HIV infection	I. Laboratory criteria: Positive result on a screening test for HIV antibody (e.g., repeatedly reactive enzyme immunoassay) followed by a positive result on a confirmatory (sensitive and more specific) test for HIV antibody (e.g., a reactive Western blot or immunofluorescence antibody test) Or Positive result of a detectable quantity on any of the following HIV virologic (nonantibody) tests: a. HIV nucleic acid (DNA or RNA) detection (e.g., DNA polymerase chain reaction [PCR] or plasma HIV-1 RNA) b. HIV p24 antigen test, including neutralization assay c. HIV isolation (viral culture) Or II. Physician diagnosis: Diagnosis of HIV infection, based on the laboratory criteria above, that is documented in a medical record by a physician.
AIDS	I. Documentation of an HIV infection And one of the following: II. Depressed $CD4^+$ T Lymphocytes defined as either of the following: a. $CD4^+$ T-lymphocytes count of less than 200 cells/μL b. $CD4^+$ T-lymphocyte percentage of total lymphocytes of less than 14% Or III. Diagnosis of any of the following AIDS indicator conditions: Candidiasis of bronchi, trachea, or lungs Candidiasis, esophageal[a] Cervical cancer, invasive Coccidioidomycosis, disseminated or extrapulmonary Cryptococcosis, extrapulmonary Cryptosporidiosis, chronic intestinal (greater than 1 month's duration) Cytomegalovirus disease (other than liver, spleen, or nodes) Cytomegalovirus retinitis (with loss of vision)[a] Encephalopathy, HIV related Herpes simplex: chronic ulcer(s) (greater than 1 month's duration) or bronchitis, pneumonitis, or esophagitis Histoplasmosis, disseminated or extrapulmonary Isosporiasis, chronic intestinal (greater than 1 month's duration) Kaposi's sarcoma[a] Lymphoma, Burkitt's (or equivalent term) Lymphoma, immunoblastic (or equivalent term) Lymphoma, primary, of brain *Mycobacterium avium* complex or *M. kansasii,* disseminated or extrapulmonary[a] *Mycobacterium tuberculosis,* any site (pulmonary[a] or extrapulmonary[a]) *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary[a] *P. carinii* pneumonia[a] Pneumonia, recurrent[a]

Condition	Criteria
	Progressive multifocal leukoencephalopathy
	Salmonella septicemia, recurrent
	Toxoplasmosis of brain[a]
	Wasting syndrome due to HIV

[a]Condition may be diagnosed presumptively. Guidance on diagnosis of these diseases in the context of all nationally notifiable diseases is available at http://www.cdc.gov/epo/dphsi/casedef/case_definitions.htm.

in accuracy and completeness, when compared to reporting systems that include names.[10,17] Because identification and elimination of duplicate reports across jurisdictions cannot occur without a standardized means of identifying unique cases, CDC has only accepted surveillance data from areas that include names with the reports at the local level.

One important coordination function of CDC in the national HIV surveillance system is to provide a framework for deduplication of case reports from different states. This is accomplished using the recorded date of birth, sex, and soundex (an algorithm-generated code computed locally from the last name that is not unique for each name). CDC routinely produces a list of HIV cases for each state, for which the values from these three variables match with those from records in other reporting jurisdictions. Surveillance personnel across jurisdictions then communicate to identify situations where multiple reports have occurred on a single case.

Trends

HIV and AIDS case surveillance data remain the most comprehensive source of information about the epidemic in the United States and elucidate several fundamental trends.

Through December 2005, an estimated 984,155 persons had been diagnosed with AIDS in the United States and 550,394 of them had died.[18] Throughout the latter part of the 1980s and into the mid-1990s there was a rapid increase in the annual number of AIDS cases and deaths among persons with AIDS (Fig. 97-2). After 1995, the incidence of AIDS and deaths among persons with AIDS substantially decreased until 1998. Subsequently, AIDS has been diagnosed annually in approximately 40,000 persons, and 15,000–18,000 persons with AIDS have died each year through 2005.

The decreases in new AIDS diagnoses and deaths after 1995 are attributed to introduction of effective antiretroviral therapies in 1996, with concomitant slowing of the progression of HIV to AIDS and prevention of deaths among the infected.[19] The improvements in survival resulted in a continued increase in prevalence, with over 433,000 persons living with AIDS by the end of 2005.

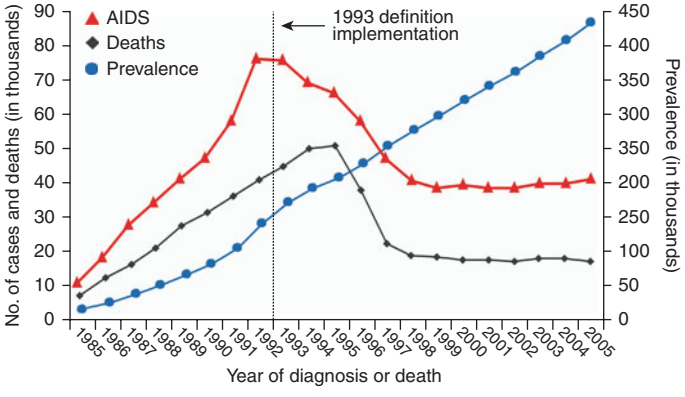

FIGURE 97-2. Estimated AIDS cases and deaths, and persons living with AIDS, 1985–2005, United States.

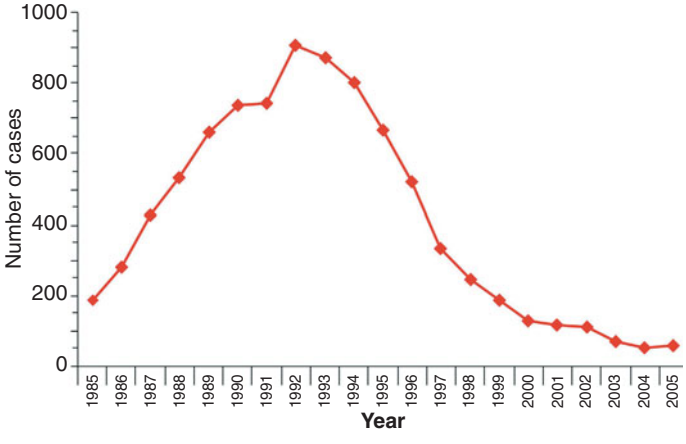

FIGURE 97-3. Estimated numbers of perinatally acquired AIDS cases, by year of diagnosis, in the United States (including U.S. territories), 1985–2005. Data are adjusted for reporting delays and cases in persons reported without an identified risk factor.

One of the most effective interventions to prevent HIV transmission has been the use of antiretrovirals in pregnant, HIV-infected women during pregnancy and after delivery in their infants.[20] AIDS surveillance data have demonstrated the enormous effectiveness of these regimens since they were put into widespread use in 1994 (Fig. 97-3).[21] The number of

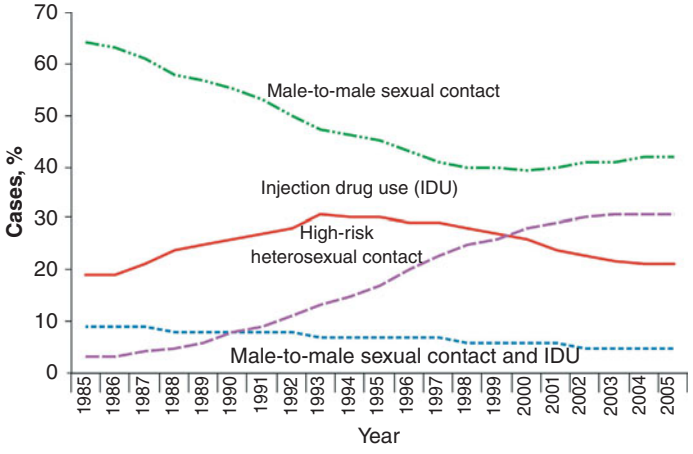

FIGURE 97-4. Proportion of AIDS cases among adults and adolescents, by transmission category and year of diagnosis, 1985–2005, United States.

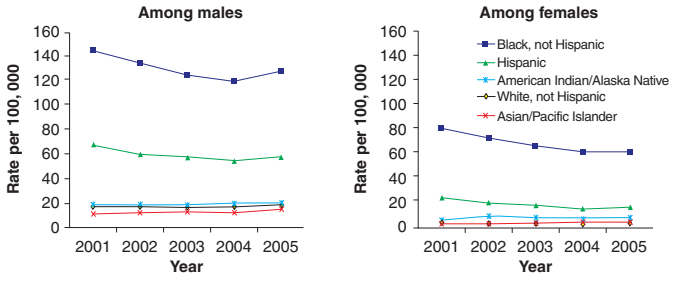

FIGURE 97-5. Annual age-adjusted rate of diagnosis of HIV/AIDS by sex and race/ethnicity–32 states, 2001–2005. HIV/AIDS designates HIV infection regardless of the presence of AIDS. The rates were directly adjusted using the 2000 U.S. population as the standard. States included in the analysis were Alabama, Alaska, Arizona, Arkansas, Colorado, Florida, Idaho, Indiana, Iowa, Kansas, Louisiana, Michigan, Mississippi, Missouri, Nebraska, Nevada, New Jersey, New Mexico, North Carolina, North Dakota, Ohio, Oklahoma, South Carolina, South Dakota, Tennessee, Texas, Utah, Virginia, West Virginia, Wisconsin, and Wyoming.

AIDS cases attributed to perinatal transmission peaked in 1992 at 952 and, subsequently, decreased to only 67 during 2005.[18]

Case surveillance data reflect changes in the relative importance of different modes of transmission; these changes suggest that priorities for prevention activities need constant reevaluation. Most AIDS cases in the United States are attributed to male–male sexual contact (Fig. 97-4). However, there has been a steady transition to cases that are attributed to heterosexual transmission, with decreases in the relative burden from injection drug use. Most of the heterosexually attributed cases occur in women.[18]

Trends in newly diagnosed HIV infections, with or without AIDS, provide a window into an earlier stage of the disease process and may more closely approximate the true incidence of transmission of HIV.[22] Information from 2001 through 2005 in 32 states that had long-standing HIV reporting demonstrate that the rates of HIV diagnoses have been relatively stable among women and men of all racial and ethnic groups (Fig. 97-5).[23] However, there were enormous racial/ethnic disparities in the rates of disease for both men and women, with rates among non-Hispanic black males and females being seven and 19 times higher, respectively, than those for white males and females.[23]

There are also large differences in the prevalence of persons living with HIV and AIDS by region of the country (Fig. 97-6). In general, rates among adults and adolescents tend to be lower in the northern Midwestern states such as North Dakota (diagnosed prevalence rates of HIV and AIDS in 2005 were 13.8 and 12.6 living cases per 100,000 persons, respectively), where relatively fewer racial/ethnic minorities reside. High rates are seen in the South, where the highest AIDS prevalence rates in 2003 were in Florida (298.8 per 100,000 persons), California (201.3 per 100,000 persons), and New York (461.3 per 100,000), where such populations are more prevalent and where there are substantial communities of men who have sex with men (MSM).[11,24,25] Although geographically specific information is important for making decisions about targeting resources to address the health-care needs of persons

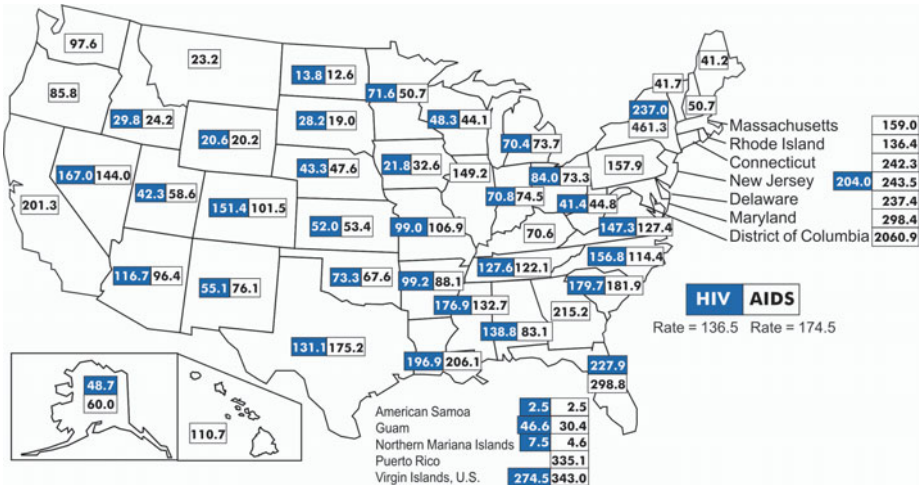

FIGURE 97-6. Estimated rates for adults and adolescents living with HIV infection (not AIDS) or with AIDS (per 100,000 population), 2005–United States.

diagnosed with HIV, this information is not considered optimal for tracking the true incidence of HIV infection, because changes in patterns of testing may affect trends in HIV diagnoses.[10]

SUPPLEMENTAL SURVEILLANCE SYSTEMS FOR HIV/AIDS–UNITED STATES

Behavioral Surveillance

Behavioral surveillance data complement the data available from HIV case surveillance, provide a context in which to interpret case surveillance data, and provide additional information to evaluate the impact of HIV prevention programs. Behavioral surveillance is an ongoing, systematic way of measuring behaviors that are related to sentinel events in life of a person who becomes infected with HIV.[26] For example, behavioral surveillance systems measure behaviors related to HIV acquisition (risk behaviors and condom use behaviors), diagnosis of HIV infection (HIV testing behaviors and barriers to HIV testing), and progression of HIV disease (care seeking, access to care, and adherence to prescribed therapy). Behavioral surveillance data are needed from the general population, from at-risk populations such as MSM and IDUs, and from persons living with HIV infection (Table 97-3).

In the United States, behavioral surveillance among persons at risk of HIV infection is realized in the National HIV Behavioral Surveillance System (NHBS). NHBS has been conducted in 25 cities by state and local health departments, in collaboration with CDC, since 2003.[27] The 25 cities represent those cities with the highest AIDS prevalence in the United States as of 2003 and represent approximately 70% of the United States' burden of AIDS. NHBS collects data in waves, with a 3-year project cycle in which data are collected 1 year among MSM, 1 year among IDUs, and 1 year among high-risk heterosexuals (HRH). The recruitment methods used in the surveillance system vary; MSM are recruited using a time-space sampling approach,[28,29] and IDU are recruited using respondent-driven sampling.[30,31] Methods for recruitment of HRH are under development, for implementation in 2007. The system collects data from persons at high risk for HIV infection, who are asked to consent to an anonymous interview. The interview includes questions about risk behaviors for HIV acquisition, HIV testing history and knowledge of serostatus, and use of local HIV prevention services.

Behavioral surveillance data are important to many aspects of public health prevention programs and surveillance. For diseases such as HIV, with a long latent period between infection and clinical manifestations, behavioral surveillance provides endpoints that are more proximate to HIV infection and that allow evaluation of progress toward primary prevention goals.[32] For example, a campaign to reduce infections among IDUs may be judged a success if, 5 years after its implementation, rates of new diagnoses of HIV infection among IDUs decrease. However, the ability to measure the rate of needle sharing in the months following the implementation of the campaign provides a more proximate, if intermediate, outcome for evaluation. Also, behavioral surveillance data on HIV testing provide a context in which to interpret case surveillance data: since cases are only reported to the surveillance system after they are diagnosed, surveillance case reports can be influenced by changes in patterns of HIV testing.[33] In the past, these types of data have been provided by nonsurveillance approaches, such as episodic HIV testing surveys,[34–36] and by evaluation of programmatic data from publicly funded counseling and testing programs;[37] in the future NHBS will be the primary ongoing source of such surveillance data.[27]

Resistance surveillance

Surveillance for resistance to antiretroviral drugs is a critical supplemental surveillance activity that provides data for the formulation of treatment recommendations and provides an evidence base for empiric choice of therapy for HIV

Table 97-3. Sentinel Events, Behaviors, and Populations for HIV Behavioral Surveillance

Sentinel Event	Sentinel Behaviors	Sentinel Populations
Exposure	Risk behaviors	
	Acquisition	At risk, general, and infected
	Transmission	Infected
Diagnosis of HIV infection	Testing behaviors	At risk, general, infected
Morbidity (AIDS)	Care seeking; adherence	Infected
Death	Care seeking; adherence	Infected

Behaviors related to sentinel events are targets for behavioral surveillance data collection.

infection.[38] Resistance to antiretroviral drugs is a concern in the management of HIV infection, because, in treated patients, the emergence of resistant quasispecies is almost inevitable unless pharmacologic therapy is successful in totally suppressing replication, and the patient is flawlessly adherent to therapy.[39] The high levels of resistance observed in treated individuals have raised concerns about trends in the transmission of resistant strains.[40] A high rate of such transmission could compromise the success of standardized, initial regimens; increase the cost and complexity of providing care to newly diagnosed patients;[38] and compromise the efficacy of available medications to prevent transmission through postexposure prophylaxis[41] or perinatal exposure.

There is a need for surveillance for resistance to antiretroviral drugs in the United States, because surveys in convenience samples of patients have serious biases, which limit the generalizability of their findings. Most investigations that have attempted to assess trends over time have involved relatively small numbers of patients from highly selected clinical settings, where there is limited variability in the modes of transmission.[42–44] One of the largest assessments of the drug resistance mutations in newly diagnosed, treatment-naïve patients was conducted in 10 U.S. cities during the period 1997–2001 and involved testing of 1082 patients.[45] The overall prevalence of resistance to antiretroviral agents was 8.3% but varied substantially by the presumed route of transmission for the infected person. MSM had the highest prevalence at 12%, 8.2% of IDUs had resistant strains, and heterosexual transmission was associated with a 5.1% prevalence.

Transmission of drug-resistant virus appears to be occurring with sufficient frequency to warrant surveillance as a regular public health activity. Therefore, many public health programs have begun to obtain resistance information as part of the surveillance for transmission incidence.[46] These systems involve acquisition of an aliquot of the diagnostic phlebotomy specimen used to execute the confirmatory Western Blot and forwarding to a public health laboratory. In this laboratory, the specific virus from this specimen is isolated, amplified, and sequenced to identify mutations associated with resistance to antiretroviral medications. Most of these programs are in the initial stages of development and will take several years to produce sufficient data to guide public health prevention and treatment practices.[46]

Seroprevalence surveys

Seroprevalence surveys that are ongoing and systematic may serve as a supplemental surveillance system. Unlinked anonymous serosurveys, in which remaindered blood specimens collected for other purposes are tested anonymously, have a key advantage in that in certain populations they provide estimates of seroprevalence that are not biased by the decision of individuals to seek testing. They are most often applied in settings of special interest to HIV prevention programs, such as in STD clinics, drug treatment centers, adolescent clinics, and obstetrical delivery services.

In the United States, unlinked seroprevalence surveys, supported by the federal government and coordinated by CDC, were conducted from the late 1980s until 1997.[47–50] The surveys of childbearing women were discontinued in 1995, and all other federally funded surveys ended 2 years later.[51] Results from the U.S. surveys suggested that the prevalence of HIV infection during the early 1990s remained stable, with the aggregate rate across all survey areas for childbearing women remaining between 0.1% and 0.2%, for the period 1989–1994. By 1995, when these surveys were discontinued, the highest prevalence was observed in New York (0.46%), and some states had no detected infections in pregnant women. Higher prevalence rates were measured among patients attending 29 STD clinics in 16 cities during 1997, where the median value among all participating clinics was 3.9%, with a range of 0.5–11.4%. Prevalence was highest among MSM (19.3%).[51]

Systematic and ongoing collection of HIV seroprevalence data also occurs among applicants for Job Corps and for military service and among blood donors.[51] However, the usefulness of this information for epidemiologic purposes is limited. Persons with behavioral risk factors for HIV are explicitly discouraged from donating blood, or entering the military, and eligibility for the Job Corps program varies among areas. The interpretation of trends in prevalence data has been further complicated by the introduction of effective therapies, which inevitably results in increases in the number of persons infected, regardless of the underlying transmission rates.

The only national data on HIV testing of a probability sample of the U.S. population is from the National Health and Nutrition Examination Survey (NHANES).[52] During 1999–2002, this survey found a prevalence of 0.43% (95% confidence interval, 0.25–0.72%) among persons 18–49 years of age. This was an increase from the prevalence of 0.33% (95% confidence interval, 0.22–0.52%) found when this survey was conducted during the early 1990s.[52] However, this difference was not statistically significant, due to the imprecision associated with the relatively small numbers of infected persons identified in both waves.

Incidence surveillance

Surveillance for incident HIV infections, as opposed to surveillance for newly diagnosed cases of HIV infection, is critical for targeting prevention programs and evaluating their impact. One method for estimating HIV incidence is to identify relatively recently infected persons among those who are being tested. The most widely used approach is known as the serologic testing algorithm for recent HIV seroconversion (STARHS).[53] The approach relies on the understanding that

in the first 6–12 months after HIV infection, the host antibody response to HIV changes, both quantitatively and qualitatively. A variety of assays has been developed, which measure these labile aspects of antibodies to HIV infection. The results of these assays allow identification of persons with immune response profiles indicative of recent infections (i.e., within 6 months).[54]

These serologic methods for identifying recently infected persons were initially implemented on specimens collected in a variety of clinical settings, where large numbers of persons were tested during the 1990s and were conducted on anonymized specimens. These investigations generally indicated that incidence rates were highest in MSM and were stable throughout the decade.[55–57] However, because most of these incidence studies were not population based and because the studies were susceptible to selection biases that resulted from changing patterns in the populations seeking care and testing at the participating facilities, the findings of these studies were not generalizable.[58] In order to establish a national system of incidence surveillance, CDC has supported efforts in the areas with the highest HIV morbidity to apply STARHS to the serum specimens from persons identified as new diagnoses through population-based HIV surveillance.[59]

Clinical outcomes surveillance

Clinical outcomes surveillance is concerned with documenting outcomes of HIV infection, which are not consistently captured as part of case surveillance. For example, AIDS case surveillance systems document the diagnosis of an AIDS-defining opportunistic illness (AIDS-OI) when it is the first indication of AIDS; however, subsequent AIDS-OI diagnoses are not routinely ascertained. Clinical outcomes surveillance systems may also provide data useful in evaluating quality of care for HIV infection, by documenting adherence to care and treatment guidelines.[60] Thus, clinical outcomes surveillance provides important insight to secondary prevention practices and outcomes.

In the late 1980s, CDC, in collaboration with 10 state and local health departments, developed a supplemental surveillance system to help define the spectrum of HIV disease in the United States.[61] This project, the Adult/Adolescent Spectrum of HIV Disease Project (ASD), collected detailed information from the medical records of persons receiving care for HIV infection in clinic and hospital settings from 1991 to 2004. This system was designed as a longitudinal medical records abstraction project, and observed over 60,000 persons in care for HIV infection over this period. The data were used to inform the revision of the AIDS case definition in 1993,[62] as well as to inform the development of guidelines for clinical care of HIV. After the expansion of the AIDS case definition in 1993, the case surveillance system had very limited capacity to measure the incidence of opportunistic illnesses, since most AIDS cases were diagnosed based solely on immunologic criteria, with limited capacity to document subsequent opportunistic illness diagnoses. ASD served as a primary mechanism to measure opportunistic illness incidence (an important indicator of the success of secondary prevention) in the United States (Fig. 97-7).[63,64]

The primary limitations of ASD were the lack of representativeness of the data and the fact that only 10 U.S. states were supported to collect these data. To address these limitations, CDC and 20 state health departments have recently undertaken the development of a new system for clinical outcomes surveillance.[65,66] This new system, the Medical Monitoring Project, is a surveillance system that will use probability sampling methods to obtain a nationally representative sample of persons in care for HIV infection, in the United States. Each year, 6000–8000 HIV-infected persons will be selected using multistage cluster sampling;[67] for each person selected, medical records will be abstracted, and consent to interview will be sought. Data from medical records will focus on treatments for HIV, laboratory values, and HIV-related diagnoses. Interviews will represent behavioral surveillance for persons living with HIV infection and will collect data on risk behaviors for HIV transmission, as well as behaviors (such as care seeking and adherence to antiretroviral therapies) that have impact on the prevention of morbidity and mortality (e.g., secondary prevention). Data from the first national sample will be available in 2008.

The key advantage of the MMP system is that it will produce surveillance data that are representative of the underlying population, without requiring collection of data on all patients. The underlying methodology has been demonstrated in the Health Care and Services Utilization Study (HCSUS),[68–70] which was a one-time study of persons receiving care for HIV infection.

HIV/AIDS SURVEILLANCE–INTERNATIONAL SETTINGS

Developed countries

The World Health Organization (WHO) recommends that AIDS case surveillance be conducted in all countries.[71] AIDS case surveillance has been ongoing in most developed countries, including those of Western Europe, Canada, Australia, and Japan, since the mid-1980s. However, the availability of effective therapy for persons with HIV infection in these countries has resulted in substantial decreases in the number of AIDS cases and HIV-related deaths.[72] To better monitor the underlying trends in HIV transmission, case surveillance of persons diagnosed with HIV infection, regardless of the level of immunosuppression, has been implemented in many developed countries.[72–74] These HIV reporting systems are of variable quality and have been in place for variable lengths of time. Many use coded patient identifiers similar to those used by some jurisdictions in the United States. The inability to reliably deduplicate HIV infection case reports in countries where code-based systems are used leads to increased uncertainty in interpretation of data, especially in comparisons involving small differences in trends within and among these countries. Despite these challenges, these systems are based on standardized case definitions are supervised by experienced public health scientists, and the data collected represent the most comprehensive, population-based information available regarding the status of the HIV epidemic in these countries. The major epidemiologic characteristics of HIV in selected developed regions of the world are discussed below.

Western Europe. Trends in AIDS cases in Western Europe have been consistent with those observed in the United States, but with generally lower rates of disease in most countries (Fig. 97-8).[73] For example, in 2002, the AIDS incidence rate in Western Europe was 2.4 cases per 100,000 persons, whereas in the United States it was 14.7.[24,73] However, there is substantial variation in rates among European nations, with Spain and Portugal experiencing relatively high rates.

The highest rates of HIV and AIDS diagnoses in Western Europe continue to be observed among MSM in urban centers. In recent years, European countries have experienced increases in syphilis and gonorrhea cases among MSM, which suggest important changes in behaviors associated with HIV transmission.[73,75,76] Increases in reported HIV cases among MSM in the UK and Germany have paralleled increases in other sexually transmitted infections.[76,77] However, it is unclear whether these trends in HIV are the result of increases in testing or greater rates of transmission.[72] Injection drug use continues to play a major role in the epidemic in Italy, Spain, and Portugal, where, in recent periods, up to half of the cases have been attributed to this mode of transmission.

One of the most striking recent trends in European countries that have ongoing surveillance of newly diagnosed HIV infections is the number of cases attributed to heterosexual contact. During the latter part of the 1990s and early 2000s, cases attributed to heterosexual contact increased over 100%.[78] This trend is particularly notable in the UK, where many of the heterosexually acquired cases were identified in immigrants from sub-Saharan Africa (Fig. 97-9).

Canada. The HIV epidemic in Canada has been relatively stable during the late 1990s, with the number of AIDS cases and new HIV diagnoses remaining constant during the period 1996–2002. However, changes in the distribution of the major risk factors occurred. During this period, MSM became the predominantly affected group, with an increase in the percentage of cases among MSM increasing from 30% to 40%. The estimated percentage of new HIV cases diagnosed among IDUs decreased from 47% to 30%, while the proportion of new diagnoses attributed to heterosexual transmission increased from 17% to 24%.[79]

Developing countries

HIV/AIDS surveillance in resource-limited settings focused initially on case surveillance, using a clinical case definition that did not require HIV serologic testing, due to the its gen-

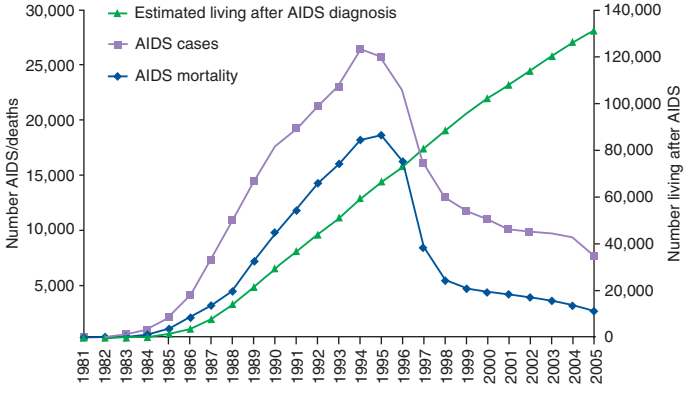

FIGURE 97-8. Number of AIDS cases, AIDS deaths among AIDS cases, and persons living with AIDS by year, 1986–2002, western Europe. Countries included are Denmark, Germany, France, Italy, Portugal, Spain, UK, and Netherlands.

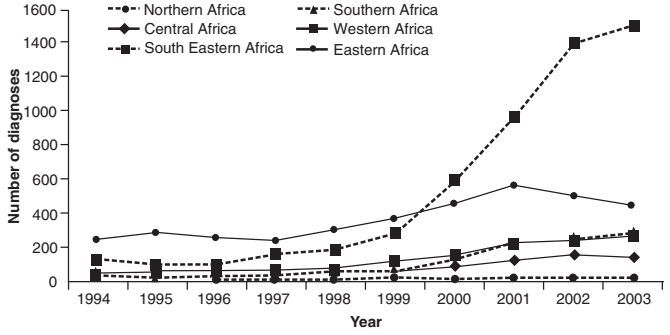

FIGURE 97-9. Probable region of infection for reported heterosexual HIV infections that were probably acquired in Africa (diagnosed in UK), 1994–2003. Only cases with identified probable country of infection are included.

eral lack of availability. The clinical case definition developed during a conference in Bangui, Central African Republic, in 1986, defined AIDS as the presence of two major conditions (e.g., wasting and chronic diarrhea) and one minor condition (e.g., varicella zoster), or single diagnoses of disseminated KS or cryptococcal meningitis.[80] In Latin America, based on the increasing availability of serologic testing, the Pan American Health Organization at a 1989 conference in Caracas proposed a definition based on a laboratory diagnosis of HIV infection and a system of points assigned to various AIDS-related conditions, which was subsequently revised in 1992.[81] Focusing primarily on the African context, WHO published a revised definition in 1994, which proposed the continued use of the Bangui definition when serologic testing was not available but expanded the definition to include a positive HIV test and any one of a set of clinical conditions.[82]

Although case surveillance was important for identifying the presence of infection in a country, it was inadequate for assessing the extent of the epidemic. The primary focus of HIV surveillance in resource-limited settings became HIV seroprevalence surveys in selected populations that could be easily accessed. These populations included women in antenatal care, blood donors, military recruits, and, in some countries, persons at high risk, such as IDUs and sex workers.[83] Such serosurveys began to define the extent to which HIV infection was prevalent in most countries of the world and to describe the large variation in disease burden and epidemiology from country to country.

However, by the late 1990s, it was recognized that existing surveillance was not systematically addressing the data needs for a comprehensive response to the epidemic or adequately reflecting differences among countries.[84] Surveillance strategies had not been adapted to the characteristics of the epidemic in each country. Tracking of risk behaviors was limited. Insufficient use was being made of data from other sources that could usefully complement HIV prevalence surveys, most notably data on other STDs.

Based on a workshop held by WHO and UNAIDS in Berlin in 1997, a set of new recommendations was developed, focusing on "second-generation surveillance."[85] A key principle of second-generation surveillance is that it is important to consider the epidemic state within a country, defined as low level, concentrated, or generalized (Table 97-4), a concept adapted from a similar typology described in a report of the World Bank.[86] In generalized epidemics, monitoring of HIV prevalence, STDs, and behavioral risks in the general population through serologic screening of pregnant women or national demographic and health surveys are a priority, whereas, in concentrated and low-level epidemics, the primary focus should be on monitoring HIV seroprevalence, other STDs, and risk behaviors among sentinel popula-tions at high risk of acquiring or transmitting HIV. Second-generation surveillance

Table 97-4. Classification of HIV/AIDS Epidemics

Low grade
Principle: Although HIV infection may have existed for many years, it has never spread to significant levels in any subpopulation. Recorded infection is largely confined to individuals with higher risk behavior: e.g., sex workers, drug injectors, and men having sex with other men. This epidemic state suggests that networks of risk are rather diffuse (with low levels of partner exchange or sharing of drug injecting equipment), or that the virus is only very recently introduced.
Numerical proxy: HIV prevalence has not exceeded 5% in any defined subpopulation.
Concentrated
Principle: HIV has spread rapidly in a defined subpopulation but is not well established in the general population. This epidemic state suggests active networks of risk within the subpopulation. The future course of the epidemic is determined by the frequency and nature of links between highly infected subpopulations and the general population.
Numerical proxy: HIV prevalence over 5% in at least one defined subpopulation. HIV prevalence below 1% in pregnant women.
Generalized
Principle: In generalized epidemics, HIV is firmly established in the general population. Although subpopulations at high risk may continue to contribute disproportionately to the spread of HIV, sexual networking in the general population is sufficient to sustain an epidemic independent of subpopulations at higher risk of infection.
Numerical proxy: HIV prevalence over 1% in pregnant women.

Adapted from UNAIDS/WHO. *Guidelines for Second Generation HIV Surveillance. Geneva*: *World Health Organization and Join United Nations Programme on HIV/AIDS,* 2000.

guidelines also recommended that biological data (e.g., data on HIV infection and other STDs) be compared with behavioral data collected through surveys and that better overall use be made of complementary data sources, including STD surveillance data, HIV/AIDS case reporting, data on HIV infection among persons with TB, and death registration, to provide a more comprehensive picture of the epidemic.

A further concept of second-generation surveillance is to work toward obtaining information on the evolution of the epidemic within a country, by obtaining measures of incidence. An indirect indicator of trends in incidence has been examination of trends in HIV seroprevalence among adolescents and young adults (i.e., 15–24-year-olds), because such trends are more likely to reflect recent infection than trends among older age groups; for many surveys, this has required substantially increasing sample sizes among this age group. Following the development of serologic assays for recent HIV infection (STARHS assays) in the United States, the use of STARHS or related methods is increasing for estimating incidence in developing country settings. Studies have recently validated certain STARHS assays with non-B subtypes that are common in developing countries; certain methodologic issues in the interpretation of these data, based on sampling biases and statistical considerations, are still being addressed.[87]

With the rapidly increasing availability of antiretroviral therapy, even in settings with minimal infrastructure, new issues in surveillance are emerging, which relate to monitoring aspects of HIV/AIDS care.[88] Chief among these is the surveillance of resistance to antiretroviral drugs, focusing on therapy-naïve persons. The many questions about the long-term effects and impact of using antiretroviral therapies on such a large scale will likely compel the development of supplemental surveillance systems or studies that can provide for monitoring of risk behaviors, STDs, tuberculosis and other opportunistic infections, adverse events, and mortality among persons on antiretroviral therapies.

Estimates of HIV seroprevalence derived from a variety of data sources are reported annually by the WHO and UNAIDS.[89] In 2006, HIV prevalence among adults aged 15–49 years was estimated to be 5.9% in sub-Saharan Africa, 1.2% in the Caribbean, 0.9% in Eastern Europe and Central Asia, 0.6% in South and Southeast Asia, and 0.5% in Latin America, with lower estimates of prevalence in other geographical regions. Within each of these regions, prevalence varies substantially; for example, in several sub-Saharan countries, HIV prevalence among adults exceeds 25%.

STD SURVEILLANCE

CASE DEFINITIONS—UNITED STATES

Case definitions for most sexually transmitted diseases were revised in 1996.[90] Current case definitions are presented in Table 97-5.

CASE SURVEILLANCE: METHODS, ISSUES, MAJOR FINDINGS—UNITED STATES

Methods of case surveillance

Only a few sexually transmitted diseases are reportable in all states and notifiable to the CDC: syphilis (including congenital syphilis), gonorrhea, chancroid, and chlamydia. Other STDs are reportable in certain states but not nationally. Both providers and laboratories are required to report positive results of tests for STDs to local health departments. Surveillance systems are mostly passive, relying on voluntary reporting from providers and laboratories. For syphilis and occasionally for other STDs, case reporting is linked directly to public health intervention, in the form of field investigations to ensure treatment of STDs and testing of sexual partners of the index case.

In the case of syphilis, providers and laboratories are required to report reactive serologic test results, even if a diagnosis of syphilis has not been made. However, health departments often develop guidelines (based on the titer, age of patient, and local epidemiology) to determine which syphilis case reports should result in field investigation. This is required because a reactive serological test for syphilis may not necessarily indicate active, untreated infection. On the basis of such guidelines, some local health departments may choose not to evaluate or contact individuals determined to be at low risk of having or transmitting active disease.[91,92]

In 2002, case reports of chlamydia, gonorrhea, and syphilis accounted for more than 1.3 million cases, which was >80% of all infectious disease notifications to CDC.[93] Still, these case reports are considered to be a substantial underestimate of the true burden of disease. For example, the incidence of chlamydial infections in the United States was estimated to be about 2.8 million new infections per year in 2000, compared with reported cases of about 700,000.[94]

Trends

Chlamydia. *Chlamydia trachomatis* infections are the most commonly reported notifiable disease in the United States. They are the most prevalent of all bacterial STDs and, since 1994, have comprised the largest proportion of all STDs reported to CDC. In women, chlamydial infections, which are usually asymptomatic, may result in pelvic inflammatory disease (PID), which is a major cause of infertility, ectopic pregnancy, and chronic pelvic pain. As with other inflammatory STDs, chlamydial infection may facilitate the transmission of HIV infection.

Although highly prevalent, trends in chlamydial infections are hard to describe with confidence for several reasons. First, screening recommendations and practices for chlamydia have changed greatly over the past 10 years. For example, a new Health Plan Employer Data and Information Set (HEDIS)

Table 97-5. STD Case Definitions for Public Health Surveillance[90]

Notifiable STDs:

Chancroid (revised 9/96) clinical description

A sexually transmitted disease characterized by painful genital ulceration and inflammatory inguinal adenopathy. The disease is caused by infection with *Haemophilus ducreyi.*

Laboratory criteria for diagnosis:

- Isolation of *H. ducreyi* from a clinical specimen

Case classification probable: a clinically compatible case with both (1) no evidence of *Treponema pallidum* infection by darkfield microscopic examination of ulcer exudate or by a serologic test for syphilis performed greater than or equal to 7 d after onset of ulcers and (2) either a clinical presentation of the ulcer(s) not typical of disease caused by herpes simplex virus (HSV) or a culture negative for HSV.

Confirmed: a clinically compatible case that is laboratory confirmed.

Chlamydia, genital infections (revised 9/96) clinical description

Infection with *C. trachomatis* may result in urethritis, epididymitis, cervicitis, acute salpingitis, or other syndromes when sexually transmitted; however, the infection is often asymptomatic in women. Perinatal infections may result in inclusion conjunctivitis and pneumonia in newborns. Other syndromes caused by *C. trachomatis* include lymphogranuloma venereum (see Lymphogranuloma venereum) and trachoma.

Laboratory criteria for diagnosis:

- Isolation of *C. trachomatis* by culture, or
- Demonstration of *C. trachomatis* in a clinical specimen by detection of antigen or nucleic acid

Case classification

Confirmed: a case that is laboratory confirmed.

Gonorrhea (revised 9/96) clinical description

A sexually transmitted infection commonly manifested by urethritis, cervicitis, or salpingitis. Infection may be asymptomatic.

Laboratory criteria for diagnosis:

- Isolation of typical gram-negative, oxidase-positive diplococci (presumptive *N. gonorrhoeae*) from a clinical specimen, or
- Demonstration of *N. gonorrhoeae* in a clinical specimen by detection of antigen or nucleic acid, or
- Observation of gram-negative intracellular diplococci in a urethral smear obtained from a male

Case classification probable: (1) demonstration of gram-negative intracellular diplococci in an endocervical smear obtained from a female or (2) a written morbidity report of gonorrhea submitted by a physician.

Confirmed: a case that is laboratory confirmed.

Syphilis (all definitions revised 9/96)

Syphilis is a complex sexually transmitted disease that has a highly variable clinical course. Classification by a clinician with expertise in syphilis may take precedence over the following case definitions developed for surveillance purposes.

Syphilis, primary clinical description

A stage of infection with *T. pallidum* characterized by one or more chancres (ulcers); chancres might differ considerably in clinical appearance.
Laboratory criteria for diagnosis:

- Demonstration of *T. pallidum* in clinical specimens by darkfield microscopy, direct fluorescent antibody (DFA-TP), or equivalent methods

Case classification probable: a clinically compatible case with one or more ulcers (chancres) consistent with primary syphilis and a reactive serologic test (nontreponemal: Venereal Disease Research Laboratory[147] or rapid plasma reagin {RPR}; treponemal: fluorescent treponemal antibody absorbed {FTA-ABS} or microhemagglutination assay for antibody to *T. pallidum* {MHA-TP}).
Confirmed: a clinically compatible case that is laboratory confirmed.

Syphilis, secondary clinical description

(*Continued*)

Table 97-5. (*Continued*)

A stage of infection caused by *T. pallidum* and characterized by localized or diffuse mucocutaneous lesions, often with generalized lymphadenopathy. The primary chancre may still be present.

Laboratory criteria for diagnosis:

- Demonstration of *T. pallidum* in clinical specimens by darkfield microscopy, DFA-TP, or equivalent methods

Case classification probable: a clinically compatible case with a nontreponemal (VDRL or RPR) titer greater than or equal to 4.

Confirmed: a clinically compatible case that is laboratory confirmed.

Syphilis, latent clinical description

A stage of infection caused by *T. pallidum* in which organisms persist in the body of the infected person without causing symptoms or signs. Latent syphilis is subdivided into early, late, and unknown categories based on the duration of infection.

Case classification probable: no clinical signs or symptoms of syphilis and the presence of one of the following:

- No past diagnosis of syphilis, a reactive nontreponemal test (i.e., VDRL or RPR), and a reactive treponemal test (i.e., FTA-ABS or MHA-TP)
- A past history of syphilis therapy and a current nontreponemal test titer demonstrating fourfold or greater increase from the last nontreponemal test titer

Syphilis, early latent clinical description

A subcategory of latent syphilis. When initial infection has occurred within the previous 12 months, latent syphilis is classified as early latent.

Case classification probable: latent syphilis (see Syphilis, latent) in a person who has evidence of having acquired the infection within the previous 12 months based on one or more of the following criteria:

- Documented seroconversion or fourfold or greater increase in titer of a nontreponemal test during the previous 12 months
- A history of symptoms consistent with primary or secondary syphilis during the previous 12 months
- A history of sexual exposure to a partner who had confirmed or probable primary or secondary syphilis or probable early latent syphilis (documented independently as duration less than 1 year)
- Reactive nontreponemal and treponemal tests from a person whose only possible exposure occurred within the preceding 12 months

Syphilis, late latent clinical description

A subcategory of latent syphilis. When initial infection has occurred greater than 1 year previously, latent syphilis is classified as late latent.

Case classification probable: latent syphilis (see Syphilis, latent) in a patient who has no evidence of having acquired the disease within the preceding 12 months (see Syphilis, early latent) and whose age and titer do not meet the criteria specified for latent syphilis of unknown duration.

Syphilis, latent, of unknown duration clinical description

A subcategory of latent syphilis. When the date of initial infection cannot be established as having occurred within the previous year and the patient's age and titer meet criteria described below, latent syphilis is classified as latent syphilis of unknown duration.

Case classification probable: latent syphilis (see Syphilis, latent) that does not meet the criteria for early latent syphilis, and the patient is aged 13–35 y and has a nontreponemal titer greater than or equal to 32.

Neurosyphilis clinical description

Evidence of central nervous system infection with *T. pallidum*

Laboratory criteria for diagnosis:

- A reactive serologic test for syphilis and reactive VDRL in cerebrospinal fluid (CSF)

Case classification probable: syphilis of any stage, a negative VDRL in CSF, and both the following:

- Elevated CSF protein or leukocyte count in the absence of other known causes of these abnormalities
- Clinical symptoms or signs consistent with neurosyphilis without other known causes for these clinical abnormalities

Table 97-5. (*Continued*)

Confirmed: syphilis of any stage that meets the laboratory criteria for neurosyphilis.

Syphilis, late, with clinical manifestations other than neurosyphilis (late benign syphilis and cardiovascular syphilis) clinical description

Clinical manifestations of late syphilis other than neurosyphilis may include inflammatory lesions of the cardiovascular system, skin, and bone. Rarely, other structures (e.g., the upper and lower respiratory tracts, mouth, eye, abdominal organs, reproductive organs, lymph nodes, and skeletal muscle) may be involved. Late syphilis usually becomes clinically manifest only after a period of 15–30 y of untreated infection.

Laboratory criteria for diagnosis:

- Demonstration of *T. pallidum* in late lesions by fluorescent antibody or special stains (although organisms are rarely visualized in late lesions)

Case classification probable: characteristic abnormalities or lesions of the cardiovascular system, skin, bone, or other structures with a reactive treponemal test, in the absence of other known causes of these abnormalities, and without CSF abnormalities and clinical symptoms or signs consistent with neurosyphilis.

Confirmed: a clinically compatible case that is laboratory confirmed.

Comment: Analysis of CSF for evidence of neurosyphilis is necessary in the evaluation of late syphilis with clinical manifestations.

Syphilitic stillbirth clinical description

A fetal death that occurs after a 20-week gestation or in which the fetus weighs greater than 500 g and the mother had untreated or inadequately treated syphilis at delivery.

Comment: For reporting purposes, syphilitic stillbirths should be reported as cases of congenital syphilis.

Syphilis, congenital (revised 9/96) clinical description

A condition caused by infection in utero with *T. pallidum.* A wide spectrum of severity exists, and only severe cases are clinically apparent at birth. An infant or child (aged less than 2 y) may have signs such as hepatosplenomegaly, rash, condyloma lata, snuffles, jaundice (nonviral hepatitis), pseudoparalysis, anemia, or edema (nephrotic syndrome and/or malnutrition). An older child may have stigmata (e.g., interstitial keratitis, nerve deafness, anterior bowing of shins, frontal bossing, mulberry molars, Hutchinson teeth, saddle nose, rhagades, or Clutton joints).

Laboratory criteria for diagnosis:

- Demonstration of *T. pallidum* by darkfield microscopy, fluorescent antibody, or other specific stains in specimens from lesions, placenta, umbilical cord, or autopsy material

Case classification probable: a condition affecting an infant whose mother had untreated or inadequately treated syphilis at delivery, regardless of signs in the infant, or an infant or child who has a reactive treponemal test for syphilis and any one of the following:

- Any evidence of congenital syphilis on physical examination
- Any evidence of congenital syphilis on radiographs of long bones
- A reactive CSF VDRL
- An elevated CSF cell count or protein (without other cause)
- A reactive fluorescent treponemal antibody absorbed–19S-IgM antibody test or IgM enzyme-linked immunosorbent assay

Confirmed: a case that is laboratory confirmed.

Comment: Congenital and acquired syphilis may be difficult to distinguish when a child is seropositive after infancy. Signs of congenital syphilis may not be obvious, and stigmata may not yet have developed. Abnormal values for CSF VDRL, cell count, and protein, as well as IgM antibodies, may be found in either congenital or acquired syphilis. Findings on radiographs of long bones may help because radiographic changes in the metaphysis and epiphysis are considered classic signs of congenitally acquired syphilis. The decision may ultimately be based on maternal history and clinical judgment. In a young child, the possibility of sexual abuse should be considered as a cause of acquired rather than congenital syphilis, depending on the clinical picture. For reporting purposes, congenital syphilis includes cases of congenitally acquired syphilis among infants and children as well as syphilitic stillbirths.

(*Continued*)

Table 97-5. (*Continued*)

Non-notifiable STDs:

Genital herpes (herpes simplex virus) (revised 9/96) clinical description

A condition characterized by visible, painful genital or anal lesions.

Laboratory criteria for diagnosis:

- Isolation of herpes simplex virus from cervix, urethra, or anogenital lesion, or
- Demonstration of virus by antigen detection technique in clinical specimens from cervix, urethra, or anogenital lesion, or
- Demonstration of multinucleated giant cells on a Tzanck smear of scrapings from an anogenital lesion

Case classification probable: a clinically compatible case (in which primary and secondary syphilis have been excluded by appropriate serologic tests and darkfield microscopy, when available) with either a diagnosis of genital herpes based on clinical presentation (without laboratory confirmation) or a history of one or more previous episodes of similar genital lesions.

Confirmed: a clinically compatible case that is laboratory confirmed.

Comment: Genital herpes should be reported only once per patient. The first diagnosis for a patient with no previous diagnosis should be reported.

Genital warts (revised 9/96) clinical description

An infection characterized by the presence of visible, exophytic (raised) growths on the internal or external genitalia, perineum, or perianal region

Laboratory criteria for diagnosis:

- Histopathologic changes characteristic of human papillomavirus infection in specimens obtained by biopsy or exfoliative cytology, or
- Demonstration of virus by antigen or nucleic acid detection in a lesion biopsy

Case classification probable: a clinically compatible case without histopathologic diagnosis and without microscopic or serologic evidence that the growth is the result of secondary syphilis.

Confirmed: a clinically compatible case that is laboratory confirmed.

Comment: Genital warts should be reported only once per patient. The first diagnosis for a patient with no previous diagnosis should be reported.

Granuloma Inguinale clinical description

A slowly progressive ulcerative disease of the skin and lymphatics of the genital and perianal area caused by infection with *Calymmatobacterium granulomatis*. A clinically compatible case would have one or more painless or minimally painful granulomatous lesions in the anogenital area.

Laboratory criteria for diagnosis:

- Demonstration of intracytoplasmic Donovan bodies in Wright or Giemsa-stained smears or biopsies of granulation tissue

Case classification confirmed: a clinically compatible case that is laboratory confirmed.

Lymphogranuloma venereum clinical description

Infection with L1, L2, or, L3 serovars of *C. trachomatis* may result in a disease characterized by genital lesions, suppurative regional lymphadenopathy, or hemorrhagic proctitis. The infection is usually sexually transmitted.

Laboratory criteria for diagnosis:

- Isolation of *C. trachomatis,* serotype L1, L2, or L3 from clinical specimen, or
- Demonstration by immunofluorescence of inclusion bodies in leukocytes of an inguinal lymph node (bubo) aspirate, or
- Positive microimmunofluorescent serologic test for a lymphogranuloma venereum strain of *C. trachomatis*

Case classification probable: a clinically compatible case with one or more tender fluctuant inguinal lymph nodes or characteristic proctogenital lesions with supportive laboratory findings of a single *C. trachomatis* complement fixation titer of greater than 64.

Confirmed: a clinically compatible case that is laboratory confirmed.

Mucopurulent cervicitis (revised 9/96) clinical description

Cervical inflammation that is not the result of infection with *N. gonorrhoeae* or *Trichomonas vaginalis.* Cervical inflammation is defined by the presence of one of the following criteria:

Table 97-5. (*Continued*)

- Mucopurulent secretion (from the endocervix) that is yellow or green when viewed on a white, cotton-tipped swab (positive swab test)
- Induced endocervical bleeding (bleeding when the first swab is placed in the endocervix)

Laboratory criteria for diagnosis:

- No evidence of *N. gonorrhoeae* by culture, Gram stain, or antigen or nucleic acid detection, and no evidence of *T. vaginalis* on wet mount

Case classification confirmed: a clinically compatible case in a female who does not have either gonorrhea or trichomoniasis.

Comment: Mucopurulent cervicitis (MPC) is a clinical diagnosis of exclusion. The syndrome may result from infection with any of several agents (see *Chlamydia trachomatis,* Genital Infections). If gonorrhea, trichomoniasis, and chlamydia are excluded, a clinically compatible illness should be classified as MPC. An illness in a female that meets the case definition of MPC and *C. trachomatis* infection should be classified as chlamydia.

Nongonococcal urethritis (revised 9/96) clinical description

Urethral inflammation that is not the result of infection with *N. gonorrhoeae.* Urethral inflammation may be diagnosed by the presence of one of the following criteria:

- A visible abnormal urethral discharge, or
- A positive leukocyte esterase test from a male aged less than 60 y who does not have a history of kidney disease or bladder infection, prostate enlargement, urogenital anatomic anomaly, or recent urinary tract instrumentation, or
- Microscopic evidence of urethritis (greater than or equal to five white blood cells per high-power field) on a Gram stain of a urethral smear

Laboratory criteria for diagnosis:

- No evidence of *N. gonorrhoeae* infection by culture, Gram stain, or antigen or nucleic acid detection

Case classification confirmed: a clinically compatible case in a male in whom gonorrhea is not found, by culture, Gram stain, or antigen or nucleic acid detection.

Comment: Nongonococcal urethritis (NGU) is a clinical diagnosis of exclusion. The syndrome may result from infection with any of several agents (see *Chlamydia trachomatis,* Genital Infection). If gonorrhea and chlamydia are excluded, a clinically compatible illness should be classified as NGU. An illness in a male that meets the case definition of NGU and *C. trachomatis* infection should be classified as chlamydia.

Pelvic inflammatory disease (revised 9/96) clinical case definition

A clinical syndrome resulting from the ascending spread of microorganisms from the vagina and endocervix to the endometrium, fallopian tubes, and/or contiguous structures.

In a female who has lower abdominal pain and who has not been diagnosed as having an established cause other than pelvic inflammatory disease (PID) (e.g., ectopic pregnancy, acute appendicitis, and functional pain), all the following clinical criteria must be present:

- Lower abdominal tenderness, and
- Tenderness with motion of the cervix, and
- Adnexal tenderness

In addition to the preceding criteria, at least one of the following findings must also be present:

- Meets the surveillance case definition of *C. trachomatis* infection or gonorrhea
- Temperature greater than 100.4°F (greater than 38.0°C)
- Leukocytosis greater than 10,000 white blood cells/mm^3
- Purulent material in the peritoneal cavity obtained by culdocentesis or laparoscopy
- Pelvic abscess or inflammatory complex detected by bimanual examination or by sonography
- Patient is a sexual contact of a person known to have gonorrhea, chlamydia, or NGU

Case classification confirmed: a case that meets the clinical case definition.

Comment: For reporting purposes, a clinician's report of PID should be counted as a case.

measure for chlamydia was recently implemented, to document screening of sexually active women 15–25 years of age who receive medical care through managed care organizations. This HEDIS measure is expected to result in increased chlamydia diagnosis and reporting, because health plans will report data on proportion of women screened as a measure of quality of care. Second, diagnostic tests have increased in sensitivity in the past decade, with the increasing availability and use of nucleic acid amplification tests.[95] Third, until 2000, not all states had regulations requiring the reporting of chlamydia infections. Finally, evolving screening recommendations have resulted in differential screening of women, as compared to men. This latter trend is changing with the increasing availability of urine testing, a less invasive method of testing men and women.

In 2005, 976,445 chlamydia infections were reported to CDC. This case count corresponds to a rate of 332.5 cases per 100,000 population. The rate varied considerably by sex: The rate of chlamydia among women (496.5 per 100,000 population) was over three times the rate among men (161.1 per 100,000 population); this is likely because of the larger number of women screened for this infection. The chlamydia rate in men increased by 43%, compared with a 16% increase in women from 2001 to 2005 (Fig. 97-10); this likely represents increased testing among men in this period.

Because of the expansion of chlamydia screening activities, the number of reported new diagnoses of chlamydia is not useful for examining trends in disease burden in the general population. To better monitor trends in disease burden, an alternate measure, prevalence of chlamydia among persons screened in defined populations, may be used (Fig. 97-11). This is not influenced by the expansion of screening programs. In 2005, the median state-specific chlamydia test positivity among 15–24-year-old women who were screened during visits to selected family planning clinics in all states and outlying areas was 6.3% (range 3.0–20.3%).

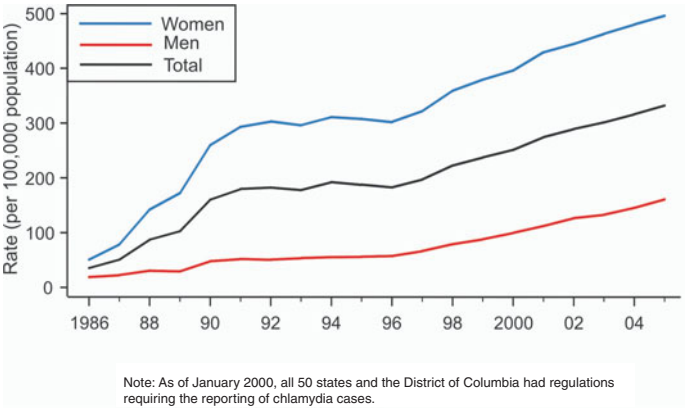

FIGURE 97-10. Annual rates of reported *Chlamydia* infections per 100,000 population, by sex, 1984–2005, United States.

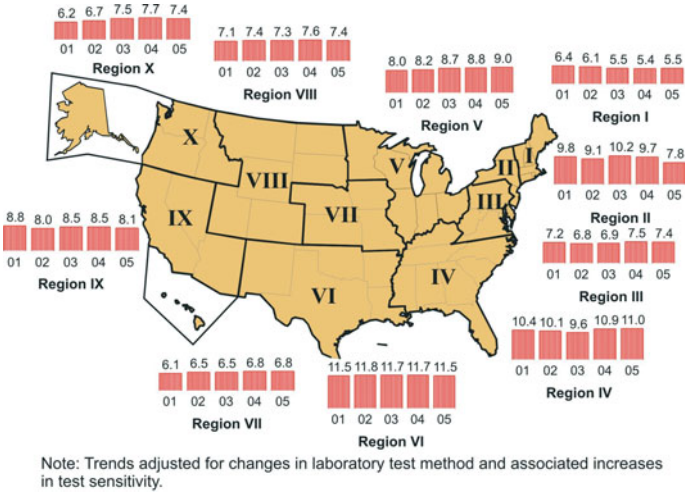

FIGURE 97-11. *Chlamydia* positivity among 15–24-year-old women tested in family planning clinics, by HHS regions, 1988–2005. Trends are adjusted for changes in laboratory test method and associated increases in test sensitivity.

