measured by NMR and MS, respectively, for the ethanol from a set of commercial beers, as well as ethanol from grain spirit, beet sugar and wheat malt (Rossmann, 2001). The authors of this work noted the narrow range of D/H values and ^{13}C abundance observed for beers from different regions within the same country (Germany).

High-resolution NMR of beer extracts

This section summarizes the work carried out so far on the analysis of beer extracts by NMR, often in tandem with other analytical techniques. Many of these studies have addressed the characterization of the carbohydrate constituents of beer. The most abundant carbohydrates in beer are those derived from starch during the mashing step (Baxter and Hughes, 2001) with the resulting wort containing

glucose, maltose, some branched non-fermentable dextrins and some residual straight-chain dextrins. Beer also contains non-starch polysaccharides such as arabinoxylans and β-glucan which, although depolymerized to some extent, remain present in beer and may be the cause of undesirable precipitation and filtration problems. An early study of barley β-D-glucan has been carried out by ^{1}H and ^{13}C NMR and resulted in the assignment of several oligosaccharides produced by the treatment of barley flour with a fungal β-D-glucanase (Bock *et al.*, 1991).

A 1D and 2D NMR study, in tandem with matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI-TOF MS), on chromatographically separated carbohydrate fractions of beer has resulted in the identification of several new derivatives of trehalose, sucrose, maltooligosaccharides and linear glucose oligomers with α(1→3) and α(1→4) linkages (Vinogradov and Bock, 1998). The same work comprised a study of the branching pattern of beer dextrins by enzymatic degradation and subsequent NMR analysis. Beer arabinoxylans have also been investigated using NMR methods (Bock *et al.*, 1991; Broberg *et al.*, 2000; Ferré *et al.*, 2000). One of these studies describes the characterization of nanomole amounts of arabinoxylan oligosaccharides, fractionated by high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD) (Broberg *et al.*, 2000). This was achieved by a specific NMR probe adapted for measurement of low sample amounts by the use of a smaller diameter NMR tube and magic angle spinning technology. The authors employed a range of 2D NMR experiments for the detailed assignment of oligosaccharides in the samples. Figure 93.1 shows the anomeric regions of the ^{1}H NMR spectra of arabinoxylan subfractions obtained firstly by size-exclusion chromatography (UF4, UF5 and UF6) and further fractionated by HPAEC-PAD (fractions a to e). Some NMR assignments are shown for fractions UF5, demonstrating the specificity of the method. The same NMR tools were used for the characterization of the substrate preference and specificity of an arabinoxylan arabinofuranohydrolase newly isolated from germinated barley (Ferré *et al.*, 2000). More recently, water-soluble high molar mass arabinoxylans from barley have been obtained by size-exclusion fractionation and characterized by ^{1}H NMR, amongst other techniques (Dervilly *et al.*, 2002).

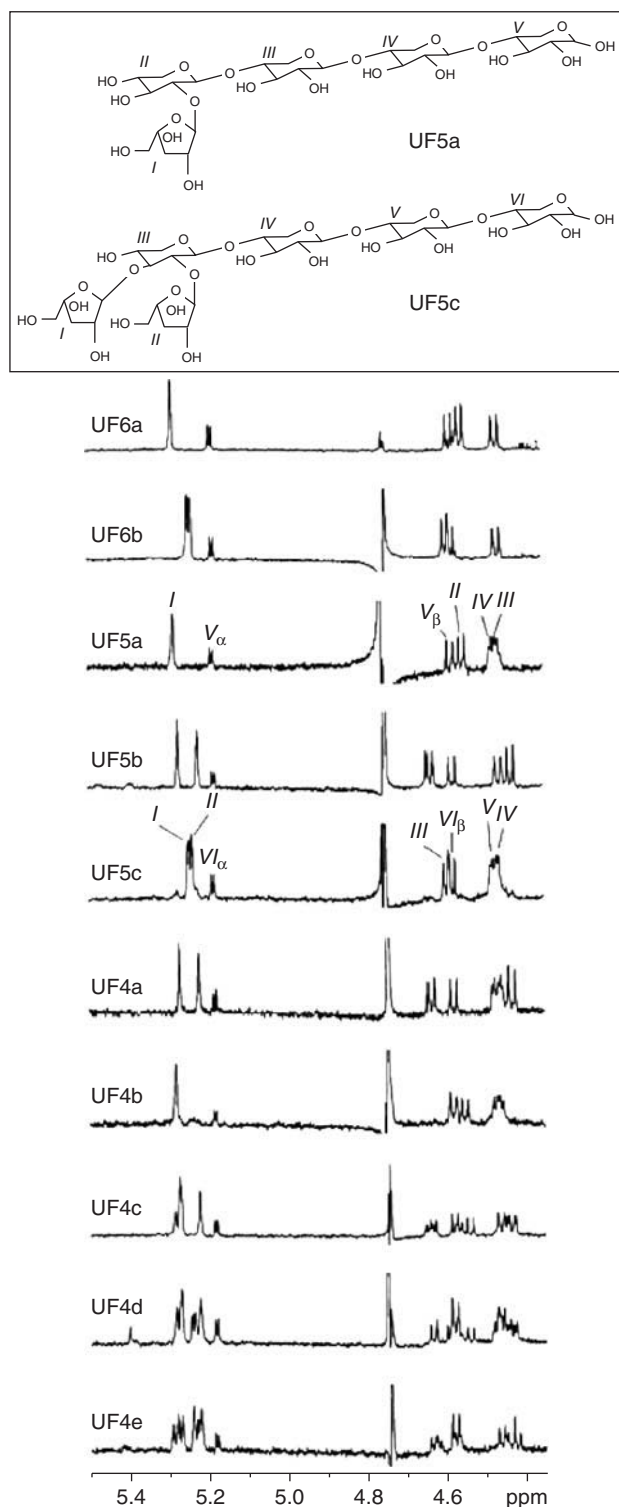
Since hops determine the taste and flavor of beer, the analysis of hop components and their derivatives is of great importance in the brewing industry. The major components responsible for bitterness are the hop bitter acids: the α- and the β-acids. During brewing, the former give rise to iso-α-acids and these and their derivatives are known to impart the typical bitter taste of beer. NMR characterization of α-acids, iso-α-acids and their reduced products (isohumulones) has been achieved by several ^{1}H and ^{13}C NMR studies of hop extracts as well as of standard compounds (Pusecker *et al.*, 1997; Pusecker *et al.*, 1999,


Figure 93.1 Anomeric regions of 1D ^{1}H NMR spectra of arabinoxylan subfractions. The anomeric regions of 1D ^{1}H NMR spectra of subfractions UF6a–b, UF5a–c and UF4a–e (arabinoxylan fractions) recorded with 256 scans at 500 MHz with a 4-mm ^{1}H-observe nano NMR probe on approximate sample amounts between 3 and 26 nmol (3 and 18 μg, respectively). The assignments of some characteristic signals of the novel oligosaccharides in subfractions UF5a and UF5c are indicated in the figure (reprinted from Broberg *et al.* (2000); Copyright 2000, with permission from Elsevier).
Figure 93.2   LC-NMR contour plots for a CO_2 hop extract and for isohumulones. LC-NMR contour plots with NMR projection (left side) of (a) CO_2 hop extract: 1 = co-humulone, 2 = humulone, 3 = ad-humulone, 4 = unknown, 5 = colupulone, 6 = lupulone, 7 = adlupulone; (b) isohumulones: 1 = *trans*-iso-co-humulone, 2 = *cis*-iso-co-humulone, 3 = *trans*-isohumulone, 4 = *trans*-iso-ad-humulone, 5 = *cis*-iso-humulone, 6 = *cis*-iso-ad-humulone (reprinted from Pusecker *et al.* (1999); Copyright 1999, with permission from Elsevier).

Hoek *et al.*, 2001; Nord *et al.*, 2003). The qualitative analysis of these compounds was shown to benefit greatly from the on-line coupling of LC with NMR (LC-NMR), as shown by a study of hop extracts and isohumulones in which unambiguous identification of many components was achieved (Pusecker *et al.*, 1999). Figure 93.2 shows the LC-NMR plots obtained for a CO_2 hop extract and for isohumulones. In another study, the components of isohumulone mixtures have been fully characterized by ^1H and ^{13}C NMR (Nord *et al.*, 2003). Following initial quantitative NMR studies for these compounds, to aid in hop extract analysis and standardization (Pusecker *et al.*, 1997), an improved quantitative NMR method has been proposed based on the integration of selected signals in the NMR spectrum (Hoek *et al.*, 2001). In an attempt to better control beer properties related to hops, a method for predicting the acidity of iso-α-acids in beer based on ^{13}C NMR was proposed (Friedrich and Galensa, 2002). Indeed, a relationship between ^{13}C chemical shift and iso-α-acids acidity was found, enabling the estimation of the solubility and stability properties of these compounds.

Many compounds other than carbohydrates and hop acids play extremely important roles in beer quality, and the value of NMR spectroscopy to detect many different compound types simultaneously has been recognized as useful for rapid beer evaluation. This approach has been applied to 2-butanol beer extracts (Khatib *et al.*, 2006), making use of multivariate analysis, namely PCA, to detect differences in the aromatic compounds present. It was shown that PCA applied to 2D *J*-resolved NMR spectra gave good separation between the extracts of different beers. Such separation was interpreted in terms of the contents of nucleic acid derivatives, amino acids, organic acids, alcohols, cholines and carbohydrates.

Other works on beer extracts have used a different perspective, exploiting hops as potential source of new bioactive compounds and using NMR for structural determination (Chadwick *et al.*, 2004; Stavri *et al.*, 2004). For instance, a bioassay-guided fractionation of a hexane hop extract was carried out in order to identify antimycobacterial constituents, using the mycobacterial species *Mycobacterium fortutium* (Stavri *et al.*, 2004). Another example is the full NMR characterization of the constituents of a hop extract obtained by supercritical CO_2 separation, aiming at identifying compounds with estrogenic activity (Chadwick *et al.*, 2004).

Attempting to investigate the role of specific components on the brewing process, an NMR study has enabled the identification of a new flavanol glucoside from barley and malt (Friedrich and Galensa, 2002) and the evaluation of its quantitative change during malting. This type of compound is believed to be involved in the formation of beer haze and, possibly, also in beer flavor stability. A different and more practical approach was taken to measure NMR T_2 relaxation times, which reflect molecular mobility, for mash, spent grain suspensions, worts and carbohydrate solutions, to investigate a possible correlation with the rheological properties of such systems (Gotz *et al.*, 2003).
Figure 93.3 Typical 1D ^{1}H NMR spectrum of whole beer. Typical 1D ^{1}H NMR spectrum of a whole beer sample after degassing in an ultrasound bath for 10 min. The sample was inserted into an NMR tube with 10% D_2O and 0.02% TSP-d_4 (sodium 3-(trimethylsilyl)propio nate-d_4), as a reference for ^{1}H chemical shift (δ). The inserts show vertical expansions of the high field (right) and low field (left) regions of the spectrum and some assignments are shown (Phe, Tyr, His correspond to the 3-letter codes of phenylalanine, tyrosine and histidine).

The authors concluded that the characteristic viscosities of those materials may be measured through NMR T_2, in relatively short times and avoiding, in some cases, the errors of conventional rheometric methods.

High-resolution NMR of whole beer

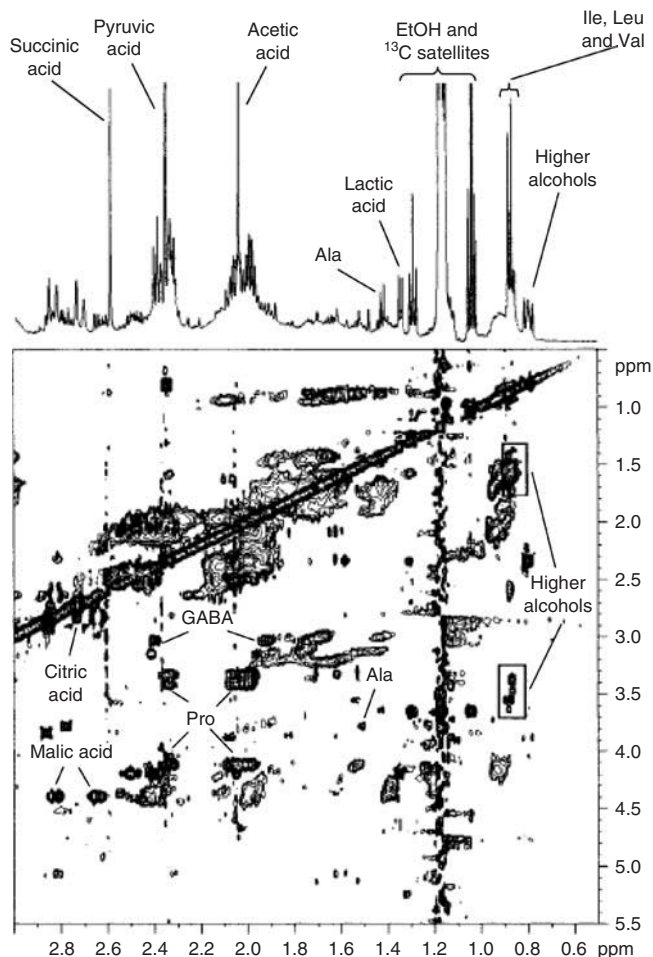
The direct characterization of beer by NMR presents the attractive feature of being simple, rapid and non-invasive since the only sample preparation required is degassing for a few minutes. Figure 93.3 shows a typical ^{1}H NMR spectrum of intact beer, where the high number of peaks is clear, as is the problem of signal overlap in all regions of the spectrum. Overlap with broad components is evident in all regions reflecting the presence of large M_r compounds, as well as the expected mixture of low M_r compounds. Over the past few years, a number of strategies have been applied to attempt (1) the continuously increasing assignment of new compounds in intact beer and (2) to find a user-friendly method for spectral interpretation and analysis of large numbers of samples, for practical use to be made of the methods. The first approach for disentangling 1D ^{1}H NMR information is to carry out 2D NMR experiments. These experiments spread the 1D information in 2D and, the use of a range of different experiments based on homonuclear (^{1}H/^{1}H) (Figure 93.4) and heteronuclear (usually, ^{1}H/^{13}C) correlation, have enabled the assignment of about 30 compounds in intact beer (Duarte *et al.*, 2003a). However, when sample complexity is high, such as in beer, this does not suffice and complementary methods are required. Hyphenated methods such as LC-NMR have proven useful, not only for the analysis of beer extracts but also for intact beer (Duarte *et al.*, 2003a; Duarte *et al.*, 2003b; Gil *et al.*, 2003). Making use of the addition of an MS dimension, in the form of LC-NMR/MS, has enabled the identification of many


Figure 93.4 Expansion of a 2D homonuclear (^{1}H/^{1}H) correlation NMR spectrum recorded for whole beer. Expansion of a 2D total correlation spectroscopy (TOCSY) spectrum recorded for whole beer. The 1D NMR projection is shown at the top and some assignments are shown at the bottom. Ala, Ile, Leu, Pro and Val correspond to the 3-letter codes of alanine, isoleucine, leucine, proline and valine; GABA correspond to γ-aminobutyric acid.
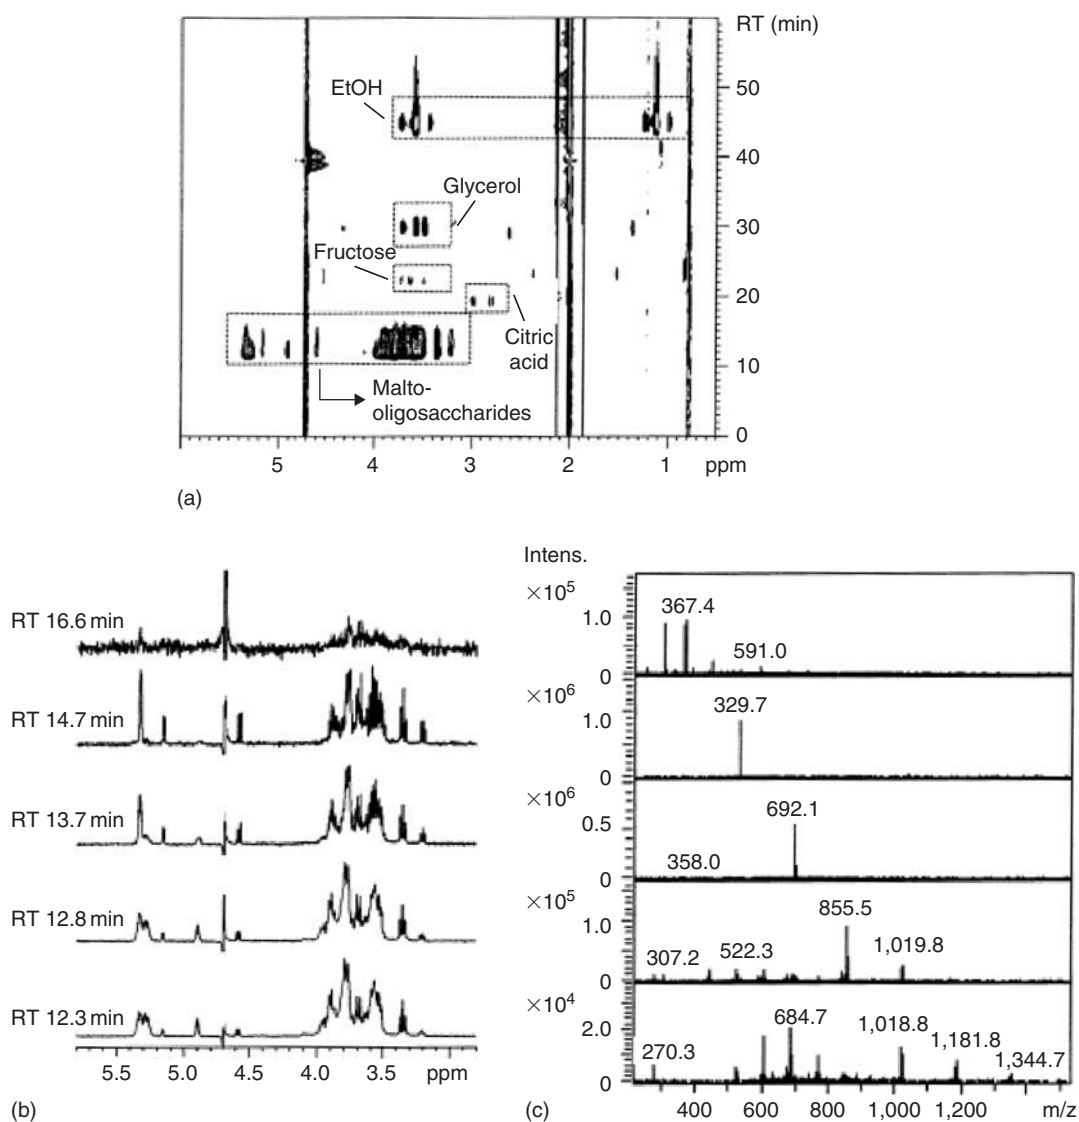

Figure 93.5 LC-NMR plot, selected NMR spectra and corresponding MS spectra obtained for an ale beer. (a) LC-NMR on-flow record obtained for an ale beer (whole sample). aromatic compounds and of oligosaccharides differing in size and branching degree. Figure 93.5 shows the LC-NMR plot obtained for a beer, using an ion-exchange resin. Examples of the ^{1}H NMR spectra taken across the LC-NMR plot are shown, together with the corresponding MS spectra. Their analysis enabled several oligosaccharide fractions to be characterized in terms of average size and degree of branching. Another NMR-based tool of great value for the qualitative analysis of beer is diffusion ordered spectroscopy or DOSY, a technique which results in a representation of 1D NMR spectra as a function of compound diffusivity. This leads to a 2D plot such as that shown in Figure 93.6. In spite of signal overlap not allowing accurate diffusivity information to be obtained, the

DOSY method presents considerable promise for (1) identification of both low and high M_r compounds through the knowledge of their diffusivity properties and (2) detection of unexpected interactions or bonding between different moieties, detected through their common diffusivity. Comparison of the DOSY spectra of different beers has enabled a clearer picture of the aromatic composition to be obtained, unveiling new compounds for which molecular size could be estimated and some evidence of slow-diffusing polyaromatic species (Gil *et al.*, 2004).

The aid offered by multivariate analysis for NMR interpretation and tackling large sample groups has become increasingly clear over the last few years. The work carried out has mainly employed PCA and some applications have comprised
Figure 93.6 Typical 2D DOSY plot obtained for a whole beer sample. Some assignments are shown for lower and higher M_r compounds. Amino acids are identified by their 3-letter codes; Un: unassigned compound.

Figure 93.7 PCA of the sugar regions (3.1–5.8 ppm) of the ^1H NMR spectra of a set of beers. Results of PCA of the sugar regions (3.1–5.8 ppm) of the ^1H NMR spectra of a set of beers: (a) scores scatter plot of PC1 vs. PC2 for spectra processed with line broadening 10 Hz and (b) corresponding PC1 loadings profile. Labels A, B and C indicate different brewing sites situated in different countries; for each site, beers produced in different dates are shown as: (◆) A1, (■) A2, (▲) A3; (◇) B1, (□) B2, (△) B3 and (*) C1, (−) C2, (+) C3. Grouping shapes were drawn manually in the scores scatter plots to aid the eye. Negative and positive PC1 values correspond, respectively, to signals from branched dextrins and from glucose and linear dextrins.

the separation of beer samples in terms of type: ales, lagers and alcohol free (Duarte *et al.*, 2002; Duarte *et al.*, 2004). Beer types were found to differ particularly in terms of their aromatic composition, as a reflection of the different types of fermentation procedures employed. In addition, the NMR/PCA method enabled sample groups differing in carbohydrate composition to be identified. In a subsequent work, the high throughput of a flow injection NMR system has been used and PCA of the NMR spectra of a large set of beers showed that (1) beers from barley malt may be distinguished from those from wheat malt, (2) beers from the same brewing sites tend to cluster together and (3) beers with some degree of deterioration may be identified (Lachenmeier *et al.*, 2005). The effect of different brewing sites on the composition of beer has been further investigated through the NMR/PCA strategy (Almeida *et al.*, 2006), indicating that considerable compositional changes affect some organic acids, dextrins and aromatic compounds, even when beer type and recipe are, in principle, kept unchanged. This should reflect fine differences in hardware setup, materials and even local uses and culture. Figure 93.7 shows an example of the separation of lager beers produced in different countries (sites A, B and C), in terms of their dextrin characteristics. This opens the possibility of using NMR and multivariate analysis for the rapid monitoring of the brewing process.

Besides PCA, PLS also has found useful applications in the analysis of beer (Nord *et al.*, 2004; Lachenmeier *et al.*, 2005). This method has been used to calibrate the NMR method against specific reference methods and this has been applied to the quantitation of organic and amino acids in intact beer (Nord *et al.*, 2004) and to the determination of reference parameters such as original gravity or ethanol and lactic acid contents (Lachenmeier *et al.*, 2005). A short review has recently summarized the use of state of the art NMR in several issues of beer production and characterization (Duus, 2005).

Summary Points

- NMR spectroscopy is perhaps the most powerful method for the full structural analysis of compounds in concentrated extracts; in this respect, applications to beer comprise mainly the study of hop components and of carbohydrates.
- New NMR technology like nano-probes or hyphenated techniques have promising potential for extract analysis at low nanomolar concentrations and for unveiling structurally similar compounds.
- Direct NMR analysis of intact beer has added attractiveness for simple and rapid applications at the industrial level.
- Direct qualitative analysis is made possible by exploiting state of the art methods like hyphenated NMR and DOSY.
- Handling of large-sample groups with a view to routine practical applications requires the use of multivariate analysis for NMR interpretation and validation of results; PCA and PLS regression are powerful tools applied until now for the discrimination of beers according to several different parameters.

Methods for the Vibrational Spectroscopy Analysis of Beers

Salvador Garrigues and Miguel de la Guardia Department of Analytical Chemistry, University of Valencia, Valencia, Spain

Abstract

The main possibilities and drawbacks of vibrational spectroscopy techniques, infrared (both in the middle and near infrared ranges) and Raman, for the analysis of beers have been reviewed taking into consideration methods proposed in the scientific literature for the determination of as many as possible compounds and parameters of beers. Details about the procedures available and comments on the future developments in this field have been based on the experience of authors and extended checking of the characteristics of the procedures published till now.

Introduction

Vibrational spectroscopy covers a vast wavenumber range, from 12,500 to $10\,cm^{-1}$, between the visible and the microwave frequencies and offers interesting information about the transitions between the fundamental and excited vibrational stages of molecules.

Infrared (IR) and Raman spectroscopy are the main vibrational techniques and, on considering IR, middle infrared (MIR) and near infrared (NIR) must be evaluated separately with regard to functional differences in instrumentation and nature of the bands obtained from the interactions between IR radiation and molecules.

Nowadays, based on the developments in instrumentation and software for data treatment, vibrational spectroscopy has become an important tool for quantitative analysis in addition to its traditional applications in qualitative analysis.

Taking into consideration the aqueous nature of beer samples and the tremendous absorption of water in the MIR and NIR ranges, it is clear that old filter-based and dispersive instruments and classical materials used to build cells were scarcely suitable to obtain data about these samples. However, the new developments in fast techniques based on diode array detectors and Fourier transform-based instruments offer exciting possibilities to cumulate hundreds of scans per spectrum in a short time and thus provide an excellent signal-to-noise ratio, absolutely necessary to obtain spectra in the presence of water as a solvent and/or matrix.

The possibilities offered by vibrational spectrometry to measure transmission and reflectance modes together with its flexibility to obtain spectra from solid, liquid, and gas samples, can be considered as their major advantage for applied analysis (Cadet and de la Guardia, 2000).

However incorporation of flow analysis (FA) strategies to the measurements in both, IR and Raman, increases clearly the features of the procedures based on vibrational spectrometry, increasing the speed and precision of
Figure 94.1   Transmittance NIR spectra of water, an ethanol standard, a maltose standard and regular beer using air as a reference.

determinations and reducing drastically the reagent's consumption and waste generation, thus, contributing to the development of environment friendly methodologies (Garrigues and de la Guardia, 2002).

In this chapter, we will consider the main applications that can be found in the literature for the analysis of beers by IR and Raman spectroscopy, and we will look to the future developments in this field.

Vibrational Spectra of Beers

The water content of beers is approximately 90–92% m/m, so the characteristic vibrational spectra of beers are strongly dominated by water and affected by the contribution of two other main constituents: ethanol and carbohydrates.

We can consider maltose as the representative carbohydrate in beers because it is the major sugar in malt and cereals used in the brewing process and the main building block for dextrins.

Briefly, to interpret vibrational spectra of beers it is necessary to consider the spectra of water, ethanol, and maltose.

In the NIR interval between 700 and 2,500 nm (approximately 18,285–4,000 cm^{-1}), water presents four intense absorption bands which increasing order of intensity correspond to 970 nm a combination band ($2\nu_1 + \nu_3$), 1,200 nm combination band ($\nu_1 + \nu_2 + \nu_3$), 1,450 nm corresponding to

($\nu_1 + \nu_3$), and 1,930 nm due to the combination ($\nu_1 + \nu_2$), where ν_1 is the vibration corresponding to symmetric stretching mode, ν_2 the bending mode, and ν_3 an asymmetric stretching one (Maeda *et al.*, 1995). For a pathlength of 0.2 mm, the band at 1,930 nm presents an absorbance intensity of approximately 1.1 absorbance units, whereas the absorbance at 1,450 nm is around 0.25 units. Pathlengths higher than 3 mm provide a saturation of the aforementioned two bands as can be seen in Figure 94.1, which corresponds to NIR spectra obtained by transmittance measurements in a glass vial with an optical pathlength of 6.5 mm. Under these conditions, water bands at 1,200 and 970 nm can be clearly seen.

Figure 94.1 also shows the NIR spectrum of ethanol and maltose standards and the signal corresponding to a regular beer. It can be appreciated that in the region between 1,550 and 1,800 nm water absorbs less than ethanol, maltose, and beer. For a pathlength equal or lower than 1 mm, this behavior can also be observed in the region between 2,000 and 2,400 nm. Then, if we use water as a reference apart from a complete transparency below 1,350 nm, the aforementioned two spectral windows can be used for determination of ethanol and maltose.

The spectral range between 1,550 and 1,820 nm is shown in Figure 94.2a, in which the characteristic spectra of ethanol, maltose and those of three different types of beer can be observed: regular, low-alcohol content (below 1% v/v) and alcohol-free beer. As it can be seen, ethanol presents
Figure 94.2 Transmittance NIR spectra using water as a reference.

a band at 1,570 nm whereas maltose occurs at 1,590 nm. Both bands correspond to the first overtones of the OH vibration of alcohols. Approximately 1,700 nm bands corresponding to first overtones of CH stretch-vibration can be seen. For ethanol, bands at 1,684 and 1,692 nm are due to the first overtone of the two —CH₃ asymmetric stretching modes and bands at 1,714 and 1,729 nm to the —CH₂— and —CH₃ asymmetric stretching, respectively, whereas maltose exhibits a wide band probably due to the highly varying environment of the different CH bands within the carbohydrate molecule (Adachi *et al.*, 2002).

In the region between 2,200 and 2,400 nm, three peaks for ethanol – 2,260, 2,300 and 2,350 nm – can be observed. Maltose exhibits a broad band between 2,050 and 2,200 nm that can be assigned to combination bands of the OH vibrations of alcohols. Two less intense peaks are present around 2,280 and 2,320 nm.

Water presents a high absorption in the middle range (4,000–300 cm⁻¹), and because of that the pathlength value used for transmission measurements markedly affects terribly the spectra obtained.

Water has two intense bands around 3,400 and 1,600 cm⁻¹, which correspond to fundamental vibrations of —OH groups. Owing to the high absorbance of water in the MIR, attenuated total reflectance (ATR) technique or transmittance with a pathlength of the order of 0.01–0.05 mm are required to obtain an adequate transparent region using water as a reference. Figure 94.3 shows ATR spectra of water, also for ethanol, maltose standards and a regular beer.

Spectra shown in Figure 94.3 is evidence of the differences between ethanol, beer and maltose as compared with water in the regions around 3,000 and 1,000 cm⁻¹. Inset figures correspond to MIR spectra obtained using a blank
Figure 94.3   ATR-MIR spectra of water, an ethanol standard, a maltose standard and regular beer using air as a reference. Inset figures: detailed selected regions of the spectra using water as a reference.

of water. As it has been indicated in the Introduction section of this chapter, Fourier transform-based spectrometers enable a fast recording of the whole spectrum and final spectra is obtained by accumulating a significant number of scans to increase the signal-to-noise ratio.

It can be appreciated that both, ethanol and maltose, present absorption bands in the selected regions: ethanol strongly absorbs at 877, 1,052 (phase C—C—O stretch), 1,086, 2,850, 2,900 and 2,970 cm^{-1}, whereas maltose shows several overlapping bands ranging from 998 to 1,155 cm^{-1}, also the bands at 2,850 and 2,900 cm^{-1}.

As compared with the NIR region, the MIR ethanol and maltose spectra present an important degree of overlap and thus, for direct analysis of beer, the use of derivative spectra and/or chemometric data treatment is necessary.

Figure 94.4 shows typical ATR–FTIR (Fourier transform infrared) spectra of ethanol and maltose standards, and those of three different beer samples (alcohol-free, low content and regular), all of them in absorbance mode together with the first- and second-order derivative signals. It is noticeable how ethanol can be then clearly distinguished from the maltose contribution.

Raman spectroscopy has been proposed for the analysis of ethanol in beverages (Galloway, 1992; Mendes *et al.*, 2003; Nordon *et al.*, 2005) and also in ethanol-fuel

(Mendes *et al.*, 2003), because Raman spectrum of ethanol presents well-defined emission bands.

The most important Raman band of ethanol is presented at 883 cm^{-1} shift and corresponds to the symmetric C—C—O stretching. Other typical bands are located at 1,097 cm^{-1} (CH_3 bending), 1,053 cm^{-1} (asymmetric C—C—O stretching), 1,276 cm^{-1} (CH_2 wagging) and 1,455 cm^{-1} (C—OH bending). Additionally, three bands are present between 3,000 and 2,800 cm^{-1} corresponding to CH stretching modes. As compared with Raman spectra of beers, the main signal differences are due to the contribution of maltose, also providing in some cases a shift of the spectral baseline due to the sample fluorescence.

Vibrational Analysis of Beers

Traditional techniques such as NIR, MIR or Raman spectroscopy could be applied to the determination of the main analytes present in beers.

It is clear that, based on the characteristic bands present in untreated samples reported in the previous section, analytes such as ethanol or maltose could be determined directly in previously degassed samples by transmittance or reflectance measurements.
Figure 94.4 Selected regions in the ATR spectra: zero order, first derivative and second derivative.

In this section, we will detail the methodology found in the literature for beer analysis based on the selection of the most appropriate bands in zero-order or first-order spectra and the use of external calibrations built from pure standard solutions or previously analyzed samples.

We have not considered the multivariate-based calibration techniques, which will be commented in the next section devoted to chemometric methods.

NIR spectroscopy

Table 94.1 summarizes papers found in the literature concerning transmission, reflectance, or transflectance measurements in the NIR range.

The main part of studies concern the determination of ethanol (Coventry and Hunston, 1984; Halsey, 1985; Gallignani *et al.,* 1993; Luo and Liu, 1998; Schropp *et al.*, 2002; Engelhard *et al.*, 2004) or ethanol and maltose (Gallignani *et al.*, 1994a), ethanol and extract (Schropp *et al.*, 2002) or ethanol and original gravity (Halsey and Buckee, 1985).

Beer samples, previously analyzed, are used to look for specific bands in the NIR, suitable for ethanol determination; and Coventry and Hunston (1984), established that absorbance measurements at 1,386 nm in the zero-order spectra and measurements at 1,672 nm in the first-order

derivative were the most adequate for direct determination of ethanol; it was confirmed that first derivative data provided the best regression coefficient and the lowest standard error for analysis of samples not used to build the calibration.

However, Halsey (1985) confirmed that transmittance measurements provide more accurate results for ethanol determination than transflectance ones.

We confirmed that using peak-to-valley measurements between 1,680 and 1,703 nm in the first derivative spectra of degassed beers, an accurate determination of ethanol in the range 0.3–25% v/v, with a limit of detection of 0.1% v/v and using aqueous standards of ethanol for calibration (Gallignani *et al.*, 1993) can be done.

The aforementioned results were extended to the determination of both maltose and ethanol, using zero-order measurements at 1,414 nm and 1,693 nm (with a baseline established between 1,657 and 1,720 nm), respectively, a limit of detection of 0.07% v/v ethanol using water as a reference being obtained. However, the use of a 4.5% m/v maltose solution as a reference offers a simplified procedure for ethanol determination with a sampling frequency of 120 h^{-1} (Gallignani *et al.*, 1994a).

Luo and Liu (1998) also proposed external calibration with pure ethanol standards in water and the use of water as a blank for determination of ethanol up to 24% v/v

Table 94.1 NIR methods employed for beer analysis

Measurement mode instrument	Data treatment calibration	Analyte	Band/spectral range considered	Figures of merit	Comments	Reference
Dispersive (transmission) Varian Cary 500	Linear regression 5 ethanol/water standards (water as a reference)	Ethanol	1,692 nm (ethanol) and 1,719 nm (maltose presents the same absorption than 1,692 nm)	DR = 0–8% v/v LD = 0.07% v/v Correlation coefficient = 0.9995 (34 samples)	• Pathlength = 10 mm, resolution = 1 nm • Interpretative difference spectroscopy: measurement of the difference at two wavelengths • Valid for normal and low-alcohol content beers	Engelhard et al. (2004)
Dispersive (transmission) Anton Para Analyzer	Instrument calibration with water and a 10% v/v ethanol solution	Alcohol Real extract Original extract	1,150–1,200 nm	DR = 0.01–14.40% v/v, P = 0.02% v/v, R^2 = 0.9997 DR = 2.03–11.35% m/m, P = 0.01% m/m, R^2 = 0.9999 DR = 4.78–28.30% m/m, P = 0.02% v/v, R^2 = 0.9997	• Samples degassing by shaking and filtration • Analysis of 119 samples and comparing results obtained with those obtained by a distillation reference method • Original and real extract calculations require the determination of density using the DMA 4500 (Anton Paar)	Schropp et al. (2002)
Dispersive transmittance	External calibration Water as a blank	Ethanol	Absorbance at 1,382 + 1,691 + 1,730 nm	DR = up to 24% v/v P (n = 6) = 2.5–4%	• Sample diluted to 25 ml • Multiwavelength overlapping spectrometry	Luo and Liu (1998)
Dispersive transmittance (b = 10 mm) Perkin Elmer Lambda 9	External calibration using water as a reference	Ethanol Maltose	1,693 nm (baseline 1,657–1,720 nm) for ethanol 1,414 nm for maltose	For ethanol LD = 0.07% v/v P = 0.2% (regular beers) and 2.0% (low-alcohol beers)	• Degassing by filtration • Stopped flow strategy for a fast filling and cleaning of measurement cell • Comparison of different baseline corrections	Gallignani et al. (1994a)
	Simplified stopped flow method using 4.5% m/m maltose as reference	Ethanol		P = 0.5% (regular beers) and 1.1% (low-alcohol beers) Sampling frequency: 120 h^{-1}		
Dispersive transmittance Perkin Elmer Lambda 9	Simple regression External calibration: ethanol/water standards	Ethanol	First derivative Peak to valley lecture between 1,680 and 1,703 nm	DR = 0.3 – 25% v/v LD = 0.1% v/v P = 0.3%	• Sample degassing by filtration	Gallignani et al. (1993)
Transmittance Transflectance		Ethanol Original gravity			• Direct analysis of beers by NIR • Transmittance measurements more accurate than transflectance ones • Presented at the European Brewing Committee 20th Congress, Helsinki	Halsey and Buckee (1985)
Transmittance Neotec 6350 MKII (Pacific Scientific Gardner)	Absorbance and first derivative Beer samples: 30 for calibration and 114 for prediction	Ethanol	1,100–2,500 nm (30 scans per sample) Absorbance: 1,386 nm 1st derivative: 1,672 nm	Absorbance: SEC = 0.86, SEP = 1.08, R = 0.82 First derivative: SEC = 0.29, SEP = 0.54, R = 0.99	• Degassing by filtration	Coventry and Hunston (1984)

b, pathlength; DR, dynamic range; LD, limit of detection; P, precision; R, coefficient of regression; SEC, standard error of calibration; SEP, standard error of prediction.

using the sum of the absorbance data obtained at 1,302 + 1,691 + 1,730 nm in zero-order spectra.

Engelhard *et al.* (2004) have proposed the use of the technique called interpretative difference spectroscopy to compare the absorbance of ethanol and maltose at 1,692 nm with that of maltose at 1,719 nm. A limit of detection of 0.07% v/v is obtained using a pathlength of 10 mm with a series of five external standards of ethanol in water.

It can be concluded that NIR permits the direct measurement of ethanol in all types of beers without the need of a previous distillation or the use of multivariate calibrations.

MIR spectroscopy

Simple regression and external calibration from MIR spectra have been proposed for the determination of ethanol (Gallignani *et al.*, 1994b, c; Maudoux *et al.*, 1998; Gallignani *et al.*, 2005; Armenta *et al.*, 2006), maltose (Gallignani *et al.*, 1994c), dissolved CO_2 (Wilks, 1988) and oils (Skinner, 1996); the possibilities to determine carbohydrates (Haberkorn *et al.*, 2002) by using the standard addition approach is also evident.

For details about methods employed for MIR analysis of beers see Table 94.2. In the case of CO_2 determination, in-line measurements can be made by ATR measurements obtained at 4.26 μm (Wilks, 1988).

The method proposed for oils in beers is based on data at 2,930 cm^{-1} after beer filtration through polytetrafluoroehylene (PTFE) membranes or stirring with diatomeus earth followed by extraction with freon (Skinner, 1996), thus providing a methodology comparable to that employed for oil and grease determination in waters. It is interesting to note that contents up to 0.2 mg/l oil were found in beers, probably due to contamination from engines used in the brewing process.

Preliminary studies about ethanol determination were based on transmission measurements using 0.029 mm pathlength cells and first-order derivative measurements between 1,052 and 1,040 cm^{-1} after smoothing of the signals; a limit of detection of 0.025% v/v is reported (Gallignani *et al.*, 1994b). The aforementioned limit of detection provides a good tool for the analysis of low-alcohol content beers for which a maltose correction by measurements between 1,160 and 1,144 cm^{-1} in the first-order derivative spectra must be done (Gallignani *et al.*, 1994c). However, for beer samples with alcohol content equal or higher than 1% v/v, second-order derivative measurements at 1,046 cm^{-1} corrected with a baseline established between 1,055 and 1,037 cm^{-1} does not require a maltose correction and provides a limit of detection of 0.035% v/v.

In recent years it has been proposed that ethanol can be determined by absorbance measurements at 871 cm^{-1}, corrected with a baseline established between 844 and 929 cm^{-1}, after online liquid–liquid extraction with chloroform (Gallignani *et al.*, 2005).

The use of vapor phase-FTIR, based on the direct injection of 1 μl degassed sample in a carrier stream of nitrogen gas at 90°C, provided a limit of detection of 0.07% (v/v) from measurements of the peak area between 1,150 and 950 cm^{-1} for a gas cell with a pathlength of 3.2 m and a volume of 110 ml (Perez-Ponce *et al.*, 1996). Recently, it has been evidenced that a low-cost device of 38 mm pathlength and 470 μl internal volume, which provides a limit of detection of 0.15% v/v (Armenta *et al.*, 2006) can be used.

Haberkorn *et al.* (2002) have developed a mid-IR flow through sensor for carbohydrate determination by sequential injection analysis (SIA) using 4% agarose polymer beads (Gelatin Sheparose 4B) with immobilized amyloglucosidase and based on differences between absorbance measurements at 1,049 cm^{-1} and the maximum absorbance in the range 1,090–1,070 cm^{-1} in the spectra obtained before and after enzymatic reaction. Beer samples were analyzed by standard addition approach.

On comparing methods proposed for beer analysis in the NIR and MIR range, it can be concluded that MIR provides a sensitive and versatile tool for direct measurements and to use simple external calibration lines in most of the proposed applications.

Chemometric Methods in Beer Analysis

Complex data treatment of spectra offers unique tools for multiparametric determination, and taking into account the great number of data provided by vibrational spectra is not at all surprising, MIR and NIR spectra have been used to obtain as much as possible information from untreated samples.

In the case of beer analysis, transmission and ATR data in the MIR and transmission and transflectance data in NIR, in addition to Raman spectra, have been employed to determine ethanol (Maudoux *et al.*, 1998; Norgaard *et al.*, 2000; Mendes *et al.*, 2003; Iñón *et al.*, 2005, 2006; Llario *et al.*, 2006; Lachenmeier, 2007); original extract (Norgaard *et al.*, 2000; Westad and Martens, 2000; Iñón *et al.*, 2005, 2006; Llario *et al.*, 2006); original gravity (Maudoux *et al.*, 1998; Lachenmeier, 2007), and, in some cases, other parameters like relative density, pH, lactic acid, bitterness and color (Lachenmeier, 2007), or nitrogen and polyphenols (Maudoux *et al.*, 1998).

Multivariate calibration strategies, from principal component analysis (PCA) to artificial neuronal networks (ANN) and, specially, partial least squares (PLS) have been employed for vibrational data treatment of beers.

PCA was used to classify beers based on their ethanol content; MIR data obtained in ATR mode together with nuclear magnetic resonance (NMR) data (Duarte *et al.*, 2004) were employed.

Table 94.3 shows a brief summary of applications found in the literature for multivariate analysis of beers based on

Table 94.2 MIR methods employed for beer analysis

Measurement mode instrument	Data treatment calibration	Analyte	Band/spectral range considered	Figures of merit	Comments	Reference
FTIR transmission (b = 38 mm) Bruker Tensor 27	Simple regression External calibration: ethanol/water mixtures	Alcohol	Peak area between 1,130 and 992 cm^{-1} (baseline: 1,158–957 cm^{-1})	LD = 0.15% v/v P = 0.2% Volume sample = 1 μl Sample frequency = 30 h^{-1}	• Ultrasonic sample degassing • Simple and low cost device for FTIR-vapor phase • Comparison with head space-GC	Armenta et al. vibrational spectra and, as it can be seen, there are many alternatives based on the use of different data sets and software programs.

However, for a critical evaluation of the different strategies proposed, the size and selection criteria must be considered to establish the calibration set and the use or not of a validation sample set.

Pioneering studies of Maudoux *et al.* (1998) were based on NIR spectra obtained by transmission or reflectance after drying $800\,\mu$l of beer at $50°C$ in a glass filter. On using the spectral information in the range $1,100–2,500\,nm$, it was confirmed that reflectance mode was better than transmittance in all cases. Multiple linear regression (MLR) data treatment on second derivative spectra provided the best results for ethanol and original gravity prediction, PLS being the best treatment to obtain accurate data on real extract, total nitrogen, and total polyphenols.

Studies made by Martens *et al.* for PLS–NIR determination of original extract on transmission data obtained using a dispersive instrument and a pathlength of $10\,mm$ evidenced that interval-PLS provided better results than the use of full spectra. Jackknife (Westad and Martens, 2000) and PC forwarded stepwise selection and recursively weighted regression (Norgaard *et al.*, 2000) were used for variable selection, being the best procedure, for a working range between $1,202$ and $1,298\,nm$ (49 variables). They provided the same predictive features for just 2 factors as compared with the jackknife, which requires 4 factors working in the wavelength range $1,152–1,330\,nm$ (9 selected variables).

Mendes *et al.* (2003) selected the wavelength ranges $7,824–9,113\,cm^{-1}$ and $5,529–6,025\,cm^{-1}$ to determine ethanol by PLS–NIR using transflectance measurements and 12 pure standards as a calibration set. The method provided better features than the use of second derivative Raman spectra.

On considering our contribution in the field of beer analysis using chemometrics (Iñón *et al.*, 2005, 2006; Llario *et al.*, 2006), we can conclude that both NIR and MIR offer excellent tools for ethanol, original, and real extract determination in beers. For each measurement technique and measurement mode, specific wavenumber ranges must be selected to enhance the analytical results. It is also necessary to move from a spectral range to another on modifying the bandpass and, thus, for NIR transmission measurements the use of flow cells of $1\,mm$ involves the selection of spectral windows between $2,298–2,337\,nm$, $2,259–2,348\,nm$ and $2,249–2,303\,nm$ for ethanol, original extract, and real extract, respectively, being selected for a $6.5\,mm$ bandpass at $1,667–1,742\,nm$, $1,667–1,686\,nm$ and $1,162–1,684\,nm$ (Iñón *et al.*, 2005). The simultaneous treatment of MIR and NIR data involves the need to consider nonlinear relationships and thus ANN offers the best performance (Iñón *et al.*, 2006).

Lachenmeier (2007) used a Wine Scan instrument to obtain FTIR transmittance data, which, treated off-line by

PLS considering full spectral range, provided good prediction features for ethanol and original gravity, and relatively good results for lactic acid and relative density. The instrument does not seem adequate for pH, bitterness, and color determination.

From published studies it is clear that chemometric and vibrational spectroscopy offers a great combination to evaluate major components in beer samples. However, in our opinion additional studies are required to extract as much possible information from vibrational spectra of beers and it could be also convenient to combine IR data with those obtained by other methodologies such as inductively coupled plasma-mass spectrometry (ICP-MS) and mass spectrometry (MS), which could incorporate information concerning elemental composition and trace organic compounds to create chemometric tools suitable to control all the parameters involved in both the origin of raw materials and the brewing process.

Beer Analyzers Based on Vibrational Spectroscopy

Ales and lager are two major categories of beers. Yeasts used in fermentation determine the differences between these types. Color, bitterness, and gravity are additional variables that further describe all beers. Color is determined by the type and amount of malt; bitterness depends on the type and amount of grain and hops used in the beer's production; and gravity refers to the beer density, related to dissolved sugars and alcohol content.

Local and global beer producers need to produce vast quantities of highly reproducible and comparable beer at many different sites and, because of this and legal requirements related with alcohol taxes, it is absolutely necessary to ensure the quality of the final product.

Beer analysis traditionally involves methods such as catalytic oxidation, fractional distillation, and gas chromatography. The high number of analysis to ensure the quality of the final product and the need for a fast response to detect changes in the production process have encouraged the commercialization of specific instruments for beer analysis.

One of the more popular and accurate beer analyzers has been the SCABA by Foss. From a degassed beer or wort sample this instrument determines, by U-shaped oscillator measures, the specific gravity and, using a catalytic sensor, the alcohol vapor in equilibrium with sample. pH and color of all beer types can also be measured. This analyzer requires only $50\,ml$ of sample and has a capacity to do 20 determinations per hour. However, in the year 2000 the production of this instrument was stopped and 2007 was the last date for parts availability of the SCABA model 5610.

As it has been described in previous sections of this chapter, vibrational techniques, especially NIR-based ones, offer tremendous possibilities for direct alcohol measurement in

liquid samples and because of this, in the past years, many of the commercialized beer analyzers incorporated NIR units for an accurate and fast determination of ethanol and other parameters such as original gravity and extract content.

Some examples of beer analyzers based on vibrational procedures are shown in Table 94.4. As it can be seen, most of them use transmittance measurements. Old fiber-based systems have been replaced by scanning monochromators, solid-state diode array detectors, or interferometer systems based on Fourier transform. A spectral range between 850 and 1,050 nm is commonly used but an extended range to 570 nm is required when these instruments incorporate color measurement modules.

In some cases, NIR spectrometers have been adapted for beer analysis, such as the Perkin Elmer Brewer's assistant, by incorporating a flow cell with an autosampler unit. Also specific software permits the determination of parameters such as alcohol content, original and present gravity from FT-NIR spectra and to estimate other properties as real or apparent extract, degree of fermentation, and energy value. This instrument requires only 5 ml of sample volume and can process 50 beers per hour.

Beer analyzer calibration is made, usually, by means of beer samples previously characterized by reference methods; complex mathematical routines based on the use of chemometrics for calculations are required.

In the past years, Anton Paar has commercialized a beer analyzer that combines a NIR alcoholyzer with an oscillating U-tube density meter. Using a high-resolution spectrometer and a patented selective alcohol measurement approach based on a narrow highly alcohol-specific range of the NIR spectrum, the alcohol contents is precisely determined. From density measurement the extract density is calculated. Original extract, degree of fermentation, and calories are also determined. One of the main advantages of this instrument is that it does not require chemometric calibration procedures needed by traditional NIR-based instruments: the system is simply adjusted with air and water and, occasionally, with an ethanol/water solution. Some details of this instrument, about the measuring range for the different parameters controlled and repeatability characteristics can be seen in Table 94.4. Only 30 ml degassed beer is required per measurement and studies comparing this instrument with the distillation method have shown no significant deviation of the mean values, the reproducibility being 0.025% v/v for alcohol determination.

In a collaborative study for ethanol determination in low alcohol and nonalcohol beers, 10 beer samples covering 5 ethanol levels were analyzed by 17 participant laboratories. Fourteen of these participants used the Anton Paar NIR analyzer and the results reported a repeatability of 0.022% and a reproducibility of 0.103% that was achieved for this instrument (Toivola et al., 2005). For accurate determination of alcohol in low-alcohol content beer samples (>0.37% v/v) the NIR method was recommended.

NIR analyzers designed for reflectance measurement of solids and used for quality control of malt and other grains, incorporate in some cases a liquid module that permits the routine analysis of beer.

Among the different beer analyzers shown in Table 94.4, it is important to comment on the Infratec™ 1256 beverage Analyzer (Foss). This system, suitable for analysis of different types of alcoholic beverages, permits a direct measurement of the samples into their bottles without sample preparation in less than 45 s. This high throughput analysis makes the use of this instrument to control the production at-line possible. The analyzer incorporates a selection of ready-to-use calibrations (regression programs) for different types of beverages, based on PLS and artificial neural network. Alcohol content, original extract, and color can be directly predicted and other calculated parameters are real extract, apparent extract, degree of fermentation, energy, specific gravity, original gravity, present gravity, extract gravity, spirit indication, and refractive index.

All beer analyzers performed accurately when samples were analyzed under controlled conditions, and any of them is adequate for online measurements.

Infrared Engineering (Essex, UK) developed an industrial beer analyzer, namely Liquidata, based on transmittance measurements using a 1 mm path length sensor probe that is inserted into the beer stream. This system works in the 750–3,000 nm range, among which five key wavelengths were identified for water in beer, eight are significant to ethanol, and five relevant to sugars. Eleven beers, covering alcohol content from 0% to 12% v/v and original gravity between 20° and 90°, were used for instrument calibration. The differences between the Liquidata results and those obtained by reference methods are adequate with the tolerance levels specified by brewers and a standard error of prediction lower than 0.04% ethanol was achieved for any beer analyzed with this system (Benson, 1996).

McNab Inc. also presented at the 107th Master Brewers Association of the Americas (Anniversary Convention, Cincinnati, Ohio, USA) a NIR probe (KSA monitor) for online alcohol determination in beer production by transmission measurements. This instrument is appropriate for brewing plants that produce multiple brands and identifies in-line brand changes.

VitalSensors Technologies developed a sensor for online determination of CO_2 in beer streams, based on ATR MIR measurements. This sensor is a solid-state device and operates at a wavelength of 4.27 μm. Errors due to density are eliminated and the sensor requires no maintenance. Other potential applications for using MIR-based sensors are the determination of ethanol, carbohydrates, and dissolved sugars.

However, in spite of the high number of specific instruments available for beer analysis and their applicability to solve real problems of production and control, there is a lack of information regarding the fundamentals and validation of results reported and, because of this, additional

Table 94.4 Examples of commercial beer analyzers based on the use of vibrational spectroscopy

Instrument	Technique	Parameter: range (precision/accuracy) Calculated parameters	Details/remarks
Quik-Check 10L (Leco Corporation)	NIR-transmission	Alcohol: 3–6% (A = ±0.035%) Original gravity: 30–60ºS (A = ±0.2%)	• Requires calibration against known standards (well-characterized samples) • Electronic temperature controlled cell • Sample aspirated with an internal pump
Rapitec 5665 Beer Analyzer (Foss)	NIR dispersive: fast scanning monochromator (1,100–2,500 nm)	AlcoholExtract	• Source: tungsten lamp • Detector: lead sulphide • Analysis time: 60 samples/h • Sample size: 50 ml/min • Supplied with a selection of a beer calibrations • Last year of production: 2001 (parts availability until 2008)
Infratec™ 1256 Beverage Analyzer (Foss)	NIR dispersive: scanning (850–1,050 nm/ 570–1,100 nm with color module)	Alcohol Original extract Color *Real extract, apparent extract, degree of fermentation, energy, specific gravity, present gravity, extract gravity, refractive index*	• At-line operating • Without sample preparation: beer inside bottle • Regression programs: PLS and ANN • Analysis time: <45 s • Sample volume: min 215 ml
Infratec™ 1241 Grain Analyzer with Sample Transport/Beer Module (Foss)	NIR (transmission) dispersive: scanning (850–1,050 nm/ 570–1,100 nm with color module)	Barley malt: protein, moisture, extract and soluble protein Green malt: moisture contentBeer: alcohol and real extract *Original extract, real degree of fermentation, calories*	• Source: Tungsten halogen lamp • Detector: silicon • Resolution: 2 nm • Regression programs: PLS and ANN • Sample preparation: degassing
Brewer's Assistant (Perkin Elmer)	FT-NIR with autosampler	Alcohol content: 0–12% v/v Original gravity: 1,019–1,095 Kg/l (19–95°S) Present gravity: 0,998–1,030 Kg/l (–1.8 to 26°S) Other properties: real extract, apparent extract, degree of fermentation, energy value	• Quartz NIR cell with auto sampler • Pathlength: 0.5 mm • Sample volume: 5 ml • Analysis time: approximately 50 samples/h • Regression program: PLS
Alcolyzer Plus Beer Analyzing System (Anton Paar)	NIR dispersive: high resolution scanning	Alcohol content: 0–12% v/v (P = 0.01% v/v) Density (with an oscillating U-tube density meter): 0–3 g/ml *Real extract: 0–20% m/m (P = 0.01% m/m) Original extract: 0–30% Plato (P = 0.03% Plato) Degree of fermentation (%) Calories (Kcal/Kg)*	• Does not require chemometric calibration • Sample volume: 30 ml • Analysis time: 15 samples/h
Series 1000 Alcohol Analyzer (NIR Technology Systems)	NIR transmission: solid-state diode array (860–1,020 nm)	Alcohol content	• Pathlength: 30 mm • Calibration using standard samples
LIQUIDATA Infrared Engineering	NIR (transmission) dispersive: 750–3,000 nm	Alcohol (SEP <0.04% v/v)	• On-line measurements • 1 mm pathlength probe
VS-1000C (VitalSensors Technologies)	NIR (attenuated total reflectance)	CO_2 dissolved	• Wavelength: 4.27 μm • Measurement directly in the product stream
KSA monitor (McNab, Inc.)	NIR-absorbance	Alcohol	• On-line measurements • Does not require recalibration per beer brand • Alcohol reading not affected by changes in color, turbidity or presence of sugars

A: accuracy; FT: Fourier transform; *P*: precision.

research must take place to clearly show the users the ways to improve their analysis based on vibrational spectroscopy and this is the reason for the continuous publication of methodologies that involve adaptation of MIR, NIR, or Raman general instruments to the determination of, as much as possible, beer parameters based on the use of different measurement modes and chemometric approaches (see section "Chemometric Methods in Beer Analysis").