Gonorrhea. Gonorrhea is the second most commonly reported notifiable disease in the United States. Infections due to *Neisseria gonorrhoeae*, like those resulting from *C. trachomatis*, are a major cause of PID. In addition, epidemiologic and biologic studies provide strong evidence that gonococcal infections facilitate the transmission of HIV infection.[96,97]

From 1975 through 1997, the national gonorrhea rate declined 74%, following implementation of the national gonorrhea control program in the mid-1970s (Fig. 97-12). Rates have subsequently plateaued, although a small increase was observed in 2005. Before 1996, rates among men were higher than rates among women. Since then, rates among men and women have remained similar. Diagnostic testing for gonorrhea is changing, with the increasing use of less invasive and more sensitive nucleic acid amplification tests and decreasing use of culture methods.[98]

In 2005, 339, 593 cases of gonorrhea were reported in the United States. The rate of gonorrhea in the United States was 116 cases per 100,000 population in 2005, the lowest rate since reporting began in 1975. Substantial disparity in gonorrhea rates in 2005 was observed by race/ethnicity: The rate among African Americans was 18 times greater than the rate for whites. The highest rates by age were seen among adolescents and young adults, aged 20–24 years, particularly African Americans. In 2005, the gonorrhea rates among 15–19-year-old African American women (2814 per 100,000 population), 20–24-year-old African American women (2543 per 100,000), and 20–24-year-old African American men (2362 per 100,000) were the highest race/age-specific rates observed.

Syphilis and congenital syphilis. The rate of primary and secondary (P&S) syphilis reported in the United States decreased during the 1990s; in 2000, the rate was the lowest since reporting began in 1941 (Fig. 97-13). The low rate of infectious syphilis and the concentration of the majority of

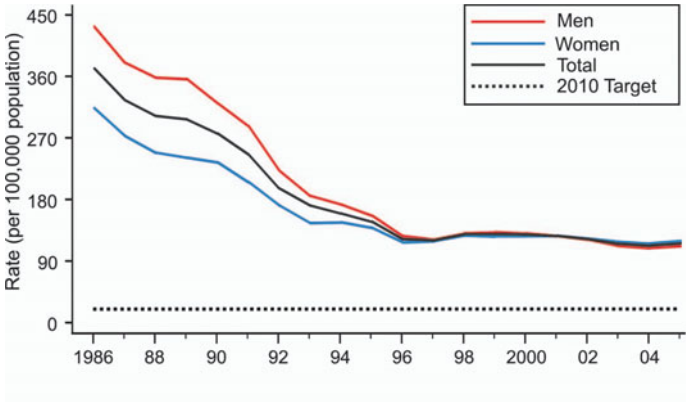

FIGURE 97-12. Rates of reported gonorrhea cases per 100,000 population, by sex, 1981–2005, United States.

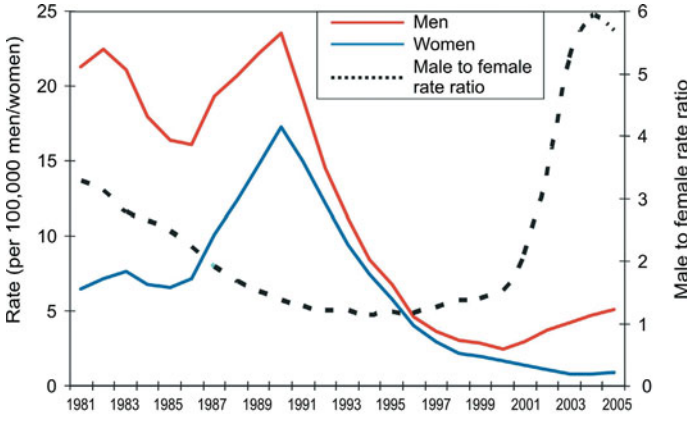

FIGURE 97-13. Rates of reported P&S syphilis cases and male to female case ratio, 1981–2005, United States.

syphilis cases in a small number of geographic areas in the United States led to the development of the CDC's National Plan to Eliminate Syphilis,[99] which was announced by the Surgeon General in October 1999 and updated in 2006.[100] Although the rate of P&S syphilis in the United States declined by 89.7% during 1990–2000, the rate of P&S syphilis remained unchanged between 2000 and 2001 and increased from 2001 to 2005. The number of P&S syphilis cases reported to CDC increased 43% from 6103 cases in 2001 to 8724 in 2005. The rate of P&S syphilis in the United States in 2005 (3.0 cases per 100,000 population) was 43% higher than the rate in 2001 (2.1 cases per 100,000 population).

Trends in syphilis rates vary considerably between men and women. For example, overall increases in rates during 2000–2005 were observed predominantly among men. Outbreaks of syphilis among MSM have been reported since 2000, characterized by high rates of HIV coinfection and high-risk sexual behaviors.[101–106] The rate of P&S syphilis increased 70% among men (from 3.0 cases to 5.1 cases per 100,000 men) between 2001 and 2005. During this time, the overall rate declined 36% among women (from 1.4 to 0.9 cases per 100,000 women), although there was a slight increase in 2005.

Information on the risk behaviors of persons infected with syphilis have not been collected nationally, and, thus, the numbers of persons with reported syphilis who are MSM are not known. In the absence of data on male–male sexual behaviors, the male-to-female case ratio has been used as a proxy for transmission among MSM. The male-to-female rate ratio for P&S syphilis increased from 2.1 in 2001 to 5.7 in 2005, suggesting increases nationally among MSM during this period (Fig. 97-13).

Between 1990 and 2005, the overall rate of congenital syphilis decreased 91% in the United States.[107] The continuing decline in the rate of congenital syphilis likely reflects the substantial reduction in the rate of P&S syphilis among women that has occurred during the last decade.

SUPPLEMENTAL SURVEILLANCE SYSTEMS FOR STDS—UNITED STATES

Representative national surveys

Special surveillance-related studies include population-based sample surveys such as the NHANES. This nationally representative probability sample survey of the noninstitutionalized U.S. population has examined the prevalence of antibodies to HPV-16,[108] antibodies to herpes simplex virus types 1 and 2,[109] and chlamydia and gonorrhea.[110] Other surveys include the National Hospital Discharge Survey (NHDS), which is a continuous survey of a probability sample of records of patients discharged from acute care hospitals in the United States. The National Ambulatory Medical Survey (NAMCS), a survey of private physicians' office practices, and the National Hospital Ambulatory Medical Survey (NHAMCS), an emergency room discharge survey and hospital outpatient clinic survey, are both performed through abstraction of information from medical records. The National Disease and Therapeutic Index (NDTI) is a probability sample survey of private physicians' practices, which provides estimates of the number of initial visits to private physicians' offices for many conditions, including STDs. While subject to many limitations, NDTI has for many years been the only source of national data on office visits for genital herpes, genital warts, and trichomoniasis.[107]

Prevalence monitoring

Prevalence monitoring is the assessment of STD prevalence among persons in defined populations who are routinely screened. In this context, prevalence refers to the number of persons with positive test results divided by the number of persons screened the first time in a defined time interval (for example, the number of women who are screened for chlamydial infection at a family planning clinic in a year, excluding

repeat test results). Because in practice there are relatively few repeat test results, positivity (the number of positive tests/number of adequate test results) is often used as a surrogate for prevalence. Positivity data are often more easily obtained than are data on prevalence, because of the difficulty in identifying and excluding repeat tests from these calculations. In most clinic settings, chlamydia positivity differs little from prevalence.[95]

In the United States, the systems best developed for monitoring STD prevalence have been established by the regional infertility prevention projects, which are in each of the 10 Public Health Service regions.[111] These federally funded projects, which have the primary purpose of providing support for chlamydia screening of women seeking family planning services, have made it possible to monitor chlamydia positivity among approximately 2.8 million women annually who are screened for chlamydial infection in selected family planning clinics, prenatal clinics, STD clinics, and juvenile detention centers. Some regional infertility prevention projects also provide support for gonorrhea screening. These systems have made it possible to compare state-specific prevalence across the United States, for women screened for chlamydial infection in family planning clinics and for chlamydia and gonorrhea in some other settings. Other sources of STD prevalence monitoring data include results of STD screening of persons entering jails and juvenile detention facilities, of MSM seen attending STD clinics and other primary-care settings, and screening of adolescent and young adult women and men entering the National Job Training Program (Table 97-6).[107]

Gonococcal resistance surveillance

The treatment and control of gonorrhea has been complicated by the ability of *N. gonorrhoeae* to develop resistance to antimicrobial agents. Surveillance for antimicrobial resistance is critical for establishing a rational basis for the empiric selection of gonococcal therapies. In the United States, antimicrobial resistance in *N. gonorrhoeae* is monitored through the Gonococcal Isolate Surveillance Project (GISP). GISP is an ongoing system for sentinel surveillance of resistance through the analysis of isolates from STD clinics in approximately 28 cities. The first 25 isolates from male patients with gonococcal urethritis in each of these cities are analyzed for the minimum inhibitory concentration of antimicrobials using a standardized agar dilution method. Detailed data from each city participating in GISP is available in CDC's annual report on this project.[112]

Resistance to ciprofloxacin (a fluoroquinolone) was first identified in GISP in 1991.[112] From 1991 through 1998, fewer than nine ciprofloxacin-resistant isolates were identified each year, and these isolates were identified in only a few GISP clinics. In 2000, 19 (0.4%) ciprofloxacin-resistant GISP isolates were identified in seven GISP clinics. In 2005, 581 (9.4%) ciprofloxacin-resistant GISP isolates were identified in 25 of 27 clinics (Fig. 97-14).

The proportion of fluoroquinolone-resistant *N. gonorrhoeae* (QRNG) isolates from MSM increased from 1.6% in 2001 to 29% in 2005. During the same time period, the proportion of QRNG isolates from heterosexuals increased from 0.6% in 2001 to 3.8% in 2005. As of June 2006, cephalosporin resistance had not been identified in GISP and the proportion of GISP isolates demonstrating decreased susceptibility to ceftriaxone or cefixime has remained very low.

STD SURVEILLANCE—INTERNATIONAL SETTINGS

Although the burden of curable STDs globally is estimated to exceed 300 million new cases annually, systems for public health surveillance of STDs vary in coverage and quality in developed countries outside of the United States[113] and are particularly weak in resource-constrained countries.[114] Key factors limiting the availability of STD surveillance data in developing countries

Table 97-6. Gonorrhea Prevalence in Different Populations and Clinical Settings, 2005[107,110]

Women		Men	
Population (age)	Prevalence	Population (age)	Prevalence
Juvenile corrections	4.7%	MSM attending STD clinics	11%
Adult corrections	2.8%	Adult corrections	2.3%
Job training program (16–24)	2.4%	Job training program (16–24)	2.2%
Prenatal care clinics (15–24)	0.9%	Juvenile corrections	1.0%
Family planning clinics (15–24)	1.0%	NHANES, 1999–2002 (14–39)	0.16%
NHANES, 1999–2002 (14–39)	0.33%		

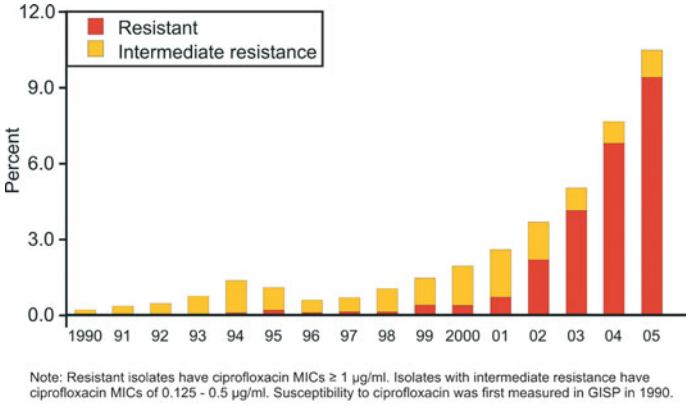

FIGURE 97-14. Percentage of *N. gonorrhoeae* isolates from men in sexually transmitted disease clinics (Gonococcal Isolate Surveillance Program, or GISP) with intermediate resistance or resistance to ciprofloxacin, 1990–2005, United States.

are lack of services for effective diagnosis and treatment of STDs, lack of availability of sensitive diagnostic tests that are sufficiently inexpensive to make them broadly available, and lack of information systems that provide for reliable reporting.

Given these constraints, WHO/UNAIDS have developed strategies for strengthening STD surveillance in resource-poor settings.[114] Key components include (1) case reporting of a limited set of STD syndromes and of congenital syphilis cases; (2) prevalence assessment and monitoring, focusing on populations that are routinely screened, vulnerable populations at high risk of STDs, and integration of STD testing into national demographic and health surveys where feasible; and (3) monitoring of antimicrobial resistance in *N. gonorrhoeae.*

STD syndromic surveillance

STD syndromes currently recommended by WHO/UNAIDS for reporting in developing country settings are urethral discharge in men and genital ulcers in men and women. Other syndromes are considered too nonspecific to provide an accurate reflection of STD incidence.[115] Most cases of vaginal discharge are caused by bacterial vaginosis and vulvovaginal candidiasis, which are not considered STDs. Although the differential diagnosis of lower abdominal pain in women includes PID due to sexually transmitted pathogens, in the absence of diagnostic tests, the findings are too nonspecific to be reliably reported through public health surveillance in resource-poor settings.

Any reporting of STD syndromes will reflect the quality and coverage of primary health-care services; therefore, trends in syndromic reporting must be interpreted in the context of changes in the health-care system. Expansion of services may result in larger numbers of case reports; declines may be anticipated only after the system stabilizes, the control program becomes more effective, and true morbidity declines.

Reporting of congenital syphilis cases varies greatly by country and is complicated by the complexity of case definitions and lack of definitive diagnostic tests in many settings. However, strengthening congenital syphilis surveillance will be essential for strengthening control programs, and for working toward elimination of this disease.[116] Key measures to be taken include ensuring broader coverage of syphilis serologic screening of women during prenatal care, assuring the quality of diagnostic testing, and applying a sensitive epidemiologic case definition for presumptive congenital syphilis that includes infants born to women with untreated syphilis. The increasing availability of rapid syphilis diagnostic tests that are easily performed on whole blood should facilitate surveillance and control of congenital syphilis in many parts of the developing world.

As is the case for STD surveillance in the United States, prevalence assessment is an essential component of STD surveillance in resource-constrained settings, and perhaps even more essential in those settings because of the lack of availability of STD diagnostic testing as a routine component of care. However, in many developing countries, diagnostic testing is not readily available, and data on prevalence cannot be assembled from routine STD screening data in various populations. Therefore, focused prevalence assessments must be performed periodically, using sensitive diagnostic tests, during defined time intervals or on defined survey samples, to obtain reliable data.

STD surveillance programs in developing countries should make use of existing sources of data on STD prevalence, although they should be careful to interpret them in the context of that program. Some countries have substantial data on prevalence of reactive syphilis serologic test results among women screened in antenatal care, as an essential component of their national program for prevention and control of congenital syphilis,[117] and among female sex workers who are routinely screened and treated syphilis, as a component of their HIV prevention program.[118] Data on prevalence of other STDs, including gonorrhea and chlamydial infection, have usually been much more limited.[114]

One model for obtaining reliable data on a larger scale has been integration of STD diagnostic testing into population-based surveys in developing country settings,[119,120] similar to inclusion of gonorrhea and chlamydial screening that is done in the United States as part of NHANES.[121] A second option has been to integrate STD diagnostic testing into behavioral surveillance surveys of specific populations,[119,122] resulting in data on comparative prevalence among persons at various levels of risk. Such data can be of great help in designing a national STD and HIV prevention strategy.

Monitoring of antimicrobial resistance in N. gonorrhoeae

With the broad availability of antimicrobial drugs, continued monitoring of resistance in *N. gonorrhoeae* is an essential component of STD surveillance in all countries.[123]

These surveillance data are of critical importance for developing national guidelines for STD treatment, considering antimicrobial resistance profiles and local availability of drugs. WHO provides support for this activity through the Gonococcal Antimicrobial Surveillance Program (GASP), with a set of WHO collaborating centers that support various aspects of this activity.[124] Globally, resistance to penicillin has been demonstrated to be too high to include this drug in national STD treatment guidelines. Fluoroquinolone resistance has been high in Asia and in countries of some other regions of the world. Emergence of resistance to third-generation cephalosporins has been reported only rarely, although the cost of these drugs limits their use in some settings.

USES OF SURVEILLANCE DATA

HIV/AIDS

In the United States, there are three primary uses of surveillance data: (1) epidemic monitoring to estimate incidence and prevalence of HIV-related morbidity and mortality in the population, to estimate incidence of HIV infection, and to identify trends in HIV transmission and populations at risk; (2) prevention planning to target prevention interventions and evaluate their effectiveness and to facilitate access to health, social, and prevention services; and (3) allocation of HIV program funds for prevention, care, and treatment services, including funds provided to state and city governments as part of the Ryan White Care Act.

The use of HIV/AIDS data maintained by governmental agencies for purposes other than epidemiologic monitoring, including activities such as case management for referral to treatment, or the counseling and referral for testing and treatment of persons identified as sexual or needle-sharing contacts to infected persons, has been the subject of substantial controversy.[125] A set of principles that was derived through a consultative process between academics, governmental officials, public health professionals, and representatives of affected communities are provided in Table 97-7. These tenets, designed to guide public health officials in the legitimate use of data collected about persons with HIV, have been published.[126]

In the international setting, HIV seroprevalence data on pregnant women have commonly been used to make estimates of overall adult population prevalence, and increasingly data on HIV seroprevalence from national demographic and health surveys are being used for this purpose.[127] Prevalence data are used to estimate the overall burden of HIV infection using several different methods and also to make projections of future trends[128]; certain of these models factor in interventions for prevention and treatment, which may have substantial impact on the future directions of the epidemic within a country.

Table 97-7. Guidelines for the Use of Personally Identifying Public Health Data Regarding Persons with HIV/AIDS

1. Identifiable public health data can only be used for legitimate public health purposes. A legitimate public health purpose enhances or has significant potential to enhance the capacity to reduce morbidity and mortality or direct resources to prevention, treatment, or other public health interventions at the individual or population levels without creating undue burdens.
2. Research serving public health ends represents a legitimate and appropriate use of personally identifiable data related to HIV/AIDS.
3. Personally identifiable data may be shared within public health agencies or among other governmental public health agencies at the federal, tribal, state, territorial, and local levels for legitimate public health purposes.
4. Public health data should not be shared with those charged with law enforcement, immigration control, management of the public welfare system, or other nonpublic health functions, except in circumstances involving the threat of imminent danger of grave physical harm to individuals or populations.
5. Public health agencies should disseminate nonidentifiable summary data to stakeholders.
6. Population-level data should be released in a way that minimizes the imposition of new burdens on those who are vulnerable, for example, because of disease, social class, or ethnicity.
7. Ongoing public consultation should be undertaken as a means of minimizing any burdens that may be created as a consequence of the release of population-level data.

OTHER STDS

The uses of STD surveillance data reflect the varying strengths and limitations of the many different surveillance data sources for case reporting, prevalence monitoring, and surveillance for antimicrobial resistance. Even though substantial underreporting has been documented for certain STDs, the overall consistency of reporting systems for case detection and reporting of some conditions has made case reporting data useful for monitoring increases and decreases in incidence. In the United States, national trends in case reports of P&S syphilis and of gonorrhea have been considered reflective of actual trends in the incidence of these diseases and are used as the basis for establishing national disease control objectives.[129]

STD surveillance data are commonly used to identify disease outbreaks.[101,102,130] Local and state health departments have the authority to investigate outbreaks of reportable and nonreportable conditions of public health importance, including STDs.[131] These investigations can be performed to better determine the extent of disease and to identify risk factors for transmission so that focused control measures can be implemented.[116] Using traditional partner notification techniques, detailed investigations can also be used to describe social and sexual networks that provide the context for disease transmission.[132]

STD case report data can effectively be used to identify persons at risk of disease, who should be the focus of control programs. For example, the age–gender groups with the highest rates of gonorrhea are women aged 15–19 years and men aged 20–24 years.[107] Detailed mapping of case reports can be performed to assist in identifying specific neighborhoods where transmission is occurring.[133]

Data obtained from the case-reporting process are used by health departments to assure that patients have been properly treated and to facilitate or assist in the process of confidentially notifying their sex partners that they also can be confidentially evaluated and treated. In all localities, these functions are performed for patients with early syphilis and, in some localities, for patients with gonococcal and chlamydial infections.

Prevalence data from populations that are routinely screened can be used to develop and modify local criteria for screening; such data have been used extensively for developing screening criteria for chlamydial infections in the United States.[134] *Chlamydia* prevalence data have also been used to assess screening coverage, both directly, through data gathered on numbers of persons and characteristics of the populations screened, and indirectly, by considering case rates, prevalence, and estimates of the population eligible for screening.[135] States that have low rates of case reports despite high reported prevalence are most likely places where screening coverage is low.

Surveillance data on antimicrobial resistance in *N. gonorrhoeae* play an important role in developing recommendations for treatment of gonococcal infection. Such data were essential, for example, in the recommendation for abandoning penicillin as the drug of choice for treatment of gonorrhea in the United States in 1989, in favor of ceftriaxone, despite the higher cost of this drug.[136] Surveillance data on antimicrobial resistance have become increasingly important for treatment recommendations, as nonculture tests for *N. gonorrhoeae* infections come into widespread use, reducing capacity for culture and susceptibility testing at many clinical and public health laboratories. Highly resistant isolates identified through GISP trigger special investigations to determine the source.

Although most U.S. isolates with high levels of resistance to fluoroquinolones were initially linked to Asia,[137] cases of endemic transmission have occurred on the U.S. mainland and in Hawaii.[138,139] GISP has also provided early indications of the emergence of decreased susceptibility of *N. gonorrhoeae* to azithromycin.[91] Sentinel systems such as GISP also provide more detailed information on the characteristics of patients than can national surveillance data through case reports. For example, as early as 1996, GISP documented increases in the proportions of gonorrhea patients in STD clinics who were MSM,[140] heralding increasing HIV risk behavior and large outbreaks of STDs in this population.[141]

SURVEILLANCE AND THE CLINICIAN

The clinician plays critical roles in public health surveillance, as both a critical source of information through reporting cases and a beneficiary of the aggregate data produced by surveillance systems. Reporting of cases of HIV, AIDS, and reportable STDs is a legal requirement of health-care providers in the United States. Recent legal protections to the privacy of health information, conferred by the Health Insurance Portability and Privacy Act (HIPPA), are not at odds with the legal duty to report such diagnoses. Guidelines for application of the protections conferred by HIPPA specifically recognize the imperative of case reporting for surveillance purposes, and a public health "carveout" specifies that case reporting for the purposes of public health surveillance and disease control is a permissible release of protected health information.[142] State health departments are empowered to take action against licensed health-care providers who do not report cases as required, to include actions against professional licensure.

Although providers bear responsibility for case reporting, they are also beneficiaries of surveillance programs in many ways. Data from surveillance programs are used to formulate treatment guidelines and empiric recommendations for therapy. Data on disease burden are used locally and nationally to demonstrate met and unmet

needs for care resources, and to advocate for such resources. Clinicians may also routinely receive surveillance reports from the health department, describing the local HIV and STD epidemics. These data are guideposts for care, serving as an evidence base for decisions about which groups in the local community are at greatest risk of certain infections and, therefore, in which groups consideration for screening or clinical suspicion of infections should be enhanced.

98 Monitoring and Evaluation of Prevention and Control Programs for HIV/AIDS and Other STD

J. Ties Boerma, Michel Caraël, and Bernhard Schwartländer

Sound monitoring and evaluation are a core component of prevention and treatment programs for HIV/AIDS and STD. This chapter defines monitoring, evaluation and its purposes and presents a simple input-output-outcome-impact framework used in monitoring and evaluation (M&E) system design. It reviews issues related to indicator development and target setting in both international and national contexts. Measurement issues related to different components of this combined framework, such as exposure to or coverage of the intervention and behavioral and biological outcomes, are presented to guide the design of programs and interpretation of findings. The M&E framework is linked to epidemiological knowledge about the transmission of HIV and sexually transmitted disease (STD) to better guide the evaluation of programs, including the implications for study design.

DEFINING MONITORING AND EVALUATION

There are multiple definitions of monitoring and evaluation. In general, all definitions flow from a common basic M&E framework that is used to organize the data required to monitor program implementation and presents a hierarchical order for collecting and analyzing results (Fig. 98-1).[1–3] For a program to achieve its goals, inputs such as money and staff time are used to implement a process, a set of activities such as training and distribution of drugs, which should result in planned outputs such as service delivery points (e.g., for HIV testing and counseling, condom distribution, or treatment). If these outputs are well-designed and widely utilized by the populations for which they were intended, the program is likely to have immediate effects, such as number of people HIV tested and counseled. Outputs may lead to outcomes (intermediate effects, such as risk behavior change) that in turn may lead to impact (long-term effects such as a reduction in HIV or STD transmission). The left side of the input–output framework is based on program elements, the right side moves into population health issues.

Monitoring is defined as the routine tracking and reporting of priority information about a program and its intended outputs and outcomes.[1] This primarily includes monitoring of program inputs and outputs through record keeping and regular reporting systems, which is sometimes referred to as process evaluation. Data collection and results should be linked to ongoing management decisions, such as those related to supplies and logistics. However, monitoring may also include the routine tracking of short-term, immediate program outcomes, such as the number of people using a specific service, and long-term impact, such as STD or HIV incidence. Monitoring is a basic component of all programs to assess if resources are spent according to plan and whether the program is resulting in the expected outputs. Limiting the number of indicators is essential, as often too much information is collected and reported but not used for management or evaluation.

HIV or *STD Surveillance* can be considered as a form of monitoring, often targeted toward specific populations but it is mostly not directly linked to specific programs (see Chapter 97). Surveillance can be defined as the ongoing or periodic tracking of infection, disease, or risk behavior using the same data collection system over time. In case of HIV, surveillance systems typically track impact in terms of HIV and sometimes STD prevalence and outcomes in terms of sexual risk behavior.

Evaluation is defined as a rigorous, science-based collection of information about program activities, characteristics, and outcomes that determine the merit or worth of a specific program. Evaluation is also performed to understand enabling factors that may have an influence on the effectiveness of a program. Evaluation is an episodic assessment of the change in the specified results that can be attributed to the program. Evaluation studies are used to improve programs and inform decisions about future resource allocations.[1–3] This may include economic evaluation, including cost-effectiveness analysis.

Monitoring and evaluation systems often have to address partly competing demands. These include program improvement, management-related decision making, and accountability. The latter has become increasingly dominant,

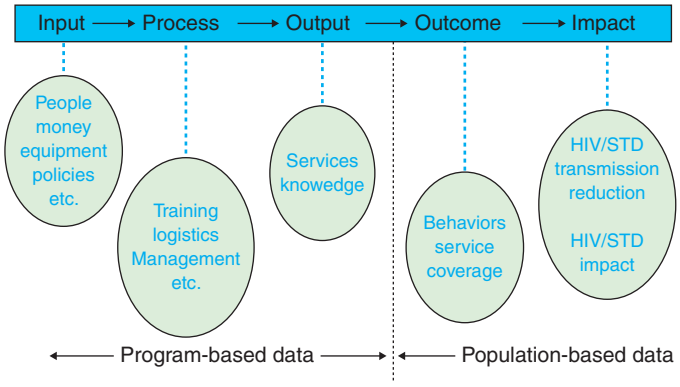

FIGURE 98-1. A framework for monitoring and evaluation.

with international donors and global health initiatives such as the Global Fund to Fight AIDS, TB, and Malaria, linking disbursements of resources to demonstrable results (performance-based funding).

Monitoring and evaluation are intertwined and many publications refer to *comprehensive* monitoring and evaluation systems.[1–4] Such a system is essential to make optimal use of limited resources and integrate lessons learned with the response required for scaling up HIV/AIDS or STD programs to achieve national level impact. At the national level, a good M&E system includes an established monitoring and evaluation unit as part of the National AIDS /STD program, clear program goals and objectives, a well defined set of indicators to track progress, a plan for data collection, and analysis and dissemination of results at all relevant levels (subnational, national, and global).[1] Given the diversity of factors influencing the spread of HIV and consequently a multifaceted response, program activities and related monitoring and evaluation systems must go beyond the reach of the Health Sector (e.g., education and labor).

During program planning stages data are collected to conduct a situation analysis. This is also referred to as *formative evaluation*, which explores the need for interventions, provides the information necessary to define realistic goals and objectives for the program interventions, and helps program planners make decisions about selection of effective, feasible intervention strategies. Formative evaluations use a mix of quantitative and qualitative research methods that can rapidly provide relevant information to program planners. Because of the nonstandardized manner in which formative evaluations are conducted, they generally do not provide good baselines for future impact evaluation.

Operations research is a special type of evaluation that investigates the operational issues in scaling-up programs and interventions. It typically addresses questions of how best to implement programs designed and evaluated in small-scale projects or under certain conditions and places. It is also used to identify bottlenecks in the implementation as programs go to scale. The main goal of operations research is to provide program managers and policy makers with the required information to develop, improve, or scale-up programs. It can be considered a practical systematic process for identifying and solving program-related problems.

INDICATORS AND TARGETS

A wide array of indicators has been proposed for monitoring HIV/AIDS and STD related program components and results.[1, 5, 6] Many international guidelines and lists of indicators aim to assist programs in developing a core set of indicators that are comparable between countries and programs. These indicators are used to monitor program context (such as the development of appropriate policies or guidelines) and effort, knowledge, attitudes and risk behavior, the availability and quality of health and other services, and HIV/AIDS and STD prevalence. Several indicators have gained major prominence because they are part of the monitoring toward the United National General Assembly Special Session (UNGASS) Declaration of Commitment on HIV/AIDS or the Millennium Development Goals (MDGs).

At the highest level, the United Nations General Assembly has agreed on two concrete targets and impact indicators that are related to the MDG to *"halt and begin to reverse the spread of HIV by 2015"*: the reduction of HIV in young people and the reduction of infants with HIV (Table 98-1). The monitoring for the framework UNGASS Declaration of Commitment on HIV includes a core set of indicators measuring commitment and action at global and national level (resources, policy, and advocacy) and a series of indicators to track program efforts in prevention, treatment, care, and impact mitigation.[7]

Indicator selection should be guided by what one would like to know to manage or monitor a program. A number of guiding principles facilitate the selection of an appropriate set of indicators for M&E of AIDS and STD programs. First, the input-output-outcome-impact framework for monitoring and evaluation needs to be used when selecting indicators to make sure the different levels are covered as appropriate and the hierarchy of indicators is clear. Second, specific qualities of the indicators need to be considered such as the link with program goals, the indicator's ability to measure change, the cost and feasibility of data collection and analysis, and comparability both with past indicators and between countries and populations. Ideally, indicators should be valid (measure the condition or event they purport to measure), reliable (produce the same result when used more than once under the same circumstances), specific (measure only the condition they purport to measure), sensitive (reflect changes in the state or event under observation), and feasible. Finally, the value of an indicator is greatly enhanced if a clear target can be set. A target that resonates with programs, supported by accurate baseline information and feasible monitoring strategies, can enhance the value of an indicator.

Table 98–1. Global Impact Targets for HIV Prevention of the United Nations

	By 2005	By 2010	By 2015
Millennium Development Goals			Halt and begin to reverse the spread of HIV
UNGASS on HIV/AIDS			
	25% reduction in HIV among young people *in the most affected countries*	25% reduction in HIV among young people *globally*	
	20% reduction of the proportion of infants infected with HIV	50% reduction of the proportion of infants infected with HIV	
Intervention coverage	90% of youth have information, education, services, and life-skills that enable them to reduce their vulnerability to HIV infection[a]	95% of youth have information, education service, and life-skills that enable them to reduce their vulnerability to HIV infection*	
Input	Annual spending on combating the epidemic in low- and middle-income countries to reach between U.S. $7 billion and $10 billion	80% of pregnant women in ANC receive VCT, ART, and breast-milk substitutes	

[a]Measured through comprehensive knowledge of HIV prevention.

Goals can be defined as general or broad objectives of initiatives or programs. Unlike specific objectives and targets, goals are not necessarily constrained by time or existing resources, nor are they necessarily attainable but are rather an ultimate desired state toward which actions and resources are directed. Examples include the "Health for All," the "Education for All," or the Global Polio Eradication initiative. Goals are often accompanied by specific targets and indicators, which are used as proxy measures to track progress against the ultimate goal. For example, the 8 Millennium development goals, which include three sets of health goals, also define quantitative targets within each goal with a clear process on how to monitor and evaluate progress.

Targets express a commitment to achieve specified outcomes in a defined period and should enable monitoring of progress toward the achievement of broader goals and objectives. Targets are instruments that can facilitate the achievement of a policy and can assist in defining priorities. They may be inspirational to facilitate achieving greater political commitment and resources but they should also be considered realistic and build on information about current rates of scale-up of services. Finally, they must be measurable so that reports on progress can be produced using intermediate targets or milestones. Targets are also critical in measuring performance of programs. While programs may achieve and demonstrate progress (increasing coverage over time), it is only progress against agreed targets that ensures accountability and enables systems of performance based funding.[8]

International goals and targets are often an important influence on the response to HIV/AIDS at country levels.A detailed review of national strategic plans for HIV/AIDS 2005–2010 conducted by UNAIDS in 19 countries in sub-Saharan Africa and Asia showed that the majority of countries explicitly acknowledge and use the targets of the UNGASS Declaration of Commitment. As a consequence of the declaration, a number of countries added specific coverage targets, others adapted the targets taking into account their planning, implementation capacities, and the availability of financial resources.

However, there is an important concern related to the development of indicators in recent years: the proliferation of indicators without concomitant investment in data collection and analysis.[9] International organizations have led the development of large and growing numbers of indicators to monitor international goals, enhance accountability, and improve country programs. M&E of HIV/AIDS programs started off with 10 priority prevention indicators in 1994 which grew to 57 indicators for national programs in 2000.[1] Since then, at least six separate publications each with dozens of indicators have been published to guide monitoring and evaluation in

specific components of HIV/AIDS programs, such as prevention for young people, care and support, or tuberculosis/HIV interventions. A major purpose of these large numbers of indicators is to help program implementers and policy makers specify what the intended achievements are. Data availability and quality are often a major constraint. And even if data are available, interpreting levels, trends, and differentials of statistics for such large numbers of indicators are beyond the capability of most programs.

There is a fundamental imbalance between investments in indicator development and measurement strategy. Most international initiatives and programs do not have an explicit data collection and analysis investment strategy and are limited to defining data sources for individual indicators. This tends to lead to quick fixes in data collection, poor data quality, and a systematic lack of investment into a comprehensive health information system that can provide regular quality data over time.[2]

MEASUREMENT ISSUES

The ability to produce reliable and valid statistics for an indicator determines the utility of the indicator. If no means of accurate measurement or estimation are available, the primary goal of the indicator to track trends for management, resource allocation, or evaluation purposes is not met. There are three major questions that need to be answered for each indicator as follows:

- Is there a good measurement instrument such as a biological test, well-established interview questions etc.?
- Is there a good vehicle for implementation of the measurement instrument, such as a population-based sample survey or surveillance system?
- Are there valid methods to adjust for known and unknown biases to obtain estimates using established models and imputation procedures?

Table 98-2 summarizes the main instruments, data collection methods, and estimation methods for measurement of indicators related to exposure to interventions or coverage (program output), behavioral outcomes, and biological outcomes (impact).

BIOLOGICAL OUTCOMES: HIV TRANSMISSION

INSTRUMENTS

The ability to say whether well-implemented HIV/AIDS and STD programs are making a difference in terms of health improvement depends on how well health outcomes can be measured. Compared with many other diseases such as tuberculosis or malaria, HIV/AIDS has the advantage of the availability of a simple low-cost biological test to ascertain the level of HIV transmission at the population level. An HIV antibody test measures prevalence of HIV infection. HIV antigen tests are available, though more difficult, more costly to apply, and less sensitive and specific than antibody tests. Standardized testing protocols have been developed for HIV testing, both for surveillance and diagnostic purposes.[10] HIV prevalence is not an adequate measure to track short-term changes in HIV transmission. Tests establishing a recent HIV infection (HIV incidence) using a single blood sample are still under development but appear to work well for an increasing number of HIV subtypes.[11,12] For instance, trends in HIV-1 seroincidence among different sentinel surveillance groups were assessed using a newly developed IgG capture BED-enzyme immunoassay (BED-CEIA) in Cambodia[13] and Atlanta, Georgia.[14] However, other studies have found that the BED-based method grossly overestimates the true incidence rate.[15, 16] Further validation studies are needed before widescale application is justified.

DATA COLLECTION

The main vehicles used to obtain population-based information on HIV incidence and prevalence trends in countries are HIV surveillance systems (see Chapter 97). The recommended selection of surveillance populations depends on the type of epidemic. In generalized epidemics, defined as epidemics with at least 1% infection rates in the adult population,[17, 18] surveillance systems have focused on pregnant women attending a selected number of (sentinel) antenatal clinics. HIV prevalence trends among such women have been available for many countries since the late eighties and form the basis for long-term trend analysis. For instance, in 2004, long-term trends could be ascertained for 75 predominantly urban antenatal clinics in sub-Saharan Africa.[19] In concentrated epidemics, where HIV has not spread into the general population but prevalence is at least 5% in at least one risk population such as sex workers, injecting drug users, or men who have sex with men, the primary focus of the surveillance system is on tracking trends in selected at-risk populations, supplemented by antenatal clinic-based surveillance.[17] In low level epidemics, where prevalence is below 5% in all risk populations, a focus on risk population only should be maintained.

Trends in the HIV incidence rate are preferable to pick up recent changes in HIV transmission and therefore the preferred monitoring and evaluation indicator. HIV incidence rate monitoring has not been used on a large scale in most countries but is a major outcome used in longitudinal research studies where multiple blood samples are collected from the same person. For M&E purposes, however, the lack of a well-established test that can be used on a single blood sample and the large sample sizes required to detect changes in HIV incidence rates have hitherto been obstacles to widespread use.

Table 98-2. Measurement Issues for Output, Outcome, and Impact Indicators: Availability of Measurement Instruments, Data Collection Strategies, and Estimation Methods

	Instrument	Data Collection	Estimation
Impact: HIV transmission	HIV antibody test Test for new infection from single sample HIV antigen test	Surveillance among high- and low-risk populations General or risk population sample surveys	Standardized software to obtain population-based estimates from sentinel or risk population surveillance data; uncertainty ranges
Impact: STD transmission	Diagnostic test for current infection Diagnostic test for past exposure Clinical diagnosis	Surveillance among high- and low-risk populations, including STD clinic attendees General or risk population sample surveys	None
Impact: Survival and functioning among HIV-infected persons	Age and sex patterns and trends in mortality; verbal autopsy; individual survival data among those on treatment; AIDS case reporting CD4 cell count HIV viral load Questions on functioning and quality of life	Vital registration systems with cause of death Population based surveys and longitudinal studies Survival on treatment studies based on clinic data and follow-up if defaulting	Model life tables to detect impact HIV/AIDS on age and sex patterns of mortality No models for cause of death patterns with HIV/AIDS Cohort analyses
Outcome: sexual behavioral trends	Interview questions–(self-reported risk behavior)	General or risk population sample surveys	None, in-depth interviews held to assess bias but no methods to adjust
Output: coverage preventive interventions and treatment	Service delivery record keeping; Interview questions	Accurate and complete reporting by service delivery points General or risk population sample surveys Surveys used for STD treatment utilization; not useful for ARV therapy	Coverage computed by using denominator estimate None

HIV prevalence rate among young people (15–24 years) has been selected as the key proxy indicator to monitor trends in HIV incidence rate in the absence of direct data on the new infection rate. This is because the time of exposure to HIV in young people is limited and therefore closer to incidence than in older age groups with a much longer duration of sexual activity. In addition, recent HIV infection in young people is not so strongly associated with increased mortality as infections acquired in the more distant past.[20] The fertility-decreasing effects of HIV will also be less important at those young ages, and this is especially relevant in the context of antenatal clinic-based surveillance in low contraceptive use countries.[21,22]

Ideally, population-based samples of young people 15–24 years provide estimates of the HIV prevalence rates among young men and women, but almost no country had conducted multiple surveys by 2007. Therefore, the major source of trend information in countries with high fertility and generalized epidemics, however, are pregnant women attending antenatal clinics. Most pregnant women under 20 years will have started sexual activity recently, and as such, prevalence in this age group should be a sensitive measure of HIV incidence. Despite the higher sensitivity of younger age groups in reflecting recent HIV infections, the 15–24-year-old age category may be more appropriate to obtain a robust

estimate of prevalence trends. HIV prevalence among sexually active people is determined by the length of exposure to sexual activity and the risk of HIV transmission, which is related to the HIV prevalence in the general population and to the level of sexual mixing between high-risk groups and the general population and between age groups. The composition of the group of pregnant women aged 15–19 years is strongly affected by changes in age at sexual debut, and prevalence in this group may not adequately reflect trends in prevalence in adolescents in the population at large.[23] In general, the later the age at sexual debut, the more atypical are young pregnant women and, therefore, the greater the degree of overestimation in ante-natal (ANC) estimates in the youngest age groups. In addition, where contraceptive use is low, HIV prevalence from ANC surveillance in the youngest age groups overestimates prevalence in the general population due to selection bias for sexual activity. In high contraceptive use populations, where young women take more effective measures to prevent both pregnancy and HIV infection, HIV prevalence in pregnant women of young age will overrepresent women with higher risks for HIV-infection and this overrepresentation would persist in older age groups.[24] Furthermore, sufficiently large sample sizes required to obtain robust age-specific prevalence estimates are not often available for these younger age groups. Figure 98-2 presents an example of trends in HIV prevalence observed among young pregnant women attending sentinel antenatal clinics in selected African countries.

Few sentinel systems in developing countries provide any data on HIV prevalence in men but such data are sometimes provided by surveillance among STD clinic attendees. HIV prevalence measured among STD patients overestimates prevalence in the general population because such patients obviously represent a high-risk group. Trends of HIV prevalence in this population may be biased due to changes in treatment seeking for STD or changes in epidemiology of STD. The magnitude of such bias is likely to differ in men and women. Patterns of health-seeking behavior and differentials in characteristics related to HIV transmission between sentinel STD clinic users and those opting for other alternatives (e.g., private clinics, pharmacies, self-treatment) may influence the estimated indicators. Among young people, especially young women, a further limitation related to the use of data from STD clinics is due to lack of access to or use of STD services by adolescents, which may also introduce bias into estimates of HIV prevalence.

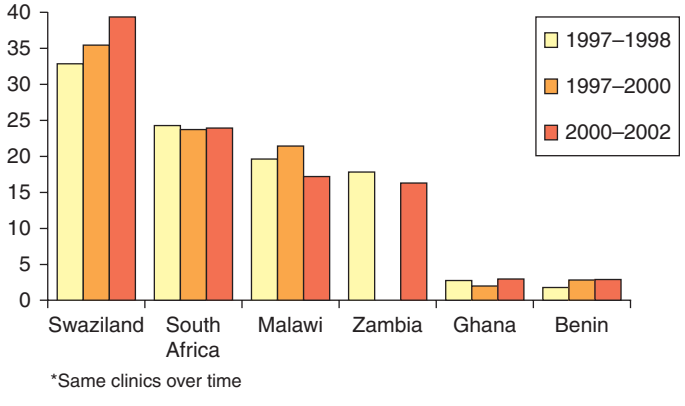

FIGURE 98-2. Median HIV prevalence (%) among women 15–24 years old attending antenatal clinics,* selected African sites, 1997–2002.

Population-based household surveys with HIV testing can provide a more representative picture of the levels and trends in HIV prevalence in the general population than surveillance systems. Since 2001, a large number of countries have conducted such surveys, which are only useful for populations with generalized epidemics, as high-risk populations are generally seriously underrepresented in surveys. Such surveys are particularly useful because they can provide information on men and nonpregnant women and on the socioeconomic determinants of HIV infection. They can also provide a detailed geographic snapshot of the spread of HIV within a country provided sample sizes are adequate. The main challenges are nonresponse rate, especially among men in urban areas, which may be due to refusal or absence during the survey. In eight national, population-based surveys supported by the Demographic and Health Surveys (DHS) during 2001–2004, nonresponse rates varied from less than 10% in women in Cameroon and Burkina Faso to nearly 30% in urban men in Kenya. However, an evaluation of the effect of the response bias on estimates of HIV prevalence showed that the impact was relatively limited.[25] Only by maintaining very high quality standards for study design, data collection and laboratory testing, can surveys produce reliable results. Considerations of costs and nonresponse may lead to a data collection strategy whereby population surveys are used every 5 years or so to calibrate the annual results of HIV sentinel surveillance among antenatal clinic attendees.

ESTIMATION METHODS

Generating valid and reliable estimates for HIV prevalence and incidence rates is also important to M&E efforts. UNAIDS, WHO and partners have developed standard methods of estimation including a software package that can be used by countries or at the subnational level. For generalized epidemics, Epidemic Projection Package (EPP) uses antenatal clinic-based HIV prevalence data to draw an epidemic curve using a four parameter epidemiological model.[26] For concentrated and low-level epidemics EPP is replaced by a workbook approach, which uses data on the size of the risk populations, the HIV prevalence among risk populations, and the contact rate between the risk and general populations to obtain an estimate of the level of the epidemic.[27] The results of either the EPP analysis or workbook approach are fed into a second software package, Spectrum, to obtain a series of

epidemiological and demographic statistics.[28] Uncertainty in the estimates of HIV/AIDS prevalence, incidence, and mortality are also presented by UNAIDS and WHO.[29] These plausibility bounds not only take into account the uncertainty associated with sampling error but also use expert opinion on other aspects of uncertainty such as the phase of the epidemic and the quality and coverage of the sentinel surveillance system that provides the underlying data.

In the context of M&E it is useful to keep in mind that the use of modeling to fill data gaps needs to be done with caution. In general, health statistics can be divided into three types: crude, corrected, and predicted.[30] Crude statistics are simply reported data without any adjustment or correction and are generally of little use to M&E. Corrected health statistics are measurements of indicators where analytical methods and techniques are used to correct for known biases such as nonrepresentativeness or misclassification bias. Corrected statistics also include measurements where the primary data collected are on an indirect consequence of the phenomenon under study. An example is estimating HIV prevalence among the adult population from data on antenatal clinics and assumptions about the association between levels and trends among antenatal clinic attendees and the general adult population. Predicted statistics are based on projections in time or from one population to another. For forward-looking decision making, when corrected statistics are not available, predicted statistics can play an important role. For monitoring progress toward agreed upon targets and evaluating what works and what does not, however, predicted statistics should not be used.

BIOLOGICAL OUTCOMES: STD TRANSMISSION

INSTRUMENTS

Diagnostic tests for many STDs are available but only some are useful for monitoring and evaluation. A combination of serological tests for syphilis can distinguish between recent, active, and past or cured infection. A positive Rapid Plasma Reagin (RPR) or VDRL test, confirmed by a positive nontreponemal test, indicates recent infection. The Treponema Pallidum Hemagglutination (TPHA) or similar test is positive if there is a history of syphilis (or other treponemal infection). A positive TPHA with negative RPR suggests past but cured infection. Serologic tests are available for herpes simplex virus-type 2 (HSV-2) as are multiple polymerase chain reaction (PCR) assays for genital ulcers, including syphilis, HSV-2, and chancroid. Urine tests using PCR or ligase chain reaction (LCR) are used to detect genital infection with Neisseria gonorrhoeae and *Chlamydia trachomatis*. Cervical specimens can also be tested using PCR assays for *C. trachomatis, N. gonorrhoeae*; human papilloma virus (HPV) and *Trichomonas vaginalis*. Some population-based surveys have used these tests but costs, laboratory, and logistical demands have hampered widescale application.[31] *T. vaginalis* infection in women can also be detected from a vaginal swab using a wet mount examination or a simplified culture method, the In-Pouch TV culture system. The latter has been used in some population surveys.[32]

In addition, clinical diagnosis of STD and self-reported diagnosis of STD through survey questions are used to measure the incidence or prevalence of STDs. The clinical diagnosis can be made with or without supporting laboratory testing, which may include microscopic examinations and cultures. The syndromic approach bases the clinical diagnosis on a systematic set of questions and physical examination findings[33] to identify genital ulcer syndromes and genital discharge syndromes. Individual interviews in household surveys have used questions on specific diseases (e.g., "Did you ever have syphilis in the last year?") or syndromic questions (e.g., "Did you have a genital ulcer in the last year?"). Neither approach has been particularly successful.

The use of clinical data to monitor trends in STDs, particularly discharge syndromes in women, has a further limitation, asymptomatic infection. Studies have shown that among women seeking reproductive health services, more than half of those with gonorrhea and at least 70% of those with chlamydial infection exhibited neither symptoms nor signs of infection.[34,35] Population-based studies of men also documented that significant proportions of those with gonorrhea or chlamydia reported no symptoms.[36]

DATA COLLECTION

In most countries, routine STD case reporting by health facilities is required by national law or regulations (such as a law on communicable diseases). However, in the majority of countries, especially in those with limited resources, STD reporting is of poor quality. Underreporting and misclassification are common problems and the clinic population is not representative of the general population due to self-medication and private sector attendance. Private providers are often particularly delinquent in reporting STD diagnoses. The denominator is frequently unknown, and extrapolation from the clinic reports to estimates of the magnitude of the STD problem or trends over time at country or regional levels is difficult. Very few countries have established an STD sentinel surveillance system in which special efforts are made to obtain accurate trends from a selected set of STD service delivery points.

Alternative sources of STD surveillance data are populations that seek health care or visit potential sentinel sites for reasons unrelated to STDs or other specific diseases. As for HIV surveillance, one important group that is accessible and representative of the general population is women attending antenatal clinics. In most countries, testing of antenatal clinic attendees is limited to RPR for active syphilis detection and treatment. Such data, however, have provided information on

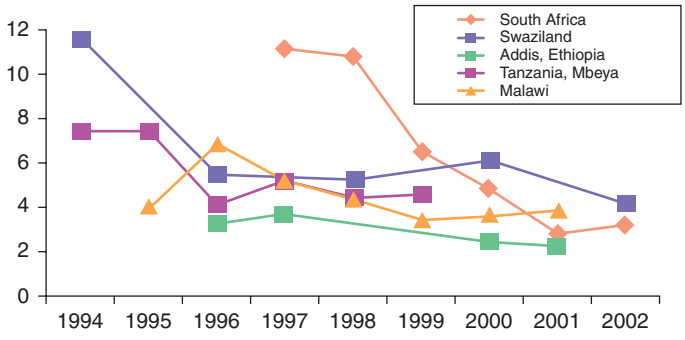

FIGURE 98-3. Syphilis seroprevalence (%) among women attending antenatal clinics at selected African sites.

trends in active syphilis (Fig. 98-3). Other possible sentinel populations include blood donors or military recruits.

In addition to disease surveillance from data collected during routine health-care delivery, special surveys can also be conducted to assess the scope and the specific types of STD burden in communities. Such studies are conducted during defined time periods and may be repeated if appropriate. Surveys of random samples of the population that include STD testing are increasingly feasible with the availability of urine-based tests and self-administered swabs.

Surveys can also be performed to measure prevalence and incidence in high-risk populations such as sex workers or truck drivers. These populations are usually not seen in general health-care facilities and STD surveillance in these groups usually requires development of specific outreach activities or special services. In addition, special clinics for risk populations may provide data for monitoring and evaluation.

In areas where etiologic diagnosis of STDs is difficult due to limited resources, only special studies can determine the common pathogens causing the syndromes and their antimicrobial sensitivity.

ESTIMATION METHODS

While there has been some investment in modeling the spread of specific STDs[37,38,39] and the role of STDs in HIV transmission,[40,41] there is very little available to countries to estimate levels and trends of STDs in the general and specific populations from the incomplete data collected for monitoring and evaluation purposes.

BIOLOGICAL OUTCOMES: SURVIVAL AND TREATMENT RESPONSES

INSTRUMENTS

In the context of M&E of HIV/AIDS programs, measurement of mortality has two aspects. The first is to measure the impact of antiretroviral or other treatment on survival among those who are or have been on treatment. This requires a good system of clinical records and a follow-up system outside of health services in case the death does not occur in the health facility or if the patient drops out of the treatment cohort before dying.

The second aspect relates to measurement of trends in mortality due to HIV/AIDS in the general population, irrespective of whether treatment was provided. The measurement instruments are those that are used for population mortality measurement in general. These are based on active reporting systems (vital registration system) or questions about deaths in the household or among relatives (household survey or census). The gold standard for determining the cause of death is autopsy. If the cause of death is not available through medical certification (using clinical information, with or without autopsy), as is the case in most developing countries, an interview with the relatives of the deceased is used to ascertain a probable cause of death (verbal autopsy). Among adults, validation of verbal autopsy studies have shown moderately high sensitivity and specificity of the algorithms for the diagnoses of AIDS and TB.[42–44]

The diagnosis of AIDS is based on the AIDS clinical case definition. Several definitions have been used based on a mix of clinical and laboratory criteria.[45] To obtain reliable trend data, consistency in the use of definitions and classification criteria is essential. CD4 T-lymphocyte cell counts are a good indicator of progression of infection to disease and may be used for monitoring purposes at the population level.

In addition, various measures of quality of life can be used. The simplest is a question on working status of the person on treatment. More elaborate measures include indices based on a set of questions related to the quality of life, e.g., standardized activities of daily living (ADL), self-reported health status in a series of domains such as mobility, cognition, and mental health. At the population level summary measures that combine mortality (years of life lost) with disability (loss of health years of life due to disability or nonfatal conditions) could be used to estimate the burden of disease due to HIV/AIDS (e.g., disability-adjusted life years (DALYs)).[46]

DATA COLLECTION

Monitoring the scaling-up of HIV therapy including antiretroviral treatment (ART) requires clinical records (with a home follow-up component, if needed, to maximize follow-up rates) that are able to provide individual level data for survival analysis. Because ART programs are still young and developing, many resource-constrained countries lack such data except for those collected in special studies.

Population mortality data are only available from countries with vital registration systems with high levels of coverage that are usually accompanied with high levels of medical certification of the cause of death. In countries without such a system, sample vital registration systems (e.g., India) or

demographic surveillance systems in local populations (e.g., Tanzania) may provide cause of death data, mainly through verbal autopsy. Special studies have also been conducted and may be institutionalized in the context of M&E. An example is mortuary investigation that allows HIV testing of corpses.[47]

Morbidity surveillance relies primarily on AIDS case reporting but severe underreporting limits the usefulness of these data in many developing countries. ART programs may improve this situation, especially if clinical and surveillance definitions are fully aligned.

ESTIMATION METHODS

The HIV/AIDS mortality levels and trends can be estimated from models that are based on HIV prevalence estimates through the use of standardized software.[26] The estimates of the incidence of AIDS cases are obtained from the same application. Survival rates of people who initiated treatment are generally computed using standard life table approaches (such as Kaplan-Meier survival analysis) to allow for left and right censoring.

BEHAVIORAL OUTCOMES

INSTRUMENTS

Sexual behavior data are an essential complement to biological evidence of changes in HIV or STD prevalence or incidence. Data on sexual behavior are generally self-reported and subject to multiple reporting biases. The validity and reliability of behavioral self-reports may not be high, as is also true for other sensitive topics such as substance abuse.[48] Individual interviews provide limited information on factors affecting the efficiency of transmission, particularly if the interviews between sexual partners are not linked and if the HIV status of the respondents is unknown. Self-reported condom use data are relatively easy to obtain in sexual behavior surveys, but, even if reporting is reasonably accurate, the ultimate impact of condom use on transmission efficiency is difficult to gauge without information on whether condoms are used during acts where sexual contact is between infected and susceptible persons.

Long questionnaires requesting specific details on most recent partnerships seem to lead to the reporting or registration of less sexual-risk behavior compared to much shorter instruments. For example, the four-city study that used the UNAIDS model questionnaire resulted in less disclosure of nonregular partners than the basic Demographic and Health Surveys (DHS) module on sexual behavior.[49] On the other hand, a detailed study in a community cohort study in Tanzania found good consistence between short and in-depth questionnaires on the last five partners within the last year.[50]

DATA COLLECTION

Structured face-to-face interviews are the dominant mode of data collection. Comparison of results from household surveys in low- and middle-income countries have indicated that reporting of sexual-risk behavior appears to be highly sensitive to survey designs.[48] Therefore, tracking of trends must be done by high quality surveys in which the methods of survey design and data collection are highly standardized and repeatable over time.

The ability of surveys to document trends can be illustrated with two examples from the USA and Zambia. Data from six surveys in the United States since the 1970s allow an assessment of trends in sexual behavior among adolescents.[51] Comparing measures over time was complicated because of differences in mode of administration of the questions, sample populations, definitions used, and survey implementation. The general picture, however, is consistent and shows some modest changes in sexual activity and an increase in condom use during the eighties and nineties.

In Zambia, which has a generalized AIDS epidemic, five national household surveys with questions on sexual behavior were conducted between 1996 and 2003.[52] These included two major types of survey design, two general Demographic and Health Surveys, and three Sexual Behavior Surveys, with similar kinds of questions on sexual behavior. Different survey methods produced significantly different estimates of sexual behavior, although some consistency in trends emerged. There is also evidence of changing reporting bias over time with respondents less likely to report a young age at sex in later surveys.

Several methods can be used as an alternative to try to elicit higher quality information on sensitive topics such as nonmarital sex.[48] These include qualitative methods to reduce the barriers to disclosure by gaining the trust of the respondents through unstructured, often repeated, interviews. Alternatively, it may be helpful to reduce or eliminate the interaction between data gatherer and respondent by using self-administered questionnaires, computer assisted interviews, and audio–computer–assisted interviews. In general, alternatives for face-to-face interviews yield higher and more plausible estimates of nonmarital sex but results are generally less favorable in low- and middle-income countries with lower levels of education and great linguistic variability.