Vibrational Spectroscopy for Control of Brewing Process

In addition to final beer analysis, vibrational spectroscopy has been applied to the different stages of the brewing process and, as for example, Meurens and Yan (2002) in the *Handbook of Vibrational Spectroscopy* include a specific chapter devoted to the applications of vibrational spectroscopy in brewing.

Figure 94.5 shows the main phases of brewing process from malting to milling, mashing, brewing, fermentation, maturation, and packaging; and it is clear that many of the main beer parameters need to be controlled in several of these steps.

Table 94.5 shows some of the contributions that can be found in the literature devoted to the use of vibrational spectroscopy for analytical purposes during the brewing process. NIR spectroscopy, in the reflectance mode, seems to be a common technique used for the quality control of dry raw materials for brewing.

Control of the barley malting process is not only important for the final quality of beer, but it is also necessary to ensure the characteristics of other raw materials such as hop, yeast, and obviously, water.

Barley is a major component of the brewing process, and parameters such as moisture, protein, β-glucan, and malt extract require a rigorous control that can be made by NIR spectroscopy as it can be seen in Table 94.5.

The Analysis Committee of the European Brewery Convention (EBC) proposed a comparative study between laboratories for determination of moisture and nitrogen content of barley and malt by NIR spectroscopy. Laboratory participants in this trial used their own calibrations and the measurements were carried out in either transmission and/or reflectance mode using whole kernels or ground samples. In this study, relative standard deviation values of NIR data were much higher than those found for the reference methods, probably due to the different calibration procedures and methodologies used by participants (Angelino, 1996). The American Society of Brewing Chemistry (ASBC) in a posterior collaborative trial (Munar *et al.*, 1998) concluded that values of moisture and protein in whole grain barley obtained by NIR did not differ significantly from those obtained with conventional techniques, and recommended the inclusion of NIR spectroscopy as analytical methods for the control of the aforementioned parameters.

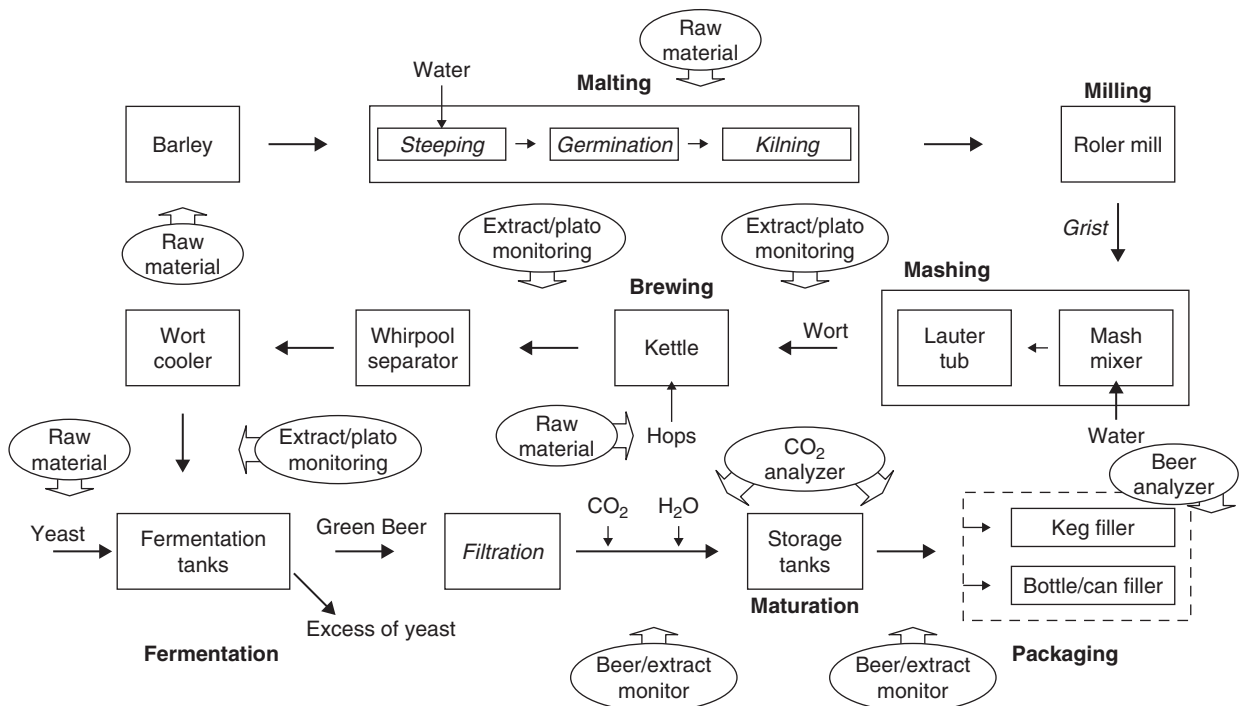
In a collaborative study using the InfraAlyzer 400, Carnielo *et al.* (1985) concluded that transfer of centrally prepared calibrations to other reflectance instruments was


Figure 94.5   Possibilities of the use of vibrational techniques during the brewing process.

Table 94.5   The use of vibrational spectroscopy in the brewing process

Technique	Analyte/parameter	Brewing process step	Reference
NIR reflectance	Malt extract	Malting (barley)	McGuire (1982)
NIR reflectance	Malting potential of barley: moisture, malt extract, protein and β-glucan	Malting (barley)	Henry (1985a)
NIR reflectance	Barley and malt quality	Malting	Carnielo et al. (1985)
NIR reflectance	α- and β-glucans	Malting (barley)	Henry (1985b)
NIR transmittance	Maltose, glucose, maltotriose, total carbohydrates, fermentable sugars, total soluble nitrogen, free α-amino nitrogen and β-glucan	Mashing (wort)	Halsey (1986)
NIR reflectance	Moisture, nitrogen, hot water extract, total carbohydrates, fermentable sugars, total soluble nitrogen and fermentability	Malting (malt)	Halsey (1987)
NIR reflectance	Moisture, protein	Malting (barley)	Yan et al. (1991)
NIR transmission MIR transmission	Maltose, glucose, total fermentable sugars, maltotriose, nitrogen and free α-amino nitrogen	Mashing (wort)	Tenhunen et al. (1994)
NIR reflectance	Glycogen in yeast	Fermentation (yeast)	Mochaba et al. (1994)
NIR reflectance MIR transmittance	Trehalose in yeast	Fermentation (yeast)	Moonsamy et al. (1995)
NIR transmission MIR reflectance	Moisture and N content in barely and malt	Malting (barley and malt)	Angelino (1996)
Transmission NIR	Wort fermentability	Mashing (wort)	Sjoholm et al. (1996)
NIR transmission	Fermentable sugar	Mashing (wort)	Wilke and Parthey (1996)
NIR reflectance	Total protein in yeast	Fermentation (yeast)	Majara et al. (1998)
NIR reflectance	Soluble substances, β-glucan and moisture	Malting (barley)	Allosio et al. (1997)
NIR reflectance (ATR)	Maltose, glucose and fermentable sugars	Mashing (wort)	Eberl et al. (1998)
MIR reflectance diffuse	Yeast strains	Fermentation (yeast)	Timmins et al. (1998)
NIR transflectance	Wort parameters	Mashing (wort)	Ratcliffe and Panozzo (1999)
NIR reflectance	α-Acid content, β-acid content and hop storage index	Brewing (hop)	Garden et al. (2000)
NIR reflectance	Protein content in barley and malt	Malting (barley and malt)	Fox et al. (2002)
NIR reflectance	Fermentability wort Apparent degree of fermentability. Final attenuation apparent extract	Mashing (wort)	Samp et al. (2003)
NIR transmission	Barley quality: germination vigour	Malting (barley)	Moller (2004)

found to be possible for the determination of moisture and protein content in barley and malt, but not in malt extract or modified malt.

Malting quality of barley is related to the amount of β-glucan dissolved at low pH under defined conditions. Malt hot water extract is another parameter used in assessment of malting quality of barley and it is a function of the amount of sugar and low-molecular-weight dextrans produced during mashing by action of α-amylase on the barley starch. Conventional methods to control the aforementioned parameters are tedious and poorly adapted to rapid screening

of early generation breeding lines. Thus, NIR reflectance could be an alternative for rapid control of barley and to predict the quality of malt obtained; it was most successful when the malt was produced without additives or addition of water during the germination process (Henry, 1985a).

The study of Moller (2004) using NIR transmittance measurements has evidenced the capability of this technique for the prediction and viability of barley. To do this, PCA and PLS regression must be combined, using the jack-knife validation to calculate the important variables to be considered and measured.

Parallel factor analysis (PARAFAC), a three-way factor analysis technique, has also been applied to the barley transformation in malt (monitoring the malting process). Appearance of soluble substances, β-glucan degradation, and moisture modification are parameters that can be controlled by PARAFAC–NIR to differentiate batches of barley during the malting process (Allosio *et al.*, 1997).

The possibilities of NIR spectroscopy to control the evolution of the content of *S*-methylmethionine during the killing process have been studied by Yan *et al.* (1991), having obtained standard errors of prediction of 3.5 ppm for the validation set of samples.

Garden *et al.* (2000) studied the application of NIR spectroscopy for the determination of α-acid content, β-acid content, and hop storage index in baled hop samples.

During the mashing process, the extraction of maltose and other fermentable sugar from solubilized starch occurs, and then the wort is obtained. This extract can be measured by transmittance or reflectance measurement.

Halsey (1986) studied the analysis of extracted wort by transmittance measurements, using a pathlength of 3 mm, after sampling, filtering, and thermostating of this extract. In a posterior study, Halsey (1987) evaluated the possibility of direct reflectance measurement of whole malt to predict wort composition (hot water extract, total carbohydrates, fermentable sugars, total soluble nitrogen, free amino nitrogen, and fermentability) from spectra on whole malt, without the need for mashing, and in less than 2 min.

Tenhunen *et al.* (1994) compared the use of transmission measurements in the NIR and MIR ranges and used Fourier transform instruments for the determination of maltose, glucose, total fermentable sugars, maltotriose, nitrogen, and free α-amino nitrogen in worts, requiring only the sample filtration. A CaF_2 transmission cell with a 0.5 mm pathlength was used for NIR in the range 2,000–2,440 nm, whereas a 0.025 mm pathlength and a spectral range 900–1,600 cm^{-1} was employed for MIR. The use of a transmission cell in MIR provided better results than a ZnSe ATR cell due to the possible deposition of some wort compounds on the ATR crystal. MIR spectroscopy provides slightly better results than NIR but sample handling by the first technique was more difficult. This negative aspect can be overcome by using FA technique (Garrigues and de la Guardia, 2002).

Eberl *et al.* (1998) proposed the use of ATR measurements for in-line NIR determination of maltose, glucose, and fermentable sugars during the mashing process; the method requiring only a few seconds to obtain the results.

Wilke and Parthey (1996) proposed the use of a NIR-based sensor for in-line measurements of fermentable sugars during the mashing process.

An enhanced method for calibration of NIR reflectance determination of fermentability wort, based on the application of an orthogonal signal correction algorithm before the use of PLS calibration was developed by Samp *et al.* (2003). This algorithm removed almost 60% of the variance in the NIR spectra, which was independent or orthogonal to the fermentability measures and the standard error of prediction; apparent degree of fermentability and final attenuation of the apparent extract were improved by 50% and 90%, respectively.

Garden *et al.* (2000) studied the application of NIR spectroscopy for the determination of α- and β-acid content, also hop storage index, in baled hop samples.

Active yeast is important for brewing high-quality beer, and traditional methods are based on fermentation performance. Content of protein, trehalose, and glycogen are parameters also used to asses the viability of yeast employed in brewing. Majara *et al.* (1998) have proposed a NIR method for the determination of protein in brewers' yeast that requires only 30 min per sample (25 min correspond to sample preparation). Moonsamy *et al.* (1995) have obtained acceptable results, as compared with enzymatic methods or by the cell dry weigh method, for a rapid NIR measurement of yeast trehalose for both dried yeast and slurry samples containing 30% m/m. Direct slurry measurements by transmittance NIR provide more accurate results than reflectance NIR on dried yeast, probably due to the absence of the drying stage. Mochaba *et al.* (1994) propose the use of NIR spectroscopy for measurement of yeast glycogen.

It can be seen that vibrational spectroscopy is highly valuable to study solid or suspended materials in addition to control wort and beer, and thus efforts must be made to not only improve the capabilities of MIR and NIR, but also to incorporate Raman measurements to evaluate the steps of the brewing process.

Concluding Remarks and Future Developments

The details of the methods available in the literature for beer analysis through IR and Raman spectroscopy are evidence of the validity of these techniques for the fast and accurate determination of major and minor components of beer together with their capability to extract information about the main characteristics of these samples.

However, additional efforts must be made to extend the applicability of vibrational spectroscopy-based techniques to obtain data about trace compounds of beer.

However, the new technology of light emitting diodes (LEDs) can offer possibilities for the development of low cost, compact, and portable devices suitable for use in the brewing process for sensoring the fermentation of malt extracts and alcohol formation.

Advances in automation, especially those based on modern flow methodologies, such as SIA (Haberkorn *et al.*, 2002) and multicommutation (Ródenas-Torralba *et al.*, 2004), could also increase the practical features of vibrational spectroscopy-based methods by increasing the sampling throughput and reducing the consumption of samples

and reagents, also by minimizing the waste generation. In this sense, advances could be expected in the coming years in the automation of vapor-phase IR spectroscopy by the incorporation of minipumps and pinch valves, which could provide continuous sensitive measurements of volatile beer components without any previous sample preparation.

Finally, the tremendous growth of chemometrics and the availability of software packages for PLS and ANN will encourage the people working in this field to model vibrational data, individually or together, with other techniques to obtain a complete picture of processes and samples. In this sense, the classical approach based on the addition of sample information and matrix treatment will also be improved by the use of second- or third-order methodologies involving the hypermatrix data treatment of spectra coming from different techniques or from a single technique but incorporating the evolution of samples with time.

Thus, we can conclude that we are at the beginning of a long trip in which the molecular information of beers obtained by IR and Raman will be of a great value for beer analysis.

Summary Points

- Infrared spectra of beers reflect the characteristics bands of their main constituents: water, ethanol, and carbohydrates (maltose).
- Ethanol presents characteristic bands in the NIR region at 1,570, 1,684, 1,692, 1,714, 1,729, 2,260, 2,300, and 2,350 nm.
- Maltose, the main carbohydrate in beers, presents broad bands at 1,590 nm, also between 2,050 and 2,200 nm, and two less intense peaks around 2,280 and 2,320 nm.
- In the MIR range, ethanol presents characteristic bands at 877, 1,052, 1,086, 2,850, and 2,970 cm^{-1}, whereas maltose has several overlapped peaks between 998 and 1,155 cm^{-1} and characteristic bands at 2,850 and 2,900 cm^{-1}.
- Ethanol and/or maltose can be determined directly in beer samples by infrared transmittance or reflectance measurements using univariate external calibrations.
- Modern beer analyzers are based on infrared (NIR) and density measurements and permit to determine several parameters in each sample in less than 1 min.
- Combined use of infrared measurements and chemometrics offers a powerful tool for beer control analysis.
- Vibrational spectroscopy can be used at-line and/or in-line for quality control of the different stages of brewing process.

Marek Sikorski Faculty of Chemistry, A. Mickiewicz University, Poznań, Poland

Abstract

Autofluorescence of beer probed by conventional and multi-dimensional fluorescence techniques – total luminescence and synchronous scanning fluorescence spectroscopy – is discussed. The spectra of beers reveal the presence of similar fluorescent components in beers of various brands, exhibiting a relatively intense short-wavelength emission ascribed to aromatic amino acids, and a less intense emission in the long-wavelength region, which may originate from the group B vitamins and polyphenolics. Application of multivariate methods to emission data treatment enables quantitative and qualitative analysis of beers based on fluorescence measurements. Examples are provided for application of the techniques to classification of beers, controlling changes during storage, and determination of bitterness of beers and their vitamin B_2 contents. The performance of fluorescence in beer analysis is compared with that of other spectroscopic methods. The potential of these methods in food analysis, screening, and quality control is discussed.

List of Abbreviations

ANN	Artificial neural network
CCD	Charge coupled device
EBC	European Brewery Convention
EEM	Excitation–emission matrix
FAD	Flavin adenine dinucleotide
FTIR	Fourier transform–infrared
ATR-FTIR	Attenuated total reflectance Fourier transform–infrared
HPLC	High performance liquid chromatography
IBU	International bitter units
IR	Infrared
kNN	k-nearest neighbors
LDA	Linear discriminant analysis
MBT	3-Methyl-2-butene-1-thiol
NAD	Nicotinamide adenine dinucleotide
NADH	Reduced form of nicotinamide adenine dinucleotide
NADP	Nicotinamide adenine dinucleotide phosphate
NADPH	Reduced form of nicotinamide adenine dinucleotide phosphate
NIR	Near-infrared
FMN	Flavin mononucleotide
NMR	Nuclear magnetic resonance
PC	Principal component
PCA	Principal component analysis
PLS	Partial least squares
RMSECV	Root mean square error of cross-validation
Rf	Riboflavin
TLS	Total luminescence spectroscopy
UV	Ultraviolet
VIS	Visible

Introduction

Beer analysis is important for evaluation of its organoleptic characteristics, quality, nutritional aspects, and safety. A wide variety of analytical methods and chemical measurements are usually implemented to characterize and quantify various beer properties and constituents. For example, bitterness units and European Brewery Convention color are assessed by photometry, organic acids are analyzed using liquid chromatography or enzymatic methods, higher alcohols and other volatile compounds are determined using gas chromatography. In most cases, analytic methods require pre-treatment of samples to separate and concentrate the target compounds. Such techniques are expensive, time-consuming, involve the use of undesirable organic solvents, and require highly trained laboratory personnel. Moreover, fractionation and separation procedures may alter the nature of the sample, and cause loss or dilution of certain compounds.

The development of fast analytical methods, which may be applied directly to the analyzed material and thus make extensive sample pre-treatment unnecessary, is of great interest in food and beverage analysis. Spectroscopic techniques are particularly useful in such applications (Oldham *et al.*, 2000), as they enable rapid and non-invasive characterization of the samples. In contrast to conventional methods, which usually focus on the analysis of a single, or of a selected few compounds or properties, spectroscopy may provide information about a very wide range of different compounds in a single measurement. This feature is especially important in food analysis because sensory properties of products and their quality are usually determined by a variety of components and their interactions. The potential of spectroscopic methods is expanded by application of multivariate methods for data analysis.

Nuclear magnetic resonance (NMR) (Duarte *et al.*, 2002; Duarte *et al.*, 2004; Nord *et al.*, 2004; Lachenmeier *et al.*, 2005; Almeida *et al.*, 2006; Khatib *et al.*, 2006), near-infrared (NIR) (Engelhard *et al.*, 2006; Inon *et al.*, 2006), and infrared (IR) (Duarte *et al.*, 2004; Llario *et al.*, 2006; Lachenmeier, 2007) spectroscopy have been proved useful for direct beer analysis. Recently, fluorescence spectroscopy has been receiving an increasing attention in food analysis (Christensen *et al.*, 2006). Fluorescence is a type of photoluminescence, a process in which a molecule, promoted to an electronically excited singlet state by absorption of UV (ultraviolet), VIS (visible), or NIR radiation, decays back to its ground state by emission of a photon. Among the benefits of fluorescence spectroscopy are its enhanced selectivity as compared to other spectroscopic methods, its high sensitivity to a wide array of potential analytes, and in general, the avoidance of consumable reagents and of extensive sample pre-treatment (Oldham *et al.*, 2000). The fluorescent analysis may take advantage of the presence of natural fluorescent food components or contaminants. On the other hand, fluorescence can be induced in food by adding fluorophores or by producing specific fluorescent derivatives of the analytes.

Conventional fluorescence techniques, relying on measurements of single emission or excitation spectra, are often insufficient in the direct analysis of complex systems. In such cases, total luminescence or synchronous scanning fluorescence techniques may improve the analytic potential of the fluorescence measurements (Ndou and Warner, 1991). Total luminescence spectroscopy (TLS) involves simultaneous acquisition of multiple excitation and emission wavelengths to increase the method selectivity. The resulting emission–excitation data matrix (EEM) provides a total intensity profile of the sample over the range of excitation and emission wavelengths scanned (Ndou and Warner, 1991; Christensen *et al.*, 2006). Synchronous fluorescence spectrometry takes advantage of the ability to vary both the excitation and emission wavelengths during the analysis: in this method excitation and emission monochromators are scanned simultaneously, synchronized so that a constant wavelength difference is maintained between the two (Ndou and Warner, 1991).

Several papers reported investigations and applications of intrinsic beer fluorescence. Fluorescence lifetimes and spectral data have been explored in diluted beers (Apperson *et al.*, 2002). Beer autofluorescence and europium-induced delayed fluorescence with multivariate data evaluation were used for determination of bitterness in beer (Christensen *et al.*, 2005); other authors developed a simple, sensitive fluorometric method for precise quantification of riboflavin in beer (Duyvis *et al.*, 2002). Total fluorescence spectroscopy and synchronous fluorescence spectroscopy were applied for characterization and differentiation of various brands of beers, for monitoring changes occurring in beer during storage under different conditions, and for quantification of vitamin B_2 (Sikorska *et al.*, 2003, 2004a, b, 2006).

In this chapter we characterize the autofluorescence of beers and present an analytical application of the fluorescence measurements.

Fluorescence Characteristics of Beer

The characteristics of beer autofluorescence are expected to be quite complex due to overlapping emissions from numerous species. Therefore, it is necessary to apply multidimensional fluorescence techniques to obtain a comprehensive description of the fluorescent components. Three-dimensional spectra are known as excitation–emission matrices or total luminescence spectra, in which one axis represents the excitation wavelength, another – the emission wavelength, and the third – the intensity (Ndou and Warner, 1991; Guilbault, 1999). Alternatively, three-dimensional spectra may be transformed into two-dimensional contour maps, in which one axis represents the emission and another – the excitation wavelength. The contours are plotted by linking points of equal fluorescence intensity. Such a presentation is more practical for visual analysis of the fluorescence patterns.

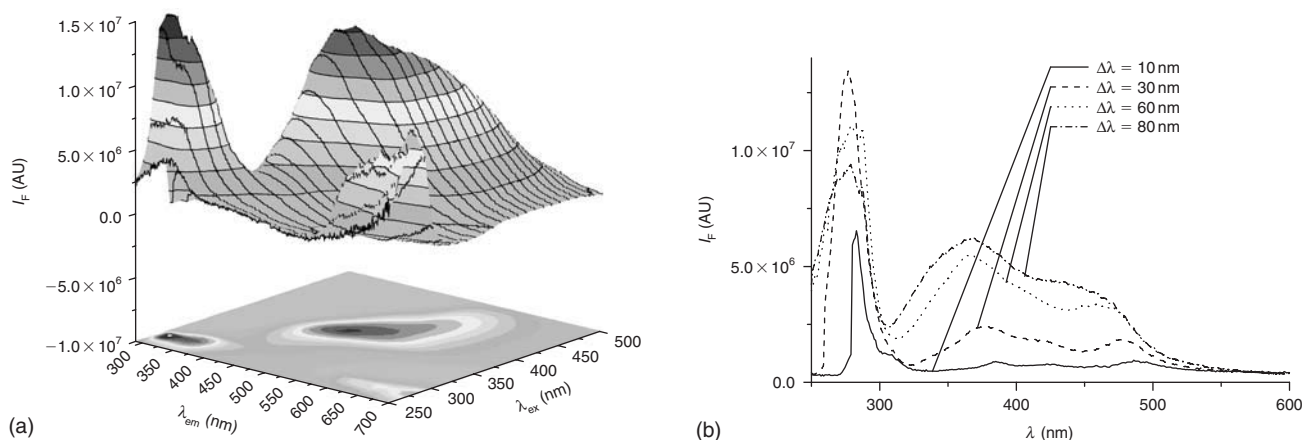
A total luminescence spectrum gives a comprehensive description of the fluorescent components of the mixture, incorporating all the information present in the absorption and fluorescence spectra of fluorescent constituents. Due to these features, the total luminescence contour map may serve as a unique fingerprint for identification and characterization of the sample studied. The spectral resolution of an excitation–emission matrix depends on the number of conventional emission scans at different excitation wavelengths, used to construct the contour plot. Acquisition of contour maps of sufficient resolution on conventional spectrofluorometers requires a large number of emission scans for each sample. The analysis may be speeded up with charge coupled device or video-spectrofluorometers; however, such instruments are not widely accessible in laboratories (Guilbault, 1999).


Figure 95.1 (a) Three-dimensional plot and contour map of total luminescence spectra of a lager beer measured for undiluted sample using front-face geometry. (b) Synchronous-scan fluorescence spectra of a lager beer measured for undiluted sample using front-face geometry, $\Delta\lambda$ (10, 30, 60, 80 nm).

For analytical purposes, the synchronous fluorescence techniques may be used instead of the TLS (Ndou and Warner, 1991). Synchronous scanning fluorescence spectroscopy is a very useful technique for the analysis of mixtures of fluorescent compounds. Both excitation and emission characteristics are included in the spectrum by simultaneously scanning both excitation and emission wavelengths, keeping a constant difference between them. As a result, the selectivity for individual components is considerably improved and much additional information on mixtures of fluorescent compounds is gained. The synchronous scanning fluorescence method is a very simple and effective means of simultaneously obtaining data for several compounds present in a mixture. Although it provides less information than the TLS, it may present a viable alternative in many cases due to its inherent simplicity and rapidity.

Undiluted beers exhibit high UV–VIS absorption, thus fluorescence measured using the conventional arrangement, the right-angle geometry, is severely distorted due to primary and secondary inner-filter effects, which may be eliminated by diluting the samples. On the other hand, dilution reduces fluorescence intensities arising from such components that are either present in low concentrations or have low fluorescence quantum yields. Measurements for undiluted samples may be performed using front- or back-face geometry (Sikorska *et al.*, 2003, 2004b, 2006). Front-face geometry avoids filter effects, although other phenomena including energy transfer and collisional quenching remain active. In the back-face geometry, due to using a triangular cell the optical path length of the exciting radiation is considerably reduced, resulting in a reduction of the primary inner-filter effect. The emitted light is still absorbed, as the optical path length for the emission is ca. 0.5 cm in a typical cell; however, the absorption at longer emission wavelengths is considerably lower than that at shorter excitation

wavelengths. All of these three geometries were used in beer fluorescence measurements: front face and back face for bulk samples and right angle for diluted samples.

The most complete fluorescent characteristics of beers were obtained in the front-face geometry (Sikorska *et al.*, 2004b). The spectra of undiluted beer (Figure 95.1a), measured using the front-face geometry, exhibit a relatively intense band with excitation at about 250 nm and emission at 350 nm. Additionally, a distinct emission band with excitation at 350 nm and emission at 420 nm, and a less intense emission band with excitation at 450 nm and emission at 520 nm are observed. In the spectra of diluted beer samples (3.2% v/v in water) the short-wavelength fluorescence with excitation at 250 nm and emission at 350 nm is present, while only a very weak emission band exists with excitation at 350 nm and emission at 420 nm, and almost no fluorescence above 400 nm in excitation and 500 nm in emission is observed. The short-wavelength emission is completely removed in spectra of undiluted beer measured using back-face geometry, while the longer-wavelength emission retains a reasonable intensity.

The emission characteristics for several lager beers studied are quite similar, indicating the presence of similar fluorescent components (Sikorska *et al.*, 2004b). On the other hand, differences in band positions, shapes, and relative intensities for various beers are easily noticeable. TLS can be used for fingerprinting of the respective beers, and may, for example, allow beer identification and quality monitoring.

The shape and intensity of synchronous spectra depend on the offset between the excitation and emission wavelengths, $\Delta\lambda$, which defines the preferred wavelength interval between the absorption and emission bands (Figure 95.1b). Generally an effective bandwidth reduction is observed at small $\Delta\lambda$ when compared to a conventionally recorded emission band, at a cost of some sensitivity reduction.

Table 95.1 Fluorescent properties of selected beer components and their concentration in beer

Fluorophore	Fluorescence properties			Concentration in beer
	Solvent	λ_{ex} (nm)	λ_{em} (nm)	
Amino acids				
Phenylalanine	Water	258	284 (Christensen et al., 2006)	5.9 mg/100 g (Moller et al., 2002), 20–105.3 mg/dm^3 (Erbe and Bruckner, 2000)
Tyrosine	Water	276	302 (Christensen et al., 2006)	14.9 mg/100 g (Moller et al., 2002), 5.7–71.3 mg/dm^3 (Erbe and Bruckner, 2000)
Tryptophan	Water	280	357 (Christensen et al., 2006)	3.1 mg/100 g (Moller et al., 2002)
Vitamins				
Vitamin B$_2$				
Riboflavin	Water	270, 382, 448	518 (Christensen et al., 2006)	0.020–0.040 mg/100 g (Moller et al., 2002), 0.0156–0.0278 mg/100 g (Vinas et al., 2004), 0.169–0.508 mg/dm^3 (Andres-Lacueva et al., 1998), 0.210–0.312 mg/dm^3 (Duyvis et al., 2002), 0.130–0.280 mg/dm^3 (Su et al., 2004)
FAD	Water	262, 370, 450	540 (Islam et al., 2003)	0.019–0.065 mg/dm^3 (Andres-Lacueva et al., 1998), 0.0014–0.0053 mg/100 g (Vinas et al., 2004)
FMN	Water	265, 370, 450	540 (Islam et al., 2003)	0.081 mg/dm^3 (Andres-Lacueva et al., 1998), nd (Vinas et al., 2004)
Vitamin B$_3$				
NAD(P)H	Water	340	470 (Friedrich, 1988)	0.65–1.1 mg/100 g (Moller et al., 2002)
Vitamin B$_6$				
Pyridoxine	Water	328	393 (Christensen et al., 2006)	0.03–0.08 mg/100 g (Moller et al., 2002)
Phenolics				
Epicatechin	Water	280	320–324 (Cho and Mattice, 1990)	65.5 mg/dm^3 (Gorinstein et al., 2000), 0.9–1.9 mg/dm^3 (Shahidi and Naczk, 2003)
Catechin	Water	280	320–324 (Cho and Mattice, 1990)	3.4–6.3 mg/dm^3 (Shahidi and Naczk, 2003)
p-Coumaric acid	Water pH = 10.7	330	435 (Sanchez et al., 1988)	2.1 mg/dm^3 (Gorinstein et al., 2000), 0.6–1.1 mg/dm^3 (Sanchez et al., 1995), 1.06 mg/dm^3 (Nardini et al., 2006), 0.026–0.129 mg/dm^3 (Montanari et al., 1999), 6.01–6.97 mg/dm^3 (Sanchez et al., 1988)
		330	443 (Gorinstein et al., 2000)	
Ferulic acid	Water pH = 11.2	340	460 (Gorinstein et al., 2000)	6.8 mg/dm^3 (Gorinstein et al., 2000), 0.131 ng/ml (Sanchez et al., 1996), 13.50 mg/dm^3 (Nardini et al., 2006), 0.116–0.274 mg/dm^3 (Montanari et al., 1999)
Gallic acid	Water	260	339 (Polewski et al., 2002)	2.9 mg/dm^3 (Gorinstein et al., 2000), 0.008–0.034 mg/dm^3 (Montanari et al., 1999)
	Water pH = 4.63	260	357 (Gorinstein et al., 2000)	

λ_{ex}, λ_{em}: wavelength of fluorescence excitation and emission maxima; NAD(P)H: reduced forms of dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP); FAD: flavin adenine dinucleotide; FMN: flavin mononucleotide.

Synchronous fluorescence spectra of an undiluted beer in the front-face geometry obtained at $\Delta\lambda = 10$ nm show a sharp, intense band with a maximum at 283 nm and a weak broad emission with maxima at 385, 426, and 488 nm (Sikorska et al., 2004b). The short-wavelength emission band is broadened in spectra measured at $\Delta\lambda = 30$ nm and its maximum is shifted to 275 nm, accompanied by an increased intensity of both this band and of the broad

emission between 300 and 500 nm. Further increasing the $\Delta\lambda$ values to 60 and 80 nm led to a decrease of the fluorescence intensity in the short-wavelength region; simultaneously, the long-wavelength broad bands grew in intensity and their maxima were shifted to the blue.

In analogy to total luminescence spectra, the synchronous fluorescence spectra of a lager beer diluted in water (3.2% v/v) exhibit mainly the short-wavelength fluorescence. No

short-wavelength emission is observable in the synchronous spectra of undiluted beer samples recorded using the back-face geometry.

Fluorescent Beer Components

The major beer components, water, ethanol, and carbohydrates, are non-fluorescent; however, beers contain a very wide range of minor components, including proteins, amino acids, vitamins, and phenolic compounds, some of which exhibit fluorescence. Thus, the intrinsic emission of beers originates from numerous fluorescent species. Consequently, a complete assignment of the spectral features is problematical. Some tentative qualitative assignments could be made, based on comparison of the observed characteristic features with the well-known fluorescent properties of the particular beer constituents.

Fluorescence properties of selected beer components are summarized in Table 95.1, along with some examples of their measured concentrations. Note that the concentrations may vary widely, depending on the beer type, reproducing diversity of the raw materials and brewing conditions.

As evident from Table 95.1, compounds exhibiting natural fluorescence belong to at least three distinct groups of beer constituents: amino acids, vitamins, and distinct phenolic compounds. The relatively intense band, observed in each beer, with the excitation at ca. 250–300 nm and the emission at ca. 300–400 nm, has been ascribed to amino acids (Apperson et al., 2002; Sikorska et al., 2004b; Christensen et al., 2005). Beer contains a variety of amino acids, however, only three of them are fluorescent, tryptophan, tyrosine, and phenylalanine, all having aromatic character. The emission in the short-wavelength region may also originate from catechin or epicatechin – the proanthocyanidin monomers. However, it was shown that contribution of polyphenols at this spectral zone is minimal since their removal by polyvinylpolypyrrolidone had not affected the observed fluorescence significantly (Apperson et al., 2002).

The broad emission at longer wavelengths originates presumably from several fluorescent components, including compounds of the vitamin B group and phenolic compounds (Sikorska et al., 2004b; Christensen et al., 2005). Indeed, beer contains many phenolic compounds, which include a wide range of structures from simple monophenols to polymeric polyphenols of varying complexity. Beer is also a rich source of water-soluble B vitamins. The emission band at ca. 450/500–600 nm could be ascribed to vitamin B_2 emission (Friedrich, 1988). The principal forms of vitamin B_2 found in nature are riboflavin, flavin mononucleotide (FMN), and flavin adenine dinucleotide (FAD), although beer contains mainly riboflavin. Vitamin B_3 (niacin) includes nicotinic acid, nicotinamide, and their coenzyme forms: nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate

(NADP). Reduced forms NAD(P)H are fluorescent (Friedrich, 1988). Vitamin B_6 group includes pyridoxine, pyridoxal, pyridoxamine, pyridoxic acid, and pyridoxal 5′-phospate, all of these compounds emit in the 385–400 nm range (Friedrich, 1988; Ramanujam, 2000). According to some authors (Apperson et al., 2002), iso-α-acids may also contribute to beer autofluorescence.

The intense short-wavelength emission band observed in the synchronous fluorescence spectra of diluted beer samples was attributed to amino acid fluorescence, mainly that of tyrosine, in analogy to the total luminescence spectra (Sikorska et al., 2004b). The long-wavelength emission in the synchronous spectra of bulk beers should originate from the vitamin B group of compounds. The existence of more than one band suggests that several substances emit in this region, possibly including phenolic compounds.

Figure 95.2 shows spectra of aromatic amino acids and vitamin B_2 recorded at $\Delta\lambda = 10$ nm. Phenylalanine, tyrosine, and tryptophan exhibit single narrow bands in the short-wavelength region with the respective maxima at 263, 283, and 296 nm. Riboflavin emission occurs in the long-wavelength region with a maximum at 489 nm. The very good match between fluorescence of tyrosine and riboflavin and the respective emission bands of beers supports the identification of these two fluorophores (Sikorska et al., 2004b). Further studies are needed to confirm assignments of the other fluorescent bands and to establish a quantitative relationship between the chemical composition of a beer and its fluorescence characteristics. Such study could be of great interest because fluorescent compounds present in beer have a strong impact on both the beer properties and its nutritional value and stability. For example, the concentration of amino acids in beer may serve as an indicator for the fermentation performance. Free amino acids present in wort are metabolized by yeast during fermentation, therefore content of amino acids in beer is determined by wort and yeast metabolism (Nord et al., 2004).

Phenolic compounds may contribute either beneficially or harmfully to several of the beer properties (Shahidi and Naczk, 2003). They are involved in physical and chemical stability, shelf life, and foam maintenance. They contribute to flavor because they cause both bitterness and astringency. Polyphenols are well known for their participation in protein–polyphenol haze development. Some beer phenolics may also act as antioxidants in the human body, contributing beneficially to the health of the consumer.

The vitamins present in beer contribute to its nutritional value. The active form of vitamin B_2, FMN, and FAD serve as prosthetic groups of oxidoreductase enzymes, which catalyze essential oxidation/reduction steps in almost every metabolic pathway (Nollet, 2004). It was shown that riboflavin possesses some disease prevention and health promotion functions, including protection against malaria, vascular disease, and certain cancers. Recently riboflavin has gained a renewed interest after it was shown to protect
Figure 95.2 Synchronous fluorescence spectra, recorded at $\Delta\lambda = 10\,nm$, of beer, tyrosine (Tyr), tryptophan (Try), and riboflavin (Rf) in water, at pH = 4; fluorescence intensity of standard compounds was normalized.

vital tissues from ischemia-induced oxidative injury resulting from heart attack or stroke (Foraker *et al.*, 2003).

Apart from its nutritional value, riboflavin have been postulated to contribute to the development of flavor changes: the sunstruck and stale flavor (Sakuma *et al.*, 1991; Burns *et al.*, 2001; Goldsmith *et al.*, 2005; Huvaere *et al.*, 2005; Huvaere *et al.*, 2006).

Niacin participates in oxidation–reduction systems and plays an essential role in the enzyme systems responsible for the metabolism of carbohydrates, fatty acids, and amino acids. Nicotinic acid and nicotinamide are used for treating cardiovascular disease, insulin-dependent mellitus, and certain cancers (Nollet, 2004).

Vitamin B_6 acts as an essential coenzyme involved in amino acid, carbohydrate, and fat metabolism. Among other roles, it is required for the formation of hemoglobin (Nollet, 2004).

Classification of Beers Using Synchronous Fluorescence Spectra

Despite their general similarity, the profiles of synchronous fluorescence spectra of individual beers vary significantly, producing unique spectral patterns (Sikorska *et al.*, 2004b). The synchronous fluorescence spectrum can serve as a spectral signature of the particular sample and may be used, for example, in qualitative analysis, quality monitoring, for beer identification, or for authentication purposes. For such applications multivariate statistical methods should be applied. Exploratory analysis of synchronous fluorescence spectra of different beers was performed using principal component analysis (PCA) (Wold *et al.*, 1987). PCA is an unsupervised multivariate method, used to analyze the

inherent structure of the data. PCA reduces dimensionality of the dataset by finding principal components (PCs) which are linear combinations of the original variables. PCs are orthogonal to each other and designed in such a way that each one successively accounts for the maximum variability of the dataset. A plot of the PC scores reveals relations existing between the samples, such as natural clustering in the data or outlier samples.

PCA modeling for undiluted and water-diluted beer samples was performed for synchronous fluorescence spectra measured at $\Delta\lambda = 10$ and $60\,nm$, respectively, with back-face and right-angle geometry. The resulting scores are shown in Figure 95.3. The PCA analysis reveals sample clustering reflecting the beer brands. Larger dispersion seen for diluted samples results from errors introduced by the dilution procedure, and additional noise appearing in measurements of week signals from the diluted samples.

The possibility of discriminating different beers on the basis of their synchronous fluorescence spectra was investigated by using two statistical methods: the k-nearest neighbors (kNN) method and the linear discriminant analysis (LDA) (Sikorska *et al.*, 2004b). The kNN method is a nonparametric classification method, which allows to analyze entire spectra, without any reduction of the datasets (Wu and Massart, 1997). In principle, the test object is assigned to a cluster, which is most represented in the set of k-nearest training objects. For each data point, the closest data points, called "nearest neighbors" are searched for, and then decision is made according to the values of these neighbors. kNN is one of the simplest learning techniques – the learner only needs to store the examples, while the classifier does its work by observing the examples most similar to the one to be classified. The k-values were chosen in the range of $k = 1, \ldots, 10$.

Additionally, LDA was performed on simplified datasets. For this purpose, six wavelengths were extracted from each synchronous spectrum measured at a particular $\Delta\lambda$ and analyzed.

Classification of various beer samples using kNN method was very good, with zero or very low classification error and low standard deviation values (Sikorska *et al.*, 2004b). The best discrimination was achieved for bulk beers using synchronous fluorescence spectra measured at $\Delta\lambda = 10$ and $60\,nm$ and for diluted beers using spectra measured at $\Delta\lambda = 10\,nm$. LDA also produced a satisfactory discrimination between different beers. The results show that to discriminate between beers, instead of recording entire spectra, the fluorescence intensity could be measured at selected excitation–emission wavelength pairs and then subjected to LDA.

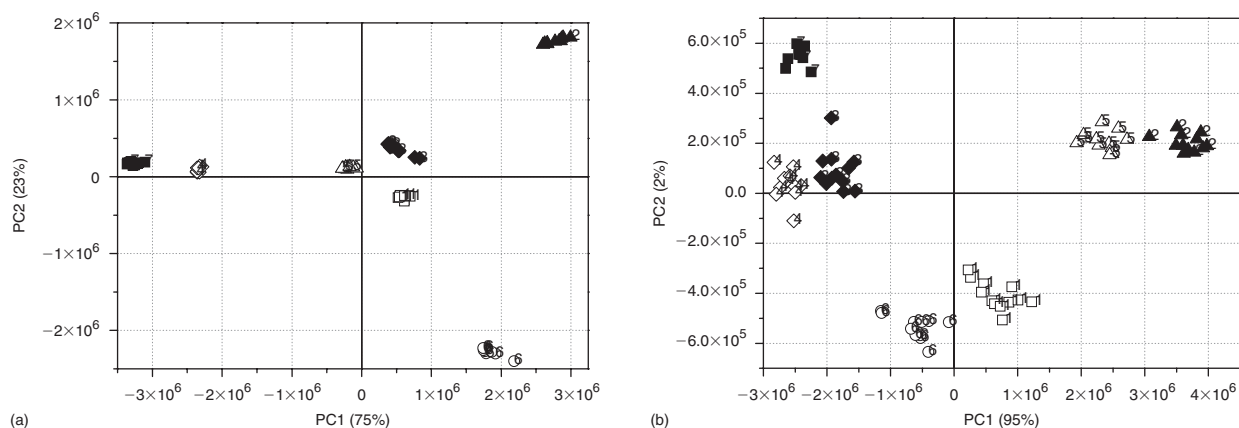
The results confirmed that both the short-wavelength UV-emission and the long-wavelength visible emission can be applied to discriminate various beers. Although both techniques could be applied for beer discrimination, the spectra of bulk samples appear to be more reliable than


Figure 95.3   Score plots for PCA model of synchronous-scan fluorescence spectra measured at $\Delta\lambda = 10\,nm$, of bulk (a) and diluted (b) lager beers of seven different brands.

those of diluted beers. Apart from qualitative distinctions, the samples also differ in fluorescence intensities of particular components. These differences should reflect variation in the contents of fluorescent compounds and might be used for quantitative evaluation of beer components.

Monitoring Beer During Storage by Fluorescence Spectroscopy

Fluorescence spectroscopy allows monitoring changes in the chemical composition of beers during storage. Recently fluorescence spectroscopy has been applied to the samples of two lager beers of various brands stored in clear glass bottles in different conditions: in darkness at 4°C, and at 22°C, one in darkness and the other one under diffuse light, for 21 days (Sikorska *et al.*, 2006). The samples were analyzed by means of various fluorescence techniques for both diluted and bulk samples.

The total luminescence spectra of fresh beer and beer stored in light differ mainly in the band occurring at 450 nm in excitation and between 500 and 600 nm in emission, in the zone characteristic for vitamin B_2 (riboflavin) and, in general, attributed to flavins present in beer. This emission disappears in beer exposed to light, result of flavin photodegradation (Heelis, 1982). The total luminescence characteristics of beers stored in the dark at 4°C and 22°C (not shown) were almost identical to those of fresh beers. Generally the changes occurring during storage are more pronounced in bulk rather than in diluted samples.

It has been shown that synchronous spectra allow discrimination between differently stored beer samples. Two lager beers A and B of different brands were used for the study. Because significant changes in fluorescence characteristics of beer during storage occurred mainly in the long-wavelength emission region, synchronous spectra of bulk beers were chosen for the multivariate analysis, with

the exploratory data analysis performed using PCA (Wold *et al.*, 1987).

Two PCA models were analyzed for synchronous fluorescence spectra of beers that were either fresh or stored in different conditions (Figure 95.4) (Sikorska *et al.*, 2006). The first model includes all the storage conditions, while the second model excludes the samples exposed to light. The distribution of samples in the score plots for both models clearly displays clustering of beer samples according to freshness and storage conditions. The samples exposed to light are clearly distinct from both fresh beer and samples stored in the dark by the negative values of the first principal component PC1, which explains 83% of the total variance. The loading for this component shows the importance of the bands attributed to flavins, with a maximum at 489 nm, and also of the short-wavelength bands at 375–450 nm. PC2 explains 15% of the total variance and is related to the changes in the 350–440 nm bands. This component differentiates the samples stored in the dark at 22°C from all other samples.

In the second PCA model the samples exposed to light were excluded. In this model, PC1 and PC2 describe 90% and 7% of the total variance, respectively. PC1 corresponds to variations in the bands with maxima at 428, 400, and 380 nm, while PC2 describes changes in the bands with maxima at 367 and 380 nm. It is important to note that convincing discrimination between samples stored in darkness at different temperatures was achieved by the PCA analysis, which we found impossible to achieve by visual inspection of the same spectra.

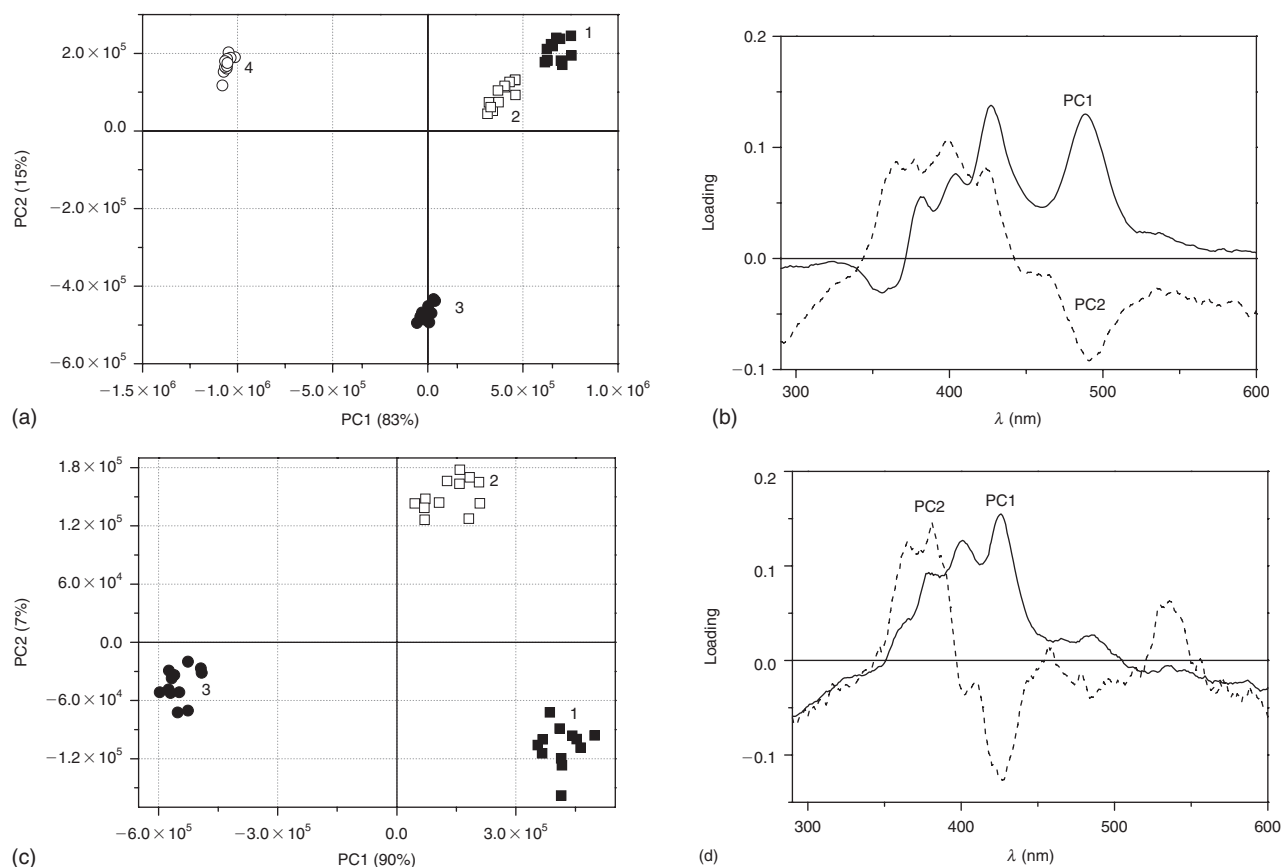
Comparison of the two PCA models shows that the main difference between beers stored in darkness and under light corresponds to changes in the spectral zone around 490 nm, which is characteristic to the riboflavin emission. These observations confirm riboflavin photodecomposition and its stability in the absence of light (Heelis, 1982; Andres-Lacueva *et al.*, 1998; Duyvis *et al.*, 2002). The differences


Figure 95.4 Score (a, c) and loading (b, d) plots for two PCA models of synchronous-scan fluorescence spectra of bulk beer A stored in different conditions, recorded for $\Delta\lambda = 10$ nm; 1 – fresh beer and samples stored for 21 days; 2 – darkness, 4°C; 3 – darkness, 22°C; 4 – exposed to diffuse light, 22°C. Series 4 was only included in the model represented in (a, b). *Source:* Reprinted from Sikorska *et al.* (2006), with permission from Elsevier.

in riboflavin emission are insignificant in samples protected from light.

Similar clustering of samples according to storage conditions was observed for synchronous fluorescence spectra recorded for $\Delta\lambda = 60$ nm with all four series of samples, and the importance of the emission originating from flavins in differentiating samples exposed to light from those stored in darkness was confirmed.

With respect to quality monitoring, it is desirable to separate products into classes, such as fresh and aged samples. To test the feasibility of such classification based on the fluorescence spectra, the kNN and LDA methods were employed. All differently stored samples of beer A could be correctly classified by kNN using synchronous fluorescence spectra recorded both for $\Delta\lambda = 10$ and 60 nm, and appropriate k-values. The classification errors increased at higher k-values and the misclassification rates were generally higher for the spectra measured for $\Delta\lambda = 60$ nm. LDA provided 100% classification for both sets of synchronous spectra. The kNN analysis of synchronous spectra of beer B for $\Delta\lambda = 10$ nm led to 3.4–5.2% classification error depending on the k-value, as a consequence of poor separation between fresh beers and

beers stored in darkness at 4°C. Much better classification was achieved in the analysis of $\Delta\lambda = 60$ nm spectra. With LDA, the fraction of correct classification was about 88% for $\Delta\lambda = 10$ nm spectra and 100% for $\Delta\lambda = 60$ nm spectra.

Alterations of intrinsic beer fluorescence occurring during aging refer directly to subtle and minor chemical changes of beer components. A comprehensive picture of mixtures of fluorescent compounds is obtained, although further studies are needed to identify specific molecules. It is feasible that stored and validated fluorescence spectra can serve as references for beer quality control purposes. Fluorescence may also be used as a tool for investigating the processes occurring in beer upon light exposure.

It is well known that beers exposed to visible light may develop a flavor known as "lightstruck," due mainly to formation of 3-methyl-2-butene-1-thiol (MBT) (Sakuma *et al.*, 1991; Burns *et al.*, 2001; Huvaere *et al.*, 2006). The mechanism of this process has been intensively studied. It is believed that the primary photophysical event that leads to the formation of the lightstruck flavor is the excitation of riboflavin to its triplet state followed by electron transfer from iso-α-acids (Huvaere *et al.*, 2004).

Evaluation of light-induced degradation of beers focused mainly on formation of sulfur-containing degradation products, in particular MBT. However, quantitative analysis of MBT in beer represents a significant challenge because of its low flavor threshold, chemical reactivity, relatively high boiling point (126°C), and propensity to adsorb onto surfaces. The methods for analysis of MBT include headspace gas chromatography (Gunst and Verzele, 1978; Peppard, 1985), gas chromatography and mass spectrometric detection (Goldstein *et al.*, 1993), solid-phase microextraction and gas chromatography with pulsed flame photometric detection (Hill and Smith, 2000), gas chromatography–mass spectrometry (Masuda *et al.*, 2000), and a purge-and-trap method with gas chromatography–mass spectrometric detector (Sakuma *et al.*, 1991). Recently Pozdrik *et al.* (2006) have shown that disappearance of riboflavin absorbance at 445 nm from beers exposed to light is directly linked to formation of the lightstruck flavor. The authors proposed simple spectrophotometric methods for determining lightstruck susceptibility based on measurement of riboflavin concentration in beer. The measurements of riboflavin fluorescence may offer an alternative to this method, providing higher sensitivity and selectivity as compared to absorption. Moreover, fluorescence may enable a simultaneous analysis of catechin and tryptophan, proven riboflavin triplet state quenchers, which provide some protection against lightstruck flavor formation (Goldsmith *et al.*, 2005).