The use of multiple methods of data collection, such as applying alternative methods to a subsample in a survey, may provide information to adjust for under- or misreporting in survey-based estimates. Moreover, biological validation, such as the detection of male semen in vaginal swabs, or the presence of an STD pathogen in genital secretions may provide additional information for validation purposes. Reporting biases are likely to be even greater among young people, especially young girls where sanctions against premarital sexual

behavior may be more severe. For instance, in a study of secondary school pupils in Zimbabwe only 13% of those infected with HIV and/or an STD admitted to having had sex.[53] In general, however, more work is required in this area to better understand the complex societal and individual factors creating biases in self-reported behaviors.

Estimation methods

No widely accepted estimation methods to correct for biases or fill data gaps are currently available.

OUTPUTS: INTERVENTION COVERAGE

■ INSTRUMENTS

Coverage can be defined as the proportion of people who receive a specific service among those who need it. It is a combination of service provision and health-seeking behavior by those who need the service. Coverage of the target population by intervention programs can be measured in different ways. The first is based on the number of people using the services from provider records. Such records provide counts of the number of events of interest, which is the numerator of the coverage estimate. Accurate data on the denominator may be harder to obtain depending on the type of coverage estimate. For instance, the need is best defined if it is recommended for a well-defined population group, e.g., an HPV vaccination program aiming to provide 3 doses to all women up to age 26 years. For treatment coverage it is often much harder to estimate the true need, e.g., the proportion of men with chlamydia infection who receive appropriate treatment.

The second method uses interview questions in household or risk population surveys. The respondents are asked questions about exposure to specific interventions. The reliability and validity of the results are affected by two factors. First, it is determined by the extent to which the intervention can be defined unambiguously and clearly in a brief question, the presence of factors that affect reporting by the respondent (e.g., stigma, cultural norms, intervention programs), and the quality of the interview and survey in general. Second, it also depends on how accurately need can be measured. For instance, estimates of coverage of condom use at last higher risk sex depend on how well the respondent reports on higher risk sex. Estimates of STD treatment coverage depend on the ability and willingness of the respondent to report a recent STD episode.

Ideally, data are collected on all steps from identification of the need to successful or effective treatment. For instance, for an STD infection this requires information on the prevalence of infection among the target population, the proportions who are symptomatic, recognize symptoms, seek care, receive care, quality of diagnostic and treatment care, and the efficacy of treatment. For prevention of mother-to-child HIV transmission, information is needed about antenatal care attendance, exposure to counseling, HIV testing, feedback of results, treatment provision and use among HIV-infected women, and the efficacy of treatment.

■ DATA COLLECTION

Data on exposure to interventions and coverage are primarily collected through household or risk population surveys. Such data may include condom use at last sex with a high-risk partner, utilization of voluntary counseling and testing services, HPV vaccination, or exposure to specific radio programs.

Service records are also used, but detailed monitoring of completeness of reporting and evaluation of reporting patterns and frequencies over time are necessary.

■ ESTIMATION METHODS

The denominator is often estimated if service records are used but otherwise no standard methods are available to estimate coverage or exposure to interventions. The estimation of some denominators is relatively straightforward. For instance, the denominator of a coverage estimate for an HPV immunization program can be drawn from census data on the number of 9- to 26-year-old females in the population. Similarly, the denominator of a coverage estimate for prevention of mother-to-child transmission of HIV programs can be obtained directly from data on HIV prevalence among pregnant women and number of pregnant women or deliveries in a population, or indirectly from census projections of the population by age and sex. Others are more difficult, e.g., the denominator of a voluntary HIV testing and counseling indicator, as the number of persons and the number of times the same person needs to be tested are subject to discussion.

EVALUATION

Evaluation aims to assess whether and how programs are successful in bringing about the anticipated improvements in health in order to strengthen their effectiveness. This requires careful measurement of the exposure to interventions, non-intervention factors affecting the outcomes, and accurate measurement of behavioral and biological outcomes before any effects can be attributed to interventions. Furthermore, a specification is required of the pathways through which programs can affect behavioral and biological outcomes, which includes nonprogram factors, such as sociocultural and economic determinants, a hierarchical structure of determinants, and a specification of interactions between different levels of the framework. Evaluation or evaluation research, as it is sometimes referred to, should be distinguished from research conducted to prove the efficacy or effectiveness of a

specific intervention. For instance, randomized community trials have been conducted to examine the effectiveness of male circumcision as a way to reduce HIV incidence among men.[54–56] The research results are leading to the incorporation of male circumcision into prevention programs. Evaluation studies are needed to assess the impact of such programs on HIV incidence.

FRAMEWORKS

A conceptual framework for the evaluation of programs or specific interventions presents a schematic simplification of the possible links and pathways between intervention and the outcome of interest. This section describes different elements of and approaches to the development of an evaluation framework.

EVALUATION AS AN INTEGRAL PART OF MONITORING SYSTEMS

Comprehensive program evaluation may focus on national or subnational levels. A major focus is on involvement of the program staff at all stages and program improvement is a primary goal. A utilization-focused evaluation approach is generally developed at the start of a program with strong involvement of program staff.[57,58] Such an approach also includes an evaluation of actual use and learning of what factors enhanced or inhibited use. External accountability is only a secondary objective.

First, a basic program logic model is developed to describe characteristics of program implementation and to specify expected outcome and impact of the program. Program staff, with or without external involvement, should conduct process or implementation evaluations before conducting outcome evaluations and outcome evaluations before conducting impact evaluations.[58] Figure 98-4 shows an example of an evaluation framework used for HIV prevention programs in the USA. The process evaluation activities on the left of the framework provide information on where resources are spent, the quality of prevention programs, the implementation status, and the ability to reach the people for whom they are intended. The next set of evaluation activities involves outcome evaluations that tell whether the programs are making a difference in changing behavior. Impact evaluation activities provide information on whether overall prevention efforts are carried out on a large enough scale and with sufficient intensity and duration to make a difference in HIV transmission in a given population. Finally, policy and economic evaluations are conducted to provide information on the political and social effects and the relative costs and effectiveness of prevention.

The California HIV Prevention Indicators Synthesis Project is a good example of a comprehensive effort to monitor HIV prevention efforts and outcomes, with strong stakeholder participation.[59] The indicators are divided into six groups: policies, characteristics of prevention interventions, characteristics of populations, utilization of interventions, risk taking and protective behaviors, and disease impact. The grouping is along the lines of the conventional monitoring and evaluation framework (input- output–outcome- impact) with the addition of the epidemiological context (characteristics of population), including size and HIV prevalence of different risk populations. For many indicators, annual data are available and for others there is a need for special surveys. For every variable there is a need to carefully interpret the data and take into account known and unknown biases.

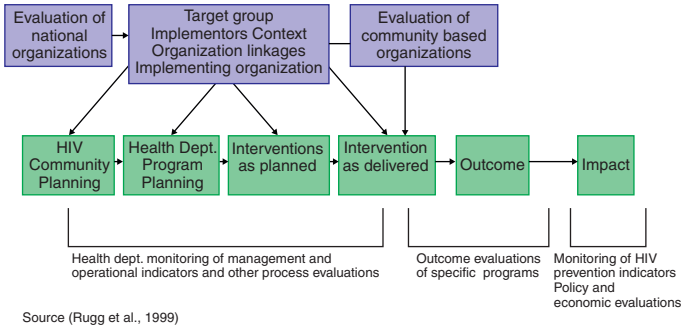

FIGURE 98-4. Evaluation framework for HIV prevention programs, USA. (From Rugg D, Buehler J, Renaud M, et al. Evaluating HIV prevention: a framework for national, state and local levels. *Am J Eval* 1999; 20: 35–56.)

POPULATION AND INDIVIDUAL VARIABLES

The importance of both macro- and microlevel factors necessitates the use of more complex models and analyses to study the causes of infectious and chronic diseases. The comparative study of HIV and STD epidemiology across populations and evaluation of similar preventive programs and interventions in different settings have highlighted the importance of contextual factors in HIV and STD epidemiology and preventions.[60] Such factors not only affect the prevalence and incidence of HIV and STDs but also the effectiveness of interventions.

In STD and HIV research the importance of population-level factors in shaping the epidemics and risks among individuals further corroborates the need for comprehensive models that include population-level and individual-level factors that contribute to disease outcomes. Multilevel analysis has emerged as a powerful statistical tool that allows the inclusion of population and individual-level variables in the same model. It is important, however, to realize that in addition to multilevel statistical analyses, the more general issues of investigating the determinants of outcomes at multiple levels are necessary.[61]

Population impact

The population impact of an intervention can be estimated from three factors[62]: efficacy of the proposed intervention, proportional contribution of the outcome of interest, and effective coverage of the intervention. These factors need to be taken into account when developing an evaluation framework. All three components face measurement challenges.

The efficacy of an intervention is generally derived from research studies. A randomized controlled trial (RCT) is the preferred method of establishing that an intervention is efficacious, but the body of RCT evidence for HIV and STD prevention is small at best. An extensive review of RCTs of individual-level, population-level, and multilevel interventions for preventing STDs, including HIV, identified 83 trials of which 41 met the inclusion criteria.[63] Interventions to prevent STDs can be classified according to level of intervention (individual, group, or community), modality of intervention (behavior change, treatment, vaccine, structural change, screening, microbicide, and surgical change), and outcome measured (acquisition in the uninfected individuals, transmission to susceptible individuals by infected individuals, and complications). Only one intervention showed efficacy against sexual transmission of HIV but 22 showed effectiveness against other STDs. In 2007, the results of three research studies in sub-Saharan Africa on the effect of male circumcision on HIV incidence in men could be added to that list.[54–56]

To estimate the fraction of the total transmission or poor health that can be addressed by the intervention is difficult and can be highly variable between populations. Grassly et al.[64] show how the ultimate impact of an intervention in reducing sexual behavior risks is strongly affected by the socioeconomic setting and public health capacity. The epidemiological context determines whether such risk reduction translates into a measurable impact on the rate of HIV incidence. Four measures of the epidemiological context are the phase of the epidemic (characterized by HIV prevalence or incidence to prevalence ratios[41]), cofactor STD prevalence, mixing of target population with other at-risk populations, and sexual behavior of populations not targeted by the intervention. The epidemiological context is dynamic: three of their four measures can be changed by interventions, the fourth (HIV prevalence) affects the probability of exposure and will change as a result of changing incidence and mortality.

The interpretation of the discrepant results of three community-randomized trials of the impact of STI treatment on the prevention of HIV infection in Mwanza, Tanzania, and Rakai and Masaka, Uganda provides an illustration.[40, 41] A synthesis of the evidence indicates that epidemiological differences between the populations were the most important explanation for the low trial impact in the Ugandan studies compared to the large impact in Tanzania. Simulation modeling of HIV and STI transmission showed that the considerably lower prevalence of curable STI due to lower risk sexual behavior and the mature HIV epidemics, with most HIV transmission occurring outside core groups with high STI rates, in the two Ugandan studies were the key factors in the differential impact.

Finally, coverage of interventions or programs has several dimensions, including need for treatment, quality of care and treatment, and user adherence. Effective coverage has been defined as the probability that individuals will receive health gain from an intervention if they need it.[65] This definition requires distinguishing between perceived and true need, which may be affected by socioeconomic, cultural, and personal factors (including treatment expectations). Biological factors such as type of STD may also play a role. Effective coverage also captures quality of the intervention and adherence to treatment.

AN EPI–DEMOGRAPHIC FRAMEWORK

The proximate determinants model presents a conceptual framework for the study of the distribution and determinants of HIV infection in populations by combining demographic and epidemiological approaches that have been used extensively in fertility and child survival research[66] (Fig. 98-5). The framework links the social system, which includes the programs and interventions, to the biological system, including the health outcomes, through a set of variables called proximate determinants, which can be influenced by changes in contextual variables or interventions. These proximate determinants affect health outcomes through a set of biological mechanisms which are the components that determine the reproductive rate of infection, defined as the average number of secondary cases that arise from any new case of infection.[67] Models of transmission suggest that this reproductive number is determined by the product of three biological factors: the rate of contact between susceptible and infectious persons, the efficiency of

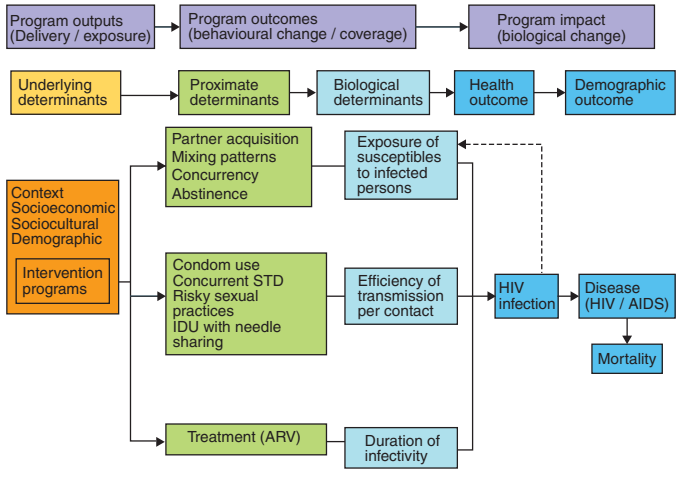

FIGURE 98-5. Proximate determinants framework showing the links between interventions programs and biological outcomes in HIV.

transmission during exposure between susceptible and infectious partners, and the duration of infectiousness.

The underlying social, economic, and environmental determinants must operate through proximate determinants to affect the biological outcome. The distinction between underlying and proximate determinants is important for the conceptualization of pathways through which underlying determinants, including interventions, may affect infection.

Even though the conceptual framework is primarily designed for the study of the distribution and determinants of disease, it can be used for intervention research since programs will have to influence one or more proximate determinants to affect HIV and STD transmission. The framework makes the pathways more transparent by which the components of a prevention program can be effective by targeting proximate determinants and underscores the limited utility of program outcomes such as increased knowledge of transmission if there is not an accompanying change in any of the proximate determinants. For example, an AIDS prevention program (an underlying determinant) may aim to increase knowledge of the modes of HIV transmission (another underlying determinant), delay sexual initiation (a proximate determinant of exposure to HIV), and increase condom use and early detection and treatment of STDs (two proximate determinants of the efficiency of transmission).

The proximate determinants schema described in Fig. 98-5 is deliberately simple and is meant to outline a process moving conceptually from underlying determinants on the left to mortality on the right. The schema does not attempt to show the complex interactions that may occur between the underlying, proximate, and biologic determinants, nor include feedback mechanisms that link outcomes on the right with determinants on the left. However, one critical feedback mechanism, HIV prevalence, is included in the schema due to its importance in estimating the probability of exposure of susceptible to infected persons.

STUDY DESIGNS

There are a number of criteria that need to be taken into account when choosing a study design for evaluation purposes.[68] The single most important criterion in assessing a method is the validity of its estimates of program impact. Other criteria include required assumptions for the method, ability to isolate program effects, costs, data requirements, and ethical considerations.

Three types of scientific inferences can be distinguished for making health policy decisions.[69] Probability statements are based strictly on RCT results. While RCTs are the gold standard for clinical decision-making purposes, they are often not sufficient by themselves for public health evaluations. Causal chains in public health are complex and require further analyses for adequacy and plausibility.[70] Plausibility statements are derived from evaluations that aim to make causal statements using observation designs with a comparison group. Adequacy statements result from demonstrations that trends in process indicators, impact indicators or both show substantial progress, suggesting that the intervention is having an important effect.

Interventions are usually multiple, their pathways to impact are complex and subject to effect modification; the intervention outcome association varies according to the presence of external factors. This may be behavioral or biological effect modification that affects the external validity of the evidence from the trials. Therefore, an intervention that works well in a given setting may be ineffective elsewhere. Evidence-based public health must rely on a variety of types of evidence.

The main challenges for evaluation of the effectiveness of programs are to carefully document trends in health outcomes and to assess whether such changes can be attributed to the programs. To be able to attribute changes to programs, evaluations need to reduce the noise introduced by nonprogram related factors as much as possible.

RANDOMIZED EXPERIMENTS

Randomized experiments are a key instrument for research on the efficacy of interventions. Evaluation research generally does not use this type of study design, as it requires major investments and is often directed toward a single intervention. Evaluation, however, may make use of methods that aim to come close to the gold standard for measuring what has happened as a result of an intervention and provides the strongest evidence of effectiveness or impact. In a randomized experiment, study subjects or groups are assigned to "treatment" and control or comparison groups randomly. Given a sufficiently large sample size, randomization enhances the chances of isolating the effects of a program or intervention by distributing confounding factors other than the exposure to the intervention equally across groups. The intention-to-treat analysis is an adaptation that allows the inclusion of all randomized individuals in the groups to which they were randomly assigned, regardless of the treatment they actually received, and regardless of subsequent withdrawal from treatment or deviation from the protocol. Such analyses, therefore, provide an assessment that takes into account issues such as noncompliance.

STD and HIV prevention programs are suited to be evaluated using community randomized control trials. The unit of randomization in such trials is the community. This design can be used to estimate the indirect or total effects of an intervention, i.e., the effects on the treatment or vaccine but might have been indirectly protected because the intervention reduced STD or HIV prevalence in the community. An application of such a trial in Mwanza, Tanzania to assess the effect of STD case management on HIV incidence used

six pairs of intervention comparison communities in three geographic strata (roadside, rural, and island communities).[71]

Despite being the gold standard, randomized experiments have been used less than is desirable on scientific grounds in public health, including the field of HIV and STD.[68] First, trials are costly and time-consuming. The need to measure HIV or STD incidence rates implies the need for large sample size. Changes in the HIV or STD incidence rates can only be expected after the program efforts have matured in a community setting and the measurement of medium and long-term health impact takes time. Second, political and ethical issues are often raised because of concerns about withholding a (potentially) desirable program from some parts of the population and may lead to opposition to the trial. Third, the generalizability of the findings of a trial, conducted in one or two localized areas may be challenged. Finally, randomized experiments are subject to several potentially serious threats to validity including contamination of the comparison group if exposed to the intervention, confounding external influences, and variations in treatment (the intervention or program). Randomized experiments, however, tend to be less vulnerable to such biases than all other evaluation designs.

QUASI-EXPERIMENTAL STUDIES

The term "quasi-experiment" refers to a group of experimental research designs in which study subjects or groups are not randomly assigned. Therefore, these studies are easier to conduct than experimental designs but are more vulnerable to threats to validity. The most commonly used quasi-experimental designs, referred to as "constructed control designs," involve the comparison of intervention and control groups that have not been randomly selected.[72] In other designs, referred to as "reflexive control designs," treatment group subjects or groups serve as their own controls and time series methods are used to measure net program impact. In a time series design, the effects of treatment or program interventions are inferred by comparing measures taken at many points in time before and after treatment or intervention. In a matched design, the response of the experimental group is compared to that of a "control" group before and after the intervention.

OTHER METHODS

A third approach consists of nonexperimental or observational study designs that have no experimental or control groups, per se. The treatments or interventions vary between populations and areas as a result of decision-making processes that are not controlled by the evaluation. Also, the criteria used to target programs or allocate resources may not be known to the evaluation researchers.

Observational studies may include cohort studies with concurrent controls, cohort studies with historical controls, and case-control studies. Cross-sectional surveys with no control groups may be repeated surveys in target populations and pre-post intervention surveys. The repeat studies may have a panel design in which data are collected from the same communities or facilities at least twice at different points in time.

In some cases, a placement bias may further complicate evaluation. The interventions and programs are focused on populations and areas where the problems are thought to be greatest or most amenable to program success. This effect, also referred to as endogeneity, has implications for the analysis, which must use multiequation random effects or fixed effects panel models.

Multilevel regression analytical methods are a useful tool that allows simultaneous investigation of how population-level (or group-level) and individual-level factors contribute to health outcomes.[61] These methods are of particular importance for STD and HIV, where population-level factors play an important role in shaping the epidemics and risk of disease among individuals. However, they have implications for study design. Cross-sectional surveys need to be complemented by group or community-level data.

An example of a broad-based evaluation of a national program, using a wide variety of data sources is the Thailand HIV/AIDS success story which is listed among 17 major achievements in public health programs in the developing world.[73] It is one of the few well-documented national program success stories.[74] The national "100% condom program," required all sex workers in brothels to use condoms with clients. Health officials provided boxes of condoms free of charge and local police held meetings with brothel owners and sex workers. Improved STD treatment, including the opening of 508 district STD clinics and STD contact tracing into brothels was also part of the program. Multiple data sources provided the basis for the evaluation. Surveys with sex workers and young men conducted by the epidemiology division of the Ministry of Public Health were the core source of data on trends for key indicators. The use of condoms in brothels increased from 14% in 1989 to 90% by mid-1992. There were also declines in the self-reported rate of new partner acquisition. HIV prevalence in sentinel surveillance populations and the clinic-based incidence of STDs fell dramatically. Prospective cohort studies in several parts of the country confirmed the suspected decline in HIV incidence.

Multicountry studies are another way to enhance the power of evaluation studies. For instance, by using a similar design in several countries and interpreting the results from several countries in an integrated manner, the evaluation of the Integrated Management of Childhood Illnesses was able to draw convincing conclusions about the effectiveness of the program.[69]

CONCLUSIONS

Sound monitoring and evaluation have become a priority component of HIV/AIDS/STD prevention and control programs to improve programs, management-related decision making, and accountability. Particularly in low- and middle-income countries, international initiatives such as the UN Declaration of Commitment; the Global Fund to Fight AIDS, Tuberculosis, and Malaria; and the U.S. President's Emergency Plan for AIDS Relief are accompanied by lists of indicators and increased reporting frequency and quality demands.

Strengthening M&E and health information systems would be an important step in building program management capacity in many countries. Too often, M&E plans are not included at the set up and planning stage of programs and rather seen as an add-on to measure results (rather than being seen as a tool for learning and iterative improvements in management). Resource allocations at national level, and from external sources, are generally far below the recommended 5–10% of program cost. Focus on M&E from the planning phases should lead to increased investments in the generation and use of relevant program and health information. At the same time, this will help programs to show greater accountability both to the people they serve and to the donors that support them, often resulting in program achievements in excess of expectations.

Despite these encouraging results, many countries still do not have the capacity and systems in place to appropriately monitor, evaluate, and manage HIV and STD programs. Many countries have basic systems in place to track prevalence of HIV infection but such systems are far more limited for STDs. Systems to measure outcomes and impact are generally poor.

This weak capacity must be seen against the dramatic increase of resources to substantially scale-up programs in prevention, treatment, and care of HIV and STDs over the last decade. Without concerted efforts to strengthen M&E capacity, these new resources may not be spent in the most efficient ways, in the best case, or may be used for activities that may do more harm than good, in the worst case. The potential for development of resistance to antiretroviral drugs during large-scale treatment programs that are not appropriately monitored may be an example. Not only would treatments lose their power in the individuals living with HIV/AIDS under treatment but also the resistant strains might be transmitted to others, posing a serious, new challenge to health systems and societies.

Systematic learning through specific evaluations, and operational research, is even less developed than systems to monitor programs and defined health indicators. Most of the limited research done in developing countries that carry the vast majority of the global burden of HIV and other STDs is designed and implemented by research institutions in the high-income countries, and there is no consistent mechanism to collect and compile the many lessons learned, good or bad, from programs that have received substantially increased support in recent years.

New and positive developments include the increasing experience and much greater focus on biomarkers as part of population-based surveys. In an increasing number of countries, population-based surveys such as the Demographic and Health Surveys now include testing for HIV antibodies, greatly enhancing the understanding of level, distribution, and trends in HIV infection and its determining factors.

While much remains to be done, an analysis of other health fields shows that HIV may well serve as a forerunner for health and program measurement in other areas. The growing appreciation of the importance of M&E in the development of high quality HIV and STD prevention and control programs will greatly enhance progress in the field.

99 STD Vaccines

Michael L. Rekart and Robert C. Brunham

INTRODUCTION

In human history, no infectious disease has been eliminated (incidence ≤0.5/100,000) without an effective vaccine. Vaccines against sexually transmitted diseases (STDs) have incredible potential to save lives, reduce morbidity, decrease global STD expenditures, reduce HIV spread, prevent AIDS, and contribute to improved reproductive health. STD vaccines will also circumvent many of the very significant challenges to nonvaccine STD prevention and control strategies.

VACCINES AND SOCIETY

Society supports modern vaccines, but the vast number of illnesses avoided and lives saved are not widely recognized (Fig. 99-1).[1] As recently as 1967, when the smallpox eradication campaign entered its final intensified phase, there were an estimated 10–15 million cases of smallpox in 31 countries.[2] Since smallpox eradication in 1977, 15–20 million lives have been saved. By 1989, over 1.4 million deaths from measles, diphtheria, and pertussis had been averted by vaccination. By the turn of the century, vaccination campaigns against diphtheria, pertussis, and polio had achieved success rates as measured by cohort coverage of 92%, 99%, and 92%, respectively.[2] In 2002, the lives of 1.3 million children were saved by vaccines.[1]

Haemophilus influenzae type B (Hib) conjugate vaccine could avert 3 million cases of serious Hib disease and 400,000–700,000 deaths annually. The pneumococcal vaccine could save 1 million lives per year. Currently available typhoid vaccines with 50–70% efficacy have the potential to avert 16 million cases of typhoid fever and 600,000 deaths annually.[2] These authors agree that "vaccines are the cornerstone of contemporary medicine and the best approach to reduce morbidity and mortality due to infectious disease."[3]

With the global incidence of curable STDs at 300–350 million and the prevalence of viral STDs over 1 billion,[4,5] the potential for STD vaccines, even imperfect ones, to reduce morbidity and mortality is vast. Syphilis, gonorrhea, chlamydia, and pelvic inflammatory disease (PID) together rank second behind obstetrical causes among women 15–44 years of age in developing countries as a cause of disability-adjusted life years (DALYs) and HIV ranks fourth.[4,6] Among men, HIV is the leading cause of healthy life lost in this same age group. Tuberculosis, the most common AIDS-associated opportunistic infection in the world, ranks second in men and third in women as the cause of DALYs.[6]

Together with their long-term health consequences, including cancers, reproductive problems, neurological consequences, and chronic liver disease, the direct and indirect effects of STDs including HIV comprise a huge global burden on health. Even in rich countries, the impact of STDs is significant despite effective diagnostic, treatment and prevention interventions. Over 12 million Americans are infected with STDs annually, including 3 million teenagers, and five STDs were among the top 10 most frequently reported diseases in the United States in 1995 accounting for up to 87% of all communicable disease cases reported.[4] STDs, including HIV/AIDS, cost the health-care system in the United States around $12 billion annually.[7]

The promise of STD vaccines is more than a dream. In British Columbia, Canada, where the hepatitis B (HBV) vaccination program advanced from grade 6 immunization in 1992 to universal infant immunization in 2001 followed by immunization of high risk groups, hepatitis B incidence declined 81% from 7.4 per 100,000 in 1992 to 1.4 per 100,000 in 2003.[8] Acute hepatitis B was eliminated among adolescents (Fig. 99-2).

Vaccines are highly cost-effective. The traditional childhood vaccines (measles, polio, diphtheria, pertussis, and BCG) are cheap to manufacture, inexpensive to deliver, safe and highly successful.[2] Childhood vaccination with these antigens can lay claim to a cost-to-effectiveness ratio of $15–25 per quality-adjusted life year (QALY). Most other routine health-care interventions and prevention programs are more costly to deliver, usually hundreds or thousands of dollars per QALY.[2] The estimated cost per QALY for Hib vaccine is $21–480 and for HBV vaccine $8–219.[2]

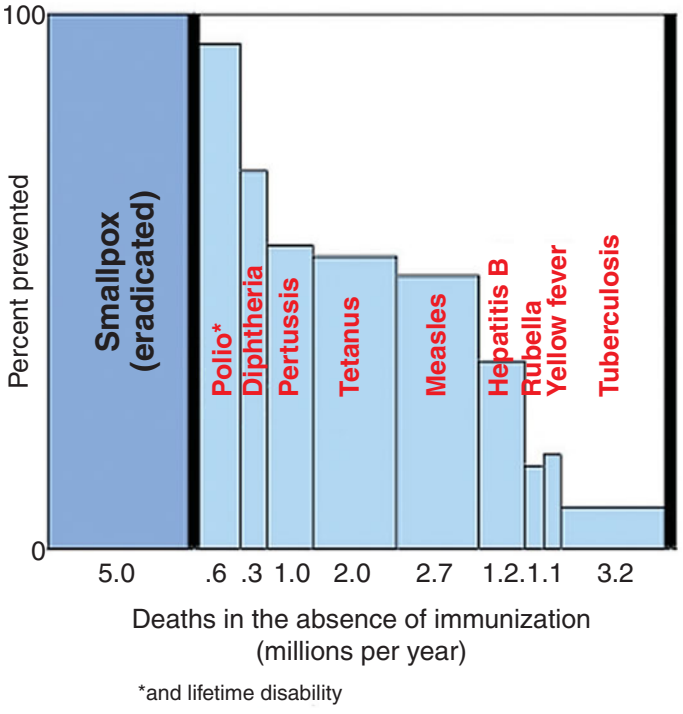

FIGURE 99-1. Deaths (global) from vaccine-preventable diseases in the absence of immunization (millions per year). * and lifetime disability (Reprinted from Diamond B. A real shot. *Nat Med* 2003; 11(Suppl 4): S3–S4. With permission from the Nature Publishing Group).

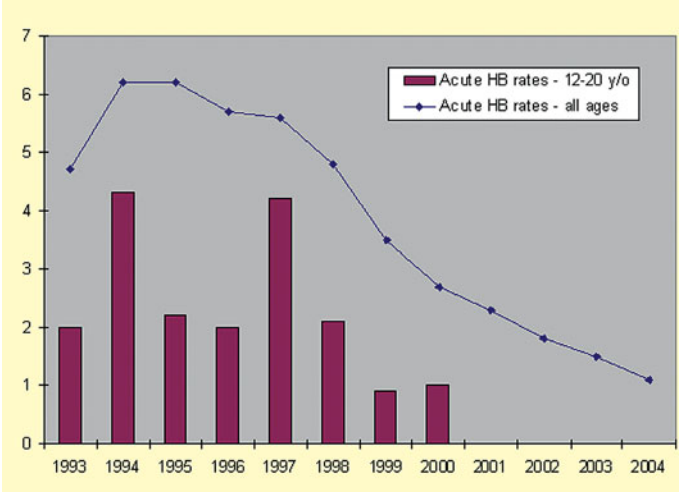

FIGURE 99-2. Acute hepatitis B (HB) rates (per 100,000) for the Province of British Columbia (blue line) and for the 12–20 year age group (red bars) after the introduction of HBV vaccination (Adapted from Patrick DM, Bigham M, Ng H, et al. Elimination of acute hepatitis B among adolescents after one decade of an immunization program targeting Grade 6 students. *Pediatr Infect Dis J* 2003; 22(10): 874–877.)

Effective STD vaccines could change the face of HIV and AIDS. In a systematic review, Rottingen and colleagues found that ulcerative STDs increased male susceptibility to HIV fourfold and female susceptibility threefold.[9] Nonulcerative STDs increased male susceptibility to HIV threefold and female susceptibility twofold. STDs significantly increase HIV infectiousness as well;[10] and HSV-2 and *T. pallidum* can directly increase HIV levels. Herpes simplex virus (HSV) infections, especially HSV-2, account for over 60% of genital ulcer disease worldwide. Its high worldwide prevalence, lack of a cure, frequency of reactivation, and ability to amplify HIV replication make HSV-2 infection the most important STD in the global HIV epidemic.[11] In Rakai, HIV risk in monogamous, serodiscordant couples was 70% higher in the presence of HSV-2 infection.[12] Wald found the population attributable risk (PAR) of HSV-2 for HIV acquisition to be 19% in populations with 22% HSV-2 prevalence and 47% in populations with 80% HSV-2 prevalence.[13]

STD vaccines will improve reproductive health, especially for women, children, and marginalized populations. PID and cervical cancer are examples. In the United States, over 1 million women experience acute PID annually with 100,000 becoming infertile as a result.[14] In sub-Saharan Africa, up to 40% of reproductive age women are infertile probably due to previous PID.[15] Cervical cancer, a malignancy associated with sexually transmitted human papillomavirus (HPV), was the second most common cancer (493,000 cases) and the most common cause of cancer deaths (274,000) among women in developing countries in 2002.[16]

VACCINES AND STD CONTROL

In addition to direct benefits, STD vaccines will circumvent the challenges to nonvaccine control strategies including behavioral change, societal impediments, biological obstacles, and translating intervention-trial efficacy into real-world effectiveness.

Several of the major determinants of sexual and health seeking behavior (substance use, knowledge, and personal skills) are not improving. Drug use is increasing in North America and globally; alcohol is almost universally legal and widely prevalent; and initiatives to combat drug and alcohol dependence have largely failed.[17] The proportion of 15–24-year-old females with adequate knowledge about HIV and AIDS is 30% for Latin America and the Caribbean, 23% for South Asia and Southeast Asia, 18% for sub-Saharan Africa, and 5% for Eastern Europe and Central Asia.[18] In 13–20-year-old students in Egypt, over 90% knew nothing about gonorrhea and syphilis.[19] In U.S. surveys, only one-third of adults have any basic awareness of non-HIV STDs.[4] Condom use in sex acts with noncohabiting partners ranges from 13% in Southeast Asia to 19% in sub-Saharan Africa.[18] In Haiti, Gabon, and Malawi, the percentages of 15–19-year-olds reporting an STD who sought care were 68%, 51%, and 42% respectively.[18] In the United States, less than 60% of persons symptomatic with an STD ever seek care.[4]

As a consequence, the global epidemic of HIV remains out of control with rising incidence rates in all geographic areas, both genders and all age groups.[18] In 2003, an estimated

4.8 million people were infected with HIV, the most for any year on record, and the proportion of sexually transmitted HIV/AIDS is increasing, mostly in women.[5,18] The global estimate of curable STDs changed little from 1995 (333 million) to 1999 (340 million).[5]

Sociocultural impediments to STD control include stigma and discrimination, sexuality taboos leading to lack of open discussion and unbalanced media messages, inadequate STD prevention and care services, low priority among decision makers, large social disruption, and widespread poor determinants of health.[4] According to UNAIDS, prevention services reach only 30% of men who have sex with men (MSM) in the Americas, 6% of MSM in sub-Saharan Africa, 32% of 2.5 million sex workers in sub-Saharan Africa, and 16% of 2.2 million sex workers in Southeast Asia.[18] In the Western Pacific, only 13% of primary school students have access to AIDS education.[18]

STDS are difficult to diagnose because of lack of symptoms, nonspecific symptoms, problems collecting specimens, and performing laboratory tests in the high-risk, and the lag time to complications. Most herpes infections are spread by asymptomatic and unaware index patients. Because STD complications occur months or years after the initial, often unrecognized, infection, STDs are often not associated in the public mind with serious illness. Treatment, a critical component in control, is restricted to bacterial and protozoan STDs. There are no cures for HPV, HBV, HSV, or HIV. Effective suppressive therapies for HIV and HSV are available but these are not accessible for patients in most of the world. For decades, effective prevention, treatment, and control strategies have been available for the "curable" STDs (gonorrhea, syphilis, chlamydia, and trichomonas), but this has not reduced their overall global incidence because of poor access and antibiotic resistance. STD vaccine delivery programs would be easier to implement, evaluate, and maintain, narrowing the dichotomy between intervention-trial efficacy and real-world effectiveness.[20,21]

Widespread and culturally ingrained cofactors exist that enhance STD transmission and are difficult to address including douching, the use of intravaginal substances, "dry sex," and the lack of male circumcision.[22] The latter has been linked to HIV infection (combined odds ratio 1.43, 1.32–1.54), urethral discharge, venereal warts, and chancroid.[23]

Because chlamydia protective immunity develops gradually over several months of infection, early treatment may block natural immunity and enhance the risk of reinfection.[24,25] The highest risk core transmitters reenter sexual networks sooner, get reinfected more easily and spread their infection throughout these networks more readily. This may explain increasing chlamydia rates in localities where chlamydia control has received priority attention. In British Columbia, the relative risk of chlamydia reinfection increased by nearly 5% per year over the course of an enhanced chlamydia control program from 1988 to 2004 (Fig. 99-3).[25] The relative risk was greater for younger individuals and women. Antibiotics have been shown to blunt the development of immunity to *C. muridarum* in mouse rechallenge models.[26] Mathematical modeling supports this hypothesis and suggests that the most efficient way to control or eradicate chlamydia in the absence of changing sexual networks is vaccination.[25]

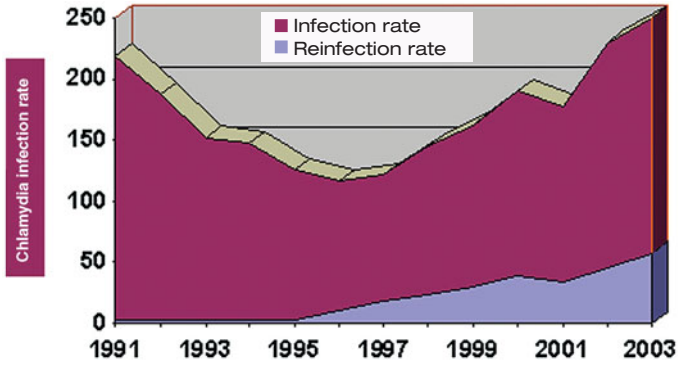

FIGURE 99-3. Annual rates of new case reports of total *C. trachomatis* genital infections (red and blue) and *C. trachomatis* genital reinfections (blue) for the Province of British Columbia (Adapted from Brunham RC, Pourbohloul B, Mak S, et al. The unexpected impact of a *Chlamydia trachomatis* infection control program on susceptibility to reinfection. *J Infect Dis* 2005; 192: 1836–1844.)

A similar immunity phenomenon has been reported for trachoma, an ocular *C. trachomatis* infection. Reinfection rates increased significantly in patients treated with azithromycin but not those treated with surgery.[27] Natural immunity may also be an important factor in syphilis epidemic cycling and reinfection rates after treatment.[28,29]

VACCINE BASICS

The word *vaccine* is derived from the Latin *vacca*, cow. Vaccines were named from Edward Jenner's use of cowpox virus inoculation against smallpox in 1796. A vaccine is a preparation of live, attenuated, or killed microorganisms or antigenic proteins derived from them, administered for the prevention, amelioration, or treatment of an infectious disease. Currently licensed vaccine formulations include live attenuated (measles), whole inactivated (hepatitis A), protein subunit (hepatitis B), polysaccharide (pneumococcal), and polysaccharide conjugate vaccines (*Haemophilus influenza* type B). DNA vaccine candidates are capable of inducing broad cellular immune responses whereas most licensed vaccines induce primarily a humoral antibody response. For tuberculosis, herpes, and HIV, cellular immunity plays a major role.

Live vectored vaccines are preparations of living, attenuated organisms (e.g., *vaccinia*) with pathogen genes inserted. Protective immune responses, especially cytotoxic T-lymphocytes, are generated against the pathogen and the vector. Vaccines often contain immune adjuvants, such as alum salts,

to improve the host antibody response. Virulence factors, such as adhesions and capsules, are preferred vaccine targets.

Human immunity is comprised of an innate and an adaptive component. Innate immunity defends against microorganisms via nonspecific immune responses to all antigens delaying the progression of infection so the adaptive immune system can respond more specifically and effectively. Adaptive immunity can be humoral or cellular. Humoral responses clear free virus particles from body fluids and prevent viral reinfection while cellular responses are directed at virus-infected cells and generating immune memory.[30] Humoral immunity is mediated by antibodies produced by B lymphocytes. Antibodies coat the invading microbe or cause conformational changes leading to pathogen inactivation, e.g., binding to cellular receptors preventing host cell entry. Cellular immunity, commonly called cell-mediated immunity (CMI), is mediated by T lymphocytes—$CD4^+$ helper cells, $CD8^+$ cytotoxic cells, and $CD4^+CD25^+$ regulatory cells. The CMI response involves both cytokine secretion and activation of immune cells—macrophages, natural killer (NK) cells, and antigen-specific cytotoxic T lymphocytes (CTLs).

Protective immunity relies on both humoral and cellular immune factors. Antigen recognition stimulates the activation and clonal expansion of antigen-specific B lymphocytes, which may ultimately protect against a secondary challenge as "memory B cells". Antibody-mediated protection may involve preexisting antibody, such as secretory IgA (sIgA) at the mucosal surface (sterilizing immunity) and/or a robust secondary immune response by serum IgG. After the expansion phase of CMI, 90% of activated cells die by activation-induced apoptosis. The remaining cells enter a memory phase, which can be maintained for long periods. These "memory T cells" are either resting or effector cells. Resting cells are found in the major lymphoid organs whereas effector cells reside in peripheral tissues. Effectors respond rapidly with cytokines and direct cytolytic activity.

The goal of vaccination is to provide at least the same degree and duration of protection as natural infection without the accompanying clinical illness. A good vaccine produces a humoral, cellular, and innate immune response protective against both clinical disease and reinfection for a lifetime with minimal immediate side reactions and no delayed effects. Administration would be simple, safe, and acceptable. The cost and benefits would outweigh the cost and risk of natural disease and the adverse consequences of vaccination.[31]

EVIDENCE FOR NATURAL IMMUNITY TO STDs

The immune system of the human genital tract is linked with the body's common mucosal and systemic immune systems. It also has unique elements. Attachment to host cells is a necessary first step in the development of infection and an immune response (see Chapter 13). Attachment (adhesion) can result in colonization, local inflammation, or invasion of the host. STDs may preferentially attach to specific cells, for instance, *N. gonorrhoeae* and *C. trachomatis* attach to columnar epithelium whereas HPV and *T. vaginalis* attach to squamous epithelium. The first lines of defense against attachment involve physical barriers (skin and mucous), the vaginal pH, and the symbiotic natural flora that discourages colonization by pathogens.

Mucous provides an obvious physical barrier to microorganisms but it also serves as a supportive substrate for opsonization by immunoglobulins and cytokine-enhanced phagocytosis. Rich in carbohydrate, the mucous may also directly interfere with adherence by binding to pathogens.[32] The stratified squamous epithelium of the vagina, ectocervix, penis, and glans represent a second barrier to infection. However, the epithelium of the cervical canal beginning at the transformation zone, the male urethra, the rectum, and the usually sterile upper female genital tract are composed of columnar epithelium, which is a single-cell-layer thick and allows antigens to be taken up more readily. STD pathogens have developed mechanisms to circumvent these defenses with varying efficiency. For example, *T. pallidum* results in new infection after 30% of sexual contacts whereas HIV transmission per sexual contact is usually less than 1%.

Innate immune responses occur quickly (within minutes), mediated by receptors that recognize stable, evolutionarily conserved signatures shared by large groups of pathogens. Innate immunity comprises: (1) ever-present antimicrobial factors, (2) early-induced cytokine secretion, (3) phagocytosis by neutrophils and macrophages, (4) lysis of infected cells by NK cells, and (5) antigen presentation to naïve T cells.[33]

Ever-present, constitutive, nonspecific antimicrobial factors include lactoferrin, natural antibody, complement, defensins, adhesions, and lysozymes ("the body's own antibiotic").[34,35] Lactoferrin, for instance, competes with pathogens for iron and has direct bactericidal activity. The male genital tract also contains zinc, polyamines, and prostaglandins.[32,36]

Cytokines are nonantibody proteins released by cells on contact with antigens that act as intercellular signalers/mediators in the immune response. Cytokines classes include (1) proinflammatory cytokines (e.g., interferon (IFN), interleukin (IL), tumor necrosis factor (TNF), granulocyte macrophage colony stimulating factor (GM-CSF), (2) chemokines (C-X-C family and C-C family), and (3) downregulatory cytokines [e.g., transforming growth factor (TGF)].

Pattern recognition receptors (PRRs), including toll-like receptors (TLRs), recognize stable, evolutionarily conserved signatures from pathogens [pathogen-associated molecular patterns (PAMPs)]. TLRs are expressed by antigen-presenting cells (APCs) in the genital tract—macrophages, dendritic cells, and neutrophils—and at lower levels, fibroblasts, endothelial, and epithelial cells. Recognition of PAMPs leads to cell activation, cytokine secretion, and attraction of inflammatory cells.[37]

After antigen is endocytosed, APCs migrate to regional lymph nodes where specific B and T cells activation takes place. Activated T cells then enter the circulation and "home" to tissues committed to antigen-specific responses.[32] This links the innate and adaptive immune systems.

In contrast to innate responses, the adaptive immune system involves a "learned response" that requires clonal expansion of T and B lymphocytes. This response is slower but more specific and long-lived. The adaptive system includes humoral and cell-mediated immune responses, both under hormonal control in females.

The humoral immune response to microbial invasion centers on the production of antigen-specific antibody (immunoglobulin) by plasma cells (derived from activated B cells), which bind microbial antigen and activate complement. Antigen–antibody complexes are then inactivated via agglutination and precipitation, blockage of pathogen receptor sites and phagocytosis. Antibody also activates complement to which pathogens succumb through a variety of mechanisms including opsonization. Immunoglobulin classes include IgA, IgD, IgE, IgG, and IgM. SIgA and IgM are produced locally by penile urethral and endocervical cells, especially the transformation zone;[35,38,39] however, most IgG in the genital tract is produced by B cells in lymphoid tissues in the rectum, small intestine, regional lymph nodes, and perhaps the nasal cavity.[40] These are called inductive sites. IgG predominates in most genital secretions, including semen and vaginal fluid, but IgA levels may be higher in cervical and urethral secretions and the preejaculate.[40] Nasal, vaginal, and perhaps transcutaneous administration of vaccine but not systemic, oral, or rectal immunization stimulate a mucosal immune response, especially sIgA, in the female genital tract.[32,39,40]

Antigen-specific antibodies are present in genital tract secretions after infection; however, their role in protection against infection is unclear. SIgA specific for pathogens such as *C. trachomatis*, *N. gonorrhoeae*, and *E. coli* has been found in semen and cervical secretions.[32] PID, tubal infertility, and ectopic pregnancy are associated with high titers of antibody to pathogens such as *C. trachomatis*.

Less is known about CMI than about humoral responses in the genital tract. Mediated by activation of $CD4^+$ helper and $CD8^+$ cytotoxic T lymphocytes, CMI responses include (1) direct lysis of infected cells, (2) activation of macrophages and NK cells, (3) stimulation of cytokines, and (4) antibody-dependent cell-mediated cytotoxicity (ADCC). T helper cells direct the immune response by stimulating the secretion of cytokines in two distinct pathways (Fig. 99-4).[41] The Th1 pathway is mediated by IL-12 and acts to enhance a predominantly CMI response to intracellular microbes through the synthesis of cytokines, especially IFN-γ and IL-12. IFN-γ activates the bacteriocidal activities of macrophages, NK cells and CTLs while inducing B-cells to produce opsonizing antibody.

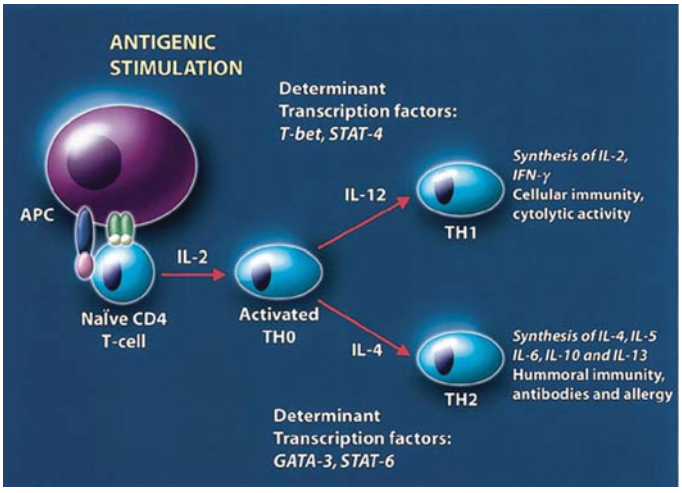

FIGURE 99-4. $CD4^+$ T-helper cell differentiation into Th1 or Th2 type depending on antigenic and cytokine stimuli. (Reprinted from Chinen J, Shearer WT. Basic and clinical immunology. *J Allergy Clin Immunol* 2003; 111(3): S814. With permission from the American Academy of Allergy, Asthma and Immunology.)

The Th2 pathway is mediated by IL-4 and acts to enhance a predominantly humoral immune response to extracellular pathogens through the synthesis of cytokines, especially IL-4 and IL-10, and the activation of B cells to produce neutralizing antibody. Specific transcription factors are required for each pathway: T-bet and signal transducer and activator of transcription (STAT) 4 for Th1 and STAT-6 and GATA-3 for Th2 cells.[41]

The extravasation of immune cells such as lymphocytes from the circulation into genital secretions is a CMI phenomenon called cell trafficking, which is controlled by adhesion molecules, e.g., intracellular cell adhesion molecules (ICAMs). After infection, genital tract epithelial cells produce cytokines that induce the expression of vascular cell and mucosal vascular addressin cell adhesion molecules (VCAMs and MadCAMs). DC-SIGN (dendritic cell-specific ICAM-3 grabbing nonintegrin) is a high-affinity ICAM-3 receptor expressed by dendritic cells.

In pregnancy, the maternal genital tract immune system must develop tolerance for a foetus with foreign antigens. Initially, the maternal–foetal interface is devoid of lymphocytes but later there is an influx of T lymphocytes with the placenta acting as an immunological barrier between the mother and the semiallogeneic foetus.[39] During pregnancy, a global depression occurs in T cell responsiveness to microbial antigens including STDs.[42]

Protective immunity for STDs requires durable humoral and CMI, including strong IgA responses, mediated by memory B and T cells. Systemic, rectal, and oral immunization are ineffective at inducing genital tract IgA antibodies. However, nasal and vaginal immunization have resulted in strong IgG and IgA antibody responses in the female genital tract and the serum.[43] These were strongest during the follicular phase of the

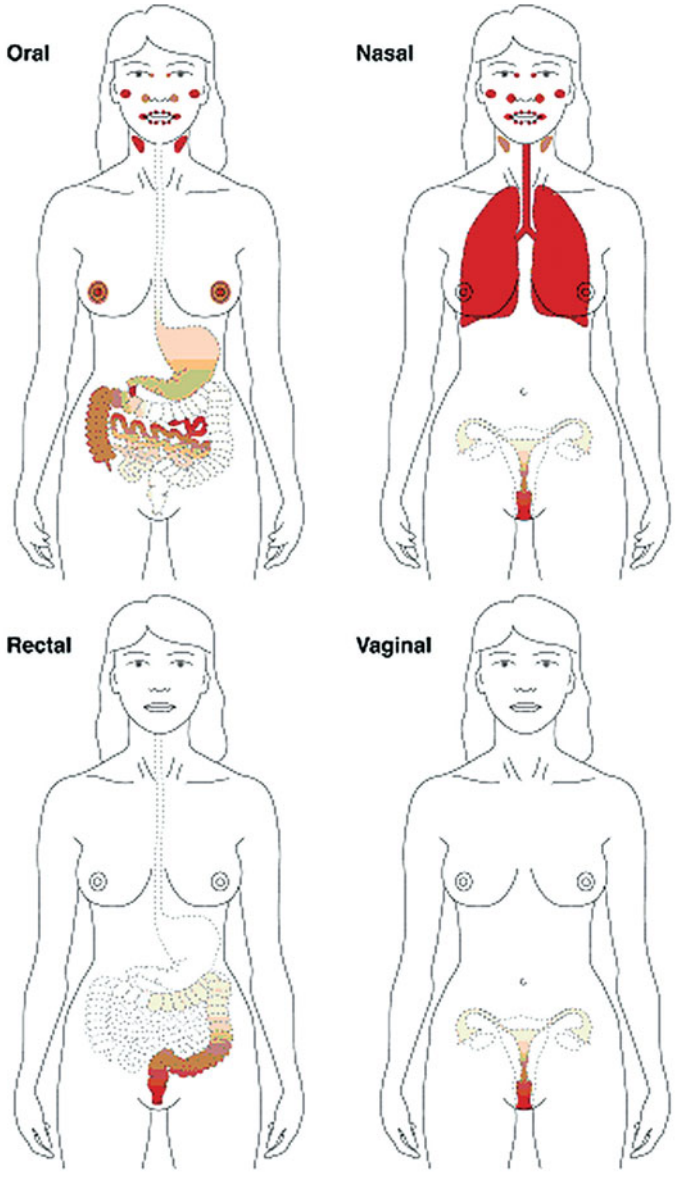

FIGURE 99-5. Routes of vaccine administration: Expression of mucosal IgA immune responses after different routes of vaccination. Shading indicates strength of response. menstrual cycle.[43] Collectively, these observations may affect STD immunization strategies (Fig. 99-5).

No STD stimulates complete protective immunity to natural infection, as occurs for several other vaccine-preventable diseases such as measles and pertussis. Distinctive immune evasion strategies are exploited by different STD pathogens. These strategies contribute to the long duration of infection and the extended time required for a protective immune response following infection.

HEPATITIS B VIRUS (HBV)

HBV preferentially infects hepatocytes but is not, itself, cytopathic. Innate, humoral, and cellular immunity all play critical roles in the host response. A vigorous immune response is delayed for about 2 months, probably due to the limited quantity of HBV antigen. At 4–7 weeks, a burst of HBV replication triggers the innate immune system, followed by the adaptive cellular response at 7–10 weeks and the adaptive humoral response at 10–12 weeks.[44] While the innate immune response predominates early, the coordinated and efficient activation of the adaptive humoral and cellular immune responses is ultimately responsible for control of HBV infection. A deficient adaptive immune response is associated with chronic HBV infection.[45–47]

The innate immune response within the liver relies on several cell lines including hepatocytes, NK cells, NK-T cells (NKT), and Kupffer cells, a macrophage unique to the liver.[45] Initially, infected hepatocytes produce IFN-α and IFN-β which interfere with HBV replication and activate macrophages which in turn secrete cytokines and chemokines. NK cells that are recruited lyse HBV-infected cells, downregulate HBV replication by producing IFN-γ and TNF-α, and produce chemokines that modify the polymorphonuclear (PMN) response.[44] In addition, liver-resident NKT cells mediate direct cytotoxicity, produce IL-4 and IFN-γ, and influence the priming of antigen-specific cells. Kupffer and dendritic cells link the innate and adaptive immune responses by acting as APCs.[44]

The cell-mediated immune response to HBV is characterized by vigorous multispecific, polyclonal antiviral $CD4^+$ and $CD8^+$ T cell responses to epitopes on all HBV proteins with a Th1 pattern of cytokine production.[46] T helper cells recognize viral peptides on APCs leading to activation and differentiation of B cells, and induction and maintenance of HBV-specific $CD8^+$ T cells. $CD4^+$ and $CD8^+$ T cells secrete IFN-γ and TNF-α and directly lyse HBV-infected cells. CTLs can "cure" hepatocytes of HBV particles, intermediates, and templates without killing them via an IFN-γ and TNF-α mediated process.[44]

The adaptive humoral immune response is characterized by the sequential production of antibodies against hepatitis B core antigen (anti-HBc), hepatitis e antigen (anti-HBe) and hepatitis surface antigen (anti-HBs). Anti-HBc is the first marker of HBV infection; anti-HBe is an early sign of recovery; and anti-HBs is neutralizing and associated with protective immunity after both natural infection and vaccination.[47]

The clearance of most HBV virions during the incubation phase of acute, self-limited hepatitis is followed by antigen-independent amplification of the HBV-specific T cell infiltrate in the liver. This process is mediated by chemokines and cytokines, especially IFN-γ, and likely accounts for disease pathogenesis, necroinflammatory liver disease and the clinical manifestations of acute hepatitis.[44–47]

After resolution of acute hepatitis, there is a substantial reduction in the absolute number of HBV-specific T cells but immune status is maintained for decades because of a very

high level of T cell responsiveness to HBV challenge.[44] Small amounts of transcriptionally active HBV probably persist in immunoprivileged sites maintaining cell-mediated and antibody-mediated immunity that, in turn, prevents HBV spread and reinfection. This nonsterilizing immunity is called concomitant immunity.

Chronic HBV infection in neonates probably results from a deficient early immune response during acute infection. However, chronic HBV in immunocompetent adults is associated with a narrowly focused and weak HBV-specific T cell response. Three explanations have been proposed: (1) insufficiently activated $CD8^+$ T cells due to partial HBV downregulation, (2) HBV replication outpacing the host response, and (3) viral escape through mutations in T cell recognition sites.[44,46] Although the T cell response in chronic hepatitis is too weak to eliminate HBV, it is likely strong enough to destroy small numbers of infected hepatocytes leading to the progressive necroinflammatory liver disease associated with chronic infection.[44]

The continuous stimulation of the antigen-specific immune response during chronic HBV infection increases the risk of progressive liver disease manifest as fibrosis, cirrhosis, and/or hepatocellular carcinoma.[45] HBe-Ag negative chronic hepatitis is characterized by a balance between HBV-specific T cells and lower levels of replicating virus resulting in less liver damage. A few patients exhibit complete recovery later with a loss of HBsAg, the major marker for active replication and infectiousness. This delayed recovery is associated with reactivation of the immune response possibly during clearance of HBeAg.[44]

Finally, it appears that high HBV viral load impairs the action of HBV-specific T cells during hepatitis and that these T cells recover when viral load decreases. In this context, the inhibition of HBV replication by antiviral drugs can restore the cellular immune response. This effect is greater for pegilated IFN than for nucleoside/nucleotide analogues.

HUMAN PAPILLOMAVIRUS (HPV)

Over 90% of incident HPV infections resolve spontaneously, presumably due to an effective immune response.[48] Other markers of an effective immune response include the rarity of reinfection with the same serotype, the lack of recurrence after ablative therapy for preinvasive lesions, the age-dependent natural history of HPV infection, the increased risk of infection in immunosuppressed patients, and the active immune response during lesion resolution.[49,50]

HPV replicates in an immunological privileged site, the keratinocyte. HPV evades the innate immune response by delaying nuclear condensation (and premature death) in the infected, differentiating keratinocyte forming the koilocyte, an abnormal, pyknotic vacuolated epithelial cell characteristic of HPV infection.[30] The virus-laden koilocyte then dies of "natural causes" and desquamates, far from immune surveillance, without releasing proinflammatory cytokines to alert the immune system.[30] Additionally, high-risk HPV subtypes downregulate IFN-α-inducible gene expression, an antiviral defense mechanism; and HR(high risk)-HPV oncoproteins E6 and E7 directly block the interferon signaling system and deregulate key cell cycle check points.[30] This local immune nonresponsiveness and low levels of viral proteins compromise the antigen processing and presentation functions of the dendritic cells in the squamous epithelium [Langerhans cells [LCs]).[30,50] The HPV antigen-specific effector cell response is thus weak or absent. With host defenses irrevocably compromised, unimpeded E6 and E7 oncoprotein expression can result in progression to high-grade intraepithelial lesions and invasive carcinoma.[30]

In most incident HPV infections, however, an effective innate immune response involving immune cells (phagocytes, LCs, and NKs) and cytokines (IFN-α, IFN-β, IL-4, and GM-CSF) allies with a strong, local CMI response leading to regression of lesions and serum neutralizing IgG antibody formation against the HPV major capsid protein L1.[30,51–53] Type-specific antibody seroconversion occurs within 18 months in 60% of HPV-16, 54% of HPV-18, and 69% of HPV-6 incident infections.[54] In natural infection, anti-L1 antibodies are stable for at least 10 years and memory B cells specific for HPV-16 and 18 have been shown.[55] Cross-reactivity at nondominant neutralizing epitopes has been demonstrated between types 6 and 11, types 31 and 33, types 16 and 31, and types 18 and 45.[30] Seronegativity can occur with transient infections and with persistent infections. Peak antibody levels are low; however, seropositive animals are protected against reinfection and this protection is serum-transferable.[30,56,57] About 50% of women with cervical cancer show antibodies to E6 and E7.[30]

The key immune response involved in the clearance of HPV infection is CMI with Th1-type immunity controlling the outcome of HPV infection. Regressing HPV lesions are correlated with local mononuclear cell infiltration and Th1 cytokines. Systemic, HPV-specific, T cell responses, such as cytotoxic T cells and DTH measured by skin testing, have also been detected in patients with regressing lesions. Immature dendritic cells present in the genital squamous epithelium (LCs) act as APCs promoting the production of HPV-specific $CD8^+$ and $CD4^+$ cells that release cytokines (including IFN) and directly lyse infected cells. Regression is also associated with significant induction of adhesion molecules (ICAM1 and VCAM1), which direct lymphocyte trafficking.[59] Nonregressing genital wart lesions, on the other hand, lack immune cells.

A role for $CD4^+CD25^+$ T regulator cells (T regs) in the natural immune response to HPV infection may be emerging. Normally, T regs suppress the immune system to prevent self-reactivity (i.e., autoimmune disease) via cell-to-cell contact and by secreting the immunosuppressive cytokines IL-10 and

transforming growth factor (TGF) β. Accordingly, T reg activity is normally downregulated during immune responses to infecting microorganisms to facilitate their elimination. Some pathogens may have evolved immune evasion mechanisms that stimulate T reg activity to immunosuppress the host and improve their own chances of survival.[59] HPV has been implicated in this phenomenon along with retroviruses, Leishmania, and malaria.[60]

A shift from Th1 to Th2 cytokine production may correlate with more extensive HPV infection and carcinogenesis.[61,62] Immunosuppression is associated with HPV persistence and resistance to treatment. Genetic defects affecting humoral immunity have little effect on HPV infection whereas persons with CMI deficiencies have higher HPV prevalence.[30] Despite the evidence of a central role for CMI, the highly successful results of recent HPV vaccine studies defines a key role for the humoral response in preventing both progression and incident HPV infections.[63–65]

HERPES SIMPLEX VIRUS (HSV)

Human herpes viruses have developed an array of mechanisms to evade the host immune response. These include targeting of antigen presentation, resistance to complement (mediated by glycoprotein C), inhibition of antibody binding (mediated by glycoproteins gE and gI) and blocking of CTL activity through inhibition of caspase activation.[66] Latency-reactivated viral production evades the immune response by replicating in an immune-privileged site and by downregulation of the Th1 antiviral response.

During early, primary infection, host resistance relies on innate immunity—IFN, macrophages, and NK cells. Within a few days, the adaptive immune system responds with neutralizing antibody and CMI, including $CD4^+$ and $CD8^+$ T cells and antiviral cytokine release.[66–68] In recurrent HSV, the immune response is activated more rapidly resulting in shorter duration of lesions and viral shedding. CMI appears to play the central role.[68] Accordingly, mucocutaneous herpes is more severe with impaired CMI than with deficiencies in humoral immunity.[68]

The immunohistology of recurrent HSV lesions reveals an initial infiltration with macrophages and $CD4^+$ lymphocytes followed by an influx of $CD8^+$ lymphocytes.[67] The late introduction of $CD8^+$ cells is probably a function of the ability of HSV to downregulate MHC class I expression on the surface of infected epidermal cells. $CD4^+$ cells appear earlier than $CD8^+$ cells since they are able to recognize infected epidermal cells expressing MHC class II. By secreting IFN-γ, $CD4^+$ cells partly restore MHC class I expression allowing recognition by $CD8^+$ lymphocytes which mop up the remaining infected cells.[67] Herpetic lesions demonstrate a Th1-pattern of cytokine production resulting in the secretion of IL-12, TNF-α, IFN-α, and IFN-γ. These cytokines attract monocytes and T lymphocytes, enhance $CD4^+$ lymphocyte secretion to a T-helper pattern, activate $CD8^+$ cytotoxic lymphocytes, and directly eliminate virus-infected cells.

IFN-γ plays a particularly key role by upregulating MHC classes I and II, activating macrophages, purging infected cells of viral proteins, and preventing HSV spread in concert with IFN-α.[67] T cell production of IFN-γ and T cell-stimulated NK activity correlate with fewer recurrences. This is called relevant immunity. Persons with frequent recurrences show lower levels of HSV-specific IFN-γ, higher levels of downregulatory Th2-type cytokines and higher titers of serum HSV antibody.[66,68] Asymptomatic HSV shedding probably results from resumed transcription of latent HSV DNA under the control of stress-induced cellular proteins with intact antiviral Th1 immunity whereas symptomatic recurrences may reflect unimpeded viral replication through downregulation of the Th1 response.[66]

Humoral immune mechanisms also have an important role in controlling infection. HSV surface glycoproteins are the targets for neutralizing IgG antibodies and antibody-dependent cell-mediated cytoxicity (ADCC). Secretory IgA likely plays a minor role.[69] HSV monoclonal antibodies protect against neurologic disease and prevent latency in animal models.[70] The quantity of neutralizing and ADCC cytoxic antibodies correlates inversely with disseminated disease in newborns but correlates directly with high frequency and severity of recurrent disease in adults. This paradox may reflect a more severe primary infection and repeated antigenic stimuli during recurrences.[71]

The HSV immune response is not optimal but several lines of evidence indicate that an effective vaccine against herpes type-2 is possible: (1) transplacentally acquired HSV-2-specific maternal antibodies are associated with reduced perinatal HSV-2;[72] (2) new infection with the same HSV-2 subtype is rare;[72,73] (3) prior HSV-1 infection ameliorates subsequent HSV-2 disease;[72,74] (4) humoral and cellular immune responses have prevented HSV in animal models;[72,75] and (5) humans develop postimmunization neutralizing antibodies to HSV-2 similar to natural infection.[72]

NEISSERIA GONORRHOEA

Potent virulence mechanisms characterize the pathogenesis of *N. gonorrhoeae* including a weak antibody response, pronounced antigenic variation, resistance to complement-mediated bacteriolysis, production of an effective IgA protease, deployment of antibody blocking strategies, and minimal protective immunity.[76] Absence of an adequate nonprimate animal model has impeded research into the immune response. Furthermore, gonococci grown in vitro may bear little similarity to organisms causing in vivo infections.[76] Barriers to the development of a gonococcal vaccine are formidable.

Little is known about the innate immune response or the effect on gonococci of local microflora, pH, and mucous. However, gonococci can effectively use lactoferrin-bound iron. The intense inflammatory response reflects the failure of innate defenses. Leukocyte homing and phagocytosis occur but whether opsonins are required and whether organisms can survive ingestion is controversial.[77]

The adaptive humoral immune response to a single infection with *N. gonorrhoeae* does not result in solid immunity to reinfection with all strains. The outer membrane of the gonococcus contains several proteins, which stimulate serum antibody production. Pili, Protein I (PI or Por), and Protein II (Opa) are the predominant antigens in the local humoral immune response.[78] Naturally occurring serum bactericidal antibodies to gonococci have been demonstrated prior to infection and strain-specific antibodies have been shown in immune sera. Both are mostly IgG.[78] Antigonococcal IgG, IgA, and IgM have been detected at the genital mucosal surface. IgA levels were often higher than those in serum at the time of infection but rapidly decreased.[78] The predominant immunoglobulin in genital secretions in gonorrhea appears to be IgG in females and IgA in males.[78] Gonococci from patients with disseminated infection are resistant to the killing action of most normal and convalescent human sera. This is called serum resistance.

CMI responses during gonococcal infection have been clearly identified. Peripheral blood lymphocytes are capable of ADCC and possess natural killing activity against *N. gonorrhoeae*.[79] Fallopian tube lymphocytes produce antigonococcal cytokines (including TNF) which may cause ensuing fallopian tube damage.[79] Antigen-specific T cell responses directed against Por have been demonstrated in humans.[80] The cytokine profile of Por-specific T cells suggests a predominantly Th2 response with the production of IL-4. Antigenic presentation and resultant T cell stimulation may occur locally, systemically, or both.[80] Delayed-type hypersensitivity (DTH) has also been documented.[81] In vitro gonococcal binding to $CD4^+$ cells arrests activation and proliferation, perhaps interfering with T cell memory.[82] Overall, there has been no consistent correlation between the development of gonococcal-specific CMI and protection.

CHLAMYDIA TRACHOMATIS

The development of a vaccine for *C. trachomatis* may be easier than for *N. gonorhoeae*. Chlamydia is not nearly as antigenically variant as the gonococcus and epidemiological evidence for immunity has been documented. Chlamydiae are obligate intracellular pathogens suggesting that CMI may be important to host resistance. However, infections are transmitted between hosts by an extracellular form, termed the elementary body, and, at this stage, antibody may be important to protection.

Epidemiologically, the strongest evidence for chlamydia immunity is that the risk of infection is inversely related to age. Teenagers and young adults are much more likely to be infected than older adults. Adaptive immunity and age-related changes in sexual behavior probably interact to explain this. Among female sex workers, years of prostitution are the proximate behavioral risk factor for chlamydia infection and infection is rare after 10 years of sex work. HIV appears to increase sex worker risk of infection suggesting that immunity is operative.

Acquired immunity is also supported by quantitative shedding of chlamydia, with younger individuals shedding larger numbers of organisms. In trachoma, a horizontally transmitted ocular *C. trachomatis* infection, increasing age correlates with lower loads of organism and shorter durations of infection. These observations suggest that age-related changes in immunity relate to rapid clearance of reinfection rather than sterilizing immunity to rechallenge.

C. trachomatis immunity is still under study. The innate immune response involves phagocytes, dendritic cells, NK cells, lymphocytes, and cytokines. With respect to humoral immunity, one early observation was that the prevalence of cervical sIgA to *C. trachomatis* was inversely related to the load of organisms shed. Since *C. trachomatis* is susceptible to neutralization in tissue culture with antibody to surface proteins such as major outer membrane protein (MOMP), sIgA *in vivo* may inhibit attachment to susceptible epithelial cells. Local antibodies may also play a role in opsonization since PMNs and macrophages are commonly found at infection sites. Lastly, certain isotypes of antibody, such as IgA, are important in targeting antigen to dendritic cells and enhancing CMI.

CMI is likely key to clearance of infection given the intracellular residence of chlamydiae. $CD4^+$ and $CD8^+$ T cell responses have been documented and at least eight different chlamydial proteins contain T cell epitopes. Th1 $CD4^+$ cells secreting IFN-γ correlate with resistance to reinfection and reduced risk of PID. The role for $CD8^+$ cells is less clear. Nonprotective Th2 or T regulatory cells secreting IL-10 are present, especially in the fallopian tubes of women with tubal infertility. They appear to increase the risk of reinfection. The durability for *C. trachomatis* immunity is uncertain. One study of STD clinic patients with prior chlamydia infection noted resistance to reinfection for only 6 months.

C. trachomatis has several immune evasion mechanisms and can cause persistent infection. Molano et al.[24] demonstrated that 50% of infected women clear infection by 1 year and 90% by 3 years. This suggests that an immune response resulting in clearance takes many months and that not all hosts mount a protective immune response. Persistence in vitro has been attributed to low concentrations of IFN-γ driving the organism into an altered biochemical form capable of long-term intracellular survival. Genital strains of

C. trachomatis genomically respond to IFN-γ in a stereotypic fashion, including the synthesis of tryptophan synthase, a key enzyme in evading the actions of IFN-γ. In the presence of IFN-γ, these strains can convert indole into an essential nutrient tryptophan, via tryptophan synthase. Indole is not synthesized by human cells and is derived only from certain components of the host microbial flora. These observations may explain the association of *C. trachomatis* mucopurulent cervicitis with bacterial vaginosis (a condition with raised vaginal indole concentrations) and to the polymicrobial nature of PID.

C. trachomatis can also evade the protective effects of antibody to surface protein. The MOMP is the dominant target of antibodies but is strain variant resulting in different immunotypes of the organism. Antibody to one immunotype may not protect against others. Furthermore, the surface of chlamydia also appears to have phase-variant proteins termed polymorphic membrane proteins (PMPs) to which protective antibodies are also directed. However, the phase variation of a PMP may allow for antigenic variation and immune escape.

Immune responses to *C. trachomatis* also appear to be involved in the pathogenesis of disease and tissue damage. Individuals persistently infected or frequently reinfected often develop reproductive sequelae. The antigen-specific patterns in protective versus pathological immune responses are different. High titers of antibody to *C. trachomatis* heat shock protein 60 (hsp 60) are found more frequently among women with PID, tubal infertility, and ectopic pregnancy than among pregnant seropositive women or those with uncomplicated cervicitis.

In aggregate, a vaccine for *C. trachomatis* appears feasible because evidence for immunity is demonstrable. A vaccine will need to be molecularly defined in order to exclude immunopathological hypersensitivity reactions to specific chlamydial antigens. Antigens for a potential vaccine will likely include the MOMP and perhaps PMPs.

TREPONEMA PALLIDUM

The causative agent of syphilis, *T. pallidum* subspecies *pallidum*, is an obligate human parasite with a worldwide distribution. Since the organism cannot be cultivated in vitro, our knowledge of the immune response is based on animal studies with limited human data. Studies at Sing Sing Prison using human intradermal challenge demonstrated resistance in individuals with untreated latent syphilis whereas those with treated latent syphilis were fully susceptible.[83] This form of concomitant immunity is operative with HBV, as previously discussed, and with Leishmania, where it is due to IL-10 secreting T regs inhibiting CD4 IFN-γ-mediated clearance at lesional sites. However, circulating Th1 $CD4^+$ cells protect the host from challenge at new cutaneous sites. This mechanism may be operative during latent syphilis. Magnusson also noted resistance to intradermal challenge in late syphilis irrespective of treatment.[83] This appears to be a different (perhaps vaccine-inducible) immune mechanism.

Syphilis is transmitted by local contact leading to penetration of intact mucous membranes and/or through microabrasions bypassing the chemical and mucous barrier and the normal, resident flora.[77] *T. pallidum* attaches to eukaryotic cells via attachment ligands followed by cell invasion and local replication. The organism then penetrates tissues by traversing the junction between endothelial cells, enters the bloodstream and disseminates throughout the body via blood and lymphatics.[84] Virulent *T. pallidum* stimulates the expression of the adhesion molecules ICAM-1, VCAM-1, and e-selectin.[84]

Early syphilitic lesions (days 1–3) show heavy mononuclear cell infiltration and cytokines IL-1 and IL-2 from monocytes and lymphocytes respectively.[77] Immature dendritic cells in the skin (LCs) act as APCs taking up spirochetes and migrating to the regional lymph nodes to activate T cells.[84] As the LCs mature, they produce proinflammatory cytokines that further activate endothelial cells and attract inflammatory cells. These cytokines include IL-1β, IL-6, IL-8, IL-12, and TNF-α. Activated T cells react strongly to several treponemal lipoproteins in the cytoplasm and the flagella, including TpN47, a key cytoplasmic protein that is not surface localized.[84] TpN47 also induces expression of the T cell chemoattractant cytokines MIP-1α and MIP-1β.[84]

On days 4–9, antigen-specific T cells are recruited to the site of infection where a predominantly Th1 cellular response leads to secretion of IFN-γ, IL-2, IL-12, and IL-10. These T cells also activate macrophages, enhance antibody production by B cells and exhibit direct cytoxicity. In primary syphilis, $CD4^+$ cells outnumber $CD8^+$ cells but that balance is reversed in secondary syphilis lesions.[77] A similar phenomenon is seen in recurrent HSV lesions, as discussed above.

Around day 10, activated macrophages together with opsonizing antibody (IgG and IgM), complement (especially c3b), and IFN-γ begin cleaning the lesion of most organisms. Between days 13 and 17, organisms decline sharply. A DTH-like mechanism appears to be operative.[84] The immune response that heals syphilitic chancres thus results from a combined Th1/Th2 effect.[85,86] As the organisms are phagocytosed and ingested by macrophages, the prostaglandin PGE_2 is produced which then downregulates the local immune response. A small number of organisms are able to resist ingestion by macrophages and persist.

The acquired humoral immune response begins with IgM quickly followed by IgG directed at seven major treponema specific antigens and nontreponemal lipid antigens. The former response is measured by the FTA-Abs and MHA-Tp tests while the RPR and VDRL tests measure the nonspecific

response. IgG with complement neutralize and immobilize treponemes, enhance phagocytosis through opsonization, and block cellular attachment. IgG persists throughout late latent syphilis in humans.[84] Treatment leads to the loss of antigen-specific antibody at a rate and to a degree dependent on the duration of the infection. Thus, both cellular and humoral responses are necessary for treponemal clearance.

A characteristic of syphilis is the ability to cause a persistent, lifelong infection in one-third of the patients despite the elimination of millions of spirochetes. Possible immune evasion mechanisms include (1) an antigenically inert cell surface due to few outer membrane proteins and/or a coat of host serum proteins ("slime layer"), (2) intracellular location or location in an immunoprivileged site, (3) a subpopulation of organisms that are resistant to phagocytosis, (4) suppression of the immune system, possibly by premature downregulation through the PGE_2 mechanism, (5) slow metabolism never reaching "critical antigen mass", (6) the ability to use iron bound to transferrin and lactoferrin (iron sequestration), and (7) the ability to use iron alternatives such as zinc and manganese.[84,87] A continuing T cell response probably acts to keep latent organisms in check, unless immunosuppression intervenes and the infection reactivates.

LICENSED STD VACCINES AND VACCINES IN DEVELOPMENT

Successful vaccination often requires not only the specific microbial antigens to elicit the protective immune response but also an adjuvant to enhance the magnitude of the immune response and to polarize it in the desired direction. Adjuvants are especially important for subunit and recombinant vaccines. The route of administration can also be critical.

ADJUVANTS

Adjuvants are components added to vaccine formulations to enhance the immunogenicity of vaccine antigens. They can be immune potentiators or delivery systems. Immune potentiators stimulate the innate response directly or through pattern recognition receptors (PRRs). Delivery systems present concentrated vaccine antigens to APCs and bring together antigens and immune potentiators. Choosing the optimal adjuvant can have beneficial results: (1) an accelerated, more robust and sustained immune response, (2) stimulation of highly active, neutralizing antibodies, (3) elicitation of a cytotoxic T lymphocyte response, (4) improving the immune capacity of persons with weakened immunity, (5) increasing the response rate in low-responder groups, and (6) reducing the amount of antigen required.[37] Until recently, adjuvant research and development has focused on enhancing the antibody response; however, the importance of vaccines against HIV, HSV, HCV, and tuberculosis has shifted the focus to adjuvants capable of eliciting a cellular immune response especially Th1 and CTL responses.[37] Only alum salts acting as delivery systems but not as immune potentiators, have been approved for human usage in prophylactic vaccines.

ROUTE OF ADMINISTRATION

Because STDs originate at mucosal surfaces, it is logical to hypothesize that a mucosal route of vaccine administration may produce a more rapid and protective immune response than systemic immunization via intramuscular or intradermal administration. This hypothesis is supported by the success of oral vaccines against gastrointestinal infections such as *Helicobacter pylori* and rotavirus, and inhaled vaccine administration against respiratory infections such as *Mycoplasma pneumoniae* and influenza virus.[88] This corollary may hold for HIV, *C. trachomatis*, *N. gonorrhoeae*, and HSV but has yet to be conclusively demonstrated. At the genitourinary mucosal surface, the humoral immune response involves locally produced IgM and IgG, serum-derived IgG, and, importantly, sIgA. The local CMI response is characterized by cytotoxic T lymphocytes and IFN-γ producing $CD4^+$ T cells.[88] Both responses are affected by the menstrual cycle. Nasal and local vaginal vaccine administration have produced the best IgA immune response at the genital-vaginal mucosal surface (Fig 99-5).

LICENSED STD VACCINES

Currently, two vaccines are licensed by the FDA for prevention of STDs, vaccines for HBV and HPV infections (Table 99-1).

Hepatitis B virus

A hepatitis B virus (HBV) vaccine has been available for over 20 years. The initial 1982 preparation was purified surface antigen or HBV envelope proteins from the plasma of infected individuals. This was replaced in 1986 by a genetically engineered vaccine manufactured in a yeast recombinant (*S. cerevisiae*) expressing the gene for the surface antigen. This yeast-derived vaccine is immunogenic, safe and cost-effective in preventing HBV infection in neonates, children, and adults.[89] An additional HBV vaccine is derived from mammalian cells using an identical process.[90] HBV vaccination is also protective against hepatitis D (delta), which requires simultaneous or prior HBV infection to replicate. Combined hepatitis B and hepatitis A vaccine preparations have proven highly effective and HBV vaccines have been combined with other vaccines, notably a tetravalent preparation with HAV, diphtheria, tetanus, and pertussis.

Seroprotection after vaccination is defined as anti-HBs status $\geq$10 mIU/mL. This is achieved in over 95% of young vaccinees. HBV vaccines are well tolerated with minimal side

Table 99-1. STD Vaccines: Characteristics of the Natural Host Immune Response, Vaccine Status, and Vaccine Key Issues

STD	Target cells	Nature of Infection/ Disease	Host Immune Response *Innate*	*Humoral*	*CMI*	Antigenic Diversity	Protective Immunity	Vaccines: Status and Key Issues
HBV	Hepatocyte	Acute Chronic	Phagocytes hepatocytes, NK, NKT, Kupffers APC/DCs, IFN-α, β, γ TNF-α, IL-4 lysozymes	Anti-HBc Anti-Hbe Anti-HBs	**Th1 response** CD4/CD8 (CTL) IFN-γ, TNF-α, IL-12 DTH	Rare	Concomitant	Status—licensed Key issues Duration of protection, vaccine escape mutants Birth dose & follow-up doses in poor countries Cost including administrative infrastructure Vaccine mistrust, 3 dose IM regimen
HPV	Keratinocyte	Latent	Phagocytes APC/DCs, NK cells IFN-α, β; GM-CSF IL-4	IgG, IgA, anti-L1 anti-E6/E7, IL-4	**Th1 response** CD4/CD8 (CTL) INF-γ, IL-12, TNF-α DTH	Low	Type-specific	Status—licensed Key issues Duration of protection, cross-protection Cost, distribution, 3 dose IM regimen, who to vaccinate Coverage of cancer types, changes to Pap programs Increased sexual activity, parental approval of STD vaccine
HSV	Squamous epithelium Sensory ganglia	Acute Latent	Phagocytes, NK, NKT LC cells, natural IgM T-bet, IFN-α, β, γ TNF-α, IL-1, 8, 12, 15, 18; Complement	IgG complement	**Th1 response** CD4/CD8 (CTL) IFN-α, β, γ; IL-2 TNF-α, ADCC	None	Type-specific	Status—phase I, II Key issues Vast array of immune evasion techniques Immune mediators and immunogenic proteins unknown HSV rapidly enters immune protected sites Lack of credible animal model
Ng	Columnar epithelium	Acute	Phagocytes, NK cells APCs, IL-1	**Th2 response**	CD8 (CTL), IL-2 IL-12, TNF-α, DTH ADCC	High	No	Status—early preclinical Key issues Antigenic diversity between strains and within strains

Table 99-1. (*Continued*)

STD	Target cells	Nature of Infection/ Disease	Host Immune Response *Innate*	*Humoral*	*CMI*	Antigenic Diversity	Protective Immunity	Vaccines: Status and Key Issues
				IgG, IgA, IgM "natural"serum antibodies, IL-4 IL-10, complement				Low antigen levels avoid immune system stimulation Lack of credible animal model Anti-Rmp blocking antibodies, Masking by LOS sialylation
Ct	Columnar epithelium	Acute Subacute	Phagocytes, NK cells IFN-γ, APC/DCs TNF-α, IL-1, 8 lysozymes	IgM, IgG, anti-hsp60 anti-MOMP IL-10, sIgA	**Th1 response** CD4/CD8 (CTL) IFN-γ, TNF-α IL-12	Low	Gradual	Status–early preclinical Key issues Molecularly defined vaccine Heterotypic infections cause immunopathology Need for immune-potent adjuvant Strategies to target dendritic cells
Tp	Squamous/ columnar epithelium	Acute	Phagocytes lymphocytes APC/LCs, IL-1β, IL-2 M1Pα, Mipβ, PGE_2	IgG, IgM anti-TROMPS complement C3b	**Th1 response** CD4/CD8 (CTL) IL-6, 8, 10, 12, IFN-γ TNFα, DC-SIGN DTH	Low	Concomitant	Status–early preclinical Key issues *T. pallidum* cannot be cultivated Immune protected sites Aantigenically inert surface No critical antigenic mass Immune down-regulation by PGE_2 mechanism Subpopulation resistant to phagocytosis Iron sequestration Chancre clearing by combined Th1/Th2 response
	CNS, CV, MS	Latent						

Bold indicates primary immune response

Data in this table was extracted from peer-reviewed publications (see text for references and explanation of abbreviations). Ng, *Neisseria gonorrhoeae*; Ct, *Chlamydia trachomatis*; Tp, *Treponema pallidum*.

effects. Factors associated with nonresponse include age more than 40 years, male gender, obesity, tobacco smoking, HIV infection, immunocompromising chronic diseases, hemodialysis, subcutaneous or buttock injection, vaccine freezing, and an accelerated schedule.[91] Symptomatic hepatitis B infection is extremely rare after successful immunization even though anti-HBs levels may become nondetectable in up to 50% of individuals within 5–10 years. Immunization also prevents perinatal infection in infants born to HBsAg-positive mothers. The usual immunization course is three doses including a final booster at least 4–6 months after the initial two-dose primary series. Neither anti-HBs testing nor late booster doses are routinely recommended after vaccination.

Long-term follow-up (9–15 years) of HBV vaccinees in Alaska, Quebec, Taiwan, and Italy have shown that (1) HBV vaccine provides excellent protective immunity for at least a decade, (2) breakthrough infections are asymptomatic, rare (≤1.26/1000 persons-years), and mostly affect persons who did not demonstrate seroprotection at the time of primary vaccination, (3) anti-HBs antibody levels fall faster and further for infants and small children, (4) some vaccinees do not demonstrate an anamnestic response to a single booster (again associated with younger age) but all of those studied who received a second booster did respond, and (5) pre- and postbooster anti-HBs levels correlate.[92–98] A routine adolescent wellcare visit might present an opportunity to deliver a "precautionary" HBV booster along with HPV, DPT, and meningococcal vaccines.[99] However, few are advocating across-the-board HBV boosters at this time.

In spite of early evidence to support high-risk, targeted HBV vaccination, this immunization strategy failed.[100] This has important implications for other STD vaccines. Routine childhood and infant vaccination is now the goal of the WHO, CDC, and most official bodies. To date, 151 of 193 WHO member countries have adopted universal childhood HBV vaccination policies; 76 have a policy for administering the first dose soon after birth; and six have policies for vaccinating adolescents.[101] Seventy-two percent of the high prevalence member states have adopted universal infant immunization and 53% of those recommend a birth dose. Infant and childhood vaccination programs on every continent have been successful including The Gambia, China, Indonesia, Senegal, Canada, Thailand, Alaska, and Taiwan.[8,101–108] WHO's goal is HBV vaccination in all countries by 2007 and 90% coverage by 2010. Dramatic successes in the prevention of HBV infections and hepatocellular carcinoma have been reported.[108] STD patients were initially recommended for HBV vaccination but this quickly expanded to all persons attending STD clinics.[108] In the Unites States, the Healthy People 2010 goal for HBV vaccination of STD clients is 90%. Success in STD clinics and correctional facilities has been well documented.[106,108]

Several important challenges remain in the global effort to eliminate new HBV infections through vaccination. Chief among these are the cost (including the administrative infrastructure), the administration of a dose at birth and follow-up doses, the mistrust of vaccines, the potential impact of virus mutants and inadequacies in the existing vaccination program infrastructure that are amplified by a three-dose regimen.[101,109] The monovalent HBV vaccine price is only $0.30 USD but this is still costlier than other routine infant immunizations. The world's poorest countries require financial support to deliver this vaccine. The highly effective birth dose can be challenging since most births occur at home without immediate access to health-care. Administration by trained traditional birth attendants has been successful in Indonesia.[101] Finally, HBV immunization programs in Africa have been shown not to negatively impact existing vaccination programs;[101] in fact, they may provide a boost to existing WHO Expanded Programme on Immunization (EPI) efforts.[110] Vaccine freezing and wastage can be a problem, however. One potential challenge is HBV vaccine escape mutants. While antibodies induced by HBV vaccination are neutralizing across all subtypes, point mutations in the HBV genome have been found which bind vaccine-induced antibodies. The mutant HBV is not neutralized. These mutants are being investigated.[111]

If everyone were immunized against HBV today, 350 million chronically infected carriers would still need treatment. The success of postexposure immunization has raised the possibility of a therapeutic HBV vaccine. Additionally, HBsAg clearance has been observed in individuals who received bone marrow transplants from HBV-immune donors.[44] This correlated with detection of $CD4^+$ T cell reactivity against HBc in the blood. These and other data suggest that therapeutic vaccination should include HBcAg.[45] The Hepacore Project is attempting to develop a therapeutic vaccine based on chimeric HBc VLPs.[112]

To induce a $CD8^+$ T cell response, studies have focused on DNA immunization and HBV polymerase, a highly immunogenic $CD8^+$ target essential for early virus replication.[44] Since inhibition of HBV replication can be separated from the mechanisms of liver injury, a therapeutic vaccine could stimulate tissue-sparing cytokine production and/or antibodies to prevent the antigen-nonspecific amplification of the intrahepatic infiltrate and thereby inhibit liver damage.[44] Some have suggested strategies to optimize the immune response to enable a therapeutic vaccine to be successful; for instance, inhibition of viral replication by antiviral drugs.[45] Lamivudine treatment has been associated with improved HBV-specific helper and cytotoxic T cell function in chronically HBV-infected individuals.[45,113]

Human papillomavirus

Human papillomavirus (HPV) type 16 was first identified as a significant factor in the pathogenesis of preinvasive and

invasive cervical cancer in 1983. Over 200 types have now been described; 40 can infect the genital tract and more than 20 types have been associated with cervical cancer.[114] Seventy percent of cases of cervical cancer are associated with types 16 and 18; and 90% of genital warts are associated with types 6 and 11. In 1991, papillomavirus-like particles were created in the laboratory allowing accelerated vaccine research. These virus-like particles (VLPs) are empty viral capsids, which copy the structure of the natural virion but are devoid of DNA. They are noninfectious but generate a potent immune response.

In 2002, the remarkable efficacy of a preventive HPV-16 vaccine was demonstrated in a phase II randomized, multicenter, double-blind study involving 2391 young women 15–26-year-old.[114–116] Using VLPs of the L1 protein in the viral capsid, the vaccine was protective against preinvasive disease (efficacy = 100%), persistent HPV-16 infection (efficacy = 100%) and transient HPV infection (efficacy = 91%). Efficacy against persistent infection remained 100% even including participants who had violated the study protocol. The three-dose regimen had few side effects and generated an antibody response in 99.7%. At month 7, the mean antibody level was 58.7 times as high as women with natural infection.[115] Immunogenicity bridging studies have demonstrated anti-HPV titers two-to-threefold higher in boys and girls 9–15 years of age compared to females over 15. The antibody levels generated in girls are constant over the 9 to 11 year age range but fall off significantly when the vaccine is given at 12–13 years of age.[117–118]

Highly consistent results were subsequently obtained from a bivalent (HPV-16/18) vaccine in a phase IIb trial[119] and a quadrivalent (HPV-6/11/16/18) vaccine in one phase II and two phase III trials.[65,120] Participants were from North America and South America, Europe, and the Asia-Pacific. The bivalent vaccine (Cervarix®, GlaxoSmithKline Biologicals) is manufactured in an baculovirus/insect cell expression system whereas the quadrivalent vaccine (Gardasil®, Merck and Co., Inc.) uses a yeast system (*Saccharomyces cerevisiae*).[114,116] Cervarix® includes an adjuvant composed of 500 μg of aluminum hydroxide with 50 μg of 3-deacylated monophosphoryl lipid A (AS04).[114,116] Gardasil® includes an adjuvant of 225 μg of aluminum hydroxyphosphate sulfate.[65] The vaccines should be stored at +2°C to +8°C and not allowed to freeze.

In mid-2007, the updated results of four randomized, double-blind, placebo-controlled trials in individuals over 15 years of age involving the quadrivalent vaccine were reported.[121–124] In susceptible women, vaccine efficacy was 99–100% for the following endpoints related to vaccine-containing HPV types: condyloma (venereal warts), cervical intraepithelial neoplasia (CIN2-3), adenocarcinoma *in situ* (AIS), cervical cancer, vulval intaepithelial neoplasia (VIN2-3), vaginal intraepithelial neoplasia (VaIN2-3), vulval cancer and vaginal cancer. The intention-to-treat analyses of all randomized women (including those who were naive or infected with vaccine-containing HPV types at day 1) demonstrated vaccine efficacies of 44% for HPV-16/18-related CIN2-3, AIS and cervical cancer; 18% for any cervical endpoint; 71% for HPV-16/18-related VIN2-3, ValN2-3, vulval and vaginal cancers; 49% for any vulval or vaginal endpoint; 73% for HPV-6/11/16/18-related condyloma; and 51% for any condyloma. An update of the original phase II Cervarix® trial after 4.5 years showed continued vaccine efficacy against HPV-16/18 incident infection (96.9%), 6 and 12 month persistent infection (94.3% and 100% respectively) and CIN (100%).[125] An interim analysis of a large, international phase III bivalent vaccine trial (n=18,644) showed near 100% vaccine efficacy against HPV-16/18-related CIN2+ in susceptible subjects.[126] This study also demonstrated significant cross-protection against 6-month persistent infections with HPV-45 (59.9%), HPV-31 (36.1%), HPV-52 (31.6%) and against 12-month persistent infections with 12 combined oncogenic HPV types excluding HPV-16 and HPV-18 (27.1%). Gardasil® generates cross-reactive and cross-protective antibody concentrations against HPV-31 and HPV-45, as well.[117] Gardasil® has shown partial cross-protection against persistent infection (combined efficacy 27%) and against CIN2/3 and AIS (combined efficacy 39%) caused by 10 non-vaccine oncogenic HPV types (HPV31/33/35/39/45/51/52/56/58/59).[126a]

The sharp fall-off in efficacy in the intention-to-treat analyses for Gardasil® probably relates to previous exposure to vaccine-containing types, as well as the role of oncogenic HPV types not present in the vaccines. Type-replacement has not been ruled out.[127] These data and others underscore the critical value in vaccinating girls before the onset of sexual activity, i.e., 9–12 years of age.

In already-infected quadrivalent trial participants who received vaccine, there was no significant protection against CIN2-3 disease related to vaccine-containing serotypes, but there was a trend towards a reduction in the combined incidence of CIN1-3 and adenocarcinoma *in situ* in those with recent-onset infection with vaccine-containing HPV types, i.e. HPV DNA in cervicovaginal specimens but non-detectable circulating antibodies to that HPV type on Day 1.[117,128]

A cohort of Gardasil® recipients (n = 241) followed for 60 months after dose 1 exhibited high, sustained vaccine efficacy with no evidence of waning immunity.[114,116] Antibody titers peaked 30 days after dose 3, declined until month 18, and then plateaued for the 5 years of follow-up. This plateau was well above naturally acquired HPV-11 and HPV-16 antibody levels but similar to natural infection with types 6 and 18.[114,116] Similar results have been documented for a Cervarix® cohort followed for 4.5 years.[65] The administration of a challenge dose of Gardasil® at 60 months produced a classic anamnestic response:[129] Additionally, enhanced humoral and memory B cellular immunity was generated when the bivalent vaccine was adjuvanted with MPL/ASO4 (as is the case with Cervarix® compared to aluminum salt only.[130]

Both vaccines were safe and well-tolerated. No adverse effects were seen in the pregnant vaccine recipients or their breastfed infants.[65,114] Gardasil® can be given with HBV vaccines and there is no need to restart the vaccination series if it is interrupted.[114,116] Since both vaccine preparations are non-infectious, administration to immunocompromised patients is not contraindicated. The antibody response to Gardasil® in already-infected recipients is faster, stronger, and longer lasting.[65] Neither vaccine is recommended in pregnancy, for males, or for females older than 26 or younger than 9 years. HPV vaccine studies in each of these groups are underway and no additional risks are anticipated.[65] Changes in Pap screening recommendations are inevitable once HPV immunization programs are implemented; for instance, HPV-negative women probably require less frequent Pap smears. However, vaccine recipients may already be infected (and at risk of cancer) and HPV types associated with 30% of cervical cancer cases are not included in current vaccine formulations.

By the end of 2006, Gardasil® was licensed in 49 countries, including FDA approval on June 9, 2006. Cervarix® was licensed in Australia in May 2007. Everyone agrees that these vaccines will be most effective for young girls before initiation of sexual activity although sexually active girls and women even with previous Pap abnormalities, may benefit since they may not be infected with all four vaccine types. The expense of the recommended three-dose schedule ($360USD) has already stimulated proposals for two-dose trials (personal communication—S. Dobson, G. Ogilvie).

Issues remain. The duration of protection remains unknown although follow-up data indicates at least a decade of protection, as discussed previously. By vaccinating only girls before they become sexually active, one might expect an 85% reduction in cervical cancer, a 44–70% reduction in abnormal Pap smears attributable to HPV, and a 95% reduction in cervical cancer deaths.[51] Mathematical modeling, however, suggests advantages to vaccinating both men and women.[131] It is unknown whether nonvaccine high-risk HPV types will fill the void counteracting vaccine benefits.[131] This is called type replacement.

Different models have estimated the cost per QALY to be in the range of $3000 to $24,300 USD for HPV vaccines administered to females at 12 years of age.[114] One analysis predicted that the most cost-effective HPV strategy was vaccination followed by biennial Pap screening beginning at age 24 years; however, vaccination followed by annual screening beginning at 18 years of age showed the greatest overall reduction in cancer incidence and mortality.[132] A different model predicted a 61.8% reduction in cohort cervical cancer with a cost-effectiveness ratio of $14,583 per QALY when 12-year-old girls were vaccinated with HPV 16/18.[133] In this model, vaccinating males was not cost-effective. Models that evaluated the catch-up vaccination for 12–24-year-old females predicted more rapid declines in both cervical cancer incidence and precursor lesions.[114]

Oncogenic HPV can cause several other cancers including penile, oropharyngeal, laryngeal, oral and anal neoplasms. This argues for vaccinating boys, men, and women outside 9–26 years of age. Plus, women can acquire HPV at any age. Merck is sponsoring a clinical trial of Gardasil® in 4000 men, including 500 self-identified gay men. Lastly, vaccine formulations including HPV 6 and 11 will prevent most genital warts.

In studies of adolescents and adult women, vaccines against HPV and herpes were acceptable with vaccine efficacy, health profession endorsement, and cost as significant determining factors.[134–136] Nurse practitioners and physicians specializing in Obstetrics and Gynecology are willing to administer these vaccines;[137,138] and studies on parental attitudes have shown a willingness to accept STD vaccination of adolescent children.[134,137] Many jurisdictions in Canada, the United States, and elsewhere are planning to roll-out HPV vaccination programs in 2007 or 2008.

A 2003 WHO consultation recommended histologically classified cervical intraepithelial neoplasias (CIN) of moderate or high-grade and cancer as the efficacy measure for population-based studies with special reference to developing countries.[139]

Amid the euphoria, some have called for second generation HPV vaccines to addresses problems with the current VLP products.[140] VLP vaccines are expensive to produce and difficult to distribute because of the need for a cold chain, the three intramuscular injections and the hard-to-access primary target group (preadolescent girls), especially in developing countries.[140] Also, type-specific protection is risky in places that lack Pap testing to rule out infection with other oncogenic types. An HPV DNA vaccine would be simpler to produce; an HPV viral vector vaccine might be compatible with mucosal delivery; and an HPV L2 vaccine would likely be broadly cross-neutralizing.[140] A combined prophylactic and therapeutic HPV vaccine using L1/L2 and E6/E7 chimeric VLPs is feasible.

Progress toward a therapeutic HPV vaccine has not been as dramatic although three therapeutic vaccine candidates are in phase II trials. Most research has focused on the early viral proteins (E1, E6, and E7) that are required for viral DNA replication, maintenance, and papilloma formation. E6 and E7 are consistently expressed in tumour cells. Therapeutic vaccination of animals has been successful and small, preliminary studies in humans have shown an HPV-specific antibody response, HPV-specific cytotoxic T lymphocytes, and wart clearing.[141–143]

STD VACCINES IN DEVELOPMENT

Of the remaining STDs, vaccine research is most advanced for HSV, *N. gonorrhoeae*, *T. pallidum*, and *C. trachomatis* (Table 99-1).

Herpes simplex virus

Research into herpes vaccination has been ongoing for over 80 years. Predictably, the optimal vaccine would induce both humoral and cellular immunity; however, for HSV, the principal humoral and CMI mediators of infection are poorly understood and the key immunogenic proteins have not been well delineated.[67,144,145] The virus rapidly enters neurons and nerve ganglia which are immunologically protected sites. Finally, some HSV immune evasion mechanisms are effective only in primates, compromising the reproducibility of research findings from animals.[145]

The primary goal of a prophylactic HSV vaccine is sterilizing immunity, the prevention of infection. Failing that, the prevention of latent infection would be highly desirable. The most important goal of a therapeutic HSV vaccine would be to eliminate latent infection or, at least, to prevent recurrent clinical disease and/or asymptomatic viral shedding. No vaccine candidates have achieved any of these goals. Therefore, HSV vaccine trials have adopted more modest objectives, including a reduction in the amount of virus necessary to infect and establish latency, prevention and/or decreased severity of primary clinical herpes, decreased severity and frequency of clinical recurrences, partial protection of the ganglia (decreased magnitude of latent infection leading to less frequent recurrences), shedding less virus and shedding less often.[146]

Killed virus vaccine candidates have failed and the focus for HSV vaccine development has shifted to (1) replication-incompetent mutants, (2) replicating vectors with HSV genes encoding immunogenic proteins, (3) subunit vaccines, and (4) DNA vaccines.

Replication-incompetent mutant virus vaccines are derived from infectious HSV viral strains missing a gene essential to the reproductive cycle. After infection, viral replication proceeds until the missing gene product is required. By then, a broad immune response will have occurred since the mutant has intact immunogenic proteins.[147] An early study failed[147] but two later trials using a mutant with a Th2-polarizing gene deletion demonstrated promising therapeutic results in animal trials and phase I/II human trials. Previous research demonstrated that recurrent HSV disease is prevented by virus-specific Th1 cytokines, especially IFN-γ, but facilitated by Th2 cytokines, especially IL-10.[66] In 2 randomized, double-blind trials involving persons with ≥5 recurrences in the previous year, recurrences were prevented in 37.5% and 43.5% ($p = 0.068$ and 0.024, respectively) and significantly reduced in the remainder.[66,148]

Replicating vector vaccine candidates involve HSV gene insertion encoding immunogenic proteins into a replication-competent viral or bacterial vector, such as vaccinia, adenovirus, and *Salmonella*.[68] The vaccine recipient develops humoral and cellular immunity to the HSV proteins encoded by the vector. Animal studies have been successful but human trials have not been completed. These candidates have three drawbacks: (1) the HSV-specific immune response is limited to a single protein or epitope; (2) individuals may already be immune to the vector and eliminate it prior to HSV-protein immune responses; and (3) safety concerns. Nonetheless, new attenuated-virus vaccine vectors are under development.[144]

Recombinant DNA technology has permitted the safe production of HSV glycoprotein free of virus and viral DNA. Subunit vaccine research has centered on glycoproteins D and B. Both are highly conserved in the majority of HSV strains (over 98% in the case of gD) and both stimulate neutralizing antibody, antibody-dependent cellular cytotoxicity, and $CD4^+/CD8^+$ virus-specific immune responses.[147] Although protective in animals, only one or two glycoproteins may not produce broad or durable immunity in humans.[147] In two randomized, double-blind trials of a gD2gB2 glycoprotein vaccine with the adjuvant MF59, decreased HSV-2 acquisition was not achieved. However, a transient 50% protection for 5 months and a difference in efficacy by gender was noted (24% less infection in females vs. 4% in males).[72,147]

Two additional subunit vaccine trials followed using a gD2 glycoprotein candidate with the adjuvants alum and MPL (3-de-O-acylated monophosphoryl lipid A), a potent inducer of humoral and cellular immunity.[149] Both studies demonstrated significant protection from symptomatic herpes (73%, $p = 0.01$ and 74%, $p = 0.02$) in women without preexisting antibody to HSV-1 or HSV-2.[68] There was a nonsignificant trend to reduced HSV infection in HSV-1 and HSV-2 negative women (46% and 39%) but no effect in HSV-1 seropositive women or men. The vaccine was safe, well tolerated and induced both gD-specific neutralizing antibodies and Th1 CMI responses.[68] The adjuvant appears to be the critical difference between these two sets of studies. A larger NIH trial using the latter formulation is underway. Mathematical modeling suggests a more substantial effect for reduced asymptomatic viral shedding than for prevention of disease. In the model, disease prevention without reduced viral shedding may result in increased HSV incidence, confirming previous predictions.[146,150] The authors recommended universal herpes immunization.

Finally, research is underway into DNA vaccines consisting of bacterial plasmids that express HSV proteins.[144,145] This approach could stimulate multiple arms of the immune system using a mixture of plasmids encoding various peptides and proteins involved in both CMI and humoral immune responses.[144] An effective HSV vaccine will provide additional benefits for nongenital HSV disease including neonatal herpes, oral-facial herpes, herpetic keratitis, herpetic encephalitis, and eczema herpeticum.[146] These effects would be optimized by universal childhood immunization.

Neisseria gonorrhoeae

Progress in *N. gonorrhoeae* development has been hindered by the lack of a credible animal model of mucosal disease, marked antigenic diversity between strains, and antigenic variation within strains over time.[151] Trials of a formalin-killed, piliated whole organism vaccine, a gonococcal purified pilus vaccine, and a recombinant protein I (Por) vaccine have all failed.[152]

Piliation, a virulence factor, has been the focus of vaccine research. Anti-pilus antisera reduce gonococcal adhesion to epithelial cells, opsonize gonococci for phagocytosis, and protect cells in vitro from gonococcal cytotoxicity. Human studies showed antibodies in serum and genital secretions, and protected volunteers from homologous but not heterologous challenge. This protection was easily overwhelmed by increasing the inoculum.[153] Because of antigenic variation, pilus vaccine research has been temporarily abandoned.[154] However, more stable pilus-associated proteins may be future vaccine candidates.[152]

Por is the major gonococcal outer membrane protein. Although genetic variation occurs in the surface-exposed loops, the membrane-spanning regions are conserved.[155] The protein is encoded by a single copy gene, *por*, and there are two structurally distinct types, PIA and PIB, each with several serotypes.[152] Antibodies to Por promote complement-mediated killing and opsonization, and inhibit interaction with epithelial cells.[155] The immune response to Por during salpingitis may stimulate serotype-specific protection against recurrences with the same serotype.[152] For these reasons, Por is considered a good vaccine candidate. A failed Por vaccine human trial may have been due to contamination with blocking antigen Rmp[79] which stimulates antibodies that block killing of serum resistant strains.[79,153] Por vaccines may also be inhibited by sialylation of lipooligosaccharide (LOS) blocking surface exposure of Por epitopes and inhibiting complement fixation.[153] Encouragingly, recent research supports one dominant PIA type, a common PIB type, and similarity in individual Por variable regions.[155] This suggests vaccines targeting a limited number of Por protein epitopes might provide protection against several strains.[155] Recombinant strains of *Salmonella typhimurium* that express Por and stimulate both humoral and CMI are considered oral vaccine candidates.[154]

Many outer membrane components have been considered vaccine candidates including Opa proteins (Protein II), LOS core sugars, H.8 antigen, IgA protease, anaerobically expressed proteins (Pans), transferrin, and lactoferrin. Ultimately, the ideal gonococcal vaccine antigens should have little antigenic variation, not be protected by anti-Rmp blocking antibodies, not masked by LOS sialylation and contain epitopes that are both conserved and stimulate protective antibodies.[154] Por remains the leading candidate.

Chlamydia trachomatis

Despite active preclinical research and development for over 20 years, no vaccine for the prevention of sexually transmitted *C. trachomatis* has entered clinical trials. Vaccines for trachoma prevention have shaped the current approach to vaccines for sexually transmitted chlamydia.

Three important lessons were from trachoma vaccine trials in both humans and primates.[156] Human trials demonstrated that parenteral immunization with whole inactivated chlamydial elementary bodies induced short-lived (<1 year) protection. Primate trials demonstrated protection when the vaccine immunotype matched the challenge strain immunotype (homotypic immunity) and showed that mismatch of immunotypes not only resulted in infection but also enhanced inflammatory responses. Heterotypic infection was associated with immunopathology. These observations suggest that a chlamydia vaccine must be molecularly defined (containing only protective not disease-enhancing antigens) and have better immunogenicity than whole bacterial cells. This has become the central paradigm of chlamydia vaccinology.

The molecular basis for the immunotype (or serovar) classification of *C. trachomatis* appears to be due to allelic variation in a single copy gene that specifies the synthesis of MOMP. MOMP is rich in T and B cell epitopes. Interestingly, T cell epitopes cluster in sequence-constant regions, while B cell epitopes cluster in sequence-variable regions. Monoclonal and polyclonal antibodies to MOMP can neutralize *C. trachomatis* in tissue culture and MOMP antibody-coated organisms cannot infect experimental animals. Neutralizing antibodies to MOMP are directed to conformational epitopes. Because of these favorable immunological properties, MOMP has been extensively studied as a vaccine with disappointing results. Using denatured MOMP extracted from *C. trachomatis* elementary bodies, primates were parenterally and mucosally immunized but made poor antibody responses and were fully susceptible to challenge infection.[157] Possible reasons for failure include the denatured state of the vaccine protein and the need for better adjuvants. More promising results were obtained using the mouse model of *C. muridarum* genital infection and MOMP in its native conformation. This suggests that conformationally intact MOMP is essential for a *C. trachomatis* vaccine.[158]

Genomics has made substantial contribution to the search for more broadly conserved antigens that induce protection. Eight different chlamydiae strains and species have been sequenced in their entirety including human immunotypes A, D, and L2 of *C. trachomatis*, the mouse strain *C. muridarum*, and the guinea pig strain *C. caviae*. These animal systems in which host-adapted chlamydia produce infection have strong immune correlates to human *C. trachomatis* infection. This includes the essential role of $CD4^+$-dependent CMI in clearing infection and the role of $CD4^+$ T cells and B cells in resistance to reinfection.

Based on these animal models, a new regulatory roadmap for chlamydia vaccine research is being defined. Vaccines that have successfully passed evaluation in two animal model systems can enter human trials for phase I and II immunogenicity and safety evaluation. Thus, vaccine candidates that induce immunity in the mouse model can be confirmed in the guinea pig model. If the antigen protects both animals, the orthologous protective antigen in *C. trachomatis* is eligible for testing in phase I/II human trials. This roadmap, while offering a way forward, is clearly labour-intensive since nearly 800 proteins are, in principal, vaccine candidates. Seiving these candidates by using bioinformatics to identify surface proteins, secreted proteins and virulence factors will narrow the list. Alternatively, using proteomics to identify chlamydia proteins able to enter the major histocompatibility complex antigen processing and presentation pathway can focus vaccine research on the few proteins that are T cell antigens. Since primates can be infected with human strains of *C. trachomatis*, primate studies may also be useful to evaluate immunotype restriction of immunity and vaccine hypersensitivity.

Identifying protective antigens for a molecularly defined *C. trachomatis* vaccine is necessary but not sufficient. Delivery of vaccine to dendritic cells, polarizing the immune response to generate appropriate protective effectors and triggering B and T effector/memory cell migratory patterns to genital mucosal surfaces are all important but unanswered research questions. As discussed previously, adjuvant will be critical to a fully immunogenic *C. trachomatis* subunit vaccine. Alum, a currently licensed adjuvant for human vaccine, is likely to be inappropriate since it polarizes to a Th2 helper phenotype for antibody responses. A *C. trachomatis* vaccine must elicit a Th1 response. Promising adjuvants include CpG oligonucleotides and other defined ligands which trigger TLRs and induce polyclonal Th1 responses. While both systemic and mucosal responses are essential to protective immunity, a *C. trachomatis* vaccine will probably be initially evaluated via parenteral delivery.

Treponema pallidum

Achieving effective acquired immunity to *T. pallidum* is strongly supported by four lines of evidence: (1) only one-third of the untreated human syphilis patients develop late complications;[159] (2) "chancre immunity" to reinfection is observed during the early stages of active, untreated infection and is associated with strong humoral and CMI responses;[160] (3) human experiments have shown that, after intradermal challenge, the development of lesions and changes in syphilis serology were dependent on the length of prior infection and that untreated, infected subjects developed no lesions or serologic changes;[83] and (4)supporting evidence exists in animal models.[160]

The cloning of genes subsequent to the sequencing of the *T. pallidum* genome, recombinant technology, and new outbreaks of infectious syphilis in industrialized countries have renewed interest in a syphilis vaccine.[154,161,162] Our inability to cultivate the organism presents a significant challenge to vaccine development. Because DTH appears to be a dominant protective immune response in chancre resolution, an effective vaccine needs to induce DTH as a primary effect.[154,163] In animal models, vaccine candidates protect against infection with homologous but not heterologous strains. *T. pallidum* repeat protein K (TprK) may be the source of this antigenic variability.[163,164]

Vaccine research is focused on recombinant treponemal antigens and proteins especially TROMPS (Treponema rare outer membrane proteins) which mediate attachment, invasion, acquisition of nutrients and cell stability. Candidates include Tp92 which promotes opsonization and phagocytosis and is 95–100% conserved across strains, TprK which demonstrates some cross-reactivity between strains, recombinant endoflagellar proteins, TpN47, TpN19, and TmpB. All have demonstrated at least partial protection in animal models. TpN47 may be involved in upregulation of HIV replication in monocyte precursors infected with HIV and in upregulating expression of the HIV receptor CCR5.[84] Interestingly, Tp92 shares sequence similarity with *N. gonorrhoeae* and *C. trachomatis* membrane proteins.[165] Treponemal components in some rabbit syphilis vaccines may cause downregulation of the immune system requiring neutralization.[166] Finally, BCG has been proposed as an ideal vaccine vector because it generates a strong DTH response.[154]

THE FUTURE OF STD VACCINES

Several factors will impact the effectiveness of any STD vaccination deployment strategy. First, is the vaccine candidate a take-type or a degree-type vaccine? A take-type vaccine results in either full protection or no protection whereas a degree-type vaccine protects all of those vaccinated from a percentage of challenges.[167] Second, STD vaccine targeting is affected by the reproductive rate (*Ro*) of the STD involved. Low efficacy vaccines can reduce endemic prevalence because most new hosts are at low risk. However, elimination is problematic because most infectious reservoirs are difficult-to-access, high-risk, core group transmitters.[167] To eliminate STDs with a high reproductive rate (e.g., >4), the critical threshold of coverage (vaccine coverage multiplied by vaccine efficacy) needs to be high and may not be attainable with low efficacy vaccines.[167] Mathematical modeling supports universal vaccination or vaccinating the two highest risk populations.[167]

A third consideration is vaccinating only women because of (1) their greater risk of disease, (2) better opportunities

to deliver vaccines (prenatal and family planning clinics), (3) the usual necessity of a female reservoir or host for ongoing transmission, and (4) evidence that women respond more vigorously to some vaccines, e.g., HSV vaccines. A more vigorous immune response in women may also be the cause of more severe STD complications. Modeling supports the targeting of take-type vaccines to one gender.[167]

Finally, HBV vaccine programs suggest combined approaches for STDs broadly distributed within the population. For STDs highly concentrated in core transmitter groups, vaccination of groups with the highest risk and the second highest risk may be more cost-effective. This strategy is reminiscent of circle vaccination, which helped to eradicate smallpox. The final answer will come from mathematical modeling combined with practical considerations around delivery and follow-up. The answers may differ for different STDs.

Acquiring an STD is accompanied by social stigmatization and public health STD programs run the risk of increasing this discrimination for individuals and populations. Additionally, the structural nature of stigma and discrimination can negatively affect access to vaccines for marginalized groups such as sex workers and drug users. The criminalization of sex workers, the lack of resources for the poor and the paucity of user-friendly care for street youth and drug users may block vaccine delivery reducing coverage and effectiveness. These are often the same populations with the highest risk and prevalence. The general population may be reluctant to accept STD immunization and parents may find it difficult to admit that their children may not always make the safest sexual decisions.