Analysis of Vitamin B$_2$ Using Intrinsic Beer Fluorescence

The concentration of vitamin B$_2$ in beer is an important factor in assessing its nutritional value and flavor stability. The methods used for flavin quantification include high performance liquid chromatography (HPLC), enzymatic, microbiological, and fluorometric techniques. In most cases, these methods require pre-treatment of samples to separate and concentrate the target compounds.

Recently a method has been proposed for determination of vitamin B$_2$ in beer using its native fluorescence (Duyvis *et al.*, 2002). Briefly, the method is based on the riboflavin standard addition directly to the diluted beer. Subsequent titration with the apo-form of riboflavin-binding protein, which is efficiently and specifically quenching the riboflavin fluorescence, allows subtracting of the background fluorescence of beers, due to fluorescent species other than riboflavin. It has been proved that the fluorescence observed enables to determine riboflavin quantitatively, as other flavins only occur in beers in negligible amounts. Duyvis *et al.* (2002), using this same method, have obtained riboflavin content for lager beers in the range of 0.56–0.83 μmol/dm^3, comparable to riboflavin content in beer in the range of 0.45–1.35 μmol/dm^3 determined by Andres-Lacueva *et al.* (1998) using the HPLC method.

Alternatively, the concentration of riboflavin in beer may be determined by direct measurements of fluorescence spectra combined with multivariate regression method (Sikorska, 2006).

The front-face emission spectrum of beer measured at $\lambda_{exc} = 450$ nm exhibits a single band with its maximum at 550 nm ascribed to the riboflavin fluorescence (Duyvis *et al.*, 2002; Sikorska *et al.*, 2004b, 2006). In the synchronous fluorescence spectra taken at $\Delta\lambda = 30$ and 60 nm, the longest-wavelength emission band belongs to riboflavin (Sikorska *et al.*, 2004b, 2006). The linear regression analysis between fluorescence intensity at the peak of riboflavin emission and real vitamin B$_2$ content in beers provides fairly good results. The correlation coefficients of 0.839, 0.860, and 0.858, respectively, for the readings extracted from the emission spectra ($\lambda_{max} = 550$ nm), and from the synchronous fluorescence spectra recorded at $\Delta\lambda = 30$ nm ($\lambda_{max} = 478$ nm) and $\Delta\lambda = 60$ nm ($\lambda_{max} = 464$ nm), respectively. However, the analysis of entire spectra instead of intensity at one wavelength should improve the results, as the model based on multivariate input data should be more robust against possible matrix interferences and differences in background fluorescence.

Partial least squares (PLS) regression was used for testing correlation between the emission and synchronous fluorescence spectra (X) and the real riboflavin concentration (Y) in beers. PLS is a method used for relating the variations in one or several response variables (Y-variables) to the variations of several predictors (X-variables), with explanatory or predictive purposes (Brereton, 2000). PLS models both the X- and Y-matrices simultaneously to find such latent variables in X that will best predict the latent variables in Y.

Emission spectra ($\lambda_{ex} = 450$ nm), and the synchronous fluorescence spectra recorded at $\Delta\lambda = 30$ and 60 nm were used for the analysis (Sikorska, 2006). Riboflavin concentration was determined by fluorometric titration in beer samples, including untreated and irradiated beers and beers with addition of riboflavin. The riboflavin concentrations were in the range of 0.22–3.03 μmol/dm^3, the global mean riboflavin concentration was 0.84 ± 0.71 μmol/dm^3.

All regression models were validated using full cross-validation. Cross-validation is a strategy for validating calibration models based on systematically leaving out groups of samples in the modelling, and testing the left-out samples in the model based on the remaining samples. The regression models were evaluated using the correlation coefficient (r), and the root mean square error of cross-validation (RMSECV) parameter, as a term indicating the prediction error of the model. The RMSECV is defined by:

$$\text{RMSECV} = \sqrt{\frac{\sum_{i=1}^{N}\left(y_i^{\text{pred}} - y_i^{\text{ref}}\right)^2}{N}}$$

Table 95.2 Results of the PLS regression of riboflavin, Rf, content and the fluorescence spectra

PLS model	Spectra range and transformation	Number of samples	Number of latent variables	r	RMSECV (μmol/dm³)
Emission spectra	465–700 nm full range	34	5	0.971	0.15
Synchronous fluorescence spectra. $\Delta\lambda = 30$ nm	250–600 nm full range	36	4	0.974	0.15
	440–520 nm Rf band	36	2	0.967	0.17
Synchronous fluorescence spectra. $\Delta\lambda = 60$ nm	250–600 nm full range	35	3	0.959	0.20
	440–520 nm Rf band	35	2	0.960	0.19

r: correlation coefficient; RMSECV: root mean square error of cross-validation.

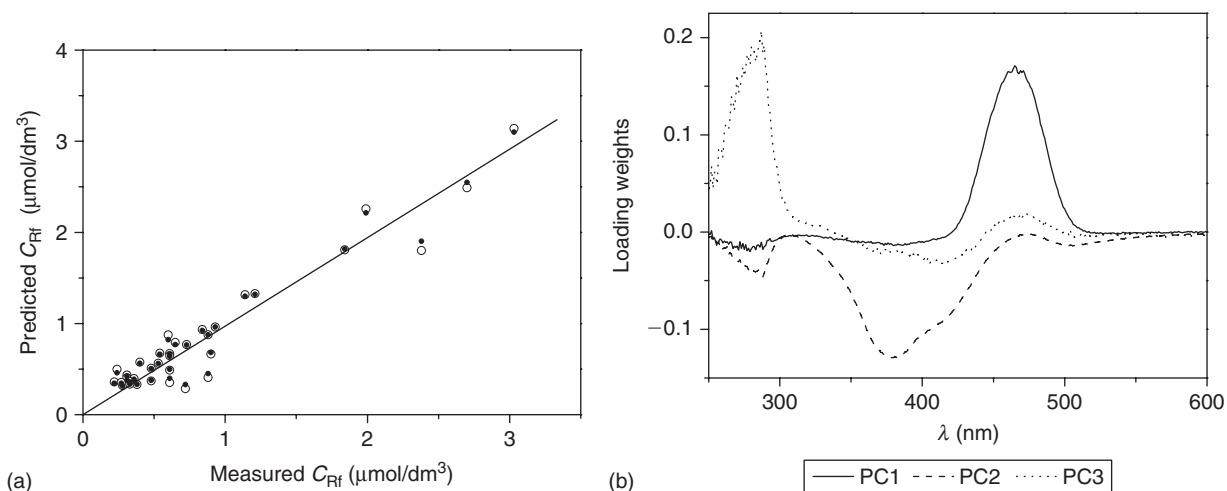

Figure 95.5 Results of the PLS regression based on the entire front-face synchronous fluorescence spectra of beers measured at $\Delta\lambda = 60$ nm and the riboflavin concentration obtained by fluorometric titration. (a) Plot of the riboflavin concentration predicted by the PLS model vs. the concentration measured by reference analysis. (b) Loading weights for the first three PCs of the PLS analysis.

where y_i^{pred} is the predicted concentration value for a sample in the cross-validation procedure, y_i^{ref} is the reference value, and N is the number of samples.

The calibration results are summarized in Table 95.2 and Figure 95.5. Figure 95.5a shows a typical plot of the riboflavin content predicted by the PLS model based on the synchronous fluorescence spectra taken at $\Delta\lambda = 60$ nm vs. the concentration obtained using the reference analysis. The linearity of the plot indicates good performance of the model in predicting the concentration of riboflavin (Sikorska, 2006).

All of the obtained PLS models underline a strong correlation between the fluorescence spectra and the riboflavin concentration. The best fitting parameters were obtained using the emission spectra and the synchronous fluorescence spectra measured at $\Delta\lambda = 30$ nm.

The changes in the spectral range analyzed did not affect significantly the PLS results. The models analyzing

full spectra performed very similarly to those restricted to the spectral zone corresponding to the riboflavin band. However, the number of latent variables was lower for the restricted model. Analysis of the loading weights for PLS regression analysis performed on synchronous fluorescence spectra recorded at $\Delta\lambda = 60$ nm (Figure 95.5b) shows that the PC1, which explains the majority of the Y variance (78%), corresponds to the long-wavelength band with the maximum at 464 nm, with only minor contributions of other spectral ranges, with PC2 and PC3, respectively, explaining 15% and 1% of the total Y variance. Similar results were obtained for PLS regression using synchronous fluorescence spectra recorded at $\Delta\lambda = 30$ nm.

These results and the rather good correlation between the riboflavin concentration and the single-wavelength fluorescence intensity obtained in univariate regression indicate that the interferences affecting riboflavin quantification

are rather insignificant even in undiluted beer samples. The values of RMSECV error for the obtained models corresponded to about 20% of the average riboflavin content over the entire set of beers studied. The relatively high error values may result from analyzing a diversity of beers, 10 different brands, including both untreated and irradiated beers with a wide range of the riboflavin content and diverse matrix constituents. We believe these error values will be significantly reduced in brand-specific models.

Method for Determination of Bitterness in Beer

Bitterness in beer is dependent primarily on the amount of iso-α-acids, which originate from the hop. Determination of these properties in beer and wort is a routine analysis in the brewing industry because bitterness is an essential quality parameter. Christensen et al. (2005) proposed two fluorescence methods for quantitative determination of bitterness in beer. One method was based on excitation–emission matrices of beer autofluorescence. The method requires only dilution and degassing of beer prior to measurements. Multivariate PLS regression models to bitterness expressed in international bitter units (IBU) using six PLS components for 21 beer samples, including light and dark beers. The prediction error (RMSECV) of 2.77 IBU was obtained. The RMSECV was reduced to 1.81 IBU when analysis was performed only on the light beer samples.

An alternative method used the analysis of delayed fluorescence induced by adding lanthanide ions to the beer sample (Christensen et al., 2005). The delayed fluorescence results from the selective chelation of the lanthanide, europium, by the carbonyl structure in the iso-α-acids and the unique fluorescent properties of the resultant europium complex. PLS models yielded an RMSECV error of 2.65 IBU for all beers, while a model for the light beer samples gave an RMSECV of 1.75 IBU.

Comparison Between Fluorescence and Other Spectroscopic Methods in Beer Analysis

Spectroscopic methods applied for direct beer analysis include NMR (Duarte et al., 2002, 2004; Nord et al., 2004; Lachenmeier et al., 2005; Almeida et al., 2006; Khatib et al., 2006), mid-IR (Fourier transform–infrared, FTIR) (Duarte et al., 2004; Llario et al., 2006; Lachenmeier, 2007), and NIR (Engelhard et al., 2006; Inon et al., 2006) spectroscopy. Table 95.3 provides some examples of direct beer analysis using spectroscopic methods.

All discussed techniques require little or no sample preparation. The IR, NIR, and fluorescence methods mostly use relatively inexpensive and simple instrumentation and enable faster spectral measurements, as compared to NMR.

Therefore, they are attractive methods for routine measurements and can be used to screen samples and generate preliminary data that allow the analyst to decide whether a sample requires detailed characterization, perhaps by a more expensive and complex technique. FTIR, NIR, and fluorescence spectroscopy are cheaper, simpler, and faster methods of obtaining compositional information on foodstuffs, compared to NMR.

Much richer information concerning chemical components is provided using ^1H NMR as compared to other spectroscopic techniques. Analysis of ^1H NMR spectra of beers enables the identification of a wide variety of compounds ranging from organic acids, amino acids, and alcohols to higher molecular weight compounds such as lipids and large aromatic compounds like polyphenolics. NIR spectroscopy due to its low sensitivity is limited to the major beer constituents (e.g. alcoholic strength, original gravity). The spectra are more specific in the mid-IR range as compared to NIR, and clear response bands can be observed. The analysis of minor components is possible using FTIR spectroscopy, as for example required in bitterness evaluation and lactic acid quantification in beers. Fluorescence is restricted by its nature to emitting compounds only. This represents both a limitation and a possibility, whereas the multidimensional character enhances the selectivity of fluorescence in comparison to other methods. Moreover, its superior advantage is the highest sensitivity among the spectroscopic methods, which enables analysis of beer components inaccessible by other techniques.

Conclusions

Summarizing, the autofluorescence of beer was characterized, and the potential of fluorescence spectroscopy for qualitative and quantitative analysis of beers was demonstrated. It was shown that several classes of compounds may contribute to beer fluorescence, including vitamins, amino acids, and phenolics. The presented results demonstrated that rapid fluorescence measurements conducted directly on the beer samples and combined with multivariate data analysis can be used for qualitative and quantitative analysis. This method can be applied for beer discrimination according to the brand and freshness. It seems that fluorescence could be used as a simple and sensitive tool for monitoring changes in beer related to the sunstruck flavor formation. Quantitative determination of vitamin B_2 and bitterness is also possible after an appropriate calibration. Further studies are needed to resolve various issues that are important for practical application of the fluorescence techniques, among which are the method verification for specific kinds of beer, and its applicability for quantification of other fluorescent constituents, such as phenolic compounds and amino acids. Such studies will contribute to creation of convenient and widely applicable fluorescence-based methods for beer quality assurance.

Table 95.3 Examples of application of spectroscopic methods for direct analysis of beer

Spectroscopic methods	Technique	Method of data analysis	Application
NMR			
	^{1}H NMR	PCA	Discrimination between ale and lager beers (Duarte et al., 2002) and according to content of dextrins, maltose, and glucose (Duarte et al., 2004)
	^{1}H NMR	PLS	The quantification of organic acids and amino acids (Nord et al., 2004)
	Flow-Injection ^{1}H NMR	PCA, PLS	Discrimination of beers made with barley malt and wheat malt, clustering of beers from the same brewing sites, discrimination of beers with deteriorated quality Quantitative determination of original gravity, ethanol, and lactic acid (Lachenmeier et al., 2005)
	^{1}H NMR	PCA	Discrimination of beers differing in production site and date. Identification of lactic and pyruvic acid, linear dextrins, adenosine/inosine, uridine, tyrosine/tyrosol, and 2-phenylethanol (Almeida et al., 2006)
	2D J-resolved NMR	PCA	Differentiation of beer. Identification of adenine, uridine, xanthine, tyrosine, proline, succinic acid, lactic acid, tyrosol, isopropanol, cholines, carbohydrates (Khatib et al., 2006)
IR			
	FTIR-ATR	PCA	Discrimination of beers according to alcohol contents (Duarte et al., 2004)
	FTIR-ATR	PLS	Determination of original and real extracts and alcohol content (Llario et al., 2006)
	FTIR	PLS	Quantitative determination of ethanol, density, original gravity, and lactic acid. Semi-quantitative determination of pH, bitterness, and EBC color – screening analysis (Lachenmeier, 2007)
NIR			
	NIR	Difference absorption	Determination of ethanol (Engelhard et al., 2006)
Combined FTIR–NIR			
	ATR-FTIR and NIR	PLS, ANN	Determination of real extract, original extract, and ethanol (Inon et al., 2006)
Fluorescence spectroscopy			
	Synchronous fluorescence spectra	PCA	Discrimination of beers of different brands and stored under different conditions (Sikorska et al., 2004b, 2006)
	Synchronous fluorescence spectra, emission spectra	PLS	Determination of vitamin B$_2$ (Sikorska, 2006)
	Excitation– emission matrix	PLS	Determination of bitterness (Christensen et al., 2005)

EBC: European Brewery Convention; FTIR: Fourier transform–infrared; FTIR-ATR: attenuated total reflectance Fourier transform–infrared; ANN: artificial neural network.

Summary points

- Autofluorescence of beer was characterized, and the potential of fluorescence spectroscopy for qualitative and quantitative analysis of beers demonstrated.
- Several classes of compounds may contribute to beer fluorescence, including vitamins, amino acids, and phenolics.

- Rapid fluorescence measurements conducted directly on the beer samples and combined with multivariate data analysis can be used for:
  ◦ qualitative and quantitative analysis;
  ◦ beer discrimination according to the brand and freshness.

- Fluorescence may be used as a simple and sensitive tool for monitoring changes in beer related to the sunstruck flavor formation.
- Quantitative determination of vitamin B$_2$ and bitterness is possible after an appropriate calibration.
- Further studies are needed to resolve important practical issues, including:
  - method verification for specific kinds of beer,
  - its applicability for quantification of other fluorescent constituents, including:
    - phenolic compounds, and
    - amino acids.
  - this will allow to create convenient and widely applicable fluorescence-based methods for beer quality assurance.

Capillary Electrophoresis Methods Used for Beer Analysis

Antonio Segura-Carretero, Sonia Cortacero-Ramírez and Alberto Fernández-Gutiérrez Department of Analytical Chemistry, Faculty of Sciences, University of Granada, Granada, Spain

Abstract

In this chapter, an overview of capillary electrophoretic methods developed for determining different components of beer samples is presented. The different electrophoretic methods for the analysis of carbohydrates, alcohols, amino acids, amines, nucleic derivatives, inorganic and organic anions, vitamins, phenolic acids, bitter acids, aldehydes and sulfur compounds have been chronologically classified and the experimental and instrumental conditions of the electrophoretic method proposed are described in detail. The last section is dedicated to multicomponent analysis by capillary electrophoresis.

Introduction

Beer is a beverage which contains a great number of components, and their determination requires a potent analytical technique such as capillary electrophoresis (CE). CE is a versatile analytical tool that has emerged as a highly promising technique which needs an extremely small amount of sample and reagents and is capable of rapid and high-resolution separations and, what is more, the use of different detectors give an important potential for the analysis of beer components.

This technique permits the direct injection of samples almost without pre-treatment using pressure, vacuum or electrokinetics. Once injected, the sample components move differentially through the capillary under the influence of a high voltage, resulting in a rapid separation. CE is a very versatile technique, mainly because different methods are available such as capillary zone electrophoresis (CZE), micellar electrokinetic chromatography (MEKC), isotacophoresis (ITP), capillary electrochromatography (CEC), capillary gel electrophoresis (CGE) and capillary isoelectric focusing (CIEF) (Marina *et al.*, 2005) allowing the analysis of charged and uncharged compounds, almost all molecules and even whole organisms.

The physical and chemical properties of beer components also influence the different detectors selected. Nowadays, many detection systems can be used, such as ultraviolet (UV)–vis absorption, fluorimetry, phosphorimetry, mass spectrometry (MS), electrochemistry, conductivity and nuclear magnetic resonance, among others. The different detection systems described for CE, and the analytes in beer which can be analyzed are summarized in Table 96.1 (Khun and Hoffstetter-Kuhn, 1993; Fernández-Gutiérrez *et al.*, 2005).

Therefore, the development of CE methods for beer analysis has greatly increased which is reflected in the number of published reports, (Lindeberg, 1996; Sadecka and Polonsky, 2000; Cortacero-Ramírez *et al.*, 2003a). Figure 96.1 shows the number of publications about CE methods for beer analysis.

Analysis of Beer Components by CE

Beer, which is composed of around 8,000 compounds, is a complex sample. In this section, we describe the analysis of the different types of compounds and the possibility of multicomponent analysis using CE.

Analysis of carbohydrates

Carbohydrates are the main non-volatile components of beer (3.3–4.4%) and therefore monitoring the carbohydrates in wort and bottled beers is very important to modern brewing technology, particularly in the development of new kinds of beer and in the selection of raw materials and yeast strains. Three polysaccharides, starch, pentosan (arabinoxilan) and β-glucan together with sucrose are the primary sources of carbohydrates in beer (Vinogradov and Bock, 1998). The main monosaccharides are glucose and fructose, the disaccharides are maltose (14% of total wort carbohydrate) and sucrose (5% total wort carbohydrate)

Table 96.1 Different detection systems for capillary electrophoresis used in the analysis of beer components

Detection mode	Approximately LOD (mol)	Advantages	Disadvantages	Analytes
Optic techniques				
Spectrophotometry				
Direct	10^{-13}–10^{-15}	Easy to use and relatively universal	Relatively low sensitivity	Hop acids, phenolic acid, purines and pyrimidines
Indirect	10^{-12}–10^{-15}			Carbohydrates, inorganic and organic anions
Spectrofluorimetry				
Direct	10^{-15}–10^{-17}	Higher sensitivity than UV detection, high selectivity	Not universally usable	Vitamins
Indirect	10^{-14}–10^{-16}	Universal and rather high sensitivity	Restrictions in the choice of buffers	Amines, amino acids
Pre-column derivatization	10^{-18}–10^{-21}			Amines, amino acids
Post-column derivatization	10^{-17}			
Laser-induced fluorescence	10^{-18}–10^{-20}	The highest sensitivity	Types of analytes restricted	Amines, amino acids
Raman Spectroscopy	10^{-15}	High specificity	Types of analytes restricted	
Refraction index	10^{-14}–10^{-16}	High specificity		Carbohydrates
Electrochemistry techniques				
Conductometry	10^{-15}–10^{-16}	Peak area correlates linearly with migration time	Relatively low sensitivity not universally usable	Alditols, alcohols, amino acids
Amperometry	10^{-18}–10^{-19}	Very high sensitivity and selectivity	Limited to electroactive compounds, difficult to establish	Alditols, alcohols
Other techniques				
Mass spectrometry	10^{-16}–10^{-17}	Universal	Cost of equipment	Hop acids, iso-α-acids
Radiochemistry method	10^{-17}–10^{-19}	Specificity	Highly restricted	
Figure 96.1 Evolution of use of the capillary electrophoretic method in beer analysis.

and the principal trisaccharide is maltotriose. Many of the carbohydrates emanate from the malt itself and others are produced during mashing (Hornsey, 1999).

CE has great potential for the separation of complex carbohydrate samples, but two major difficulties have to be overcome. Firstly, with the exception of a few naturally charged mono- and oligosaccharides, most carbohydrates molecules lack readily ionizable charged functions, a condition which excludes their direct differential migration and, in turn, separation with CE. Secondly, most carbohydrates neither absorb nor fluoresce, hindering their sensitive detection. These difficulties have lead to the use of the inherent properties of carbohydrates including: (i) the ease with which these molecules can be readily converted *in situ* to charged species by complex formation with other ions, such as borate and metal cations, which then ensure their differential electromigration and, in turn, separation in an electric field and (ii) the reactivity of the reducing end and other functional groups of sugar molecules (i.e. carboxylic acid groups and amino groups) which can be readily labeled with UV-absorbing or fluorescent tags, thus providing the centers for sensitive detection. In addition, the electrochemical oxidation of carbohydrates at the surface of metallic electrodes provides another means by which underivatized carbohydrates can be sensitively detected (Rassi El, 1996).

Among the methods published for the analysis of carbohydrates, we can find the research of Guttman *et al.* (1996) who proposed a method for determining carbohydrates in the biopharmaceutical and food and beverage industries (brewing) by CE fingerprinting.

Another method is the pre-column derivatization of carbohydrates with *p*-aminobenzoic acid and their separation as borate complexes by means of CZE, using a capillary tube of fused silica containing 20 mM borate buffer, pH
* This peak in an artifact of PABA labeling

Figure 96.2 Electropherograms of PABA-carbohydrate from different beer samples. Peak assignment: (1) glucose, (2) maltose, (3) maltotriose, (4) maltotetraose, (5) maltopentaose, (6) maltohexaose, (7) maltoheptaose and R, derivatization reagent (*p*-aminobenzoic acid). Operation conditions: 20 mM sodium tetraborate, pH 10.2, capillary LT 57 cm, LD 50 cm, ID 75 μm; 20 kV, 8 s hydrodynamic injection. *Source*: Reproduced from Elsevier, Cortacero-Ramírez *et al*. (2004a).

10.2, as carrier. In this method, on-column UV-monitoring at 280 nm allows the detection of carbohydrates with a reducing end. This has been successfully applied to different types of beer (see Figure 96.2) (Cortacero-Ramírez *et al*., 2004a).

Sucrose, galactose, fructose, glucose and maltose have also been analyzed in beer using microchip CE and a nickel amperometric detector. For this separation 35 mM NaOH in deionized water is used; the injections are carried out by applying the desired potential for 3 s and the voltage applied is 1,000 V (Wang *et al*., 2004).

Cortacero-Ramírez *et al*. (2005a) use CE with indirect detection for the separation of five carbohydrates: sucrose, maltotriose, maltose, glucose and fructose. Indirect detection is an easy procedure that avoids the need for pre- or post-column labeling. This procedure can be used universally, and it is particularly useful for compounds that do not possess the necessary physical properties to allow direct detection. It is based on the displacement of a running electrolyte (chromophore or fluorophore) usually containing a co-ion with functions that can be detected through a

decrease in the measurement signal. The method has been used to determine carbohydrates during the brewing process of a non-alcoholic beer.

Alditols and alcohols

In beers the most important alcohol is ethanol, which is present in most beers at levels in at least twice as high as other alcohols. This important fraction is formed during beer fermentation. Its formation is linked to yeast protein synthesis and is formed from keto-acids, which in turn may be formed by transamination or deamination of the amino acids in the wort, or synthesized from wort carbohydrates.

For the analysis of these compounds, Chen and Huang (1995, 1997) have developed an end-column amperometric detector for CE based on an incorporated Ni-microelectrode used for the determination of 10 alditols and alcohols, obtaining satisfactory performance with respect to the stability of the background current, lowering of detection limit (down to the sub-fmole level) and reproducibility. Its application demonstrates the presence of ethanol, glycerol, myo-inositol, erythritol, xylitol, arabitol and mannitol in two Taiwan beers.

Wang *et al*. (2004) have used a nickel electrode to detect alcohols in beer. Nickel is deposited directly at the end of an electrophoretic glass microchip using an electroless deposition procedure leading to a sensitive amperometric detector for alcohols. They have evaluated the integrated CE–electrochemical detection microsystem for the separation of ethanol and methanol in different beer samples.

Simonet *et al*. (2004) propose a method using CZE and a capillary containing the immobilized enzymes (alcohol dehydrogenase and lactate dehydrogenase) to enhance the sensitivity for the determination of ethanol. The running buffer used is a mixture of 15 mM β-NAD$^+$ in 50 mM phosphate buffer at pH 7.0. Separation is accomplished by using an applied voltage of 10 kV and a capillary temperature of 20°C, and the sample is injected under high pressure (20 psi) for 10 s with detection performed at 340 nm.

Amino acids

Beer contains an average of between 0.2 and 0.6 g/100 ml of protein-derived material. The amino acids are modulators of the flavor of beer and are responsible for the organoleptic quality. The lack of a strong chromophore for aliphatic amino acids has certainly been one of the limitations in the analysis of most natural amino acids by CE, but a common option is determination by direct UV detection at 185 nm or indirect UV detection using background electrolytes (BGEs).

Underivatized amino acids (lysine, histidine, arginine, glycine, alanine, serine, tryptophane, phenylalanine, tyrosine and proline) are determined in beer samples by CE with direct UV detection at 185 nm using a 10 mM phosfate buffer containing 30 mM octanesulfonic acid (pH

2.36) (Klampfl *et al.*, 1998; Klampfl, 1999). The main advantages are the simplicity and the speed of the method, allowing a fast screening of the amino acid patterns. No pre-treatment or derivatization steps are necessary, but the limits of detection (LODs) are relatively high for the aliphatic amino acids (10–50 mg/l). Bednar *et al.* (2001) proposed a method to determine aspartic and glutamic acids enantiomers in beer by CE with indirect detection using 10 mM sorbic acid/histidine, pH 5 and 10 mM of vancomycin.

High-voltage contactless conductivity detection (CCD) of underivatized amino acids in both acidic and basic media has been demonstrated (Tanyanyiwa *et al.*, 2003). The method determines 12 amino acids using buffer solutions at pH values of about 2.5. Lactic acid as BGE gives the best results in terms of LODs for arginine, lysine and histidine, which are approximately 2×10^{-7}, 3×10^{-7} and 4×10^{-7} M, respectively. The use of basic conditions at pH 10–11 generally produces more stable baselines and more consistent sensitivities allowing the determination of a range of 20 amino acids. In beer samples 11 amino acids are identified by this method. Coufal *et al.* (2003) also analyzed 20 underivatized essential amino acids using CZE with CCD. A simple acidic BGE containing 2.3 M acetic acid and 0.1% w/w hydroxyethylcellulose (HEC) allows the electrophoretic separation and sensitive detection of all 20 essential amino acids in their underivatized cationic form. The addition of HEC to the BGE suppressed both the electroosmotic flow and the analyte adsorption on the capillary surface, resulting in an excellent migration time reproducibility and a very good analyte peak symmetry.

To achieve better sensitivities, two alternative detection strategies are frequently used: derivatization of amino acids with a strong chromophore or suitable fluorophore labeling.

Tivesten *et al.* (1997) have developed a method for chiral determination of aspartic and glutamic acid. These compounds are derivatized using a fluorogenic reagent, *o*-phthaldialdehyde-2,3,4,6-tetra-*O*-acetyl-1-thiol-β-D-glucopyranose. With a neutral surfactant, octylglucoside, the D- and L-aspartic and glutamic acid derivatives are resolved outside the micellar retention window creating a high selectivity toward other amino acids. The method is applied for both aspartic and glutamic acid in their D- and L-forms in beer samples. The precapillary derivatization of 20 amino acids with naphthalene-2,3-dicarboxaldehyde (NDA) has been investigated by Dong *et al.* (2002). CZE with electrochemical detection is used for the analysis of these amino acids. The optimum conditions of separation and detection are borate, pH 9.48, for the electrolyte, 18 kV for the separation voltage and 1.15 V vs. a saturated calomel electrode for the detection potential. LODs of concentration for individual amino acids are between 1.7×10^{-7} and 1.8×10^{-6} M for injection voltage of 6 kV and injection time of 10 s. The relative standard deviation

(RSD) is between 0.80% and 2.3% for the migration times and 1.4% and 6.4% for the electrophoretic peak currents. Only 10 amino acids can be well separated. This method is applied to the determination of amino acids in beer by the standard addition method. The recovery for the amino acids in beer is 91–109%.

Table 96.2 shows the experimental and instrumental conditions for analyzing amino acids in beer samples by CE.

Amines

Beer has been commonly reported to be a health risk for some consumers due to the biogenic amines it contains. Volatile amines originate from the malt and the hops used, and the conditions during mashing and boiling influence their concentration in beer.

Preston *et al.* (1997) introduced a method using CE with simultaneous UV–vis, and LIF detection was applied to identify and quantify selected amines (ammonia, ethylamine, isoamylamine and dibutylamine) in beer following derivatization with 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole. The fluorescence detection method is more selective and sensitive for the determination of aliphatic amines in beer than UV–vis absorbance detection.

Sodium citrate buffer at pH 2.5 and sodium phosphate buffer at a concentration of 25 mM (pH 6.5) is used for determination of histamine in non-alcoholic malt beer and beer samples (Mahendradatta and Schwedt, 1998). Two types of extractions, solid-phase extraction (SPE) and liquid–liquid extraction (LLE) are carried out, best results being obtained with SPE.

Zhang *et al.* (2002) used CZE for the determination of histamine using end-column amperometric detection with a carbon fiber microelectrode, at a constant potential. The optimum conditions of separation and detection are 10 mM phosphate buffer, pH 5.6 for the buffer solution, 15 kV for the separation voltage and 1.35 V for the detection potential. The linear range is from 6.3×10^{-7} to 1.5×10^{-5} M with the regression coefficient of 0.9997, and the detection limit is 4.0×10^{-7} M (signal to noise ratio (S/N) = 3). The proposed method has been successfully applied to the direct determination of histamine in beer samples without any sample clean-up procedures.

To increase sensitivity and selectivity other authors use CE with LIF for the analysis of amines. Zhang and Sun (2004) developed a rapid and sensitive method for the simultaneous determination of histamine and histidine by CZE with LIF detection. A fluorogenic derivatization reagent, NDA is successfully applied to label the histamine and histidine, respectively. The optimal derivatization reaction is performed with 1.0 mM NDA, 20 mM NaCN and 20 mM borate buffer, pH 9.1 for 15 min. The separation of NDA-tagged histamine and histidine can be achieved in less than 4 min with 40 mM phosphate buffer (pH 5.8) as the running buffer. The detection limits for histamine and

histidine are 5.5×10^{-9} and 3.8×10^{-9} M, respectively ($S/N = 3$). The RSD for migration time and peak height of derivatives are less than 1.5% and 5.0%, respectively. The method has been successfully applied to the analysis of histamine and histidine in beer samples.

Cao et al. (2005) have studied the analytical potential of a fluorescein analog, 6-oxy-(N-succinimidyl acetate)-9-(2′-methoxycarbonyl) fluorescein (SAMF), as a new labeling reagent for the determination of amino compounds by CE with LIF detection. The derivatization is performed at 30°C for 6 min in boric acid buffer at pH 8.0. The derivatives are baseline-separated in 15 min with 25 mM boric acid running buffer (pH 9.0), containing 24 mM sodium dodecyl sulphate (SDS) and 12.5% v/v acetonitrile. LOD for biogenic amines reaches 8×10^{-11} M ($S/N = 3$). The method has been applied to the determination of biogenic amines in three different beer

samples with satisfactory recoveries varying from 92.8% to 104.8%.

Casado-Terrones et al. (2006), have compared the performance of two CE instruments, one commercial and one homemade device, for the determination of derivatized aminated compounds with fluorescein isothiocyanate (FITC). The commercial CE system first uses an argon ion laser as excitation source; the homemade CE device uses an inexpensive blue light-emitting diode (LED) as the light source and a charge-coupled device (CCD) as the detection system. After fine optimization of several separation parameters in both devices, a co-electroosmotic flow CE methodology is achieved in coated capillary tubing with 0.001% hexadimetrine bromide (HDB), and 50 mM sodium borate at pH 9.3 with 20% 2-propanol for the determination of several amines and aminoacids. Both systems have been applied to beer samples.

A sensitive CE method has been developed by Cortacero-Ramírez *et al.* (2007) for the simultaneous determination of 10 biogenic amine using LIF. Sample amines are first derivatized with FITC and filtered, and then separated with an uncoated capillary tubing in the presence of 50 mM sodium borate and 20% acetone at pH 9.3 at 30 kV. It is possible to analyze biogenic amines in brewing-process samples and in beer samples in less than 30 min, obtaining detection limits between 0.3 μg/l for ethylamine and 11.9 μg/l for 1,6-hexanodiamine.

Nucleic acid derivatives

Few methods exist for the determination of nucleic acid derivatives in beer by CE. Klampfl *et al.* (2002) have presented a quick and simple method for the determination of five purine bases (adenosine, guanosine, adenine, hypoxanthine and xanthine) and five pyrimidine bases (cytosine, cytidine, uridine, thymine and uracil) in beer samples using CZE with direct UV detection at 254 nm as well as MS detection using an electrospray ionization (ESI) interface. For this purpose, a carrier electrolyte and composition compatible with both methods of detection containing 300 mM diethylamine (DEA) is selected. LOD are in the range between 0.1 and 0.3 mg/l and calibration plots are found to be linear over at least two orders of magnitude.

Cortacero-Ramírez *et al.* (2003b, c, 2004b, c, d), have also determined purine and pyrimidine bases among other components by CZE-DAD and MEKC-DAD (for more detail see section "Multicomponent analysis").

Inorganic and organic anions

The measurement of the concentrations of inorganic and organic anions, in all phases of beer production, can be used to help track metabolic products of fermentation and correlate beer flavor trends. For the determination of these types of components CZE is normally used with indirect detection.

DeVries (1993) has determined organic acids (malate, citrate, succinate, pyruvate, acetate and lactate) by CE with indirect UV detection at pH 5.5 and the levels of organic acids in beer are tracked from cold wort to packaged beer.

Soga and Ross (1997) and Soga and Wakaura (1997) have determined three inorganic anions (chloride, sulfate and phosphate) and nine organic anions (oxalate, formate, malate, citrate, succinate, pyruvate, acetate, lactate and pyroglutamate) in beer using 2,6-pyridinedicarboxylic acid (pH 5.6) containing 0.5 mM cetyltrimethylammonium bromide, as BGE and indirect UV detection at 350 nm in less than 7 min. The LODs for all analytes are in the range of 0.9–2.5 mg/l. The method described allows the quantitative analysis of low-molecular-mass ionic components in beer using indirect UV detection as well as conductivity detection, providing RSD between 0.5% and 6.6% for the peak areas and excellent LODs ranging from 0.02 mg/l for chloride to 0.41 mg/l for phosphate.

For the determination of inorganic and organic anions in different types of beer, Klampfl and Katzmayr (1998) and Klampfl (1999), found it to be advantageous to use CZE with conductivity detection in series with UV detection at 254 nm. With a running buffer composed of 7.5 mM 4-aminobenzoic acid and 0.12 mM tetradecyltrimethylammonium bromide (pH 5.75 adjusted by the addition of histamine), conductivity detection proved to be more sensitive for the faster migrating anions, whereas UV detection was found to be superior for analytes with mobilities similar to that of 4-aminobenzoic acid. The combination of direct conductivity detection and indirect UV detection is useful for CZE analysis of samples such as beer containing both inorganic anions and organic low-molecular-mass anionic solutes, such as carboxylic acids. Using this technique, low LODs and LOQs can be obtained over a wide range of analyte mobilities. Conductivity detection is more suitable for ions with mobilities that are highly different from those of the carrier electrolyte co-ion, whereas indirect UV detection is superior for analytes showing the same or only small differences in mobility. This has been demonstrated for different varieties of beer samples, including fast migrating solutes, that is, chloride, sulfate and oxalate, as well as slowly migrating ingredients such as lactate, phosphate and pyroglutamate. Carbonate is determined in beer samples using on-line gas diffusion coupled to CE in a flow arrangement (Kuban and Karlberg, 1998).

The use of highly absorbing anionic dyes as probes and isoelectric ampholytes as buffers in BGEs combined with the use of an LED as a light source has been studied for ultrasensitive indirect photometric detection in CE (Johns *et al.*, 2000). Two dyes, tartrazine and naphthol yellow S, with histidine as the ampholytic buffer, were selected for detailed investigation. For the naphthol yellow *S*-histidine BGE, linearity and reproducibility were also evaluated, with excellent linearity being observed over a range of 5–500 mM, and reproducibility less than 1% for migration times and 2–8% for normalized peak areas. The approach has been successfully applied to several real samples including tap water, mineral waters and beer.

Masar *et al.* (2003), have used a poly(methylmethacrylate) CE chip, provided with a high sample load capacity separation system (a 8,500 nl separation channel combined with a 500 nl sample injection channel) and a pair of on-chip conductivity detectors, for CZE determination of oxalate in beer. Hydrodynamic and EOFs of the solution in the separation compartment of the chip are suppressed and electrophoresis is a dominant transport process in the separations performed on the chip. A low pH of the carrier electrolyte (3.8), implemented by aspartic acid and bis-tris propane, provides an adequate selectivity in the separation of oxalate from anionic beer constituents and, at the same time, a sufficient sensitivity in its conductivity detection. Under these working conditions, this anion can be detected at a 0.5 μM concentration in samples containing chloride (a major

anionic constituent of beer) at a 1,800 higher concentration. Such a favorable analyte/matrix concentration ratio allows accurate and reproducible (typically, 2–5% RSD values of the peak areas of the analyte depending on its concentration in the sample) determination of oxalate in 500 nl volumes of 20–50 fold diluted beer samples. Short analysis times (about 4 min), minimum sample preparation and reproducible migration times of this analyte (0.5–1.0% RSD values) are characteristic for the CZE chip.

CZE with direct detection have been used when the components absorb. Therefore, a separation and determination of a mixture of 19 low-molecular-mass organic acids usually present in beer samples (oxalic acid, fumaric acid, ketoglutaric acid, mesaconic acid, malic acid, pyruvic acid, phthalic acid, benzoic acid, pyroglutamic acid, sorbic acid, 4-aminobenzoic acid, 4-hydroxybenzoic acid, protocatechuic acid, gallic acid, *p*-coumaric acid, homovanillic acid, syringic acid, ferulic acid and sinapinic acid) has been carried out by Cortacero-Ramírez *et al.* (2005b) using CZE electrophoresis. A polycation (HDB) is added to the electrolyte, which dynamically coats the inner surface of the capillary and causes a fast EOF. The main factors affecting reversal of the EOF such as the type of modifier and concentration and influence of organic solvents have been studied. Other modifiers, such as cetyltrimethylammonium bromide and tetradecyltrimethylammonium bromide have also been investigated. The composition of the running buffer is 25% 2-propanol, 0.001% HDB and 50 mM sodium phosphate (pH 8). The different instrumental parameters affecting the capillary electrophoretic separation used as optimum are a –15 kV voltage with a hydrodynamic injection for 7 s with UV detection at 210 nm. Figure 96.3 shows an electropherogram in the condition previously described.

Vitamins

Beer contains small amounts of vitamins and a moderate intake can make a contribution to the daily vitamin requirements for health (http://www.beerandhealth.com).

L-Ascorbic acids are often added to beer as antioxidants, D-erythorbic acids have the same antioxidative properties as L-ascorbic acid and are sometimes substituted for L-ascorbic acid because they are cheaper. Marshall *et al.* (1995) have achieved baseline separation of L-ascorbic acid and D-erythorbic acid using a buffer consisting of 50 mM SDS and 5 mM dipotassium hydrogenorthophosphate (pH 9.2). Ten beers were analyzed for total L-ascorbic acids using this buffer. Baseline separation of L-ascorbic and D-erythorbic acids are also maintained when SDS is used for the separation. Replacing the 5 mM phosphate buffer (pH 9.2) with a 1:1 mixture of 20 mM tetraborate and 20 mM phosphate buffer (pH 8.6) results in enhanced separation of the two isomeric acids and a much shorter run time (6 min).

Klampfl *et al.* (2002) and Cortacero-Ramírez *et al.* (2003b, c, 2004b, c, d) determined adenine (vitamin B4)
Figure 96.3 Separation of aliphatic and aromatic acids by co-electroosmotic CZE. Peaks: (1) oxalic acid (300 mg/l), (2) fumaric acid (10 mg/l), (3) ketoglutaric acid (100 mg/l), (4) mesaconic acid (10 mg/l), (5) malic acid (300 mg/l), (6) pyruvic acid (100 mg/l), (7) phthalic acid (10 mg/l), (8) benzoic acid (10 mg/l), (9) pyroglutamic acid (50 mg/l), (10) sorbic acid (10 mg/l), (11) 4-aminobenzoic acid (10 mg/l), (12) 4-hydroxybenzoic acid (10 mg/l), (13) protocatechuic acid (10 mg/l), (14) gallic acid (10 mg/l), (15) *p*-coumaric acid (10 mg/l), (16) homovanillic acid (10 mg/l), (17) syringic acid (10 mg/l), (18) ferulic acid (10 mg/l), (19) sinapinic acid (10 mg/l). Electrophoretic conditions: 50 mM sodium phosphate (pH 8), 0.001% HDB and 25% 2-propanol, hydrodynamically injection for 7 s, voltage –15 kV. *Source*: Reproduced from Elsevier, Cortacero-Ramírez *et al.* (2005b).

together with other analytes by CE with direct UV detection in different beer samples, finding that their content in beers with a reduced alcohol content, such as non-alcoholic beers and the light beers is higher than in other beers.

Su *et al.* (2004) described a simple, inexpensive and reliable method for the routine analysis of riboflavin in beer by CE–LED detection. A simple and straightforward sample preparation is involved and the method is based on an inexpensive blue LED as the light source combined with an on-line sample concentration technique. For this detection system, using a normal MEKC, stacking-MEKC and dynamic pH junction techniques, the LOD are found to be 480, 20 and 1 mg/l, respectively. In addition, the number of theoretical plates for riboflavin is determined to be 3.8×10^4 by means of a dynamic pH junction and this is improved to 3.2×10^6 when the dynamic pH junction-sweeping mode is applied. The concentrations of riboflavin in 12 samples of different types of commercial beer were found to be in the range of 130–280 mg/l.

The application of a UV-LED to on-line sample concentration/fluorescence detection in CE is described by Chang *et al.* (2006). The utility of a UV-LED (peak emission wavelength at 380 nm) is demonstrated by examining riboflavin. LOD for riboflavin is determined to be 0.2 mg/l

by the normal MEKC mode, which improves to 3–7 μg/l when the dynamic pH-junction technique is applied. With this system, the concentration of riboflavin in beer can be determined.

Phenolic acids

Beverages of plant origin contain significant amounts of phenolic acids, these compounds have been well-described during recent years for their properties as antioxidants and scavengers of reactive oxygen and nitrogen species (Bourne et al., 2000). In beer, phenolic acids are extracted into boiling wort; these compounds emanate from both malt and hops.

CE using amperometric detection has been used to detect phenolic acids in beer samples (Moane et al., 1998). The electrophoretic separation requires the phenolic acids to be charged and therefore the pH is above their pK_as. However, electrochemical detection is optimum when the pH is 7.2. Cationic and neutral compounds in the beer samples interfere with electrochemical detection by passivating the electrode surface. These compounds are removed using a reversed-polarity injection technique to elute them from the separation capillary into the sample reservoir prior to electrophoretic separation. Electrophoretic peaks in the samples are identified by both matching their migration time and electrochemical properties with standards. The use of voltametric characterization provides improved peak identification for complex samples. Holland et al. (1999) have determined ferulic acid in beer by CE using an integrated on-capillary dual electrode electrochemical detector.

Rapid separation of a group of eight antioxidants by co-electroosmotic CE and their preliminary determination in foods (cereal, wine and beer) is described by Hernández-Borges et al. (2005). The compounds studied were protocatechuic acid, salicylic acid, p-hydroxybenzoic acid, vanillic acid, syringic acid, p-coumaric acid, ferulic acid and sinapinic acid. The best separation is achieved by the use of a running buffer consisting of 125 mM boric acid, 49 mM disodium hydrogen phosphate, 0.002% (w/v) HDB and 2.5 mM α-cyclodextrin, at pH 7.5; the analysis time is less than 3.5 min. Migration time and peak area reproducibility, studied on the same day ($n = 4$) and on three different days ($n = 12$), shows the method is reproducible. Antioxidants are extracted from beer samples by SPE with C-18 cartridges. This study shows that five of the eight compounds can be detected in beer samples.

Cortacero-Ramírez et al. (2005b) have also determinated 12 phenolic acids together with 7 organic acids using CE electrophoresis (see details in section "Inorganic and organic anions").

Beer bitter acids

The organoleptic characteristics of beer are mainly determined by the bitter-tasting iso-α-acids, which, in the brewing process, are formed from the α-acids occurring in hops. Quantification of the individual iso-α-acids is not straightforward, but recent results obtained by MEKC are promising. This capillary separation technique combines electrophoretic propulsion with chromatographic partitioning. The separation medium is a fused silica capillary, typically 50–75 μm ID filled with a buffer containing a surfactant that forms a micellar microphase (Van Ginkel et al., 1992).

Vindevogel et al. (1991) have used MEKC-UV for the separation of six iso-α-acids using 30 mM phosphate buffer (pH 7.6) containing 40 mM SDS at 254 nm. Similar electrophoretic conditions are used to determine the total iso-α-acids previously preconcentrated by SPE (Szücs et al., 1993). However, this method is labor intensive and difficult to automate. Therefore, a second approach, involving direct injection of beer with on-column focusing, has been investigated. Finally, 40 mM SDS, 65 mM phosphate and a 25 s injection time were selected for quantitative analysis. McLaughlin et al., (1996) have also optimized a separation of iso-α-acids and β-acids from hop extracts by MEKC-UV at 214 nm, using a buffer 25 mM sodium tetraborate adjusted to pH 8.55 with 100 mM boric acid with 100 mM SDS.

MEKC has been used by Royle et al. (2001) for the separation of a sample of iso-α-acids and samples of reduced iso-α-acids (rho-, tetrahydro- and hexahydro-derivatives). Separation is performed in a fused silica capillary (64.5 cm total length and 56 cm to the detector, 50 μm ID) using 50 mM borate buffer containing 40 mM SDS at pH 9.3. Separations are monitored at 200 nm, with full spectral collection from 190–600 nm. Cortacero-Ramírez et al. (2004c) have also used MEKC-UV, to determine iso-α-acids among other components of beer. A buffer of 25 mM sodium borate and 110 mM SDS at pH 10.5 is selected as optimum.

Recently, CE has been coupled to MS. In general, if a separation technique is coupled with MS, the detection limits are better than those using UV detection, and the interpretation of the analytical results is more straightforward and more information is obtained because MS detection provides molecular weight and structural information. On-line coupling of CZE-ESI-MS for the separation and characterization of iso-α-acids in beer was investigated for the first time by García-Villalba et al. (2006). The CE-ESI-MS separation method consists of a running buffer 160 mM ammonium carbonate/ammonium hydroxide, pH 9, voltage 20 kV, 7 s injection time, sheath liquid 2-propanol/water 50:50 (v/v) with 0.1% TEA delivered at a flow ratio of 3 μl/min, a drying gas flow ratio at 4 l/min and at 150°C, nebulizing gas pressure 6 psi and MS analyses carried out using a compound stability of 25%. Figure 96.4 shows an electropherogram and mass spectra of an extra beer.

Aldehyde and ketone compounds

Acetaldehyde is determined in beer samples using capillary pieces containing immobilized enzymes (alcohol
Figure 96.4 Electropherogram and mass spectra of an extra beer. Separation conditions were buffer ammonium carbonate/ammonium hydroxide 160 mM at pH 9; 50 μm ID fused silica capillary, 100 cm detector and total length, 20 kV, 7 s of hydrodynamic injection at 0.5 psi. Sheath liquid: 2-propanol/water 50:50 (v/v) containing 0.1% TEA, flow rate of 3 μl/min. Dry gas: 4 l/min, 150ºC. Nebulizing gas pressure 6 psi. MS analysis was carried out using negative polarity. Compound stability: 25%. Peak numbers: *Unknown peak; 1, *trans* iso-humulone and *trans* iso-adhumulone (*m/z* 361.2); 2, iso-cohumulone (*m/z* 347.2). *Source*: Reproduced from American Chemical Society, García-Villalba *et al*. (2006).

Table 96.3   Analysis of beer samples

Peak Number	Analytes	Concentration (mg/l)

dehydrogenase and lactate dehydrogenase). On reaching the enzyme, the analyte is converted into a product with a high electrophoretic mobility, the migration time for which is a function of the position of the enzyme reactor. The running buffer is 12.5 mM β-NADH in 50 mM phosphate buffer at pH 7.0, voltage of 10 kV, capillary temperature of 20°C, hydrodynamic injection at 20 psi for 10 s and detection at 340 nm (Simonet *et al.*, 2004).

Do Rosario *et al.* (2005) have described a method for the determination of methylglyoxal (aldehyde form of pyruvic acid) in beer and yeast cells suspension matrices using *o*-phenylenediamine as derivatizing agent and SPE followed by CZE-DAD. 25 mM sodium phosphate running buffer at pH 2.2, 30 kV and 25°C gives the best instrumental conditions for the optimum separation of methylglyoxal in a suitable analytical time (<0 min), using an uncoated fused silica capillary of 75 μm inner diameter and an effective length of 45.1 cm with an extended light path and the wavelength set to 200 nm. Under optimized instrumental conditions, good reproducibility of the migration time (<1.1%), precision (<5%), an excellent linear dynamic range from 0.1 to 3.6 mg/l ($r^2 = 0.9997$), and low LODs (7.2 μg/l) are obtained for methylglyoxal measurements, using the internal standard system. This system could be used for routine quality control analysis as it is very cost-effective.

Sulfur compounds

The importance of numerous volatile sulfur compounds in the overall flavor of beer and in control of processing operations has long been recognized. The occurrence of hydrogen sulfide in fermentation gas has led to many surveys on the mechanisms of the formation of this compound and of mercaptans.

On-line gas diffusion coupled to CE system in a flow arrangement is a suitable technique for automated pre-treatment of samples with a complicated matrix composition (Kuban and Karlberg, 1998). The sample is merged with a modifying solution, that is a strong acid, in a flow system to transform the analytes of interest into their respective gaseous forms. With this method sulfite is not found in beer samples.

Multicomponent analysis

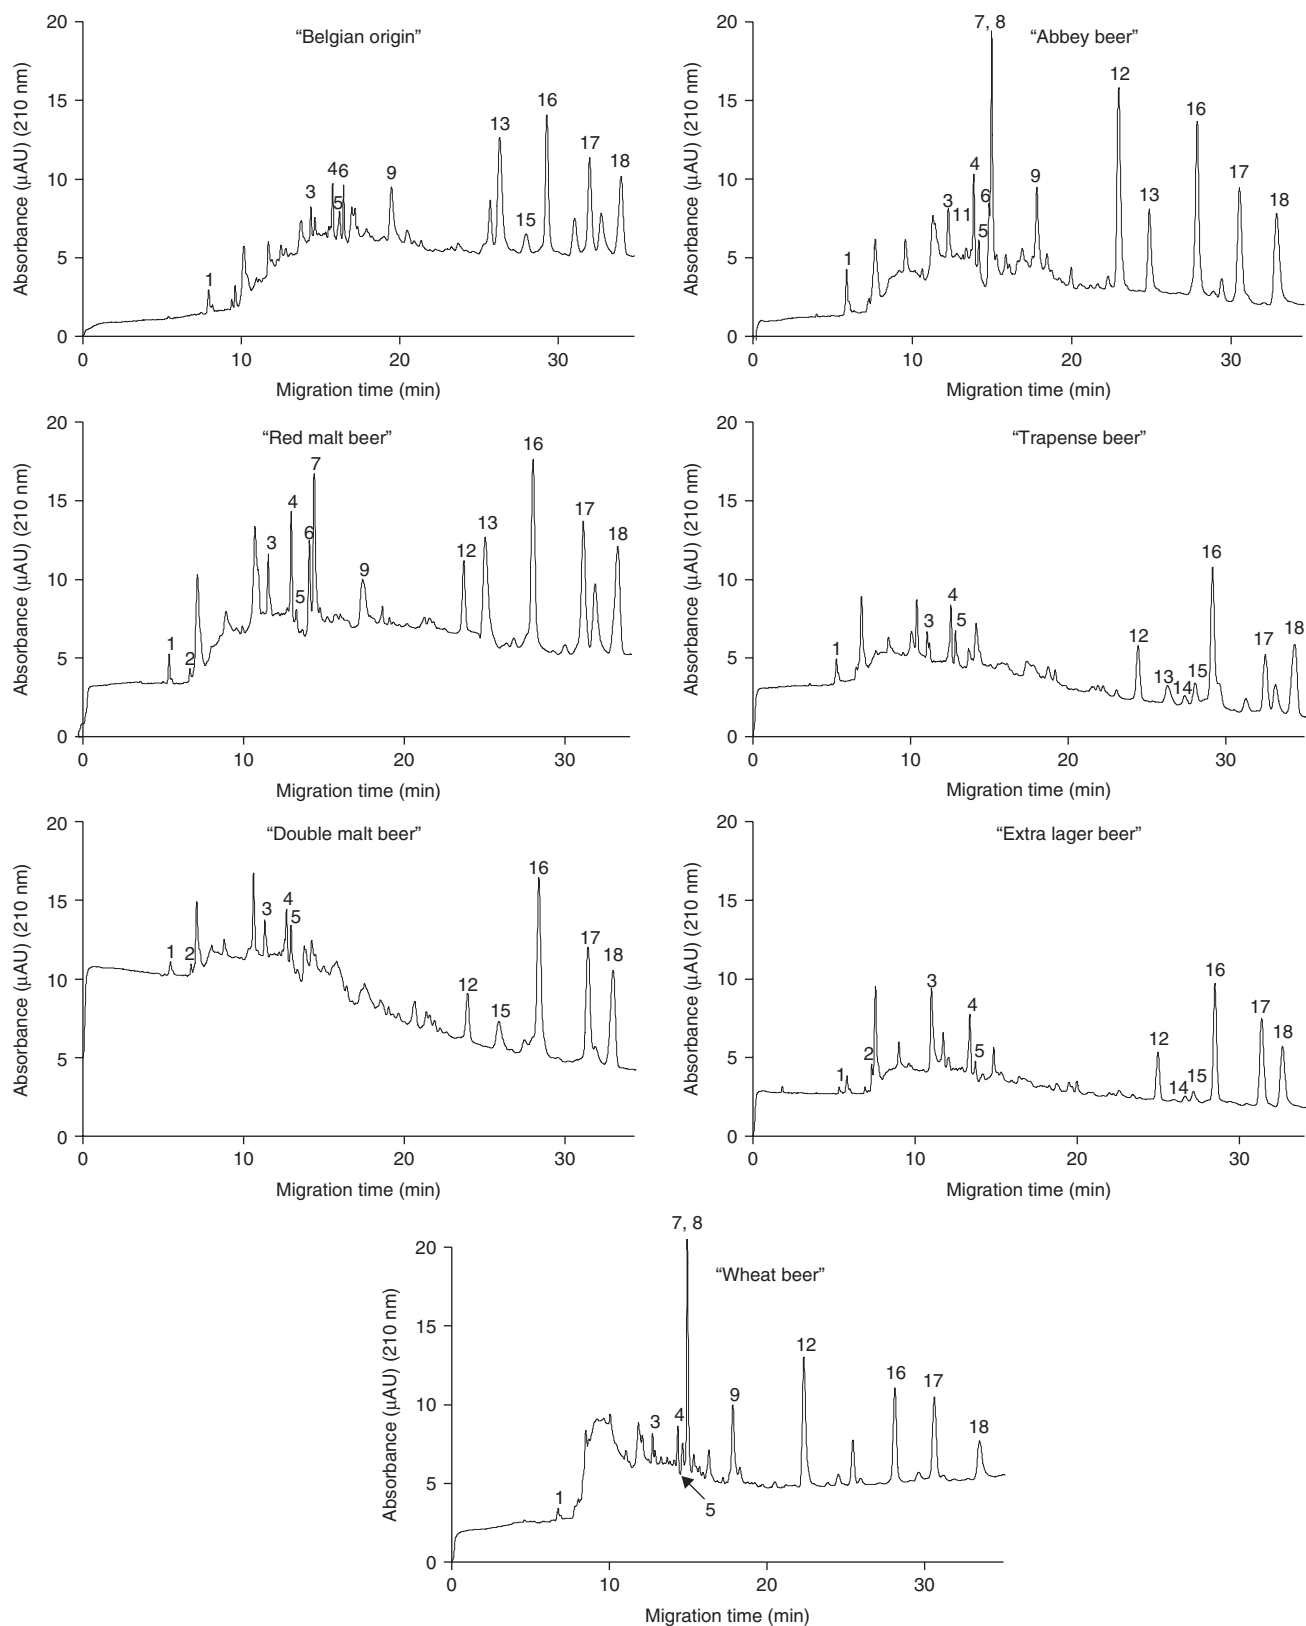
Breweries are an important branch of the food and beverage industries, and a large number of analytical determinations for processing as well as quality control are carried out in breweries every year. CE is a versatile technique and permits the analysis of a great number of components. Simultaneous determination of alcohols, amines, amino acids, flavonoids, and purine and pyrimidine bases in bottled beer samples directly without any pre-treatment has been carried out by CZE-DAD (Cortacero-Ramírez *et al.*, 2003a, b, c, 2004b). The best separation of the cited analytes is achieved in 70 mM sodium tetraborate solution and pH 10.25. LODs are from 2.1 to 5.6 mg/l for the 18 compounds studied. The developed method is rapid, sensitive and quantitative and has been applied to seven types of international bottled beers of different origins bought locally (see Table 96.3 and Figure 96.5).