On the positive side, research consistently shows that the decision to be vaccinated or to allow vaccination of children or dependents relates to an understanding of the risk of the disease targeted, perceived vaccine efficacy and safety, cost and affordability, and recommendations from health-care workers.[134,136,137,168,169] Universal infant and school-mandated vaccine programs are the least stigmatizing. Universal infant vaccination has been the most successful strategy in the United States for increasing 19–35-month-old infant coverage with all three HBV vaccine doses (from 16% in 1991 to 92% in 2004).[170] A California law requiring seventh grade students to have documented receipt of three doses of HBV vaccine as of July 1, 1999 was associated with an increase in coverage from 15.8% to 68.5%. Ninety percent of the students not in compliance were in the process of completing the three-dose series.[171]

Combining STD vaccines with other routine vaccines may also be effective. A combination vaccine containing diphtheria-tetanus-whole cell pertussis-hepatitis B, extemporaneously mixed with a Hib vaccine (DTPw-HBV/Hib) administered at 6, 10, and 14 weeks of age after a birth dose of HBV vaccine was highly immunogenic and well tolerated in a large study from the Philippine.[172] The seroprotection rate to hepatitis B was 94.3%. Noninjection routes of

Table 99-2. Lessons Learned from Hepatitis B Vaccination Programs That Can Inform Vaccination Efforts for Other STDs

1. An STD vaccine which evokes primarily a humoral immune response can be highly effective at preventing a disease for which the natural immune response involves innate, humoral, and *CMI*.
2. There is no harm or benefit in immunizing persons already infected.
3. Protection continues after protective antibodies have fallen below detectable levels.
4. Acceptance of STD vaccines by parents, young people, and persons at risk depends on an understanding of the disease, recommendations by health workers vaccine effectiveness, safety, and affordability.
5. Properly implemented STD vaccination programs can be highly successful.
6. Vaccinating infected mothers can prevent perinatal infection.
7. Noncompletion of the recommended vaccine series can still result in some level of protection.
8. STD vaccination programs in developing countries need not negatively impact other vaccine programs.
9. When an STD vaccine is costlier than childhood vaccines, developing countries may need financial assistance.
10. Mistrust of vaccines and inadequate infrastructure are significant challenges in developing countries.
11. STD vaccine risks may not materialize. HBV vaccine did not result in autoimmune disease, diabetes, optic neuritis, chronic fatigue syndrome, demyelinating diseases, or reactions to thimerosal or aluminum.
12. Vaccine escape mutants are not necessarily important. HBV mutants were seen infrequently in highly endemic areas, involved one genome region, rarely caused vaccine breakthroughs, and did not disrupt vaccination efforts.
13. STD vaccine nonresponse factors may include male gender, age over 40 years, obesity, tobacco use, hemodialysis, buttock or subcutaneous injection, vaccine freezing, accelerated schedules, HIV, and compromised immunity.

administration or shorter courses can also increase coverage but effectiveness, safety, and cost will be the critical factors in vaccine acceptance. Herd immunity will hopefully protect those who decline vaccination.

STD vaccine programs might provide a disincentive to safer sexual behavior and result in an increase rather than a decrease in STD incidence. This has impacted HIV spread where it is called treatment optimism. Highly active antiretroviral therapy (HAART) has made AIDS appear less serious or even curable resulting in increases in unsafe sex among gay men.[173,174] This may prove especially important for low efficacy vaccines since the public is most familiar with high efficacy childhood vaccines. Pre- and postvaccination counseling will need to make the average person aware of the importance of postvaccination safe sexual behavior, especially when vaccine efficacy is not high.[174]

For a degree-type vaccine, a simple inverse relationship exists between vaccine efficacy and increases in unsafe sex.[167] If a vaccine is 75% efficacious, a concomitant 75% increase in unsafe sex will cancel its effect. If, however, unsafe sex increases beyond the vaccinated cohort, an increase in STD incidence can result. Take-type vaccines are less susceptible to changes in sexual behavior. STD vaccination in combination with nonvaccine control interventions can have an additive or synergistic effect depending on the effectiveness of the other interventions and whether the vaccine is degree-type or take-type.[167]

HBV vaccination programs have given us valuable insights into STD vaccine issues (Table 99-2).[91,175–177] An immunization program for persons at high-risk in the United States and Canada quickly expanded to universal infant immunization and routine vaccination of adolescents. Because of the subsequent increases in acute HBV infection in 20–39-year-old males, and in men and women older than 40 years, a national immunization program for adults may be the next step.[175]

Humanity has shown the capacity to eliminate globally endemic and epidemic diseases through the use of childhood vaccines. However, the potential benefit from STD vaccines is highest in countries and communities where vaccine access is likely to be the lowest. The equitable distribution of STD vaccines within countries and globally may represent a far greater challenge than vaccine development itself.

100 HIV Vaccines

Anne Duerr, Lawrence Corey, and Judith N. Wasserheit

In 2006, the HIV/AIDS pandemic marked its 25th year. To date, roughly 60 million people have been infected and 20 million have died of AIDS. Approximately 15,000 people become infected with HIV every day. Although a number of prevention strategies have been implemented (such as education, counseling, behavioral interventions, early detection and treatment of STDs, and prescreening of blood products) they have proven inadequate for controlling the spread of HIV in many populations.[1] The past decade has seen the introduction of effective antiretroviral therapies (ART) in industrialized nations and the first stages of their dissemination to developing countries, the "heartland" of the epidemic. This effort, however, has been woefully inadequate at meeting the needs of those who require treatment.

Even if one were able to reach all those in need, however, the pandemic can never be fully addressed by treatment alone. Treatment will not prevent events that happen very early after infection, such as transmission to sexual partners during the postinfection peak of viremia[2] and the massive destruction of CD4 cells that occurs in the gut within weeks of infection.[3] Transmission also carries with it real risks for complications, such as ART-induced lipodystrophy.[4] Thus, there is an urgent need for effective and affordable prevention strategies that can be widely implemented. The most feasible and promising of these strategies is an HIV vaccine.

Designing and developing an effective HIV vaccine has been a major scientific challenge. Despite initial optimism, the search for an HIV vaccine has continued for more than 20 years without reaching its goal. HIV infection offers few clues to guide the search: there are no established correlates of immunity, no documented cases of spontaneous recovery from AIDS or HIV infection, and no animal models that faithfully predict HIV disease and vaccine responses in humans. However, several experimental and biological models and insights suggest that developing a useful vaccine is possible, and several novel concepts are in clinical trials.

Some portion of this chapter was previously published in Duerr A, Wasserheit JN, Corey L. HIV vaccines: New frontiers in vaccine development. *Clin Infect Dis* 2006; 43(4): 500–511.

CHALLENGES TO HIV VACCINE DEVELOPMENT

GENETIC COMPLEXITY OF HIV: GLOBAL VARIATION

The global variation in HIV poses a formidable challenge to vaccine development, since the prevention of infection with diverse viruses requires the development of either a small number of broadly protective vaccines or a large number of vaccines that protect against a more limited range of viruses. Compared with other infectious disease pathogens, such as influenza, HIV exhibits extraordinary genetic diversity and complex molecular epidemiology (Fig. 100-1).

Rapid viral evolution and founder effects have contributed to heterogeneity in the global distribution of HIV. Based on full-length genome sequence analysis, HIV is classified into three main groups: M (main), O (outlier), and N (non-M, non-O). The vast majority of HIV subtypes identified to date belongs to M group. Group O is found predominantly in Central Africa; group N isolates are very rare and all have come from Cameroon. The M group contains 22 circulating genetic forms. Of these 22 forms, 9 are designated HIV subtypes (subtypes A-D, F-H, J, and K); these subtypes differ by roughly 25–35% in *env* sequences and by roughly 15% in the *gag* gene.[5] There are 13 circulating recombinant forms (CRFs) that are identified by number in the order of their discovery followed by the letters of the parental subtypes. These CRFs are thought to have arisen by intersubtype recombination in an individual infected with two or more subtypes. All HIV subtypes are thought to have arisen in central Africa, where genetic diversity is greatest. In most other regions of the world, one or a few subtypes or CRFs predominate. On a global scale, the predominant genetic forms are subtype C (southern Africa, India), A (east and central Africa, Eastern Europe), B (North and South America, Europe, Australia), and CRF02_AG (west and central Africa) (Fig. 100-2).

SUBTYPE SPECIFICITY OF THE IMMUNE RESPONSE

The challenge of achieving cross-subtype protection in human vaccine trials is foreshadowed by studies in nonhuman primate models, which generally fail to show protection against challenge with heterologous simian immunodeficiency virus (SIV) isolates. The antibody response to most vaccine immunogens is nonneutralizing; these antibodies bind to HIV but do not prevent it from infecting target T cells or macrophages. Even if protein immunogens elicit neutralizing responses, the responses are limited. Vaccine candidates generally fail to elicit neutralizing antibody against primary isolates (recent clinical viral isolates) or against viruses of subtypes other than that of the immunogen, despite the fact that shared epitopes have been identified. Neutralizing antibodies can be identified in sera from infected individuals. Human monoclonal antibodies that neutralize isolates of multiple subtypes have been isolated, although such broadly neutralizing antibodies are very rare.[6,7] In general, neutralization serotypes do not correlate with HIV subtypes, and insights into a classification system that defines serotypes of HIV-1 infection might therefore provide insights into the development of an effective HIV vaccine.

Cellular responses to natural infection or immunization are generally broader than humoral responses. Cross-clade cytotoxic T lymphocytes (CTLs) are detected in individuals infected with a single HIV subtype.[8] Vaccination with subtype B vectors results in CTL responses that recognize multiple subtypes, although intraclade responses are generally stronger.[8–16] This cross-clade recognition is due not only to generation of CTL that recognize conserved epitopes common to several clades but also to the promiscuity of the T cell receptor (TCR), which can accommodate variability in the epitope peptides it recognizes. CD8 epitopes are typically linear sequences of 9–11 amino acids; these amino acids are presented to the TCR in conjunction with the major histocompatibility complex (MHC) molecule, which accounts for up to 65% of the contact with the TCR.[17] The interaction with the TCR and the epitope is not uniform across all amino acid residues of the epitope. Recognition of the primary and secondary TCR contact residues is most important for binding of the epitope to the TCR; binding is relatively unaffected by amino acid substitutions at noncontact residues or by conservative amino acid substitutions in contact residues.[17] In theory, promiscuity in TCR binding could result in recognition of up to 10^6 sequence variants.[17] TCR flexibility in recognizing HIV epitopes has been demonstrated using cloned CTL lines from infected individuals.[15,18] Similar results were seen in macaque CTLs elicited by infection or immunization.[19,20] CTLs generated to 5 parent epitopes in human leukocyte antigen (HLA) transgenic mice recognized between 50% and 97% of variant epitopes (from clades A, B, C, D, F, G, H, J, and K as well as CRFs and groups N and O viruses). Conservative amino acid substitutions and those that did not disrupt the HLA-binding motif were more likely to be tolerated.[17] Recognition of epitope variants was also demonstrated by peripheral blood mononuclear cells (PBMCs) from HIV-infected individuals and by CTL lines derived from human PBMC. Epitopes varied considerably in both predicted and actual epitope cross-recognition; these data are currently being used to design vaccine candidates that incorporate broadly recognized epitopes.

STRATEGIES FOR ADDRESSING VIRAL DIVERSITY

A variety of approaches have been proposed to design immunogens that will elicit B and T cell responses capable of recognizing a broad array of isolates. The importance of inducing broad immunity is underscored both by the extent of global viral diversity and by recent reports of superinfection of individuals with established HIV infection after exposure to HIV from a second source.[21,22] The three most common immunogen-design strategies to address this issue are the use of consensus, ancestral,

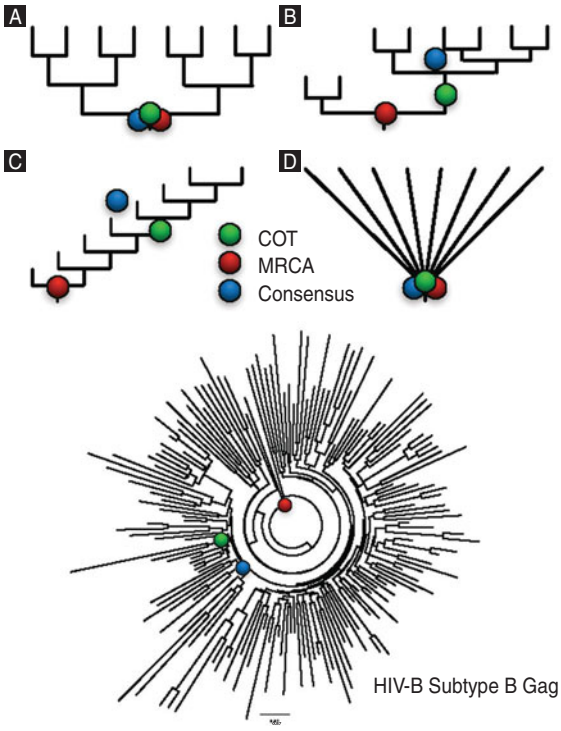

FIGURE 100-3. Top: A-D: 4 Hypothetical phylogenetic trees, each constructed using eight isolate sequences, demonstrating the relative positions of the center of tree (COT), most recent common ancestor (MRCA), and consensus sequences. Bottom: Position of COT, MRCA, and consensus placed on the maximum likelihood phylogenetic tree constructed using subtype b gag sequences. or center-of-tree (COT) sequences (Fig. 100-3). The goal of strategies utilizing these three centralized sequences, all of which preserve many known CTL epitopes, is to reduce the "distance" between the immunogen sequence and the infecting (challenge) virus isolates.[23,24] The simplest and arguably more representative are the subtype consensus sequences, which are based on the most common amino acid at each position of the aligned available naturally occurring sequences. M group consensus sequences can be built by generating consensus sequences for individual subtypes and then generating a consensus sequence of all subtype consensuses.[25] Ancestral sequences are built using the phylogenetic trees constructed from known contemporary sequences; the hypothetical ancestral sequence is recreated using maximum likelihood phylogenetic analysis. Centralized (consensus or ancestral) sequences for a given subtype (e.g., C) are closer to the sequences of other subtype isolates than a natural subtype C isolate sequence would be. The centralized sequences lie at the root of the subtype so one saves the distance from the root to the individual contemporary isolates.[23] The final type of consensus sequence is COT, which minimizes the evolutionary distance to all isolates in the data set.[23,24]

The genes produced from these centralized sequences are artificially made and may not retain important structural features and biologic functions (Table 100-1). One such sequence has been tested to date: a group M consensus envelop glycoprotein.[23] Because the evolution of hypervariable regions proceeds via insertion and deletion, a consensus sequence was difficult to generate. Instead, a single-isolate sequence was used for five highly variable regions (V1, V2, V4, V5, and a region of the gp41 cytoplasmic domain) to facilitate proper folding; M group consensus was present in the constant and V3 regions. This test-of-concept study showed that the consensus gene retained at least some biologic activity (e.g., CD4 and coreceptor binding, ability to form dimers/trimers) and cross-reacted with patient sera of multiple subtypes. When injected into mice, the synthetic immunogen DNA-induced T cell responses (in an IFN-γ ELISpot assay) against subtypes B, C, and consensus peptides. In guinea pigs, synthetic peptide antigen was able to elicit neutralizing activity against selected primary strains, although neutralizing activity was of limited breadth and strength. A second consensus sequence—a full-length ancestral *env* sequence—was generated using 38 HIV-1 subtype B sequences. This sequence coded for a 160 kDa glycoprotein that was able to bind to and fuse with cells expressing CCR5.[26] When used in a DNA-prime, protein-boost regimen, it elicited only weakly neutralizing antibodies in rabbits. Thus, this analysis appears to offer more promise in defining methods to induce more broadly reactive T cell epitopes than neutralizing responses, likely related to the greater dependence of neutralization on the conformational aspects of the HIV-1 virion.

HIV VARIABILITY WITHIN INDIVIDUALS

A very high degree of viral diversity is generated by HIV secondary to the high error rate of reverse transcriptase and its inability to correct these errors, coupled with the extremely high level of viral replication (billions of new virions are generated each day).[10] It is estimated that this level of mutation could produce variants with a single nucleotide change at every position in the genome thousands of times per day during chronic infection.[27] This high mutation rate is ultimately responsible for the global variation in HIV subtypes discussed above and also results in a high degree of intrahost variability. In other words, high variability exists within the viral swarm in a given individual. The implications of ongoing replication and resultant intrahost variability for successful drug treatment have been clear for some time. Treatment regimens that successfully "shut down" viral replication limit the production of progeny HIV virions. Treatment regimens that permit ongoing replication allow the generation of new virus, some of which will harbor mutations conferring resistance to antiretroviral drugs. These regimens fail when the fitness cost of the resistance mutation is low enough to allow the mutant virus to replicate successfully in the presence of an antiretroviral drug.

Table 100-1. Strategies for Addressing Viral Diversity

Vaccine Source	Differences (%)	Construction	Advantages	Disadvantages
Single-subtype isolates	5–15		• Genes are derived from a viable virus; likely to adopt native conformations • Properties of the isolate are known • Furthest along in development	• Poor cross-reactivity possible with isolates from same or different subtypes
Subtype consensus	3–8	Most common amino acids at each position among subtype isolates	• Easy to construct; • Most representative of known isolates	• Derived consensus is influenced by sampling – only reflects isolates that have been sequenced. This may limit utility if sampled sequences not representative • Relationship to newly transmitted strains unclear
M-group consensus	5–15	Consensus of subtype consensus constructs		• May be unable to assume appropriate structure
Subtype ancestral	3–8	Inferred from phylogenetic tree	• More likely to include epitopes uncommon during chronic infection (due to escape) • Unlikely to change as new sequences are added to database	• Including such uncommon epitopes is only important if they are seen currently among recently transmitted isolates • Influence of outlier sequences may cause divergence from center of sequence distribution
Subtype center of tree (COT)		Inferred from phylogenetic tree	• Influence of outliers reduced • Reduces distance to circulating strains when phylogenetic tree is asymmetric	• May be unable to assume appropriate structure

Similar scenarios are relevant for vaccine strategies that do not induce sterilizing immunity but that, after infection, ameliorate clinical course by eliciting anti-HIV CTL responses. Experiments in nonhuman primate models indicate that the CTL response limits viral replication in vaccinated animals. The degree of suppression varies; in some animals, viral replication appears to be completely suppressed, while limited residual viral replication continues in others. Viral escape from the selective pressure exerted by initial cellular responses is also seen in infected humans. Several investigators have documented mutations within HIV CTL epitopes that allow "CTL escape."[28] These mutations allow the viral variants to circumvent the established CTL response directed towards the wild type epitope and are associated with the disease progression.[29–31] Recent experiments in macaques have documented vaccine failure associated with similar mechanisms of CTL escape. In one experiment, CTL responses were elicited in macaques using DNA vaccines in combination with IL-2 protein or plasmids.[32,33] All controls and vaccinated macaques became infected; six of eight controls died within 2 years. Of the eight macaques receiving the DNA vaccine plus IL-2, seven controlled viremia and remained healthy for 2 years. One animal initially controlled viremia but showed late clinical vaccine failure, went on to develop simian AIDS, and died. Virologic studies showed initial suppression of viremia to undetectable levels. However, by 20 weeks postinfection the initial viral swarm had been replaced with a variant with a mutation in the immunodominant CTL epitope.

A single point mutation was associated with a 100-fold decrease in affinity for the histocompatibility locus (Mamu-A*1) and a 1000-fold decrease in recognition by the dominant CTL elicited by the vaccine. While additional CTL responses were seen subsequently, they were insufficient to contain viral replication and the animal went on to develop an AIDS-like syndrome. Thus, in a manner analogous to the evolution of drug resistance, the emergence of escape mutations led to the clinical failure. Vaccines that elicit high-level CTL responses to multiple epitopes are more likely to avoid failure due to CTL escape, just as the use of combination antiretroviral therapy is more likely to prevent drug resistance. In addition, strategies that elicit CTL and are capable of recognizing large numbers of variant epitopes (through promiscuous binding) may more successfully control infection.

Immune selection pressure may also drive viral variation among individuals within a population (interhost variability). An analysis of HIV variation suggests that viral evolution within a population is driven by a process of mutation within individuals that gives rise to CTL escape mutants that are limited by functional considerations within that individual (fitness cost) and selection pressures in the subsequent host.[34] These opposing forces help shape the consensus wild-type variant in the population. The efficacy of HIV vaccines that elicit CTL responses could be limited if transmission of CTL escape mutants from one host to another results in a predominance of these variants in the population. Longitudinal studies in humans suggest that CTL escape mutations may be maintained in the original host despite a fitness cost due to immune selective pressure by CTL directed to the wild-type epitope. Population level studies show both positive (increased heterogeneity) and negative (maintenance of consensus sequence) associations with different HLA class 1 alleles.[34] Positive associations presumably arise due to CTL escape in the manner described above. Leslie and colleagues studied such negative associations in clade C- and clade B-infected populations and suggested that negative associations also arise when CTL escape mutations are stably transmitted.[35] A negative association is seen when the escape mutation accumulates in a population to a level that defines a new consensus sequence. The loss of the original epitope and fixation of the variant sequence has important implications for vaccine development, as it would render ineffective strategies targeting such epitopes.

In experiments in nonhuman primates, a cloned SIV containing three mutations associated with CTL escape was used to study reversion of CTL-escape variant viruses. Virions carrying the escape mutations showed reduced replication kinetics in vitro, suggesting that the escape mutations carried a fitness cost. Two mutations reverted rapidly to wild type when introduced into a new histocompatibility-mismatched host.[36] These latter experiments suggest that reversion of CTL escape mutations does occur, especially if the CTL escape mutation is associated with reduced fitness, and that vaccine strategies that elicit CTLs to epitopes that extract a high fitness cost for escape will be more successful. Replication of the less fit escape mutant will be more easily controlled within the vaccinated host and the escape variant will be more likely to revert to wild type in a new host.

APPROACHES TO PROPHYLACTIC VACCINES

NEUTRALIZING ANTIBODIES

More than 85 HIV vaccine trials involving over 30 products have been conducted to date. Initial HIV vaccines targeted the production of neutralizing antibodies. These antibodies not only bind to infectious HIV but do so in a manner that prevents productive interaction with target cells, thereby "neutralizing" HIV infectivity. This approach is appealing because subsequent exposure of the vaccinee to HIV would be expected to stimulate an anamnestic response, resulting in rapid production of antibodies that would block infection. Several licensed vaccines, such as those against polio, mumps, and rubella, elicit antibody-mediated protective immunity[37] and, while cellular immunity may be an important protective element for many vaccines, neutralizing antibody is recognized as the immune correlate of sterilizing immunity.

Neutralizing antibodies in HIV-infected persons

Much of the antibody response to natural infection with HIV is nonneutralizing and the role that neutralizing antibodies play is still being elucidated. Strong, broadly cross-reactive neutralizing antibodies have been detected in some but not all long-term nonprogressors who remain disease-free for 10 years or more without treatment.[38] In other individuals, neutralizing antibody responses were thought to develop slowly and to be of low titer.[39,40] However, newer assays that measure responses to autologous virus, rather than heterologous primary isolates or laboratory adapted strains, show rapid development of significant neutralizing responses.[41] These cell-based infectivity assays employ recombinant viruses expressing HIV envelope proteins derived from the same plasma sample being tested for neutralizing activity and thus measure antibody responses to autologous contemporaneous virus. Examination of 14 study participants shortly after infection revealed that only 2 developed negligible neutralizing activity against autologous isolates; the remaining 12 showed moderate- to high-level neutralization. These responses appeared to develop rapidly (within 8 weeks) and initial responses were narrowly focused (i.e., they did not neutralize heterologous virus).[42] Serial sampling showed ongoing viral evolution in a manner consistent with escape and replacement of neutralization-sensitive virus with successive populations of resistant virus. Although the

neutralization responses are insufficient to limit replication in an infected individual, the authors speculate that even this level of humoral immunity might effectively prevent infection from the small amounts of virus expected to cross the mucosa during sexual transmission.[41,42]

A number of HIV envelope proteins' features help it evade effective surveillance by the humoral immune system. The HIV envelope is a trimer of heterodimers; each heterodimer comprised a surface subunit (gp120) and a transmembrane subunit (gp 41) that are noncovalently bound to each other. Maintenance of this native trimeric structure may be necessary to elicit neutralizing antibodies. Conversely, the native structure shields many potentially neutralizing epitopes such as the coreceptor binding site, which becomes accessible only after CD4 binding.[42] Longitudinal follow-up of infected patients revealed an additional potential means of escape from neutralization. The mutations associated with immune escape were not clustered within known neutralization epitopes but instead involved changes in surrounding glycosylation sites. Mutational substitution studies demonstrated that changes at these sites affected neutralization of distant epitopes.[43] The authors postulated that the extensive N-linked glycosylation found on the outer surface of the HIV envelope spike sterically hinders antibody binding to neighboring neutralizing epitopes on V1/V2, V3, and receptor binding sites and termed this phenomenon the "glycan shield" mechanism of immune escape.[42] Subsequent studies of transmission within couples found little variability in sequences obtained from the newly infected partner, consistent with the transmission or outgrowth of a single sequence. Variable loops (V1–V4) in this partner were generally shorter and had a decreased number of glycosylation sites compared to sequences in the "donor" partner.[44] Virus from the recently infected partner appeared to be up to 10 times more sensitive to neutralization, suggesting that there is a transmission fitness cost associated with the resistance to antibody neutralization seen in the donor partner. If this is the case, protective humoral immunity may be more easily elicited than studies in chronically infected individuals might imply.

Despite the difficulty of inducing broadly neutralizing antibodies that react with multiple primary isolates and/or laboratory-adapted strains, they have been detected (albeit rarely) in infected individuals. The construction of monoclonal antibodies derived from such individuals has allowed more detailed study of these broadly neutralizing epitopes. The best-characterized examples include the following: F105 and b12, which are specific for the CD4 binding site on gp120; 2G12, which recognizes a complex epitope on gp120; and 2F5 and 4E10, which recognize linear epitopes on gp41 (Fig. 100-4). The ease with which these epitopes could be incorporated into a vaccine is unclear. For example, the b12 monoclonal has an unusual extended antigen-binding finger that accesses a normally recessed epitope on gp120 and

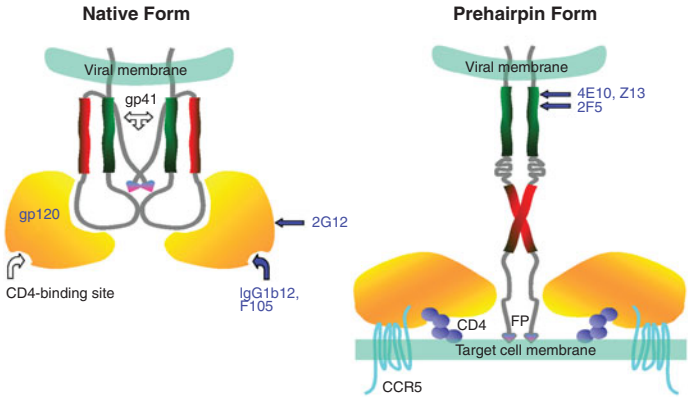

FIGURE 100-4. Schematic revealing the location of neutralizing antibody epitopes on gp120 and gp41 (shown in the native form and the transient, prehairpin form). (Reproduced with permission from Ferrantelli F, Ruprecht RM. Neutralizing antibodies against HIV—back in the major leagues? *Curr Opin Immunol* 2002; 14: 495–502.)

blocks CD4 binding.[43] The feasibility of targeting gp41 domains involved in virus fusion with the target cell, as 2F5 and 4E10 do, may be limited by steric hindrance and by the rapidity of the fusion process.[27,43,45]

When three of these monoclonals were tested in vitro against a panel of newly transmitted clade B isolates, 4E10 alone neutralized all isolates, 2F5 neutralized 80%, and 2G12 neutralized 37%.[7] The combination of b12, 2G12, 2F5, and 4E10 has shown strong cross-clade neutralization against clades B, C, A, and D in vitro.[46]

Passive transfer studies in nonhuman primates

Several groups have used these monoclonal antibodies to block infection in test-of-concept trials in nonhuman primate models. Initial trials showed that HIV immunoglobulin (HIVIG) or individual monoclonal antibodies failed to protect macaques against the subsequent IV challenge with SHIV 89.6P (a chimeric SIV virus with an HIV envelope). In contrast, double and triple combinations of monoclonal antibodies that were delivered 24 hours before IV challenge resulted in protection against infection or ameliorated clinical course in infected animals.[47] Ruth Ruprecht and her colleagues have used combinations of three or four neutralizing monoclonal antibodies given to neonatal rhesus macaques before or immediately after oral exposure to SHIV. Thus far, 22 of 31 treated infant macaques were completely protected while all controls were infected.[6,46,48–50] In separate experiments, monoclonal antibodies (alone or in combination with HIV immune globulin) were infused into female macaques prior to intravaginal challenge with SHIV 89.6PD. All control animals were infected and showed high viral load and CD4 depletion. Complete protection was seen in 8 of 14 passively immunized macaques; the remainder became infected but showed low-level viral replication and only modest declines in CD4 count.[47]

Clinical trials INVOLVING ANTIBODIES

Phase 1 safety studies have been conducted with four of these monoclonals. They have been found in adults to be safe and well tolerated, with in vivo concentrations in the range of those that cause >99% neutralization in vitro.[46,51] Initial clinical studies of passive immunization with broadly neutralizing monoclonal antibodies in HIV-infected individuals have not resulted in significant reduction in viral load.[52] The potential utility of passive immunization for the prevention of HIV transmission has been widely discussed. The feasibility of this approach using monoclonal antibodies has recently been questioned due to concerns about low neutralization capacity for nonclade-B HIV,which predominates in areas of high mother-to-child transmission, and concerns regarding the implications of the polyspecific activity associated with some monoclonals.[53]

Initial trials using recombinant monomeric HIV envelope proteins (gp160 or gp120) to elicit neutralizing antibodies yielded disappointing results. While the products proved very safe in phase 1 and 2 trials,[54–56] the antibody response was generally low titer and, while it was capable of neutralizing the vaccine strain or lab-adapted HIV, it could not neutralize primary isolates (virus isolated from recently infected individuals), which are thought to most closely resemble infecting virus.[57] Two phase 3 trials of recombinant gp 120 (rgp120) products have recently been completed: a clade B candidate was tested in the United States, Canada, Europe, and Australia; and a clade B/E mixture was tested in Thailand. Neither vaccine prevented infection nor ameliorated postinfection course.[58–61]

Current vaccine approaches to eliciting broad neutralization include the construction of immunogens that preferentially expose epitopes capable of inducing neutralizing antibodies. Selective mutagenesis has been used in an attempt to increase the response to neutralizing epitopes, while diminishing that to other, often more dominant, nonneutralizing epitopes.[62] Another approach seeks to reduce the impact of nonneutralizing epitopes by shielding them by selective addition of n-glycosylation motifs.[63] The immunogenicity of monomeric gp120 engineered using these 2 approaches has been tested in rabbits. While the former approach appeared more effective than wild type gp120 in eliciting neutralizing activity against primary HIV isolates, the latter approach did not show appreciable neutralization of any of the primary isolates that were tested.[64] Deletion of hypervariable loops to expose conserved epitopes[65] and exposure of highly conserved epitopes in the membrane proximal region are also being explored.[66]

CELLULAR IMMUNITY

Most ongoing trials of HIV vaccine candidates involve products that aim to induce HIV-specific CTLs. These cells recognize HIV epitopes displayed on cell surfaces in conjunction with HLA. Thus, these immune effector cells recognize infected cells but not free virus. They limit the spread of infection by destroying infected cells via apoptosis, or by secreting chemokines and cytokines that interfere with subsequent rounds of infection. Experimental challenge studies suggest that this type of approach is less likely to reduce acquisition of infection than a vaccine that elicits broadly neutralizing antibodies. It is anticipated, instead, that HIV-specific cellular immunity will limit HIV replication and reduce plasma viral load—specifically setpoint viral load, the relatively stable plasma viral load typically seen after acute infection. A number of studies have shown that setpoint peripheral viral load is predictive of subsequent disease course.[67] In addition, plasma viral load predicts transmission to sexual partners; transmission decreases with reductions in plasma viral load and may be completely prevented when viral load drops below 1500 copies/mL.[68] Thus it is anticipated that CTL induced by HIV immunogens may limit the effects of HIV infection at both the individual level (disease progression) and the population level (HIV transmission).

T cells in HIV-infected persons

The role of HIV-specific CTL in the control of HIV infection is supported by observations in HIV-infected individuals. During primary infection in humans, control of viremia is temporally correlated with the development of CTL responses.[69,70] CTLs may also operate to control viral replication in long-term nonprogressors, who maintain low viral loads and high CD4 counts over long periods without treatment and who often have high levels of CTLs.[71] A longitudinal study of a single patient documented the effects of CTL escape through the accumulation of mutations in five CTL epitopes; these changes were accompanied by loss of T cell reactivity to 4 of the 5 epitopes and increases in HIV viral load.[30] Although observational studies of CTL in infected individuals generally support their role in limiting viral replication, two recent studies failed to demonstrate a relationship between level of HIV-specific $CD8^+$ cells in vitro and HIV viral load.[72,73] This apparent discrepancy may be explained by HIV-induced immune dysfunction and decreases in cytolytic activity of $CD8^+$ cells during chronic infection.[74] These in vivo changes may not be detected by in vitro assays for HIV-specific T cell activity.

CTL Vaccine studies in nonhuman primates

Perhaps more compelling evidence for the role of CTL comes from studies of SIV-infected macaques. In these experiments, depletion of CD8 cells from chronically infected animals was followed by rapid increases in SIV viral load and reconstitution with CD8 cells resulted in suppression of viremia.[75,76] In addition, longitudinal follow-up studies of infected macaques demonstrated that CTL escape is associated with the loss of control of viremia.[32]

Vaccine studies in nonhuman primates also point to a role of $CD8^+$ CTL in control of viremia after infection. More direct evidence of a role for vaccine-induced CTL in controlling viremia comes from a recent study in rhesus macaques vaccinated with attenuated SIV mac 239 Δ3.[77] This vaccination strategy did not prevent infection of animals upon challenge with SIVmac251 but did result in lower postinfection viral loads compared to controls. CD8 depletion at the time of challenge resulted in higher levels of viremia compared to nondepleted vaccinated animals.

While HIV-1 specific CTL are present in HIV infected persons, a wide variety of CTL functions are impaired even in LTNP with HIV-1. At present, it appears that CTLs stimulated by CTL-based vaccines appear to have many of these functions restored. As such, it is hoped that vaccine-induced cellular immunity will control viral replication in the vast majority of individuals. Two outcomes of vaccination may contribute to the relative success of CTLs induced by immunization. T cell help is necessary for generating and maintaining an effective CD8 response. This process is limited in HIV infection, as HIV preferentially destroys $CD4^+$ cells. Vaccination of HIV-uninfected individuals should elicit a fully functional T-helper response, which should in turn assist in the development of an anti-HIV CD8 response that is qualitatively better than that seen in a natural infection.[27] Second, the fact that exposure to the vaccine immunogen is limited, and not continuous as it is in natural infection, will allow for the generation of CD8 memory T cells, which are anticipated to be most effective in controlling the subsequent infection.[27]

Clinical trials of CTL vaccines

In 2007, the majority of HIV vaccines in clinical testing elicit primarily CTL-based responses. Many vaccines based on viral vectors, such as poxviruses, adenovirus, and alphaviruses, have been tested in humans and found to be safe.[54–56] While many of these products have shown limited immunogenicity in humans, in phase 1 and 2 trials several adenovirus candidates induce high-level CTL responses as measured in chromium-release CTL assays, or in ELISpot or intracellular cytokine staining assays, which measure HIV-specific T cell activity. HIV vaccines based on DNA plasmids also show a favorable safety profile, although these vaccines have been less immunogenic in vitro than was predicted by preclinical tests in nonhuman primates. (These and other CTL vaccines will be discussed further in the "HIV Vaccine Design Strategies" section.)

Measuring the effects of CTL vaccines in clinical trials

Based on their effect in animal models, it is anticipated that current vaccine candidates aimed at eliciting cellular immunity will have only a modest effect, if any, on acquisition of HIV infection but will ameliorate clinical course in vaccinees who become infected. Therefore, no effect may be seen using traditional measures of vaccine efficacy, which are based on reduction in infection rates. A variety of alternate or surrogate endpoints have been proposed for vaccine candidates of this type. These endpoints include vaccine efficacy for delaying disease progression among vaccinees (VEp) or vaccine efficacy for preventing transmission to sexual or needle sharing partners by reducing infectiousness (VEi).[78,79]

Many surrogate endpoints are based on reductions in peak viremia during the acute infection period and/or in setpoint viral load. Reductions in HIV viral load, in turn, are expected to result in amelioration of clinical course and reduced transmission to partners. Trials could potentially compare mean viral load 1–3 months after diagnosis of infection in vaccine versus placebo recipients. Marked initial suppression of viral replication suggests reductions in both progression and transmission, and viral load during this early time period could be used as a surrogate for either. Potential limitations of this approach include the fact that the initial effect may not be durable due to immune escape and viral replication, leading in turn to parallel increases in progression and transmission.

Because of the limitations of early viral load, it is unlikely that vaccine trials will rely solely on it. Potential surrogate endpoints that occur later after infection (6–24 months) relate to disease progression and include laboratory markers such as viral load, absolute CD4 count, and the number of $CD4^+$ memory T cells. Because many individuals may have initiated ART at later timepoints (>24 months after first detection of HIV infection), it may be helpful to use composite endpoints such as time to CD4 count <350 or initiation of antiviral therapy. Another potential comparison at late timepoints is median HIV viral load in HIV-infected vaccines versus placebo recipients.[79] Early clinical markers other than AIDS-defining illness among all individuals, including those taking ART, may provide additional surrogate endpoints. These late endpoints can be used to confirm conclusions drawn from earlier surrogates. Because of the ethical obligation to provide ART for infected trial participants, it is unlikely that vaccine effects on late outcomes, such as AIDS-defining illnesses or death, will occur in HIV vaccine trials.[80,81]

MUCOSAL IMMUNITY

Most HIV transmission occurs sexually and therefore involves the transmission of HIV across the epithelium of the vagina, rectum, or penile urethra. Vaccine approaches that generate mucosal immunity to HIV should consist of several immunological steps. First, a vaccine should systematically generate and expand HIV-specific adaptive immune responses. Second, the vaccine, adjuvant, or delivery mechanism should support the generation of HIV-specific cells that migrate to mucosal sites. Finally, HIV-specific cells must be expanded within the mucosal tissue, where they would most likely be effective.

The biology of HIV transmission at mucosal surfaces is not completely understood. M cells (specialized epithelial cells), dendritic cells, or epithelial cells can mediate HIV entry into the mucosal lamina propria. M cells may mediate the transport of virus in the oropharynx, small intestine, and rectum, but are absent in the genital mucosa.[82] HIV-infected cells can also cross epithelial barriers in the human small intestine by transcytosis in vesicles. HIV may most efficiently gain access to potential host cells in the female genital mucosa (T cells, dendritic cells, and macrophages) through microabrasions in the epithelium. Transmission involving dendritic cells likely also occurs in the intact female genital tract mucosa, where these cells bind HIV-1 gp120 through DC-SIGN and perhaps other cell surface receptors. Experiments in nonhuman primate models show intra- and subepithelial dendritic cells or $CD4^+$ cells as primary targets of viral replication shortly after cervicovaginal SIV infection.[83,84] Dendritic cells that capture HIV at the epithelial surface (e.g., the vaginal lumen) can deliver it to underlying T cells in the subepithelium and disseminate it to lymphoid organs.

Transmission across mucosal surfaces can be inhibited at various points by either antibody or cytotoxic T cells. HIV-specific antibody at mucosal surfaces might inhibit HIV infection in a number of ways. Antibody present in secretions can block attachment of pathogens to the epithelial surface in a process known as immune exclusion. Even nonneutralizing antibodies influence transmission at this stage by cross-linking antigen, enhancing pathogen entrapment in mucus, and preventing contact with mucosal surfaces.

Mucosal immunity in uninfected persons exposed to HIV

Natural history studies and challenge studies in nonhuman primates have shown that mucosal responses are of potential importance in protection against HIV acquisition. Observational studies conducted in highly exposed persistently seronegative (HEPS) women have reported the presence of HIV-specific IgG and IgA in vaginal secretions,[85–89] but this finding is not universal.[90–92] Much of the controversy in the field results from the lack of validation and standardization of the assays used to measure antiviral immunity and the lack of unexposed control subjects in some studies. In ex vivo transcytosis assays, IgA (but not IgG) isolated from Kenyan commercial sex workers (CSWs) resulted in a decrease in transmission of nonsyncytium-inducing (NSI) HIV across polarized epithelial monolayers.[93] Inhibition of transcytosis was also seen in vitro when isolated HIV-specific immunoglobulin (secretory IgA, IgG, and IgM) was preincubated with HIV prior to assay or when dimeric HIV IgA was added to the basolateral surface of epithelial monolayers.[94] However, the extent to which this in vitro assay mimics events in vivo is uncertain, as the IgA in most assays was monomeric and therefore not the form normally present at these surfaces (dimeric IgA at the basolateral surface and dimeric IgA plus secretory component at the apical surface).[95]

The detection of HIV-specific T cells in mucosal samples from highly exposed HIV-uninfected CSWs in Africa and Asia, as well as in discordant couples, also points to the potential role of mucosal responses in influencing HIV acquisition. Several investigative groups have demonstrated HIV-specific T cells using ELISpot assays in cervicovaginal specimens of such subjects.[96,97] These reactions appeared to be mediated by CD8 cells and often responded to the same epitopes in cervix and blood.[96] These findings of mucosal T cell responses in seronegative persons have suggested that eliciting immune responses in cells that migrate into mucosal surfaces will be important in enhancing vaccine protection. Whether such responses can be effectively elicited from systemically administered vaccines (as seen with measles or hepatitis B) or will require mucosal administration is one of the most critical unanswered questions in the HIV vaccine field.

Studies in nonhuman primates

There is a significant body of literature in animals and some in humans that suggests that vaccines delivered onto mucosal surfaces are more likely to elicit mucosal immune responses than those given systemically. Mucosally applied vaccines also offer greater protection against mucosally applied experimental challenge.

Studies of mucosally administered HIV vaccines in nonhuman primates have demonstrated high levels of protection from infection or disease progression after the subsequent experimental challenge. These vaccines include intranasal immunization with *nef*-deleted SHIV,[98] Sabin poliovirus vectors,[99] replication-competent Adenovirus serotype 5 (Ad5) (oral, nasal, or intramuscular administration),[100] DNA plasmids with or without IL-2/Ig DNA boosted with MVA (prime and boost administered nasally),[101] or a DNA prime/MVA boost delivered rectally.[102] Conceptually, such studies indicate that mucosally applied vaccines can be protective. The mechanism by which mucosally applied vaccines establish immunity remains unclear. It is also possible that vaccines administered parenterally can elicit mucosal immune responses, if trafficking and local expansion of HIV specific cells occurs.

Clinical trials of vaccines delivered mucosally

Clinical development of these vaccines must balance the need to induce immunity at mucosal surfaces with safety concerns that limit some mucosal applications, such as potential neurotoxicity of replication-competent viral vectors delivered nasally. Initial clinical studies using mucosal delivery of canarypox HIV vaccine (ALVAC 205) to the nose, mouth, vagina, or rectum followed by gp120 delivered intramuscularly (IM) demonstrated that this approach was safe but not

effective for eliciting a mucosal immune response.[103] This area remains one of active research; several candidates, including a replication-competent adenovirus vector, are under development.

HIV VACCINE DESIGN STRATEGIES

Initial attempts to produce vaccines that protect against infection with HIV followed strategies that have been used successfully to eliminate or control other pathogens (Table 100-2, Fig. 100-5).

LIVE, ATTENUATED VACCINES

Perhaps the most successful example is the use of attenuated viral vaccines against smallpox and polio. Attenuation of the pathogenic effect is achieved by repeated passage of the virus in vitro. The attenuated viruses produced in this manner

Table 100-2. Potential Advantages and Disadvantages of Major HIV Vaccine Design Strategies

Immunogen	Advantages	Disadvantages
Live, attenuated SIV/HIV	• Successfully used for other pathogens • Protective in some NHP systems	• Safety concerns • Attenuated variants cause disease in juvenile, and some adult, macaques • Attenuated viruses cause disease in humans
Inactivated SIV/HIV	• Successfully used for other pathogens	• Safety concerns re. consistent inactivation • No/few neutralizing antibodies • No CTLs
Envelope proteins	• Successfully used for other pathogens • Safe • Targets humoral immunity	• Narrow neutralizing specificity • No CTLs • No protection in two efficacy trials
Peptides	• Safe • Inexpensive • Potentially useful for wide antigenic diversity	• Poorly immunogenic in human trials • Formulation/adjuvant development required
DNA	• Presents immunogen in conjunction with HLA • Immunogenic in mice, NHP • Safe • Able to give multiple doses	• Poor immunogenicity in humans • Concerns about DNA integration
Viral vectors: (a) poxviruses	• Widely used in vaccines (vaccinia/smallpox vaccine) • Can be highly immunogenic • Induces cellular immunity	• Safety concerns (vaccinia) • Response to vaccinia limited by preexisting immunity (smallpox vaccination) • Limited immunogenicity (canarypox) • Limited/narrow neutralizing antibody response
(b) adenoviruses	• Highly immunogenic • Robust CTL response • Safe	• Response limited by preexisting immunity (especially Adeno serotype 5)

replicate in the vaccinee but do not cause disease. In vivo replication often elicits broad durable immune responses that, in many cases, are associated with sterilizing immunity and/or complete protection from disease. Early attempts to replicate these successes in HIV vaccine development investigated the efficacy of attenuated SIV vaccine candidates. The first of these candidates, SIV1A11, was produced by protracted passage in vitro.[104] Vaccination with this attenuated strain did not result in disease but showed limited efficacy in protecting vaccinated macaques against the challenge with pathogenic SIV.

Subsequent experiments using attenuated SIV built on the observation that development of simian AIDS was reduced in animals infected with SIV variants harboring *nef* deletions. Infection of macaques with experimentally constructed *nef*-deleted variants appeared to lead to CD4 preservation. Vaccinees were reported to resist challenge with pathogenic homologous or heterologous SIV.[105,106] These observations were apparently replicated in humans; a benign clinical course was reported for a group of six individuals who were exposed through blood transfusion to HIV carrying a deletion in *nef*.[107,108] However, the safety of this approach was called into question by late-onset immunosuppression in three of the transfusion recipients[109] and by progression to AIDS in infant and adult macaques infected with *nef*-deleted SIV, apparently related to recombination in vivo and emergence of more pathogenic variants over time.[110] In addition, durability of the vaccine effect was questioned due to lack of protection against challenge of macaques 3–6 years after vaccination with *nef*-deleted SIV.[104] Thus, although attempts to produce appropriately attenuated SIV strains are still ongoing, this approach has largely been abandoned due to concerns relating to safety, especially since ongoing replication of these attenuated virions may provide opportunities for mutations restoring pathogenicity.

INACTIVATED HIV VACCINES

Another approach that had been used successfully for other vaccines, such as rabies and polio, was the use of inactivated or killed HIV. Initially, this approach also appeared promising. Of the nine macaques immunized with formalin-inactivated SIV and adjuvant, eight were protected when challenged with 10 animal-infectious doses of SIV 2–3 weeks after boosting.[111] These promising results were not replicated, however, when similarly immunized animals were challenged with SIV that varied slightly from the immunizing strain or when challenge occurred after the peak response.[112] Further investigations revealed that the immune response in early nonhuman primate experiments was directed against xenoantigens on the surface of inactivated SIV. That is, immunity was directed against cell surface antigens retained in virions as they bud rather than against antigens specified by SIV itself.[113,114] An additional problem with this approach has been the loss of HIV- or SIV-specific antigens from the viral surface in the process of inactivation. A novel approach has recently been proposed by Poon et al., who used low-dose formaldehyde fixation of HIV prior to heat-inactivation of HIV to produce immunogen that retains envelope in a manner that preserves at least some neutralization epitopes.[115,116] Vaccination of mice with an immunogen based on a full-length infectious clone HIVsx treated in this manner resulted in low-level neutralizing activity against primary isolates of several clades. Vaccination of macaques with these constructs resulted in sporadic low-level responses.[116] Whether such work can effectively result in preserving conformational structures that elicit the levels and breadth of neutralization required is unclear. Safety concerns relating to residual infectivity in the inactivated product are also issues associated with this approach.

PEPTIDES/SUBUNITS

Given the problems with the two traditional vaccine approaches mentioned above, attention turned to the use of peptide or subunit vaccines to elicit neutralizing antibodies. Early efforts focused on use of gp120 immunogens to elicit antienvelope antibodies. Experiments in nonhuman primates indicated that neutralizing antibodies were elicited by this route, and it was hoped that this approach could be used to induce sterilizing immunity (i.e., that it would prevent infection completely).[117–119] However, the majority of experiments indicated that the antibody response was narrowly limited to the HIV strain used in the vaccine (or one that resembled it closely) and that this approach did not offer protection from challenge with primary isolates or other heterologous strains.[120,121]

Despite these discouraging results, two phase 3 efficacy trials were launched in the late 1990s using recombinant gp120 immunogens produced from cell-line adapted HIV strains. The first trial used envelop antigens from two different subtype B strains and was tested among 5403 volunteers in the United States, Canada, and Europe. This vaccine did not provide protection against infection (vaccine efficacy = 6%, 95% CI = [–17%, 24%]) and did not affect HIV disease course in participants who became infected.[61] A similar trial using subtype B and subtype E immunogens did not demonstrate protection from infection or HIV disease progression among injection drug users in Thailand.[122] The failure of these trials to show a protective effect strengthened the argument against empirical testing of vaccine candidates without better understanding of how the candidate might elicit protective immunity. It is widely held that development of immunogens that elicit broadly neutralizing antibodies is simultaneously critical for the field and its major challenge. A formal collaboration of scientists (The Neutralizing Antibody Consortium [NAC]) began in 2003 to address this scientific challenge. Current approaches include (1) use of immunogens that maintain or mimic the native trimeric structure of envelope proteins, (2) use of immunogens that favor presentation of neutralizing epitopes over nonneutralizing epitopes, (3) protection of stable intermediates that present conserved epitopes that are exposed during virus entry, and (4) use of epitopes identified by studies of broadly neutralizing monoclonal antibodies such as 2F5, 4E10, and 2G12 (see above).[45]

DNA VACCINES

Another recent approach involves the use of DNA plasmids to deliver DNA coding for HIV proteins or HIV epitopes. These plasmids do not integrate into the host cells of vaccinated individuals but rather remain episomal and act as expression vectors, producing peptides that can induce cellular immunity. They may contain sequences coding for large peptides or polyproteins produced by creating fusions of several HIV genes, or may code for individual HIV epitopes. Inclusion of strong promoters and enhancers, as well as codon optimization (substitution of common human amino acid codons for less frequent codons found in the HIV insert) of the inserts, help ensure high-level HIV protein expression. In contrast to viral or bacterial vectors, protein production in response to DNA vaccines is limited and can focus the immune response more narrowly on the HIV insert sequences. The HIV peptide immunogen synthesized within antigen-presenting cells after uptake of the plasmid is presented on the cell surface in conjunction with MHC class 1 antigens. Peptide immunogens produced within cells that do not present antigen are released at cell death and can be taken up by antigen-presenting cells, which in turn, present them on their cell surface in conjunction with HLA class 1.

Although immunization using DNA plasmids with HIV inserts elicited substantial cellular responses in mice and nonhuman primates, these products have been poorly immunogenic in humans. One attempt to increase immune response has included the use of genetic adjuvants, specifically the coadministration of DNA vectors coding for cytokines, most notably IL-12 and IL-15. In a second approach, DNA is used as the prime in a heterologous prime-boost strategy, with a protein or vector vaccine as the boost. Initial experiments using this approach in nonhuman primates were very promising. Animals primed with DNA and boosted with pox-virus vaccines (MVA or fowlpox) showed strong CD8 T cell responses.[123,124] While this approach did not prevent SHIV infection in vaccinated animals after parenteral or mucosal challenge, it was associated with control of viral replication and amelioration of clinical course.[125,126]

VIRAL VECTORS

Perhaps the most widely used approach at present is the use of recombinant viral or bacterial vectors as "Trojan horses" carrying HIV genetic sequences. These vaccine candidates enter the host cell, where they elicit immunity to the vector and to the product of the HIV gene they carry. This approach is useful for eliciting cellular immunity since the HIV genes are transcribed within the targeted cell and thus enter the HLA class 1 processing pathway.

Poxviruses

The prototype for this approach is vaccinia, a poxvirus used as a vector in the global smallpox campaign. Recombinant HIV vaccines constructed using this replication-competent vector elicited cellular immune responses to SIV and HIV antigens in nonhuman primate models.[127] However, vaccinia was abandoned in favor of more attenuated strains following a case report of vaccinia dissemination and death in an immune-compromised, HIV-infected individual.[128] Among the attenuated vaccinia strains, modified vaccinia Ankara (MVA) and the New York strain (NYVAC) have been most widely studied. The strain that gave rise to MVA was used initially in Turkey in smallpox vaccine production. In the 1950s, this strain was brought to Germany where it was further attenuated by repeated passage through chick embryo fibroblasts, a process that resulted in accumulation of multiple mutations and deletion of about 15% of the genome.[129] A very favorable safety profile was seen in the 120,000 vaccinees who received this product in Turkey and Germany as part of the smallpox campaign; MVA has subsequently been used in experimental HIV, malaria, and cancer vaccines.[129] NYVAC was developed through deletion of 18 open reading frames and is blocked at an early stage of replication.

These attenuated viruses retain little or no ability to replicate in human cells but can elicit humoral and cellular responses to the vaccine inserts (and to viral sequences). As with DNA constructs, attempts to enhance immunogenicity include repeated dosing, administration with costimulatory molecules such as cytokines, and use in heterologous prime-boost regimens. In nonhuman primate models, vaccination with MVA-based SIV vaccines decreased SIV viral load and ameliorated disease course after challenge.[130] Priming with SIV DNA plasmid followed by MVA or NYVAC boosting elicited SIV-specific cellular immunity[123,131] and ameliorated postinfection course in animals that become infected upon challenge.[125,132] Initial prime-boost trials in humans have been disappointing: only 10–20% of participants in trials of a DNA/MVA regimen showed anti-HIV cellular responses by ELISpot.[133] Several phase 1 trials of both MVA and NYVAC are ongoing or in the planning stages, and preliminary results show improved immunogenicity with second-generation MVA and NYVAC constructs.

Canarypox is the HIV vaccine vector studied most extensively in humans to date. These viruses are host-range restricted and undergo abortive replication in human cells. Engineered foreign genes in vector inserts are transcribed and translated, allowing immunogen expression and presentation without vector replication in the host cell. Data from 1126 HIV-uninfected volunteers indicate that HIV vaccines using these vectors are safe and well tolerated with a reactogenicity profile similar to that of existing vaccines licensed for use in adults.[55] Additionally, canarypox vectors showed no significant safety concerns when tested in over 400 HIV-infected volunteers.[134] During the past 15 years, over 30 phase 1 and 2 trials involving more than 1500 participants have been conducted with first- and second-generation canarypox HIV vaccines (such as ALVAC), mostly in the United States through the AIDS Vaccine Evaluation Group (AVEG).[134] These trials were initially met with enthusiasm because the vaccine candidates were not limited by preexisting vaccinia immunity, could be used in homologous or heterologous prime-boost regimens, and appeared to induce both humoral and cellular immunity. However, as with other approaches, the neutralizing antibody response was limited and did not neutralize primary isolates.[134] These poxvirus vectors were the first to convincingly demonstrate a T cell response to HIV antigens after vaccination. Initial studies that utilized in vitro stimulation to enhance detection of T cell responses suggested that in up to 30–40% of such responses could be detected from volunteers if multiple samples were obtained during the course of vaccination. Recent assays using a more stringent stimulation directed at defining circulating memory T cells suggest the responses are present in 8–10% of persons, well below the amount seen with recombinant adenovirus vectors.[9,56,134–136] Because of initial encouraging cellular responses, a pivotal trial was conducted in 2001–2003 using a second-generation ALVAC prime (vCP1452) and a recombinant gp120 (AIDSVAX™ B/B subunit) boost to qualify this regimen for efficacy testing. Responses seen in this trial did not meet the preset immunogenicity criteria and plans for an efficacy trial of this regimen were therefore abandoned.[137] Several preclinical and clinical studies are ongoing with the aim of optimizing the immunogenicity of these vectors. In Thailand, a phase 3 trial of a canarypox vector (vCP 1521) containing the HIV-1 clade B *env*, *gag*, and protease genes, in combination with gp120 (clades B and E) completed enrollment in January 2006; follow-up is ongoing and is expected to end in mid-2009.[138]

Adenoviruses

The most promising candidates at present are HIV vaccines constructed using adenovirus vectors. These viral vectors are rendered replication-defective by mutations and the deletion of an adenovirus gene. HIV genes are inserted in its place under the control of exogenous promoters and regulatory elements that drive high-level expression of the HIV insert and adenovirus genes. The replication-incompetent adenoviruses retain the ability to infect cells and to deliver their genome to the nucleus.

Two different products are in advanced clinical testing at present. The first, produced by Merck, contains an admixture of three adenoviruses containing codon-optimized subtype B *gag*, *pol*, or *nef* genes, respectively. These three HIV genes are conserved (80% to >90% conserved) across subtypes. The Merck adenovirus vectors containing *gag* alone or a trivalent preparation containing *gag*, *pol*, and *nef* produce robust cytotoxic $CD8^+$ T cell responses in macaques (500–1000 γ-interferon-producing cells/10^6 PBMCs after vaccination with 10^{11} viral particles).[139,140]

The Merck trivalent adenovirus vaccine provided protection in animal models. Vaccinated macaques were intravenously challenged with SHIV 89.6P, a pathogenic SIV/HIV chimeric virus. Although there was no protection from infection, HIV replication was suppressed. Test animals experienced a mild course of infection, which did not progress to AIDS during the follow-up period.[141,142] Although there is debate about how accurately these experiments will predict results in humans, these results are promising.

In phase 1 testing, the Merck Ad5 HIV vaccines have been safe and well tolerated in 1200 study participants to date.[143] T cell responses have been elicited in 70% of trial participants, with slightly lower response rates among participants with prior adenovirus immunity.[143] Interestingly, compared with Merck's monovalent product, their trivalent Ad5 vaccine appears to increase the frequency and breadth of responses and to reduce the response disparity between participants with and without preexisting Ad5 immunity (Table 100-3).[143] A test-of-concept efficacy trial of the Merck Ad5 product

Table 100-3. Comparison of ELISpot Responses Elicited by MRK *gag*-Only and Multigene Ad5 Vaccines

Dose level	Ad 5 Titer	Week 30 Elispot Response											
		Monogene			Multigene								
		Gag			Gag			Pol			Nef		
		N	%	GM	*N*	%	GM	*N*	%	GM	*N*	%	GM
1×10^9 vp/d	≤200	32	72%	207	20	75%	281	20	45%	490	20	60%	196
	>200	14	21%	105	17	35%	219	17	18%	233	17	24%	223
1×10^{10} vp/d	≤200	32	53%	221	22	73%	205	22	59%	342	22	68%	177
	>200	24	29%	287	14	71%	405	14	43%	641	14	57%	401

Dose level for the trivalent represents the gag-only component.

vp/d, viral particles per dose; *N*, number in each group; %, percentage of responders; GM, geometric mean ELIspot response for responders only.

ELIspot responder: ≥55 SFC/10^6 PBMCs and ≥fourfold over media control.

began in late 2005 and is fully enrolled. This 3000-person phase 2B trial (the STEP study), is being conducted by Merck and the HIV Vaccine Trials Network (HVTN) in the North and South America, Australia, and the Caribbean to evaluate efficacy in reducing either HIV acquisition among all trial participants or viral load setpoint among vaccinees who become infected with HIV.[144] A second 3000-person, cross-clade, test-of-concept trial began enrollment in early 2007 to assess the safety, immunogenicity, and efficacy of this same clade B vaccine in the Republic of South Africa, where clade C HIV predominates.

The second Ad5 candidate, developed by the U.S. National Institutes of Health's (NIH) Vaccine Research Center (VRC), is designed to provide multiclade protection. It is an admixture of four adenoviruses, one of which contains a subtype B *gag-pol* gene fusion. The other three adenoviruses contain subtype A, B, or C envelope genes. This VRC construct has also elicited strong humoral and cellular responses in macaques. The magnitude and breadth of the response was improved by prior priming of the product with the DNA plasmids discussed above.[145,146] In nonhuman primate studies, the VRC DNA prime/adenovirus boost vaccine did not protect animals from infection. However, viral replication was suppressed and vaccinated macaques experienced a mild course of infection, which did not progress to AIDS during the follow-up period.[141,146,147] In recent experiments in nonhuman primates, ameliorated course and prolonged survival in vaccinated animals after SIVmac251 challenge was associated with preservation of central memory cells.[148] In phase 1 trials, both the DNA product and the adenovector candidate were safe and immunogenic when administered individually.[149–151] The VRC prime-boost vaccine regimen, consisting of three doses of DNA boosted with a single dose of Ad5, elicited greater humoral and cellular responses in the majority of trial participants.[152] Of note, the VRC Ad5 candidate seems to stimulate more frequent CTL responses to *env* antigens than to structural gene products. Phase 2 testing of the VRC DNA-adenovirus prime-boost regimen was conducted in the United States, the Caribbean, South America, and Africa. This regimen is being evaluated in a large test-of-concept trial that began in these same regions in late 2007. This trial will enroll 8500 participants and is being conducted collaboratively by the NIH VRC, the HVTN, the International AIDS Vaccine Initiative (IAVI), the U.S. Military HIV Research Program (USMHRP), and the Centers for Disease Control and Prevention (CDC). Safety and preliminary efficacy will be evaluated in three regions, where clades A, B, and C predominate, respectively.

A blunted immune response to Ad5 HIV vaccines because of prior exposure to Ad5 (a common respiratory virus)[139,140,146,147] presents a potential problem for use of this approach in some of the regions that are hardest hit by the HIV pandemic. In these regions, high-titer Ad5 seroprevalence increases rapidly during childhood to 50–80%.[153] A number of strategies to overcome this problem are currently being investigated, including use of adenovirus vectors of

uncommon serotypes, production of chimeric adenoviruses, priming with DNA, or prime-boost combinations of Ad5 with other adenovirus or poxvirus vectors.[139,140,146]

ADJUVANTS

Another area of ongoing research is adjuvanting of HIV vaccine candidates. Many of the current vaccine strategies do not produce immune responses that are robust, long-lived and appropriately focused on production of neutralizing antibodies or cytotoxic responses. Adjuvants could overcome this by targeting the antigen to antigen-presenting cells or increasing immune response by stimulating production of cytokines and costimulatory molecules or both. Adjuvants such as polymeric microspheres (e.g., polylactide-coglycolide or PLG) have been tested with HIV vaccine candidates to increase immune response through facilitating interactions with antigen-presenting cells.[154] The complementary approach, induction of relevant cytokines and upregulation of costimulatory molecules, is used by other adjuvants such as CpG, unmethylated cytosince-guanine dinucleotides, which acts as a ligand for toll-like receptor 9 (TLR9).[155] Stimulation of TLRs in turn enhance and direct immune response. A related approach is the administration of vaccine candidates with costimulatory molecules such as Il-12, IL-15, or granulocyte-macrophage stimulating factor (GM-CSF) in an attempt to manipulate the immune response and increase cell-mediated immunity to the coadministered HIV vaccine antigen.[156]

CONCLUSIONS

Major advances in the HIV vaccine field have been made in the last 3 years. Most of this progress has been in the development of recombinant vector-based immunogens directed at producing memory T cell responses to HIV-1 in order to reduce the effects of the acute, rapid immunodeficiency that accompanies initial HIV infection, a universal feature of acute infection regardless of symptoms. Advanced clinical trials are underway to evaluate whether the first generation of these vaccines is efficacious. These studies will determine whether the current viral vector vaccines are capable of eliciting the quantity and quality of T cell responses that are needed to alter the course of HIV-1 infection for individuals and populations around the globe. If these trials are successful, the world will enter a new phase of defining the strategies through which these vaccines can be used to control the HIV pandemic.

101 Prevention and Control of STD and HIV Infection in Developing Countries

Gina A. Dallabetta, Teodoara Elvira C. Wi, and Graham Neilsen

INTRODUCTION

Sexually transmitted infections (STIs), a diverse group of infections, are responsible for a large burden of morbidity and mortality in the developing world because of their role in facilitating HIV transmission and because they have a significant adverse impact on reproduction and child health.[1,2] In the 1990s, STIs were the focus of considerable attention from international donors interested in both HIV control and women's health.[3] These efforts were supported by evidence of strong links between STIs and HIV transmission and the political agenda where family planning was put in the context of broader reproductive health initiatives.[3] The international focus on and funding for STI control has decreased recently for several reasons. The global focus on HIV prevention was overshadowed by the large international efforts and funding shifts to scale up treatment and mitigation programs for persons with AIDS.[4] Three community-based randomized clinical trials provided conflicting results on the impact of STI treatment on HIV transmission, leading to more nuanced recommendations.[5–9] In addition, syndrome management, a case-management approach promoted widely for settings with limited resources, had poor performance characteristics in women, especially in low prevalence settings.[10–12] Existing STI control efforts are hampered in many countries by failure to implement basic management principles. Moreover, advocacy efforts to gain political and financial commitment to address the burden of STIs and their sequelae are hindered by stigma and lack of data on disease burden and documentation of intervention effectiveness.[13]

STIs AND HIV IN THE DEVELOPING WORLD

SEXUALLY TRANSMITTED INFECTIONS

Incidence and prevalence rates of STIs are significantly higher in the developing world but can vary widely across sites.[14] Global estimates of the impact of STIs, however, underestimate their importance because STIs are extremely underdiagnosed, underreported, or their sequelae are classified under maternal, child, or cancer morbidity and mortality statistics and not under the broad category of STIs.[13] There is evidence that bacterial STIs are decreasing in many countries as a result of the implementation of STI case management, including syndromic management, along with overall HIV prevention efforts.[15–17] Viral STIs are now more common in many areas.[18–22]

In developing countries, STIs are inadequately treated for a myriad of reasons. Low priority in strategies and plans and consequent low budgets leave these programs underresourced in the public sector.[23] There are limited efforts to engage and improve private sector services where the majority of patients will seek care initially.[24–26] Diagnostics and drugs are not available either due to cost or poor logistics systems.[18,27,28] Delays in patients seeking care because of lack of symptom recognition, stigma associated with genital symptoms, the asymptomatic nature of many STIs, and lack of access to services also contribute.[29,30]

SEXUAL TRANSMISSION OF HIV

In addition to the stage of HIV infection, STIs are an important determinant of increased genital HIV viral shedding.[2,31,32] The most compelling evidence that STI treatment impacts HIV transmission are the studies that document declines in genital tract HIV shedding after treatment.[33–36] Yet three of the four clinical trials done to examine the question as to whether STI treatment reduces HIV transmission have shown no impact.[5,6,8,37] These disparate results are felt to be due to underlying differences in the study populations with respect to the prevalence of curable STIs, the stage of the HIV epidemic, and the sexual risk behaviors of the population.[38–40] In addition, these four clinical trials examined the role of treating curable STIs only; the role of HSV-2 and its treatment were untested.

The biological relationship between HIV and STIs is little disputed. However, the programmatic implications of STI treatment to reduce HIV transmission at the community

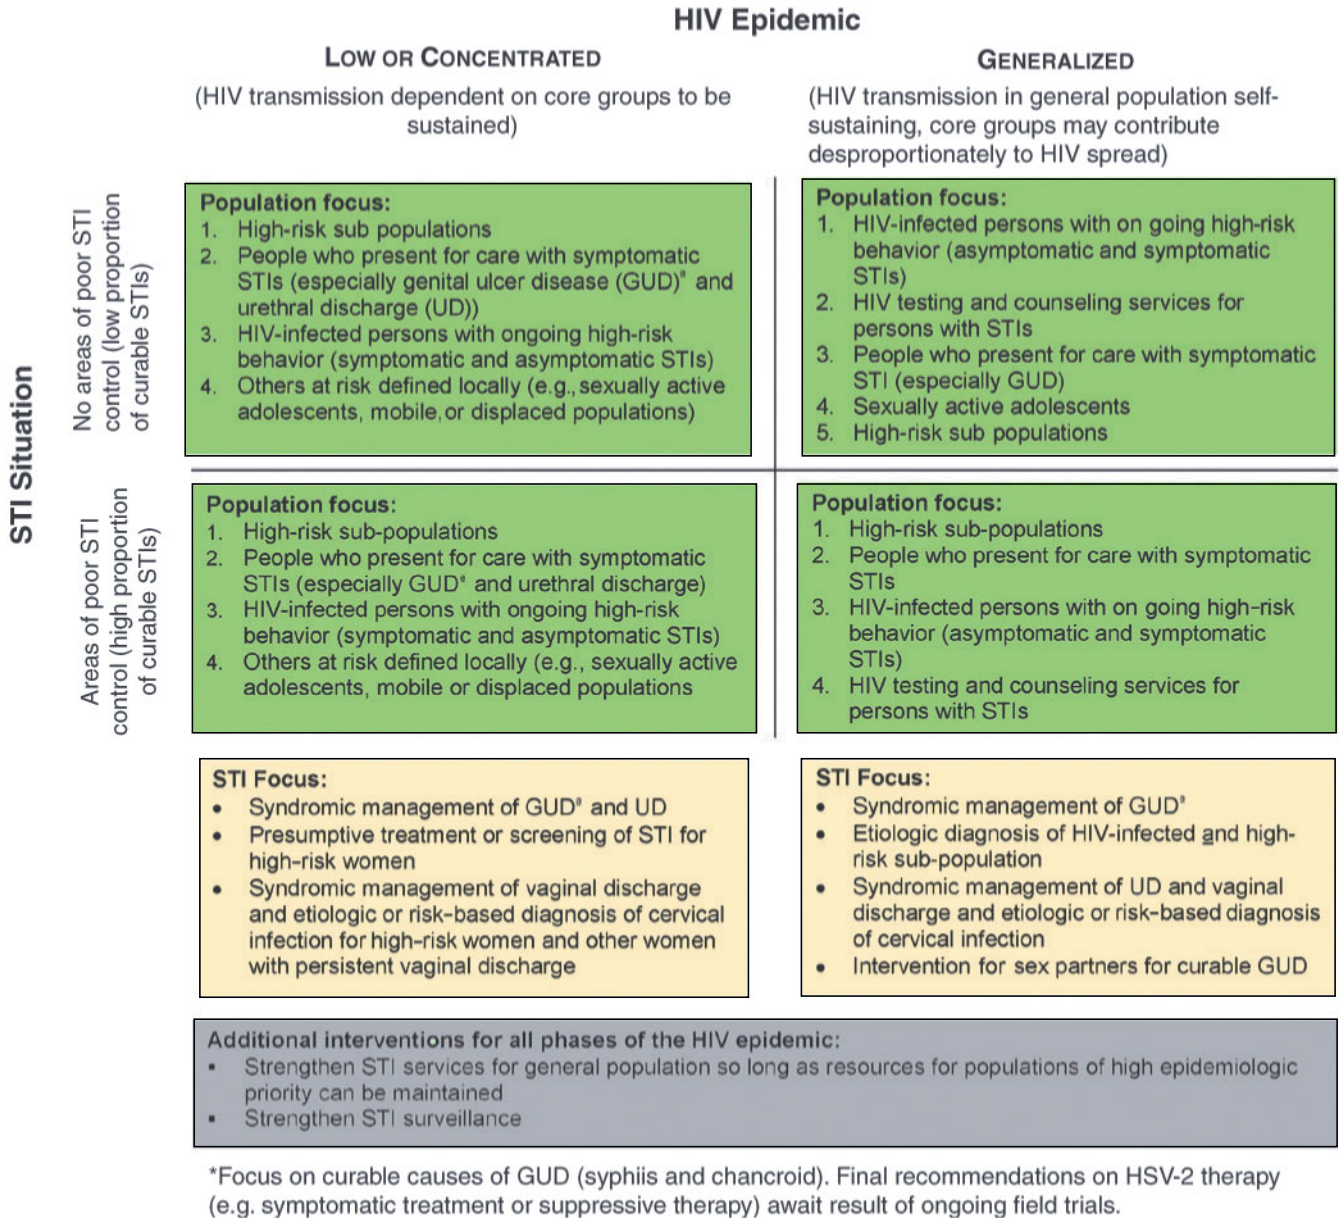

FIGURE 101-1. Framework for priority setting of subpopulations for STI control measures with consideration of the HIV epidemic and STI situation. (Adapted from WHO/UNAIDS. *Consultation on STI Interventions for Preventing HIV: Appraisal of the Evidence.* World Health Organization and Joint United Nations Program on HIV/AIDS, in press.).

level have been difficult to prove. Recommendations for directing how STI control should be instituted for HIV prevention depend on the detailed knowledge of the stage of the HIV epidemic and the state of STI control.[9, 41] These recommendations are outlined in Fig. 101-1[9].

PRINCIPLES AND PRIORITIES FOR STI CONTROL AND HIV PREVENTION

STI control programs aim to reduce the rate of incident infections through a combination of prevention and treatment strategies. These include behavior change to reduce sexual risk, increase use of barrier methods, and treatment of persons with STIs. Additional insights into transmission dynamics, new technologies and approaches such as suppressive or prophylactic therapies, male circumcision, vaccines for STIs, and microbicides, when available, will add additional tools and program demands to current control efforts.

Comprehensive STI prevention and control in developing countries should include a wide range of approaches to address STIs at all levels of health system and within targeted communities according to national priorities as outlined in Table 101-1. Ideally, these approaches should be incorporated into a comprehensive STI strategy with implementation plans that clearly state the goals and priorities of the program based on knowing the local STI and HIV epidemic, the

Table 101-1. Government's Role in Comprehensive STI Prevention and Control Program

National-level policy

Setting goals and prioritization

Allocation of resources on:
- prevention and treatment of STIs
- additional data needs

Political advocacy for a supportive policy and legal framework

Leadership on community discourse on sexual matters, stigma, and discrimination

National program evaluation

National-level normative functions

Development and distribution of guidelines
- case management guidelines for general population and high-risk subpopulations
- laboratory and quality assurance
- surveillance system

Planning and guidance of specific activities for STI control
- focused interventions for high-risk subpopulations (usually with HIV program)
- syphilis screening and treatment and ophthalmia prevention in antenatal clinic settings
- HPV immunization program
- chlamydial screening and treatment for women
- private sector partnerships
- other as prioritized

Articulation of an evaluation plan with indicators

Development of monitoring and evaluation system

Operationalization functions

Organization of health services to meet goals
- integration of STI clinical service delivery
- supervision into primary health care and private providers
- establishment of referral systems for more complex management

Establishment of special services to meet the needs of key high-risk subpopulations and linking with HIV prevention programs

Establishment of links with sexual and reproductive health services, HIV services, and others per priorities

Design of behavior change communication to:
- reduce stigma and discrimination
- reduce STI risk behaviors
- increase health-seeking behavior

Organization of logistic management systems to ensure uninterrupted supplies of commodities, antimicrobials, condoms, water based lubricants, and laboratory reagents

Establishment of training systems to train health-care providers on:
- clinical management including quality
- functioning of the clinic infrastructure
- monitoring system

Provision for ongoing information about technical issues

Establishment of supportive supervision and monitoring feedback system

Fostering of a culture of data use at all levels

implementation mechanisms to reach the goals, and an articulation of what other actors will be involved and their role in meeting the goals.[42]

STI TRANSMISSION DYNAMICS

The epidemiology of STI transmission has defined the basic strategies for prevention interventions for STIs. Following from the classic model of Anderson and May, $R_0 = c \times \beta \times D$, interventions can prevent spread of an STI within a population by (1) reducing the rate of exposure to STI by lowering the rate of partner change; (2) by reducing the efficiency of transmission; or (3) by shortening the duration of infectiousness for that STI through treatment. These approaches are summarized in Fig. 101-2.[43]

Recent research reveals a more complex picture of STI epidemiology. This complexity is based on the fact that populations consist of diverse subpopulations each with distinct subpopulation characteristics and consequent infection patterns.[44] Sexual networks and concurrency are important in STI transmission dynamics, and an individual's position in the network is important in determining risk of transmission or acquisition.[45] Characteristics of specific STI pathogens (transmission probability and duration of infectiousness), partner numbers and duration of relationships, and the effectiveness of the health system also impact how specific STI epidemics evolve.[46]

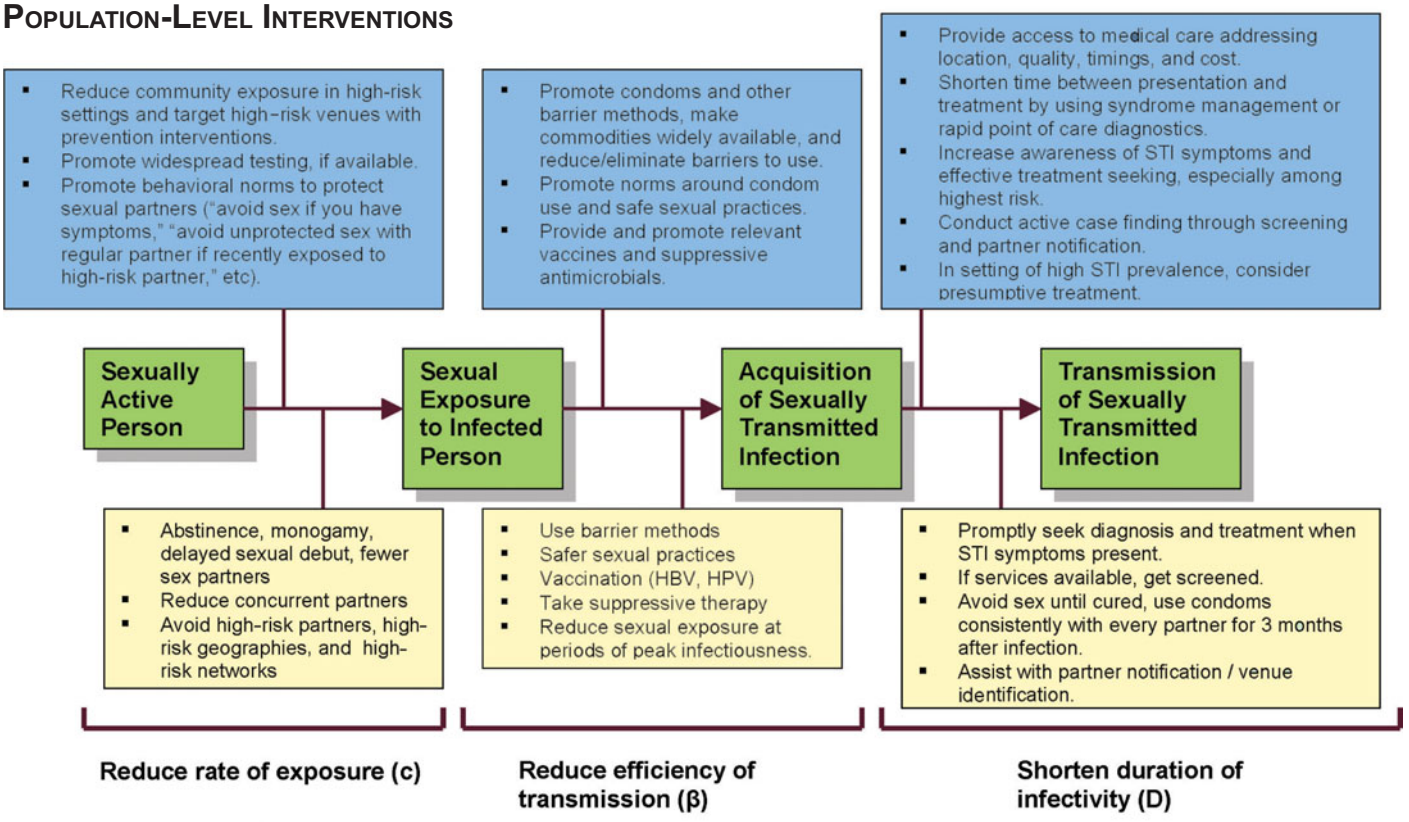

FIGURE 101-2. Individual and population-level interventions for STI control. (From Holmes K, DeLay P, Cohen M. STD control: A public health priority. In: Dallabetta G, Laga M, Lamptey P, eds. *Control of Sexually Transmitted Diseases: A Handbook for the Design and Management of Programs.* Arlington, VA: Family Health International, 1997.)

PRIORITIES FOR STI PROGRAMMING

Ideally, all decisions about prioritization of STI control efforts to control STIs and to impact HIV transmission should be based on understanding the STI and HIV epidemic in the specific country. In most developing country settings data are limited. Nonetheless, population-level behavioral data is becoming increasingly available as a result of HIV prevention programming, and special surveys are being done in countries or special modules for men and HIV are being added to other large behavior surveys.[47] The surveys often provide information on sex worker contact by men or reported numbers of sexual partners by men and women. Similarly, information on prevalence levels of specific STIs and HIV coupled with some behavioral data is more available.

High-risk subpopulations play a disproportionate role in STI and HIV transmission and should be a primary focus of STI prevention and treatment interventions. Second, individuals with STI-related symptoms, particularly genital ulcer disease and urethral discharge, presenting for care represent individuals from a high-risk subpopulation or network and should be provided effective services. A disproportionate number in individuals with acute HIV infection, the most infectious stage of HIV infection, are identified among STI patients suggesting that the STI and HIV are cotransmitted.[48] In addition, STI services can impact potential transmission from current HIV-infected individuals by providing prompt, effective treatment.[49] Individuals with STIs should be involved in finding and treatment of partners and can also be utilized to identify high-risk locations where prevention interventions should be focused.

After focusing on high-risk subpopulations, on individuals with presenting with symptoms and HIV-infected persons, the program will need to decide what, if any, specific STI pathogens should receive program resources and attention. These decisions will depend on several factors:[50] (1) their overall incidence, prevalence, distribution, and public health impact of specific STI pathogens; (2) clinical characteristics (e.g., symptomatic or not) and sequelae; (3) availability of prevention tools and technologies such as rapid, accurate diagnostics; affordable, preferably single-dose treatments; and vaccines; (4) ability of the health system to absorb the new interventions in terms of training, logistics, monitoring, and surveillance; and (5) the political and cultural acceptability of the intervention among the general population as well as the affected communities. Congenital syphilis prevention, for example, should be implemented by every program.[51,52] The recent licensing of a human papillomavirus (HPV) vaccine to prevent cervical cancer offers great possibilities to prevent

disease, but cost and politically positioning a vaccine for STIs will need to be addressed.[53] The vast majority of chlamydial infections are asymptomatic, especially in women, but account for considerable individual morbidity and mortality as well as profound social and economic impact in women in terms of divorce, stigma, and poverty induced by infertility.[54]

HUMAN RIGHTS AND GENDER EQUITY

STI control programs including HIV prevention interventions work with subpopulations who are already marginalized and are least able to realize their human rights. Central to all programming for these groups is a respect for human rights with institution of policies around confidentiality and respect.[55] Programs, in order to provide services to these subpopulations, may have to address a wider range of health and safety issues within a human rights framework to help ensure active participation of marginalized groups and to prevent coercion. Women and girls are more vulnerable to STIs including HIV infection due to gender inequalities. In some settings, gender norms and relations around marriage, harmful traditional practices, and barriers to women's education increase their risk. Ensuring equal opportunities for women to access prevention and sexual and reproductive health services, reducing violence against women, and protecting their rights is essential for STI control. It is important to engage men and boys in efforts for a long-standing impact on gender inequalities.

PRIMARY PREVENTION STRATEGIES FOR STI AND HIV CONTROL

Keeping individuals and communities uninfected from STI and HIV is fundamental to STI and HIV control. Primary prevention interventions are a crucial component for control, especially in resource-poor settings with limited treatment and diagnostic options, and in the face of a shifting pattern of STIs from curable bacterial STIs to noncurable viral STIs. Moreover, primary prevention strategies to decrease exposure to infectious persons through partner reduction or decrease efficiency of transmission through condoms or other barrier methods would have impact over all, or most, of the STIs, as opposed to vaccines, suppressive therapy, or screening tests which are pathogen-specific. As a result of HIV prevention programming and HIV awareness, there appears to be a change in sexual risk behaviors in some developing countries with specific behavior changes being reported such as delayed sexual debut, increased monogamy, reduced number of partners, increased condom use, and avoidance of sexual contact with sex workers.[15,56–58]

BEHAVIOR CHANGE PROGRAMMING

Effective behavior change programs, or sexual health promotion activities, have multiple aims. At the individual level, the goal is to reduce risk behaviors that can allow individuals to acquire and transmit HIV and other STIs. This includes safer sexual behaviors such as remaining sexually abstinent or delaying initiation of sexual activity, decreasing the number of sexual partners, decreasing the number of concurrent sexual partners, and using condoms consistently and correctly.[59] In addition, programs attempt to stimulate open discussion on the underlying factors for risk, risk behaviors and settings and local solutions, counter stigma, and influence the social responses. The ultimate goal is to change social norms around preventive behaviors, making them more normative.[60]

For subpopulation groups who may have higher risk behavior and may have less access to health services because of social issues (e.g., sex workers, men who have sex with men (MSM), injecting drug users (IDUs), migrant workers, and sexually active adolescents), communication strategies using outreach and peer education have been the cornerstone of interventions. Through active outreach, access to those who are at increased risk of STIs has been possible.[61]

Additional behavior change goals are to change community attitudes and reduce stigma and discrimination, to create a demand for information and services related to STIs and HIV, to improve symptom recognition by individuals in order to seek appropriate care earlier, and increase overall knowledge and understanding of specific STIs.

Finally, behavior change goals converge with advocacy goals of (1) informing policy-makers and key opinion leaders about the consequences and burden of specific STI pathogens; (2) advocating for intervention options and cost-effective approaches; and (3) articulating policy and legal reforms that would enhance prevention and control efforts.

STRUCTURAL INTERVENTIONS

Structural and environmental interventions have the potential to alter the prevention environment making it supportive of behavior change objectives, be it at the level of availability of services, social or political.[62] Such approaches can focus on ensuring the availability of commodities, equipment, materials, or settings that are necessary to practice healthy behaviors. These may include ensuring availability of condoms, lubricants, STI services, HIV counseling and testing, or developing policies to ensure condoms in venues associated with sexual encounters. The 100% condom use policy of Thailand, where government policy required that condoms be used in brothel-based commercial sex encounters and made establishment owners responsible for condom use by their clients, is one such example.[63] Condom social marketing, another example, uses a mix of marketing strategies to motivate and encourage individuals to use condoms while making condoms more accessible by distributing to nontraditional sales outlets and making them more affordable.[64,65] Other structural interventions at the policy level have included changes

in laws to decriminalize or legalize sex work or MSM sexual behavior, or levy legal penalties against hotel or brothel owners if preventive regulations are not implemented.[62] Policy interventions such as safe work policies for brothels, antistigmatization efforts for marginalized groups, alcohol taxes, and media campaigns to reduce violence against women have also been done. Where assessed, structural interventions were found to be cost-effective, especially in addressing populations with low HIV prevalence but high vulnerability.[66,67]

At a more local level, increasing the social, economic, and political power of marginalized groups by empowering them to alter their local environment, and consequently their risk for STIs and HIV, has resulted in more sustainable prevention interventions in a brothel area in Kolkata (Calcutta), India.[68]

PREVENTION TECHNOLOGIES

Barrier methods

Male latex condoms. There is strong evidence that male latex condoms reduce transmission of HIV by 80–85%, gonococcal and chlamydial infection, herpes simplex virus (HSV), HPV, and reduce the risk of unintended pregnancy.[69–72] Condom failures occur due to method or device failures as well as user failures. Key to effective condom promotion is a focus on ensuring quality condoms in the programs, getting them where they are needed, and education on proper and consistent condom use.[73] Enhancing skills to negotiate condom use, to use condoms, and intensifying risk reduction counseling can increase acceptability to sexual partners.[73]

Female controlled barrier methods. Female controlled methods where partner negotiation during sexual intercourse could be avoided and methods that could be used without detection during sex would be powerful tools for women. Studies show that availability and use of female condoms offer at least as much protection as male latex condom use and may increase the overall number of protected sex acts.[74] There are several constraints to large-scale implementation of female condom use. First is the higher cost of the female condom compared to the male condom and limited data to assess the cost-effectiveness of female condom programs. Second are the program requirements of introducing the female condom that are more complex than for male condoms.[75]

Observational studies on the effectiveness of the diaphragm to prevent STIs have shown evidence of protection from gonorrhea, pelvic inflammatory disease (PID), and cervical dysplasia.[76] A randomized controlled trials on the HIV prevention effectiveness of the diaphragms in southern Africa showed no added benifit in addition to condoms and HIV prevention services in prevention of HIV transmission.[76a] Several microbicides are in various stages of development; there is currently none available for use.[77]

Other prevention technologies

Vaccines. Cervical cancer is the second most common cancer in women in the world.[78] In 2006, a quadrivalent HPV-associated cervical cancer vaccine was approved for use in the United States, the UK, and elsewhere.[79] The current cost is prohibitive in developing countries although several efforts are underway to make it available.[53] Sexual transmission of hepatitis B has been documented mainly in developed countries.[80] Hepatitis B vaccine has been available for many years and preexposure vaccination is recommended for individuals at risk. For HSV-2, both preventive and therapeutic vaccines are under development. HIV vaccines, similarly, are under development.

Male circumcision. Circumcised men appear to be at lower risk of syphilis (although there was a significant heterogeneity among the syphilis studies), chancroid, and borderline significant reduced risk for HSV-2 infection.[81] Recent randomized controlled trials from sub-Saharan Africa have had remarkably consistent results across three trials showing that male circumcision reduces risk of acquiring HIV from a female partner by about 50–60%.[82–84] Whether this new prevention intervention will be positioned as a public health intervention and widely promoted or provided on an as needed or targeted basis will depend greatly on the country's overall circumcision rates, HIV rates, as well as cultural and religious considerations.

Herpes simplex virus type 2 (HSV-2) suppressive therapy. HSV-2 is the major cause of genital ulcers in both the developed and developing countries.[85] Viral shedding of HSV-2 occurs frequently in infected individuals with clinical or subclinical disease and is a significant risk factor for transmission. Suppressive HSV-2 therapy has been shown to decrease transmission to uninfected heterosexual partners, and daily suppressive therapy and condoms are recommended for HSV-2 serodiscordant couples.[86] In a recent report, HSV-2 suppressive therapy reduced HIV both in the genital secretions and plasma in dually infected women.[87] Several ongoing randomized controlled trials are investigating the effect of symptomatic and suppressive therapy on HIV transmission and acquisition.[88]

STI MANAGEMENT APPROACHES

Experiences in some low- and medium-income countries such as Thailand, Nairobi, Botswana, and parts of South Africa have shown that it is possible to control the common curable STIs, even in settings with high transmission dynamics, through a comprehensive strategy of prevention and treatment.[9,16,89,90] Prompt, effective, and comprehensive STI case management (see Table 101-2) remains an important pillar of STI control within existing networks of healthcare facilities, both public and private.

Even the most well equipped STI clinics will have limited impact on STI control if there is poor utilization of STI services.

Table 101-2. Elements of Comprehensive STI Case Management

Prompt, accurate diagnosis
Provision of effective treatment for STIs (preferably single-dose treatment) with minimal delay after presentation
Education and counseling on • the nature of infection • mode of transmission • the need for adherence to treatment • risk reduction measures • proper use of condoms • need for treatment of all sexual partners • recommendations for HIV testing • the need to use condoms with all partners for 3 mo and (re)test for HIV
Provision of condoms and demonstration of condom use
Partner treatment
The opportunity for follow-up examination to assess treatment outcome

An operational model for estimating program effectiveness for tuberculosis was adapted to STIs and highlights the major barriers to STI case management as illustrated in Fig. 101-3[91].

The degree and severity of symptoms associated with various STI pathogens greatly influence treatment seeking behavior. The difference in percentage between infected and symptomatic would be small in men with gonorrhea and would be large in women with chlamydial infection. As such, different control interventions would be necessary for each disease; prompt access to effective services for men with gonorrhea would be an important approach, while for women with chlamydial infection screening and treatment would be needed.[50]

Approaches to addressing each level of "drop-off" from infected person to cure and partner treatment are outlined in Fig. 101-3. While improving STI care provided in health-care facilities can address some of the barriers, workplace and flexible community-level interventions are needed to increase the coverage and use of STI services by those who are infected. Linking STI services to ongoing outreach programs being implemented by HIV prevention programs is one way to address access of high-risk subpopulations.[92]

STI MANAGEMENT OF SYMPTOMATIC PERSONS

Provision of effective services to symptomatic STI patients and their partners should be among the top priorities of an STI control program. Symptomatic STI patients may be aware that they are infected and are more likely to seek care. While bacterial and protozoan STIs can be cured, viral STIs can only be treated to reduce the severity of an episode and suppress recurrence. Nonetheless, individuals with viral STIs can still benefit the STI services by receiving counseling on safer sex, partner notification, counseling regarding HIV testing, and general health information. Ultimately, the goals of STI case management are to (1) provide appropriate treatment to cure and decrease infectivity; (2) reduce risk-taking behavior; (3) ensure that sexual partners are treated to break transmission; and (4) to decrease HIV transmission.

Syndrome case management

The syndromic case management endorsed by WHO/UNAIDS in the early 1990s still remains the standard of care in resource-poor settings for the management of the most common STI syndromes. This approach addresses the limitation of etiologic and presumptive clinical diagnosis.[93,94] Syndrome management was originally designed and promoted to help clinicians manage symptomatic patients. It was never intended to be used as a tool for case finding or for screening asymptomatic patients and predictably, this misuse of the approach led to disappointment. Syndrome management was most commonly misapplied in settings servicing women (e.g., family planning clinics and antenatal care settings). Most gonococcal or chlamydial cervical infections in women are subclinical or asymptomatic, so there would be no syndromic presentation. The second misconception around syndrome management was that it was implemented as the key, and sometimes only, strategy in STI control programs and was viewed and promoted as a simplistic solution to a complex problem.[3] While service provision to symptomatic individuals is a core component to comprehensive STI control programs, it cannot stand alone. Approaches to STI control need to be more multifaceted working across multiple programs to achieve the goals.[42]

STI syndromes are easily identifiable groups of symptoms and signs. Syndrome management provides treatment for the most common organisms causing the syndrome.[11] Algorithms (flowcharts) have been developed for the management of the major STI syndromes: urethral discharge, genital ulcer disease, vaginal discharge, scrotal swelling, and lower abdominal pain. Risk assessments that are locally adapted are utilized to improve the diagnostic validity for gonococcal and chlamydial cervical infection. The advantages and disadvantages of syndrome management are outlined in Table 101-3.

The syndromic approach is effective and cost-effective for urethral discharge and genital ulcer disease syndromes.[95,96] However, most algorithms do poorly in detecting herpes infection.[96] Vaginal discharge algorithms are not highly effective in managing gonococcal and chlamydial cervical infection, the majority of which are asymptomatic.

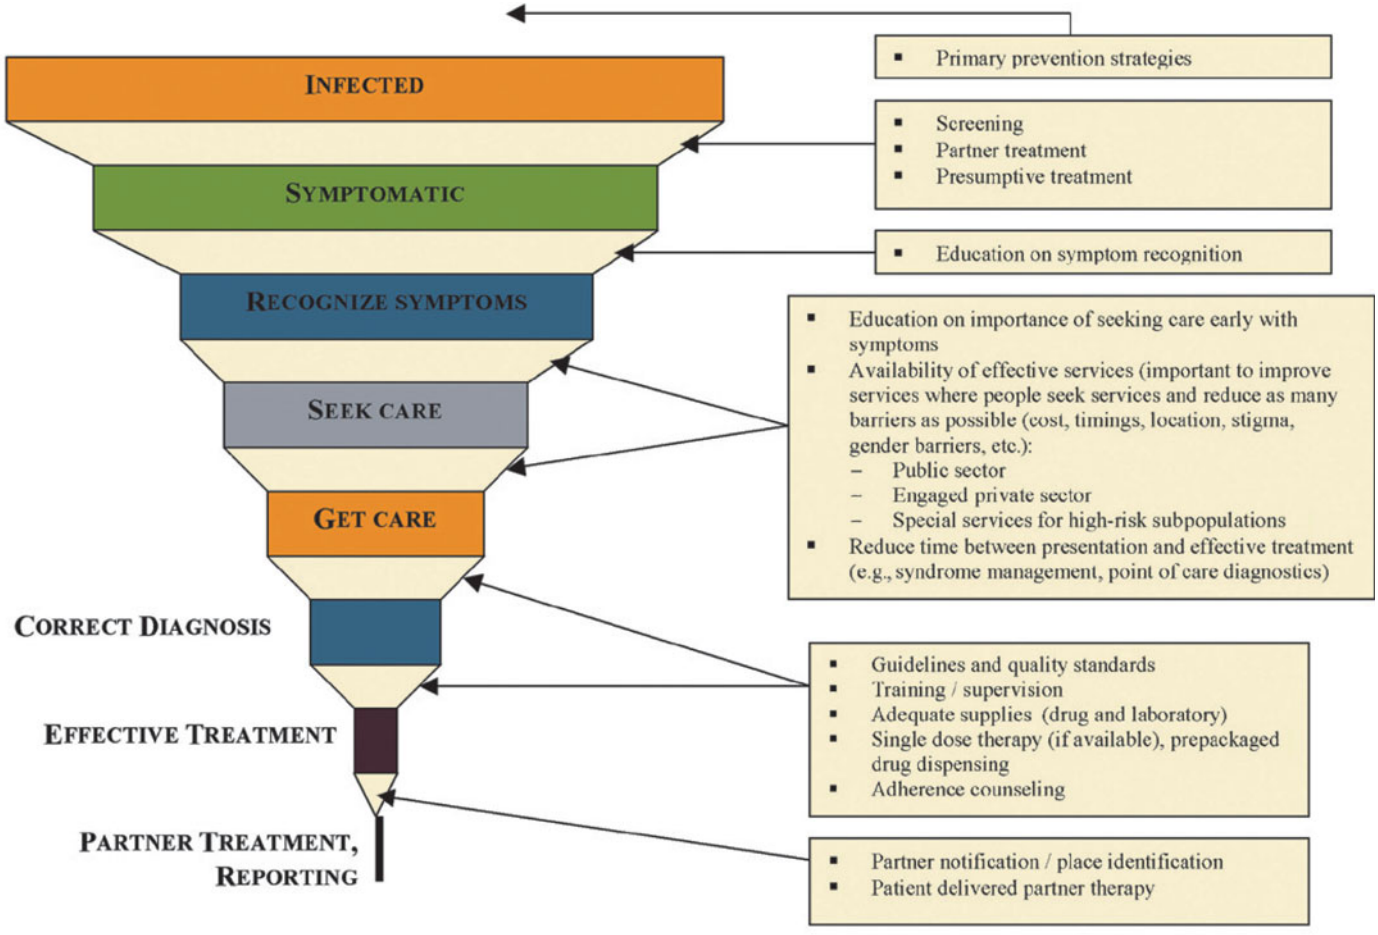

FIGURE 101-3. STI clinical services operational model.

Combining risk assessment and clinical signs of cervical inflammation has a higher positive predictive value for cervical infection.[11] Vaginal discharge symptoms are more likely a manifestation of vaginal infection, trichomoniasis, bacterial vaginosis, or candidiasis. In female populations where gonococcal and chlamydial infections are low, syndromic treatment for vaginal infections only is recommended. In high prevalence settings, syndrome management or presumptive treatment could be considered. Moreover, in settings of medium prevalence of infections, selective screening may be appropriate. Given the limited tools available for screening women for gonococcal or chlamydial infections, strategies should be centered on finding symptomatic men and improving counseling and partner notification.[97]

Algorithms should be adapted to the local patterns of STIs, syndrome etiologies, antimicrobial susceptibility, sexual behavior and other risk factors, health-care seeking behavior, availability of point of care tests, and programmatic capacity. They should be validated and updated on a regular basis. The changing etiologies of STI syndromes, increasing HSV-2 in genital ulcers, for example, also need to be considered in developing and revising the algorithms.[16]

Syndromic management is not a perfect strategy but is better than the clinical practices that it replaced and more cost-effective than clinical and laboratory diagnosis.[98] Until inexpensive, simple, and accurate STI diagnostics are developed and made available for use in developing countries, a modified, adapted syndromic approach is still the most feasible symptomatic case management approach.

SCREENING AND CASE FINDING

Many STIs are asymptomatic and this can lead to serious sequelae if they are not treated early. STI case finding or screening are required to detect subclinical and asymptomatic STIs. A two-tier screening process of identifying individuals at highest risk of infection through a risk assessment with high sensitivity, based on local risk factors for cervical infections, and testing those identified to be at higher risk reduces the cost of STI screening programs.[99] Besides screening asymptomatic individuals, symptomatic STI patients seeking care should also be screened for other STIs, such as syphilis in men with urethritis and through routine offers of HIV testing.

Table 101-3. Advantages and Disadvantages of Syndrome Management

Advantages
Responds to patient's complaint
Provides for immediate treatment at presentation
Treats for most possible infections (depends on algorithm design)
Avoids costs of laboratory tests
Can be implemented at primary care levels
Standardizes reporting for improved case reporting, supervision, quality assurance, and stock management
Can be modified to incorporate simple laboratory tests
Sensitive and specific for urethral discharge and genital ulcer disease
Disadvantages
Overtreatment leading to increased drug costs, and possible adverse drug events, alterations in vaginal flora, and potential for increased antibiotic resistance
Limited applicability in women with vaginal discharge (recommended for vaginal infections only in populations with low STI prevalence)
Requires staff training or retraining
Physicians resist using it
Health programmers fail to understand purpose of syndrome management
Do not plan for syphilis screening
Use inappropriately for screening

Table 101-4. Interventions at Clinic-Level to Improve Efficiency of Syphilis Screening

- **Promote** early antenatal attendance before the fourth month of pregnancy
- **Train** personnel on syphilis testing and treatment
- **Integrate** syphilis screening in antenatal care
- **Ensure** a functioning commodity and reagent logistics management system
- **Provide** point of care testing so that results are immediately available and treatment provided without the need for a return visit
- **Implement** epidemiologic treatment of sexual partners of pregnant women who test positive
- **Revise** protocols to add an additional second test at the last trimester to screen for incident cases
- **Improve** quality of care during pregnancy, delivery, and neonatal period

Antenatal syphilis screening and treatment programs should be implemented by all STI control programs given its cost-effectiveness described below. Screening of high-risk subpopulations is cost-effective because a case treated or prevented in a person from these subpopulations prevents the person from infecting several others.[100] One analysis reported that the "dynamic" benefits of treating bacterial STIs in high-risk subpopulations were about 10 times more than the "static" benefits as measured in disability adjusted life years (DALYs) because of the impact of preventing ongoing transmission.[23]

Antenatal syphilis screening

The cost-effectiveness of antenatal syphilis screening has been well documented.[51] Adverse pregnancy outcomes occur in 80% of women with active syphilis including stillbirths, perinatal death, and serious neonatal infection. Syphilis screening is cost-effective even in low prevalence settings because of the high medical and societal cost of congenital syphilis.

Despite the cost-effectiveness of this intervention, antenatal syphilis screening and treatment programs and congenital syphilis screening control programs remain inefficient and several clinic-level remedies have been proposed (Table 101-4).[101] All of these remedies for improved syphilis screening and treatment require priority setting from public health authorities and accountability for implementation through the health system.

Several studies have documented that point of care screening and treatment can increase the percentage of women screened and treated using nontreponemal tests (RPR or VDRL) or newer point of care testing methodologies using immunochromatographic strip (ICS) tests.[102–105] This simple and relatively inexpensive test has a great potential to increase coverage for antenatal screening to prevent congenital syphilis and has been shown to be cost-effective.[104] These point of care approaches remove only one of the many barriers to effective syphilis screening and treatment programs for pregnant women.

Screening of high-risk subpopulations

Female sex workers. High rates of curable STIs have been observed worldwide in commercial sex settings where condom use rates are low and where there is limited access to effective

STI treatment services.[106] Effective prevention and treatment of STI among sex workers requires attention to both symptomatic and asymptomatic infections. Regular screening for asymptomatic infections among sex workers using laboratory tests is cost-effective given the high rates of STIs and can result in reduced STI prevalence over time.[89,107,108] However, this is often not possible because of the limited availability or poor quality of available screening tests and functioning laboratories.

Numerous sex worker interventions implemented under HIV prevention programs are currently providing clinical services for sex workers including regular screening and treatment of symptomatic STIs coupled with behavior change programming and condom promotion. These interventions have reported increases in condom use and some have documented decreases in STI and HIV prevalence.[17,107–110] Most STI management protocols for sex workers utilize a combination of syndromic treatment of symptomatic STIs, regular STI screening using algorithms with risk scoring, clinical examination with speculum examination to detect signs of cervicitis, and simple laboratory tests to identify leukocytes or gonococci on cervical smears by Gram staining. In addition, they provide regular syphilis screening and treatment. Though this is less than ideal, it is feasible in most settings and can be implemented in a scaled manner. Regular screening of sex workers provides opportunities for regular clinic-based health education and risk reduction counseling, condom promotion, and distribution.

Some developing countries use registration of sex workers and required health check-ups to control STIs.[111] Where this has been investigated, STI prevalence rates are higher in the unregistered sex workers as a result of severely limiting access to STI care for sex workers who are not registered because of age or other legal constraints such as lack of identity papers or "entertainment" licenses. A more appropriate approach is to ensure high quality and accessible services to all sex workers.

Men who have sex with men (MSM). STI and HIV rates in MSM populations in developing countries indicate that they are at increased risk.[112,113] There are, however, no reports on impact of treatment and screening strategies for MSM or on any evaluation of STI syndromic algorithms for management of anal STIs. Most treatment guidelines for MSM in these settings, if they exist, are based on a paper of STI syndromes in MSM in the United States and clinical experience of clinicians.[114]

Injecting Drug Users (IDUs). HIV interventions for IDUs often focus solely on decreasing risk from injecting. IDUs are also at risk for STIs and in many countries act as an amplifier of HIV risk into heterosexual networks through commercial and transactional sex.[115] Interventions working with IDUs need to provide sexual health services, condoms, and STI treatment, as part of comprehensive prevention services.

Sexually active adolescents. Sexually active adolescents are an underserved group with high incidence of STIs and HIV. They have several additional barriers to getting sexual health service because services are oriented to older adults or they are inadvertently discouraged from doing so by judgmental provider attitudes, cost, or clinic timings. Health-seeking behavior is also a significant obstacle in some settings. Tailoring existing services to address adolescents' specific reproductive health needs or developing new services accessible to them have been successful in reaching youth, although few interventions have been implemented at scale.[116,117]

EPIDEMIOLOGIC/PRESUMPTIVE TREATMENT

Epidemiologic treatment, or presumptive treatment, of individuals or populations is given when there is a high likelihood of having that infection(s). Treatment is not dependent on the presence of symptoms or signs, or on results of laboratory tests, but on an identified increased risk of current infection. Epidemiologic or presumptive treatment addresses the problematic issue of asymptomatic infection. An example is the epidemiologic treatment of sex partners of patients with an STI whereby the partner is at a much higher risk of having the same infection.

Presumptive treatment is currently being implemented, either as a one-time intervention at the first contact with services, or on a periodic basis, as an STI control intervention in high-risk subpopulations such as sex workers.[106] The experience in Madagascar and the Philippines, where one-time presumptive treatment for gonococcal and chlamydial infection was provided to female sex workers in existing STI services at first visit, resulted in a rapid reduction of STI rates.[118,119] The reduced STI prevalence was sustained through ongoing provision of routine STI services. In Laos, where STI services for sex workers are being established, presumptive treatment provided a short-term intervention to rapidly decrease STIs.[120] Periodic presumptive treatment among female sex workers in South Africa achieved a decline in gonococcal and chlamydial prevalence among them and a documented reduction in bacterial genital ulcer diseases and urethral discharge among miners in the area.[90] A South African study has shown that such programs for sex workers are highly cost-effective and that periodic presumptive treatment actually improves their cost-effectiveness.[121] Experience in Zimbabwe and the Philippines indicates that prevalence reverts back to preintervention levels without ongoing service provision.[119,122]

Presumptive treatment cannot stand on its own as an STI control intervention. Implicit in the logic of employing epidemiologic or presumptive treatment is that it is a temporary measure to reduce prevalence that will be sustained through more routine STI service provision.[123,124]

OTHER ELEMENTS OF COMPREHENSIVE CASE MANAGEMENT

HEALTH EDUCATION AND COUNSELING

The STI consultation provides an opportunity not only to diagnose and treat STIs but also to educate on ways to prevent infections in future. A patient's decision to come to a clinic suggests that they would be more receptive and provides the opportunity to counsel about partner treatment, to educate on condom use, the treatment regimen, and about HIV infection risk. As part of STI and HIV risk reduction counseling, each individual should be given information that allows him or her to decide voluntarily about HIV testing. Given the potential for STI and HIV coinfection and the disproportionate impact of acute HIV infection in sexual transmission dynamics, patients with STIs should be counseled accordingly.[125]

Counseling, as opposed to health education, is essential for risk reduction and psychosocial support.[126] Counseling requires specific skills and considerable time, both of which are often not available in the routine clinical setting. A qualified health-care provider should be designated specifically and adequately trained to provide counseling. In some settings, individuals from high-risk subpopulations are trained to be counselors and work in specific clinics with high numbers of patients from these subpopulations. These counselors are often more acceptable to patients, although large investments in training and ongoing supervision are sometimes necessary.

PARTNER NOTIFICATION

Partner notification is a well-established component of comprehensive STI case management but is often difficult to implement.[93] Partners of the index patient, the person identified with an STI, are reached through several different strategies: (1) patient-led—the index patient finds and refers (enhanced through provision of a referral card); (2) provider led-based—on information provided by the index patient, the provider notifies the partner; and (3) conditional (contractual) referral—index patients are asked to notify and refer partners by a specific date after which the provider will notify.[127] Provider referral for developing countries has the disadvantage of more restricted avenues of access to potential partners, such as telephone numbers and addresses, in addition to the additional program costs and concerns about confidentiality that limit the disclosure of information identifying partners. Additional barriers to partner referral include fear of partner discord or violence, multiple partners or casual partners, as well as financial barriers and acceptability of the treatment location to the partner.[127]

Patient delivered partner therapy evaluated in Uganda was shown to be more effective than the enhanced patient referral through contact cards in the treatment of sexual partners.[128] This approach may overcome some of the difficulties to partner notification described above such as accessibility of clinical services or costs and may be more acceptable to the index patient.

Given the limitations of the syndromic approach and diagnostic options for women, partner notification by men with urethritis, both men and women with genital ulcers and individuals with reactive syphilis serology should be prioritized. Because of the poor sensitivity and specificity of syndrome management algorithms for vaginal discharge in women, partner notification for male partners is not warranted. The harm and negative social consequences resulting from partner notification should be weighed carefully in the recommendation to refer partners. Partner notification should be voluntary and confidential, and treatment of the index case should not be withheld in efforts to treat partners.

ANTIBIOTIC PRESCRIBING AND PATIENT ADHERENCE

In many developing countries, there is inappropriate prescription drug use initiated by both providers and patients.[129] From the patient perspective, there are the misperceptions that antibiotics are necessary for every illness or that injections are more effective than oral medication. Additionally the widespread, unregulated, over-the-counter use of antibiotics results in self-medication often for both treatment and also for prophylaxis before a risky sexual encounter. When medication is prescribed, poor adherence to dosage regimens is common as a result of poor understanding by patients and financial constraints. On the provider side, lack of knowledge and training, perceptions of patient demands, economic pressure, and social norms, among others have been described.[129]

To address some of these issues, STI syndrome packets have been developed. Prepackaged STI syndrome blister packs have been shown to increase patient adherence (when antibiotic dosing is multiday) and improve provider prescribing habits and overall STI treatment advice in the clinical setting.[130,131] Prepackaged syndrome treatment packets have been enhanced with partner referral cards, condoms, and STI educational material. Two reports in the literature describe the positioning prepackaged urethritis treatment kits to be sold by private physicians or in nearby pharmacies by prescription.[132,133] In the evaluation of both these efforts, there was high reported adherence to the antibiotic regimen as well as reported partner referral and condom use during treatment.

ROLE OF STI CLINICAL SERVICES FOR HIV PREVENTION

STI clinical services have an important responsibility to address HIV infection prevention both in the management of HIV-infected individuals and in the counseling about HIV

and referral for HIV testing of STI patients of unknown HIV status. Persons presenting with STIs have already demonstrated that they are in sexual networks with high-risk behavior. From numerous HIV prevalence studies globally, HIV prevalence in STI clinic attendees is consistently higher than HIV prevalence in antenatal or general population settings. Treating STIs in dually-infected persons, given the impact of STIs on genital HIV shedding, is a priority.[49,134] Where resources exist, routine screening of HIV-infected persons who have ongoing high-risk behavior should be considered.

The recent data from Malawi suggesting that STIs and HIV are cotransmitted makes high quality counseling and access to HIV testing services more urgent.[48] Acute HIV infection would not be detected on routine HIV serological tests at the time of presentation with an STI, but since acute HIV infection is hyperinfectious, consistent condom use with all partners and repeat testing in 3 months should be emphasized at STI clinics.[125] In an STI clinic in Malawi, investigators were able to identify 90% of acute HIV infections by taking serum samples from discordant rapid HIV tests and testing with a standard p24 antigen assay.[135] This approach potentially offers a way to identify acute infection in well-equipped developing country settings. In the vast majority of settings, however, HIV testing and counseling services at STI clinics simply do not exist, or are underemphasized in national plans.

STI PROGRAM SUPPORT COMPONENTS

An effective program management system is critical to setting-up and maintaining efficient STI prevention and care. The STI program should have a clear understanding of the HIV epidemics and an overview of the STI situation in the country, key areas of activity, and the spectrum of interventions being undertaken. It is essential that both government and externally supported interventions are coordinated to avoid duplication and ensure that they are directed toward the priority strategies of the country. This coordination is more easily accomplished if there is a national STI prevention and control strategy, STI case management guidelines, training curricula for staff at different levels of the health service, and well-defined reporting and monitoring indicators.

As HIV prevention interventions are similar to many program activities in STI prevention, there needs to be close coordination and coplanning between the two programs. The STI program should have access to expertise in technical, program management, and policy issues related to STI control through an STI technical advisory group. Efficient logistics management is necessary for preventive and care services to maximize the use of limited resources. Availability of essential STI drugs, condoms and lubricants, laboratory diagnostics tests, medical supplies, and communication materials requires trained personnel and a functioning logistics system.

CAPACITY BUILDING

Capacity building to improve human resources and operational capacities of institutions is a prerequisite for effective STI programming. Capacity building is not just training of staff but refers to the strengthening of the full range of supporting systems and activities that allow for staff to be fully effective in their work from good physical infrastructure to adequate supplies to supportive supervision to respect.[136] A systematic approach to capacity building consisting of developing operational guidelines and supervisory tools, training, regular supportive supervision and monitoring, and good management support in India resulted in a rapid scale-up of quality and standardized STI services that had reached about 70% of the 183,000 estimated female sex workers in the coverage area with clinical STI services in a short time frame.[137]

Training of staff should be based on adult learning principles, targeted and competency-based. Refresher trainings should be conducted to reinforce previous learning and provide opportunities for networking of trainees. Ongoing dissemination of technical and programmatic updates can be done through involving professional associations and through the Internet. These strategies could also reach private practitioners, who are commonly providing STI care.