Figure 96.5   Electropherogram of beer samples of different origins. Conditions: 70 mM sodium borate buffer; pH 10.5; separation voltage, 20 kV; detection at 210; capillary, 50 cm × 75 μm ID (separation length, 50 cm); hydrodynamic injection, 5 s. Peak identification: 1 = tryptamine, 2 = tyramine, 3 = tyroso,; 4 = cytidine, 5 = adenosine, 6 = tryptophan, 7 = thymine, 8 = adenine, 9 = phenylalanine, 10 = rutin, 11 = maltol, 12 = tyrosine, 13 = uracil, 14 = epicatechin, 15 = catechin, 16 = guanosine, 17 = uridine, 18 = xanthine. *Source*: Reproduced from Springer-Verlag, Cortacero-Ramírez *et al.* (2004b).

Cortacero-Ramírez *et al.* (2004c, d) have developed a capillary electrophoretic method using MEKC-DAD to simultaneously analyze 26 beer constituents in a single procedure, including alcohols (furfuryl alcohol, maltol, tyrosol and 2-phenylethanol), iso-α-acids (iso-humulone, iso-cohumulone and iso-adhumulone), amino acids (phenylalanine, tryptophan and tyrosine), flavonoids (rutin, epicatechin and catechin) isoflavonoids (daidzein and genistein), vitamins (thymine and nicotinic acid), purine and pyrimidine bases (cytidine, adenosine, adenine, uracil, guanosine, hypoxanthine, uridine, adenosine-3′-monofosfate and xanthine).

After filtration, sample components are separated with uncoated capillary tubing and a 25 mM sodium borate and 110 mM SDS buffer at pH 10.5. Analyses are run at 14 kV and 8 s of hydrodynamic injection with UV detection at 210 and 270 nm that permits the resolution and determination of these compounds in beer samples. The method has been successfully applied to the direct determination of beer constituents without any sample clean-up procedures.

Summary Points

- This chapter has been written with the aim of summarizing all the publications on the use of CE in beer, and to investigate increasing the use of this technique in breweries routine analysis.
- Beer analysis is very important for quality control. In CE beer samples can often be directly injected into the separation capillary or require only minimal pre-treatment, such as dilution, derivatization or filtration.
- Solutes, which cannot be determined by direct sample injection have to be extracted and often concentrated. For extraction, the SPE procedures are typically used which have advantages of simplicity, rapidity, solvent elimination, high sensitivity, small sample volume, lower cost and simple automatization.
- Beer also contains many important components beneficial for health and the prevention of diseases, which can be analyzed by CE.
- Quantitative analysis is possible and the performance is comparable to that achieved with chromatographic techniques.

Manual and Robotic Methods for Measuring the Total Antioxidant Capacity of Beers

Justin A. Fegredo, Max C.Y. Wong, Helen Wiseman and Victor R. Preedy Department of Nutrition and Dietetics, King's College London, London, UK

Abstract

It is well known that antioxidants are able to confer some protective effect against numerous pathologies such as cardiovascular disease. Alcoholic beverages such as red wine have thus attracted particular attention in recent years due to their high concentration of antioxidants such as phenolic compounds. However, research and information on the *in vitro* total antioxidant capacity (TAC) of beer has been limited, despite human studies suggesting that antioxidants in such beverages are bioavailable.

In this chapter, we provide comprehensive protocols for four commonly used assays for TAC: the oxygen radical absorbance capacity (ORAC), ferric reducing ability of plasma (FRAP), Trolox® equivalent antioxidant capacity (TEAC) and total phenols by Folin–Ciocalteu reagent (TP-FCR) assays. We have tested these assays for linearity and precision, finding excellent correlations and coefficients of variation, and furthermore applied these assays to measure the TAC of beers, red wines and orange juices. We found that the mean TAC of a number of ales (mean TEAC, 7.02 ± 0.08 mM Trolox® equivalents (TE); FRAP, 2.71 ± 0.18 mM; ORAC, $7{,}516 \pm 404$ μM TE; TP-FCR, 398 ± 30 mg/l) was several-fold lower than that of red wines (mean TEAC, 36.87 ± 1.04 mM TE; FRAP, 19.77 ± 1.25 mM; ORAC, $27{,}963 \pm 908$ μM TE; TP-FCR, $1{,}807 \pm 94$ mg/l) but comparable to that of commercially available orange juices (mean TEAC, 6.86 ± 0.28 mM TE; FRAP, 2.88 ± 0.94 mM; ORAC, $5{,}662 \pm 630$ μM TE; TP-FCR, 648 ± 45 mg/l). In addition, all of the assays showed strong linear correlations with one another (mean $r^2 = 0.96$, range 0.91–0.99).

The availability of comprehensive protocols for these assays will enhance research into TAC of beers and augment the evidence base for their benefit in health and wellbeing.

List of Abbreviations

6-FAM	6-Carboxyfluorescein
AAPH	2,2′-Azobis(2-amidinopropane)
ABTS	2,2′-Azino-bis(3-ethylbenzthiazoline-6-sulfonic acid)
AUC	Area under curve
FRAP	Ferric reducing ability of plasma
ORAC	Oxygen radical absorbance capacity
QC	Quality control
TAC	Total antioxidant capacity
TEAC	Trolox® equivalent antioxidant capacity
TP-FCR	Total phenols by Folin–Ciocalteu reagent
TPTZ	2,4,6-Tripyridyl-*s*-triazine
Trolox®	6-Hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid
β-PE	β-Phycoerythrin

Introduction

The physiological activity of antioxidants has long been recognized as conferring some protective effect against numerous pathologies (Halliwell and Gutteridge, 1999). Although there are several endogenous antioxidant defense mechanisms, low-molecular-mass radical scavenging agents available as dietary antioxidants have received particular attention (Halliwell and Gutteridge, 1999). Beverages with a high antioxidant capacity, such as red wine and beer (Frankel *et al.*, 1995; Montanari *et al.*, 1999; Pellegrini *et al.*, 2000), have thus received special interest, and indeed it is their antioxidant component which is thought to account for some of their protective properties (Frankel *et al.*, 1993). *In vivo* studies in human volunteers have furthermore demonstrated that these antioxidants are bioavailable, and a significant increase in total antioxidant capacity (TAC) of plasma has been observed following ingestion of both red wine (Fernandez-Pachon *et al.*, 2005) and beer (Ghiselli *et al.*, 2000). It can therefore be concluded that the *in vitro* measurement of TAC of such beverages is of direct biological relevance.

Total Antioxidant Capacity As a Tool for Measuring Antioxidant Protection

Measurement of TAC (i.e. the total antioxidant protection provided by a sample) is both less costly and arguably of

greater biological relevance than measurement of individual antioxidants (e.g. individual polyphenols) since it takes into account both synergistic interactions (Huang *et al.*, 2005) and the contribution of presently unidentified antioxidant components (Rice-Evans *et al.*, 1996). Historically, assays for TAC have been classified according to their mathematical foundation (as either endpoint or area-under-curve (AUC) methods), although recently a newer classification has evolved according to whether the assays involve hydrogen atom transfer or electron transfer (Huang *et al.*, 2005). Hydrogen atom transfer-based assays, such as the oxygen radical absorbance capacity (ORAC) assay, typically involve monitoring competitive reaction kinetics – antioxidants compete with an oxidizable molecular probe to reduce free radicals; by monitoring

oxidation of the probe, the degree of antioxidant protection for the probe (and hence TAC) can be derived (Huang *et al.*, 2005). Electron transfer-based assays, such as the ferric reducing ability of plasma (FRAP), Trolox® equivalent antioxidant capacity (TEAC) and total phenols by Folin–Ciocalteu reagent (TP-FCR) assay, involve one redox reaction (i.e. the transfer of an electron between two chemical species); TAC is then quantified by using the oxidant (i.e. the electron acceptor) as an indicator of reaction endpoint (Huang *et al.*, 2005). The mechanism behind these four assays is summarized in Table 97.1. Nevertheless, regardless of the assay employed, due consideration needs to be given to accuracy, precision (repeatability and reproducibility), linearity and limits of detection and quantification (see Table 97.2 for definitions).

Table 97.1 Commonly used assays for TAC

Assay	Mechanism
TEAC	Antioxidants present in the substrate promote reduction of an ABTS$^{\bullet+}$ radical cation which absorbs light at wavelength 734 nm. As in the ORAC assay, Trolox® is commonly used as an antioxidant standard (Re *et al.*, 1999).
FRAP	Antioxidants present in the substrate promote reduction of a ferric-2,4,6-tripyridyl-*s*-triazine (TPTZ) complex to its ferrous counterpart. Absorbance of the Fe^{2+}–TPTZ complex at 593 nm is monitored and correlated with TAC. Ascorbic acid is commonly used as an antioxidant standard (Benzie and Strain, 1996).
ORAC	Antioxidants present in the substrate compete with a 6-carboxyfluorescein (6-FAM) probe for reduction of thermally generated free radicals derived from 2,2′-azobis(2-amidinopropane) (AAPH). TAC is assessed by monitoring fluorescence of the 6-FAM probe. 6-Hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox®) is commonly used as an antioxidant standard (Naguib, 2000).
TP-FCR	The mechanism behind this assay is unclear. However, the presence of antioxidants results in a blue species (possibly $PMoW_{11}O_{40})^{4-}$ which absorbs light at 760 nm and can be used to quantify TAC (Huang *et al.*, 2005). Gallic acid is commonly used as an antioxidant standard (Singleton *et al.*, 1999).

Table 97.2 Definition of assay parameters

Assay parameter	Definition
Accuracy	Accuracy refers to the closeness of agreement between actual test results and those expected according to true, accepted or reference values.
Coefficient of variation (CV)	CV quantifies the variability of a set of measurements around their arithmetic mean. It is calculated as (standard deviation/mean) and often multiplied by 100 to be expressed as a percentage. CV below 10–15% is generally regarded as acceptable.
Limit of detection and quantification	Limit of detection (blank plus three standard deviations of the blank) is defined as the minimum assay signal that can be *qualitatively* distinguished from noise. Limit of quantification is more stringent (blank plus nine standard deviations of the blank) and is the level above which a *quantitative* determination can be reliably made.
Linearity	An assay is said to be linear if the output is proportional to the input (e.g. in the FRAP assay, absorbance at 593 nm is proportional to concentration of ascorbic acid).
Repeatability	Repeatability refers to the precision (variation in repeated measurements taken from a single system) under consistent conditions (i.e. using the same instrumentation, the same operator and measuring repeats over short time periods). Often expressed as CV (see above) between measurements.
Reproducibility	Reproducibility refers to the precision (variation in repeated measurements) when using the same measurement procedure under inconsistent conditions (i.e. different instrumentation, operators or measuring repeats over longer time periods). Often expressed as CV (see above) between measurements.

Note: Assay parameters such as accuracy, linearity, limit of detection and quantification, and precision (repeatability and reproducibility) are important indicators of method reliability and due consideration should be given to such measures before the assays are employed.

Feasibility of the Assays in Determining Total Antioxidant Capacity

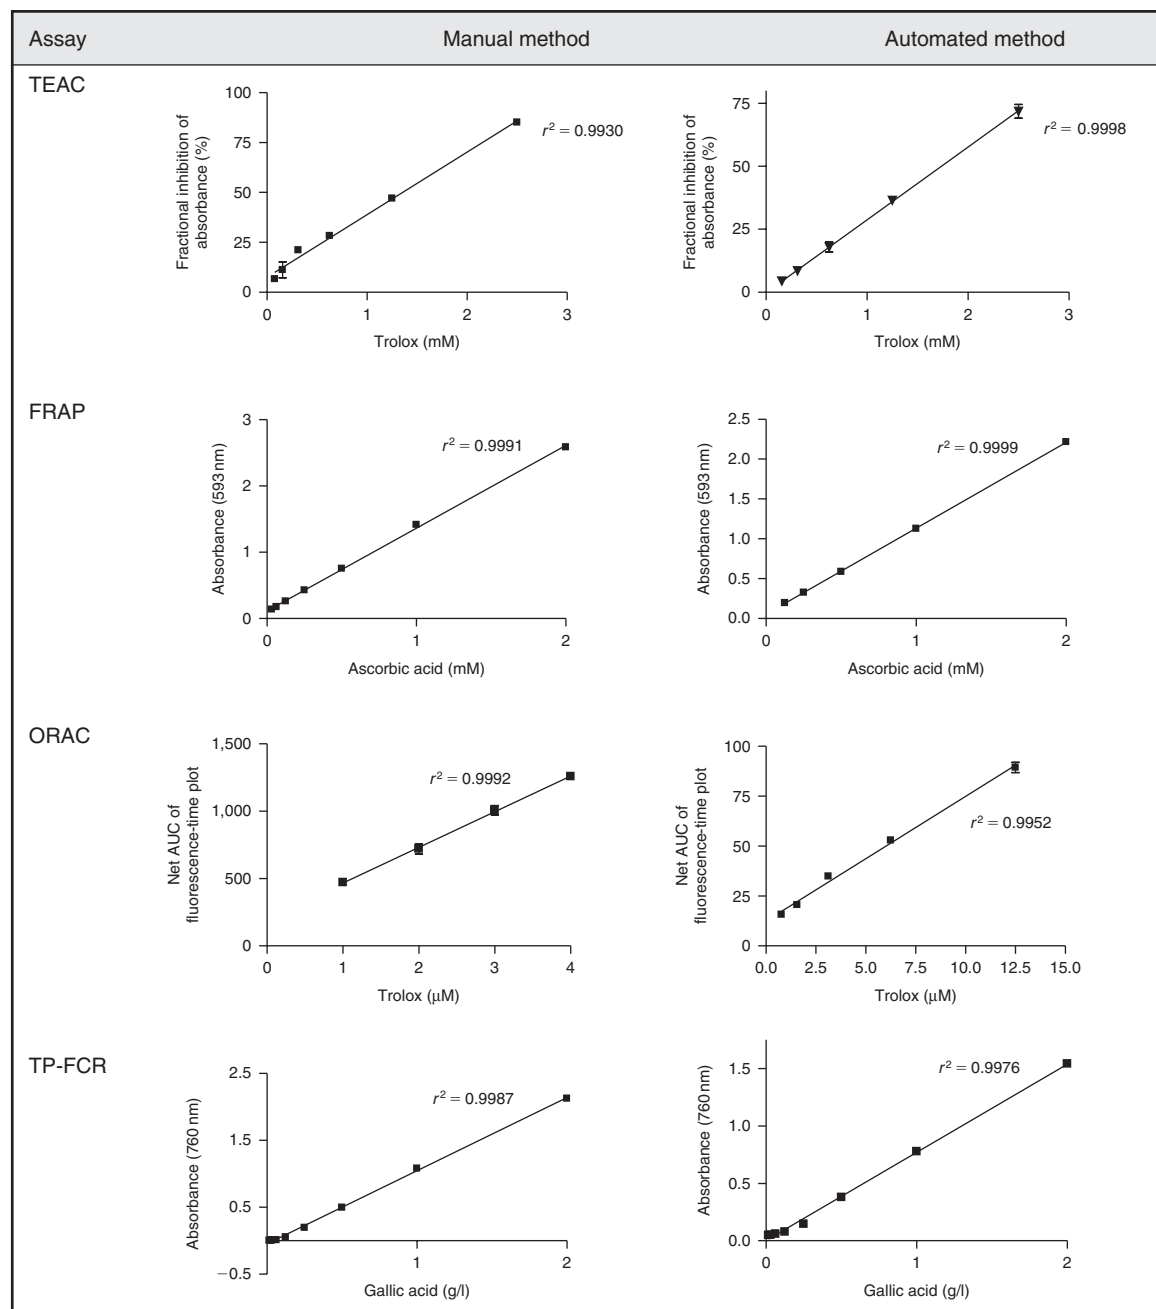
The assays outlined in Table 97.1 are commonly used both *in vitro*, that is, with beers (Montanari *et al.*, 1999) and *in vivo*, that is, with plasma after consumption of beer (Ghiselli *et al.*, 2000) for the assessment of TAC. They are easy to perform manually (using cuvettes and a spectrophotometer or fluorimeter) and furthermore are all amenable to high-throughput analysis; we have adapted these methods for use with the Biomek® FX Laboratory Automation Workstation (a liquid handling robot) and the BioTek® Synergy™ HT Multi-Detection Microplate Reader. Moreover, we have tested both manual and automated moieties of these assays for linearity (Figure 97.1) and repeatability (Table 97.3), with good results. In all four assays (both


Figure 97.1   Linearity of some commonly used assays. Data are expressed as mean ± SEM ($n = 3$, error bars are too small to see). Both manual and automated methods of performing four common assays for TAC demonstrate good linearity when assessed using antioxidant standard solutions.

Table 97.3   Inter- and intra-assay precision of some commonly used assays

Assay	Inter-assay variation Manual (%)	Automated (%)	Intra-assay variation Manual (%)	Automated (%)
TEAC	11	10	6	5
FRAP	6	9	1	5
ORAC	4	8	2	1
TP-FCR	1	<1	<1	1

Note: Data are expressed as coefficients of variation (%) for the inter- and intra-assay variation of four assays for total antioxidant capacity, performed by either manual or automated techniques. Inter-assay variation refers to disparity in the value of an unchanged sample tested in different runs of an assay; intra-assay variation refers to disparity in the value of an unchanged sample tested in the same run of an assay.

Table 97.4   Preparation of beer samples

Assay	Diluent	Dilution strength[a]
TEAC[b]	5 mM phosphate buffered saline (0.9% w/v), pH 7.0	12.5%, 25%, 50%
FRAP	None necessary	None
ORAC	75 mM phosphate buffer, pH 7.0	5%
TP-FCR	None necessary	None

Notes: Each of the assays for total antioxidant capacity requires dilution with a different diluent and dilution factor.

[a] These dilution strengths are variable depending on the antioxidant capacity of beer samples tested; pilot assays may be necessary. In the case of the TEAC assay, concentrations of sample should be such that they produce between an inhibition of absorbance which is 20–80% that of the blank.

[b] For the TEAC assay, at least three dilutions of sample should be prepared for a dose–response curve to be constructed.

For sample blanks, the reagents rather than samples are replaced with the appropriate diluent.

In addition to blank measures, a suitable sample must be chosen for use as an assay quality control (QC); this is necessary to ensure homogeneity between different batches of results. The QC used should not be changed between assays but should be demonstrated to return consistent results over time. For uniformity, the QC chosen should be prepared and assayed in the same way as the samples (see Table 97.4). In addition, employing the QC at several concentrations will contribute to providing a robust data set, as this will serve to confirm assay linearity.

Laboratory Protocol for the TEAC Assay

This is adapted from previous publications (Miller *et al.*, 1993; Re *et al.*, 1999).

Antioxidant standard preparation

- Prepare 25 ml of 2.5 mM 6-hydroxy-2,5,7,8-tetramethyl-chroman-2-carboxylic acid, or Trolox® (0.6257 g/l), in 5 mM phosphate buffered saline (pH 7.4) as a stock solution of antioxidant standard by which to calibrate the data. Dissolution may be facilitated by gentle sonication. This stock solution is stable for 4 weeks when stored at 4°C or 6 months at −20°C in the dark.
- Prepare fresh working standard solutions of concentration 2.5, 1.25, 0.625, 0.3125 and 0.15625 mM by serially diluting the stock Trolox® solution with 5 mM phosphate buffered saline (pH 7.4). Of each concentration, one run requires $3 \times 10\,\mu l$ (manual) or $3 \times 70\,\mu l$ (automated).

Reagent preparation

- Prepare 1 l of 5 mM phosphate buffered saline (0.9% w/v, pH 7.4) by mixing equal volumes of 1.12 mM NaH_2PO_4 (0.1343 g/l) and 3.88 mM Na_2HPO_4 (0.5509 g/l) and adding 9 g/l of NaCl. Use a magnetic stirrer to ensure proper mixing, and verify pH with a pH meter. Adjust as

manual and automated), the measured TAC of beers is well above their limits of quantification and these tests can therefore be seen as accurate and reliable. In the next section, we present detailed laboratory protocols for performing these assays using both manual and automated techniques. Universal laboratory health and safety precautions must be adopted when following any of the procedures outlined in these protocols.

Laboratory Protocols

The samples for each assay should be prepared as shown in Table 97.4.

Blank measures are necessary to control for the effect of assay reagents in the absence of sample (reagent blanks), or sample in the absence of assay reagents (sample blanks). For reagent blanks, the sample will be replaced by an equivalent volume of diluent which is specific to each assay, for example, distilled water is used as a blank in the FRAP assay; 75 mM phosphate buffer (pH 7.0) in the ORAC assay, etc.

Table 97.5   Measures required for each run in the TEAC assay

Measure	Repeat	Volume[a] of test reagent	Volume[a] of working ABTS[•+]
Reference	Single	1,010 μL DW[b]	None
Sample blank	Triplicate	10 μl sample	None (replaced with 1.0 ml DW[b])
Reagent blank	Triplicate	10 μl 5 mM PBS[b], pH 7.4	1.0 ml
Standard[c]	Triplicate	10 μl Trolox®	1.0 ml
Sample[c]	Triplicate	10 μl sample	1.0 ml
QC	Triplicate	10 μl QC	1.0 ml

Notes: For the TEAC assay, each run involves comparing absorbance at 734 nm at 6 min of a blank, several concentrations of standard, several concentrations of sample and a QC.

[a] Refers to volume required for the manual assay. In the automated assay the total volume will be scaled down from 1,010 μl to the size of the microplate well volume (i.e. 3 μl of test reagent plus 300 μl of working ABTS[•+]).
[b] DW, distilled water; PBS, phosphate buffered saline.
[c] This should be performed in triplicate at *all* working concentrations. That is, standard, three repeats at 2.5 mM plus three at 1.25 mM, etc.; sample, three repeats at 25%, three at 12.5%, etc.

necessary by adding solid NaH_2PO_4 or Na_2HPO_4 powder directly to buffer solution.

- Prepare 25 ml 14 mM 2,2′-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) diammonium salt solution, or ABTS (7.6816 g/l), in 5 mM phosphate buffered saline (pH 7.4).
- Prepare 25 ml 4.9 mM $K_2S_2O_8$ (1.3246 g/l) in 5 mM phosphate buffered saline (pH 7.4).
- Mix equal volumes of 14 mM ABTS and 4.9 mM $K_2S_2O_8$ to produce a stable ABTS[•+] stock solution. A dark blue-green solution should be formed immediately; allow this to stand in the dark at room temperature for 12–16 h before use. The stock solution is stable for 2 days when stored in the dark at room temperature.
- Prepare a working ABTS[•+] solution by diluting ABTS[•+] (approximately 1/40 dilution) stock solution to an absorbance of 0.70 ± 0.02 AU at 734 nm and 30°C using 5 mM phosphate buffered saline (pH 7.4). One run requires 12 × 1.0 ml (manual) or 96 × 300 μl (automated for 96-well microplate). Verify absorbance using an absorbance spectrophotometer and store in the dark.

Performing the TEAC assay

Table 97.5 shows the measures required for each run in the TEAC assay.

The manual TEAC assay

1. Pre-incubate *all* reagents (including samples, standards, etc.) at 30°C.
2. Prepare 2 ml, 1 cm light path visible range cuvettes for each measure by adding 10 μl test reagent (as shown in Table 97.5). Note the purpose of the reference cuvette is simply to zero the absorbance of the spectrophotometer; it contains only distilled water.

3. Start the reaction by adding 1.0 ml ABTS[•+] to each cuvette and mix well, according to Table 97.5.
4. Incubate the cuvettes at 30°C and record absorbance at 734 nm at 6 min (or other chosen endpoint).

The automated TEAC assay

1. Pre-incubate *all* reagents (including samples, standards, etc.) at 30°C.
2. Prepare a stock plate containing each test reagent (Table 97.5) at a minimum well volume of 70 μl (e.g. 3 wells with 70 μl of QC). The robot will later transfer 3 μl to a separate test plate in which the absorbance is to be measured.
3. Prepare the test plate by adding 300 μl of distilled water to all wells which will contain a *sample blank*. The distilled water is added to make up the volume which would otherwise be occupied by ABTS[•+] radical solution.
4. Set the robot to pipette 300 μl of ABTS[•+] radical solution into each well of the test plate (except those containing sample blanks).
5. Set the robot to then transfer 3 μl of test reagent (e.g. phosphate buffered saline, Trolox® standard, sample or QC) from the stock plate to test plate, and to mix the well contents by aspirating fluid from the bottom of the well and dispensing it at the surface.
6. Transfer the test plate to the microplate reader and incubate at 30°C; absorbance at 734 nm is read at 6 min (other endpoints can be chosen).
7. The absorbance data can be imported into Microsoft Excel for analysis.

Calculation of TEAC

- Preliminary data handling: check coefficients of variation (CV) for sample/standard repeats within assays and QC between assays. Exclude CV > 10–15%.

- Calculate fractional inhibition (FI) of ABTS$^{\bullet+}$ radicals using mean raw absorbance (A) data at 6 min (or chosen endpoint):

$$FI = \frac{\left[\begin{array}{l} A_{734} \text{ of reagent blank } - A_{734} \text{ of test solution} \\ - A_{734} \text{ of sample blank} \end{array}\right]}{A_{734} \text{ of reagent blank at 6 min}}$$

- Plot dose–response (DR) curves (i.e. concentration vs. fractional inhibition) for (1) Trolox® and (2) each sample.

$$TEAC \ (mM) = \frac{Gradient \ of \ sample \ DR \ curve}{Gradient \ of \ Trolox \ DR \ curve}$$

Laboratory Protocol for the FRAP Assay

This is adapted from a previous publication (Benzie and Strain, 1996).

Antioxidant standard preparation

- Prepare (fresh) 100 ml of 2 mM ascorbic acid (0.3522 g/l) in distilled water as a stock solution of antioxidant standard by which to calibrate the data. An ascorbic acid standard curve can be prepared by serial dilution down to 1.00, 0.50 and 0.25 mM. Of each concentration, one run requires $3 \times 100 \, \mu l = 300 \, \mu l$ (manual) or $3 \times 70 \, \mu l = 210 \, \mu l$ (automated). Ascorbic acid solution is both light and air sensitive, and should be stored in a sealed brown bottle and covered with foil (at room temperature).

Reagent preparation

- Prepare 20 ml of 40 mM HCl solution.
- Prepare 20 ml of 10 mM 2,4,6-tripyridyl-*s*-triazine, or TPTZ (3.1230 g/l), in 40 mM HCl.

- Prepare 20 ml of 20 mM $FeCl_3 \cdot 6H_2O$ (5.4060 g/l) in distilled water.
- Prepare 1 l of 300 mM sodium acetate buffer, pH 3.6 as follows: add 3.1 g sodium acetate trihydrate ($C_2H_3NaO_2 \cdot 3H_2O$) to 16 ml glacial acetic acid ($C_2H_4O_2$) and make up to 1,000 ml with distilled water.
- Prepare FRAP reagent ($12 \times 3.0 = 36$ ml for one manual run; $96 \times 300 \, \mu l = 28.8$ ml for one automated run) by mixing together the sodium acetate buffer, TPTZ and $FeCl_3 \cdot 6H_2O$ solutions in a volumetric ratio of 10:1:1, respectively. FRAP reagent is light sensitive; cover with foil.

Performing the FRAP assay

Table 97.6 shows the measures required for each run in the FRAP assay.

The manual FRAP assay

1. Pre-incubate *all* reagents (including samples, standards, etc.) at 37°C.
2. Prepare 4 ml, 1 cm light path visible range cuvettes for each measure by adding the test reagent to distilled water (as shown in Table 97.6). Note the purpose of the reference cuvette is simply to zero the absorbance of the spectrophotometer; it contains distilled water.
3. Start the reaction by adding FRAP reagent to each cuvette and mix well, according to Table 97.6.
4. Incubate the cuvettes at 37°C and record absorbance at 593 nm at 6 min (or other chosen endpoint; we have found greater stability of absorbance after 30 min).

The automated FRAP assay

1. Pre-incubate *all* reagents (including samples, standards, etc.) at 37°C.
2. Prepare a stock plate containing each test reagent (Table 97.6) at a minimum well volume of 70 μl (e.g. 3 wells

Table 97.6   Measures required for each run in the FRAP assay

Measure	Repeat	Volume[a] of reagents Test reagent	Distilled water	FRAP reagent
Reference	Single	None	3.4 ml	None
Sample blank	Triplicate	100 μl sample	3.3 ml	None
Reagent blank	Triplicate	100 μl distilled water	300 μl	3.0 ml
Standard curve[b]	Triplicate	100 μl ascorbic acid	300 μl	3.0 ml
Sample	Triplicate	100 μl sample	300 μl	3.0 ml
QC	Triplicate	100 μl QC	300 μl	3.0 ml

Notes: For the FRAP assay, each run involves comparing absorbance at 593 nm at 6 min of a blank, standard, sample and a QC.

[a] Refers to volume required for the manual assay. In the automated assay the total volume will be scaled down from 3.4 ml to the size of the microplate well volume (e.g. 10 μl of sample plus 30 μl of distilled water plus 300 μl of FRAP reagent).

[b] This should be performed in triplicate at *all* working concentrations. That is, three repeats at 2 mM, three at 1 mM, etc.

with 70 μl of QC). The robot will later transfer 10 μl to a separate test plate in which the absorbance is to be measured.

3. Prepare the test plate by adding 330 μl distilled water to all wells which will contain a *sample blank*. The distilled water is added to make up the volume which would otherwise be occupied by the 30 μl of distilled water and 300 μl of FRAP reagent.

4. Set the robot to pipette 30 μl of distilled water and 300 μl of FRAP reagent into all wells of the test plate (except those containing *sample blanks*).

5. Set the robot to then transfer 10 μl of distilled water (reagent blank), ascorbic acid standard, sample and QC from the stock plate to test plate, and to mix the well contents by aspirating fluid from the bottom of the well and dispensing it at the surface.

6. Transfer the test plate to the microplate reader and incubate at 37°C; absorbance at 593 nm is read at 6 min (other endpoints can be chosen; we have found greater stability of absorbance after 30 min).

7. The absorbance data can be imported into Microsoft Excel for analysis.

Calculation of FRAP

• Preliminary data handling: check coefficients of variation (CV) for sample/standard repeats within assays and QC between assays. Exclude CV > 10–15%.

• Calculate net absorbance (A) of each sample and each standard, using mean raw absorbance (A) data at 6 min (or chosen endpoint):

$$\text{Net } A_{593} \text{ of sample} = A_{593} \text{ of sample}$$
$$- A_{593} \text{ of sample blank}$$
$$- A_{593} \text{ reagent blank}$$
$$\text{Net } A_{593} \text{ of standard} = A_{593} \text{ of standard}$$
$$- A_{593} \text{ of reagent blank}$$

• Produce a standard dose–response curve (i.e. concentration of ascorbic acid vs. net absorbance). Interpolation of net absorbance of an unknown sample will thus give TAC in *ascorbic acid equivalents*.

• Since ascorbic acid can accept two electrons while the reduction from Fe^{3+} to Fe^{2+} ions requires one, the *ferric* reducing antioxidant power is obtained by:

$$\text{FRAP} = \text{Ascorbic acid equivalents} \times 2$$

Laboratory Protocol for the ORAC Assay

This is adapted from previous publications (Cao *et al.*, 1993; Naguib, 2000; Huang *et al.*, 2002).

Antioxidant standard preparation

• Prepare 25 ml 2.5 mM Trolox® (0.6257 g/l) in 75 mM sodium phosphate buffer (pH 7.0) as a stock solution of antioxidant standard by which to calibrate the data. Dissolution may be facilitated by gentle sonication. This stock solution is stable for 4 weeks when stored at 4°C or 6 months at −20°C in the dark.

• Prepare fresh working standard solutions of concentration 100, 200, 300 and 400 μM by diluting the stock Trolox® solution with 75 mM sodium phosphate buffer (pH 7.0) at dilution factors of 1:25, 2:25, 3:25 and 4:25, respectively. These will form 1, 2, 3 and 4 μM Trolox® solutions in final concentration; one ORAC unit is defined as the net protection provided by 1 μM Trolox® in final concentration. Of each concentration, one run requires $3 \times 30 = 90$ μl (manual) or $3 \times 70 = 210$ μl (automated).

Reagent preparation

• Prepare 1 l of 75 mM sodium phosphate buffer (pH 7.0) by mixing equal volumes of 31.5 mM NaH_2PO_4 (3.7803 g/l) and 43.5 mM Na_2HPO_4 (6.1742 g/l). Use a magnetic stirrer to ensure proper mixing, and verify pH with a pH meter. Adjust as necessary by adding solid NaH_2PO_4 or Na_2HPO_4 powder directly to buffer solution.

• Prepare fresh 12 mM 2,2′-azobis(2-amidinopropane), or AAPH (3.2542 g/l), in 75 mM phosphate buffer (pH 7.0); this is a free radical generating solution. One run requires $12 \times 1.5 = 18$ ml (manual) or 96×150 μl = 14.4 ml (automated). The radicals are thermally generated, thus AAPH solution should be stored in an ice bath and discarded within 8 h.

• Prepare 25 ml of 6.0×10^{-4} M 6-carboxyfluorescein, or 6-FAM (0.2258 g/l), in 75 mM phosphate buffer (pH 7.0) for use as a fluorescent probe stock solution. This can last several months at 4°C in the dark.

• Prepare a fresh working 6-FAM solution of concentration 6.0×10^{-8} M by diluting the stock solution with 75 mM sodium phosphate buffer (pH 7.0) at a dilution factor of 1:10,000. One run requires 12×750 μl = 9 ml (manual) or 96×75 μl = 7.2 ml (automated). This should be prepared daily and stored in the dark.

Performing the ORAC assay

Table 97.7 shows the measures required for each run in the ORAC assay.

The manual ORAC assay

1. Pre-incubate all reagents (including samples, standards, etc.) at 37°C, *except for* the 12 mM AAPH; this must remain in the ice bath.

2. Prepare 4 ml, 1 cm light path fluorescence cuvettes for each measure by adding 30 μl test reagent (as shown

Table 97.7   Measures required for each run in the ORAC assay

Measure	Repeat	Volume[a] of reagents Test reagent	6-FAM (μl)	75 mM PB[b], pH 7.0 (μl)	AAPH (ml)
Sample blank	Triplicate	30 μl sample	None	2,970	None
Reagent blank	Triplicate	30 μl 75 mM PB[b], pH 7.0	750	720	1.5
Standard curve[c]	Triplicate	30 μl Trolox®	750	720	1.5
Sample	Triplicate	30 μl sample	750	720	1.5
QC	Triplicate	30 μl QC	750	720	1.5

Notes: For the ORAC assay, each run involves comparing fluorescent emission of a blank, standard, sample and a QC.

[a] Refers to volume required for the manual assay. In the automated assay the total volume will be scaled down from 3.0 ml to the size of the microplate well volume (e.g. 3 μl of sample, 75 μl of 6-FAM, 72 μl of 75 mM PB (pH 7.0) and 150 μl of AAPH; total volume 300 μl).

[b] PB, phosphate buffer.

[c] This should be performed in triplicate at *all* working concentrations. That is, three repeats at 100 μM, three at 200 μM, etc.

in Table 97.7) to 750 μl working 6-FAM solution and 720 μl 75 mM phosphate buffer (pH 7.0). Mix well by inversion.

3. Initiate the reaction by adding 1.5 ml AAPH solution and continue to incubate the reaction mixture at 37°C.

4. Measure initial fluorescence (emission wavelength 520 nm, bandpass 20 nm; excitation wavelength 495 nm, bandpass 15 nm) at the start of the reaction, and subsequently every 60 s, until a plateau is reached in fluorescent emission; at this point the reaction is complete.

The automated ORAC assay

1. Pre-incubate all reagents (including samples, standards, etc.) at 37°C, *except for* the 12 mM AAPH; this must remain in the ice bath.

2. Prepare a stock plate containing each test reagent (Table 97.7) at a minimum well volume of 70 μl (e.g. 3 wells with 70 μl of QC). The robot will later transfer 3 μl to a separate test plate in which the absorbance is to be measured.

3. Prepare the test plate by adding 297 μl of 75 mM phosphate buffer (pH 7.0) to all wells which will contain a *sample blank*. The phosphate buffer is added to make up the volume which would otherwise be occupied by 6-FAM and AAPH.

4. Set the robot to pipette 75 μl of 6-FAM, 72 μl of 75 mM phosphate buffer (pH 7.0) and 3 μl of test reagent into all wells of the test plate (note *sample blank* wells will only receive the test reagent).

5. Remove AAPH solution from the ice bath and set the robot to pipette 150 μl into all wells (except for *sample blank* wells) of the test plate and mix by aspiration and dispensing.

6. Transfer the test plate to the microplate reader and incubate at 37°C. Measure initial fluorescence (emission wavelength 520 nm, bandpass 20 nm; excitation wavelength 495 nm, bandpass 15 nm) at the start of the reaction and

subsequently every 2 min for approximately 3 h (or until each well has reached a plateau in fluorescent emission). At this point the reaction is said to be complete.

7. The kinetic curve for fluorescent emission can be imported into Microsoft Excel for analysis.

Calculation of ORAC

- For each measure (please refer to Table 97.7), a kinetic curve for time vs. raw fluorescent emission can be plotted to completion – this should be converted to relative fluorescent emission (where maximum and minimum intensities are given nominal values of 1 and 0, respectively).
- Calculate AUC of the time vs. relative fluorescence plots, for each cuvette/well.
- Data should be screened at this point: check coefficients of variation (CV) for sample/standard repeats within assays and QC between assays. Exclude CV > 10–15%.
- Calculate the net AUC of standards, samples and QC as follows:

$$\text{Net AUC} = \text{mean AUC}_{\text{standard/sample/QC}} - \text{mean AUC}_{\text{reagent blank}} - \text{mean AUC}_{\text{sample blank}}$$

- Produce a standard dose–response curve (i.e. final concentration of Trolox® vs. net AUC). Note that a working 100 μM Trolox® standard is actually 1 μM in final concentration; this is important because one ORAC unit is defined as the net protection area provided by 1 μM Trolox® in *final concentration*. Interpolation of net AUC of an unknown sample on this standard curve will thus give TAC in Trolox® equivalents (TE).

Laboratory Protocol for the TP-FCR Assay

This is adapted from a previous publication (Singleton *et al.*, 1999).

Table 97.8 Measures required for each run in the TP-FCR assay

Measure	Repeat	Volume[a] of reagents Test reagent	DW^b (ml)	2N FCR (μl)	20% Na_2CO_3 (μl)	DW^b (μl)
Reference	Single	None	3.0	None	None	None
Sample blank	Triplicate	30 μl sample	1.8	None	None	1,170
Reagent blank	Triplicate	30 μl DW^b	1.8	150	450	570
Standard curve[c]	Triplicate	30 μl gallic acid monohydrate	1.8	150	450	570
Sample	Triplicate	30 μl sample	1.8	150	450	570
QC	Triplicate	30 μl QC	1.8	150	450	570

Notes: For the TP-FCR assay, each run involves comparing absorbance at 760 nm at 2 h of a blank, standard, sample and a QC.

[a] Refers to volume required for the manual assay. In the automated assay the total volume will be scaled down from 3.0 ml to the size of the microplate well volume (e.g. 3 μl of sample, 180 μl of distilled water, 15 μl of 2N FCR, 45 μl of 20% Na_2CO_3 and finally 57 μl of distilled water to make up volume to 300 μl).

[b] DW, distilled water.

[c] This should be performed in triplicate at *all* working concentrations. That is, three repeats at 2 g/l, three at 1 g/l, etc.

Antioxidant standard preparation

- Prepare 50 ml 2 g/l gallic acid (or 2.2117 g/l gallic acid monohydrate – more water soluble) in distilled water as a stock solution of antioxidant standard by which to calibrate the data. This stock solution is stable for 1–2 days at 4°C, or can be frozen for several months in aliquots of usable size.

- Prepare fresh working standard solutions of concentration 2, 1, 0.5, 0.25, 0.125 and 0.0625 g/l by serial dilution of the stock gallic acid solution with water. Of each concentration, one run requires $3 \times 30 = 90 \mu l$ (manual) or $3 \times 70 = 210 \mu l$ (automated).

Reagent preparation

- Prepare 100 ml 20% Na_2CO_3 (200 g/l) in distilled water using a magnetic stirrer to ensure proper mixing (one run requires $12 \times 450 \mu l = 5.4$ ml (manual) or $96 \times 45 \mu l = 4.32$ ml (automated)). *TAKE CARE: dissolution of Na_2CO_3 in water is exothermic; the solution will become hot.*

- Prepare 50 ml 2N Folin–Ciocalteu's phenol reagent according to Singleton *et al.* (1999) – we used a commercially available version. One run requires $12 \times 150 \mu = 1.8$ ml (manual) or $96 \times 45 \mu l = 1.44$ ml (automated). This working reagent is light sensitive.

Performing the TP-FCR assay

Table 97.8 shows the measures required for each run in the TP-FCR assay.

The manual TP-FCR assay

1. Prepare 4 ml, 1 cm light path visible range cuvettes for each measure by adding 30 μl test reagent (as shown in Table 97.8). Note the purpose of the reference cuvette is simply to zero the absorbance of the spectrophotometer; it contains distilled water.

2. To each cuvette, add 1.8 ml of distilled water and 150 μl of 2N Folin–Ciocalteu's reagent (Table 97.8); mix well. After 1 min and before 8 min, add 450 μl of 20% Na_2CO_3 and 570 μl of distilled water (Table 97.8); this will produce a final volume of 3.0 ml.

3. Allow these cuvettes to stand in the dark at room temperature, and record absorbance at 760 nm at 2 h (or other chosen endpoint).

The automated TP-FCR assay

1. Prepare a stock plate containing each test reagent (Table 97.8) at a minimum well volume of 70 μl (e.g. 3 wells with 70 μl of QC). The robot will later transfer 3 μl to a separate test plate in which the absorbance is to be measured.

2. Prepare the test plate by adding distilled water to all wells which will contain a *sample blank*. The distilled water is added to make up the volume which would otherwise be occupied by Folin and Ciocalteu's reagent and Na_2CO_3 solution.

3. Set the robot to pipette 180 μl of distilled water, 3 μl of test reagent and 15 μl of Folin–Ciocalteu's phenol reagent into each well, and to mix the well contents by aspirating fluid from the bottom of the well and dispensing it at the surface. Remember that distilled water and Folin–Ciocalteu's reagent are not added to *sample blank* wells. Program the robot to then pause for 180 s, and then to subsequently add 45 μl of 20% Na_2CO_3 followed by 57 μl of distilled water to each well (except for *sample blank* wells). This will produce a total volume of 300 μl per well, which should again be mixed by aspiration and dispensing.

4. Allow the test plate to stand in the dark at room temperature for 2 h (or chosen endpoint), then transfer to the microplate reader and read absorbance of each well at 760 nm.
5. The absorbance data can be imported into Microsoft Excel for analysis.

Calculation of TP-FCR

- Preliminary data handling: check coefficients of variation (CV) for sample/standard repeats within assays and QC between assays. Exclude CV > 10–15%.
- Calculate net absorbance (A) of each sample and each standard, using mean raw absorbance (A) data at 2 h (or chosen endpoint):

$$\text{Net } A_{760} \text{ of sample} = A_{760} \text{ of sample}$$
$$- A_{760} \text{ reagent blank}$$
$$- A_{760} \text{ sample blank}$$
$$\text{Net } A_{760} \text{ of standard} = A_{760} \text{ of standard}$$
$$- A_{760} \text{ of reagent blank}$$

- Produce a standard dose–response curve (i.e. concentration of gallic acid vs. net absorbance). Interpolation

of net absorbance of an unknown sample will thus give TAC in *gallic acid equivalents*.

Use of the Assays in Assessing the Total Antioxidant Capacity of Beers

We have tested several beverages, including draft and bottled ales, red wines and orange juices for TEAC, FRAP, ORAC and TP-FCR (Table 97.9). Draft ales appeared to have a marginally higher TAC than bottled ales in all four assays, although this was not significant. However, ales in general appear to have higher radical quenching ability than orange juices (ORAC assay: ales, $7,515 \pm 404 \,\mu$M TE; orange juices, $5,662 \pm 630 \,\mu$M TE; $p < 0.05$) but lower reducing capacity (TP-FCR assay: ales, 398 ± 30 mg/l; orange juices, 648 ± 45 mg/l; $p < 0.01$). As expected from previous studies (Pellegrini *et al.*, 2000) red wines demonstrate the highest TAC in all four assays.

Practical Aspects in the Determination of Total Antioxidant Capacity

The experimental protocols that we have included in this chapter are comprehensive and have been used in our laboratory with great success. Whilst we have found these assays

Table 97.9   Total antioxidant capacity of various beverages

Beverage	Assay			
	TEAC (mM TE)	FRAP (mM)	ORAC (μM TE)	TP-FCR (mg/l)
Draft ales				
Fuller's London Pride	7.11	2.86	7,580	418
Timothy Taylor's Landlord	7.05	2.73	8,369	400
Old Speckled Hen	7.68	3.05	8,857	461
Premium Spitfire	7.10	2.87	7,529	398
Guinness	6.82	2.86	6,459	407
Bottled ales				
Whitechapel Porter	7.09	3.76	9,119	576
Bishops Finger	7.19	3.49	9,554	517
Master Brew	6.94	2.02	6,853	306
Whitstable Bay	6.70	1.92	6,722	257
Spitfire	6.75	2.15	6,415	266
1698	6.84	2.11	5,216	375
Red wines				
Los Torunos Merlot, Chile (2004)	38.82	21.51	28,239	1,891
Cabernet Sauvignon, Prahora Valley (2002)	35.28	17.34	26,271	1,620
Cono Sur Pinot Noir, Chile (2004)	36.51	20.45	29,380	1,911
Orange juices				
Waitrose Freshly Squeezed	7.23	3.92	5,253	674
Sainsburys Pure	7.04	3.71	4,834	709
Costcutter	6.31	1.00	6,899	560

Note: Data are values for the TAC of several beverages as assessed by the TEAC, FRAP, ORAC and TP-FCR assays. Red wines have the greatest TAC, several-fold higher than ales and orange juices, which are comparable.

to be effective, many of the practical aspects will depend on the instrumentation and other resources available. For example, microplates are available in several configurations, with variable material, color and pre-treatment. In our assays we have chosen to use clear, untreated, polystyrene flat-bottomed 96-well microplates (Corning catalog *#9017*). However, solid black plates are available; these serve to minimize well-to-well crosstalk and are particularly useful in fluorescence-based assays such as the ORAC assay. Careful consideration should be given to choice of assay reagents, especially those used during sample preparation. For example, use of a phosphate buffer as a diluent is entirely acceptable in the TEAC and ORAC assays; however, samples to be assessed by FRAP should be diluted using water, since phosphate buffer forms a precipitate with FRAP reagent. Aside from the diluents, the active reagents in each assay can be modified; indeed newer generations have subtly different requirements. For example, the original TEAC assay employed metmyoglobin which in the presence of hydrogen peroxide catalyzed oxidation of ABTS to form the ABTS$^{\bullet+}$ radical cation (Miller *et al.*, 1993). The improved TEAC assay combines ABTS with potassium persulfate, producing a stock ABTS$^{\bullet+}$ radical solution which is thought to possess greater stability (Re *et al.*, 1999). In the ORAC assay, the choice of fluorescent probe is flexible: several probes have been employed including β-phycoerythrin (β-PE) (Cao *et al.*, 1993) and 6-carboxyfluorescein (Naguib, 2000). Of these the latter appears to be of greater use due to both stability and absence of interaction with polyphenols in the test substrate (Ou *et al.*, 2001). Choice of antioxidant standards by which to calibrate the data is also variable, although the standards of choice appear to be Trolox® (TEAC and ORAC), gallic acid (TP-FCR) and ascorbic acid (FRAP).

We reiterate that experimental procedure should be adapted with respect to the equipment available. For example, our liquid handling robot allows different handling protocols for liquids of different viscosity, thus plasma (used for *in vivo* TAC assays) will be pipetted differently to less viscous fluids (such as beer). In addition, although most absorbance-based assays use standard maximal wavelengths to monitor reaction kinetics, fluorescence-based assays such as the ORAC assay have employed variable emission and excitation wavelengths and bandpass sizes.

Inherent Limitations in Assays for Total Antioxidant Capacity

It is well known that the various assays for TAC are not directly comparable and may demonstrate only weak correlations with one another (Cao and Prior, 1998). One reason for this is the differential sensitivity of each assay toward specific antioxidants in the test substrate. For example, proteinaceous substances have a relatively low contribution to TAC when assessed by FRAP, compared to other assays (Cao

et al., 1998). Another important explanation is that assays such as FRAP and TP-FCR measure only the reducing capacity of a sample *without exposing it to radical species* (cf. TEAC in which samples are exposed to ABTS$^{\bullet+}$ and ORAC in which samples are exposed to peroxyl radicals), thus no indication is given of radical scavenging ability. We reiterate that the conditions under which these assays are performed are non-physiological, for example, temperature (TEAC, 30°C; TP-FCR, room temperature) and pH (FRAP, pH = 3.6; TP-FCR, pH ≈ 10). Handling of antioxidants and free radicals under physiological conditions is likely to differ somewhat and consequently when performed *in vitro* these assays have only limited biological relevance.

One final but fundamental methodological consideration in the TEAC, FRAP and TP-FCR assays is the use of an arbitrary "endpoint" or definitive moment at which the reaction is said to be complete. This underestimates TAC because it does not allow the reaction to reach full completion and in addition does not allow for antioxidants which exhibit a lag phase (Huang *et al.*, 2005). In contrast, assays such as ORAC employ an AUC technique to reaction completion, allowing both degree and length of inhibition to be combined into a single quantity (Cao and Prior, 1998). It has been proposed that TP-FCR be used as the definitive test for reducing ability, whilst ORAC be used as an indicator of radical scavenging ability (Huang *et al.*, 2005).

Conclusion and Future Directions

This chapter presents comprehensive protocols for the *in vitro* measurement of TAC. Given that the antioxidant component of such beverages is bioavailable and would thus help to reduce oxidative stress, we anticipate that the application of these assays to beers will serve to provide a stronger basis for the function of beer in health and wellbeing.

Summary Points

- Antioxidants are protective against numerous pathologies, such as cardiovascular disease.
- Assessing the TAC of a sample is more useful than assaying individual antioxidants as it can be seen as a "holistic" measure of antioxidant protection.
- Assays for TAC demonstrate good linearity and repeatability, and can be automated for high-throughput analysis of samples.
- *In vitro* antioxidant capacity has some biological relevance as the antioxidants in beer have been shown to be bioavailable.
- TAC of ales is comparable to that of orange juices but several-fold lower than that of red wines. TAC of draft ales is marginally but non-significantly higher than that of bottled ales.
- Wider application of these assays will undoubtedly have an important function in the fields of nutrition and

pathology, and provide further evidence for the use of beer in maintenance of health and wellbeing.

Methods for the HPLC Analysis of Phenolic Compounds and Flavonoids in Beer

Pavel Jandera Department of Analytical Chemistry, Faculty of Chemical Technology, University of Pardubice, Pardubice, Czech Republic

Abstract

A variety of high-performance liquid chromatography (HPLC) methods are available for the determination of the individual phenolic acids, polyphenols, flavonoids and related compounds contributing to the antioxidant activity of beer. Successful separation of the individual compounds requires appropriate selection of columns, mobile phases and optimization of the operation conditions. Ultraviolet/visible, fluorimetric and electrochemical detection techniques for HPLC determination of phenolic compounds are compared with special attention to the highly sensitive and selective coulometric array detectors. Hyphenated techniques employing coupling of HPLC with mass spectrometry or with nuclear magnetic resonance are valuable tools for identification and structure elucidation of phenolic and related compounds in beer, hops and malt extracts. Finally, sample pre-treatment for HPLC of natural antioxidants is addressed.