There has been very limited focus and investment on supervision. It is presumed, or hoped, that training will ensure the desired performance of staff. Supportive supervision should be established to direct and support staff so that they can perform their duties more effectively. Supervision with clear evaluation criteria is one of the most important mechanisms to assess performance and outputs.

QUALITY ASSURANCE

Providing quality services at the primary health-care facilities will encourage STI patients to seek care at these facilities. Quality services are technically sound, based on evidence-informed standard guidelines and procedures, efficient, cost-effective, accessible and acceptable to the client-base, ensure ethical standards, maintain confidentiality, and result in patients reporting their satisfaction. Clinic guidelines and standard operating procedures should be developed to provide guidance on STI case management and other aspects of clinical services. An example of the spectrum of areas covered in such guidelines is presented in Table 101-5. Supervisory tools to monitor quality can be developed based on the adopted guidelines and standards.

When STI clinical services have laboratory testing on-site, internal and external laboratory quality assurance systems should be in place.

Table 101-5. Spectrum of STI Clinic Operations Needing Written Guidelines and Standards

Clinic operations
- community approach
- coordination with outreach services
- clinic structure and setup
- clinic equipment
- staffing and operations
- staff training and skills

Clinical management of sexually transmitted infections
- STI management of sex workers
- STI management of men who have sex with men
- STI management of symptomatic patients
- Standard treatment
- medications and commodities
- allergic reactions and anaphylaxis
- referral of patients
- documentation

Education and counseling of patients
- components of health education and counseling
- lubricant and condom promotion and distribution
- information, education, and communication materials
- counseling and referral for HIV testing

Laboratory services
- simple laboratory tests
- higher-level laboratory tests
- laboratory standard operating procedures and quality control systems

Infection control
- universal precautions
- cleaning, disinfecting, and sterilizing equipment
- disposal of hazardous waste
- postexposure prophylaxis

Ethical standards, confidentiality and right of refusal

Monitoring, evaluation, and reporting

Technical support and supervision

INFORMATION FOR DECISION-MAKING

In order to effectively plan, manage, and evaluate a national STI program, several streams of information are needed at different levels of the program.[138,139] Monitoring and data use at all levels are an essential element of good program management but are often neglected. Information for decision making can be categorized into four groups that include formative assessments, process monitoring, effectiveness evaluation, and special studies (Table 101-6).

Formative assessments

Formative assessment is the first step in the program cycle where current data on HIV prevalence, STI prevalence and incidence, quality of services, current use of services, and acceptability and accessibility issues are considered. Formative assessments can also involve community-mapping efforts to identify high-risk subpopulations and estimate their size. This information is necessary to identify program goals and set targets, to develop program implementation plans and budgets, and to plan data collection activities.

Experience globally has shown that it is possible to find and access high-risk subpopulations and provide services. Recent work has found that targeting sex partner meeting places may complement traditional STI control tools.[140,141] Several methodologies have been developed and modified to identify high-risk subpopulations or high-risk venues including information supplied by index patients in clinical services, geographic and social mapping, participatory situational assessments, and the PLACE methodology. Most of these approaches entail using members of the community or target population as key-informants and as guides. Number and locations, where high-risk sexual activity takes place or "hotspots" are mapped, sizes of subpopulation are estimated and baseline behavioral data are obtained.[142] The approaches are also important opportunities to promote trust and participation of high-risk subpopulations.

These mapping and size estimation exercises need to be repeated at regular intervals, annually or semiannually to recognize and adapt to the fluidity in sex work typologies and locations including "hotspots" that are influenced by police pressures and social and economic changes. Additionally, access to high-risk subpopulations increase over time as trust is gained. More formal methods of size estimation have also been developed.[143]

Process monitoring

Attention to service delivery, quality, and coverage through monitoring program inputs and outputs is essential for program management. The indicators, for the most part, are collected as part of routine program activities and should be linked to important program activities. Indicators should be reviewed with project staff on a regular basis while managers can be presented key indicators or "dashboard" indicators. Routine process indicators should be reported by every implementing unit providing data "at scale." In contrast, evaluation activities described below can only be done in

Table 101-6. Information for Decision Making in STI Control Programs—Examples of Types of Data

Formative Assessment	Process Monitoring	Effectiveness Evaluation	Special Studies
• HIV prevalence by population groups	• Quality and coverage of training	• Sentinel site reporting	• Evaluation and updating of STI syndromic management algorithms for general populations, sex workers, and MSM
• STI prevalence by population groups	• Outreach and education efforts	• Intermittent surveys of health-seeking and sexual behavior in multiple subpopulation groups	• Costing, cost-benefit, and cost-effectiveness
• Service quality assessments	• Service utilization	• Intermittent surveys of HIV prevalence and incidence in multiple subpopulation groups	• Incidence and prevalence of STI-related complications such as PID or congenital syphilis
• Health-care seeking behavior	• Duration of symptoms	• Intermittent surveys of STI prevalence in multiple subpopulation groups	• Prevalence assessments of viral STIs such as HSV-2, HPV, and HBV
• Mapping and size estimation of prioritize subpopulations	• Estimated coverage of high-risk subpopulations with STI services	• Intermittent STI syndrome-etiology assessments	• Outbreak investigations
	• Estimated uptake (number of new attendees)	• Case reporting	• Estimation of the economic costs of STIs
	• Number of clinic visits (new vs. repeat/follow-up), age, and sex of clinic attendees	• Antimicrobial resistance (should be routine but often special studies)	• Field evaluation of new rapid diagnostics
	• Number and distribution of STI syndromes		• Health systems research to investigate practical solutions to current constraints of implementation within the current health systems
	• Number of condoms distributed, number of condom outlet sites		• Operations research on detection of acute HIV infection in prevention programs (e.g., utility, approaches, cost, etc.)
	• Percentage days of stock out of antibiotics		
	• Service quality—routine and special assessments		

fewer sites because of expense and difficulty, so the effectiveness of the entire STI program must be inferred based on process indicators from all sites. Monitoring the quality of STI services is essential. Tools or checklists used by supervisors on quality of critical components in STI case management services both collect the information in a systematic manner and ensure that quality issues are immediately addressed in the field. Protocols for systematic quality assessments also exist.[144]

Effectiveness evaluation

Evaluating the effectiveness of an STI control program involves assessing or estimating the impact of the program on the prevalence and incidence of STIs, the sequelae of various STIs, and STI-related behaviors such as treatment seeking, condom use, and HIV-test acceptance. Because this information is difficult and expensive to collect, STI control efforts are evaluated using a combination of passive data collection, case reporting, supplemented with special surveys of STI and HIV prevalence, assessment of STI syndrome etiologies, antimicrobial resistance monitoring, and risk behavior prevalence together forming some of the components of an STI surveillance system. Surveillance data are not only used for program evaluation but also used to determine the need for public health action.

Special surveys are done to supplement the information from passive reporting systems that includes information from all reporting units supplemented with sentinel site reporting and includes behavioral, STI, and HIV prevalence in various subpopulations and syndrome etiologies. Many HIV prevention programs do behavioral surveillance monitoring. Including STI testing and relevant STI questions in these studies has been shown to be possible.[145] Most developing countries do not have a functioning routine system to monitor antimicrobial susceptibility of *Neisseria gonorrhoeae* although there are regional efforts.[146] Given the increasing resistance of *N. gonorrhoeae* globally, susceptibility of the organism to recommended therapy should be assessed on a regular basis.

Special studies

To complement process monitoring, evaluation activities, and formative assessments, special studies including clinical,

microbiological and socio-behavioral research, and operations research are necessary to improve STI programming and inform priority setting. See Table 101-6.

LABORATORY SERVICES

While syndromic management was developed to address the needs of health-care settings in the developing world where laboratory services were inaccessible or not affordable, the intent was not to preclude the development of laboratory services. Laboratory services must be continued to be strengthened in STI programs. Basic laboratory testing such as syphilis serologic testing, HIV testing, and basic microscopy should be available in peripheral health-care centers, with increasing diagnostic capability as services become larger.[147] Since laboratory services are often viewed as expensive and unnecessary, this basic support is often lacking.

The availability of nucleic acid amplification tests have allowed for simpler biologic specimens to be taken (e.g., urine or vaginal swabs) and for sensitive and specific diagnosis.[148] Their expense and the need for sophisticated laboratory infrastructure have limited their use for routine diagnosis in developing countries. Instead, these diagnostics have been used mainly to study the epidemiology of STIs and to support population-based surveillance activities, enlarging the database for policy-makers. One of the urgent needs in STI control is the development of sensitive and specific "bedside" or point of care diagnostic tests, particularly for *N. gonorrhoeae* and *Chlamydia trachomatis* to detect lower genital tract infections in women. A fuller discussion of laboratory management in developing countries is discussed in Chapter 104 in this volume.

CHALLENGES TO STI/HIV CONTROL PROGRAM IN DEVELOPING COUNTRIES

EFFECTIVELY UTILIZING THE PRIVATE SECTOR

A vast range of providers deliver STI services in developing countries. Patient choice depends on availability of services, needs, and perceptions of the patients about disease seriousness, cost, confidentiality, user-friendliness, and efficacy as well as overall market forces. There have been a handful of documented attempts evaluating how private providers can be incorporated into achieving STI public health goals.

Many observers report that pharmacists and drug clerks are an underutilized resource for STI syndrome management, at least for urethral discharge and vaginal discharge and prevention messaging as they provide private, accessible, rapid, well-stocked, and to some extent anonymous services.[149–151] Three studies implemented syndrome management training of pharmacists and showed modest improvement in treatment for assessed syndromes, promotion of partner treatment, and/or condom use but performance deteriorated with time after training.[151–153] One report suggested that training of pharmacists in syndrome management would be a cost-effective intervention, although the analysis was hindered by lack of information on what proportion of the population used pharmacies.[154] Social marketing of male urethritis treatment kits with drugs, condoms, partner referral cards, and STI educational material is being attempted in several countries (Myanmar, Laos, Nepal, Cambodia, Pakistan, India, Madagascar, Dominican Republic, Benin, and Togo) to address the treatment seeking behavior of symptomatic men and poor drug dispensing habits of pharmacists.[155] In one reported study of socially marketed urethritis kits from Uganda, cure rates compliance and reported condom use were higher than in a control group.[132] Utilization of pharmacies as legitimate providers, however, will require policy modifications with pharmaceutical regulatory boards, infrastructure to support training, supervision and enforcement, and approval from the medical establishment.[151]

Voucher schemes have been utilized as a means of involving the private sector by increasing the affordability of specific health-care treatments. On a large scale, however, they are prohibitively expensive to manage if there are large numbers of service delivery points.[156] However, in high-risk subpopulations, vouchers appear to be cost-effective in increasing STI service coverage.[157]

Health franchising, where private providers are grouped under a branded name and supported by training, supervision, advertising, and other assistance such as supplies, has been used as a way to increase access to and assure quality of reproductive health services for women and adolescents.[158] Where these efforts have been evaluated, the franchised services appeared to have increased client satisfaction and shown some health improvement, although there were ongoing challenges associated with quality assurance and costs associated with demand generation.[158] One franchise network in India is working with private providers to improve case management of STIs in men. In addition to quality assurance issues, one challenge in this STI franchise has been the positioning of demand generation for STI services in such a way so as to not stigmatize the private practitioners participating in the program (personal communication, Krisila Benson).

Other interventions have worked with the private commercial employers (e.g., trucking and oil companies and construction sites) who employ large numbers of single-sex workers who are usually away from home and are at higher risk for STIs.[90,159,160]

Other considerations for involving the private sector include postgraduate education, but skills need to be maintained through systems that support regular engagement.[156] Public–private partnerships, where the government encourages

referrals to private providers and/or provides private providers with free treatment, have been used for tuberculosis control.[156] There is no documentation of similar efforts for STIs.

COLLABORATIVE IMPLEMENTATION

The new draft global strategy for prevention and control of STIs now calls for collaborative implementation with other programs.[42] Successful implementation of this vision can be informed by the more or less unsuccessful attempt at integration of HIV/STI programs with family planning and maternal and child health programs that was promoted to control the spread of HIV and STIs and improve women's reproductive health.[161] Analysis of this integration attempt by vertical programs found that while policy formulations were often clear, implementation was disjointed and disorganized, hindered both by a failure to allocate responsibilities clearly between program staff associated with the numerous programs involved and a lack of clear communication.[162] There was, in addition, little commitment organizationally to improving quality and equity. Donor activities exacerbated some of these problems when they would support selective components of reproductive health. At the implementation level, additional responsibilities were being added to programs that were already functioning poorly.[161] In fact, integrated services have shown limited evidence of having any effect on STI prevention or STI risk behaviors and condom use, and there is a call for more systematic appraisal of the benefits and the costs, and less ideology.[163]

SCALING

Many STI and HIV control programs have limited to no impact because they provide services to only a small proportion of the populations that need them. There is an urgent need for optimal coverage and intensity of programs for STI and HIV in all settings to have an impact.[55] Scaling up interventions involve expanding geographic and target coverage, reaching additional target populations, broadening the scope and intensity of the intervention, and influencing national policies.[164]

In most developing countries, there are major constraints to scaling up effective interventions.[165] Nonetheless, experiences in some countries have shown that it is possible to scale up effective and innovative interventions.[166,167] Key components of scaling up include: (1) strong political commitment with multisectoral involvement; (2) adequate community involvement and mobilizing communities to act collectively to ensure that the initiatives are owned and responded to by all levels of the community; (3) sound technical design with interventions that can be adopted in the public and private sector; (4) adequate capacity building and technical support; (5) effective, decentralized management systems; and

Table 101-7. Core Elements of Comprehensive STI Control Package

Primary prevention package of reducing sexual risk
- barrier method promotion and provision
- behavior change in sexual partner choice and number

Comprehensive STI case management for symptomatic patients in primary health-care settings and where people seek care (if possible)
- treatment at presentation
- risk reduction counseling
- condom use and provision
- medication instruction including adherence
- partner notification or place identification
- HIV test offered
- special efforts to offer STI services to persons with HIV infection

Focused STI case management services for high-risk subpopulations aiming for high coverage
- active high-risk venue finding
- flexible service delivery
- links with groups for persons living with HIV and AIDS

Special services for specific STI pathogens
- syphilis screening in pregnant women
- neonatal eye prophylaxis for neonatal conjunctivitis
- other interventions based on data

General population educational issues
- about STIs and consequences
- promotion of appropriate treatment seeking behavior

Assessment, monitoring, evaluation, special studies
- managing against targets
- scaling with quality for high coverage
- knowing the epidemic

(6) clear objectives, focused targeting based on strong monitoring and evaluation systems and formative assessment on the needs of the community.[166]

CONCLUSIONS

The limited success of STIs control in developing countries is not solely because programs lack point of care diagnostics, increasing antibiotic resistance, shifting pathogens, poor treatment seeking behavior, or complex transmission dynamics. More fundamentally, it is a lack of political will to invest in appropriate control measures and to maintain and strengthen existing basic health systems and lack of data on burden, sequelae, and effectiveness.[13] That political will shall be even harder to achieve because of politically motivated erotophobia, i.e., the inability of senior leaders to find the courage to guide healthy, constructive public discussion about sexual matters. Without attention to these fundamentals, no new prevention development, be it a diagnostic, a microbicide, or suppressive therapy, will have a major impact because there will be no functioning system to deliver it at the necessary scale.

The effective and cost-effective interventions that are being recommended in this chapter are essentially the same as have been recommended for the last 10 years (Table 101-7)—STI treatment of high-risk subpopulations, comprehensive case management of symptomatic STIs, antenatal syphilis screening and treatment and ophthalmia neonatorum prophylaxis, condom promotion, and risk reduction counseling. There is also increasing emphasis on the role STI clinics can play in identifying and counseling HIV-infected persons and STI diagnosis and management of HIV-infected individuals. For STI prevention and control, attention to scaling up these interventions with quality and prioritized, based on knowledge of the local situation, is the need of the hour.

102 Approach to the Management of HIV/AIDS in Developing Countries

Mauro Schechter and Robin Wood

INTRODUCTION

Since the identification of HIV as the cause of AIDS in the early 1980s, the standard of care and treatment has changed markedly in the developed countries, resulting in substantial improvements in HIV-associated mortality and morbidity. In contrast, treatment and care in developing countries has evolved more slowly. In resource-poor countries, before the full extent of the demographic and social impact of the epidemic became manifest, the emphasis of public health and international agencies focused on prevention. As the number of patients with HIV-related disorders began to overwhelm already overstressed health systems, care for persons with HIV/AIDS was perceived as an infinite demand yielding little public health benefit. However, the humanitarian need to alleviate the plight of increasing numbers of people living with HIV/AIDS led to debates pitting care versus prevention. Care was initially limited to chemoprophylaxis and treatment of certain opportunistic infections (OIs) and excluded treatment with antiretroviral drugs that were considered unaffordable. In 2002, price reductions of branded antiretroviral drugs and increasing competition from cheaper generic formulations decreased the cost of first-line antiretroviral therapy (ART) from over U.S.$10,000 per year to as low as U.S.$150 per year,[1] thereby increasing the feasibility of their use in resource-poor settings.

In recent years, an international consensus has emerged on the need to address HIV/AIDS with a comprehensive response including treatment, care, and prevention. In March 2004, the United Nations General Assembly declared that the failure to deliver antiretroviral treatment for HIV/AIDS is a global health emergency. The WHO subsequently launched a global effort, in collaboration with other international agencies, to provide ART to 3 million people living with AIDS by the end of 2005.[2] On September 2005, at the World Summit of the United Nations, Heads of State called for universal access to HIV treatment.

The statistics describing the HIV pandemic are mind numbing with the present reality far exceeding projected estimates made in the early 1990s.[3,4] HIV/AIDS affects both health and wealth of households, thereby aggravating preexisting poverty.[5,6]

HIV-related morbidity and mortality is affecting vital services such as healthcare and teaching. As a direct result of HIV, many African countries will suffer shortages of primary school teachers.[7,8,9,10] The added stress to health systems has particularly affected hospital medical wards. HIV-infected patients have been reported to constitute 52% and 70% of medical admissions to hospitals in Uganda[11] and Malawi[12] and 80% of tuberculosis (TB) admissions to a large hospital in South Africa.[13]

In the developed world, ART has dramatically decreased the morbidity and mortality of HIV infection, resulting in a transfer of medical services from predominantly in-patient to outpatient care.[14–16] A similar impact of ART on morbidity, mortality, and health-resources utilization has been demonstrated in Brazil, a middle-income country where free and universal access to ART has been available since 1996.[17] Recently, data from a variety of settings have conclusively demonstrated that the provision of ART in developing countries is feasible, is cost-effective, and complements prevention efforts.[18–20]

It is the combination of humanitarian imperative to alleviate suffering and the prospect of effective and potentially cost-saving medical management of HIV/AIDS that has fuelled the international efforts to extend the proven individual and societal benefits of ART to resource-poor countries. Focus is now concentrated on the operational challenges that need to be addressed in order to rapidly increase the numbers accessing treatment in the developing world, while continuing to address HIV prevention and other healthcare needs.

THE ROLE OF HIV TESTING

Considerable controversy surrounds the issue of testing for HIV-infection in developing countries due to stigma and the possible infringement of the right to autonomy and privacy. Moreover, in the absence of effective treatment, the benefits

of being aware of one's HIV status may not exceed the real or perceived disadvantages due to stigma. Women are particularly vulnerable and may be subjected to domestic violence, evicted from their homes, and forced into poverty because of their HIV status.[21–22] However, the benefits of HIV testing include the potential for prevention of transmission, knowledge of prognosis, institution of primary chemoprophylaxis, and accurate diagnosis of the HIV/AIDS-related illnesses,[23] with considerable benefits for both individual and society.

Although universal voluntary knowledge of HIV serostatus is widely considered as an essential prevention tool, HIV testing services in resource-poor countries reach only a small proportion of those potentially exposed to HIV-infection. As access to antiretroviral treatment and to services for the prevention of mother-to-child transmission of HIV infection is scaled up, there is an opportunity to simultaneously expand access to voluntary counseling and testing programs. To address prevention and care programs, the WHO has estimated that up to 180 million individuals per year will need to be counseled and tested for HIV-infection.[24] Community voluntary counseling and testing programs are client-initiated, allowing people to voluntarily learn their status and receive counseling to reduce acquisition or transmission of HIV-infection. Within the healthcare services, an "opt-in" strategy has been the norm but increasingly provider-initiated or "opt-out" approaches are being promoted. As part of the worldwide effort to expand access to prevention of mother-to-child transmission and antiretroviral therapy, routine testing within health-care settings (with the right to refuse) has been recommended in the 2004 joint UN and WHO policy statement on HIV testing.[24] The recommendations identify four clearly distinguishable types of HIV testing:

1. Client-initiated testing, to learn HIV status through voluntary counseling and testing.
2. Diagnostic testing as part of medical investigation of persons with signs and symptoms consistent with HIV/AIDS, including all tuberculosis patients.
3. Routine HIV testing at sexually transmitted diseases (STDs) clinics and antenatal services and in high prevalence settings where ART is available.
4. Mandatory screening of blood, tissue, or organ donors, in cluding semen donation for artificial insemination.

In 2004, in order to increase uptake of national maternal-to-child prevention and treatment programs, Botswana began routine "opt-out" HIV screening in perinatal and other health-care settings. Early results indicate routine testing increased uptake of HIV testing without any reduction in the number of women seeking antenatal care; nonetheless, many women did not learn their status because laboratory testing was offsite.[25] On-site rapid testing reduces the logistics of returning results to the site and the inevitable drop out due to clients failing to return. HIV testing remains open to potential abuse and must always be performed within a framework that is cognizant of human rights.

THE NATURAL HISTORY OF HIV/AIDS IN DEVELOPING COUNTRIES

NATURAL HISTORY OF HIV INFECTION

Knowledge of the natural history of HIV-infection in developing countries is incomplete. Nonetheless, there are considerable data to suggest that progression to AIDS and/or death may be faster in developing countries. Many factors may potentially result in shorter survival of HIV-infected patients in resource-poor settings, including more frequent exposure to primary pathogens such as *Mycobacterium tuberculosis* and *Salmonella* spp., limited access to health-care services, under-resourced medical services, quality of water supply, and poor nutritional status.

Information on early events soon after HIV infection comes primarily from studies of persons infected with subtype B in North America and Europe. Symptomatic acute HIV infection is often referred to as the acute retrovirus syndrome and is reported to occur in the vast majority of recently infected individuals from developed countries. The acute retrovirus syndrome is often described as a mononucleosis-like syndrome with the onset of symptoms occurring around the time of seroconversion. There are very few reports on early events after acute infection from developing countries. In studies conducted in Brazil, Kenya, and India, in comparison with reports from developed countries, a significantly lower frequency of symptomatic seroconversion was reported. Although the majority of seroconverters in these lower income countries reported at least one symptom attributable to seroconversion, a minority reported three or more symptoms.[26] There are also scant data on early virologic and immunological events following seroconversion in developing countries. In a study conducted in Brazil involving seroconverters who were followed for up to 36 months, viral load dynamics were similar to those observed in developed countries, but CD4 counts appeared to decline at a faster rate.[27]

The spectrum of some major HIV-related conditions in the various regions of the world is shown in Table 102-1. However, besides the likely existence of considerable local variation within regions, the cohorts on whom present knowledge is based are probably subject to selection biases. Additionally, data may be further distorted due to the use of variable diagnostic criteria.[28–39] Factors influencing regional variations include the prevalence of infectious conditions, particularly localized tropical diseases, and the proportion of individuals surviving with advanced immune suppression. Opportunistic diseases associated with advanced immune suppression such as cytomegalovirus disease are less

Table 102-1. Regional Variation in the Spectrum of HIV-Associated Disease[25–36]

Disease	Europe, North America	Africa	South America	Asia
Tuberculosis	+	+++	++	+++
Toxoplasmosis	+/++	++	++	++
PCP	+++	+/++	++	++
Bacterial infections	++	+++	++	++
Kaposi's sarcoma	++	++	++	−/+
Cryptococcosis	+	++	+	++
MAC	++	+	+	−/+
HIV wasting	+	+++	++	+
HIV encephalopathy	++	+	+	−/+
CMV disease	++	+	+	+
Lymphoma	++	+	+	+
Leishmaniasis	−/+	+	++	++
Penicilliosis	−	−	−	++
Paracoccidioidomycosis	−	−	++	−

frequently reported in developing world cohorts whereas TB and bacterial infections, which can cause disease in individuals with relatively intact immune systems, are overrepresented. Thus, it is necessary to be aware of local variations in HIV/AIDS-associated conditions, particularly among returning travelers, or when presumptive diagnoses are made.

While the availability of ART has greatly modified the natural history of HIV-1 infection and despite the rapid expansion of access to therapy, there are very few reports on the spectrum of disease in individuals on ART in developing countries.

VIRAL DIVERSITY

Human immunodeficiency virus type 1 (HIV-1) has considerable diversity and at least 10 different subtypes and multiple subtype recombinants having been described. Additionally, there are a growing number of reports of individuals infected with more than one subtype. Subtypes differ from each other by at least 25–35% of amino acid sequences in the envelope proteins.[40] The biological relevance of HIV-1 subtypes is still undefined, although it may be of importance for the pathogenesis of HIV-1 infection, vaccine development, transmission, and diagnostics.[41] Much of the current information on the geographic distribution and prevalence of HIV-1 subtypes are based on small cross-sectional studies.

The results of longitudinal studies assessing the role of viral subtype on disease progression have given variable results. Comparative studies of serotypes A and D, which are very prevalent in East Africa, have shown no differences in survival of perinatally infected Ugandan children.[42] However, in one study adults infected with subtype D had a 29% faster progression to death.[43] In Senegal, where subtypes A, C, D, and G are prevalent, the hazard ratio for progression to AIDS of female sex workers infected with non-A-subtype was eightfold higher than those infected with subtype A.[44] In a study conducted in Southern Brazil, where subtypes B and C dominate, no difference in progression to AIDS was discernable between the main subtypes.[45] In Brazil, molecular studies have shown that subtype B encompasses two variants. The first corresponds to the B subtype variant that predominates in the United States and Europe. The second variant (B-Br) bears a characteristic motif at the tip of the V3 loop glycine/lysine/glycine/arginine (GWGR) that substitutes for the glycine/proline/glycine/arginine (GPGR) usually present in the prototypic US and European variant. In a study conducted in Rio de Janeiro, it was shown that infection with serotype B-Br was associated with lower rates of progression to AIDS or death than infection with the prototype USA and European serotype B.[46] Presently available data indicate that infecting subtype does not significantly affect response to ART.[47]

HIV-2 INFECTION

Infection with HIV-2 is common in West Africa, Portugal, and countries with close historical links to Portugal. Although HIV-2 infection is associated with similar (OIs) as HIV-1, the virus is considered less pathogenic than HIV-1

and the natural history is characterized by a more prolonged asymptomatic phase, resulting in more favorable prognosis. Additionally, HIV-2 viruses are not susceptible to non-nucleoside reverse transcriptase inhibitors (NNRTIs).

PREVENTION OF HIV-RELATED DISEASE

HIV-related morbidity and mortality is due to infections and neoplasms, which tend to occur with increasing frequency as immune suppression progresses. Primary pathogens, such as *M. tuberculosis, Streptococcus pneumoniae*, and *Plasmodium falciparum*, which can cause disease even in individuals with intact immune systems, occur over a wide range of CD4 counts, whereas less pathogenic organisms, such as *M. avium intracellulare* (MAC) and Cytomegalovirus are true OIs and thus occur almost exclusively in individuals in advanced stages of immune deficiency. The best prophylaxis for HIV-related illnesses is the reversal of immune deficiency through the use of ART. However, OIs will still occur, especially if ART is instituted at very low CD4 counts or if the response is suboptimal. Factors influencing choice of preventive strategies include the frequency and severity of the OI, the proven efficacy of the intervention in clinical trials, and cost and ease of delivery.

Preventive strategies include avoidance of exposure to pathogen, immunization, and chemoprophylaxis. Pathogen avoidance measures include access to clean water, sanitation, food-hygiene, and vector control. HIV services should minimize exposure of HIV-infected persons to *M. tuberculosis* by performing sputum collection in the open air or in well-ventilated areas. Those with positive *M. tuberculosis* smears or multidrug resistance should not be in general waiting areas.

The high recurrence rate of conditions such as *Pneumocystis jirovecii* pneumonia (PCP), cerebral toxoplasmosis, cryptococcal meningitis, and disseminated MAC infection require lifelong secondary prophylaxis after initial therapy. Secondary prophylaxis can be safely discontinued in those receiving ART who maintain a sustained (at least 3–6 months) increase in CD4 count above the threshold for which primary prophylaxis for that particular infection is routinely recommended.[48,49]

Immunization

Immunization against infections that commonly affect HIV-infected individuals is an attractive strategy. However, the potential effectiveness of this strategy is undermined by the progressive reduction of vaccine efficacy as the immune deficiency progresses. Additionally, viral replication may be temporarily increased following vaccination, an event of uncertain importance.

Pneumococcal disease has a worldwide distribution and is a major contributor to HIV-related morbidity and mortality. In developed countries, vaccination against pneumococcal infection is widely recommended. Nonetheless, in a randomized controlled trial conducted in Uganda, the use of the 23-valent polysaccharide vaccine not only failed to prevent pneumococcal disease or death but was also associated with an increase in cases of pneumonia in general.[50] Since trial participants had relatively advanced disease, this vaccine should not be used in similar populations. Data are awaited on the effectiveness of the newer conjugated pneumococcal vaccines and on response to vaccination in those receiving ART.

Hepatitis B coinfection is very common in Africa, Asia, and South America. To date, no controlled trials of hepatitis B vaccines have been conducted in HIV-infected developing world populations. Nonetheless, it is recommended to offer the vaccine to hepatitis B seronegative individuals with CD4 count >200/μL.[51]

Influenza has a worldwide distribution. However, the role of influenza vaccine in reducing developing world morbidity and mortality is undefined.

PREVENTION OF TUBERCULOSIS

The HIV pandemic presents a massive challenge to the control of TB and is the primary reason for the failure of TB control programs in resource-poor countries where HIV prevalence is high.[52] TB is also a major cause of death among people living with HIV/AIDS.[28] and may lead to increased HIV disease progression.[53] TB is more common in those with advanced immune suppression but can present at CD4 counts above the threshold presently recommended for ART initiation.[54] Randomized controlled studies have shown that a 6-month course of isoniazid reduces the risk of active disease in HIV-infected individuals with latent infection with *M. tuberculosis*[55] indicated by a positive tuberculin skin test (TST) in the absence of active TB disease. The TST reaction does not distinguish between active and latent infection and also does not have optimal sensitivity and specificity. Although in several trials primary prophylaxis was shown to decrease the incidence of active TB in TST-positive HIV-infected individuals, in only one placebo-controlled trial conducted in Haiti prior to the availability of ART, isoniazid prophylaxis was associated with increased survival.[55] A similar impact on survival was also reported in an observational study conducted in Brazil.[56]

WHO recommends that HIV/AIDS programs provide isoniazid preventative therapy as part of the package of care for people living with HIV/AIDS. However, exclusion of active TB is critically important before chemoprophylaxis is started. If isoniazid monotherapy were given to individuals with active disease, this would lead to the development of drug resistance. The recommended regimen is isoniazid 5 mg/kg up to a maximum of 300 mg daily for 6–9 months during which time patients should be clinically monitored for toxicity and for active TB.[57]

Programmatic uptake of TB prophylaxis has usually been low, probably because of fear that drug resistance will emerge

and concerns about the short duration of efficacy. The concept of TB preventative therapy is predicated on the assumption that most of the TB disease burden is due to reactivation of latent infection. However, molecular epidemiological evidence suggests that recent infection makes an important contribution to active disease in HIV-infected people living in societies with high TB prevalence.[58]

MALARIA PROPHYLAXIS

Malaria and HIV cause more than 4 million deaths per annum, of which 90% occur in tropical Africa where *P. falciparum* is the predominant species.[59a,b] HIV infection is associated with a higher risk of acquiring malarial infection, with higher parasite density, and with increased risk of clinical malaria in adults, especially those with advanced immunosuppression. In regions with unstable malaria, HIV-infected individuals are at increased risk of complicated and severe malaria and death. There are also data to indicate that antimalarial treatment failure may be more common in individuals with low CD4 counts. Although malarial infection, in turn, temporarily increases HIV replication and viral load, there is no evidence that it affects HIV-disease progression, transmission, or response to antiretroviral drugs. Nonetheless, since malaria is associated with anemia, its presence may affect the choice of antiretroviral drugs.

Coinfected pregnant women are particularly vulnerable, since parasitemia tends to be higher during pregnancy and plasmodia can infect the placenta, resulting in increased risk of anemia, preterm birth, intrauterine growth retardation, low birth weight infants, and high early mortality. HIV-infected pregnant women also tend to have a poorer response to both prophylaxis and treatment of malaria.

People living with HIV/AIDS in malaria endemic areas are considered particularly vulnerable to malaria and should be provided with insecticide impregnated nets. HIV-pregnant women at risk of malaria should also receive intermittent preventive therapy with 3 doses per week of sulfadoxine-pyrimethamine or daily cotrimoxazole. However, malarial resistance to chloroquine and sulfadoxine-pyrimethamine is increasingly diminishing the effectiveness of these prophylactic agents. Additionally, widespread use of cotrimoxazole for primary prophylaxis of OIs may favor development of resistance to sulfadoxine-pyrimethamine in malaria parasites. In regions where both infections occur, special attention must be given to the need for etiological diagnosis for febrile patients.

COTRIMOXAZOLE PRIMARY CHEMOPROPHYLAXIS

Cotrimoxazole is recommended as the chemoprophylactic drug of choice for prevention of PCP in individuals with less than 200 CD4 cells/μL in developed countries. It has also been shown to significantly decrease morbidity and mortality in studies conducted in three trials in Africa.[60,61] Despite some contradictory results; the possible lower frequency of PCP in developing countries, the possibility of promotion of drug-resistance, and controversies relative to the design of published trials, the WHO recommends its use in HIV infection and its efficacy is greatest in those with symptomatic HIV infection or CD4 cell counts less than 200/μL.[62] The survival benefit associated with primary prophylaxis with cotrimoxazole is due to prevention of PCP together with a reduced incidence of cerebral toxoplasmosis, bacterial infections, and isosporiasis. The dose usually recommended is one double strength tablet (160 mg of trimethoprin/800 mg of sulphametoxazol) daily, which is generally well tolerated. Nonetheless, cutaneous rashes can occur and may require substitution with dapsone, 50–100 mg daily. While dapsone has some anti-PCP activity, it is not effective against cerebral toxoplasmosis and bacterial infections.

THERAPY AND CARE IN DEVELOPING COUNTRIES

TUBERCULOSIS

The global burden of TB is increasing in large part because of the HIV pandemic. A third of the world population is infected with *M. tuberculosis*. Coinfection with HIV accelerates progression to active disease after exposure to *M. tuberculosis* and increases reactivation of latent tuberculous infection. TB is the main cause of HIV-related deaths in developing countries, being responsible for 30% or more of in-hospital deaths in some settings. Nonetheless, a premortem diagnosis of TB is confirmed in only approximately 50% of the cases.

In a prospective study conducted in Brazil, the overall annual risk for the development of TB among HIV-infected individuals was 5.4%, being 6.5%, 3.2%, and 10.2% in TST positive, TST negative, and anergic patients, respectively.[63] In Cape Town, South Africa, a city with a high prevalence of TB, risk of TB increases with declining CD4 cell count (Fig. 102-1), and 25% of patients with advanced HIV develop TB per annum.[64]

The clinical presentation of TB is greatly modified by immune deficiency. Smear-negative pulmonary disease is more frequent in HIV-infected individuals. Early in HIV-infection, TB presents with a classic reactivation pattern of pulmonary upper lobe infiltrates with cavitation. With increasing immunodeficiency, the chest radiographic picture often resembles tuberculous primary infection with adenopathy and mid or lower lobe infiltrates; dissemination to lymph nodes, meninges and pleural, pericardial, and peritoneal cavities is also more frequent.[65,66]

A TB diagnosis should be sought in all HIV-infected patients with a cough present for 3 or more weeks, night sweats, fever, or unexplained weight loss. Diagnosis should be sought with a minimum of three sputum smears for acid-fast

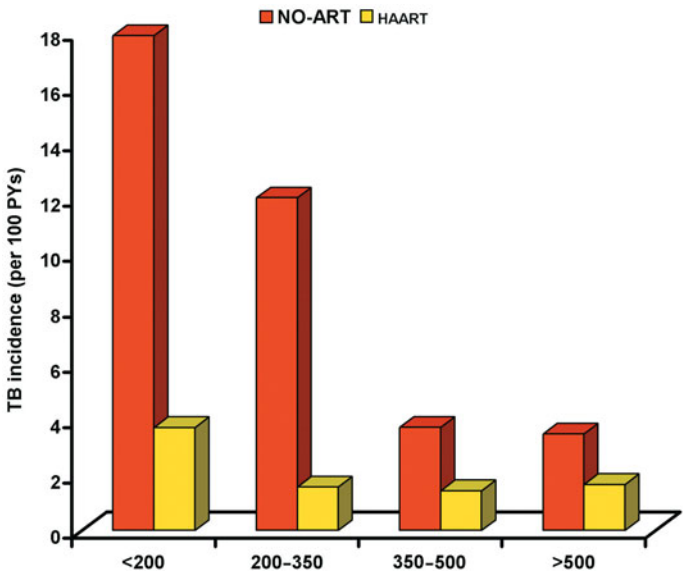

FIGURE 102-1. Tuberculosis incidence per 100 patient years for 4 strata of CD4 counts: <200, 200–350, 350–500 and >500 cells/& #956; 1 in patients not receiving antiretroviral therapy (No-ART) and those on highly active antiretroviral therapy (HAART). (Data from Badri M, Wilson D, Wood R. Effect of highly active antiretroviral therapy on incidence of tuberculosis in South Africa: a cohort study. *Lancet* 2002; 15(359): 2059–2064.)

bacilli (AFB) and a fine needle aspiration biopsy of asymmetrically enlarged lymph nodes. Diagnostic yield can be increased by saline sputum induction and mycobacterial culture. Patients with suspected smear-negative pulmonary disease should receive treatment with broad-spectrum antibiotics before a diagnosis of smear-negative TB is entertained.

In settings with very limited resources, empiric TB therapy is frequently resorted to in patients with advanced immune suppression. In these situations, it is crucial that assessment of response to TB empiric therapy is reviewed after 1 month, by which time an unequivocal clinical response is expected to have occurred. The differential diagnosis of pulmonary infiltrates includes bacterial and fungal pneumonias and Kaposi's sarcoma. Many recommend the use of cotrimoxazole prophylaxis by patients with active TB, since it has been associated with an approximately 40% increase in 2-year survival.[60–62]

TB impacts greatly on the implementation of ART programs. Screening for TB is particularly important when ART is implemented in resource-poor settings. In a community ART service in Cape Town, 57% of those commenced on ART reported a prior history of TB, 14% were referred to the service on TB therapy, and 5% were found to have active TB (Wood, unpublished data). In cohort studies from both developed and developing countries, ART reduced the incidence of TB by 70–90%.[64,66,67] However, patients receiving ART retain a heightened risk of TB, which remains higher than in the HIV-negative population. In a large study involving over 4,000 HIV-infected patients treated in low-income settings, after 3468 person years of follow-up there were 258 new TB events in the first year of highly active antiretroviral therapy (HAART). The incidence of new TB events in months 1–2, 3–6, and 7–12 were 13.7/100 (6.4–29.6), 6.0/100 (2.8–12.4), and 4.1/100 person years (2.1–8.4), respectively [manuscript in preparation]. While coexistence of other risk factors for TB, including exposure to patients with TB at HIV treatment facilities may play a role, it seems that persistent deficits in immune function are the principal cause.[68]

M. africanum, a member of the *M. tuberculosis* complex, is endemic to West Africa, where it causes a considerable proportion of pulmonary TB. Sporadic cases of *M. africanum* have been identified outside West Africa. The clinical presentation or disease course is identical to *M. tuberculosis*, although in animal models *M. africanum* appears to be less virulent. Recently it has been suggested that *M. africanum*-infected patients are more likely to be HIV positive than *M. tuberculosis*-infected patients. The data also suggest that *M. africanum* is more of an opportunist than *M. tuberculosis*. It was hypothesized that in areas where rates of HIV are low, *M. africanum* is probably out-competed by *M. tuberculosis*, while increasing HIV prevalence would be associated with an increase in *M. tuberculosis* strain diversity, including lower virulence strains such as *M. africanum*. This, in turn, highlights new complexities associated with the changing pattern of important infectious diseases in the presence of an expanding HIV epidemic.

SALMONELLA SEPTICEMIA

Infection with nontyphoidal *Salmonella*, leading HIV-infected persons to severe septicemia, has been reported in Africa[69] and Asia.[70] Bacteremia is more frequent when the CD4 counts fall below 200/μL and is associated with significant mortality (35–60%). Among the survivors, 25–45% have recurrences due to recrudescence of the original infection.[69] Antibiotic resistance patterns vary but fluoroquinolones are particularly useful when there is resistance to other antibiotics. Although secondary chemoprophylaxis is necessary, ART also prevents recurrence.

KAPOSI'S SARCOMA

Kaposi's sarcoma is the commonest cancer in HIV-infected individuals. In the USA, Europe, and Latin America, Kaposi's sarcoma almost exclusively affects male homosexuals. In Africa, it affects males and females equally, often running an aggressive course involving skin, lymph nodes, lungs, and the gastrointestinal tract. Skin lesions are variable and can be macular, papular, or nodular, with considerable localized edema when lymph nodes are involved. Diagnosis is usually made by clinical appearance although biopsy can be necessary in atypical cases. Although skin lesions frequently resolve after commencement of ART, there are anecdotal reports to indicate that disseminated Kaposi's sarcoma does not respond so well to ART.

TOXOPLASMOSIS

Infection with *Toxoplasma gondii* is acquired through the ingestion of rarely or partially cooked lamb, beef, pork, or game. Prevalence rates vary considerably worldwide.[71] In HIV-infected individuals, cerebral toxoplasmosis is the commonest clinical presentation, usually presenting with seizures or a focal neurological deficit in patients with less than 100 CD4 cells/μL. In the Cape Town AIDS cohort, cerebral toxoplasmosis is the third commonest neurological presentation (0.46/100 persons year) after cryptococcal meningitis (1.37/100 persons year) and HIV encephalopathy (0.76/100 persons year) [Wood, unpublished observations]. An autopsy study from Cote d'Ivoire found that in 10% of the cases toxoplasmosis was the likely cause of death.[28]

Diagnosis should be entertained in those with focal neurologic signs and ring enhancing lesions demonstrated through computerized tomography or magnetic resonance imaging. In the absence of radiologic facilities, the presence of recently developed focal neurologic signs in the absence of meningeal signs in patients with evidence of advance immune deficiency is highly suggestive of cerebral toxoplasmosis. In developing countries with a high prevalence of TB, cerebral tuberculomata constitutes the primary differential diagnosis and more rarely bacterial abscesses, cryptococcoma, lymphoma, and progressive multifocal leukoencephalopathy.

Response to therapy is usually rapid (7–14 days), and a clinical and/or radiological response to a trial of antitoxoplasma therapy confirms the diagnosis. The recommended standard therapy is with pyrimethamine and sulfadiazine. However, in resource-poor settings there is increasing experience with cotrimoxazole 320/1600 mg twice daily for 4 weeks then 180/800 mg twice daily for 3 months.[72–74]

LEISHMANIASIS

Leishmaniasis is a parasitic disease transmitted by the bite of infected sand flies. It is estimated that *Leishmania* spp. infect 12 million people worldwide. Leishmania-endemic regions are expanding and include areas of Central and South America, southern Europe, Asia, the Middle East, and East Africa. Leishmania/HIV coinfection is emerging as a new serious condition, which is expected to continue to increase in frequency.[75]

Three principal clinical forms of leishmaniasis occur: cutaneous, mucocutaneous (espundia), and visceral leishmaniasis (kala azar). HIV-infection increases the risk of visceral leishmaniasis by 100–1000 times in endemic areas and leishmaniasis accelerates the progression of HIV-disease, thus decreasing life expectancy.[75]

It is estimated that 500,000 new cases of visceral leishmaniasis occur annually, 90% of them in five countries, Brazil, Bangladesh, India, Nepal, and Sudan.[75] Visceral leishmaniasis presents in patients with advanced HIV-infection with fever, hepatosplenomegaly, and pancytopenia.[75] Serological diagnosis in HIV-infected individuals lacks sensitivity. Definitive diagnosis depends on isolation of the parasite, primarily from bone marrow aspirates, but also from spleen, liver, and peripheral blood. Treatment is based on a number of chemotherapeutic agents that are toxic and/or expensive and are rapidly becoming ineffective. The use of pentavalent antimony is limited by toxicity and resistance, and in some settings the first-line drug is now amphotericin B; alternatives include pentamidine and liposomal-amphotericin B; the latter is prohibitively expensive. There are contradictory data whether highly active ART prevents visceral leishmaniasis relapses in HIV-infected individuals. Secondary prophylaxis should be continued until CD4 count reaches 350 cells/μL.[76]

CRYPTOCOCCOSIS

Meningitis caused by *Cryptococcus neoformans* was reported as the cause of death in 2% of a Cote d'Ivoire autopsy study[28] and 11% in a Ugandan rural cohort.[32] Cyptococcal meningitis (CM) presents as a subacute meningoencephalitis. Diagnosis of CM is confirmed by a positive cerebro-spinal fluid (CSF) cryptococcal antigen (positive in >95%), CSF culture (positive in >95%), or Indian ink test (positive in 60–90% of cases). In addition, there may be pleocytosis and an elevated CSF pressure. CM is the commonest neurological AIDS illness in several African and Asian settings.[77] It can also occur as a devastating immune restoration disease (see below) that occurs in the first 2 months after ART is introduced, at rates of 18.2 (95% CI 8.2–40.6) and 6.2 (95% CI 1.6–25.1) cases/100 persons year in the first and second months, respectively.[78]

The usual recommended therapy is amphotericin B (0.7 mg/kg/day IV) for 14 days, with or without flucytosine (100 mg/kg/day), followed by 8 weeks of fluconazole (400 mg/day), and then fluconazole 200 mg/day as secondary prophylaxis.[79]

The high rate of cryptococcal immune recovery syndrome (see below) in ART programs in sub-Saharan Africa may be the result of the exclusive use of fluconazole for the treatment of CM. Fluconazole is a fungistatic drug, which is effective as secondary prophylaxis but has less-efficacy than amphotericin B in clearing the organism during the initial treatment phase.[80]

HISTOPLASMOSIS

Histoplasmosis is the most common of the endemic mycoses in patients with AIDS. Although it occurs predominantly in the Americas,[81] histoplasmosis has also been reported in Africa[82] and Asia.[83] Disseminated histoplasmosis usually occurs among persons with $CD4^+$ T lymphocyte counts <150 cells/μL. The most common clinical presentation is a disseminated multiorgan disease, characterized by fever, fatigue, and weight loss. Respiratory tract symptoms of cough, chest pain, and dyspnea might occur in

up to 50% of patients.[84] Detection of Histoplasma antigen in blood or urine is a sensitive method for rapid diagnosis of disseminated histoplasmosis. Histoplasma antigen is detected in the urine or blood in 85–95% of patients with disseminated disease.[85] *H. capsulatum* can be cultured from blood, bone marrow, respiratory secretions, or localized lesions in >85% of cases but isolation takes 2–4 weeks. Patients with severe disseminated histoplasmosis should be treated initially with intravenous amphotericin B followed by oral therapy itraconazole for 12 weeks, followed by secondary prophylaxis.[86]

PNEUMOCYSTIS PNEUMONIA

The reported frequency of PCP in Africa is highly variable and appears dependent on geography, cohort selection, and diagnostic methodology. The reported incidence of PCP was 0.5/100 persons year in South African miners, 2.28/100 persons year in individuals with less than 200 CD4 cells/μL in the Cape Town AIDS cohort, and it was present in 33% of Zimbabweans with radiographic changes compatible with PCP.[87,88] Clinical presentation is a classic triad of dry cough, mild fever, and increasing dyspnea on effort in patients usually, but not exclusively, with less than 200 CD4 cell/μL. Treatment is with cotrimoxazole 15/75/kg/day in divided doses for 21 days; supplemental prednisone (80 mg/day, reducing over 3 weeks) is also recommended for those with hypoxia.

PENICILLIOSIS

Caused by *Penicillium marneffei*, this systemic mycosis occurs exclusively in South East Asia, Guangxi province of China, Hong Kong, and Taiwan. The incidence of this fungal infection has increased in recent years in parallel with rising HIV-1 seroprevalence. The usual presentation is with fever, anemia, weight loss, skin lesions, generalized lymphadenopathy, and hepatomegaly and occurs in patients with advanced immunosuppression.[89] Treatment is with amphotericin B (0.6 mg/kg/day) followed by itraconazole 400 mg/day for 10 days.[90] Recurrences occur in approximately 50% of treated cases and secondary prophylaxis with itraconazole 200 mg/day is recommended.

PARACOCCIDIOIDOMYCOSIS

This deep systemic fungal infection, caused by *Paracoccidioides brasiliensis*, is rare worldwide but common in Brazil and other endemic areas of South and Central America and has been reported in travelers to these areas.[91] In HIV-infected patients, the disease can present with acute lymphohematogenous dissemination or with chronic mucocutaneous lesions, particularly affecting the oral cavity. Diagnosis is confirmed by demonstration of the fungus, culture, or histology. Initial treatment is with antifungal agents, including amphotericin B, ketoconazole, or itraconazole and subsequent maintenance therapy with ketoconazole or sulfonamides.

ANTIRETROVIRAL THERAPY

In 2003, the WHO and UNAIDS launched a strategy for expanding antiretroviral treatment to 3 million people living with HIV/AIDS in low- and middle-income countries by the end of 2005.[92–94] As a result of this strategy, by mid-2005 there were an estimated 1 million people on ART in those countries where the burden of disease is greatest (Fig. 102-2). In 2004 and in the first half of 2005, progress of roll out programs in Africa and Asia has resulted in a tripling of numbers of patients receiving ART to 50,000 and 155,000, respectively. In most African countries, reported demand is outstripping supply due to infrastructural constraints. In Eastern Europe and Central Asia, the numbers have doubled to 20,000 people. In Latin America and Caribbean, the number of patients on treatment increased to 290,000, which represents coverage of approximately 66% of estimated need.

Concerns have been raised that expanded access to ART in resource-poor settings will lead to "antiretroviral anarchy," characterized by poor adherence to therapy, widespread viral resistance to medications, and poor clinical outcomes.[95] However, emerging data indicate that adherence in developing countries is as good as or even better than in developed countries.[96] Additionally, data are fast accumulating to indicate that virological and immunological responses at 6 and at 12 months, which have been shown to predict long-term outcome, are similar to those achieved in developed countries.[97,98] For example, in a study conducted in Southern Brazil, among 454 antiretroviral naïve patients starting HAART, 72% had undetectable viral load at 6 months. When analyses were restricted to the 309 patients who started therapy in 1999 or later, when use of efavirenz and boosted protease inhibitors became more common, success rates were 90% or more for all CD4 strata.[99] While it is encouraging that similar virologic outcomes can be achieved in resource-poor settings, some have expressed concerns that these results may not necessarily be representative of those presently starting therapy or entering programs.[100]

The primary goals of ART programs are the prevention of HIV-related morbidity and mortality. Early on-treatment mortality in resource-poor settings appears to be considerably higher than in developed countries.[101–103] In one large study, mortality during the first year on HAART in approximately 5,000 HIV-infected patients treated in low-income settings was compared to 22,000 adult patients from developed countries. Compared to high-income countries, patients starting HAART in low-income settings had lower CD4 cell counts, were more likely to be female, and to start treatment with an NNRTI. Mortality was higher in low-income settings. Compared with high-income settings, the adjusted hazard

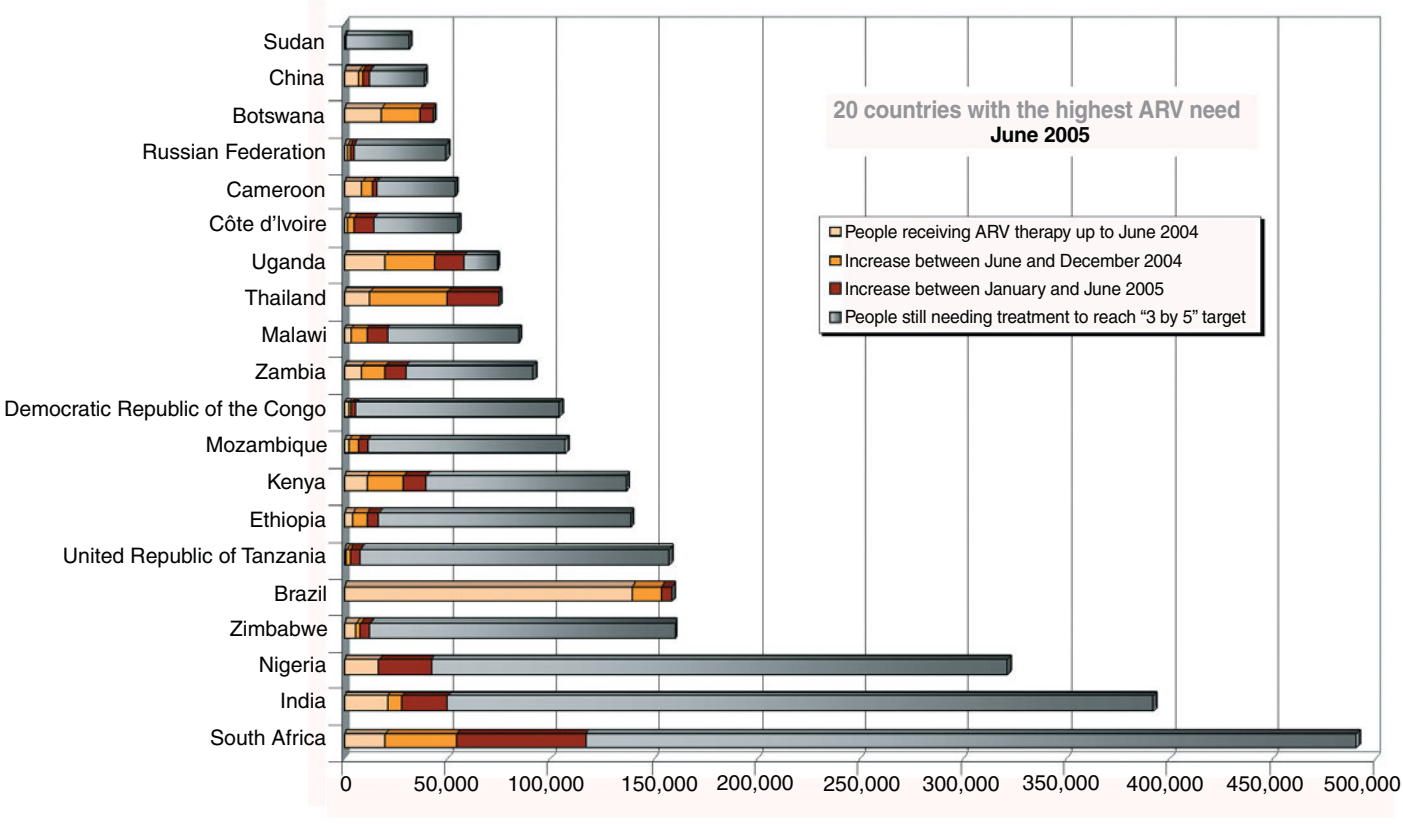

FIGURE 102-2. Progress toward "3 by 5" targets, WHO 2005.

ratio of mortality in low-income settings declined from 3.6 during the first month to 1.5 during months 7–12. At 1 year, cumulative mortality was 4.8% and 2.3% in low and high-income settings, respectively. Interestingly, the provision of treatment free of charge to patients was associated with lower mortality in low-income settings.[102] Higher early mortality may reflect more advanced immune suppression, programmatic delays in accessing treatment, and higher incidence of severe immune reconstitution syndromes (IRS).[103,104] Due to underreporting, mortality may be even higher due to high rates of program loss to follow-up.[105,106]

The global scaling-up of HIV access has been achieved as the result of a broad range of national and international efforts. Individual programs depend on these initiatives to finance physical infrastructure and to maintain a reliable supply of drugs. Additionally, many programs are dependent upon local human resources, including trained doctors, nurses, pharmacists, and counselors, which are scarce in most settings. The outcomes of programs are, therefore, constrained by many variables but are still primarily dependent on each individual patient's ability to remain within a treatment program and to maintain a high degree of adherence to the prescribed drug regimens. Patient retention on programs, even within the same city can be highly variable[107,108] and adherence within a program may also worsen over time.[107]

CHALLENGES IN IMPLEMENTING ANTIRETROVIRAL THERAPY IN DEVELOPING COUNTRIES

Until recently, high-drug costs were a major constraint to widespread implementation, but now that drug costs have decreased, the lack of infrastructure and adequately trained health-care workers may be the major constraints. The need to manage a program within a limited national infrastructure has resulted in the exploration of several public sector delivery models. Explored models to date have included distribution of drugs at district hospitals, community clinics, and TB services.