List of Abbreviations

APCI	Atmospheric pressure chemical ionization
CE	Capillary electrophoresis
CoulArray	Coulometric electrode array detector
ESI	Electrospray ionization
F_m	Flow-rate of the mobile phase, in ml/min
GC	Gas chromatography
H	Normalized peak height
HPLC	High-performance liquid chromatography
LC	Liquid chromatography
MEKC	Micellar electrokinetic chromatography
MIP	Molecularly imprinted polymer
NMR	Nuclear magnetic resonance
PB	Particle beam
PDA	Photodiode array
R_s	Resolution of the pairs of compounds with adjacent peaks
SIM	Selected-ion monitoring
SPE	Solid-phase extraction
UV	Ultraviolet
VIS	Visible
cav	Caffeic acid
cat	Catechin
chlor	Chlorogenic acid
fer	Ferulic acid
gal	Gallic acid
4hpac	4-Hydroxyphenylacetic acid
phba	4-Hydroxybenzoic acid
pro	Protocatechuic acid
van	Vanillin

Introduction

Beer contains many phenols, the greater part of which comes from the malt, the remaining from the hop. Natural compounds present in beer include great variety of monomeric phenolic compounds and polyphenols, including phenolic acids (hydroxybenzoic acid derivatives, hydroxycinnamic acid derivatives), quercetin, campherol and other flavonoid types, flavanones, flavonol aglycones, flavonol glycosides, prenylated and non-prenylated chalcones, proanthocyanidins, catechins, coumarins, etc. Phenolic acids occur in germinated barley either in the free form or bound to the cell wall. Phenolic compounds have an important effect on the oxidative stability and microbial safety of beer and not only influence the stability of beer taste, smell and color, but also exhibit important biological activity and may act as antioxidants in human body, for example reducing the concentration of free radicals and acting as protective agents against oxidation of unsaturated fatty acids. Their potential preventive protection against cardiovascular diseases and cancer is attributed mainly to increasing the antioxidant capacity of plasma. Radical-scavenging and antioxidant mechanisms inhibit DNA damage and lead to anti-microbial,

anti-inflammatory and anti-tumor effects (Holasová *et al.*, 2002; Saija *et al.*, 1995; Choi *et al.*, 2002; Erlund, 2004; Gerhauser, 2005).

Generally, similar analytical methods can be used for the analysis of antioxidants in beer, wine, fruit juices or plant extracts, the main difference being in sample preparation and treatment prior to analysis, which depends on the matrix. The traditional methods of determination of the antioxidant activity of a sample such as beer rely on the determination of the induction period before the start of auto-oxidation reaction in presence of oxygen, such as NTZ/hypoxanthine superoxide assay or ferric thiocyanate method (Antolovich *et al.*, 2002).

However, such tests do not provide information on the contributions of the individual natural antioxidants to the antioxidant activity of beer. The need for profiling and identifying individual phenolic compounds triggered replacement of traditional methods by analytical separation techniques. The limited volatility and thermal instability of many phenolic compounds have restricted the application of gas chromatography (GC) and GC/MS to their analysis, unless suitable derivatization such as trimethylsilylation is used prior to the analysis. High-performance liquid chromatography (HPLC) currently is the most popular and reliable technique for analysis of phenolic acids, polyphenols and flavonoid natural antioxidants, even though capillary zone electrophoresis (CE) (Sádecká and Polonský, 2000; Minussi *et al.*, 2003), micellar electrokinetic chromatography (Cortacero-Ramirez *et al.*, 2004) or thin-layer chromatography (Simonovska *et al.*, 2003) are also occasionally used.

HPLC has been applied for relatively long time for the analysis of isohumulones (bitter-tasting iso-α-acids) in beer and hops. Applications of HPLC to the profiling or determination of the individual antioxidants in fruit, vegetables, plant extracts, tea, wine, beer and hop extracts has attracted continuously increasing attention since the early 1990s (Hertog *et al.*, 1992, 1993; Tsuchiya *et al.*, 1997; Dalluge *et al.*, 1998). Especial attention was focused on the target analysis of specific compounds, which are believed to have especial chemo-preventive activities, namely xanthohumol (a prenylated chalcone from hop) (Miranda *et al.*, 2000), quercetin and rutin (Careri *et al.*, 2000) or *trans*-resveratrol, occurring not only in wine, but also in hop and beer (Callemien *et al.*, 2005). On the other hand, new methods are being continuously developed for simultaneous analysis of various polyphenols and related antioxidants. For example, biologically active isoflavonoids genistein, biochanin A, daidzein and formononetin in various samples of bottled beer were determined using the combination of reversed-phase HPLC and radioimmunoassay in concentrations ranging from 0.1 to 10 nmol/l (Lapčík *et al.*, 1998). The advances in the development of new methods for the determination of bioactive phenols were recently reviewed (Robards, 2003).

HPLC of Antioxidants with Spectrophotometric and Fluorimetric Detection

Routine detection in HPLC based on the monitoring of the absorption of radiation in the near ultraviolet (UV) or visible (VIS) region was almost exclusively used in the early applications of HPLC for the analysis of natural antioxidants. All phenolic compounds possess a strong chromophore system, therefore UV–VIS detection often provides good results with the detection limits in the low ppm level for real samples, especially in routine HPLC analyses aimed at the determination of target compounds (McMurrough, 1980, 1981). However, no single wavelength is ideal for all classes of phenolic and flavonoid antioxidants, as various classes display absorbance at distinctly different wavelengths. Single-wavelength UV absorption detection is usually performed at the wavelengths providing maximum detection sensitivity (Careri *et al.*, 2000): 280 nm is used most frequently for phenolic acids and flavanones, whereas better sensitivity was found at 265 nm for flavones and flavonols, or at higher wavelengths in the VIS region for anthocyanidins (360 nm). Even though the detection at a low wavelength (e.g. 225 nm) is more general, it often has problems with high background absorption and the detection at higher wavelengths often enables to overcome interferences caused by impurities absorbing at lower wavelengths (Amakura *et al.*, 2000; Revilla and Ryan, 2000). Detection limits in 1–50 ng ranges were reported for HPLC with single-wavelength detection (Bocchi *et al.*, 1996), but they vary for the individual compounds, which differ significantly in molar absorptivities. To overcome the problems in quantitation due to these differences, Tsimidou *et al.* (1992) suggested classifying various phenols into four groups and using a single calibration standard for the members of each group.

Photodiode array (PDA) spectrophotometric detection has become very popular in HPLC of natural antioxidants, as it not only allows easy selection of suitable detection wavelength providing best sensitivity of determination, but also UV spectra can be obtained on-line. This is a very useful feature of the PDA detection, as the UV spectra of the individual phenolic and flavonoid antioxidants provide considerable structural information that can distinguish the type of compounds such as simple phenol, flavone, xanthone, etc. and provides valuable clues for the identification of the individual compounds (Escarpa *et al.*, 2002). The spectra of eluting peaks at the apex and both inflexion points can be compared and used as the indicator of peak purity (possible coelution). HPLC with UV detection was used for monitoring the profile of caffeic, sinapic, syringic and vanillic acids as antioxidants in human plasma after intake of beer. This method is used to identify the impact of brewing technology on minor components with antioxidant activity present in beer (Ghiselli *et al.*, 2000).

Concentrations of (+)-catechin and ferulic acid as the markers for flavor stability of beer were measured using an HPLC/UV method (Walters *et al.*, 1997). HPLC with UV detection served as the basis of an automatic analyzer for the determination of the total polyphenols contents in beer and wort (Sakuma *et al.*, 1995).

Rapid HPLC methods with UV/VIS detection are available for screening and determination of natural antioxidants in beer after pre-column or post-column derivatization of target classes of compounds. Derivatization not only increases the sensitivity and the selectivity of determination, but also may improve the possibilities for identification of separated compounds. Post-column chemical reaction with *p*-dimethylaminocinnamaldehyde after HPLC separation was applied for the determination of phenolic compounds and flavanols, including catechin, epicatechin, gallocatechins, procyanidin B-2 and other procyanidins and prodelphinidins (de Pascual-Teresa *et al.*, 2000). The absorbance ratio at 640 and 280 nm combined with the retention time and the whole UV/VIS spectrum were used for characterization of the separated compounds (de Pascual-Teresa *et al.*, 1998).

Fluorescence detection in HPLC is more selective and sensitive than UV-absorbance detection and may be used for sensitive determination of some antioxidants shoving natural fluorescence, such as *trans*-resveratrol (Rodriguez-Delgado *et al.*, 2001, 2002). The intensity of fluorescence of some phenolic acids (*p*-hydroxybenzoic, ferulic, vanillic, etc.) is enhanced by formation of inclusion complexes with cyclodextrins. This phenomenon was utilized for the determination of the phenolic compounds in beer at ng/ml level using reversed-phase HPLC with fluorimetric detection and the buffered mobile phase containing 0.01 mol/l α-cyclodextrin (García Sánchez *et al.*, 1996).

Electrochemical Detection in HPLC of Phenolic and Flavonoid Compounds

Significantly improved detection sensitivity and selectivity for natural antioxidants taking the advantage of their reducing properties was achieved using HPLC with electrochemical detection, either amperometric or coulometric, usually with an octadecyl silica column and aqueous–organic mobile phases containing acidic buffers to suppress the dissociation of weakly acidic phenolic compounds. HPLC with electrochemical detection allows achieving detection limits in low pg levels (Bocchi *et al.*, 1996). In an early application, Roston and Kissinger (1981) determined six phenolic acids in ethyl acetate beer extracts using a dual-electrode amperometric detector with glassy carbon electrode. Lunte (1987) analyzed nine flavonoids in beverages and Hayes *et al.* (1987a, b) identified and determined 11 phenolic compounds and flavonoids in beer using reversed-phase HPLC with amperometric detection.

Coulometric detection with a porous graphite electrode through which the effluent from the chromatographic column passes (Figure 98.1) increases considerably the contact area of the electrode with sample compounds, so that nearly 100% of the analyte is subject to electrochemical reaction, in comparison with less than 10% typical with amperometric detection. The porous electrode design also increases significantly the signal stability with respect to the amperometric detection. Furthermore, coulometric detection in HPLC also greatly simplifies sample preparation as the phenolic compounds are the only electroactive substances in beer oxidizable at a low potential. Hence other compounds in beer do not interfere and the extraction of phenolic compounds from beer and wort matrices is not needed. Because of high selectivity, sensitivity and signal stability, HPLC with coulometric detection is ideally suited for the analysis of phenolic compounds and has become increasingly popular for the analysis of natural antioxidants in food, beer and other beverages.

The Coulochem II electrochemical detector with two coulometric detection cells in series, each containing a porous graphite measuring and a hydrogen–palladium reference electrode, was used for HPLC analysis of phenolic compounds and flavonoids in beer (Hayes *et al.*, 1987a, b; Nardini and Ghiselli, 2004). Dual-channel coulometric detection improves significantly stability, accuracy and reliability in comparison with single-channel detection, as the signal of the compounds of interest can be enhanced and the signal of interfering compounds can be eliminated by appropriate setting of the operating electrode potentials in the two channels (McMurrough and Baert, 1994). Nardini and Ghiselli (2004) used this method for comparison of the contents of 13 free phenolic acids and phenolic acids bound in glycosides and complexes after alkaline hydrolysis and found that 3–10 times more acids are present in the bound than in the free form in beer. Two dimeric and three trimeric proanthocyanidins (McMurrough and Baert, 1994) and flavanols prodelphinidin B3, procyanidin B3, (+)-catechin and (−)-epicatechin (Madigan *et al.*, 1994) were identified and determined in beer using a dual-electrode coulometric detector.

Unfortunately, neither amperometric nor coulometric electrochemical detection is generally compatible with the gradient elution mode, which is necessary for separation of complex mixtures of phenolic compounds. This problem has been solved by the development of a multi-channel detector with the arrays of 4, 8, 12 or 16 three-electrode electrochemical cells connected in series. The electrochemical detection with an electrode array (CoulArray) is not only very sensitive and highly selective, but also provides different and reproducible signal responses to the sample compounds at the reduction or oxidation potentials applied across the individual flow-through cells connected in series (in 4, 8, 12 or 16 channel arrays). Hence, the ratios of the areas of the dominant peak (recorded in the channel providing the

A 4-channel coulometric electrode array

highest response) to the areas of the so-called pre-dominant and the post-dominant peaks (in the channels just before and after the dominant peak channel, respectively) can be used to confirm the identification of sample compounds (Figure 98.1). Further, inverse proportionality was found between the dominant peak potential corresponding to the maximum detector response and the antioxidant activity of phenolic acids (Peyrat-Maillard *et al.*, 2000). Phenolic acids show maximum detector response at low oxidation potentials (100–450 mV), whereas flavonoids have two maxima, at 0–300 mV and at 600–900 mV. Further, the CoulArray

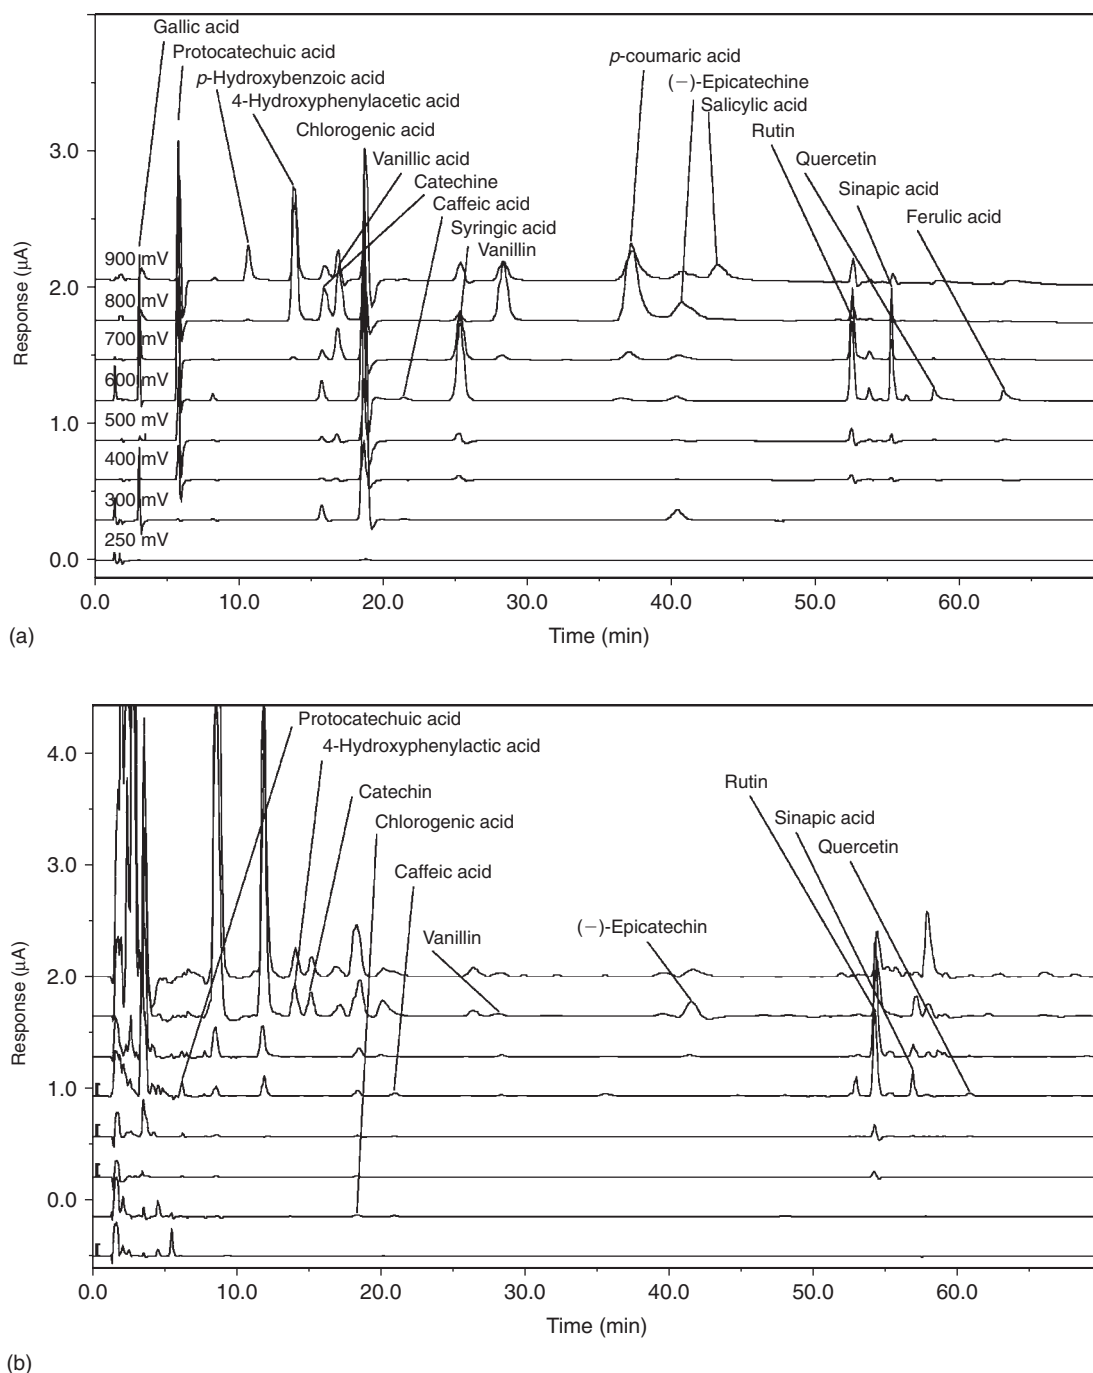
detector is controlled by the software compensating for the baseline drift during a gradient run, which may cause serious problems when gradient HPLC is attempted with other electrochemical detection systems. Finally, hydrodynamic voltammograms can be recorded as the plots of the response (peak areas) vs. several potentials applied on the measuring electrode and used as an aid in assignment of peaks to the individual phenolic compounds, in analogy to the UV spectra recorded by PDA detectors (Careri *et al.*, 2000; Rodtjer *et al.*, 2006). Signals recorded in the individual channels with different applied potentials can also be used to resolve


Figure 98.2 Chromatograms of phenolic compounds (0.001 mg/l each). (a) Standards and (b) a beer sample (diluted 1:4). Gradient elution on a C18 column with CoulArray detection.

coeluting peaks (Floridi *et al.*, 2003). Hence, electrochemical coulometric array detection is a powerful tool for the selective and sensitive detection of natural antioxidants.

Achilli *et al.* (1993) and Gamache *et al.* (1993) reported applications of a 16-channel CoulArray detector for the analysis of more than 30 phenolic compounds and flavonoids in fruit juice, wine, beer and other beverages. Guo *et al.* (1997) used similar conditions and a 12-channel

detector for the analysis of 31 phenolic compounds and flavonoids in fruit and vegetables. An 8-channel CoulArray detector was used for the analysis of phenolic compounds and flavonoids in wort and beer using gradient (Floridi *et al.*, 2003; Škeříková *et al.*, 2004). Figure 98.2 shows chromatograms illustrating the separation of standard compounds and of the phenolic antioxidants in beer. Montanari *et al.* (1999) found some differences in the concentrations

of free phenolic acids in beer samples determined by direct sample injection in HPLC with an 8-channel CoulArray detector and the results of HPLC with PDA spectrophotometric detection at the concentration levels 0.01–0.2 mg/l.

HPLC/MS and HPLC/NMR of Phenolic and Related Compounds

On-line coupling of liquid chromatography with mass spectrometry (LC/MS) has revolutionized the analysis of non-volatile compounds in food products, which usually are complex mixtures containing miscellaneous naturally occurring compounds. In this connection, the mass spectrometer may be used as a highly selective and sensitive detector, but, above all, it provides valuable information to confirm positively the identity of separated phenolic and related natural antioxidants. Further, HPLC/MS offers bi-dimensional resolution of complex samples, allowing compounds with overlapping chromatographic peaks to be distinguished. Tandem MS/MS techniques are useful for structural elucidation. Careri *et al.* (1998) presented an overview of the early applications of LC/MS methods in food analysis, including flavonoids, phenolic and related compounds.

LC/MS interfacing is less straightforward than coupling of gas chromatography with mass spectrometry (GC/MS) and various technical solutions to this problem have been suggested. Using particle-beam electron-impact interface (PB-EI-MS) in combination with HPLC, library-searchable EI mass spectra can be obtained. Using a bonded nitrile column in the normal-phase mode and gradient hexane–diethyl ether–propan-2-ol–formic acid, detection limits comparable with UV detection (2–50 ng) were achieved for phenolic acids in the selected ion monitoring (SIM) mode (Bocchi *et al.*, 1996). With a narrow-bore reversed-phase packed capillary column connected to a capillary-scale PB interface, the detection limits were reduced to the low pg range (Cappiello *et al.*, 1999).

The real success in LC/MS interfacing was achieved after the introduction of atmospheric pressure "soft" ionization techniques necessary to analyze thermally labile and highly polar natural compounds in MS. Electrospray/ionspray–mass spectrometric interface for LC rapidly supplanted thermospray ionization used in the 1980s, brought breakthrough advantages in terms of sensitivity and has been widely applied in LC/MS of phenolic compounds and flavonoids (Careri *et al.*, 1998). The electrospray ionization (ESI) technique in the negative-ion mode provides mass spectra of phenolic acids containing mainly the ions of deprotonated molecules and the ions corresponding to the losses of CO_2. Flavonol and flavone glycosides provide both the deprotonated molecules of the glycosides and the ions corresponding to the deprotonated aglycones, which are due to the loss of the sugar part of the molecule

(Sanchez-Rabaneda *et al.*, 2003a). In the SIM mode, detection limits in the sub-nanogram range were found (Careri *et al.*, 1999). HPLC with another soft ionization interface, atmospheric pressure chemical ionization (APCI), is useful for identification of flavones, flavonols and flavanones, which provide characteristic pseudomolecular anions in the negative-ion mode (Justesen *et al.*, 1998).

The APCI LC/MS technique has been applied to the analysis of iso-α-acids (bitter acids) in hop extracts and beer (Vanhoenacker *et al.*, 2004) and for the determination of *trans*-resveratrol in beer and hop extracts after preliminary removal of hydrophobic bitter compounds; 0.5 ppm *trans*-resveratrol was found in hop pellets, from which it is transferred to beer in the brewing process (Callemien *et al.*, 2005). HPLC in combination with ESI–MS detection in the negative-ion mode has been used to identify proanthocyanidins extracted from malt (Friedrich *et al.*, 2000) and from beer (Whittle *et al.*, 1999). Catechin, epicatechin, gallocatechin, epigallocatechin and several phenolic acids and proanthocyanidin dimers and trimers were identified in beer and their contents were used to distinguish various beer types.

LC coupled with tandem MS (LC/MS/MS) in the negative-ion mode is very useful for structure elucidation (Sanchez-Rabaneda *et al.*, 2003b). The collisional activation energy can be adjusted to provide different fragmentation patterns in both the sugar and aglycone parts of the molecules of phenolic and flavonoid compounds in the MS/MS product ion scans, with fragment ions characteristic for each family of natural antioxidants (Poon, 1998). Reversed-phase HPLC–MS/MS using a triple-quadrupole mass spectrometer equipped with a heated nebulizer–APCI interface was used for identification and determination of xanthohumol and six other prenylflavonoids in methanolic hop extracts and commercial beer samples by positive-ion multiple-reaction monitoring (Stevens *et al.*, 1999). LC/MS/MS was used for stable isotope dilution analysis of polyphenols (pyrogallol, catechin, epicatechin, various phenolic acids, etc.) in various matrices, including beer samples, with quantification limits 10–30 nmol/l (Lang *et al.*, 2006).

Nuclear magnetic resonance (NMR) spectrometry is a powerful complementary technique if the mass spectral data are insufficient for structural assignment. However, the disadvantage of NMR is its limited sensitivity and need for isolation of relatively large quantities of pure substances, so that on-line coupling of HPLC with NMR is only at the early stage development. The NMR spectra of phenols are often complex and do not allow unambiguous identification of the isolated compounds, therefore HPLC is usually simultaneously coupled to both NMR and MS. Large sample quantities are injected (often using a semi-preparative column) and ^1H NMR spectra are acquired more frequently in the stop-flow mode than under the real-time separation conditions. Further, the selection of mobile phase is limited and deuterated solvents should be

used where possible to avoid signal interferences, for example, mixtures of acetonitrile and D_2O with small amount of formic acid. HPLC/NMR coupling was employed for the analysis of hop bitter acids (Pusecker *et al.*, 1999) and of phenolic acids and related compounds in beer (Gil *et al.*, 2003).

Selectivity and Optimization of HPLC Separation of Phenolic and Flavonoid Compounds in Beer

Phenolic acids, polyphenols and both glycoside and aglycone flavonoids are almost exclusively separated in reversed-phase HPLC mode. Many natural antioxidants are strongly polar compounds, requiring highly aqueous mobile phases for successful separation. On the other hand, some flavonoids are rather non-polar and mobile phases with a higher concentration of organic modifier are necessary to accomplish their elution. Most phenolic compounds are weak acids, which are more or less dissociated in the mobile phases depending on their structure and – to a lesser extent – on the concentration of the organic solvent(s) in the mobile phase. The retention in reversed-phase HPLC generally decreases with increasing concentration and decreasing polarity of the organic modifier in the aqueous–organic mobile phase and with increasing polarity and degree of dissociation of the analytes. Gallic acid with three phenolic –OH groups elutes first, followed by dihydroxy- and monohydroxybenzoic acids. Flavonoid compounds generally elute later than simple phenolic compounds; as a rule, aglycones are retained more strongly than the corresponding glycosides. To improve the separation of compounds strongly differing in polarities in a single run, gradient elution with increasing concentration of the organic modifier (usually acetonitrile or methanol) is often used.

The non-dissociated form of a phenolic acid is more or less retained on an alkyl silica gel column, depending on the number of hydroxyl groups and other polar substituents and on the hydrocarbon matrix, whereas the ionic form is usually very little retained, if at all. Moreover, the peaks of the acid anions are often asymmetrical, may show strong tailing and sometimes even splitting. Hence, aqueous–organic mobile phases containing acidic buffers are typically used to suppress the dissociation, to increase the retention and to improve the peak symmetry of phenolic compounds in reversed-phase HPLC. Alternatively, ion-pairing reagents can be added to the mobile phases, such as tetraalkylammonium salts, which form more strongly retained neutral ion associates with the anions of phenolic acids.

Not only the retention, but also the separation selectivity, resolution and sensitivity strongly depend on the pH of the mobile phase, which should be optimized to obtain best separation of polar phenolic compounds. Figure 98.3

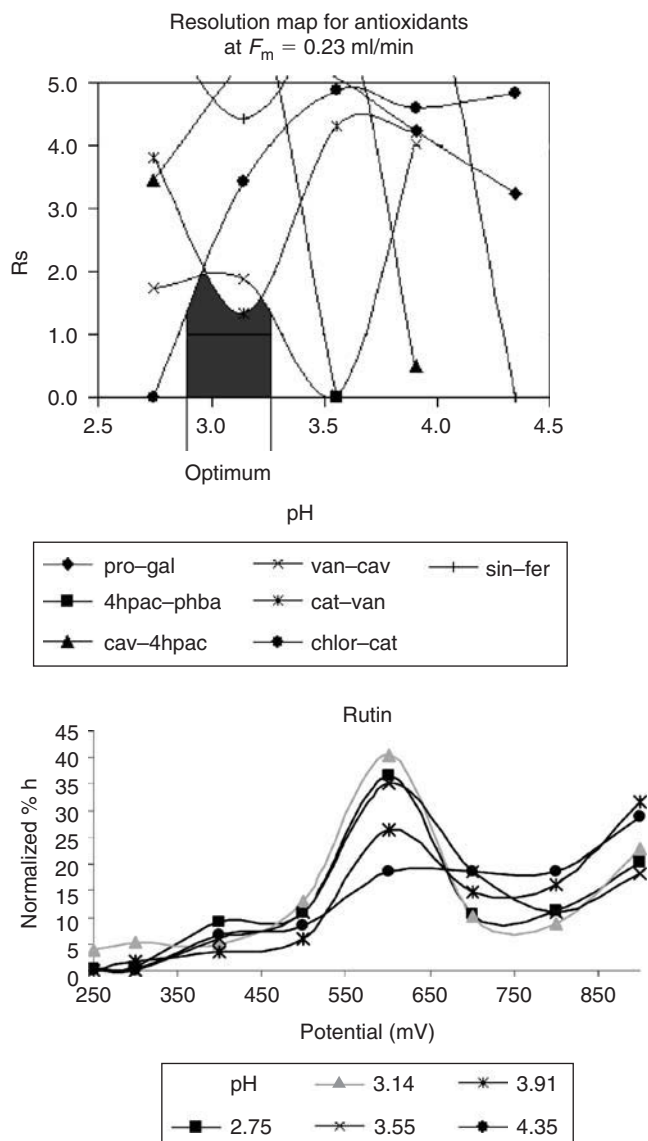
shows the dependence of the resolution and of the signal response of phenolic acids occurring in beer on the pH of the mobile phase. Another important point in the selection of the mobile phase for HPLC is the compatibility with the detection technique used: non-volatile buffers and salts should be avoided in HPLC/MS of phenolic compounds (ammonium acetate with acetic or formic acid in aqueous acetonitrile is usually suitable mobile phase). Sensitive electrochemical detection requires mobile phases composed of high-purity components, which should not contain


Figure 98.3 pH effect on the chromatographic resolution and sensitivity. R_s – resolution of the pairs of compounds with adjacent peaks. pro – protocatechuic acid, gal – gallic acid, 4hpac – 4-hydroxyphenylacetic acid, phba – 4-hydroxybenzoic acid, cav – caffeic acid, van – vanillin, cat – catechin, chlor – chlorogenic acid, sin – sinapic acid, fer – ferulic acid. even traces of electrochemically active impurities and acetonitrile is preferred to methanol as the organic modifier. To decrease the baseline noise using coulometric detection, the whole LC system should be passivated by flushing with diluted nitric acid for a short time before the first analysis.

Generally, an alkyl silica column, such as C18, is used most frequently for HPLC of phenolic compounds in beer. In the earlier isocratic applications, mobile phases contained ammonium phosphate (Lunte, 1987), or acetate buffer and citric acid (Kenyherz and Kissinger, 1977). The use of mixed ternary mobile phases containing methanol, 1-propanol and water was also reported (Roston and Kissinger, 1981). For simultaneous analysis of a larger number (more than 30) phenolic compounds in beer in

a single run, linear or segmented gradients were applied with increasing concentration of methanol or acetonitrile in aqueous mobile phases containing various ionic additives, such as sodium dihydrogenphosphate and phosphoric acid (Floridi *et al.*, 2003), ammonium acetate and formic acid (Řehová *et al.*, 2004), sodium dodecylsulfate, sodium phosphate and phosphoric acid (Achilli *et al.*, 1993) or nitriloacetic acid (Gamache *et al.*, 1993). The method was used for comparison of the concentrations of the individual antioxidants in various types of beer (Škeříková *et al.*, 2004). Figure 98.4 compares the average probability of occurrence and concentrations of some phenolic and flavonoid natural antioxidants found in Czech lager (pivo L) and draft (pivo T) beers.
Figure 98.4   Mean concentrations and probability of occurrence of phenolic antioxidants in Czech beer. (a) Mean concentrations of antioxidants as the average for all beer types; pivo T – draft beer, 14 different types; pivo L – lager beer, 14 different types. Three repeated analyses for each type of beer. (b) Average probability of occurrence in % of beer samples where the compound was found above the limits of determination.

Recently, five different C18 columns were compared and for each column optimum gradients were designed for the analysis of natural phenolic and flavonoid antioxidants in various samples, including beer, wort, hop extracts, wine, tea and yacon extracts (Jandera *et al.*, 2005) in connection with the electrode-array coulometric detection. Some non-alkyl chemically bonded stationary phases provide different selectivity for phenolic compounds in comparison with C18 columns, such as polyethyleneglycol silica (Blahová *et al.*, 2006) or phenyl silica (Cacciola *et al.*, 2006) bonded stationary phases, which were applied for two-dimensional serial or parallel separations of phenolic compounds in beer, wine and other samples. ZR-carbon stationary phase with a carbon layer deposited on zirconia dioxide support also provides the selectivity for phenolic acids widely differing from C18 columns. This stationary phase has outstanding temperature stability and can be used for high-temperature separations, unlike most alkyl silica columns; unfortunately this column retains too strongly flavones (Cacciola *et al.*, 2006).

Using a combination of stationary phases with different selectivities in two-dimensional HPLC is potentially promising method for increasing the peak capacity in the analysis of phenolic compounds in beer and other samples. In the so-called "comprehensive" LC × LC setup (Figure 98.5), the whole sample is analyzed on-line on each of the two columns connected via a 10-port switching valve. Figure 98.6 shows an example of contour-plot presentation of a two-dimensional LC × LC chromatogram of phenolic compounds in beer with a bonded phenyl stationary phase in the first dimension and a short chromolith monolithic C18 column in the second dimension.

Sample Treatment and Enrichment in HPLC of Natural Antioxidants

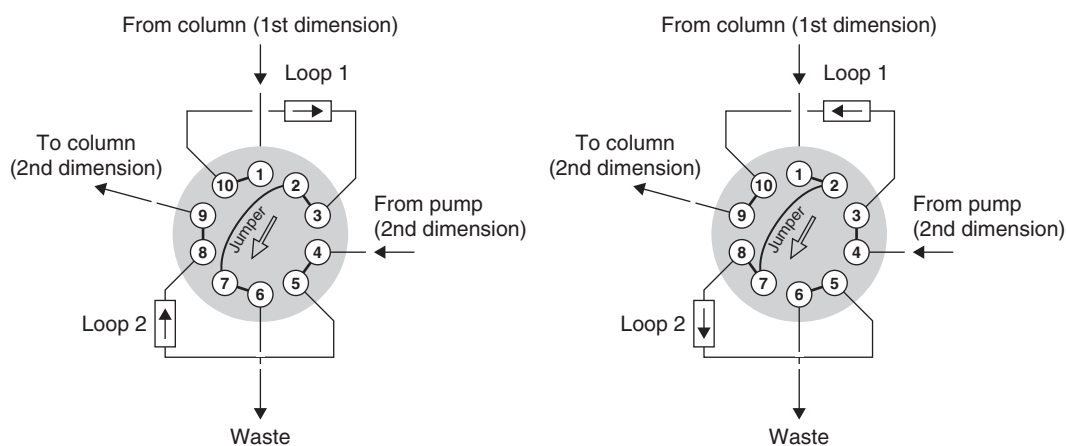
HPLC with coulometric detection is sensitive and selective enough for the detection and quantitation of phenolic compounds in beer without special sample pre-treatment. However, some flavonoids are present in low concentrations in beer and other natural samples and because of the complexity of the sample matrices, selective sample preparation


Figure 98.5   LC × LC setup with a 10-port switching valve interface and two sampling loops. Separation of a fraction trapped in one sampling loop in the second LC dimension while the next fraction from the first LC dimension fills the other loop.

methods are sometimes applied to increase the selectivity and sensitivity of prior to chromatographic analysis using other detection techniques. Pre-concentration and/or isolation of compounds are frequently performed using solid-phase extraction (SPE) (Sakkiadi et al., 2001; Alonso-Salces et al., 2005). Montanari et al. (1999) used SPE and re-extraction with ethyl acetate/methanol prior to the HPLC analysis of phenolic acids in beer samples with PDA spectrophotometric detection at the concentration levels 0.01–0.2 mg/l.

Among various flavonoids, quercetin and rutin are becoming now the topic of increasing interest due to their natural antioxidant activity. The determination of quercetin and its glycosylated analog, rutin, is typically performed with HPLC using diode array or MS detectors, with sample pre-concentration using SPE (Sakkiadi et al., 2001; Ishii et al., 2003; Dubber et al., 2005; Molnar-Perl and Fuzfai, 2005). Polymeric sorbents with molecularly imprinted target compound templates (MIPs) were applied as materials for the selective SPE and pre-concentration of rutin and quercetin from beer and other beverages before the analysis by high-pressure LC (Theodoridis et al., 2006).

Summary Points

- Phenolic compounds and flavonoids are important sources of antioxidant activity of beer.
- HPLC methods with various detection techniques are well suited for the determination of the individual compounds contributing to the antioxidant activity of beer.
- Spectrophotometric detection methods are not very sensitive, but the diode array detector allows measuring UV spectra, which are unique characteristics of phenolic and flavonoid compounds.
- Fluorescence and electrochemical detection techniques provide improved sensitivity for the determination of phenolic compounds with fluorophore groups or electrochemical activity.
- Coulometric detection, especially with a multi-channel electrode array, is ideally suited for HPLC of phenolic compounds in beer: It is highly sensitive, provides selective response for natural antioxidants, which are all electrochemically active compounds, and offers possibilities for their identification on the basis of the hydrodynamic voltammograms and on the ratios of the peak areas of the dominant, pre-dominant and post-dominant peaks recorded at various potentials applied to the individual electrochemical cells.
- HPLC/MS with ESI and APCI techniques provides valuable information on the molar mass of phenolic compounds for their identification.
- For more detailed structural information, collisionally induced LC/MS/MS spectra can be measured.
- Most frequently, HPLC in reversed-phase mode is used for the separation of phenolic compounds.

- The separation of more complex mixtures of phenolic and flavonoid compounds in beer, wine or plant extracts usually requires gradient elution with increasing concentration of methanol or acetonitrile to be used.
- For best separation selectivity and resolution, pH of the mobile phase should be optimized, usually in weakly acidic range to suppress the dissociation of weak phenolic acids.
- Limitations concerning the purity or volatility of components imposed by the electrochemical or MS detection should be considered when selecting the optimum mobile phase of phenolic compounds.
- In addition to most frequently used C18 columns, other silica gel-based chemically bonded phases such as polyethylene glycol, phenyl or carbon deposited on zirconia dioxide provide useful complementary selectivity, which can be used in two-dimensional separations to increase the number of compounds separated in a single run.
- Coulometric detection is selective enough so that other compounds present in beer do not interfere in the determination of phenolic compounds and beer samples can be analyzed directly without special requirements on sample pre-treatment.
- With other less selective or less sensitive detection methods, SPE is the technique of choice for beer sample pre-separation and enhancement.

Methods for the Assay of Iso-α-acids and Reduced Iso-α-acids in Beer

Gerd Vanhoenacker and Pat Sandra Research Institute for Chromatography, Kennedypark, Kortrijk, Belgium

Abstract

Iso-α-acids or isohumulones are hop-derived beer constituents which are formed in the brewing process. The qualitative and quantitative analysis of iso-α-acids and reduced iso-α-acids is an important element in the quality control of beers because of the distinctive influence these compounds have on beer bitterness and foam stability. Iso-α-acids are light sensitive and play a key role in the origin of the well-known lightstruck "skunky" flavor of beer. Therefore, beers are generally stored in lightproof cans or dark bottles and reduced iso-α-acids are often added to the beer to stabilize taste and foam.

An overview is presented on the current state-of-the-art in the analysis of iso-α-acids and reduced iso-α-acids in beer using analytical separation methods. The various sample preparation techniques are summarized and the application of stir bar sorptive extraction (SBSE) is highlighted. This extraction/clean-up was successfully applied for the quantitative analysis of iso-α-acids and the qualitative analysis of reduced iso-α-acids in beer. Liquid chromatography (LC) is by far the most popular analytical separation method for the assay of these compounds. In addition to the widespread liquid chromatography–ultraviolet detection (LC–UV) methods, the application of liquid chromatography–mass spectroscopy (LC–MS) and capillary electrophoresis (CE) for the analysis of bitter acids in beer is demonstrated.

List of Abbreviations

APCI	Atmospheric pressure chemical ionization
CE	Capillary electrophoresis
CEC	Capillary electrochromatography
EIC	Extracted ion chromatogram
ESI	Electrospray ionization
IBUs	International Bittering Units
LC	Liquid chromatography
LC–UV	Liquid chromatography–ultraviolet detection
LC–MS	Liquid chromatography–mass spectroscopy
MEEKC	Microemulsion electrokinetic chromatography
MEKC	Micellar electrokinetic chromatography
MM	Molecular mass
PDMS	Polydimethylsiloxane
RSD	Relative standard deviation
SBSE–LD	Stir bar sorptive extraction–liquid desorption

Introduction

The main ingredients in the brewing process are water, malted barley, yeast, and hops or hop extracts. The result is a complex collection of compounds in a water–ethanol mixture that we call beer. A schematic representation of the brewing process is depicted in Figure 99.1. The characteristic bitter taste of beer is due to the presence of hop-derived substances, the so-called iso-α-acids or isohumulones, which are formed from the almost tasteless hop α-acids during the boiling of sweet wort with hops (*Humulus lupulus* L.) in the brewery (Verzele, 1986). The analysis of hop acids, which include, in addition to α-acids, also β-acids is an important criterion to assess the quality of hops and hop extracts. During brewing, the relatively insoluble hop β-acids (lupulones) are removed or oxidized, while each hop α-acid (humulone) is transformed into its corresponding mixture of epimeric bitter-tasting iso-α-acids (*cis* and *trans* isomers) (Verzele, 1986). As a result, six iso-α-acids (isohumulones) originate from the three main hop α-acids. These compounds are not only responsible for the bitter taste of beer, but they also exhibit bacteriostatic properties and, furthermore, play an essential role in enhancing the foam stability of beer as well as in the formation of off-flavors like the lightstruck flavor (Kuroiwa *et al.*, 1963; De Keukeleire *et al.*, 1992; Smith *et al.*, 1998).

Reduced iso-α-acids such as dihydroiso-α-acids (dihydroisohumulones, also known as rho-isohumulones), tetrahydroiso-α-acids (tetrahydroisohumulones) are often used in the brewing process to enhance both the light and

  ■ Production: Catalytic hydrogenation of iso-α-acids
  ■ Properties: Light-stable

Figure 99.1 The brewing process. Schematic presentation of the various steps in the brewing process. Hops are added during the boiling of the wort. During this step, the tasteless hop α-acids are transformed into bitter-tasting iso-α-acids. At the end of the brewing process, a known amount of iso-α-acids and/or reduced iso-α-acids (dihydro- and tetrahydroiso-α-acids) can be added to control bitterness, taste, and foam and light stability.

the foam stability of beer. The structures of the main hop acids, the beer iso-α-acids, and the reduced iso-α-acids (tetrahydro- and dihydroiso-α-acids) are shown in Figure 99.2. Tetrahydroiso-α-acids also exist as *cis* and *trans* isomeric pairs resulting in six stereomers. Reduction of iso-α-acids to dihydroiso-α-acids introduces an additional chiral center, leading to two epimeric reaction products for each iso-α-acid. The group of dihydroiso-α-acids, thus, consists of 12 stereomeric members. A combination of both reduction processes leads to the formation of 12 additional hexahydroiso-α-acids (hexahydroisohumulones), which are not discussed here because of their limited use.

Quantitation of isohumulones and reduced isohumulones in beer is an important parameter in the quality control of beers because of their key role in the flavor characteristics of beer. Moreover, specific conventions regarding their use in some parts of the world stress accurate qualitative and quantitative determination. Addition of, for example, non-natural reduced forms of iso-α-acids is not allowed in German beers due to the "Reinheitsgebot" stating that only natural hop compounds may be used in the brewing

process. Analytical methods for detection and quantitation of both iso-α-acids and reduced iso-α-acids are, therefore, of utmost importance.

Chromatographic separation of all 24 structurally similar compounds (isohumulones and reduced isohumulones) in a single analysis represents a daunting task. However, for quality control purposes only part of these compounds usually need to be analyzed (e.g. isohumulones and tetrahydroisohumulones) and often complete separation/quantitation of all individual bitter acids is not required. In general, the quantitation is performed of a group (e.g. quantity of isohumulones) but superior individual separation will enhance the characterization of the typical bitter taste.

LC and LC–MS Analysis

(Partially reprinted from Vanhoenacker et al. (2004), Copyright 2004, with permission from Elsevier B.V.)

The quantitation of the bitter acids during the brewing process or in the final product can be performed mainly by two procedures. The result can then be expressed as IBUs (International Bittering Units), a value for the beer bitterness. One IBU corresponds with 1 mg/l (ppm) of isohumulone. Lager beers, for example, will have values ranging from 15 to 25 IBUs.

The first possibility is to extract the bitter acids by liquid–liquid extraction using a solvent (e.g. isooctane) and analyzing the extract with UV–Vis spectrophotometry. The obvious disadvantage of this technique is the errors generated by UV-absorbing contaminants in the extract since this technique lacks selectivity. The method also does not provide any information regarding the relative amounts of the individual bitter acids and the quantity of reduced isohumulones added during the brewing process.

To have a more detailed analysis on the relative and absolute quantities of individual bittering compounds in beer, the solutes need to be separated from each other. Liquid chromatography (LC) is intensively used for the analysis of α- and β-acids in hops (Verzele and van de Velde, 1987; Hermans-Lokkerbol and Verpoorte, 1994; Harms *et al.*, 2001) and iso-α-acids in beer (Verzele *et al.*, 1990; De Keukeleire *et al.*, 1992; Harms *et al.*, 2001). The LC analysis of iso-α-acids and reduced iso-α-acids in beer is generally preceded by a pre-concentration/clean-up step, either by liquid–liquid extraction or by solid-phase extraction on reversed-phase material (Vindevogel *et al.*, 1991; Szücs *et al.*, 1993; Clark *et al.*, 1998). Recently, a new solventless extraction method named stir bar sorptive extraction (SBSE) has been described (Baltussen *et al.*, 1999). SBSE is normally combined with thermal desorption–capillary gas chromatography analysis and the sensitivity and simplicity of SBSE have been demonstrated for the analysis of volatiles and semi-volatiles in a variety of sample matrices like water (Peñalver *et al.*, 2003), beverages (Tredoux *et al.*,
Figure 99.2 Structures and peak codes of the compounds of interest. Overview of the various hop acids (A, B), iso-α-acids (IAA), tetrahydroiso-α-acids (TH), and the *cis*-dihydroiso-α-acids (DH). Each type of acid exists as a co-, n-, and ad-homolog.

2000), biological fluids (Tienpont *et al.*, 2003), fruits, and vegetables (Sandra *et al.*, 2003). SBSE, however, can also be combined with liquid desorption (LD), which opens perspectives for the analysis of thermally labile compounds. Harms *et al.* presented the first application of SBSE–LD for the profiling of iso-α-acids in beer by LC (Harms *et al.*, 2001). However, state-of-the-art instrumentation also allows the direct analysis of the bitter compounds in beer, that is direct injection without enrichment/clean-up.

All routine LC methods use involatile buffer additives such as phosphate and citrate for the separation of iso-α-acids and reduced iso-α-acids (Burroughs and Williams, 1999; Harms and Nitzsche, 2001). These mobile phases are not compatible with mass spectroscopic (MS) detection. Only few reports have been published on LC–MS analysis of hop acids and no literature is available on the analysis

of iso-α-acids and reduced iso-α-acids by LC–MS. Using ammonium acetate or acetic acid as mobile-phase additives and electrospray ionization (ESI) in the negative mode, hop acids were analyzed in beer after direct injection (Hofte *et al.*, 1998). Humulones (α-acids) were found to be present in beer at concentration levels of 150–200 μg/l (ppb), while lupulones (β-acids) were absent. Isohumulones and reduced isohumulones were not analyzed. Another report focused on the quantitation of 8-prenylnaringenin, a potent phytoestrogen, in hops, hop products, and beers. Reversed-phase LC was carried out on a C18 column using formic acid as a buffer additive and ESI MS in the positive mode for detection (Rong *et al.*, 2000). No quantitation was performed for the hop and beer bitter acids.

The following LC method enables simultaneous analysis of iso-α-acids and reduced iso-α-acids in beer without

sample pre-concentration using an alkaline, MS compatible mobile phase (Vanhoenacker *et al.*, 2004). The method can be fine-tuned for fast separation of iso-α-acids and tetrahydroiso-α-acids in typical European beers.

Experimental

The calibration extract containing hop α- and β-acids (ICE 1) was from "Versuchsstation Schweizerischer Brauereien" (Zürich, Switzerland). Pre-isomerized hop extract containing iso-α-acids was obtained from Hopstabil GmbH (Wolnzach, Germany). The dihydroiso-α-acids standard (all-*cis*, DCHA-Rho, ICS-R1) was from Labor Veritas (Zürich, Switzerland) and the standard for tetrahydroiso-α-acids from Kalsec (Kalamazoo, MI, USA). The standards were dissolved separately in methanol to a concentration of 1 mg/ml. These stock solutions were stored at –20°C and used to prepare standard solutions.

Beers were bought at local stores, kept at room temperature, and freshly opened prior to analysis. They were degassed by ultrasonication and a portion was filtered through a syringe filter (0.2 μm, PTFE) prior to injection.

Analyses were performed on an Agilent 1100 LC equipped with a binary pump, vacuum degasser, autosampler, column thermostat, and a diode array detector (DAD) (Agilent Technologies, Waldbronn, Germany). For complete separation two Zorbax Extend C18 columns, 150 mml × 4.6 mm ID, packed with 5 μm particles were coupled in series (Agilent Technologies, Waldbronn, Germany). The mobile phase consisted of 5 mM ammonium acetate in 20% (v/v) ethanol adjusted to an apparent pH of 9.95 with ammonia (solvent A) and acetonitrile/ethanol 60/40 (v/v) (solvent B). The flow rate was set at 1 ml/min and gradient elution was performed. The gradient was the following: 0–3 min, 0% B isocratic; 3–4 min, 0–16% B; 4–54 min, 16–40% B; 54–57 min, 40–95% B; 57–65 min, 95% B isocratic. The column temperature was maintained at 35°C; 100 μl of a degassed and filtered beer sample was injected. Detection was performed with a DAD set at 256 nm (iso-α-acids and reduced iso-α-acids) and at 330 nm (α- and β-acids). The mass spectrometer was an Agilent 1100 Series Trap version SL with an atmospheric pressure chemical ionization (APCI) source (Agilent Technologies, Waldbronn, Germany). Negative ionization was performed in the scan mode (*m/z* 150–600). The target mass was set at *m/z* 350 and maximum accumulation time at 300 ms. Interface settings were: N_2 drying gas temperature 330°C, N_2 drying gas flow 5 l/min, APCI vaporizer temperature 450°C, nebulizer 60 psi, capillary voltage 4,000 V.

The fast separation was carried out on one Zorbax Extend C18 column, 150 mmL × 3 mm ID, packed with 3.5 μm particles (Agilent Technologies, Waldbronn, Germany). The mobile phase consisted of 10 mM ammonium acetate in water adjusted to pH 8 with ammonia (solvent A) and acetonitrile (solvent B). The flow rate was set at 0.6 ml/min and gradient elution was performed. The gradient was the following: 0–5 min, 28% B isocratic; 5–11 min, 28–40% B; 11–12 min, 40–95% B; 12–15 min, 95% B isocratic. The column temperature was maintained at 30°C; 20 μl of a degassed and filtered beer sample was injected. UV detection was performed at 256 nm.

Results and discussion

LC of iso-α-acids and reduced iso-α-acids is commonly carried out in the reversed-phase mode with a C18 or a C8 stationary phase. Problems related with interaction of solutes with trace metals present in the reversed-phase material have been reported (Verzele *et al.*, 1990; De Keukeleire *et al.*, 1992). Buffers are added to the mobile phase to improve separation and reproducibility. The buffer is usually acidic (phosphate) or neutral (citrate). Here, a high-pH mobile phase was opted for, because this enhanced peak shape and efficiency. As an example, the resolution for the iso-α-acids IAA3, IAA4, IAA5, and IAA6, the most critical part of the separation, improves significantly when the pH of the mobile phase is raised from neutral to alkaline. This is caused by the increased efficiency and the enhanced selectivity for these acidic solutes at elevated pH. It was the aim to develop a method compatible with MS detection and a volatile mobile-phase additive was therefore chosen. Ammonium acetate was selected and the appropriate pH was attained using ammonia. The optimum apparent pH (in 20% v/v ethanol) was found to be 9.95. Care should be taken to accurately control the pH, since small variations cause significant changes in chromatographic selectivity. The high pH mandates selection of a stationary phase that is stable in basic media. The columns used (Zorbax Extend) are stable up to pH 11.5. Ethanol was preferred over methanol, because it consistently provided a better separation.

The mass spectra of the co-homologs, obtained by LC–MS in the negative APCI ionization mode, are shown in Figure 99.3. A distinctive fragmentation pattern is observed for each group of hop-derived acids. Iso-α-acids and reduced iso-α-acids fragment similarly via dehydration and loss of a side chain. For iso-α-acids and tetrahydroiso-α-acids, dehydration is followed by loss of a 4-methyl-3-pentenoyl or a 4-methylpentanoyl side chain, respectively. Dihydroiso-α-acids are characterized by cleavage of the 1-hydroxy-4-methyl-2-pentenyl side chain followed by dehydration. Splitting off water from α-acids sets the stage for ring opening and loss of a ring carbon together with a hydroxyl group and a 3-methyl-2-butenyl side chain. Reclosure furnishes a five-membered ring. β-Acids are marked by loss of a 3-methyl-2-butenyl side chain only.

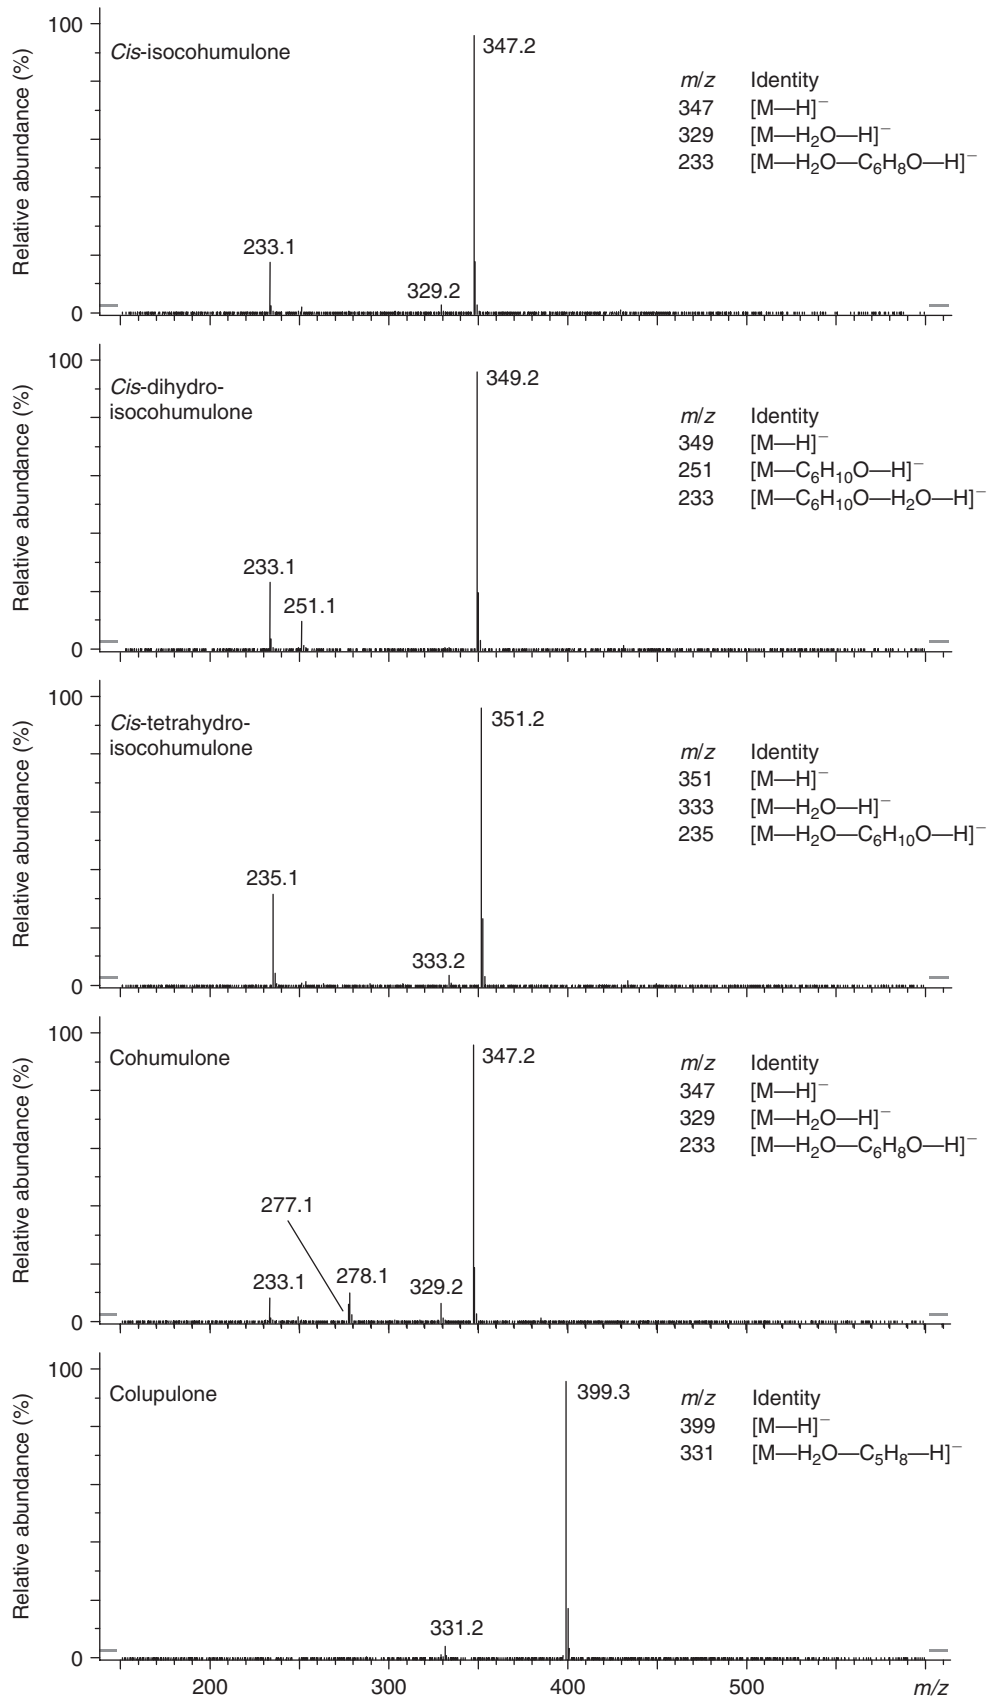
Figure 99.4 shows an LC–DAD–MS analysis of a standard solution containing ca. 10 mg/l (ppm) of each group of hop-derived acids. For UV detection, iso-α-acids and reduced iso-α-acids are monitored at 256 nm and α- and β-acids at 330 nm. In UV detection, co-elution occurs between a


Figure 99.3 Mass spectra of the co-homologs of iso-α-acids, reduced iso-α-acids, and hop α- and β-acids. MS was performed using APCI in the negative mode. Distinctive fragmentation patterns are observed for each group of hop-derived acids. Molecular and fragment ions were selected for each compound to construct the chromatograms in reversed-phase LC–MS.
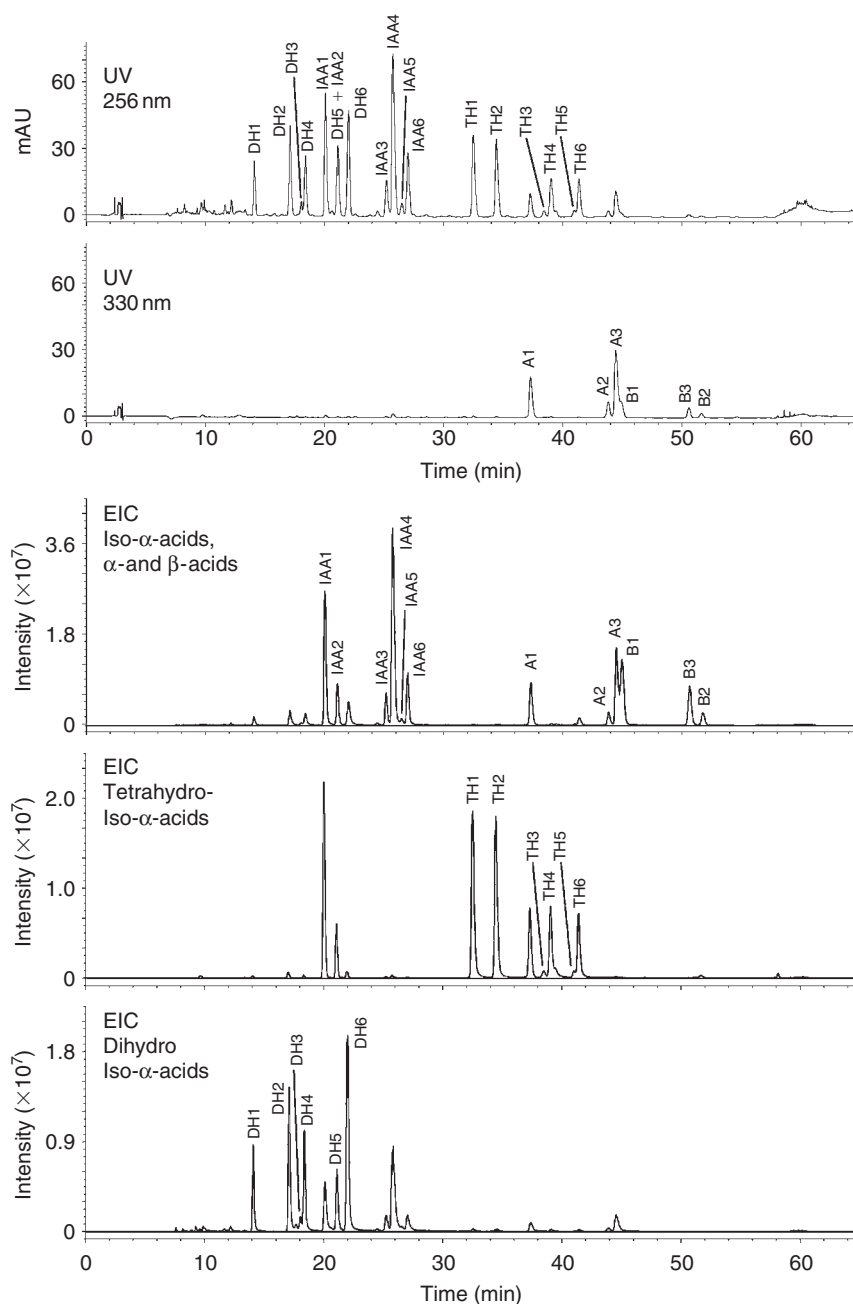

Figure 99.4 LC–UV and LC–MS chromatograms of a standard mixture of hop-derived acids. Chromatograms for the analysis of a standard mixture of hop-derived acids (10 mg/l of each group). Peak numbers: see Figure 99.2.

cis-dihydroisoadhumulone epimer (DH5) and *trans*-isocohumulone (IAA2). The MS traces are extracted ion chromatograms (EIC) composed of the molecular ions and the most important fragments. The selected ions were also used for quantitative analyses (Table 99.1). Iso-α-acids and dihydroiso-α-acids share an identical fragment ion (m/z 233 for co-forms and m/z 247 for n- and ad-forms). Also, isocohumulone, tetrahydroisohumulone, and tetrahydroisoadhumulone have a common ion (m/z 347). However, these compounds are

chromatographically sufficiently separated to avoid interference. Co-elution of DH5 and IAA2 is not problematic for MS detection, as the m/z values differ. MS selectivity, thus, enables to resolve both compounds and to quantify them correctly.

Four point calibration graphs in the range of 5–50 mg/l (ppm) were constructed by analyses of standard solutions. Because of co-elution of DH5 and IAA2 in UV detection, two separate calibration series were made, the first

series containing the reduced iso-α-acids and the second series the iso-α-acids and α- and β-acids. Repeatability of injection was performed by six consecutive injections of the calibration solution of both series at a concentration of ca. 10 mg/l (ppm) for each group of acids. The obtained relative standard deviations (RSDs) for the iso-α-acids and reduced iso-α-acids were all below 0.3% for UV detection, while these values varied between 5% and 9% for MS detection. Since UV and MS are performed on-line, the difference in repeatability is only caused by the detection. It is known that MS performs inferior in this respect compared to UV or DAD (Lazou *et al.*, 2000) and the rather high RSDs for MS detection are not unusual for ion trap MS. Poor results for the α- and β-acids are due to instability of those sensitive solutes in the injection vial. Their impact on the bitterness of beer, however, is not important; hence, they were not determined. Results for calibration and repeatability are summarized in Table 99.2.

A selection of 14 beers was analyzed by LC–UV–MS and the iso-α-acids and reduced iso-α-acids contents were quantified (Table 99.3). For iso-α-acids, the ratio of n-, co-, and ad-isohumulones and the *cis/trans* ratios were calculated for each beer. Beers that contain larger amounts of n- and ad-isohumulones are characterized by a more subtle bitterness, while the *cis/trans* ratio is relevant with respect to the flavor stability. Representative chromatograms of LC–UV analyses at 256 nm are shown in Figure 99.5.

Lager 1 is a German beer that is devoid of reduced iso-α-acids. The very high *cis/trans* ratio (>10) can be attributed to the use of advanced pre-isomerized hop products. In the other beers, this ratio varies between 2 and 5. The profile of Lager 5 is typical for a Western-European pilsner-type beer. In current brewing practice, beers (Lagers 3–6) contain a small portion of tetrahydroiso-α-acids, mainly to improve

foam stability. Smaller breweries often still use natural hop cones (Lager 2, non-alcoholic lager, Belgian Trappist). The difference between the two beers contained in clear bottles is striking. Because they are not protected from light, it could be expected that measures were taken to stabilize their flavor and bitterness. In Lager clear bottle 2, dihydro- and tetrahydroiso-α-acids have been applied, resulting in a much lower concentration of iso-α-acids. Conversely, in Lager clear bottle 1, only iso-α-acids are detected, while a high content of isocohumulone is found compared to isoadhumulone and isohumulone. Light stable beers 1 and 2 do not contain iso-α-acids, the bitterness being delivered by dihydro- and tetrahydroiso-α-acids. Wheat beers are much less bitter than lager beers, which are reflected by their low iso-α-acid contents.

The quantitative values obtained with LC–MS are close to those found with LC–UV. The only clear trend in the results is that the recovered amount of dihydroiso-α-acids is consistently higher in LC–MS compared to LC–UV. Other discrepancies in recovered amounts and calculated ratios between LC–MS and LC–UV appear at random. The significant difference between the ratios of co-, n-, and ad-isohumulones in the second lager in a clear bottle is due to co-elution of a *cis*-dihydroisoadhumulone epimer and *trans*-isocohumulone. The LC–MS chromatogram of this beer is shown in Figure 99.6. The peak area for *trans*-isocohumulone was not included in the calculations by LC–UV analysis. The peak was regarded as *cis*-dihydroisoadhumulone leading to inaccurate quantitation. The iso-α-acid content is underestimated and the dihydroiso-α-acids are overestimated. This also explains, for this particular beer, why the isocohumulone content in LC–UV is significantly lower compared to LC–MS and why the difference between the recovered amounts of dihydroiso-α-acids is small. Thus, for this particular case, results for the co-, n-, and ad-isohumulones ratios obtained with LC–MS are more reliable than those obtained with LC–UV.

A similar method can be used for fast LC–UV analysis of isohumulones and tetrahydroisohumulones in beers. Main goals in this analysis are speed and accuracy. A complete separation of all individual acids is no longer essential. Therefore, the pH can be lowered and the mobile-phase composition and gradient can be adapted to meet the specific needs of the brewer. An example of such an analysis is shown in Figure 99.7. Using these conditions, the iso-α-acids are separated from the tetrahydroiso-α-acids and can be quantified separately in ca. 12 min.

CE Analysis

(Partially reprinted from De Villiers et al. (2004), Copyright 2004, with permission from Wiley-VCH Verlag GmbH & Co. KgaA.)

An alternative to the LC separation of the bitter acids is capillary electrophoresis (CE). Electrodriven separation techniques such as micellar electrokinetic chromatography

Table 99.2   Comparison of the calibration data and repeatability of injection for LC–UV and LC–MS

	IAA (5.85, 11.70, 23.40, 58.50 ppm)		TH (5.28, 10.55, 21.11, 52.76 ppm)		DH (5.18, 10.35, 20.70, 51.75 ppm)		A/B (4.33, 8.67, 17.34, 43.34 ppm)	
	UV	MS	UV	MS	UV	MS	UV	MS
Calibration (R²)	1.0000	0.9994	1.0000	0.9987	1.0000	0.9992	0.9994	0.9946
Repeatability (RSD, %)	0.26	8.94	0.19	6.44	0.18	7.08	4.76	22.70

Note: The linearity of the method was evaluated by four consecutive injections of standard mixtures at different concentration levels (ca. 5, 10, 20, and 50 mg/l of each group). Repeatability of injection was performed by six consecutive injections of a standard mixture (10 mg/l of each group). IAA, iso-α-acids; TH, tetrahydroiso-α-acids; DH, dihydroiso-α-acids; A, α-acids; B, β-acids; R^2, correlation coefficient; RSD, relative standard deviation.

Note: LC–UV and LC–MS data for the analysis of iso-α-acids and reduced iso-α-acids in beers after direct injection. The concentration of each group of compounds is measured. For the iso-α-acids the *cis/trans* ratio and the ratio of co-, ad-, and n-iso-α-acids are also calculated. IAA, iso-α-acids; TH, tetrahydroiso-α-acids; DH, dihydroiso-α-acids.

(MEKC) (Vindevogel *et al.*, 1990; Vindevogel and Sandra, 1991), microemulsion electrokinetic chromatography (MEEKC) (Szücs *et al.*, 1996), and capillary electrochromatography (CEC) (Vanhoenacker *et al.*, 2001) have been evaluated for the analysis of hop acids while iso-α-acids were successfully separated by MEKC (Vindevogel *et al.*, 1991; Royle *et al.*, 2001). Contrary to LC, a pre-concentration step (solid-phase extraction, liquid–liquid extraction) prior to the CE analysis of iso-α-acids and reduced iso-α-acids in beer is favorable, although direct injection of beers with stacking has been described (Szücs *et al.*, 1993).

SBSE–LD is applied here for quantitative analysis of iso-α-acids and for detection of reduced iso-α-acids in various beers by MEKC (De Villiers *et al.*, 2004). The iso-α-acid content of several beers was determined and compared with results obtained with the LC method using direct beer injection.

Experimental

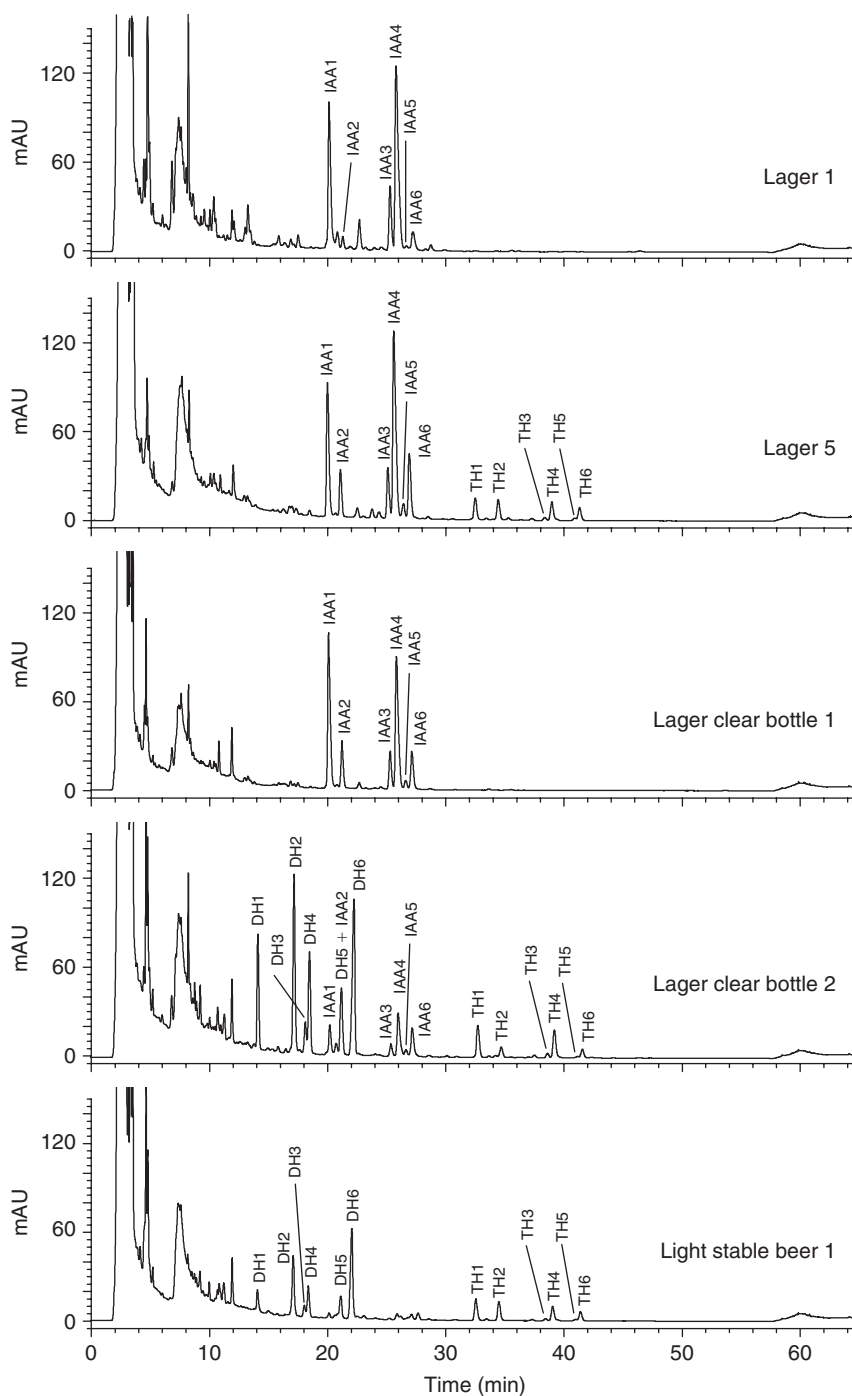
The buffer for MEKC analyses was filtered through a disposable syringe filter (0.45 μm, Nylon). Polydimethylsiloxane(PDMS)-coated stir bars (Twister™) were supplied by Gerstel (Mülheim a/d Ruhr, Germany). Beers were bought at local stores, kept at room temperature, and freshly opened prior to analysis. Pre-isomerized hop extract containing iso-α-acids was obtained from Hopstabil GmbH (Wolnzach, Germany). Dihydroiso-α-acids (DCHA-Rho, ICS-R1) were from Labor Veritas (Zürich, Switzerland) and tetrahydroiso-α-acids from Kalsec (Kalamazoo, MI, USA).


Figure 99.5 LC–UV analyses of various beers. Chromatograms for the analysis of a selection of beers after direct injection with detection at 256 nm. Significant differences can be observed between the various beers. IAA, iso-α-acids; TH, tetrahydroiso-α-acids; DH, dihydroiso-α-acids. Peak numbers: see Figure 99.2.

LC analyses for the investigation of the sorption and desorption process were performed in collaboration with A. De Villiers at the University of Stellenbosch (South Africa). For analytical conditions we refer to De Villiers *et al.* (2004). The beer samples were also analyzed by LC after direct injection. Full details of the method are described above.

MEKC analyses were performed on an HP³ᴰCE Capillary Electrophoresis System equipped with a DAD (Agilent Technologies, Waldbronn, Germany). An extended lightpath bare fused-silica capillary (Agilent Technologies, Waldbronn, Germany) with an ID of 50 μm and a total length of 64.5 cm (effective length is 56 cm) was used.

The beer flavor and bitterness are stabilized with dihydro- and tetrahydroiso-α-acids. EIC (selected ions: see Table 99.1). MS was performed using APCI in the negative mode. IAA, iso-α-acids; TH, tetrahydroiso-α-acids; DH, dihydroiso-α-acids. Peak numbers: see Figure 99.2.
Figure 99.7   Fast LC–UV analysis of a typical Western-European pilsner-type beer. Chromatogram for the fast LC–UV analysis of a typical Western-European pilsner-type beer after direct injection with detection at 256 nm. IAA, iso-α-acids; TH, tetrahydroiso-α-acids. Peak numbers: see Figure 99.2.

The buffer consisted of 40 mM phosphate (pH 10.2 with NaOH) containing 80 mM sodium dodecyl sulfate. Injection was performed hydrodynamically at 50 mbar for 10 s for the SBSE-enriched samples and for 15 s for direct injection of beer. The separation voltage was 25 kV and detection was performed at 255 nm. The capillary temperature was set at 25°C. Between runs, the capillaries were conditioned by flushing with NaOH (0.1 M) for 2 min, water for 1 min, and buffer for 3 min, consecutively.

Different sample preparation parameters, that is for sorption and desorption, were studied. The final SBSE–LD–MEKC procedure is as follows; 20 ml beer is poured in a headspace vial of 40 and 1 ml HCl (1 M) is added. A stir bar containing 24 µl PDMS is introduced and the sample

is stirred at 1,500 rpm and 25°C for 60 min. The stir bar is dipped in bidistilled water and dried on a tissue paper. The stir bar is then placed in 2 ml acetonitrile and stirred at 1,500 rpm and 25°C for 60 min. A 1 ml portion is withdrawn and evaporated to dryness under a nitrogen stream. The residue is dissolved in 0.5 ml bidistilled water and the sample is injected.

Results and discussion

Sorption and desorption kinetics were studied using LC because of its greater sensitivity compared to MEKC. The sorption step was investigated using only one stir bar. The stir bar was added to 20 ml beer acidified with 1 ml HCl (1 M). Magnetic stirring at different time intervals took place in a closed vial covered with aluminum foil. After each sorption step, the stir bar was removed and rinsed with water before being placed in 2 ml acetonitrile for 60 min (stirred as for sorption); 30 μl of the desorption liquid was then directly analyzed by LC. The stir bar was cleaned between samplings by thermal desorption for 60 min at 300°C. The results are summarized in Figure 99.8. Equilibrium between the PDMS coating and the aqueous phase was not reached after 120 min. The long equilibration time can be accounted for by slow diffusion rates of the molecules into PDMS. Since the diffusion time is proportional to the square of the film thickness of the coating, the equilibration time can be greatly reduced by decreasing the thickness of the coating. The short equilibration times found when using solid-phase microextraction demonstrates this statement (Pawliszyn, 1997). However, loss of sensitivity resulting from a thinner coating would make the analysis of the iso-α-acids impossible. For reasons of convenience, 60 min was chosen as the practical sorption time.

To study desorption, the sorption time was kept constant at 60 min. Acetonitrile was chosen as desorption solvent, because of its efficiency in desorbing relatively polar compounds from the stir bar without causing excessive swelling of the PDMS coating. Sorption took place in acidified beer. After removal and rinsing, the stir bar was placed in 2 ml acetonitrile; 10 μl of the desorption liquid was analyzed directly by LC in function of time. From the desorption graph in Figure 99.8, it can be observed that equilibrium between the two phases was reached after 60 min, and this time frame was chosen as optimum desorption time in subsequent analyses.

Next, a comparison was made between a "dry" stir bar and a stir bar saturated with a specific solvent. One stir bar was used and it was regenerated between experiments by thermal desorption (60 min at 300°C). The same beer was analyzed consecutively with a dry (thermally desorbed), acetonitrile-, and isooctane-saturated stir bar. Stirring in solvent for 20 min was applied to saturate the stir bar. Using sorption and desorption times of 60 min, the same beer was extracted as above and analyzed using MEKC. It
Figure 99.8 SBSE–LD sorption and desorption graphs for iso-α-acids. Investigation of sorption and desorption step for the iso-α-acids in the SBSE–LD sample preparation. For desorption, the equilibrium between the beer and the stir bar is reached at ca. 60 min. The equilibrium of the sorption process has not been reached after 120 min. A 60 min sorption time was chosen as a compromise.

was found that the amount of iso-α-acids absorbed into the stir bar increased in the order: dry stir bar < acetonitrile-saturated stir bar < isooctane-saturated stir bar. The effect of isooctane saturation can be explained by a swelling effect of the solvent on PDMS, which should facilitate diffusion into the phase. Further, the desorption equilibrium conditions also differ significantly, as the PDMS phase should be more hydrophobic, hence the equilibrium concentration of the acids in the desorbing acetonitrile is expected to increase. For an acetonitrile-saturated stir bar (almost no swelling), an increase in polarity of the coating caused by saturation with acetonitrile translates into improved sorption efficiency. The desorption efficiency might decrease in this case. The net effect is, however, an increase in overall extraction efficiency. Although higher recoveries were obtained compared to dry sampling for the same period of time (ca. 1.1 for acetonitrile and 1.8 for isooctane), the reproducibility was lower.

In further experiments, it was demonstrated that the desorption equilibration process could be accelerated, by either heating or sonication of the desorption liquid. This results from increased diffusion rates at elevated temperatures, as well as from possible temperature dependence of the relevant distribution coefficients. For the SBSE–LD–MEKC analysis of beer, sensitivity and reproducibility were found to be adequate and sorption and desorption were subsequently performed at 25°C without sonication.

Although iso-α-acids are generally present in sufficiently large concentrations (typically 20–50 mg/l) in beers, direct injections of beer followed by MEKC analysis is not feasible for the analysis of these compounds due to interference of matrix components. Application of SBSE–LD prior to
Figure 99.9   Comparison of MEKC analysis of direct injection of beer and injection after SBSE–LD. Result of MEKC analysis of direct injection of beer and injection after SBSE–LD. The sample preparation yields clean extracts free of most interfering compounds. IAA, iso-α-acids. Peak numbers: see Figure 99.2.

injection leads to isolation of iso-α-acids and reduced iso-α-acids from the matrix, hence, clean extracts are obtained. The comparison between direct injection and injection after SBSE–LD is shown in Figure 99.9. The more polar beer constituents (eluting before the iso-α-acids in the electropherogram) are not extracted by SBSE.

The MEKC method allows simultaneous determination of iso-α-acids and reduced iso-α-acids. A calibration graph was constructed by SBSE analysis of four simulated beer samples (5% ethanol) containing a standard solution of iso-α-acids (5.85, 14.62, 29.25, and 58.50 mg/l, respectively). Each level was analyzed in triplicate. Good linearity (correlation coefficient of 0.9985) was obtained in this concentration range. The reproducibility of the method was evaluated by six analyses of the same beer using six fresh stir bars. Each sample was injected in duplicate. RSDs on migration time and time-corrected area (area/migration time) ranged from 0.14% to 0.26% and from 2.33% to 5.76%, respectively.

A selection of local and foreign beers was analyzed using the methodology described above. Results were compared for the total iso-α-acid content and for the presence or absence of reduced iso-α-acids. Some representative electropherograms of extracts of beers are shown in Figure 99.10. As expected the German beer (Lager 1 in Figure 99.10) does not contain reduced isohumulones. The profile of the non-German lager (Lager 6 in Figure 99.10) is typical for a Western-European lager beer that usually contains iso-α-acids to which a portion of tetrahydroiso-α-acids is added

to improve foam stability. The procedure is more common in large breweries when compared to smaller ones. As already seen in the LC analyses, the difference between the two beers that are contained in clear bottles is striking. Because they are not protected from light, the taste-active compounds should be stabilized in some way. One beer is composed mainly of dihydro- and tetrahydroiso-α-acids (Lager clear bottle 2 in Figure 99.10). The concentration of iso-α-acids is significantly lower in comparison to the other beers. In the second beer presented in a clear bottle, only iso-α-acids are detected (Lager clear bottle 1 in Figure 99.10). This beer is also characterized by a relatively high content of isocohumulone.

Whereas reduced iso-α-acids were only qualitatively investigated, iso-α-acids were quantified in various beers using the constructed calibration graph. Results were compared with the results obtained by the described LC method after direct injection of the beers. The recovered amounts in MEKC are in good agreement with the amounts found by direct injection of beers by LC (Table 99.4).

SBSE–LD LC Analysis

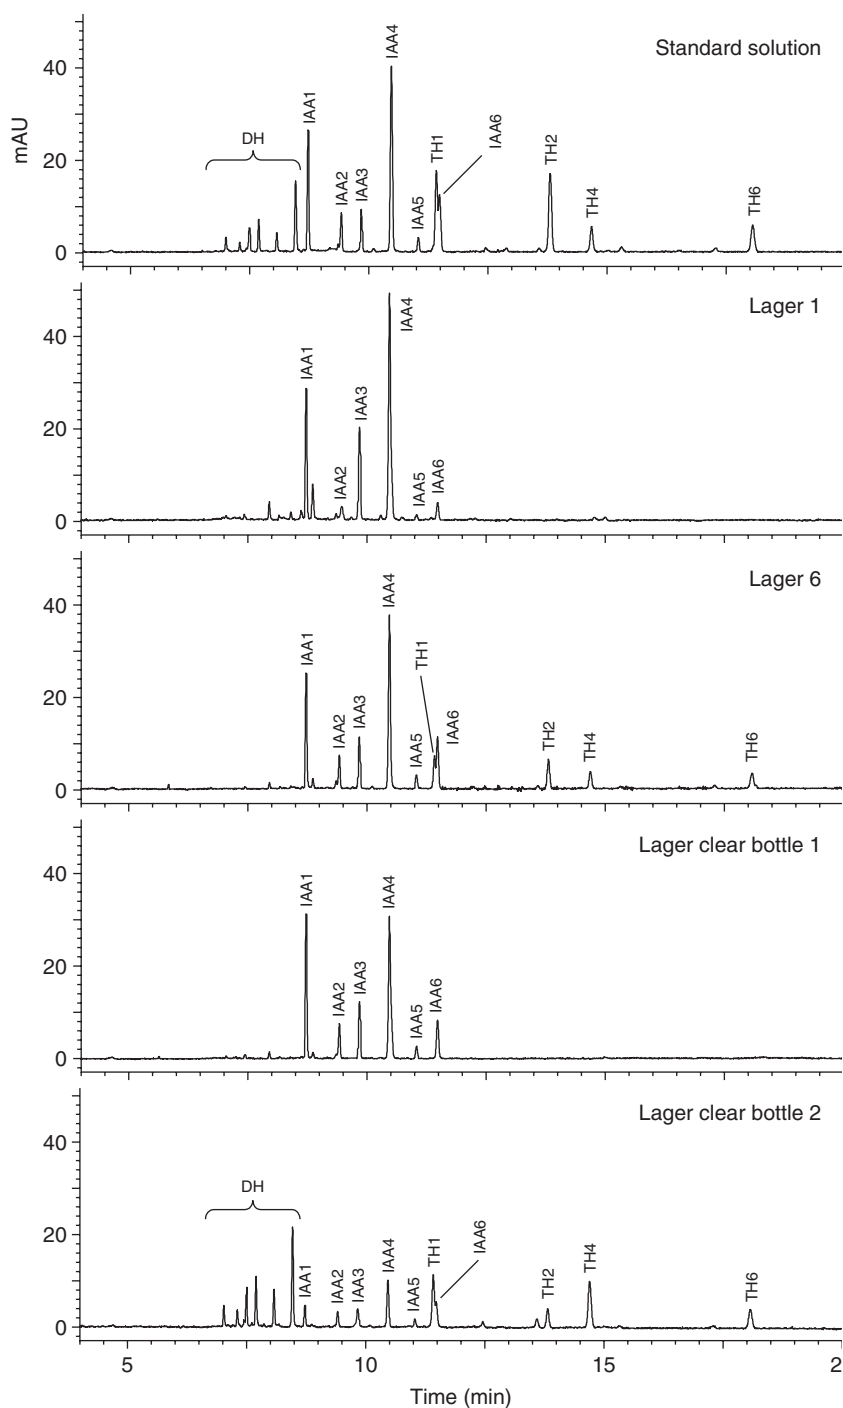
The SBSE–LD extracts analyzed by MEKC were also applied to the LC–UV method. For this comparison, the desorption liquid (acetonitrile) was diluted 10-fold with water prior to injection to reconstitute the sample to its original concentration (for a recovery of 100%). A comparison of LC–UV analyses by direct injection and by injection


Figure 99.10 MEKC analyses of a standard solution and various beers. Results for MEKC analyses of a standard mixture of hop-derived acids (20 mg/l of each group) and various beers after SBSE–LD. Significant differences can be observed between the various beers. IAA, iso-α-acids; TH, tetrahydroiso-α-acids; DH, dihydroiso-α-acids. Peak numbers: see Figure 99.2.

after SBSE–LD is shown in Figure 99.11. The peak areas obtained for the injections of the diluted extracts were compared with the peak areas obtained after direct injection of the same beer. The averaged recoveries were ca. 19.4% for iso-α-acids, ca. 43.1% for tetrahydroiso-α-acids, and ca. 8.5% for dihydro-α-acids. Using log p values calculated

with the software program KowWIN (Meylan, 2000) and the known phase ratio β, the theoretical recovery of iso-α-acids from beer (with the assumption that $K_{PDMS/beer} >> K_{o/w}$) was determined to be 45% (for log p = 2.9). It should be noted that these recoveries are not obtained under the conditions employed in this study for the beer analyses

Note: MEKC data for analysis of iso-α-acids (quantitative) and reduced iso-α-acids (qualitative) in various beers after SBSE–LD sample preparation. For the iso-α-acids, the concentration is compared with the result obtained with LC–UV after direct injection of the beers. IAA, iso-α-acids; TH, tetrahydroiso-α-acids; DH, dihydroiso-α-acids; +/–, detected/not detected.
Figure 99.11 Comparison of LC–UV analysis of direct injection of beer and injection after SBSE–LD. Overlay of chromatograms for LC–UV of beer after direct injection and injection after SBSE–LD sample preparation. The SBSE–LD extract was diluted 10 times prior to analysis. The sample preparation yields clean extracts free of most interfering compounds. IAA, iso-α-acids; TH, tetrahydroiso-α-acids. Peak numbers: see Figure 99.2.

(i.e. 60 min sorption time), since equilibrium was not established. The significant difference in recovery between the different groups of hop-derived acids can be explained by the considerable variations in polarity of these compounds, as can be deduced from the chromatograms.

Summary Points

LC–UV and LC–MS were successfully applied for the simultaneous analysis of iso-α-acids and reduced iso-α-acids in beers by direct injection. Volatile mobile-phase additives enable hyphenation to MS operated in the APCI mode.

- An alkaline mobile-phase pH improves peak shape and selectivity.
- All major bitter acids are separated within 65 min, with the exception of the pair *cis*-dihydroisoadhumulone/ *trans*-isocohumulone. Thus, quantitation of iso-α-acids in the presence of dihydroiso-α-acids using UV detection is questionable. With MS detection these compounds could be differentiated according to their *m/z* value.

Both UV and MS detection are sufficiently sensitive to analyze beers without sample pre-concentration. The performance in terms of quantification of bitter acids by LC–UV and LC–MS is compared for standard solutions and a selection of 14 beers.

- The values obtained with LC–MS are similar to those obtained with LC–UV, except for the dihydroiso-α-acids. The recovered amounts of dihydroiso-α-acids were consistently higher in LC–MS compared to LC–UV.
- MS detection proved superior to UV detection in view of enhanced sensitivity and selectivity, notwithstanding higher RSDs.
- The method can easily be adapted for fast routine LC–UV analysis of iso-α-acids and tetrahydroiso-α-acids in beer without sample pre-concentration.

SBSE–LD followed by MEKC separation represents a simple, efficient, and reproducible new method for the analysis of beer iso-α-acids. Parameters affecting both sorption and desorption were studied.

- Very clean extracts free of most interfering compounds were obtained.
- The developed MEKC method is fast and enables analysis of both iso-α-acids and reduced iso-α-acids.
- Quantitative results are in good agreement with results obtained by LC using direct beer injection.

Methods for Determining Biogenic Amines in Beer

Anastasia Zotou Department of Chemistry, Laboratory of Analytical Chemistry, Aristotle University of Thessaloniki, Thessaloniki, Greece
Zacharenia Loukou General Chemical States Laboratory, Kavala Division, Karaoli Square, Kavala, Greece

Abstract

The objective of this chapter is to provide information about the analytical methods used so far for the determination of biogenic amines in beer. Only a limited number of publications describing such methods appear in the literature and most of them include the use of high-performance liquid chromatography, with either pre- or post-column derivatization, or recently the use of capillary electrophoresis. Depending on the applied method, sample pretreatment ranges from simple degassing and dilution of the samples to tedious extraction procedures. The biogenic amines commonly found in beers are: histamine, tyramine, tryptamine, 2-phenylethylamine, putrescine, cadaverine, spermine, spermidine and agmatine at varying levels, which are affected mainly by raw materials, brewing techniques and hygiene conditions during brewing and storage.

List of Abbreviations

BNZ-Cl	Benzoyl chloride
CE	Capillary electrophoresis
DBS-Cl	Dabsyl chloride
DNS-Cl	Dansyl chloride
FITC	Fluorescein isothiocyanate
GC	Gas chromatography
GC–MS	Gas chromatography–mass spectrometry
HPLC	High-performance liquid chromatography
HPTLC	High-performance thin-layer chromatography
IEC	Ion-exchange chromatography
LLE	Liquid–liquid extraction
NBD-Cl	7-Chloro-4-nitro-benzo-2-oxa-1,3-diazole
NDA	Naphthalene-2,3-dicarboxaldehyde
ODS	Octadecyl silica
OPA	*o*-Phthalaldehyde
PNZ-Cl	*p*-Nitrobenzyloxycarbonyl-chloride
POLE	Polyoxyethylene-10-lauryl ether
RSD	Relative standard deviation
SAMF	6-Oxy-(*N*-succinimidyl acetate)-9-(2′-Methoxycarbonyl) fluorescein
SIM	Single-ion monitoring
SPE	Solid-phase extraction
TLC	Thin-layer chromatography
UV	Ultraviolet
UV–VIS	Ultraviolet–visible

Introduction

Biogenic amines are low relative molecular mass organic bases that possess biological activity and can occur in animals, plants and fermented or non-fermented food as a result of normal metabolic activity. They are usually derived from microbial decarboxylation of the corresponding amino acids or by transamination of aldehydes by amino acid transaminases (Kalač *et al.*, 1997).

Taking into account their structure and possible consequences to the human physiology, biogenic amines, mostly abundant in beers, can be divided into three groups (see also Table 100.1):

1. Aromatic, heterocyclic amines – such as histamine, tyramine, 2-phenylethylamine and tryptamine – to which some toxicity is attributed, with symptoms such as nausea, headaches, etc.
2. Aliphatic, di-, tri- and polyamines – such as putrescine, cadaverine, spermine, spermidine and agmatine – which belong to the same metabolic cycle and they increase the toxicity of the aromatic and heterocyclic amines.
3. Aliphatic volatile amines – such as methylamine, ethylamine and isoamylamine – for which no toxic effects have been reported, but whose determination is important because they can alter the organoleptic characteristics of food (Moret and Conte, 1996).

The metabolic routes of biogenic amines and ingested alcohol proceed by the same enzyme system, so it is necessary

Table 100.1   Classification of biogenic amines found in beer

| Classes of biogenic amines | Biogenic amines found in beer | |
	Trivial name	Systematic name
Aromatic heterocyclic amines	Histamine	4-(2-Aminoethyl)-1,3-diazole
	Tyramine	4-Hydroxy-phenethylamine
	Tryptamine	3-(2-Aminoethyl)indole
	2-Phenylethylamine	–
Aliphatic polyamines*	Putrescine	Butane-1,4-diamine
	Cadaverine	Pentane-1,5-diamine
	Spermine	N,N'-bis (3-aminopropyl)butane-1,4-diamine
	Spermidine	N-(3-aminopropyl)butane-1,4-diamine
	Agmatine	(4-Aminobutyl) guanidine
Aliphatic volatile amines	Methylamine	–
	Dimethylamine	–
	Ethylamine	–
	Butylamine	–
	Dibutylamine	–

*Polyamine = any of a group of organic compounds, composed of only carbon, nitrogen and hydrogen and containing two or more amino groups.

to pay special attention to fermented alcoholic beverages such as beer, where the presence of ethanol has a synergistic interaction that can increase the toxic effect of some biogenic amines (Peatfield, 1995).

The types and levels of biogenic amines in beers are affected mainly by raw materials, brewing techniques and hygiene conditions during brewing and storage (Halász et al., 1994). Biogenic amines present in beers can be divided into three groups according to their source of origin. High levels of putrescine, agmatine, spermine and spermidine are usually found in malt. Tyramine, 2-phenylethylamine and other polyamines have been determined in hop, but it has little influence on the total content of biogenic amines in beer, since the amount used in brewing is small. The second group is related to amines that are generated during mashing and wort boiling, for example tyramine, agmatine and cadaverine. The last group consists of tyramine and tryptamine that can be synthesized during mashing and fermentation (Izquierdo-Pulido et al., 1994; Hannah et al., 1988; Beatriz et al., 1999). The entire amount and the spectrum of biogenic amines arising in beers could be associated mainly with the hygiene conditions during brewing and to a lesser extent during further processing and storage. Wort contamination by microorganisms possessing specific amino acid decarboxylases, such as lactic acid bacteria or wild yeast, lead to the formation of characteristic amines like tyramine and histamine (Izquierdo-Pulido et al., 1995). Due to high consumption of beer and the possible harmful effects of biogenic amines, it is important to determine their levels. Moreover, biogenic amine levels could be used as an indicator of raw material quality, correct conditions of brewing and final product freshness. The levels of amines in North and South American, and European beers have been investigated. The various structures of amines commonly found in beers of different type and origin are given
Figure 100.1   Structure of biogenic amines commonly found in beer.

in Figure 100.1. Data on the levels of the commonly found biogenic amines in beers, analyzed over the past few years, are presented in Tables 100.2 and 100.3.

Methods for the determination of biogenic amines in foods are not numerous and only a few of these have been applied to beer. Methods that have been used throughout the years include spectrofluorometric and enzymatic techniques, the use of amino acid analyzer, thin-layer chromatography (TLC), gas chromatography (GC), ion-exchange chromatography (IEC), high-performance liquid chromatography (HPLC), being the preferred technique, and in recent years capillary electrophoresis (CE).

Due to the lack of an easily detectable common chromophore group in amines, it is necessary to increase the sensitivity of the method by pre- or post-column derivatization. Some of the reagents used are *o*-phthalaldehyde (OPA), dansyl-chloride (DNS-Cl), dabsyl-chloride (DBS-Cl), benzoyl-chloride (BNZ-Cl), *p*-nitrobenzyloxycarbonyl-chloride (PNZ-Cl), 7-chloro-4-nitro-benzo-2-oxa-1,3 diazole (NBD-Cl), fluorescein isothiocyanate (FITC), 6-oxy-(-*N*-succinimidyl acetate)-9-(2′-methoxycarbonyl) fluorescein (SAMF) and naphthalene-2,3-dicarboxaldehyde (NDA). Information about the employed techniques, the derivatization reagents and the detection systems is included in Table 100.4.

Regardless of the analytical method and the derivatizing agent used, clean-up and preconcentration steps (e.g. liquid–liquid extraction (LLE), solid-phase extraction (SPE)) before and/or after the derivatization are often required, to determine the biogenic amines at the low levels, that they are present in beers, with no interferences from other compounds (e.g. amino acids, phenolic compounds). These steps are summarized in Table 100.5.

Table 100.4   Analytical techniques, derivatization reagents and detection systems used for the determination of biogenic amines in beer

Amine	Analytical technique	Derivatization reagent	Detection system	Reference
Histamine	Spectrofluorimetry	OPA	$\lambda_{ex} = 350\,nm$, $\lambda_{em} = 430\,nm$	Izquierdo-Pulido et al. (1991, 1995)
Tyramine	Spectrofluorimetry	α-Nitroso-β-napthol	$\lambda_{ex} = 450\,nm$, $\lambda_{em} = 540\,nm$	
Ten amines	Ion-pair HPLC	Post-column with OPA	$\lambda_{ex} = 340\,nm$, $\lambda_{em} = 445\,nm$	Beatriz et al. (1999), Izquierdo-Pulido et al. (1993, 1996a, b, 2000)
Six amines	RP-HPLC	Pre-column with OPA	$\lambda_{ex} = 345\,nm$, $\lambda_{em} = 440\,nm$	Petridis and Steinhart (1995)
Eight amines	RP-HPLC	Pre-column DNS-Cl	UV = 254 nm	Buiatti et al. (1995)
Eight amines	RP-HPLC	Pre-column DNS-Cl	UV = 340 nm	Slomkowska and Ambroziak (2002)
Eleven amines	RP-HPLC	Pre-column DNS-Cl	UV = 254 nm	Zotou et al. (2003)
Eleven amines	RP-HPLC	Pre-column DNS-Cl	$\lambda_{ex} = 320\,nm$, $\lambda_{em} = 523\,nm$	Loukou and Zotou (2003)
Eight amines	RP-HPLC	Pre-column DBS-Cl	UV = 445 nm	Romero et al. (2003)
Five amines	RP-HPLC	Pre-column benzoyl-Cl	UV = 254 nm	Kalač et al. (1997)
Four amines	MECC	Pre-column 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole	$\lambda_{ex} = 488\,nm$, $\lambda_{em} = 540\,nm$	Preston et al. (1997)
Six amines	MECC	Pre-column benzoyl-Cl	UV = 200 nm	Kalač et al. (2002)
Histamine	CZE	–	Amperometric 1.35 V vs. SCE	Zhang et al. (2002)
Seven amines	CZE	Pre-column SAMF	LIF ($\lambda_{ex}/\lambda_{em} = 488/520\,nm$)	Cao et al. (2005)
Ten amines	CE	Pre-column FITC	LIF ($\lambda_{ex}/\lambda_{em} = 488/520\,nm$)	Cortacero-Ramirez et al. (2005)
Four amines	HP-TLC	DNS-Cl	FL ($\lambda_{ex}/\lambda_{em} = 338/505\,nm$)	Linares et al. (2001)
Twenty-two amines	GC	Pre-column isobutyl chloroformate	MS at SIM	Fernandes et al. (2001)

CE, capillary electrophoresis; CZE, capillary zone electrophoresis; DBS-Cl, dabsyl chloride; DNS-Cl, dansyl chloride; FITC, fluorescein isothiocyanate; FL, fluorescence; GC, gas chromatography; HP-TLC, high-performance thin-layer chromatography; LIF, laser induced fluorescence; MECC, micellar electrokinetic chromatography; MS, mass spectrometry; OPA, o-Phthalaldehyde; RP-HPLC, reversed-phase high-performance liquid chromatography; SAMF, 6-oxy-(N-succinimidyl acetate)-9-(2′-methoxycarbonyl) fluorescein; SIM, single ion monitoring; UV, ultraviolet.

Table100.5 Procedures described in the literature for the analysis of biogenic amines in beer

Amines	Sample preparation	Liquid–liquid extraction	Solid-phase extraction			Reference
			Conditioning	Washing	Elution	
Histamine	Alkalization	For histamine: n-butanol, re-extracted with HCl (0.1 M)	–	–	–	Izquierdo-Pulido et al. (1991, 1995)
Tyramine		For tyramine: ethyl acetate, re-extracted with HCl (0.1 M)				
Ten amines	Homogenization, decarbonation and filtration	–	–	–	–	Beatriz et al. (1999), Izquierdo-Pulido et al. (1993, 1996a, b, 2000)
Eight amines	Saturation, degassing	With 10 ml of n-butanol – chloroform 1:1 (v/v). Mixture blending for 30 min. 1 ml of the organic phase + 2 drops of HCl, taken to dryness at room temperature. Dissolved with 1 ml of saturated sodium dicarbonate.	–	–	–	Buiatti et al. (1995)
Eight amines	Degassing	–	ODS cartridges MeOH/H$_2$O	20 ml 40% MeOH + 6 ml 40% MeOH	10 ml 100% MeOH	Slomkowska and Ambroziak (2002)
Eleven amines	Degassing and PVP treatment	–	DSC-18 cartridges MeOH/H$_2$O	Two volumes water/acetone (80:20 v/v)	3 ml ACN	Loukou and Zotou (2003a, b) Zotou et al. (2003)
Five amines	Degassing	With 10 ml of diethyl ether; 5 ml of the extract evaporated with a warm air stream and the residue dissolved in 0.4 ml of 71% (v/v) MeOH.	–	–	–	Kalač et al. (1997)
Six amines	–	With diethylether after evaporation of the solvent and dissolved in methanol.	–	–	–	Kalač et al. (2002)

ACN, acetonitrile; MeOH, methanol; ODS, octadecyl; PVP, polyvinylpyrrolidone.

Methods of Analysis

One of the first procedures developed focused on the most toxicologically important amines namely histamine and tyramine. Izquierdo-Pulido *et al.* (1991, 1995) used a different extraction method for each amine. Histamine was extracted with *n*-butanol after sample alkalization, re-extracted with hydrochloric acid (0.1 M) and determined as a fluorescent complex with OPA. The emission and excitation wavelengths were 350 and 430 nm, respectively. Tyramine extraction similarly occurred in an alkaline sample and was carried out with ethyl acetate. After re-extraction with hydrochloric acid, the tyramine complex with α-nitroso-β-napthol was measured again by spectrofluorimetry ($\lambda_{ex} = 450$ nm and $\lambda_{em} = 540$ nm). As other biogenic amines are also of interest, comprehensive and more selective methods were developed.

Liquid chromatographic methods

Ten amines – histamine, tyramine, serotonin, phenylethylamine, tryptamine, cadaverine, putrescine, agmatine, spermidine and spermine – were separated in one run using ion-pair partition chromatography on a reversed-phase column by Izquierdo-Pulido *et al.* (1993). After separation, the amines were detected as fluorescent OPA derivatives. Determination limits of the method ranged from 0.3 to 0.4 mg/l, except for serotonin and spermine, which were slightly higher. Based on this work, Beatriz *et al.* (1999) determined the levels of biogenic amines in Brazilian beers. This method was also used to provide data on the contents of biogenic amines in different types of European beers (Izquierdo-Pulido *et al.*, 1996a). Since biogenic amine levels could be used as an indicator of raw material quality, correct conditions of brewing and final product freshness, Izquierdo-Pulido *et al.* (1996b) used their previous work (Izquierdo-Pulido *et al.*, 1993) to locate differences among breweries. In recent years, Izquierdo-Pulido *et al.* (2000) tried to determine the effect of tyrosine on tyramine formation during beer fermentation. Loret *et al.* (2005) also used ion-pair chromatography with OPA post-column derivatization to measure the quality of the beer fermentation process in Belgian samples.

Though post-column derivatization is more common when OPA is used, Petridis and Steinhart (1995) described a simple and selective HPLC method for determining biogenic amines in beers and other beverages with pre-column OPA derivatization. Sample preparation was based on a rapid amine extraction using 10% trichloroacetic acid and a cation exchange column for extract purification. For the RP-HPLC analysis, OPA/2-mercaptoethanol was used for the pre-column derivatization, followed by fluorescence detection ($\lambda_{ex} = 345$ nm, $\lambda_{em} = 440$ nm). A separation of 15 biogenic amines was achieved within 70 min. The recoveries for histamine, tyramine, putrescine, cadaverine, tryptamine

and 2-phenylethylamine were higher than 95%. The detection limits lied between 0.1 and 0.5 pmol/injection (20 µl), depending on the amine and a good linearity was achieved in the range 0.5–500 pmol ($r > 0.99$).

Arlorio *et al.* (1999) combined an extraction pre-separation step with ion-pair chromatography. The extraction steps were carried out with either butanol or an ionic exchanger. The authors concluded that many interfering compounds were eliminated by the pre-separation step. However, this procedure appeared to be laborious and detection limits were not given.

Buiatti *et al.* (1995) separated eight amines (histamine, tyramine, 2-phenylethylamine, tryptamine, cadaverine, putrescine, spermidine and spermine) using 1,7-diamino-heptane as internal standard. Amine derivatives, prepared prior to HPLC analysis with dansyl chloride, were eluted from a reversed-phase column by an acetonitrile/dipotassium hydrogen-phosphate system, adjusted to pH 7 with ortho-phosphate/water. The acetonitrile concentration increased linearly from 65% to 90% during 0–6 min. UV detection was carried out at 254 nm. The amines were extracted from beers using liquid–liquid extraction (LLE). When saturated with anhydrous sodium carbonate, degassed beer samples were submitted to extraction using 10 ml of *n*-butanol–chloroform 1:1 (v/v) . The mixture was blended for 30 min. An aliquot of 1 ml of the organic phase was introduced into a screw-capped tube and two drops of hydrochloric acid were added. After the sample was taken to dryness at room temperature, it was dissolved with 1 ml of saturated sodium dicarbonate. Dansylation was performed by adding 1 ml of DNS-Cl reagent (5 mg/ml in acetone). The reaction mixture was left for 1 h at 40°C. A different approach was proposed by Slomkowska and Ambroziak (2002) who also used pre-column dansylation to determine the content of eight biogenic amines in Polish beers. Degassing of the beer samples was the only step prior to dansylation procedure. The preparation of dansyl derivatives was as follows: A 1-ml volume of the working standard solution or the degassed beer sample was pipetted into a screw-capped vial. Subsequently, the following reagents were added to the tube: 1 ml of 5% trichloroacetic acid, 250 µl internal standard, 1 ml of 5% Na_2CO_3 and finally 1 ml DNS-Cl in acetone. The mixture was left in the dark for 90 min at 50°C. SPE was used as a clean-up step prior to chromatographic separation, using C18 cartridges. Washing was carried out with 20 ml of 40% methanol and then with an additional volume of 6 ml. The elution of dansyl derivatives was performed with 10 ml of 100% methanol. UV detection at 340 nm was used. The method showed satisfying recoveries while the detection limits ranged from 0.19 mg/l for spermidine to 0.49 mg/l for 2-phenylethylamine.

Dansylation with UV detection after separation on an octa-decyl silica (ODS) column was used to determine the levels of 11 amines (histamine, tyramine, methylamine, ethylamine, 2-phenylethylamine, isoamylamine, tryptamine, cadaverine,

putrescine, spermidine and spermine) in Greek beers by Zotou *et al.* (2003). The method involved pre-column derivatization of the amines with dansyl chloride and subsequent SPE of the derivatives through C18 cartridges. The pH of 5-ml beer aliquots was adjusted to 9.5 with borate buffer. A 2-ml volume of the resulting solutions was transferred to reaction vials and 400 μl of the 1,7-diaminoheptane internal standard solution and 800 μl of a 1% w/v DNS-Cl solution were then added and the mixtures were brought to a total volume of 4 ml with acetone–water (3:1). Vigorous agitation followed and the reaction mixtures were left in darkness for 30 min at 65°C. After derivatization, the reaction vials were left to cool at room temperature and acetone was removed under a stream of nitrogen. The remaining aqueous phase of the derivatized sample was then applied to an SPE clean-up procedure, using Supelco DSC-18 cartridges (500 mg/3 ml). The cartridges were activated with two volumes of methanol followed by two volumes of water. After the samples had passed through, the cartridges were washed with two volumes of water–acetone (80:20 v/v) and dried under vacuum. The samples were finally eluted with 3 ml of acetonitrile and the eluates were evaporated to dryness under nitrogen. The residues were reconstituted with acetonitrile and the resulting solutions were injected to the chromatograph. The separation was achieved on an Inertsil ODS-3 column (250 × 4 mm ID, 5 μm) using a 35-min gradient elution method with a binary system of acetonitrile–water, a flow rate of 1 ml/min with UV detection at 254 nm. Before analysis samples were degassed by ultrasonication for 15 min followed by the removal of polyphenols with polyvinylpyrrolidone (PVP). Limits of detection ranged from 0.1 ng for methylamine and ethylamine to 1.5 ng for tryptamine injected on-column. The method showed good linearity, satisfactory recovery results and high levels of sensitivity and precision.

Dansyl derivatives combine the unique feature of being both fluorescent and detectable in the UV region. Taking advantage of this feature and also of the fact that DNS-Cl reacts with both primary and secondary amino groups providing very stable derivatives, in contrast to OPA, which reacts only with primary amines yielding unstable derivatives, Loukou and Zotou (2003a) proposed quantification of the dansylamides of 11 biogenic amines in beer by fluorescence detection, at $\lambda_{ex} = 320$ nm and $\lambda_{em} = 523$ nm. Sample pretreatment, derivatization process, SPE clean-up and chromatographic conditions were identical to those reported previously by Zotou *et al.* (2003). Linearity was obtained for concentrations ranging from 0.008 to 40.0 mg/l. The limits of detection were found to be 0.08 ng for methylamine and ethylamine to 2.0 ng for histamine injected on-column. A comparison between UV and fluorescence detection of the dansyl derivatives was performed by means of significance *t*-tests, at the 5% level, using the results obtained from the analysis of beer samples (Loukou and Zotou, 2003b). Statistically significant differences were found only for ethylamine and spermine.

Eight biogenic amines, as dabsyl derivatives, were determined in beer samples, intermediate products and raw materials (malt and maize) by Romero *et al.* (2003). Beers and worts were filtered through a 0.20-μm millipore membrane filter, prior to the derivatization process. If necessary, worts were centrifuged before filtration to eliminate yeast remains and solid materials. An aliquot of 1.5 ml of diluted beer or hydrochloric extract was transferred to a vial, adjusted to pH 8.2 with reaction buffer and water was added to 3.8 ml. After thorough mixing on a vortex-mixer, 1.6 ml of dabsyl chloride solution was added and it was mixed again. The mixture was heated in a water bath for 21 min at 70°C, shaking at 1 and 15 min. Then, a 4.6-ml volume of the dilution solution was added and allowed to stand for approximately 20 min in the water bath, shaking from time to time. The C18 column was equilibrated at 40°C and the dabsyl derivatives were separated at a flow rate of 1 ml/min, using gradient elution, with a binary system of eluent A (sodium acetate + 10% v/v dimethylformamide + 0.23% v/v triethylamine, at pH 5.0 with dilute acetic acid) and eluent B (87.5% v/v acetonitrile + 10% v/v *tert*-butylmethylether + 2.5% v/v water). The detection wavelength was 446 nm. Bottled and canned beers representing different types of Spanish-produced beers (non-alcoholic, low alcohol, lager, special and extra) were studied. To study the amine contents throughout the brewing process, the same batch from two breweries of the same trademark, which use traditional (Brewery A) and modern (Brewery B) technologies, respectively, was monitored. Samples of raw materials and semi-products were collected at the different stages: maceration, fermentation, maturation and bottling. The results of the analysis indicate that in brewing, technology and hygiene are the decisive factors that determine the amine concentrations in the final product and not their levels in the raw materials.

Pre-column derivatization of five beer amines in Czech beers was reported by Kalač *et al.* (1997) based on the work of Křížek and Hlavatá (1995). Biogenic amines in beer and in solid raw materials were determined after their derivatization with benzoyl-chloride as *N*-benzamides by an HPLC method with isocratic elution. The *N*-benzamides were monitored at 254 nm. Two parallel analyses were necessary. Histamine and tyramine were determined by the first and the other three amines by the second. Histamine and tyramine were determined in 35-ml aliquots of beer, degassed under vacuum, to which 1,7-diaminoheptane was added as an internal standard. The mixture was alkalized with sodium hydroxide solution; benzoylchloride was added followed by sonication. The procedure continued with acidification to pH 6.0 with perchloric acid, addition of a phosphate buffer and sodium chloride and mixing. The *N*-benzamides formed were extracted into 10 ml of diethyl ether. A 5-ml aliquot of the extract was evaporated with a warm air stream and the residue was dissolved in 0.4 ml of mobile phase (71% v/v methanol in water).

A 10-μl aliquot of the extract was then injected for HPLC analysis. Cadaverine, putrescine and tryptamine were determined in 40-ml aliquots of degassed beer. A solution of 1,6-diaminohexane was used as an internal standard. The sample pretreatment was the same as that described above, but only a 1-ml aliquot of diethyl ether extract was evaporated and dissolved in 0.3 ml of 63.5% (v/v) methanol in water. The injected volume was again 10 μl. The detection limits (approximately 0.3 mg/l) were similar for all amines. No significant differences were observed between beer types (pale/dark, original extract of wort 10%/12%) and amine concentrations. Testing three batches for changes in the amine concentration during the brewing process showed that the formation of amines occurred principally during the main fermentation.

The reagent *p*-nitrobenzyloxycarbonyl chloride (PNZ-Cl) has also been used for pre-column derivatization of biogenic amines in fermented beverages and vinegars (Kirschbaum *et al.*, 1999). This method was applied to the determination of histamine, tyramine, 2-phenylethylamine, tryptamine, cadaverine, putrescine, spermidine, spermine and serotonin in beer with UV detection at 265 nm. More recently, an HPLC method for the simultaneous analysis of amino acids and biogenic polyamines, using a new procedure for pre-column derivatization of amino groups with *N*-(9-fluorenylmethoxycarbonyloxy) succinimide and fluorometric detection at $\lambda_{ex} = 262$ nm and $\lambda_{em} = 630$ nm was described (Lozanov *et al.*, 2004). The separation of 20 amino acids and 4 biogenic polyamines (putrescine, cadaverine, spermine and spermidine) was achieved within 32 min on a sequence of three short (50 mm) reversed-phase C18, 5-μm columns with elution buffers based on dibutylamine phosphate. The method linearity, calculated for each amino acid and polyamine, had a correlation coefficient higher than 0.991, in concentrations ranging from 0.2 to 50 μM, except for spermine and methionine, where the correlation coefficients were $r = 0.984$ and $r = 0.979$, respectively. The stability of derivatives in acidified samples at 4°C and room temperature was demonstrated. The limit of quantification was estimated to be around 50 pM in 50-μl sample injection. The repeatability of the method, expressed as relative standard derivation (RSD), ranged from 1.1% to 6.7%

CE methods

In recent years, CE has evolved into an interesting alternative to HPLC, because of the higher efficiencies, faster separation times, ease of operation and the low sample volumes required. The attractive features of CE include also the almost zero solvent consumption, the high speed and the high-throughput chemical analysis of a wide variety of substances.

CE with simultaneous ultraviolet absorbance and laser-induced fluorescence (LIF) detection was applied to identify and quantify selected amines in beer, following derivatization

with 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-Cl). Quantification was performed using the method of standard addition to avoid pH-dependent variations in the reactivity of the derivatizing agent with the added benefit of verifying peak identity. An inexpensive and "easy-to-use" on-column fiber optic fluorescence detection cell was built using two optical fibers, a 125-μm excitation and a 400-μm collector fiber, positioned against the bare capillary wall using commercial HPLC fittings. The alignment and positioning provided a detection limit of 1 pmol for dibutylamine using a modest laser power of 5 mW (Preston *et al.*, 1997). The pH of the beer was adjusted to 9.0 with 0.1 M NaOH prior to derivatization. For standard addition and peak identification, beer samples were spiked using concentrated amine solutions. Samples were derivatized by adding equal volumes of the beer sample, methanol saturated with sodium acetate and a solution of 10 mg/ml NBD-Cl in methanol. The mixture was then heated at 60°C for 2 h in a sealed container. The derivatized material was diluted 1:4 prior to injection.

Formation of six biogenic amines in bottled beers was investigated in seven laboratory experiments (Kalač *et al.*, 2002). Amines were determined as *N*-benzamides by micellar electrokinetic capillary chromatography. Biogenic amines were derivatized by benzoylchloride in 40-ml aliquots of beer sample. The amines were thus converted to *N*-substituted benzamides, which were extracted in a further step by diethylether; after evaporation of the solvent they were dissolved in methanol. Analyses were carried out on a fully automated system for capillary zone electrophoresis, equipped with a multi-wavelength UV–VIS scanning detector. Separations were achieved using a plain fused silica capillary column, 43 cm total length (36 cm effective length to the detector) and 75 mm inner diameter. The procedure was described in detail by Křižek and Pelikanova (1998). Detection limits were 0.6, 0.8, 0.8, 0.8, 1.0 and 4.1 mg/l for cadaverine, putrescine, tyramine, tryptamine, histamine and spermidine, respectively. Reproducibility of the analytical procedure was tested by parallel analyses of seven beer samples from one bottle.

Histamine in beers has also been determined by capillary zone electrophoresis with an end-column amperometric detection using a carbon fiber microelectrode, at a constant potential (Zhang *et al.*, 2002). The optimum conditions of separation and detection were 10 mmol/l phosphate buffer, pH 5.6 for the buffer solution, 15 kV for the separation voltage and 1.35 V (vs. an SCE reference electrode) for the detection potential. The linear range was between 6.3×10^{-7} and 1.5×10^{-5} mol/l with a regression coefficient of 0.9997, and a detection limit of 4.0×10^{-7} mol/l. This method did not require any sample clean-up procedures or derivatization for the determination of histamine to beer samples.

Zhang and Sun (2004) introduced a rapid and sensitive method for the simultaneous determination of histamine and histidine by capillary zone electrophoresis with lamp-induced fluorescence detection. A fluorogenic derivatization reagent,

NDA was successfully applied to label the histamine and histidine, respectively. The optimal derivatization reaction was performed with 1.0 mM NDA, 20 mM NaCN and 20 mM borate buffer, pH 9.1 for 15 min at room temperature. The separation of NDA-tagged histamine and histidine could be achieved in less than 200 s with 40 mM sodium dihydrogen phosphate adjusted to pH 5.8 with H_3PO_4 as the running buffer. Sample injection was performed in the hydrodynamic mode with sampling height at 9 cm for 30 s. Separations were carried out at a constant voltage of 18 kV. Beer samples were diluted with water before derivatization. The detection limits for histamine and histidine were 5.5×10^{-9} and 3.8×10^{-9} M, respectively. The RSDs for migration time and peak height of derivatives were less than 1.5% and 5.0%, respectively.

The analytical potential of a fluorescein analog, SAMF as a labeling reagent for the labeling and determination of amino compounds by CE with LIF detection ($\lambda_{ex}/\lambda_{em} = 488/520$ nm) was investigated (Cao *et al.*, 2005). Biogenic monoamines and amino acids were chosen as model analytes to evaluate the analytical possibilities of this approach. The derivatization conditions and separation parameters for the biogenic amines were optimized in detail. The derivatization was performed at 30°C for 6 min in boric acid buffer (pH 8.0). The derivatives were baseline-separated in 15 min with 25 mM boric acid running buffer (pH 9.0), containing 24 mM SDS and 12.5% v/v acetonitrile. The concentration detection limit for biogenic amines reaches 8×10^{-11} mol/l. The proposed method was applied to the determination of biogenic amines in three different beer samples with satisfying recoveries varying from 92.8% to 104.8% and RSDs from 0.2% to 4.9%. The samples were diluted with water prior to derivatization. Under these conditions no interference from amino acids was observed. Finally, comparison of several fluorescein-based probes for amino compounds was discussed. With good labeling reaction, excellent photo-stability, pH-independent fluorescence (pH 4–9) and the resultant widely suited running buffer pH, SAMF has a great prospect in the determination of amino compounds in CE.

Cortacero-Ramirez *et al.* (2005) developed a sensitive capillary electrophoretic method for the simultaneous determination of 10 biogenic amines (agmatine, 1,6-hexanodiamine, cadaverine, putrescine, dibutylamine, histamine, tyramine, butylamine, dimethylamine and ethylamine), which usually appear in beer samples (special and nonalcoholic), using LIF. Sample amines were first derivatized and filtered and then separated with an uncoated capillary tubing in the presence of 50-mM sodium borate and 20% acetone at pH 9.3, at 30 kV. An 800-µl aliquot of each sample, previously degassed by ultrasonication, was derivatized using 495 µl of 0.2 M carbonate buffer at pH 9, 1,000 µl of FITC solution (10 mM), 1,000 µl of acetone and doubly deionized water to a final volume of 5 ml in a test tube. This solution was put into a thermostated bath for 2 h at

50°C and 2 ml of the resulting solution was diluted to a final volume of 10 ml with doubly deionized water before the analysis by CE. In the case of extra, special and non-alcoholic beer, a 1,500-µl aliquot was taken for the derivatization. After the derivatization procedure, the sample was passed through a 0.45 µm membrane filter prior to injection. It was possible to analyze biogenic amines in brewing-process samples and in beer samples in less than 30 min, obtaining detection limits between 0.3 µg/l for ethylamine and 11.9 µg/l for 1,6-hexanodiamine.

Other methods of analysis

Another technique for beer amine determination is the amino acid analyzer. This procedure employs a potassium citrate buffer system and a post-column ninhydrin reaction (Halász *et al.*, 1999). Samples (0.6 M perchloric acid extract of malt and previously decarbonated beer) were pre-separated on a column-packed Dowex 50WX8 cation-exchange resin (4 × 1 cm ID) to eliminate free amino acids and to concentrate amines. The eluate was evaporated to dryness on a water bath and the dry residue was redissolved in 0.01 M HCl and filtered through a 0.45-mm membrane filter. Analysis of amines (putrescine, histamine, cadaverine, agmatine, spermidine and spermine) was carried out by an amino acid analyzer. A potassium citrate buffer system was required to eluate the amines at a flow rate of 40 ml/h. The column temperature was maintained at 67°C. Colorimetric detection was accomplished at 570 nm after ninhydrin reaction.

Derivatives with DNS-Cl have also been separated by a high-performance thin-layer chromatographic method (HPTLC). The effects of non-ionic surfactants as mobile phase additives on the fluorescence intensity of dansyl derivatives of biogenic amines in HPTLC were investigated. Beer samples were degassed prior to dansylation. To a 2-ml aliquot of amine-solution (1 mg/ml) or beer, a 2-ml volume of saturated sodium hydrogen carbonate solution and 3 ml of DNS-Cl reagent (5 mg/ml) were added. The solution was mixed for 1 min and transferred quantitatively into microwave dansylation vessels. The vessels were closed and introduced into the microwave cavity. The reaction was carried out at 40% power (252 W) for 5 min, maintaining a maximum pressure of 3.4 bar inside the reactor. When the vessel was cold, the mixture was extracted with two portions of 2 ml of toluene and diluted to 10 ml with this solvent. This microwave assisted dansylation reduced analysis time. The dansyl derivatives of putrescine, cadaverine, spermidine and spermine were separated by HPTLC, with silica gel as stationary phase and an eluent consisting of chloroform–triethylamine (2 + 1 v/v) containing 5% m/v of polyoxyethylene-10-lauryl ether (POLE). A fiber-optic-based fluorescence instrument for *in situ* scanning was used for quantitative measurements ($\lambda_{ex}/\lambda_{em} = 338/505$ nm). The compounds were determined over the range 0.5–85 ng, with RSDs between 0.44% and 1.16%. The detection limits of the amines ranged between

0.28 and 0.39 ng. It is shown that the presence of POLE in the mobile phase enhances both the fluorescence intensity and the signal-to-noise ratio of the chromatographed dansyl derivatives (Linares *et al.*, 2001).

A gas chromatography–mass spectrometry (GC–MS) method was developed by Fernandes *et al.* (2001) for simultaneous measurement of the concentrations of 22 volatile and non-volatile biogenic amines (methylamine, dimethylamine, ethylamine, diethylamine, propylamine, isopropylamine, butylamine, isobutylamine, amylamine, iso-amylamine, 2-methylbutylamine, hexylamine, pyrrolidine, piperidine, morpholine, 1,3-diaminopropane, putrescine, cadaverine, 1,6-diaminohexane, 2-phenylethylamine, tyramine and histamine) in alcoholic beverages. The method was based on a previously reported two-phase derivatization procedure with isobutyl chloroformate, which reacted quantitatively with all the amines in 10 min. After eliminating excess reagent, by treatment with alkaline methanol or by evaporation (tyramine and histamine determination), the derivatized extracts were analyzed by GC–MS with single-ion monitoring (SIM). Quantification of amines was achieved by the use of a set of eight different internal standards, including five deuterated isotopic analogs. The method has excellent analytical characteristics. It has been used to assay the concentrations of these biogenic amines in 13 samples of commercially available beers. Eleven biogenic amines were found in all the samples; putrescine (maximum 6.9 mg/l) and tyramine (maximum 1.7 mg/l) were the most abundant. Histamine was found in all samples at very low levels (maximum 147 mg/l).

An enzyme sensor array for the simultaneous determination of the three biogenic amines (histamine, tyramine and putrescine) by pattern recognition using an artificial neural network and its application to different food samples, among them beer, was described by Lange and Wittmann (2002). A combination of a monoamine oxidase, a tyramine oxidase and a diamine oxidase (with specific activities sufficient for rapid detection) are immobilized each on a separate screen-printed thick-film electrode via *trans*-glutaminase and glutaraldehyde to compare these cross-linking reagents with regard to their suitability. To calculate the amount of a specific biogenic amine, the raw data from multichannel software were transferred to a neural network. The sensor array takes 20 min to complete (excluding statistical data analysis) with only one extraction and subsequent neutralization step required prior to sensor measurement. However, the lower detection limits with this sensor (range between 5 and 10 mg/kg) compared to chromatographic methods appeared to lack sensitivity.

Summary Points

- There is currently much work ongoing globally, as researchers try to better understand the impact of biogenic amines and polyamines in our foods.

- In beer, bacterial contamination is a key source of biogenic amines and this is a source that can be controlled to ensure that the beer meets all quality and safety standards.
- Better methods of analysis for biogenic amines are being developed which allows for better monitoring.
- Liquid chromatographic methods with pre- or post-column derivatization followed by UV or fluorescence detection are the preferred methods of analysis, while in recent years CE methods are gaining ground.
- Sample pretreatment is usually simple, consisting only of degassing, though post-derivatization clean-up steps using SPE are usually needed.

Beer and ESR Spin Trapping

Kevin Huvaere and Mogens L. Andersen Food Chemistry, Department of Food Science, University of Copenhagen, Frederiksberg C, Denmark

Abstract

The exposure of beer to light, heat, and oxygen negatively affects flavor properties and causes a reduced storage stability of bottled beer. As the deteriorating processes involve short-lived highly reactive radicals, methods to detect the presence of these intermediates have gained significant attention. In particular, detection of radicals in beer and beer-related model systems by the technique of spin trapping followed by electron spin resonance (ESR) spectroscopy has become an important tool for unraveling the mechanisms of degradation reactions in beer, for evaluating the flavor stability, and for predicting shelf life of beer.

List of Abbreviations

CIDEP	Chemically induced electron spin polarization
DMPO	5,5-Dimethyl-1-pyrroline N-oxide
EPR	Electron paramagnetic resonance
ESR	Electron spin resonance
MBT	3-Methylbut-2-ene-1-thiol
MNP	2-Methyl-2-nitrosopropane
PBN	N-$tert$-butyl-α-phenylnitrone
POBN	α-(4-Pyridyl 1-oxide)-N-$tert$-butylnitrone
RF	Riboflavin
TEMPO	2,2,6,6-Tetramethylpiperidine 1-oxyl
TR-ESR	Time-resolved electron spin resonance

Introduction

Lager beer is a product with a delicate aroma that can be altered by exposure to light, oxygen, and heat (Vanderhaegen et $al.$, 2006). These external factors are capable of initiating redox reactions in beer, which eventually are perceived by the consumer as changes in taste and flavor, and, in more severe cases, as the presence of turbidity due to haze formation. In recent years, it has become clear that the main intermediates in these reactions are radicals, that is, molecules that bear unpaired electrons and that are very reactive toward most types of organic molecules. The knowledge of the mechanisms how radicals destroy beer components is essential for optimizing production steps in view of improved beer quality, but also for predicting beer stability in relation to its shelf life.

Radical Detection

ESR spectroscopy

Electron spin resonance (ESR) spectroscopy detects radicals and, as these compounds show paramagnetic behavior, the technique is also referred to as electron paramagnetic resonance (EPR) spectroscopy. Since an electron is a charged particle spinning around its axis (next to orbiting around the nucleus), it generates a magnetic dipole. When placed in an external magnetic field two energetically different spin states (α and β) result, a phenomenon known as the Zeeman effect. The corresponding energy separation, E, is proportional to the strength of the magnetic field, H, as expressed by the fundamental equation $E = g\beta H$ (where β is the Bohr magneton and g is the Landé factor, which depends on the structure of the radical) (Figure 101.1).

Furthermore, from $E = h\nu$ (where h is Planck's constant and ν is the frequency of the electromagnetic radiation), it follows that $h\nu = g\beta H$ and transitions between the two states, if present in a magnetic field of constant strength, are induced by interaction of the electron with electromagnetic radiation of a discrete frequency. This is, in fact, the basic principle for ESR spectroscopy. However, most commercial ESR spectrometers are equipped with a fixed-frequency microwave source (between 9 and 10 GHz, X-band) and, consequently, samples are placed in a magnetic field with varying strength. Continuous wave ESR instruments, which are the most common type, record the signal, which originates from microwave absorption, as its first derivative and display it as a function of the strength of the applied magnetic field (Figure 101.1). Most organic radicals (including spin adducts) have g factors around 2, and their X-band ESR spectra are, therefore, observed at $H \sim 3,300$ G.
Figure 101.1 Energy separation between the two spin states of an electron (α and β) induced by applying an external magnetic field (the Zeeman effect). When resonance occurs, the corresponding signal is detected by continuous wave ESR and recorded as a first-derivative spectrum.

Figure 101.2 Overview of important spin traps and their resulting spin adducts after radical ($R^\bullet$) addition.

As the resonance of an unpaired spin is limited to the transitions between the β- and the α-state of the electron, only one line will appear in the resulting ESR spectrum (Figure 101.1). However, in view of deciphering radical structures, it is important to note that electron delocalization leads to interaction of the unpaired spin with other paramagnetic nuclei, such as ^{1}H and ^{14}N. Thus, hyperfine couplings arise and the ESR signal is split into additional lines. Both the number of lines and the magnitude of the couplings are essential for obtaining valuable information about the radical structure, as will be seen in following paragraphs.

Detection of radicals in beer

Although ESR spectroscopy allows radical detection in concentrations down to $1\,\mu M$ under normal conditions, steady-state concentrations of radicals in beer, as a result of oxidation reactions, remain too low for direct detection. However, indirect detection can be aimed at by the technique of spin trapping, whereby highly reactive radicals are converted into stable radicals that accumulate to concentrations detectable by ESR (Rosen *et al.*, 1999). Such reaction is carried out by adding a so-called spin trap, a diamagnetic molecule that captures reactive radicals to form

a stable spin adduct (Figure 101.2). Most spin traps contain either a nitrone or a nitroso moiety, structural features which, after radical addition, result in a nitroxyl radical with unique stability. Practically every ESR study of beer, wort or related model systems has applied spin trapping for detection of radicals (Kaneda *et al.*, 1988; Uchida and Ono, 1996; Andersen and Skibsted, 1998).

Oxidation in Beer

Shelf life prediction

Uchida *et al.* demonstrated that the spin trapping technique could be used to predict the stability of lager beer (Uchida *et al.*, 1996). In an oxygen-rich atmosphere, spin adduct formation after heating of beer in the presence of a spin trap was observed to follow a two-phase course (Figure 101.3). Initially, during the so-called lag phase or lag time, the formation of radicals was slow and, as a consequence, the level of generated spin adducts was very low. After the lag phase, the rate of radical formation increased and signals of spin adducts intensified linearly with time. It was proposed that the low rate of radical formation during the lag phase is caused by the presence of antioxidants, which quench radicals prior to initiating autooxidation cycles or, in the experimental setup, prior to adding to a spin trap. Thus, the length of the lag phase is the result of the competition
Figure 101.3 The determination of a lag time or lag phase during oxidation of beer is based on the intensity of ESR signals of the observed spin adducts.

Figure 101.4 The mechanism of ethanol oxidation in an aerated beer matrix involves a 1-hydroxyethyl radical, resulting from hydrogen abstraction by a hydroxyl radical ($^{\bullet}$OH). This reactive intermediate originates from a Fenton-type reaction involving hydrogen peroxide and iron or copper ions.

between formation of radicals caused by the action of prooxidants and the quenching of radicals by antioxidants. A long lag phase indicates a high antioxidants-to-prooxidants ratio, while a short or absent lag phase suggests a small or negligible level of antioxidants compared to that of the prooxidants. Consequently, the lag time has been used as a criterion for endogenous antioxidant activity in beer, also referred to as EA value (Uchida *et al.*, 1996). In this respect, sulfite is suggested as one of the most important antioxidants in beer (Kaneda *et al.*, 1996; Uchida and Ono, 1999; Andersen *et al.*, 2000) and correlations between sulfite concentrations and lag times for radical formation in beer, as determined by ESR spin trapping, have been reported in several cases (Uchida *et al.*, 1996; Forster *et al.*, 1999; Nøddekær and Andersen, 2007). Obviously, different types of beer are expected to give different correlations, as levels of prooxidants and antioxidants may vary significantly.

As the length of the lag phase measured for fresh beer was found to correlate with the shelf life of beer during storage under normal conditions, spin trapping followed by ESR detection has become a fast and powerful tool for evaluating the flavor stability and for controlling quality during the production of beer (Uchida *et al.*, 1996; Forster *et al.*, 1999; Uchida and Ono, 2000).

Radicals observed during aerobic oxidative processes in beer

Spin trapping has become an important tool for studying the course of aerobic oxidative processes in beer, as such mechanisms involve several radicals and reactive oxygen species. The suggested intermediates are highly reactive and they participate in numerous reactions with various beer constituents. Eventually, the resulting reaction products
are responsible for the changes in taste and aroma that are observed by the beer consumer.

One of the major oxidative reactions in beer includes the conversion of ethanol into acetaldehyde and, according to spin trapping experiments, a mechanism as depicted in Figure 101.4 was proposed. A 1-hydroxyethyl radical, $^{\bullet}$CH(CH$_3$)OH, has been identified (by using different spin traps; PBN: $a_N \sim 16.0\,G$; $a_H \sim 3.3\,G$, DMPO: $a_N \sim 15.9\,G$; $a_H \sim 22.9\,G$) as the radical that is predominantly leading to formation of ESR-detectable spin adducts (Andersen and Skibsted, 1998). This species is produced when a hydroxyl radical abstracts a hydrogen atom from ethanol, which is the most prevalent organic compound in beer. Indeed, the reactive hydroxyl radical shows little selectivity and, in this particular matrix, reacts preferentially with the relatively high-concentrated ethanol. Spin adducts of hydroxyl radicals are, therefore, only observed at high concentrations of spin trap molecules, which then efficiently compete with ethanol as a reaction partner (Andersen and Skibsted, 1998).

Hydroxyl radicals in beer are, most likely, generated by a Fenton-type reaction, in which hydrogen peroxide is reduced by iron(II) or copper(I):

$$H_2O_2 + Fe^{2+} + H^+ \rightarrow {}^{\bullet}OH + Fe^{3+} + H_2O$$

$$H_2O_2 + Cu^+ + H^+ \rightarrow {}^{\bullet}OH + Cu^{2+} + H_2O$$
Evidence for the pivotal role of iron and copper in radical formation followed from the observation of increased levels of spin adducts after addition of metal ions to beer (Uchida and Ono, 1996; Andersen and Skibsted, 1998; Uchida and Ono, 1999), whereas a reduced formation of spin adducts resulted from the presence of metal chelating agents (Uchida and Ono, 1996).

The substrate for Fenton reactions, hydrogen peroxide, originates from the disproportionation of superoxide, $O_2^{\bullet-}$, or its corresponding acidic form, the hydroperoxyl radical, $HOO^{\bullet}$. The formation and accumulation of hydrogen peroxide during aerobic oxidation of beer have been demonstrated by direct chemiluminescence spectroscopy (Uchida and Ono, 1999). Furthermore, it was shown by spin trapping experiments that the addition of hydrogen peroxide to beer led to an increased formation of radicals, whereas the presence of catalase, a peroxide-consuming enzyme, hampered radical formation (Uchida and Ono, 1996). Moreover, hydrogen peroxide levels in beer decreased after addition of sulfite (Uchida and Ono, 1999) and, referring to its role of main antioxidant in beer, it was suggested to be the result of a two-electron nonradical process with hydrogen peroxide (Andersen et al., 2000).

Unlike for beer, the use of the spin trapping technique for detecting radicals in different types of wort has been less successful. Oxidation reactions are, most likely, also occurring in wort, but, apparently, the resulting radicals give rise to unstable spin adducts that do not accumulate into detectable amounts (Andersen and Skibsted, 2001).

Light-induced Oxidation of Beer

Lightstruck flavor

It is commonly known among brewers and beer lovers that exposure of beer to light results in significant quality loss, characterized by the development of an offensive taste and obnoxious odor. The phenomenon was first reported by Lintner back in 1875 and was referred to as lightstruck flavor (Lintner, 1875). The resulting off-flavor was principally attributed to the formation of 3-methylbut-2-ene-1-thiol (MBT) (Gunst and Verzele, 1978), also called *skunky thiol* due to its resemblance to compounds that prevail in the anal gland secretions of a skunk. Human scent is particularly sensitive to MBT and few nanograms per liter are sufficient to make lager beers unpalatable (Irwin et al., 1993).

Increasing quality demands forced breweries to tackle the problem and scientists were involved to investigate the harmful effect of light on beer. As such, in 1963, research conducted under the supervision of Kuroiwa at the Kirin Brewery in Japan led to a breakthrough in the elucidation of the mechanism for lightstruck flavor formation in beer (Kuroiwa et al., 1963). Remarkably, MBT was not observed on irradiation of unhopped beers, imputing hop-derived compounds a pivotal role in its formation mechanism (Kuroiwa and Hashimoto, 1961). In particular, isohumulones (Figure 101.5) were under suspicion, as their structural features allowed formation of a 3-methylbut-2-enyl
Figure 101.5 Isohumulones result from thermal isomerization of humulones. Reduced derivatives of isohumulones include tetrahydro-isohumulones (side-chain double bonds reduced) and dihydroisohumulones (α-hydroxyketone moiety reduced to a vicinal diol).

radical, which, on interaction with a suitable sulfur source, would eventually lead to the formation of MBT. Resulting from thermal isomerization of hop-derived humulones during wort boiling, isohumulones occur in concentrations varying from 10 to 100 mg/l beer and are largely responsible for the typical bitter taste. Although the intervention of iso-humulones seemed straightforward, degradation appeared to occur by an intricate mechanism. Indeed, the blue part of the visible spectrum (350–500 nm) was found most active in developing lightstruck flavor, but isohumulones are transparent in this wavelength region. Therefore, ribo-flavin (RF, vitamin B$_2$), which is naturally present in beer (few hundreds of micrograms per liter) (Andrés-Lacueva *et al.*, 1998; Duyvis *et al.*, 2002) and shows a strong absorp-tion around 375 nm and around 445 nm, was put forward to act as a sensitizer. Upon irradiation, energy harvested by RF was suggested to be transferred to isohumulones, pro-voking disintegration of the α-hydroxyketone moiety with formation of a 4-methylpent-3-enoyl radical (Figure 101.6). Subsequent decarbonylation produces a 3-methylbut-2-enyl radical, which, after capture by a suitable sulfur source, would finally produce MBT, the compound characterizing lightstruck flavor. Although interpretation of the reaction mechanism was largely based on hypotheses, supported by minor experimental evidence, the formalism soon became established in the brewing community. As a consequence, further research stagnated and details about the consecu-tive reaction steps, essential for verifying the validity of the proposed mechanism, remained elusive. Moreover, the pre-mature insights served as a basis for the development of the so-called light-stable derivatives of isohumulones. As the α-hydroxyketone moiety in isohumulones was suspected

to be particularly vulnerable, reducing this moiety to a vici-nal diol, as in dihydroisohumulones (Figure 101.5), was thought to inhibit photochemical degradation. On the other hand, reduction of the side-chain double bonds, as in tetrahydroisohumulones, would eventually prevent for-mation of a 3-methylbut-2-enyl radical, the main precursor of MBT.

To finally establish the underlying chemistry of light-struck flavor formation and to evaluate the claimed stability of the reduced isohumulones, the photodegradation process was reinvestigated using modern spectroscopic techniques, including EPR spectroscopy that served as a powerful tool in unraveling the details of the mechanism.

Photochemistry of isohumulones

In view of photochemical reactivity, isohumulones consist of an enolized β-tricarbonyl chromophore, which shows a maximum absorbance around 255 nm with a shoulder around 270–280 nm (Maye *et al.*, 1999). The high molar extinction coefficient ($\varepsilon > 10^4 \text{M}^{-1}\text{cm}^{-1}$ at 275 nm) indi-cates a π–π* transition, which leaves the n–π* absorption of the isolated carbonyl in the 4-methylpent-3-enoyl side chain negligible (for structural features, see Figures 101.5 and 101.6). Consequently, isohumulones were found prone to photochemical breakdown on exposure to UV-B light (280–320 nm), but not to visible light (Blondeel *et al.*, 1987; Heyerick *et al.*, 2003). A detailed mechanis-tic study, involving excitation by a 308-nm laser pulse followed by time-resolved ESR (TR-ESR) spectroscopy, allowed direct detection of short-lived radicals with high spectral resolution (Burns *et al.*, 2001). The presence of
Figure 101.6 The essential elements that are involved in the development of lightstruck flavor, as proposed by Kuroiwa (the Kuroiwa premise). Cleavage of the α-hydroxyketone moiety is pivotal in the formation of radical intermediates that eventually produce MBT.
Figure 101.7 Radicals derived from isohumulones and tetrahydroisohumulones, respectively, as observed after a 308-nm laser flash and subsequent detection by time-resolved ESR spectroscopy.

hyperfine couplings furnished essential structural information for characterizing reactive intermediates, hence it was found that direct photodegradation of isohumulones produced a strong emissive signal that was ascribed to the presence a five-membered-ring ketyl radical and a 3-methylbut-2-enyl radical (Figure 101.7). Indeed, the incipient 4-methylpent-3-enoyl radical, resulting from homolytic cleavage of the α-hydroxyketone moiety (Norrish Type I cleavage), should be rapidly decarbonylated. As spin density in the 3-methylbut-2-enyl radical is spread by extensive delocalization, the large number of hyperfine interactions (originating from coupling to multiple hydrogen atoms) decreased the intensity of the observed signal. On the other hand, tetrahydroisohumulones, which have both side-chain double bonds reduced with respect to isohumulones (Figure 101.7), showed a significantly different TR-ESR spectrum. Although radicals were still produced on cleavage of the unaltered α-hydroxyketone moiety, the resulting 4-methylpentanoyl failed to decarbonylate on a μs-timescale (Vollenweider and Paul, 1986). Thus, an acyl radical was observed and the lack of hyperfine couplings resulted in a more intense ESR signal. Reducing the side-chain carbonyl group, as in dihydroisohumulones, inhibited radical formation after a 308-nm laser flash and corroborated the mechanism of cleavage of the α-hydroxyketone moiety (as was observed for isohumulones and tetrahydroisohumulones). Although dihydroisohumulones did not directly lead to fragmentation, TR-ESR investigations still provided valuable mechanistic information. Indeed, on irradiation of these reduced derivatives in a frozen matrix, a net emissive signal arising from the triplet mechanism of chemically induced electron spin polarization (CIDEP) could be

observed. This β-tricarbonyl triplet was not observed with isohumulones or tetrahydroisohumulones, probably due to instantaneous cleavage reactions, but its interference was indirectly deduced from the net emissive polarization of the observed spectra. Further evidence for formation of the triplet state of the β-tricarbonyl moiety followed from addition of the spin probe 2,2,6,6-tetramethylpiperidine 1-oxyl (TEMPO) to a solution of dihydroisohumulones. Although TEMPO does not exhibit any polarization on its own, the resulting spectrum showed an emissive signal. This particular polarization was ascribed to the magnetic interaction between the excited β-tricarbonyl triplet and the unpaired spin on the TEMPO molecule. From these observations, it was concluded that formation of the triplet-excited state of the β-tricarbonyl chromophore is the early photochemical event on absorption of UV-B light. Ensuing energy transfer to the isolated side-chain carbonyl moiety eventually induces a Norrish Type I cleavage, producing a ketyl radical and an acyl radical which, in the case of isohumulones, is readily decarbonylated to form a 3-methylbut-2-enyl radical. As dihydroisohumulones have the α-hydroxyketone moiety reduced to a vicinal diol, energy transfer fails and radicaloid decomposition is averted. In accordance with the findings from irradiation with UV light, these compounds are marketed and sold as a fully light-stable alternative for natural isohumulones.

The Kuroiwa model revisited

Although exposure of isohumulones to UV-B light produced a 3-methylbut-2-enyl radical, according to the Kuroiwa formalism (visible) blue light accounts for the formation

of lightstruck flavor. Furthermore, beers packed in green bottles are particularly prone to photodegradation, yet colored glass is impenetrable for UV light (Sakuma *et al.*, 1991). Therefore, the intervention of RF in the photoreaction was thought to induce degradation by energy transfer, but this mechanism was later refuted due to unfavorable thermodynamics (Hastings *et al.*, 1992). As the interaction between RF and isohumulones remained an apparent discrepancy, a comprehensive insight of the underlying chemistry was aimed at. Therefore, model systems were investigated using a combination of TR-ESR and spin trapping followed by continuous wave ESR spectroscopy. After excitation of a solution containing isohumulones and flavin mononucleotide (an RF derivative used in model systems due to its enhanced water solubility) with a 355-nm laser pulse, the TR-ESR spectrum resulted in broad signal with a prominent emissive component (Heyerick *et al.*, 2005). The line width of ~19.0 G suggested a significant delocalization of the unpaired spin and was indicative of a reduced flavin semiquinone radical (Kay *et al.*, 1999). Detection of such species referred to an electron or hydrogen transfer mechanism which, obviously, would imply the occurrence of radicals derived from isohumulones (or derivatives). Indeed, superimposed signals were detected in the spectra produced by irradiation of isohumulones and tetrahydroisohumulones in the presence of flavin mononucleotide, but unambiguous identification was hampered by overlap with the intense flavin radical signal. Still, valuable mechanistic information was retrieved when the spin probe TEMPO was added to solutions containing isohumulones and flavin mononucleotide. Excitation by a 355-nm laser pulse, followed by TR-ESR analysis, resulted in a strongly emissive three-line spectrum which was ascribed to transfer of spin polarization when a triplet-excited state encounters an unpaired electron. This observation suggested the interference of triplet-excited flavin mononucleotide in the reaction mechanism, a finding which was in agreement with results that were obtained from laser flash photolysis coupled to transient absorption spectroscopy (Huvaere *et al.*, 2004a; Goldsmith *et al.*, 2005).

But, to claim deeper insight in the mechanism of lightstruck flavor formation, characteristic information about the radicals derived from isohumulones and reduced analogs was essential. Therefore, model solutions containing isohumulones (or derivatives) and a flavin compound were irradiated in the presence of spin traps, such as 5,5-dimethyl-1-pyrroline N-oxide (DMPO) and 2-methyl-2-nitrosopropane (MNP) (Huvaere *et al.*, 2005). Under these conditions, radicals arising from photooxidation of isohumulones add to the spin trap, giving rise to a relatively stable radical (Figure 101.2). Although only indirect information can be deduced from simulating the signals corresponding to these spin adducts, the coupling constants of the unpaired spin to nitrogen (a_N) and (if present) to hydrogen (a_H) have characteristic values and allow identification of the incipient radical. In this

respect, the use of MNP provides direct structural information as the multiplicity of the splitting pattern is directly related to the number of hydrogens prevailing on the radical center to be trapped. However, MNP fails to trap oxygen-centered radicals, as the resulting spin adducts are highly unstable and readily decompose. Therefore, radical trapping experiments were also carried out using DMPO as spin trap, as it produces detectable spin adducts with various types of radicals (carbon-, oxygen-, and sulfur-centered). Still, collecting information on the nature of the trapped radical is complicated, as the triplet arising from the nitroxyl radical is doubled by the presence of the DMPO β-hydrogen (Figure 101.2).

Preliminary experiments including photooxidation of isohumulones by triplet-excited flavins in the presence of DMPO furnished readily detectable spin adducts, but elucidation of the structural features of the trapped radical(s) announced as an intricate exercise. However, as oxidation of isohumulones was presumed, their behavior under oxidizing conditions was first examined by electrolysis in an electrochemical cell (Huvaere *et al.*, 2003). As no flavins were involved, the simplified model system allowed various functionalities in the isohumulones (and also in its derivatives) to be fully explored. Remarkably, it was found from applying cyclic voltammetry that these compounds could only be oxidized when present in their salt (anionic) form, whereas the corresponding undissociated (acidic) form remained electrochemically inactive. Since the salt form, which prevails in the beer matrix, is characterized by ionization of the enolized β-tricarbonyl chromophore (which, as seen in Figure 101.5, is present in isohumulones as well as in its derivatives and consists of a delocalized π-system spread over four carbon and three oxygen atoms), electron release and concurrent formation of radicals, obviously either carbon- or oxygen-centered, was suggested to arise from this moiety. Addition of DMPO to a solution of salts of isohumulones in acetonitrile, followed by electrolysis, produced a single spin adduct with a_N ~ 13.2 G and a_H ~ 8.9 G that was assigned to trapping of an oxygen-centered radical (Figure 101.8). Addition of MNP showed a distinctly different picture, as adducts with two radicals (a_N ~ 13.6 G and a_N ~ 7.9 G, respectively) were observed. Both MNP adducts should originate from carbon-centered radicals and, as they only show coupling to nitrogen, no hydrogens are bond to the radical center. Indeed, the value of a_N ~ 7.9 G is characteristic for trapping of an acyl radical that possibly results from secondary stabilization pathways. On the other hand, the value of a_N ~ 13.6 G suggests trapping of a tertiary carbon with low-electron density, as a similar value has been reported for trapping of a trichloromethyl radical by MNP (Buettner, 1987). Consequently, the incipient radical was identified as a carbon-centered triacylmethyl radical (for structure, see Figure 101.9). Substituting dihydroisohumulones for isohumulones resulted in a similar adduct with MNP (a_N ~ 15.3 G),
Figure 101.8 Experimental (*Exp.*) and simulated (*Sim.*) spin patterns of radicals derived from isohumulones after electrolysis (under a nitrogen atmosphere) and trapping by DMPO (*upper panel*) and MNP (*lower panel*), respectively.

as could be expected from oxidation of the ionized β-tricarbonyl moiety. Failure to observe a spin adduct with an acyl radical (as in the case of isohumulones) should be attributed to the presence of the diol moiety instead of an α-hydroxyketone. Spin trapping with DMPO gave rise to a spin adduct with $a_N \sim 13.1\,G$ and $a_H \sim 9.5\,G$, which was very similar to the observations made for the electrolysis of isohumulones. However, two extra spin adducts were formed ($a_N \sim 14.5\,G$; $a_H \sim 20.2\,G$ and $a_N \sim 14.7\,G$; $a_H \sim 25.7\,G$, respectively) that were ascribed to the trapping of carbon-centered radicals, most likely resulting from secondary reactions of the incipient oxygen-centered radical.

Thus, experiments involving electrolysis and subsequent spin trapping coupled to ESR analysis have demonstrated that the ionized β-tricarbonyl chromophore in isohumulones and its derivatives is a suitable target for oxidation. In this respect, it was investigated whether this moiety showed a similar reactivity in the presence of oxidizing species such as triplet-excited flavins (Huvaere *et al.*, 2005). In the case of tetrahydroisohumulones, radical addition to DMPO produced a characteristic spin adduct ($a_N \sim 14.8\,G$; $a_H \sim 18.1\,G$) that was ascribed to the trapping of an acyl radical. Furthermore, an extra species with $a_N \sim 15.4\,G$;

$a_H \sim 22.7\,G$ appeared in the ESR spectrum and a similar adduct resulted after photooxidation of isohumulones or dihydroisohumulones. Such spin adduct was previously observed in an analogous model system, but was, in that particular case, ascribed to the trapping of a 1-hydroxyethyl radical (Laane *et al.*, 1999).

Since DMPO generally furnishes poor structural information when investigating carbon-centered radicals, experiments were repeated with MNP as a spin trap. Thus, the spectrum observed after irradiation of a solution containing isohumulones (or derivatives) and RF showed a signal ($a_N \sim 16.5\,G$) that was attributed to a spin adduct resulting from photochemical interaction between RF and MNP. Unless this extensive background signal, characterization of radicals derived from photooxidation of hop-derived compounds was not compromised. Indeed, irradiation in the presence of isohumulones resulted in an MNP adduct with a value of $a_N \sim 14.1\,G$, while photooxidation of dihydroisohumulones resulted in an adduct with $a_N \sim 15.2\,G$. As the values of the respective coupling constants were in good agreement with the values observed on electrochemical oxidation, these spin adducts were, likewise, ascribed to the trapping of low-electron density triacylmethyl radicals (Figure 101.9). A similar adduct ($a_N \sim 14.2\,G$) resulted from irradiation of tetrahydroisohumulones, while an additional species with $a_N \sim 8.1\,G$, corresponding to the trapping of an acyl radical, was ascribed to the trapping of a 4-methylpentanoyl radical (for structure, see Figure 101.7). This finding was in agreement with spin trapping experiments with DMPO, as well as with detailed product analyses identifying 4-methylpentanal as a major degradation product (Huvaere *et al.*, 2004b). Since a 4-methylpentanoyl radical results from cleavage of the α-hydroxyketone moiety, its unsaturated counterpart, a 4-methylpent-3-enoyl radical, would be expected to arise from photooxidation of isohumulones. However, no such radical was added to MNP, as decarbonylation to a stabilized 3-methylbut-2-enyl radical readily occurred (Figure 101.9) and eventually led to the formation of 2-methylbut-2-ene as major reaction product (Huvaere *et al.*, 2004b). Still, traces of an adduct with a 4-methylpent-3-enoyl radical could be observed when DMPO was used as spin trap.

From these spin trapping experiments, followed by ESR spectroscopy, it was clearly demonstrated that isohumulones release an electron in the presence of oxidizing species such as triplet-excited flavins. The resulting radicals are highly reactive and stabilization pathways induce fragmentation that eventually furnishes a 3-methylbut-2-enyl radical, the main precursor of MBT. This radical cannot be formed from reduced derivatives of isohumulones and, according to the definition, these compounds do not lead to light-struck flavor formation. However, the observation of spin adducts after (photo)oxidation of tetrahydroisohumulones and dihydroisohumulones, respectively, indicates that these compounds produce reactive radicals as well, which possibly
Figure 101.9 The mechanism of lightstruck flavor formation as a result of visible-light irradiation. Radicals that are identified by spin trapping followed by ESR spectroscopy are depicted in a box as their respective spin adducts.

lead to formation of flavor-active volatile compounds (Huvaere *et al.*, 2004b). Thus, it was concluded that, despite the structural modifications, reduced isohumulones are not resistant toward flavin-mediated photodecomposition.

The role of sulfur radicals

Although research into the photochemical degradation of isohumulones produced evidence for the formation of a 3-methylbut-2-enyl radical as a precursor of MBT, still the origin of the thiol group (—SH) remained obscure. However, the presence of this particular sulfur moiety is pivotal, as it is largely responsible for the repulsive odor that MBT produces. In this respect, cysteine, as well as sulfur-containing peptides and proteins occurring in the beer matrix, has been suggested to act as sulfur donor (Sakuma *et al.*, 1991). Details about a possible reaction mechanism remained forthcoming, until it was found from experiments with laser flash photolysis that these sulfur-containing compounds strongly affected the triplet lifetime of the excited flavin (Cardoso *et al.*, 2004). This effect could not be observed for compounds such as alanine, hence, it was concluded that the presence of the sulfur atom was pivotal for interaction. Moreover, detailed fundamental insights in the reaction mechanism were obtained from combining

ESR spectroscopy with comprehensive product analyses by mass spectrometry (Huvaere *et al.*, 2006). Indeed, during irradiation of cysteine (and derivatives thereof) in the presence of flavin mononucleotide, a broad ESR signal (line width ~18.5 G) corresponding to the reduced flavin radical could be observed, indicating that an electron transfer (coupled to instant proton migration) mechanism was operative. Structural information about cysteine-derived intermediates only followed from addition of spin traps to the reaction mixture. Remarkably, MNP failed to produce detectable adducts after photooxidation of cysteine, but DMPO resulted in the formation of two adducts with $a_N \sim 15.2\,G$; $a_H \sim 17.2\,G$ and $a_N \sim 15.0\,G$; $a_H \sim 15.7\,G$, respectively. The coupling constants of the former adduct were characteristic of a trapped cysteinyl radical (Davies *et al.*, 1987; Mottley *et al.*, 1987), which was formed by photooxidation and subsequent deprotonation of the resulting cysteine radical cation (Figure 101.9). The second adduct was not identified before but it was suggested to arise from addition of a sulfur-centered radical to DMPO, as coupling constants were very similar to those reported for a sulfenyl radical (RS•). Moreover, since a comprehensive study by mass spectrometry revealed hydrogen sulfide (H_2S) as the major reaction product derived from photooxidation of cysteine, the intervention of a sulfhydryl

radical (•SH) was suggested and, consequently, the second DMPO adduct was ascribed to the trapping of •SH (Huvaere *et al.*, 2006). The feasibility of a C—S bond cleavage was confirmed when *S*-methylcysteine was substituted for cysteine, as photooxidation resulted in trapping of a thiomethyl radical ($a_N \sim 15.3\,G$; $a_H \sim 18.0\,G$ observed for the DMPO adduct). This finding was in agreement with the detection of methanethiol and dimethyl disulfide as major reaction products.

The mechanism of lightstruck flavor formation unraveled

The observation of a sulfhydryl radical (•SH) after photooxidation of cysteine, in combination with the knowledge that, under similar conditions, isohumulones decompose to produce a 3-methylbut-2-enyl radical, strongly supported the premise that radical recombination leads to lightstruck flavor formation. The mechanism was corroborated by the detection of MBT after visible-light irradiation of model systems containing isohumulones, cysteine, and a flavin derivative (Huvaere *et al.*, 2006). As a result of these findings, details about the reactions leading to lightstruck flavor formation may now be considered as fully unraveled.

Summary Points

- Spin trapping and ESR spectroscopy is a powerful tool for studying oxidation reactions that occur in the beer matrix.
- Spin trapping and ESR spectroscopy can be used for predicting the flavor stability of beer and for quality control during the production of beer.
- Fenton reactions most likely initiate radical formation in beer and give rise to the reactive (but unselective) hydroxyl radical, •OH, that attacks beer constituents with formation of (flavor-active) degradation products.
- The most important radical adducts observed in an aerated beer matrix result from trapping of a 1-hydroxyethyl radical, •CH(CH$_3$)OH.
- Light-induced reactions in beer, leading to the formation of MBT as the principal contributor to lightstruck flavor, are the result of radicaloid breakdown of hop-derived compounds.
- Irradiation with UV light causes direct decomposition of isohumulones, eventually furnishing a 3-methylbut-2-enyl radical (the main precursor of MBT).
- Visible-light irradiation of isohumulones in the presence of a flavin derivative produces a 3-methylbut-2-enyl radical, as a result of electron abstraction (by triplet-excited flavins) and subsequent radical stabilization pathways.
- Triplet-excited flavins oxidize cysteine (and derivatives), generating a sulfhydryl radical (•SH) as an important intermediate in the formation of lightstruck flavor in beer.

- From spin trapping experiments followed by ESR spectroscopy, it was demonstrated that dihydroisohumulones, which are claimed to be light-stable, do not resist photooxidation by triplet-excited flavins and disintegrate upon interaction.

Methods for Determining Ethanol in Beer

Domenica Tonelli Department of Physical and Inorganic Chemistry,
University of Bologna, Viale Risorgimento, Bologna, Italy

Abstract

Ethanol, together with water and carbohydrates, is one of the
main components of beer. Its concentration ranges from 0.05%
(v/v) in alcohol free beers to about 12.5% in the strongest
ones. An accurate and rapid determination of ethanol in beer
is important for regulatory applications and process control in
brewing industries, and on-line continuous monitoring is often
desired. Classical methods such as refractometry, densitometry,
or redox titration of the distilled sample, as well as gas chro-
matography, are routinely used in industry and in government
control laboratories, but they are time- and labor-consuming
procedures. To replace these techniques efforts have been made
to develop methods with low-cost instrumentation and/or
without complex sample pre-treatment. Biosensors based on
alcohol oxidase and alcohol dehydrogenase enzymes have been
fabricated and successfully applied to ethanol determination
in alcoholic beverages. Furthermore, infrared spectroscopy in
the mid- and near-infrared region as well as techniques such
as flow injection have provided interesting possibilities to also
automate ethanol determination.

List of Abbreviations

ADH	Alcohol dehydrogenase
AOX	Alcohol oxidase
ATR–FTIR	Attenuated total reflectance–Fourier transform infrared
CoPC	Cobalt phthalocyanine
CPE	Carbon paste electrodes
FIA	Flow injection analysis
GC	Gas chromatography
FID	Flame ionization detector
GD	Gas diffusion
GLC	Gas–liquid chromatography
HPLC	High performance liquid chromatography
HRP	Horseradish peroxidase
IR	Infrared
MB	Meldola's Blue
MGD	Membraneless gas diffusion
MIR	Mid-infrared
NAD	Nicotinamide adenine dinucleotide
NIR	Near-infrared
PAD	Pulsed amperometric detection
PV	Analytical pervaporation
SPE	Screen printed electrodes

Introduction

Beer is one of the oldest known alcoholic beverages, and
is obtained by fermentation of cereals germinated in water
in the presence of yeast. Fruits, herbs, and spices may also
be used to give beer a particular character (Varnam and
Sutherland, 1996). By 6000 BC, when the ancient cities
of Mesopotamia were built, the brewing of beer was
established. These beers would probably have been quite
thick, higher in protein, lower in alcohol, and sweeter than
those we are accustomed to today (Hughes and Baxter,
2001). The different combinations of ingredients, pro-
duction processes, and storage conditions give rise to an
enormous variety of beers – ales and lagers being defined
as the two main types according to the conditions of their
fermentation processes (Hughes and Baxter, 2001). There
has been great interest in studying the chemical composition
of beer, as this information is valuable for the assessment
of beer quality and the development of new products. The
main components of beers are water, carbohydrates, and
ethanol. Ethanol content is an organoleptic parameter affect-
ing both the beer classification (in term of taxes) and its taste
(Varnam and Sutherland, 1996; Council Directive 92/84/
EEC: OJ L 316, 1992, 31.10.1992 Bulletin, 10-1992).
It is usually expressed in % (v/v). A range of other alcohols
affect the flavor of beer, but they are present at levels at least
two orders of magnitude lower than that of ethanol. Across
the world, the alcohol content in beers ranges from less than
0.05% in alcohol free beers to a maximum of about 12.5%
in the strongest beers. It has been recognized for a very
long time that beer can make an important contribution
to the diet. Beer contains an average of 0.2–0.6 g/100 ml of

protein-derived material, which is substantially more than other alcoholic beverages, such as wine (Pueyo *et al.*, 1993). Proteins and some amino acids are partially responsible for the nutritional value and stability of beer. In fact, they influence beer foam and haze stability. In addition, there are carbohydrates (3.3–4.4%) (Gallignani *et al.*, 1994), which have a marked influence on sweetness and can influence mouthfeel and sour and bitter perceptions, phenolic compounds such as cinnamic acids, benzoic acids, catechins, and flavonols which are responsible for beer flavor, physical stability, and antioxidant activity, organic acids (e.g. acetic, formic acids), bitter acids (isohumulones), and inorganic ions (Engelhard *et al.*, 2004). The range of inorganic compounds in beer is 0.5–2 g/l. It has been established that these minerals, which include major cations, trace metals and anions, influence both the taste and the clarity of the finished beer. The salt taste of beer is a direct consequence of the presence of inorganic anions and cations. Beer contains small amounts of vitamins of the B-group together with vitamins A, C, D, E, and K. Beer analysis is important for the evaluation of (i) organoleptic characteristics, (ii) quality, (iii) nutritional aspects, and (iv) safety, since beer is a biotechnological product having extraordinary economic implications. To optimize the brewing process, breweries have a strong interest in fast and easy quantification methods for the most important process and product parameters. Ethanol content is the single most important parameter for beer characterization. Nowadays, rapid and reliable determination of ethanol in a variety of samples has received much attention, since this compound plays an important role in clinical, food, and industrial analysis. Ethanol is the most common toxic substance involved in medical-legal cases, and is frequently a contributory factor in a variety of accidents. Usually, the pharmacological effects are observed at blood ethanol concentrations of about 10 mmol/l whereas lethal levels are 10 times this concentration (Liden *et al.*, 1998). The determination of ethanol in alcoholic beverages is a very important task due to its social and economical implications, particularly in relation to the taxes imposed in different countries on its use. This analysis is carried out in many laboratories, not only by producers, but also in government and customs laboratories.

Properties

The properties of ethanol are well known. It is a flammable liquid, its vapor concentrations being explosive in the range 3.3–19% (v/v) in air. Ethanol is clear and colorless with an odor and taste which are generally considered pleasant. It is reported to be detectable by nose at 350 ppm, while higher levels of about 5,000–10,000 ppm can cause irritation to the eyes and mucous membranes of the upper respiratory tract. Poisoning from ethanol normally comes from the consumption of alcoholic beverages, rather than from inhalation. Ethanol

Table 102.1 Physical and chemical properties of ethanol

Property	Data
Boiling point (1 atm)	78.5°C
Freezing point	−114.1°C
Flash point	9–11°C
Density (d_4^{20})	0.789 g/ml
Viscosity (20°C)	1.17 cP
Refractive index (n_D^{20})	1.361
Molecular weight	46.07
Solubility (water)	∞
pK_a	16

has marked hypnotic properties and depressive activity in the upper brain, which leads to changes in behavior including motor coordination, tolerance, dependence, and aggression even though it gives the initial impression of being a stimulant (Hunt, 1996). It can be toxic if consumed in excess (the lethal dose in rats is 13.7 g/kg) even if its toxicity is much lower than the superior homologs (Criddle, 1995). Its physical properties are reported in Table 102.1 and derive mainly from the presence of the hydroxyl group, which also determines the chemical properties of the compound.

From the analytical point of view, the most important property is the ease by which the molecule can be oxidized to give acetaldehyde and, in some cases, acetic acid according to the pathway: $CH_3CH_2OH \rightarrow CH_3CHO \rightarrow CH_3COOH$.

Analysis of Ethanol

Many methods have been reported for ethanol determination. Traditionally, government legal requirements, taken together or separately, usually determine the choice of the method. These methods are essentially based on the following techniques: (i) distillation followed by physical or chemical measurements, (ii) chromatography, (iii) infrared spectrometry, (iv) enzyme methods, and (v) flow injection. Some of them are relatively expensive, time consuming, complex to perform and require laborious sample pre-treatment. Thus, there is an increasing demand for inexpensive, rapid, and reliable methods for ethanol determination. Electrochemical techniques, especially those employing sensitive amperometric biosensors, are particularly suited to this kind of analysis.

Distillation

The current official methods approved by the Excise authorities in most countries for determining alcohol content are based on physical measurements (usually, density or refractive index) carried out after a previous distillation of the sample, to separate the alcohol. As an example, the procedure adopted by the Analytical Division of the European

Brewery Convention for the determination of ethanol is based on the distillation of the beer, which has been first shaken and then filtered to remove dissolved CO_2, and the measurement of the density (D), after making up to a standardized final volume, of the distillate (European Brewery Convention, 1987). The density of the distillate is usually measured by traditional methods, such as the density bottle, pycnometer or hydrometer, or more frequently using electromagnetically induced oscillation techniques. These techniques are based on the principle that when a column of a liquid, at constant temperature, is electromagnetically excited, its period of oscillation (T), determined by comparison with a reference frequency produced by a crystal oscillator, is related to its density by the relationship: $D = A(T^2 - B)$, where A and B are calibration constants. The results of this method are unaffected by viscosity, volatility, or turbidity of the sample (Criddle, 1995). In case refractometry is used to quantitate ethanol, calibration curves are obtained from readings carried out on solutions with different alcohol percentages, against doubly distilled water (Gales, 1990). These methods are usually time consuming, require some kind of sample preparation and often well-trained laboratory staff, and are slow and difficult to automate. Moreover, they are macro-major methods and require a large sample and a quite high alcoholic degree. Alternatively, ethanol content can be estimated by chemical methods, such as simple volumetric redox titrations based on oxidation with chromium(VI) (Pilone, 1985) or xenon trioxide (Jaselskis and Warriner, 1966) or spectrophotometric assays (Caputi Jr. *et al.*, 1968; Hart and Fisher, 1971; Lau and Luk, 1994). It is common knowledge that potassium dichromate oxidizes ethanol to acetic acid. This reaction is used in the analysis of wines and beverages followed by the titrimetric dosage of the acetic acid formed (or of the excess of added dichromate with ferrous ammonium sulfate), but the above-mentioned problems of rapidity, specificity, and sensitivity are not resolved. Spectrophotometric methods for the determination of ethanol, being more sensitive, require a smaller quantity of sample (e.g. 1 ml) and allow to quantitate a lower alcohol content in beverages (e.g. less than 1%). However, these methods are also not selective and, requiring the distillation of the sample, are subject to the quantitative recovery of distillate. Magrì *et al.* (1997) described a spectrophotometric method based on the measure of chromium(VI) consumed by the reaction with ethanol, estimated by the decrease of the absorbance at 267 nm. The reaction is complete in about 15 min at room temperature and the method was successfully applied to the analysis of micro-samples of commercial beverages (beers, wines, and spirits) without the previous distillation of ethanol.

Chromatography

Various instrumental methods have been proposed to provide a direct determination of ethanol, based on gas chromatography (GC) (Caputi Jr. and Mooney, 1983; Cutaia, 1984) and liquid chromatography (Morawski *et al.*, 1983; Iwachido, 1986; Calull *et al.*, 1992). The use of gas–liquid chromatography (GLC) as a general analytical technique is now well established and it is rare to find a modern analytical laboratory without such equipment. Due to its volatility, ethanol lends itself to analysis by GLC with flame ionization detector (FID) since this detection is insensible to water. Polar columns of poly(ethyleneglycol) are generally used, and quantitation is performed by the internal standard technique using one of the propanols as standard (Gales, AOAC, 1990). Advantages of GLC are selectivity and high speed of analysis, compared with distillation. Furthermore, accuracy and precision are the same or even better than distillation. GLC is now accepted as a standard procedure for beer analysis in the United States and is the most common preferred method used for ethanol determination (Ough and Amerine, 1988). However, GLC equipment is still relatively expensive, requires skilled operators and often laboratory sample pre-treatment. Since a rapid method with a high degree of automation and cost-effectiveness is of considerable importance in the beverage mass-production industry, several techniques, aimed to simplify the complex and time-consuming classical procedures for analysis of alcoholic content, have been elaborated in the last few years.

Infrared spectroscopy

Quantitative analysis using optical spectroscopy is based on the Beer-Lambert Law, which states that there is a linear relationship between how much light is absorbed by a sample and the product of the concentration of the absorbing species and its pathlength. Infrared (IR) spectrometry in the mid-infrared (MIR) and the near-infrared (NIR) provides interesting possibilities for the direct determination of ethanol in beverages. By using the transmission mode, NIR spectroscopy offers the possibility of carrying out the determination employing ordinary glass or quartz cells. On the other hand, in the mid-range, it is necessary to use cells equipped with water-resistant windows and very small pathlengths ($b \leq 50\,\mu m$), to reduce the high absorption of infrared radiation by water (Gallignani *et al.*, 2005). Beers are aqueous solutions: as a consequence, only the spectral region in which water does not present significant absorption can be used for analytical purposes. In the mid-range, this region ranges between 3,050 and 800 cm^{-1}, except the CO_2 region comprised between 2,382 and 2,314 cm^{-1} (Llario *et al.*, 2006).

Figure 102.1 shows the spectrum obtained by attenuated total reflectance Fourier transform infrared spectroscopy (ATR–FTIR) of four different types of beers. They were recorded with samples of beer degassed for 5 min and filtered before filling the ATR cell.

In the spectrum of the beer without alcohol a series of bands between 1,200 and 950 cm^{-1} can be observed,
Figure 102.1 ATR–FTIR spectra of main types of beer samples: (a) beer without alcohol; (b) normal beer; (c) 100% malt beer; and (d) German beer. Spectra were shifted in the absorbance axis for clarity purposes. Reprinted with permission from Llario *et al.* (2006). Copyright: Elsevier.

corresponding to C—C and C—O vibration in carbohydrates, which may be correlated to the real and original extracts. The German beer is the sample with the highest extract value, and it can be seen that the band in the sugar region is the highest one. On the other hand, the sample without alcohol has the lowest extract value, and accordingly it has the lowest absorption in the aforementioned spectral region. In the region above $2,600 \, cm^{-1}$ the bands observed correspond to aliphatic vibrations, which are ascribed to stretching fundamental and deformation combination bands of methylene groups. When comparing the spectrum of the beer without alcohol to that of a normal beer, it can be observed that the main differences correspond to the bands located at $875 \, cm^{-1}$ (in-phase C—C—O stretching), $1,052 \, cm^{-1}$ (out-of-phase C—C—O stretching), $1,800 \, cm^{-1}$ (C—C skeletal stretching), and $2,970 \, cm^{-1}$ (asymmetric stretching band of methyl group), due to the absorbance of ethanol. Therefore, in all instances, special attention has to be paid to the presence of sugars in the sample, which leads to an important interfering effect on the analytical bands of ethanol. To solve this analytical problem, different strategies have been proposed, for example, based on the use of derivative FTIR. The method is based on first-order derivative FTIR measurements between the peak at $1,052 \, cm^{-1}$ and the valley at $1,040 \, cm^{-1}$ (see Figure 102.1) by using a micro-flow transmittance cell with ZnSe windows. It provides accurate results in the determination of ethanol in beer without requiring any previous chemical treatment of the sample or previous separation or extraction step. The limit of detection corresponds to 0.025% (v/v) and results obtained in the analysis of real samples of beer agree with those found by different reference procedures. For the determination

of ethanol in beverages containing high concentrations of sugars, it is necessary, previously, to determine the sugar content by measuring the derivative value between $1,164$ and $1,147 \, cm^{-1}$ and, subsequently, to correct the negative interference of sugars on the determination of ethanol between $1,052$ and $1,040 \, cm^{-1}$ (Gallignani *et al.*, 1994).

With the purpose to definitively avoid the interfering effect of sugars, a new approach has been proposed by Gallignani *et al.* (2005), which involves the separation of the analyte from the matrix by means of a liquid–liquid extraction. The methodological proposal for the determination of ethanol in all types of alcoholic beverages includes the quantitative on-line liquid–liquid extraction of ethanol with chloroform, through a sandwich type cell equipped with a poly(tetrafluoroethylene) membrane, using a two-channel manifold and direct measurement of the analyte in the organic phase, by means of FTIR. The quantification is carried out by measuring the ethanol absorbance at $877 \, cm^{-1}$, corrected by means of a baseline established between 844 and $929 \, cm^{-1}$. The procedure, which does not require any sample pre-treatment, except for the simple degassing of beer, has been applied to determine ethanol in different alcoholic beverages such as beers, wines, and spirits. The results obtained highly agree with those obtained by a derivative FTIR spectrometric procedure and by headspace-GC with FID detection. Moreover, the consumption of chloroform is very low (about 20 ml/h) and the solvent could be easily recycled through its distillation. This method is simple, fast, precise, and accurate, and it can be easily adapted to any infrared spectrometer equipped with a standard transmission infrared cell. As a consequence, it represents a valid alternative for the determination of ethanol in alcoholic beverages, and could be suitable for routine control analysis.

In the last decade, NIR spectroscopy has become an important analytical tool as it normally requires little sample preparation, is inexpensive, and can be performed quickly. Infrared quantitative analyses typically involve the measurement of many samples with varying concentrations, known as the training set. A calibration is calculated from these spectra. This may be a simple curve, or may involve chemometric procedures like partial least square regression or multilinear regression to build up the calibration models. The calibration is normally based on the correlation between the absorbances of the samples at certain wavelengths and the target molecule concentrations in the calibration set, usually obtained by reference analysis.

From this calibration, the concentration of the substance in an unknown sample may be predicted. A calibration set is needed because the presence of another component can affect the spectrum of the compound of interest, and these procedures account for the resulting non-linearity in spectral response. A chemical case where this non-linearity is most pronounced, and therefore whose analysis needs special care, is in hydrogen-bonded systems, for instance, alcohols and water, as it occurs in beer. The absorption properties
Figure 102.2 (a) NIR absorption difference spectra of ethanol/water mixtures with ethanol concentration of 0–8% (reference: water, $d = 1$ cm). (b) Correlation of the difference of absorbances at 1692 and 1719 nm, $\Delta A_{1,692-1,719}$, with $c_{EtOH,real}$. Reprinted with permission from Engelhard *et al.* (2004). Copyright: Society for Applied Spectroscopy.

of beer in the NIR spectral range are strongly dominated by the absorption of water and the other two main constituents, namely ethanol and carbohydrates. Maltose is considered as the representative carbohydrate because it is the major sugar in beer and the main building block for dextrins, which are the most important class of carbohydrates. Thus, for the interpretation of the NIR absorption spectra of beer, the knowledge of the NIR spectra of water, ethanol, and maltose is essential. The work of Engelhard *et al.* (2004) provides an interesting review on the assays used for alcohol determination and proposes a quantification method based on the interpretative difference of the absorption of radiation in the NIR spectral region using univariate statistics. The so-called "interpretative spectroscopy" has gained interest in recent years. Workman Jr. (1996) described several conditions to be fulfilled by an analytical method based on interpretative spectroscopy.

The bands used for the quantification of the analyte should have a known molecular assignment and the measured signal must be highly correlated with the analyte without interference. Furthermore, independence from other sample properties is essential.

Engelhard *et al.* (2004) validated their method by analyzing various beer samples with an ethanol concentration range between 0.5% and 8%. The method requires less expense in calibration and spectrometric equipment. The absorption was evaluated in the region of the first overtone of CH vibrations. For ethanol the two peaks at 1,684 and 1,692 nm are caused by the first overtone of the two CH_3 asymmetric stretching modes, whereas the features at 1,714 and 1,719 nm are assigned to CH_2 asymmetric stretching and CH_3 symmetric stretching vibrations, respectively. It is of particular advantage that the overall absorbance here is low enough (typically 2.5

with an optical pathlength of 1 cm) that samples of beer as such can be investigated in standard 1 cm cuvettes, which facilitates sample handling in routine analysis. To distinguish ethanol absorption from the carbohydrate background, measurements at a minimum of two wavelengths are necessary.

The two wavelengths were selected according to the assignment of the absorption bands of the main substances contained in beer in the NIR region, that is water, ethanol, and maltose, and the difference between the absorbances at these wavelengths was used for ethanol quantification. The wavelength pair at 1,692 and 1,719 nm was chosen: at 1,692 nm ethanol displays an absorbance maximum significantly over the 1,719 nm level, whereas the maltose absorption is equal at both wavelengths. The difference of absorbances between these wavelengths is proportional to the ethanol content of beer, but independent of its carbohydrate content.

As an example, Figure 102.2 shows the NIR absorption difference spectra of ethanol/water mixtures with ethanol concentration ranging from 0% to 8% used by Engelhard *et al.* (2004) to perform calibration. The limit of detection was 0.07 vol. %.

As the calibration is independent of the individual properties of the respective kinds of beer, this NIR spectroscopic method is very well suited to supplement fast process control in breweries.

Enzyme methods

For the analysis of ethanol in alcohol free and low alcohol beers, enzymatic procedures using different detection techniques such as fluorimetry, spectrophotometry or electrochemistry provide very sensitive and accurate methods. Enzymes, being essential components of living systems,

catalyze almost all chemical reactions that take place in biological processes: they are flexible protein biocatalysts with very well-defined binding sites for the substrate. Many enzymes require the presence of a cofactor that may be firmly attached to the protein or may be added, in which case it is termed coenzyme. In food analysis, enzymatic assays are often carried out because of their high specificity. Furthermore, the ability of a single enzyme molecule to catalyze the conversion of a lot of substrate molecules provides an amplification effect, which enhances the sensitivity of the analysis. Enzymes are the most commonly employed catalytic reagents in analytical chemistry. They are usually used in an immobilized form so that they can be repeatedly used, with a consequent decrease in the cost of the analysis. When an enzyme or a biologically derived sensing element is either integrated or in intimate contact with a physico-chemical transducer, the device is named a biosensor. The biochemical transducer converts the analyte into a chemical and/or physical property which is sensed and converted into a proper signal by the physical transducer. Enzymatic redox reactions are particularly related to electrochemical transducers, since an electron transfer is involved in the reaction mechanism of the enzyme. The physical combination of immobilized enzymes and electrodes can be accomplished in several ways: the enzyme is (i) immobilized in a membrane which is held in close proximity to the electrode surface, (ii) immobilized directly on the electrode surface, (iii) immobilized in an electrically conducting matrix, such as carbon–oil mixture, known as the carbon paste electrode (CPE). The enzyme substrate diffuses from the solution to the electrode surface, reaching the enzyme active site where it undergoes the enzymatic reaction. The product of the reaction will in turn diffuse to the electrode surface where the analytical reaction will take place. The determination of ethanol in beverages is carried out both by addition of the enzyme to the sample solution (commercial kits) and, more frequently, by means of a biosensor. Biosensors can be considered a big group of devices used to simplify methods of alcohol determination in beverages. Besides sensitivity and selectivity, biosensors have some advantages such as a simple measurement procedure and a short response time, which allow measurements both in batch and in flow conditions. Many reports on immobilized enzyme alcohol biosensors have appeared after Nanjo and Guilbault (1975) developed the first amperometric alcohol biosensor. In addition to the above-mentioned features, electrochemical amperometric biosensors have low cost and potential for miniaturization (Santos *et al.*, 2003). The great number of commercially available enzymes together with many kinds of immobilization techniques of several reagents and biological catalysts over different supports have contributed to the development of enzymatic electrodes (Gorton, 1995). Two enzymes are extensively used in the determination of ethanol, namely alcohol oxidase (AOX) and alcohol dehydrogenase (ADH), and alcohol oxidase–peroxidase coupled

enzyme systems and biosensors based on microbial or plant tissue materials have also been developed, as reported in the literature (Akyilmaz and Dinckaya, 2003).

ADH Biosensors   Ethanol is oxidized to acetaldehyde using nicotinamide adenine dinucleotide (NAD^+) and ADH, according to the reaction:

$$CH_3CH_2OH + NAD^+ \rightleftarrows CH_3CHO + NADH + H^+$$
The equilibrium lies toward ethanol but it is easily displaced to acetaldehyde formation by increasing the pH or removing acetaldehyde. The produced NADH is generally determined by measuring its absorbance at 334, 340, or 365 nm, or amperometrically. Alcohol biosensors based on ADH usually exhibit high selectivity and are oxygen independent; however, due to the need to add the coenzyme NAD^+ to the sample, ethanol determination is quite expensive with such biosensors. Moreover, NAD^+ needs to be close to the enzyme, without becoming irreversibly entrapped or linked (Azevedo *et al.*, 2005). Even more important, ADH-based sensors show limited operational stability and require high overpotential for the electrochemical oxidation of NADH to occur, as reported by Rebelo *et al.* (1994). These high potentials can cause interference from other electroactive substances present in beer samples. Furthermore, the intermediates produced during the oxidation can lead to electrode fouling. For this reason, various inorganic and organic mediators have been proposed for the electrochemical oxidation of NADH (Santos *et al.*, 2002). The above-mentioned problems can lead to a decrease in sensitivity, although it has been demonstrated that incorporation of NAD^+ into the conductive matrix of carbon paste overcomes the problems for some biosensors based on ADH. Santos *et al.* (2003) have described a reagentless amperometric biosensor for direct measurement of ethanol in a great variety of alcoholic beverages, including beer. The sensor was based on a CPE modified with ADH, NAD^+ cofactor, and Meldola's Blue (MB) adsorbed on silica gel coated with niobium oxide. The MB mediator showed excellent stability, improvement in the electrochemical activity, allowing the electro-oxidation of NADH at an applied potential of 0.0 V vs. saturated calomel electrode. Furthermore, the biosensor showed a wide linear response range (from 0.1 to 10 mM), an excellent operational stability (95% of the activity was maintained after 300 determinations) and storage stability (more than 3 months, when stored in a refrigerator).

AOX Biosensors   In case of AOX, a flavoprotein, ethanol is oxidized in the presence of oxygen to give hydrogen peroxide according to the reaction:

$$CH_3CH_2OH + O_2 \rightarrow CH_3CHO + H_2O_2$$
AOX is an oligomeric enzyme consisting of eight identical sub-units arranged in a quasi-cubic geometry, each containing a strongly bound cofactor, flavin adenine dinucleotide molecule. AOX exhibits an inherent non-selectivity since other primary alcohols are enzymatically converted. For the analysis of beer, this property is not limitative because of the high concentration ratio of ethanol in respect to other alcohols. Due to the strong oxidizing character of oxygen, the oxidation of alcohols by AOX is irreversible. The classical way to follow a reaction catalyzed by AOX is to monitor the production of hydrogen peroxide or the consumption of O_2 (Azevedo et al., 2005). The consumption of oxygen can be measured by optical detection but, more commonly, it is estimated amperometrically with a Clark-type O_2 electrode (Clark Jr. and Lyons, 1962). The cell consists of a platinum disk cathodic electrode inserted in a centrally located cylindrical insulator, which is surrounded by a ring-shaped Ag anode, at its bottom. The insulator and the electrodes are mounted inside a second cylinder which contains a buffered solution of potassium chloride. A thin gas permeable membrane, through which O_2 diffuses, is held at the bottom end of the tube by an O-ring. When the platinum electrode is poised at $-600\,mV$ (vs. Ag/AgCl), the reduction of oxygen occurs and a current proportional to its concentration is recorded. The first AOX-based biosensor for measuring ethanol concentration consisted in a Clark-type electrode covered by a membrane onto which AOX was immobilized by cross-linking with glutaraldehyde (Nanjo and Guilbault, 1975). The signal output of the electrode is the difference between the value recorded for base O_2 level and the decreased value, obtained after the enzymatic reaction has occurred. The amperometric biosensors which are based on the measurement of the depletion of oxygen do not suffer from the interference of other sample constituents. The major drawback is related to the dependence on oxygen which reduces the accuracy and reproducibility of the measurement, and to the fact that the minimum detectable concentration is not very low since the background signal of the device is high. The Clark-type electrode can be used also to monitor the production of H_2O_2. In such a case, the Pt working electrode is poised at a positive potential ($+600\,mV$ vs. Ag/AgCl) to oxidize hydrogen peroxide (see Figure 102.3).

Enzyme electrodes based on the direct detection of H_2O_2 constitute the so-called first generation of biosensors (see Figure 102.4a). After the pioneering work by Guilbault and Lubrano (1974) many other sensors were developed based on the direct detection of H_2O_2 using enzyme-membrane electrodes. More recently, carbon paste electrodes and screen printed electrodes have been developed using different immobilization procedures. These kinds of biosensors have many advantages such as the relative ease of manufacturing, wide linear range of response, but suffer from the interference of other reducing compounds present in the samples to be analyzed, due to the rather high working potential
Figure 102.3 Schematic representation of an AOX-based biosensor of the first generation which exploits the production of H_2O_2 detected by a Clark-type electrode, modified with a membrane containing the enzyme, used to monitor the production of H_2O_2. The Pt working electrode is poised at a positive potential ($+600\,mV$ vs. Ag/AgCl) to oxidize hydrogen peroxide according to: $H_2O_2 \rightarrow O_2 + 2H^+ + 2e^-$.

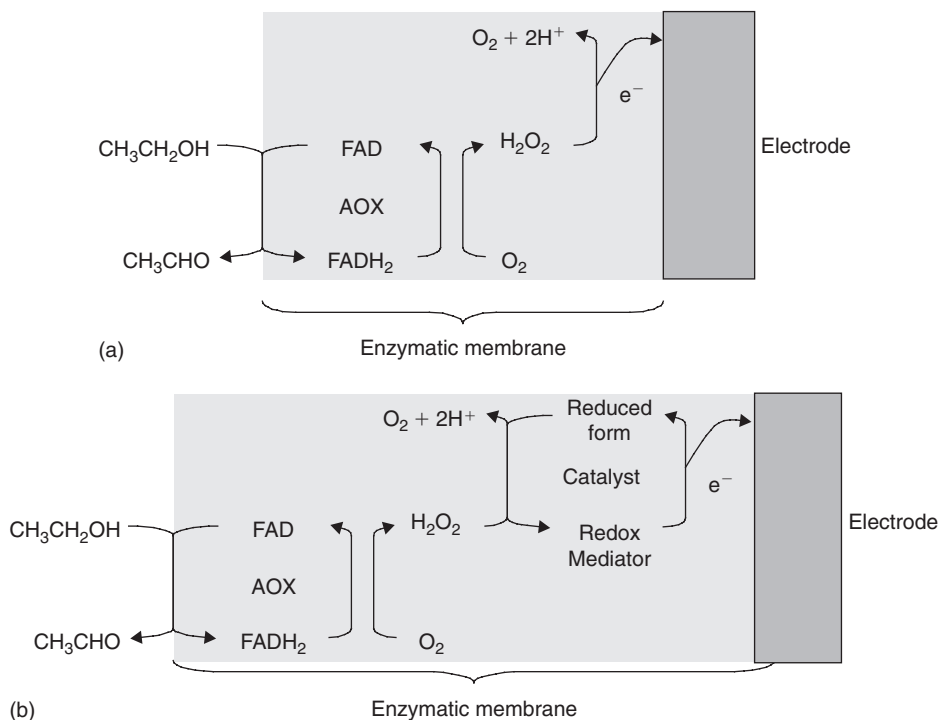
that has to be applied for the oxidation of the enzymatically generated H_2O_2. A way to overcome the problem related to the direct detection of H_2O_2 is to decrease the applied potential by modifying the electrode with an electrocatalyst for the oxidation of H_2O_2 (see Figure 102.4b) or to use a bienzymatic electrode construction. In the latter approach AOX is used in combination with horseradish peroxidase (HRP), an enzyme capable of catalyzing the electroreduction of H_2O_2 to H_2O at low applied potentials (0 to $+200\,mV$), even in the presence of soluble oxygen, as demonstrated by Kulis et al. (1981). Since then many other bienzyme electrodes with oxidases and peroxidases have been proposed using either direct or mediated electron transfer. Boujtita et al. (2000) have fabricated a disposable amperometric biosensor for the measurement of ethanol in beer based on a cobalt phthalocyanine (CoPC) modified screen printed carbon electrode coated with AOX and a permselective membrane (polycarbonate or nitrocellulose acetate). CoPC acts as electrocatalyst for the oxidation of H_2O_2 produced by the enzymatic reaction, and the reduced form of Co is oxidized at $+400\,mV$ vs. Ag/AgCl. The electrochemical regeneration of Co^{2+} provides the analytical signal, the magnitude of which is directly related to the amount of ethanol in the beer sample. The permselective


Figure 102.4   Reaction scheme for the catalytic oxidation of ethanol by AOX with (a) direct and (b) mediated hydrogen peroxide detection.

membrane on the surface of the biosensor acts as a barrier to interferents present in solution. The measurement procedure consist of a simple dilution of the sample in phosphate buffer and the determination of ethanol was carried out from a pre-constructed calibration graph, by recording the steady-state current. To test the possibility of using the device in the field, that is outside of the laboratory, the authors also tested chronoamperometry to determine ethanol in the same samples of beer, obtaining good results. In such a case, small volumes of beer samples were deposited on the printed strip to cover both the working and the reference electrode, and the response was recorded, applying the same potential of $+400\,mV$ vs. Ag/AgCl. It is worth mentioning that screen printed technology is gaining popularity in biosensors construction since it offers the possibility of mass-producing biosensors at low cost. Taking into account that robust, durable, and reusable biosensors are highly desired for the determination of alcohols in food and beverages, Guzmán-Vázques de Prada et al. (2003) have proposed composite graphite–Teflon electrodes incorporating the AOX enzyme coupled with HRP as well as the redox mediator ferrocene. These were constructed by simple and rapid physical inclusion of the enzymes and ferrocene in the bulk of rigid cylindrical pellets of the mixture graphite–70% Teflon, which are easily renewable by polishing with SiC paper. Furthermore, the absence of membranes on the electrode surface and the closeness of the enzymes and redox mediator to the electrode material allow fast responses

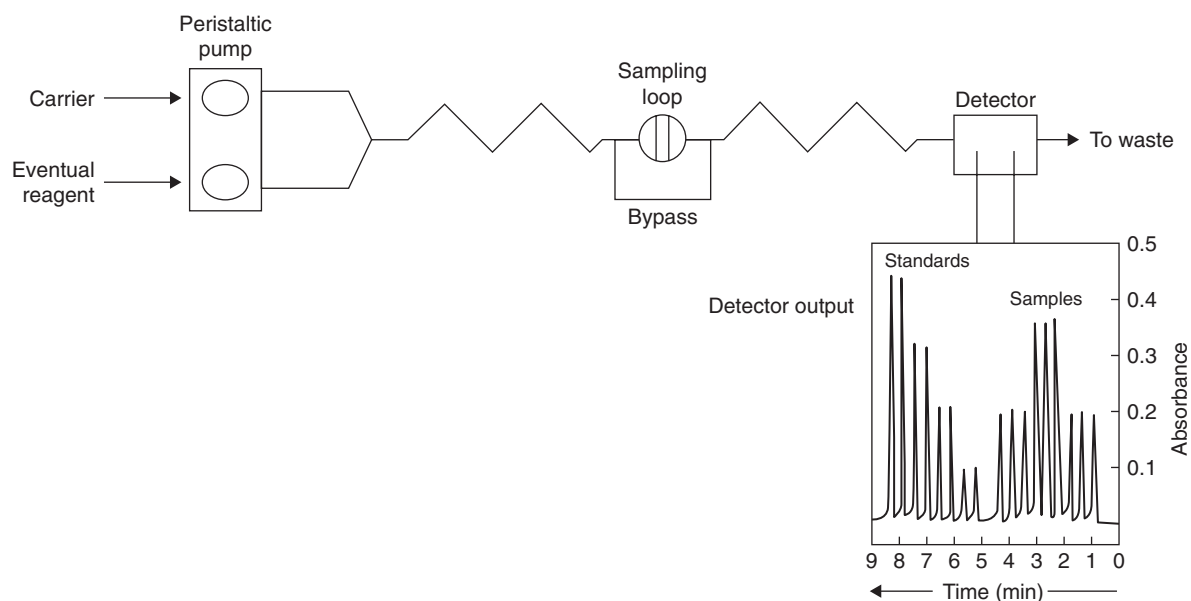
both in batch and in flow-through conditions. The bienzymatic electrode operates by applying to the working electrode a potential of $0.00\,V$ vs. Ag/AgCl/KCl (3 M) and recording the steady-state current in stirred solutions of diluted samples of beer. The time needed for the analysis of each sample is about 5 min. An interference study was carried out taking into account the substances that may be present, such as lactic and ascorbic acid (added as antioxidant), and citric, malic, and acetic acids which are used in some beers as flavoring agents. Neither malic acid nor citric acid affected the ethanol amperometric response of the bienzyme sensor, while a negative error was found for lactic and acetic acids, due to the fact that AOX catalyzes their oxidation also. Ascorbic acid also affects the ethanol response, but in this case the interference arises from its electrochemical oxidation at the applied potential. Nevertheless, the usual concentrations of these substances in beer are much lower than those necessary to produce a significant error in ethanol determination. The composite electrode was used for the analysis of different kinds of beer at low, medium, and high ethanol concentration, working both in batch and in flow modes, and the results were in agreement with those obtained with a commercial enzymatic kit using a colorimetric detection. The same bienzymatic system has been used in the development of commercial colorimetric alcohol sensors to estimate blood ethanol by detection of alcohol in breath or saliva (Adams, 1988). Other cases that require fast and reliable methods for ethanol determination will surely


Figure 102.5 Schematic diagram of a flow injection apparatus. Samples and eventual reagents are transported through flexible plastic tubing by the action of a peristaltic pump. The most satisfactory injection systems are based on sampling loops similar to those used in liquid chromatography. The quantitative determination of the analyte is performed by injecting fixed volumes of standards and samples.

benefit from the commercial development of more AOX-based sensors.

Flow injection

A great deal of effort has been devoted to the automation of ethanol determination by flow analysis techniques. A simple scheme of a flow injection apparatus with the recorder output is reported in Figure 102.5.

Amperometric detection in flow systems is an appealing approach due to its high sensitivity, low cost, and high speed of analysis. During the last two decades of the previous century, much work has been carried out to develop electrochemical detectors for liquid chromatography with high sensitivity and low detection limits. Various metal electrodes can be used for the oxidation of ethanol, but they suffer from a rapid loss of activity due to a fouling of the surface by accumulation of reaction products. Pulsed amperometric detection (PAD) after dual-pulse clean-up of the electrode has been widely used for detection of alcohols in high performance liquid chromatography (HPLC). The PAD technique applies brief oxidative and reductive potential pulses to the working electrode to clean and activate the surface between steps to an intermediate potential for detection. Fung and Mo (1996) described a procedure for ethanol determination in beer based on flow injection dual-pulse staircase voltammetry with a Pt electrode in 0.1 M sodium hydroxide. Amperometric detection of ethanol in several alcoholic beverages by anodic oxidation in alkaline media on a copper/copper oxide electrode in flow injection systems has been reported by Paixão *et al.* (2002).

It was verified to be in a good agreement with the results obtained by an alternative GC technique and labeled data, and the method has been found suitable for industrial applications. Recently, many reports on the application of chemically modified electrodes as amperometric detectors in flow systems have been published. As an example, Warriner *et al.* (2002) have proposed a Pt reagentless electrochemical sensor with a poly-L-lysine and PVC overlaying membrane, based on PAD, for monitoring ethanol formation during fermentation process. By using this configuration, problems associated with pH dependency of ethanol oxidation and interference from electroactive sugars were addressed. Biological recognition has been also successfully utilized in analytical flow techniques to increase selectivity. The enzymes have been commonly immobilized on a solid support contained in a small column or bound onto an electrode to be used as biosensors with electrochemical transduction. The linear range of enzymatic measurements is limited by the saturation kinetics of the respective enzyme. For this reason, most of the samples have to be diluted prior to analysis: this is an additional source of error, especially for gas-containing beverages such as beer. A further source of error is the interference caused by other chemical compounds within the sample. This drawback can be overcome by a separation technique. For volatile or semi-volatile compounds, separation of these species from the matrix is conveniently performed in flow injection using two types of membrane-based apparatus: gas diffusion (GD) or analytical pervaporation (PV) unit. Inside the GD unit, a hydrophobic membrane is normally fitted to allow passive transfer of gaseous compound from one side

(donor stream) to the other side of the membrane (acceptor stream). In this way, selective detection of partially diffusible volatiles is accomplished (Pacey and Karlberg, 1989). Baadenhuisen and Seuren Jacobs (1979) introduced GD via hydrophobic membranes to flow injection analysis (FIA) and thus minimized interferences. Kindervater *et al.* (1990) optimized an amperometric FIA system and modified GD membranes to determine ethanol in beverages, without prior dilution. In all cases, the specificity of the detection system used was significantly increased by the use of a GD unit. PV is also a membrane-based kit for on-line separation of volatile compounds from donor to acceptor stream and is perfectly compatible with flow-based measurements. Pervaporation is a non-chromatographic membrane-based separation technique which has been employed for a long time in the industrial field: it selectively separates a liquid mixture by partial vaporization through a nonporous polymeric membrane. The separation is not based on relative volatilities, as in the case of distillation, but rather on the relative rates of permeation through the membrane. PV can be defined as the combination of evaporation and GD in a single module. Although the principle of PV is similar to GD, a constant volume of air gap is usually maintained between the level of donor solution and the membrane (Luque De Castro and Papaefstathiou, 1988). PV offers some advantages over GD, when applied to liquid suspension samples, because the membrane does not come into direct contact with samples. This prolongs the lifetime of the membrane. Recently, a flow analysis-pervaporation method for the determination of ethanol in beverages using vibrating tube density detector has been described, reporting a sample throughput of 15 samples/h (Gonzales *et al.*, 2003). In the case of the vibrating tube density detector either a straight or more usually a U-shaped tube causes mechanical resonant vibrations. The square of the resonance frequency is inversely proportional to the sum of the mass of tube and tube content. As both the tube mass and the tube inner volume are known values, the vibrating tube method allows the density of unknown fluids to be determined in a single measurement, after the instrument has been calibrated with two fluids, usually water and air, which give low and high tones for high and low density, respectively. The U-tube is kept oscillating continuously at the characteristic frequency, which depends on the density of the filled-in sample. The oscillation period is measured and converted into density by the equation of the mass-spring model: $f = 1/2\pi\sqrt{[c/(M + \rho V)]}$, where f, frequency; c, spring constant; M, mass; ρ, density; and V, volume. Although GD and PV units are very useful for selective analysis of volatile species, they are rather expensive, especially when membranes have to often be changed. In a very recent paper, Choengchan *et al.* (2006) have presented a new diffusion unit, named membraneless gas diffusion (MGD), since it does not employ a hydrophobic membrane, for the separation and collection of ethanol.

In the MGD method the reaction between ethanol vapor and dichromate in acidic solution leads to the production of chromium (III), which is monitored spectrophotometrically at 590 nm. The MGD unit provides a greater mass transfer than GD unit and, having no membrane, it does not suffer from membrane malfunction caused by exposure to reagents, and its cost is lower. The authors have demonstrated the validity of the MGD unit for quantitative analysis of ethanol in alcoholic beverages.

Summary Points

- It is well known that beer can make an important contribution to the diet.
- Ethanol has marked hypnotic properties and depressive activity in the upper brain, even though it gives the initial impression of being a stimulant.
- The determination of ethanol in alcoholic beverages is a very important task, due to its social and economical implications.
- Classical methods of analysis are based on distillation followed by chemical titrations, or by measurements of density or refractive index.
- Nowadays, an instrumental technique, GC, is generally preferred for direct determination of ethanol, since classical methods are more time consuming.
- Rapid and cheap methods with a high degree of automation are especially desired by the brewery industry and by government and customs laboratories.
- Infrared spectrometry, especially in NIR and MIR regions, is a more recent technique which provides interesting possibilities for the direct determination of ethanol.
- Methods based on enzymatic reactions in solution are rapid and selective, but expensive.
- Biosensors based on different detection techniques, such as fluorimetry, spectrophotometry or electrochemistry, are tools which allow sensitive, accurate, and cheaper determinations.
- Flow analysis technique with amperometric or spectrophotometric detection is an appealing approach for the automation of ethanol analysis in beer.

Quantification of Beer Carbohydrates by HPLC

Isabel M.P.L.V.O. Ferreira REQUIMTE, Serviço de Bromatologia, Faculdade de Farmácia, Universidade do Porto, R. Aníbal Cunha, Porto, Portugal

Abstract

Methods for quantification of carbohydrates in beer are summarized. Quantification of total sugars in beer is usually performed by spectrophotometric methods that give an approximate value of sugar content. Enzymatic methods are generally specific for only one or more sugars in a sample. Gas chromatographic methods are sensitive but require derivatization and are laborious when compared to liquid chromatographic techniques.

High performance liquid chromatography (HPLC) methods can provide qualitative and quantitative analysis of beer carbohydrates. The main chromatographic systems used are anion-exchange column with water containing bases or salts as the eluent; cation-exchange column with water as the eluent; alkyl-bonded silica gel column with water as the eluent and amine-bonded silica gel column with water–acetonitrile as the eluent. High performance anion-exchange chromatography is widely used; it is based on the fact that carbohydrates in a strongly alkaline environment will ionize, thereby rendering them amenable to separation on an ion-exchange column. However, of these systems, HPLC using an amine-bonded silica gel column coupled with evaporative light scattering detection is the one mostly used, it requires no derivatization, is sensitive and works well with gradients. Other detectors can be used, such as, refractive index, pulsed amperometric detection, mass spectrometry and nuclear magnetic resonance spectroscopy/mass spectrometry. Fluorescence-assisted carbohydrate electrophoresis of glucose, fructose, saccharose, maltose, and maltotriose in beer is also described.

HPLC/ELS methods were validated for quantification of glucose, fructose, maltose, maltotriose and maltotetraose in beer. The chromatographic analyses were carried out using an amino-bonded silica column. Identification of the carbohydrates in beers was performed by comparison with the retention times of the standards. The reliability of the methods in terms of precision, accuracy and detection limit values was verified. The methods were used to study the effect of mashing methods on carbohydrate content and to compare the carbohydrate patterns of beers produced in 10 different countries.

List of Abbreviations

HPLC	High performance liquid chromatography
LC	Liquid chromatographic
HPAEC	High performance anion-exchange chromatography
RI	Refractive index
ELS	Evaporative light scattering
PA	Pulsed amperometric
NMR/MS	Nuclear magnetic resonance spectroscopy/mass spectrometry
FACE	Fluorescence-assisted carbohydrate electrophoresis

Introduction

Beer is a very complex mixture, major beer components are water, ethanol and carbohydrates comprising fermentable sugars (i.e. fructose, glucose, maltose and maltotriose) as well as glucose oligosaccharides and arabinoxylans (Brandolini *et al.*, 1995; De Keukeleire, 2000; Hughes and Baxter, 2001; Caballero *et al.*, 2003; Duarte *et al.*, 2003; Briggs *et al.*, 2004).

Monitoring of beer carbohydrate composition may therefore be an important tool for modern brewing technology, particularly in the selection of raw materials and yeast strains, product development and quality control. Quantitative evaluation of malto-oligosaccharides provides a useful control of the complex enzymatic system in beer brewing, particularly when changes in procedure are contemplated (Plaga *et al.*, 1989; Duarte *et al.*, 2003; Montanari *et al.*, 2005). In this respect it is important to control not only the total amount of fermentable carbohydrates formed but also the relative amounts of the different sugars.

Table 103.1   Summary of methodologies applied to analysis of beer carbohydrates

Method	Type of carbohydrates assayed	Advantages/disadvantages
Spectrophotometric	Total sugars	Classic method with long history of use/provide an approximate value
Enzymatic	Glucose, fructose, saccharose, galactose and polysaccharides	Specific/expensive
Gas chromatography	Monosaccharides	Very sensitive/laborious, requires derivatization
Liquid chromatography	Mono, di, oligo and low molecular weight polysaccharides	Does not require derivatization, different detectors can be used/some detectors lack sensitivity
Electrophoresis	Glucose, fructose, saccharose, maltose, maltotriose and low molecular weight polysaccharides	Requires derivatization to be used with fluorescence detector

Source: Adapted from *Analytica-EBC* (1998), Ramirez *et al.* (2005), Eliasson (2006).

Analyses of beer carbohydrates can be performed by different methodologies, including spectrophotometric, enzymatic, chromatographic and electrophoretic methods (Table 103.1).

Methods for Analysis of Beer Carbohydrates

Carbohydrates have been determined in some beers by chemical and enzymatic analysis. Spectrophotometric are classic methods with a long history, used for quantification of total sugars in beer; however, they provide only an approximate value of sugar content, because different sugars in solution react differently with the colorimetric reagent anthrone in 85% sulfuric acid (*Analytica-EBC*, 1998). On the other hand enzymatic methods are generally specific for only one or more sugars in a sample (Shanta-Kumara *et al.*, 1995). There are available enzymatic methods for quantification of glucose, fructose, saccharose, lactose, galactose and polysaccharides.

Gas chromatographic methods can also be used; however, since carbohydrates are not volatile, they must be derivatized, for example, into alditol acetates, prior to analysis. It is very sensitive, however it is laborious when compared to high performance liquid chromatography (HPLC) techniques.

Liquid chromatographic (LC) methods play an important role in determining carbohydrates, especially fermentable carbohydrates (Eliasson, 2006). HPLC methods can provide not only the qualitative analysis but also the quantitative determination (Honda, 1984; Anumula, 2000; Wei and Ding, 2000). The main chromatographic systems used for the separation of underivatized carbohydrates can be generalized as anion-exchange column with water containing bases or salts as the eluent (Torto *et al.*, 1995; Cataldi *et al.*, 2000); cation-exchange column with water as the eluent (Clement *et al.*, 1992); alkyl-bonded silica gel column with water as the eluent (Rajakyla, 1986) and amine-bonded silica column with water–acetonitrile as the eluent (Macrae and Dick, 1981; Macrae *et al.*, 1982; Nikolov *et al.*, 1985; Clement *et al.*, 1992; Ferreira and Ferreira, 1997; Ferreira *et al.*, 1998,

2005; Nogueira *et al.*, 2005). Column choice is based on the specific samples and the type of eluents to be used. High performance anion-exchange chromatography (HPAEC) is widely used, it is based on the fact that carbohydrates in a strongly alkaline environment will ionize, thereby rendering them amenable to separation on an ion-exchange column. However, of these systems, HPLC using an amine-bonded silica gel column is the one mostly used.

Carbohydrates analysis historically has used refractive index (RI) detection because of the lack of chromophores in the analytes, which are required for ultraviolet detection. RI (Boumahraz *et al.*, 1982; Nikolov *et al.*, 1985; Rajakyla, 1986; Gotsick and Benson, 1991; Clement *et al.*, 1992; Ferreira and Ferreira, 1997; Ferreira *et al.*, 1998; Castellari *et al.*, 2001) measurement is the most popular detection method for carbohydrates. However, it has many disadvantages, such as lacking sensitivity, baseline instability, temperature and flow-rate dependent, and incompatibility with gradient elution. Evaporative light scattering (ELS) detection requires no chromophores and works well with gradients. HPLC analysis of carbohydrates using gradient elution is desirable due to its decrease in analysis times. This detector is widely used as a semi-universal mass detector for HPLC (Mengerink *et al.*, 1991; Ferreira *et al.*, 2005; Nogueira *et al.*, 2005). It is based on the detection of solute molecules by light scattering after nebulization and evaporation of the mobile phase, so it is suitable to detect the nonvolatile compounds such as lipids (Marcato and Cecchin, 1996; Chang and Harris, 1998) and carbohydrates (Macrae and Dick, 1981; Macrae *et al.*, 1982; Clement *et al.*, 1992; Floridi *et al.*, 2001, 2005; Nogueira *et al.*, 2005).

Other detectors can be used such as pulsed amperometric (PA) detection which is directly compatible with the high ionic strength of alkali eluents (Klein and Leubolt, 1993; Gey *et al.*, 1996; Yan *et al.*, 1997) and MS detection for peak identification according to their mass to charge ratio. These two detectors can be installed in series or in parallel depending on the type of column (Bruggink *et al.*, 2005).

Direct analysis of beer by LC–NMR/MS (nuclear magnetic resonance spectroscopy/mass spectrometry) enables

Table 103.2 Summary of liquid chromatography methods applied to separation of beer carbohydrates

the identification of dextrins with degree of polymerization of up to nine monomers. The use of hyphenated NMR spectroscopy for the rapid characterization of the carbohydrate composition of beers may be the basis of a useful tool for the quality control of beer (Vinogradov and Bock, 1998; Duarte et al., 2003).

Electrophoretic separation of carbohydrates, glucose, fructose, saccharose, maltose and maltotriose in beer is also described (Thomas et al., 2000). Saccharides labeled with the dye 8-amino-1,3,6-naphthalene trisulfonic acid can be separated by electrophoresis and detected with fluorescence-assisted carbohydrate electrophoresis (FACE). Oligosaccharides in beer can be identified in FACE assays based on comigration with standards (e.g. oligosaccharides derived from purified starch, β-glucan and pentosan). A variety of beers, including lager, light, ale, porter and stout, demonstrated distinct saccharide patterns in FACE analysis (Ramirez et al., 2005).

Some of the LC methods mentioned above were applied to separation, identification and quantification of beer carbohydrates as summarized in Table 103.2.

HPLC/ELS for Quantification of Beer Carbohydrates

As mentioned above ELS is widely used for HPLC to obtain efficient and reproducible performance of carbohydrate analysis. This detector performs excellently with gradients. HPLC analysis of carbohydrates using gradient elution is desirable due to its decrease in analysis times. Column choice also plays a large role in carbohydrate analyses. The speed of analysis as well as the overall separation is based on column factors such as length, phase type and loading. A comparison of six different types of

HPLC columns, namely, a silica based amino, a polymer based amino, two ion-exchange columns, a polyamine and a zirconia based column was performed for the separation of monosaccharides and oligosaccharides in beer and other drinks (Wilcox et al., 2001). Columns were obtained from several manufacturers. Samples were simply filtered prior to analysis. The system included isocratic and binary LC pumps, an autosampler, mobile phase degasser and an ELS detector. Column choice should be based on the specific samples and the type of eluents to be used. Amino-bonded silica columns should be used with low water concentration mobile phases due to their inherent hydrolytic instability.

Floridi et al. (2001) described separation of fermentable and non-fermentable carbohydrates of up to 15 glucose units in wort, mashed malt and beer was obtained in 40 min by direct injection on an amino-bonded silica column, aqueous/acetonitrile gradient elution profile at room temperature and an HPLC–ELS apparatus. No chemical manipulation was involved and no derivatization was needed. The external standard method was used to calibrate the chromatographic system for carbohydrates quantification. According to authors the results were comparable with those found with the official HPLC–RI procedure and with chemical determination with Fehlung's reagent. This method was used to study the effect of mashing methods, namely, the effect of double decoction mashing method and the single decoction plus infusion mashing method on beer carbohydrates was compared (Montanari et al., 2005).

An HPLC method with an ELS detector was validated for quantification of glucose, fructose, maltose, maltotriose and maltotetraose in beer (Nogueira et al., 2005). The chromatographic analysis was carried out using an amino-bonded silica column. Gradient elution was carried out with a mixture of two solvents. Solvent A consisted of acetonitrile and

solvent B consisted of water. Carbohydrates were eluted increasing the proportion of solvent B from 19% to 25% over 40 min: 0–19 min, 19% B; 20–40 min, 25% B. The flow rate was 1 ml/min. The temperature of the heated drift tube was 45°C, the gas pressure was 3.0 bar and gain 5. The beer samples were degassed for 15 min in an ultrasonic bath, diluted (1:2) in acetonitrile and filtered. Identification of the carbohydrates in beers was performed by comparison with the retention times of the standards (Figures 103.1 and 103.2). Sugar standard solutions with different concentrations were used, according to the quantity of these

compounds in the beer matrix (0.05–5.0 g/l for fructose; 0.05–5.0 g/l for glucose; 0.05–15.0 g/l for maltose; 0.05–10.0 g/l for maltotriose and 0.05–5.0 g/l for maltotetraose). The detection limit values were estimated as the concentration providing a signal three times higher than the standard deviation of the background noise and were 0.005 g/l for fructose, 0.008 g/l for glucose and 0.01 g/l for maltose, maltotriose and maltotetraose. The reliability of the method in terms of precision and accuracy was verified in three different beer matrices, including free alcohol beer, beer with 100% malt and beer with adjuncts (Nogueira *et al.*, 2005).
Figure 103.1 Typical chromatogram for separation of five carbohydrates in a standard solution. Fructose (t_R 8.717 min), glucose (t_R 9.600 min), maltose (t_R 15.325 min), maltotriose (t_R 22.637 min), maltotetraose (t_R 30.078 min) 2 g/l each. Chromatographic conditions: Spherisorb NH_2 column, 5 μm, 250 × 4.6 mm ID.
Figure 103.2 Typical chromatogram for separation of five carbohydrates in a lager beer sample. Maltose (t_R 15.314 min), maltotriose (t_R 22.621 min), maltotetraose (t_R 30.118 min). The beer samples were degassed for 15 min in an ultrasonic bath, diluted (1:2) in acetonitrile and filtered. Chromatographic conditions: Spherisorb NH_2 column, 5 μm, 250 × 4.6 mm ID.

The HPLC/ELS method validated for quantification of glucose, fructose, maltose, maltotriose and maltotetraose in beer (Nogueira *et al.*, 2005) was used to analyze beers produced in 10 different countries (Ferreira and Martins, 2007) (see Table 103.3). General inspection of the data was carried out for each type of beer (alcohol free, lager and ale) and each carbohydrate individually, using box-and-whisker plot. Box-and-whisker plots are helpful in interpreting the distribution of data. The median (or second quartile) of a set of data separates the data into two equal parts. Data can be further separated into quartiles. Quartiles separate the original set of data into four equal parts. Each of these parts contains one-fourth of the data. The first quartile is the median of the lower part of the data. The third quartile is the median of the upper part of the data. This procedure, which is suitable for skewed data, enabled the construction of Figures 103.3, 103.4 and 103.5, where results are displayed to favor mutual comparisons, the minimum and maximum

Table 103.3 Summary of beer samples analyzed by Ferreira and Martins (2007) and grouped according to beer type and ingredients mentioned in labels

Beer type	Number of samples	Ingredients mentioned on the labels	Countries of origin
Alcohol free	4	Water, malt, hop, unmalted cereals	Portugal Spain
	3	Water, malt, unmalted cereals, sugars, hop, antioxidant (E224)	Portugal Brazil
Lager	6	Water, malt, hop	Portugal Denmark Germany Holland Czech Republic Brazil
	12	Water, malt, unmalted cereals or glucose syrup, hop, antioxidant (E224)	Portugal Denmark Holland Belgium Spain Brazil
Ale	4	Water, malt, hop	UK Germany Belgium Irland

values observed, as well as the first quartile, the median and the third quartile are presented.

Figure 103.3 presents the concentration of fructose, glucose, maltose, maltotriose and maltotetraose in alcohol free beer samples. Similar qualitative profile was obtained for the six beer samples. However, within brands quantitative differences were observed for glucose, maltose and maltotriose contents. These samples suffered short fermentation; thus, great part of fructose, maltose, maltotriose and maltotetraose remained in beer.

As expected lager and ale beers presented significantly lower sugar content owing to an extended fermentation process (Figures 103.4 and 103.5). During fermentation the yeast absorbs and ferments first all the glucose and then maltose. Some yeasts, can also utilize maltotriose. Lagers were in general more fully fermented than ales and contained less residual carbohydrates. In conclusion, strong differences between the compositions in terms of carbohydrates were observed when analyzed by HPLC/ELS.

Summary Points

- Methods for quantification of carbohydrates in beer are summarized.
- HPLC methods for qualitative and quantitative analysis of beer carbohydrates, including anion-exchange column with water containing bases or salts as the eluent; cation-exchange column with water as the eluent; alkyl-bonded silica gel column with water as the eluent and amine-bonded silica gel column with water–acetonitrile as the eluent.

- HPLC detectors for carbohydrate analyses include ELS detection, the one mostly used, RI, PA detection, MS and NMR/MS.
- HPLC/ELS methods were validated for quantification of glucose, fructose, maltose, maltotriose and maltotetraose in beer. The chromatographic analyses were carried out using an amino-bonded silica column. The methods were used to study the effect of mashing methods on carbohydrate content and to compare the carbohydrate patterns of beers produced in 10 different countries
- Sugar composition of lager, ale and free alcohol beers was evaluated by HPLC/ELS.