The need for high levels of adherence has led some to make parallels with TB control programs and proposed use of directly observed therapy. The logistics of delivery of lifelong directly observed therapy to large numbers of people is likely to be very challenging. High levels of adherence with directly observed ART in rural Haiti were achieved by integration of community health workers (*accompagnateurs*) into the treatment program.[109] A variety of other adherence strategies have been used in resource-poor settings. In Gugulethu, Cape Town, high adherence to ART, with corresponding high levels of viral suppression, has been achieved using community adherence monitors.[110] Elsewhere in Africa, patient-centered approaches, including the identification of "treatment buddies" for ongoing program support, have resulted in high levels of adherence to ART.[103,111]

STARTING ANTIRETROVIRAL THERAPY

In 1987, 6 years after the first AIDS cases were recognized and 4 years after the etiological agent, HIV, was first identified, the first antiretroviral drug, zidovudine, was approved for clinical use. In the following decade, AIDS changed from a universally fatal disease to a chronic, medically manageable condition. This extraordinary and unparalleled pace of progress has led to frequent modifications of guidelines on when to start therapy (Figs. 102-3 and 102-4).[112]

ART initiation guidelines used in developing countries are based on both clinical and laboratory parameters.[113] Developing countries face an urgent short-term need to rapidly expand antiretroviral access to a large number of patients with advanced clinical disease. However, in the longer term, there is also a need to prevent people living with HIV progressing to AIDS. Presently resources are disproportionately consumed caring for those with advanced disease. Within the antiretroviral service in Kampala, Uganda, the majority of patients accessing ART have advanced symptomatic disease with a mean CD4 count at initiation of ART of just 63 cells/μL.[114] Late presentation is costly in terms of morbidity and mortality.[104] and utilization of health-care resources and also limits the potential for restoration of immune function.[115] Treatment of patients with earlier disease is less demanding, results in better outcomes utilizing less health resources, and also decreases the proportion of the population progressing to AIDS. While entry to programs is based on presence of clinical symptoms, it is likely that patients accessing ART will continue to be severely immune compromised. In contrast, CD4 count criteria will only have utility when there is wider access to CD4 counts integrated with voluntary counseling and at all interfaces with the health-care system.

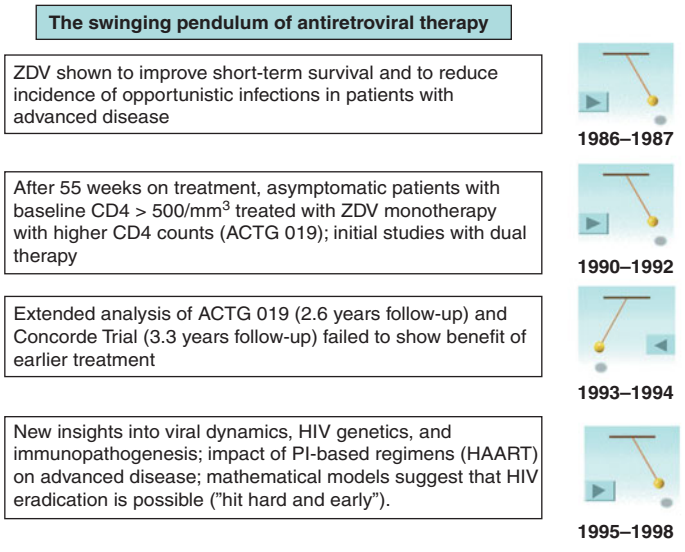

FIGURE 102-3. The swinging pendulum of antiretroviral therapy.

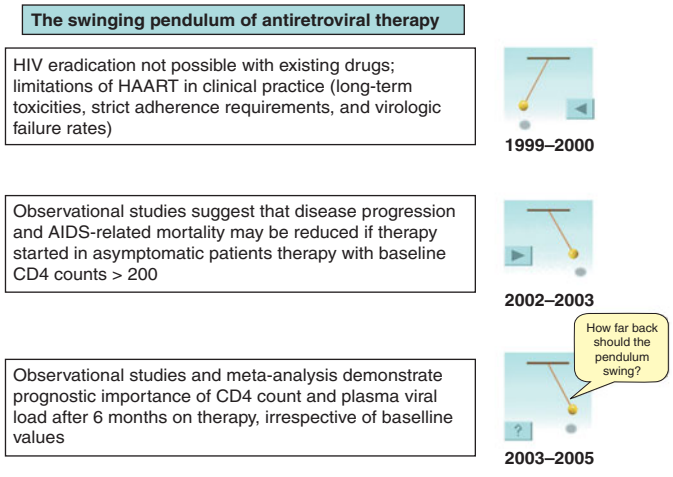

FIGURE 102-4. The swinging pendulum of antiretroviral therapy (continuation).

CHOICE OF ANTIRETROVIRAL THERAPY IN RESOURCE-POOR SETTINGS

Scaling-up of antiretroviral treatment programs in the resource-poor settings requires standardization and simplification of treatment regimens. Simplified regimens allow for a limited repertoire of drugs and side effects with which health-care workers need to become familiar with. The maintenance of a secure drug supply is simpler when a limited number of drugs are used. Many factors impact on regimen selections including cost, tolerability, pill burden, safety, the potential for interaction with other commonly prescribed medications, and the need to maintain future treatment options.

TB is the commonest OI in resource-poor settings, and standardized regimens must be carefully chosen to avoid adverse pharmacological interactions with TB drugs. Rifampicin is a potent CYP450 enzyme-inducer, which results in lowered plasma levels of protease inhibitors and has an overlapping hepatic toxicity profile with nevirapine. Rifabutin, the rifamycin of choice in the USA for patients on protease inhibitors, is presently too expensive and largely unavailable in most developing countries. Although further studies are definitely required, some experience has been gained with rifampicin—containing regimens coadministered with ART regimens including three nucleoside reverse transcriptase inhibitors (NRTIs) or two NRTIs associated with either efavirenz or ritonavir-boosted lopinavir.

As women of childbearing potential constitute the majority of patients attending public sector HIV clinics, regimens must be available which are compatible with pregnancy. The need to have "TB and pregnancy friendly" regimens and the constraints of a limited number of antiretroviral drugs presently registered in many developing countries, has resulted in convergence of regimens used in a large number of programs. Quite often, these are based on two standardized

regimens, the first consisting of two NRTIs and a NNRTI and the second of two NRTIs and a boosted protease inhibitor (PI).

Presently registered NNRTIs do not inhibit HIV-2 reverse transcriptase.[116,117] The protease inhibitors amprenavir and nelfinavir are not active against HIV-2 and protease inhibitors in general may be less robust against HIV-2.

INITIATION OF ART IN PATIENTS WITH ACTIVE OPPORTUNISTIC INFECTIONS OR MALIGNANT DISEASE

ART may interact with OIs and their specific therapies in a variety of ways. Initiation of ART may be associated with an improved response to specific therapy of an OI; there may be additive toxicity with specific therapeutic modalities or a worsening of the clinical manifestations of the OI itself. Although, in general, treatment of life-threatening opportunistic conditions should take precedence, ART is the cornerstone of treatment for conditions such as cryptosporidiosis and disseminated Kaposi's sarcoma when associated with profound immune suppression.

IMMUNE RECONSTITUTION SYNDROME

The initiation of ART in individuals with OIs may lead to an increase in clinical severity of the OI and even to the occurrence of an OI for the first time in the first few weeks after ART is started. The temporal association of the worsening (or emergence) of these conditions with control of HIV replication by ART and, in most cases, an elevation in CD4 counts has led to the hypothesis that they result from the restoration of an immune response against the antigens of opportunistic pathogens that causes immunopathology. Supportive evidence has been provided by observations that for some pathogens these conditions are associated with the restoration of pathogen-specific immune responses.

This phenomenon is often referred to as the IRS. The optimal management strategy in terms of timing of the treatment of the OI and initiation of ART is unknown and may vary with the type of OI and level of immune suppression. Prospective randomized studies are clearly required in HIV patients with TB and other OIs to determine the optimal timing of ART after an opportunistic condition is diagnosed in a previously untreated patient.

Data on the incidence of IRS after commencing ART are limited and risk factors still remain to be determined. Globally, mycobacteria are the most significant opportunistic pathogens associated with IRS. In a study conducted in India, the median time to development of clinical IRS was 42 days and the incidence of 15.2 cases per 100 patient years.[118] Patients with disseminated TB seem to be particularly susceptible to TB IRS. The most common manifestations of TB IRS are fever and lymphadenopathy, which often require corticosteroid therapy. Some patients develop severe complications that require hospitalization. Immune restoration syndrome associated with other opportunistic pathogens may also cause inflammation that results in organ failure, hospitalization, or death. Results of studies on the optimal management of IRS, particularly on corticosteroid therapy to treat and to prevent IRS, are eagerly awaited.

LABORATORY MONITORING

Prior to the initiation of ART, identification of current infections and of coexisting medical conditions that may influence choice of therapy (such as TB, diabetes, hepatitis B and/or C, renal failure, pregnancy, etc.) is very important. Nonetheless, the lack of adequate laboratory support for diagnosis and management of most conditions can be an important barrier to the implementation of treatment programs in many resource-constrained settings. Given this limitation, the WHO provided guidance on the minimal laboratory and clinical monitoring requirements.[2] These requirements were prioritized into 4 categories: absolute minimum tests; basic tests; desirable tests; and optional tests. Absolute minimum tests are prerequisites for introduction of ART in a national program. Basic tests, which are commonly used in the clinical setting, were not considered to be essential for program implementation. Desirable tests would make monitoring and evaluation of program effectiveness much more effective, while optional tests can be used in resource-rich settings. The absolute minimum laboratory tests to have before initiating ART are an HIV antibody test (in those persons >18 months of age) and a hemoglobin or hematocrit level. Additional, basic testing should include a white blood cell count and differential (to permit assessment of neutropenic side effects and the total lymphocyte count), serum alanine, and/or aspartate aminotransferase level to assess the possibility of hepatitis coinfection and to monitor for hepatotoxicity, serum creatinine, and/or blood urea nitrogen to assess baseline renal function, a serum glucose, and pregnancy tests for women. Desirable supplemental tests include bilirubin, amylase, and serum lipids. CD4 cell determinations are, of course, very desirable and every effort should be made to make these widely available. Viral load testing is currently considered optional because of resource constraints. Tables 102-2 and 102-3 contain recommendations on tiered laboratory capabilities for diagnosis and treatment of HIV/AIDS in resource-limited settings.[119]

In asymptomatic individuals, $CD4^+$ lymphocyte count is the most important laboratory parameter to assess whether ART should be started. They are also important in the assessment of the effectiveness of therapy, with significant rises of $CD4^+$ lymphocyte counts in the first several months seen in therapy naïve, adherent patients with drug susceptible virus. The current technology for measuring $CD4^+$ lymphocyte counts is too costly to perform and requires flow cytometry; these constraints severely limit the number of laboratories which can perform counts in resource-constrained settings.

Table 102-2. Recommended Tiered Laboratory Capabilities for Diagnosis and Treatment of HIV/AIDS in Resource-Limited Settings[115]

Diagnosis and Monitoring Laboratory Tests		Primary Care Level	District Level	Regional/Central Level
HIV antibody testing		Yes[a]	Yes	Yes
Hemoglobin		Desirable[b]	Yes	Yes
Pregnancy testing		Desirable[c]	Yes	Yes
Basic microscopy for TB and malaria (sputum smear for TB and blood film for malaria diagnosis)		Desirable[d]	Yes	Yes
FBC and differential		No	Yes	Yes
$CD4^+$ cell count		No	Yes	Yes
ALT		No	Yes	Yes
Diagnostic tests for treatable HIV coinfections and major AIDS-related opportunistic diseases	Full cerebrum spinal fluid (CSF) microscopy (including India ink for cryptococcal meningitis), syphilis, and other diagnostic tests	No	Yes	Yes
	Diagnostic tests for other major treatable HIV coinfections and AIDS-related opportunistic diseases (hepatitis B, hepatitis C serology, bacterial microbiology, and cultures and diagnostic tests and procedures for *Cryptococcus*, toxoplasmosis, and other major OIs)	No	Desirable	Yes
Full chemistry (including but not restricted to liver enzymes, renal function, glucose, lipids, amylase, lipase, and serum electrolytes)		No	No	Yes
HIV VL measurement		No	No	Desirable

[a]Rapid tests recommended at primary care level and conventional methodologies can be used at district and regional/central levels. For details, see specific WHO recommendations.

[b]Should be available if ZDV is being considered for use.

[c]Should be available if efavirenz is being considered for use.

[d]Referral if microscopy not available.

[e]VL test is currently not recommended for decision making on initiation or regular monitoring of ART response in resource-limited settings. Use should be considered primarily for definitive diagnosis of HIV infection in children under 18 months of age who are vertically exposed to HIV during pregnancy and to assist in decision making in more complex cases.

(Data from Lawn SD, Bekker L-G, Wood R. How effectively does HAART restore immune responses to Mycobacterium tuberculosis? Implications for tuberculosis control. *AIDS* 2005; 19: 1113–1124.)

Table 102-3. Frequency of Laboratory Tests Needed for Treatment of HIV/AIDS in Resource-Limited Settings[115]

Diagnosis and Monitoring Laboratory Tests		Baseline	Monthly During First 3 Mo (Wks 4, 8, and 12)	Every 6 Mo	As Required (i.e.,Symptom-Directed or if Clinically Indicated)
HIV antibody testing		×			
Hemoglobin[a]		×	×		×
Pregnancy testing					×
Basic microscopy for TB and malaria (sputum smear test for TB and thick blood drop smear test for malaria diagnosis)					×
FBC and differential		×	×		×
$CD4^+$ cell count		×		×	
ALT[b]					×
Diagnostic tests for treatable HIV coinfections and major AIDS-related opportunistic diseases	Full CSF microscopy (including India ink for cryptococcal meningitis), diagnostic tests for syphilis, and other sexually transmitted diseases				×
	Diagnostic tests for other major treatable HIV coinfections and AIDS-related opportunistic diseases (hepatitis B and C serology, bacterial microbiology, and cultures and diagnostic tests and procedures for *Cryptococcus*, toxoplasmosis, and other major OIs)				×
Full chemistry (including but not restricted to liver enzymes, renal function, glucose, lipids, amylase, serum electrolytes, etc.)[c]					×
HIV VL measurement[d]					×

[a]Hemoglobin monitoring during the first weeks of treatment has been recommended by some experts if ZDV is used. However, other experts suggest that the hemoglobin measurement can be monitored in a symptom-directed approach, particularly for ZDV-free regimens.

[b]The predictive value of preemptive liver enzyme monitoring is considered very low by some specialists and they recommend ALT monitoring in a symptom-directed approach in any situation. However, regular monitoring during the beginning of treatment (in monthly schedule during the first 3 months) and symptom-directed monitoring thereafter have been considered by some experts for patients using NVP-based regimens with high baseline CD4 cell count, particularly women with CD4 cells >250/mm^3 and patients with hepatitis B or C coinfection, particularly with evidence of active hepatic disease.

[c]The regular monitoring (baseline and thereafter every 6 months) of full chemistry tests, particularly lipids, liver tests, renal function, and glucose, has been recommended for patients using second-line drugs (see Table 102-3).

[d]VL measurement is not currently recommended for decision making on initiation or regular monitoring of ART response. Its use should be considered primarily for definitive diagnosis of HIV infection in children under 18 months of age who are vertically exposed to HIV during pregnancy or in special circumstances, as a complementary evaluation of more complex cases.

(Data from Lawn SD, Bekker L-G, Wood R. How effectively does HAART restore immune responses to Mycobacterium tuberculosis? Implications for tuberculosis control. *AIDS* 2005; 19: 1113–1124.)

Development of affordable and locally usable $CD4^+$ lymphocyte counts testing technology is an urgent priority.

While the total lymphocyte count correlates relatively poorly with CD4 count, in combination with clinical staging it can be a useful marker of prognosis and survival. In cases where CD4 counts cannot be assessed, the presence of a total lymphocyte count of 1200/mm3 or below may be used as a substitute indication for treatment in the presence of symptomatic HIV disease. In asymptomatic HIV-infected individual, the predictive importance of the total lymphocyte count is lower but is significantly increased if hemoglobin levels are low.[120]

The increase in total lymphocyte count on ART correlates well with change in CD4 cell count. At a group level, changes in total lymphocyte counts also correlate with viral load responses. However, changes in total lymphocyte counts have very limited utility for predicting viral load responses for individual patient management.[121] Thus, total lymphocyte counts may have a limited role as a relatively inexpensive monitoring tool of the immunological response to highly active ART in resource-constrained settings.

The level of plasma HIV-1 RNA is arguably the best parameter to monitor response to ART. However, due to its high cost and technical expertise needed, it is poorly available in most resource-constrained settings. Nonetheless, its absence should not deter the implementation of roll out programs. The lack of availability of viral load monitoring implies that treatment failure will need to be assessed immunologically and clinically, rather than virologically, with yet undetermined long-term implications on the individual and societal levels.

CONCLUSIONS

The HIV pandemic continues to expand predominantly in resource-poor countries resulting in increasing numbers of HIV-related deaths. The global community is no longer able to ignore the enormous disparities in life expectancy and access to healthcare between the developed and developing world. The 3 by 5 initiative represents the largest global health efforts in the history of medicine and has already radically changed medical management of HIV in many resource-poor settings. The future of those with this dreadful disease will be determined by the global commitment to maintain and extend the benefits of medical science and technology to the poor.

103 Approach to Management of STIs in Developing Countries

Bea Vuylsteke and Marie Laga

WHAT MAKES CASE MANAGEMENT OF STIs IN WOMEN DIFFERENT IN DEVELOPING COUNTRIES?

In theory, appropriate management of STIs could be based on the same criteria worldwide. However, in practice, the approach taken to STI case management may differ according to the realities of a specific setting. We will consider four aspects of STI management that may differ between developing and developed countries, including the aspect of the provision of treatment, the characteristics of the patients, the disease profile, and the national STI policy. Some of these features concern health care in general, while others are specific to STI care.

THE PROVIDER

Whether STI case management is provided by a primary health-care worker or a clinician in a categorical STI clinic, logistic problems are often similar. An obvious hurdle for any health-care provision is the poor infrastructure in many developing countries.[1] Bad roads and poor transport facilities make accessibility to the services difficult. In many places, a consultation room is not available or is underequipped and privacy is often lacking. Laboratory facilities may not exist and, where they do exist, they may not be efficient or capable of performing the relevant tests. Clinicians who can provide comprehensive case management must often work without the help of health educators, contact tracers, counselors, or administrative personnel. The maximum time that can be spent per patient is often not more than 5–10 minutes.

Another, and probably a most important, problem is the lack of continuous and sufficient supply of drugs or the absence of the effective, in general more expensive, drugs for the treatment of STI. There is currently, for instance, no single drug for the treatment of gonorrhea in the developing world that combines efficacy and low price.[2] Cefixime, ceftriaxone, and spectinomycin are recommended by the WHO as first-line drugs for the treatment of gonococcal infections because they remain highly efficacious all over the world.[3] However, their main drawback is their high cost. Ciprofloxacin, also recommended by WHO, has become cheaper in some countries, but resistance in South and Southeast Asia is emerging, which means that it can no longer be universally recommended.[4] Kanamycin and above all cotrimoxazole are still widely used in Africa where they remain considerably less expensive. However, their use is compromised by a high resistance pattern in almost all regions.[5]

THE PATIENT

The patient's belief in the efficacy of treatment by a formal Western-type health service is, in general, weaker in developing countries than in the industrialized world. Many patients continue to consult traditional healers, especially for STI, and self-medication is common.[6] Some may go first to the informal sector, and only later, when this treatment does not appear to work, present at a clinic.[7] Seeking treatment in an appropriate health service and compliance with treatment are also related to other social, economic, and cultural factors.[8] Many people may simply be too poor to pay for the transport to and from the health service, or for a consultation or for the drugs (full treatment regimen). In many developing countries, the dependence of women on men and their inferior social status may also play a major role.[9] For example, women may not have the time to go to the health center and STI clinics are often stigmatizing for them. Many women cannot afford informing their husband of the presence of an STI for fear of being blamed for infidelity and hence, of being chased away from the family. In a study in Nairobi, Kenya for instance, 6% of pregnant women with a positive syphilis test did not inform their partner for fear of blame and violence, despite the counseling's focus on the well-being of the unborn child.[10] In some societies, women need the permission of their husband to consult a health service. Some women may thus wait too long or never seek treatment.[9] In another study in Nairobi, Kenya, a major

gender difference in delay of health seeking for STIs was observed, 5 days for men versus 14 days for women.[11]

Another patient aspect that may compromise effective health-seeking behavior is the patient's perception of symptoms, which may differ in different cultural settings. A good example is provided by Rwanda, where high production of vaginal flow during sex is much appreciated.[12] Vaginal discharge may thus be perceived not as a sign of disease but as an indication of sexual health. However, seeking treatment for STIs presupposes the perception of a problem. In sum, the patient's capacity to seek timely treatment in an appropriate health service is directly affected not only by the availability, accessibility, and affordability of such services but also by his or her capacity to recognize the symptoms correctly; his or her belief in the efficacy of the health service; and by his or her social, economic, and cultural environment. In developing countries, these factors are certainly different from the industrialized world and some remain poorly understood.

THE DISEASE

Although the remainder of this chapter deals in detail with case management of the most common STIs, a few general points are highlighted here. Both the prevalence and the incidence of STIs tend to be considerably higher in developing countries than in the industrialized world. In addition, the relative distribution of various STIs takes on a different disease spectrum, such as higher relative frequency of chancroid as a cause of genital ulcer or *Neisseria gonorrhoeae* as etiological agent in urethritis.[13–15] Some STIs, such as donovanosis, are virtually seen only in developing countries.[16] The high rates of HIV infection in many geographical areas may have repercussions on the incidence and the natural history of STIs.[17] A study in Côte d'Ivoire for instance showed a strong association between genital ulcers and HIV-related immunosuppression in female sex workers (FSW).[18] In a case-control study in the same country, the mean clinical severity score of pelvic inflammatory disease (PID) was significantly higher among HIV-positive than among HIV-negative patients.[19]

Finally, in developing countries, patients with STIs tend to present with more severe and higher frequency of STI related complications, which is largely a result of delayed treatment or lack of effective treatment.

NATIONAL STI POLICY

Whether people will have access to acceptable and effective STI case management in a given country depends to a great extend on national policy issues, including the quality of first-level health care, the training and supervision of health-care providers, the national promotion of standardized guidelines for STI case management, the availability of effective STI drugs, and the availability of acceptable STI services for vulnerable populations.[20]

The elaboration of a comprehensive national STI policy may reveal the level of importance a government attributes to STI control. In countries struggling with limited funds and a range of pressing public health problems, STI is often not the priority for allocating resources. Reasons include an association of STIs with perceived discreditable behavior, failure to associate the diseases with the complications and sequelae, and failure to recognize the size of the problem.[20] Policy issues that have rather been an obstacle to a successful control of STIs include: control efforts have been concentrated on symptomatic patients (usually men) and have failed to identify asymptomatic individuals (usually women); service delivery has often been through specialized STI treatment facilities that provide inadequate coverage and are stigmatizing; treatment strategies have focused on unrealistic requirements for definitive diagnosis rather than on practical decision making; and ineffective low-cost antibiotics continue to be used for reasons of economy. Moreover, there has been little emphasis on education and other efforts to prevent infection, and there has been a lack of authoritative guidance on a rational, practical, and well-defined package of activities that could be the basis for prevention and care programs.[20]

Although WHO has made specific recommendations concerning different types and levels of services including public and private service providers and guidelines for STI case management, the implementation of these recommendations is often incomplete, and knowledge on the actual state of STI policies and programs is lacking.[21]

STI SYNDROMIC CASE MANAGEMENT

Since 80–90% of the population depend for their health needs and demands on the basic health services in developing countries, it is clear that STI control activities should be attempted mainly in this framework.[22] In order to offer good quality STI care in developing countries, STI case management should be completed on one patient visit, using simple diagnostic methods, that are neither time consuming nor expensive. A clinical approach has the advantage of offering prompt diagnosis and hence prompt treatment. However, a clinical "etiological" guess may be highly inaccurate for STI diagnosis. It is, for instance, very difficult to differentiate between gonococcal and chlamydial urethritis and mixed etiology on the basis of clinical observation only.[15] Similarly, the "typical" clinical presentation of primary syphilis, chancroid, and genital herpes, has a low diagnostic accuracy.[23–25] Moreover, it is impossible to identify clinically dual or mixed infections, which are both very common.

Medical training emphasizes that one should try to make the diagnosis using microbiological techniques and subsequently give specific treatment. This laboratory diagnosis-before-treatment is not an option at the basic health services level.[22] Many laboratory tests for STI diagnosis are too

sophisticated or not cheap enough to be affordable by the patients. Others are time-consuming, and test results are not available in a reasonable amount of time. This leads to a delayed treatment, or no treatment, because the patient is not returning for results. Simple, rapid, and affordable tests for most STIs have been on the priority list for STI research for years but as yet remain unavailable.

A more realistic approach at primary health-care level is a problem-oriented one and problem-solving syndromic approach has been developed.[22] The syndromic approach does not require identification of the underlying etiology. Instead, it is based on the identification of a syndrome, i.e., a group of symptoms and easily recognized signs associated with a number of well-defined etiologies. Treatment is provided for the majority of organisms locally responsible for the syndrome.

Adaptation of the syndromic approach to local circumstances will require a validation of the diagnostic algorithms (flowcharts) used.[22] This validation consists of a comparison of the diagnostic outcome of the algorithm to a gold standard. As such the sensitivity, specificity, and predictive value of the approach for different STIs will be determined. The sensitivity of the diagnostic algorithm is defined as the proportion of infections detected by the algorithm. A low sensitivity implies a high number of missed cases that results in potential serious complications and in further disease dissemination.[26] The specificity of the diagnostic algorithm is defined as the proportion of patients without infection who are correctly identified by the algorithm. A low specificity results in overtreatment, leading to unnecessary side effects, drug costs, and the psychological cost of inappropriate labeling. The positive predictive value (PPV) of the algorithm is the proportion of all diagnoses made by the algorithm that are confirmed by the gold standard diagnosis, or the real positive cases. The negative predictive value (NPV) is the proportion of all cases not infected according to the algorithm that are also not infected according to the gold standard diagnosis, or the real negative cases.

Many developing countries have adopted the syndromic approach in their national STI guidelines. Their algorithms are adapted to the local infrastructure (e.g., availability of laboratory) and examination possibilities (e.g., possibility of a speculum examination) and to the regional epidemiological situation.

There is enough evidence now that the syndromic approach is effective and has an impact on the STI epidemic. Dramatic declines in STI rates have been observed following control strategies based on the syndromic approach, such as in sex workers in Côte d'Ivoire, Senegal, and South Africa, and in STI clinics in Kenya and in Burkina Faso.[27–29] The studies of Mwanza (Tanzania) and Masaka (Uganda) demonstrated the impact of syndromic management beyond the STI clinic attendees they targeted by decreasing STI prevalences in the general population: serologic syphilis by 20%, male urethritis by 50% in Mwanza, and gonorrhea by 70% in Masaka.[30,31] The declining prevalence of bacterial infections in some of the key syndromes in parts of Africa is a testimony of the success of widespread syndromic management use.[28]

COMMON STI SYNDROMES IN DEVELOPING COUNTRIES

URETHRAL DISCHARGE

Urethral discharge is probably the most common STI syndrome in men in developing countries.[9,26] In many parts of the developing world, the estimated incidence of urethritis is considerably higher than in developed countries. For example, in a population-based study in two cities of Cameroon, 10% of the interviewed men reported at least one episode of urethritis during the past 6 months.[32] This proportion was even higher (20%) among male bar clients.[32] In a similar study in a rural area of Tanzania, the annual incidence was 7%.[33] These figures stand in sharp contrast with those reported for Europe and North America where the annual incidence of urethritis in men is less than 1%.[34,35]

Another striking difference in the epidemiology of urethritis in developed and developing countries relates to its etiology Table 103-1. While *Chlamydia trachomatis* and *Mycoplasma genitalium* are the major causes of urethritis in the developed world, *N. gonorrhoeae* continues to be the major cause of urethritis in many developing countries. Mixed infections are also not uncommon in the urethral syndrome. Common causes of nongonococcal urethritis (NGU) in developing countries are *C. trachomatis, Trichomonas vaginalis,* and *M. genitalium*.[15,37] *C. trachomatis* was present in 13% and 14%, *M. genitalium* was present in 10% and 20%, and *T. vaginalis* was present in 14% and 16% of the men with NGU in Central African Republic and West Africa, respectively. *Ureaplasma urealyticum* was detected in 26.2%, 45.6%, and 45.2% of the men with urethral discharge syndrome in West Africa, Central African Republic, and Thailand respectively. However, *U. urealyticum* was not associated with urethral discharge and was equally present in asymptomatic controls.[15,37,42]

Given these etiological patterns, a syndromic approach of urethritis requires a treatment for both gonorrhea and NGU. Fig. 103-1 shows the algorithm for the management of urethral discharge recommended by WHO. In case the patient complains of persistent or recurrent urethral discharge or dysuria, and the history does not confirm reinfection or poor compliance, then a treatment for *T. vaginalis* should be offered (algorithm "persistent/recurrent urethral discharge in men," not shown). However, it should be stressed that the clinical sign of urethral discharge is not always present. For example, visible discharge may be absent shortly after urinating

or when the patient has already taken some antibiotics. This is of particular relevance in large parts of Africa where many people combine treatment from a variety of places. In Malawi, for instance, 53% of patients with urethral syndrome reported to have sought treatment elsewhere before consulting the formal health sector.[7] As such, if urethritis is only treated when discharge is visible during physical examination, infections may be missed and remain untreated.

The algorithm for the syndromic approach of urethral discharge contributed to the first success stories of the syndromic approach in developing countries. Applying the syndromic approach to urethral discharge has resulted in effective case management of urethritis as shown in different studies.[44] In a study in Indonesia for instance, the PPV of the syndromic approach for gonococcal and/or chlamydial urethritis was between 75% and 97%, resulting in a low cost per real case treated.[40] In addition, the cure rate for urethral discharge with the syndromic approach was 99%.[40]

To decrease overtreatment, a simple laboratory test such as a Gram stain may be used for the detection of intracellular diplococci in urethral discharge. This strategy reserves the, at times, expensive treatment for gonorrhea for patients with a confirmed gonococcal infection.[36] However, gonococcal infection cannot always be excluded by Gram stain. In optimal conditions, the Gram stain has a sensitivity of 90–95% and a specificity of 95–100% for the detection of intracellular diplococci.[45] However, its validity and hence the validity of a diagnostic algorithm including Gram stain varies substantially with the experience of the laboratory technician and the field conditions within countries.[46] Including a Gram stain in a diagnostic flowchart for urethritis should only be advised when appropriate laboratory facilities are available and results can be given within reasonable time delays, i.e., no return visit is necessary for treatment.

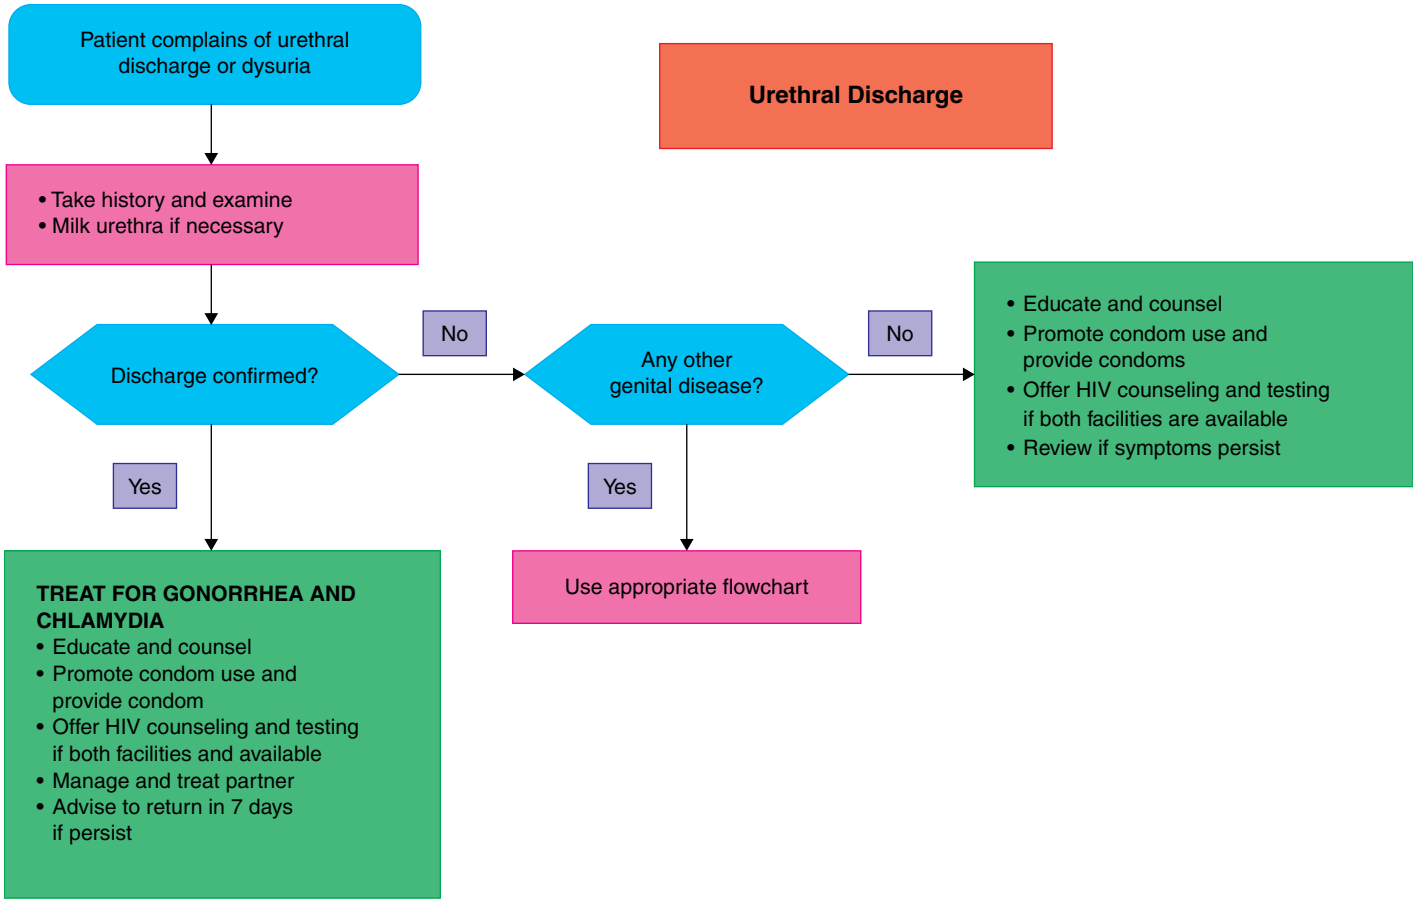

FIGURE 103-1. WHO algorithm for the management of urethral discharge.[43]

A syndromic approach of urethritis requires a treatment for both gonorrhea and nongonococcal urethritis. A number of studies have demonstrated that gonococcal antibiotherapy is becoming increasingly problematic because of growing drug resistance to the classic antibiotics like penicillin, cotrimoxazole, thiamphenicol, and tetracyclines.[41–57] These relatively inexpensive antibiotics can, therefore, no longer be recommended as a first choice treatment option.[58] More worrisome is the increasing resistance that has been recently observed against Ciprofloxacine in Asia and for the first time in Africa (South Africa) Table 103-2. This quinolone has been first-line treatment for gonorrhea in many countries because of its efficacy, single dose oral administration, and relatively low price. The first evidence is also emerging of decreased susceptibility to ceftriaxone, a third generation cephalosporin Table 103-2, but so far, this expensive third generation cephalosporin can still be recommended for the treatment of gonorrhea.

Establishing appropriate treatment strategies is further complicated by the fact that resistance patterns are changing rapidly. In Hong Kong, for example, the proportion of PPNG declined from 25% to 4% in less than 2 years. In this same period, the 4-fluoroquinolone resistance increased from 0.5% till 10.5%.[59] This illustrates the importance of monitoring of drug resistance patterns at regular intervals within countries. Updated knowledge of patterns of antimicrobial resistance is essential to arrive at a suitable standard regimen for the treatment of *N. gonorrhoeae* within the syndromic approach.

The current WHO recommendation to give systematically a drug effective against *N. gonorrhoeae* as well as a second drug (tetracycline or doxycycline) effective against *C. trachomatis* to all patients with urethral discharge, will provide adequate coverage not only for these two pathogens but probably for *M. genitalium* as well.[60] Other studies have indicated, however, that *M. genitalium* is responding much better to azithromycin, which is not readily available in most developing countries.[60,61]

GENITAL ULCERS

Like urethral discharge, genital ulcers are much more common in developing countries than in industrialized countries. However, considerable regional variation exists. There appears to be a higher prevalence of the genital ulcer syndrome (GUS) in southern African countries compared to West and Central African countries. In Zimbabwe, for instance, 63% of the male STI patients presented with genital

ulcers.[62] In this clinic, genital ulcers were the main reason for consultation. Similarly, in rural Mozambique, genital ulcers were the primary reason for consultation in 38% of all STI cases.[63] In addition to high levels of GUS in STI patients, patients with a genital ulcer tend to wait a long time before presenting themselves at a health center. In a study in Rwanda, 36% of GUS patients had waited for more than 2 weeks.[23] Similarly, in South Africa, this proportion corresponds to 35–36% among men and women respectively[64,65] while in the Gambia, 52% of all patients had waited over 2 weeks.[66] In many cases, patients continued to have sex before consultation.

Table 103-3 illustrates the different etiologies of GUS in different developing countries. Genital herpes, formerly regarded as a minor STI in most developing countries, has now emerged as a leading cause of genital ulceration in many countries where syphilis and chancroid were more prevalent previously. One of the first countries where this phenomenon was noticed was Rwanda. A study in one health center in Kigali showed that in 1986, herpes was the third and second most important cause of genital ulcers in men and women respectively. By 1992, herpes had become the second cause of genital ulcers in men and the leading cause in female patients.[23,73] During that same period, HIV prevalence among patients with genital ulcers increased from 43% to 67% in men and from 77% to 83% in women,[23,73] indicating a link between HIV and HSV-2 and explaining the changing etiological patterns for GUS. In South Africa, the relative prevalence of both syphilis and chancroid among patients with GUS has declined from 1986 to 1998. At the same time, HSV-2 has emerged as the most frequent cause of GUS.[13] A similar dramatic change in etiology of GUS was noted in Botswana, where the proportion of GUS due to chancroid decreased from 25% in 1993 to 1% on 2002, whereas the proportion of ulcers due to HSV-2 increased from 23% in 1993 to 58% in 2002.[74] (see Fig. 103-2).

HSV-2 DNA was detected in a significantly higher proportion of ulcer specimens from HIV positive patients than from HIV-negative patients.[13] Other studies also indicate that both incidence and recurrence of genital herpes are higher in HIV-infected compared with HIV-non-infected patients.[76–78] These data suggest that HIV is playing an important role in the increasing prevalence of HSV in GUS in developing countries.

Another reason for this increase may be due to the relative decrease of bacterial STD such as chancroid and syphilis. This may reflect increased condom use and an improved control of chancroid and syphilis in some regions using a syndromic approach. In Thailand, for instance, the incidence of chancroid and syphilis was reduced from nearly 39,000 and 11,855 cases in 1987–1990 and 3645 respectively in 1993.[79] In Zimbabwe, the number of cases of chancroid diagnosed clinically at the genitourinary center in Harare decreased from 2972 in 1990 to 430 in 1998.[80,81]

Two rather rare causes of GUS are lymphogranuloma venereum (LGV) and donovanosis. In its primary stage, LGV may manifest itself as ulceration. LGV was detected in 14%, 7%, 6% and 2% of patients with a genital ulcer, in Gambia, Rwanda, South Africa, and the Dominican Republic respectively.[24,66,67,73] Donovanosis as a cause of genital ulceration is limited to certain regions like Papua New Guinea, Kwa-Zulu-Natal, Eastern Transvaal in South Africa, parts of India, and Brazil.[16] Because the disease is extremely rare in most parts of the world and is often not associated with genital ulcer diseases, donovanosis is

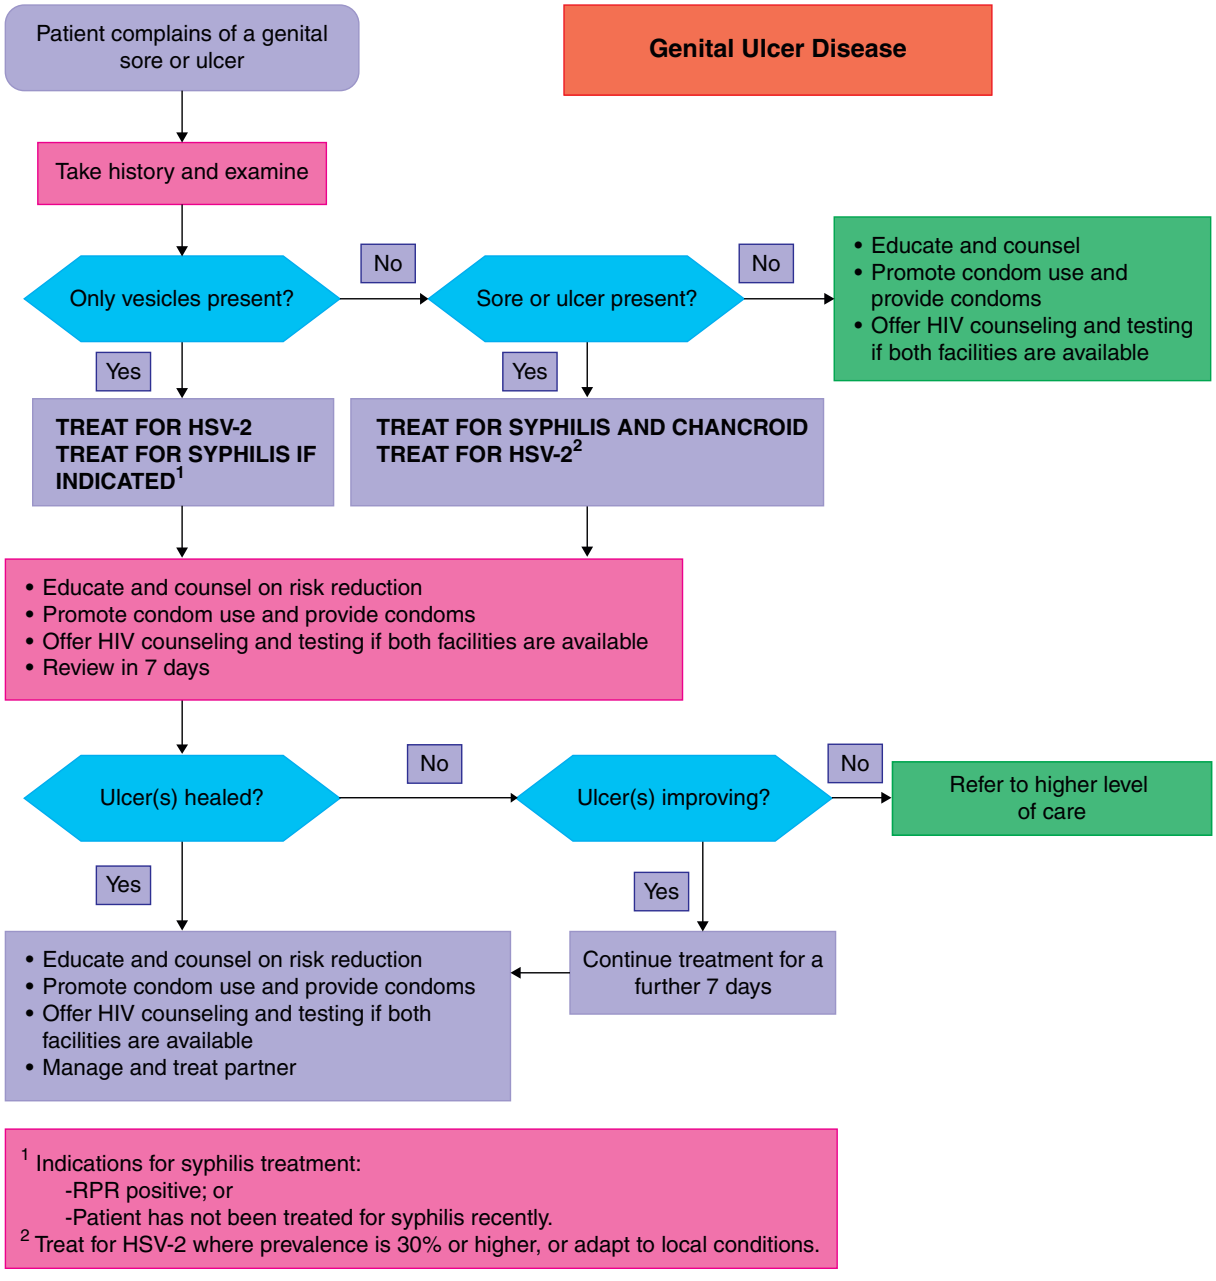

FIGURE 103-3. WHO algorithm for the management of genital ulcers.[43]

not considered in most flowcharts. The role of sexual transmission of this disease is still controversial. (see Fig. 103-3.)

Determining the underlying causes of GUS is extremely difficult on clinical grounds and mixed etiologies are frequent.[24,25] Typical vesicles were seen in only 4% of confirmed cases in Rwanda.[23] In a study in Madagascar, the sensitivity of a clinical diagnosis was 93%, 53%, and 0% and specificity was 20%, 52%, and 99% for the diagnosis of syphilis, chancroid, and genital herpes respectively.[14]

Until recently, a syndromic approach to the GUS in most developing countries recommended treatment for syphilis and chancroid, and herpes was not addressed by the GUS algorithms. This was due to the relative low prevalence of genital herpes and the unavailability of treatment. In 2001, a WHO advisory group has recognized the importance of genital herpes, and WHO is currently recommending including the treatment for HSV-2 in the management of genital ulcers, especially in settings where HSV-2 prevalence is 30% or higher.[82]

Adding a simple diagnostic test such as a RPR test to a diagnostic flowchart is not very helpful, as the test cannot exclude active syphilis. The results of an RPR test are negative in 30–50% of patients with a primary syphilitic ulcer.[83]

In many parts of the world, patients with syphilis are often coinfected with HIV. Whereas standard treatment of early syphilis and early latent syphilis in patients with HIV infection may be less effective, a few studies did not find a different clinical or serologic response after 1 dose of benzathine penicillin in HIV-positive as compared to HIV-negative patients.[84–86]

Antibiotic resistance of *Haemophilus ducreyi* against single dose antibiotic therapy is another observed problem. One study in Kenya suggests that failure of a single intramuscular injection of 250 mg of ceftriaxone is strongly associated with HIV infection.[87] Increasing resistance to TMP/SMZ and treatment failure have also been documented in Rwanda, and HIV infection and the degree of $CD4^+$ depletion were unrelated to clinical and bacteriologic outcome.[88] In conclusion, a single dose of TMP/SMZ can no longer be recommended for the treatment of chancroid in such regions. In other regions, surveillance data and studies of cost-effectiveness will have to guide therapeutic guidelines.

Giving an antiviral therapy for herpes was not considered for a long time in developing countries because of the high cost of drugs such as acyclovir. Moreover, the therapy was considered to be of limited public health importance since, in any case, it does not cure the herpes but only reduces the duration of symptoms. This picture has changed, in the light of the association between genital herpes and HIV transmission. Treating a person with acyclovir will shorten the duration of genital lesions and may eventually result in decreasing the spread of HIV.[89] In addition, generic acyclovir has become available at an affordable price. Adding acyclovir to the syndromic treatment of ulcers, however, will not necessarily lead to higher cure rates.

STI causing genital ulcers are also important causes of inguinal lymphadenopathy in developing countries. A proportion of 8.5% of the male and 4.7% of the female STD patients in Kenya were complaining of genital or inguinal swelling.[8]

Lymph nodes that are 2 cm or larger, and become fluctuant, are considered buboes. The main causes of buboes are chancroid and LGV. Buboes are frequently present in patients with genital ulcers. In Zimbabwe, 20% of the men and 6% of the women with genital ulcers presented with buboes.[62] In Rwanda, these proportions were 12.4% and 4%, respectively.[23] In women, lymphatic drainage is less superficial than in men. This could explain the fact that in these studies more men than women were having buboes. LGV is usually seen in a secondary stage of acute lymphadenitis with bubo formation, without a sign of the primary ulcer.

As proposed in the diagnostic flowchart shown in Fig. 103-4, a practical way to manage buboes is to consider them as LGV when no ulcer is visible and to manage them as a GUS when an ulcer is present. The aspiration of the bubo (through the healthy skin) may be required.

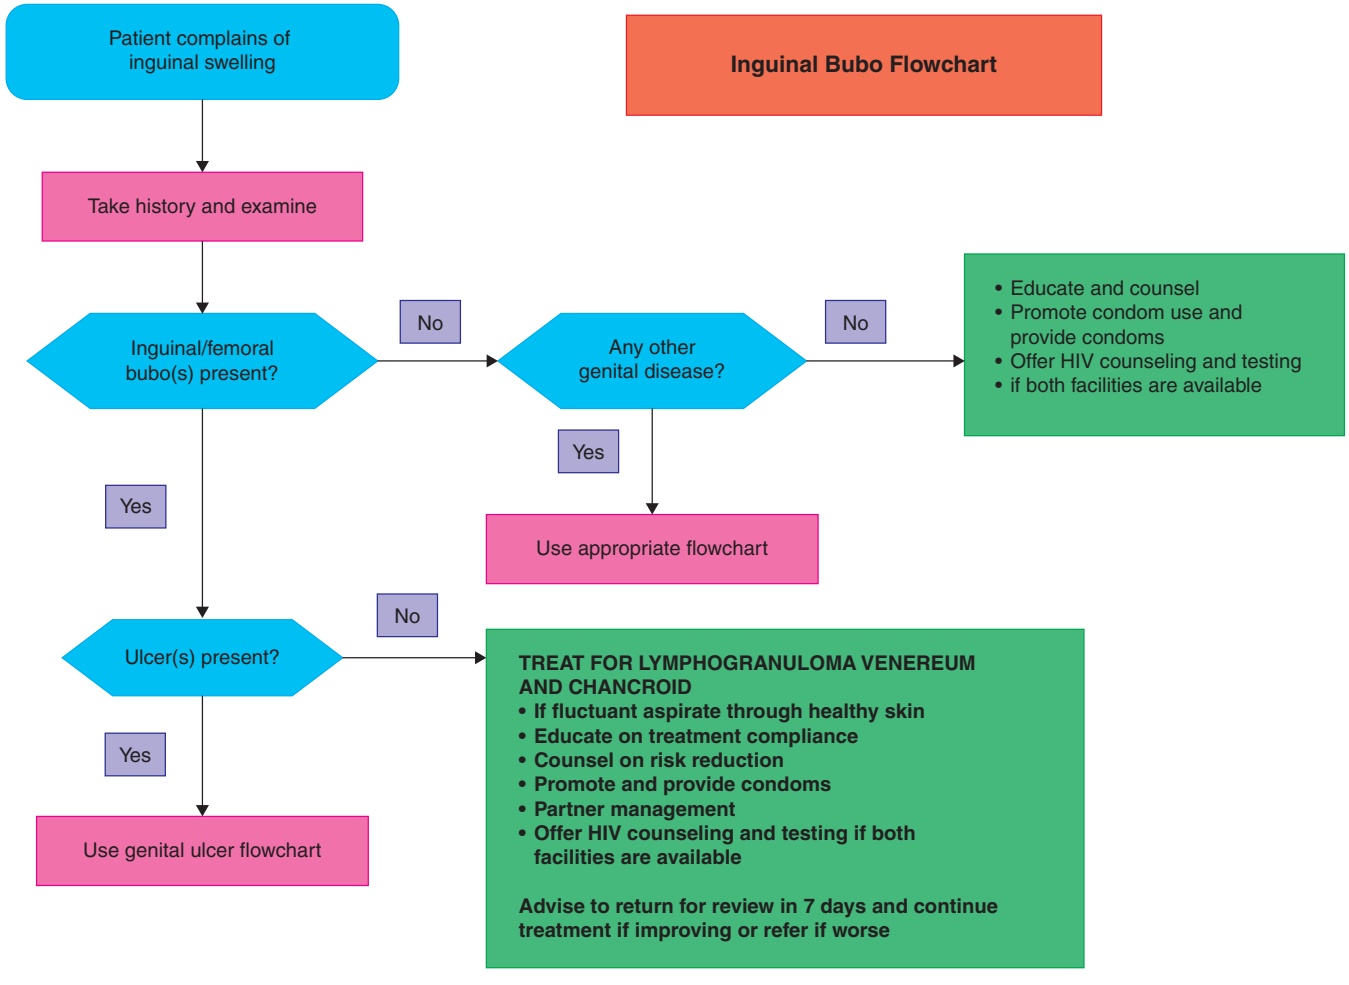

FIGURE 103-4. WHO algorithm for the management of inguinal buboes.[43]

VAGINAL DISCHARGE

Abnormal increased amount or abnormal odor or color of vaginal secretions is a very common symptom and among the most important reasons for women to seek STI care in both developing and industrialized countries.[8,62,90] These conditions may be related to both cervical and vaginal infections. The underlying causes of cervical infection in women are most frequently *N. gonorrhoeae* and/or *C. trachomatis*, which are usually localized in the endocervix. Although studies from the industrialized world have indicated that *M. genitalium* may cause mucopurulent cervicitis, no such data from developing countries are available.[91] The underlying causes of vaginal infection include sexually transmitted agents such as *T. vaginalis* but also other conditions such as bacterial vaginosis and genital candida infection.

If cervical infection remains untreated, it may cause many serious complications such as acute PID, ectopic pregnancy, and infertility.[92] A major reason why cervical infections often remain undiagnosed and hence untreated is the complete absence of symptoms and signs in many infected women. Symptomatic cervicitis represents only the tip of the iceberg. In a rural area in Mozambique, up to 89% of infected pregnant women did not report any symptoms.[63] In three family planning clinics in Dar es Salaam, Tanzania, 65% of the clients with a gonococcal and/or chlamydial infection reported no symptoms.[93] Among prostitutes in Zaire, acute newly acquired infections remained asymptomatic in 69% of all cases.[94]

The asymptomatic character of cervical infections and the failure of many women, including symptomatic women, to seek medical care, may explain the high prevalence of gonorrhea and/or chlamydia infection and related complications in some developing countries. Prevalence studies of chlamydia infection, for instance, show rates from 1.9% among teenagers in Chile[95] to 26% in rural women in Papua New Guinea.[96] Prevalence rates of gonorrhea were as low as 0.02% among pregnant women in Gabon[97] and as high as 24% in FSW in Thailand.[98]

In primary health-care settings, however, symptoms of vaginal discharge are generally due to vaginal infections and less frequently to cervical infections, as shown in Table 103-4. The most frequent causes of vaginal infection are candidiasis, bacterial vaginosis, and trichomoniasis. The possible complications of vaginal infection are much more limited except for their potential role in facilitating transmission of HIV and maybe their role in causing premature birth.[104,105] However, vaginal infections cannot be ignored because they are a very common reason why women consult health services. As such, the quality of care for these infections may have a great impact on the confidence that women have in the health service.

Nevertheless, a syndromic approach to vaginal discharge should also take cervical infection into account because of the public health importance of gonococcal and/or chlamydial infections.

However, diagnosis of cervical infections in women is complicated because of the weak association between symptoms/signs and cervical infection and the absence of simple and valid laboratory tests for diagnosis or screening of cervical infections.

Not only the vaginal discharge symptom but also clinical signs such as cervical mucopus, friability or ectopy, and lower abdominal tenderness are of limited use for the clinical diagnosis of cervical infection. Various studies have shown a low

sensitivity and/or specificity of selected symptoms and signs for gonococcal and/or chlamydial cervical infection.

The results of a meta-analysis presented in Table 103-5 showed that none of the symptoms nor clinical signs are at once sensitive and specific for cervical infection.[106] Moreover, there is almost no difference between low-risk and high-risk populations.

Studies in developing countries have demonstrated that risk markers rather than signs and symptoms are predictive for gonococcal and/or chlamydial cervical infections.[107,94] As a result, WHO has proposed to incorporate a risk assessment for cervical infection in diagnostic flowcharts for symptomatic women Fig. 103-5. This management strategy ensures that a woman with a complaint of vaginal discharge will systematically be treated for vaginal infections but her risk for cervical infection will also be assessed. When her risk assessment is positive, she should receive additional treatment for both gonococcal and chlamydial infection. Risk markers such as a symptomatic partner, being younger than 21 years of age, being single, and having more than one or having a new sexual partner in the last 3 months, have been validated in different settings, including Jamaica, Brazil, Benin, Gabon, Malawi, Tanzania, and Kenya.[36,90,97,99,100,101,108] Using a risk score assessment in Tanzania, the overtreatment rate for cervical infections decreased from 92% to 17% in pregnant women and from 89% to 36% in nonpregnant women with vaginal discharge.[92] However, in certain areas it is culturally not accepted to ask private questions on sexual behavior to women, or the prevalence of cervical infections may be too low to be considered in a syndromic approach.[109] Therefore, the risk assessment should be adapted to local circumstances and STI epidemiology.

Another main obstacle for diagnosis and/or screening of cervical infections is the absence of a simple and valid diagnostic laboratory test for *N. gonorrhoeae* and *C. trachomatis*. The current gold standard laboratory tests such as polymerase or ligase chain reaction are too sophisticated, expensive, and generally not available in most settings. Culture for *N. gonorrhoeae* may be available in some settings, but results are not readily available, which unnecessarily delays treatment. More simple laboratory tests such as Gram stain or Leuco-esterase Dipstick (LED), which are useful in detecting urethritis in men, are not helpful and not specific and sensitive enough to detecting cervical infections.[90,99] Simple, rapid, and affordable tests for the diagnosis of gonococcal and chlamydial infection have been on the priority list for STI research for years but as yet remain unavailable. The development of such tests is considered by STI control program managers and STI specialists to be an absolute priority in STI research. Major progress has recently been made in this field. A rapid (25 min), cheap (U.S. $0.85) dipstick for chlamydial infection "First burst" has been recently developed and is awaiting FDA approval. Another duplex (*N. gonorrhoeae* and *C. trachomatis*) test is undergoing evaluation.[110] These tests may represent an important

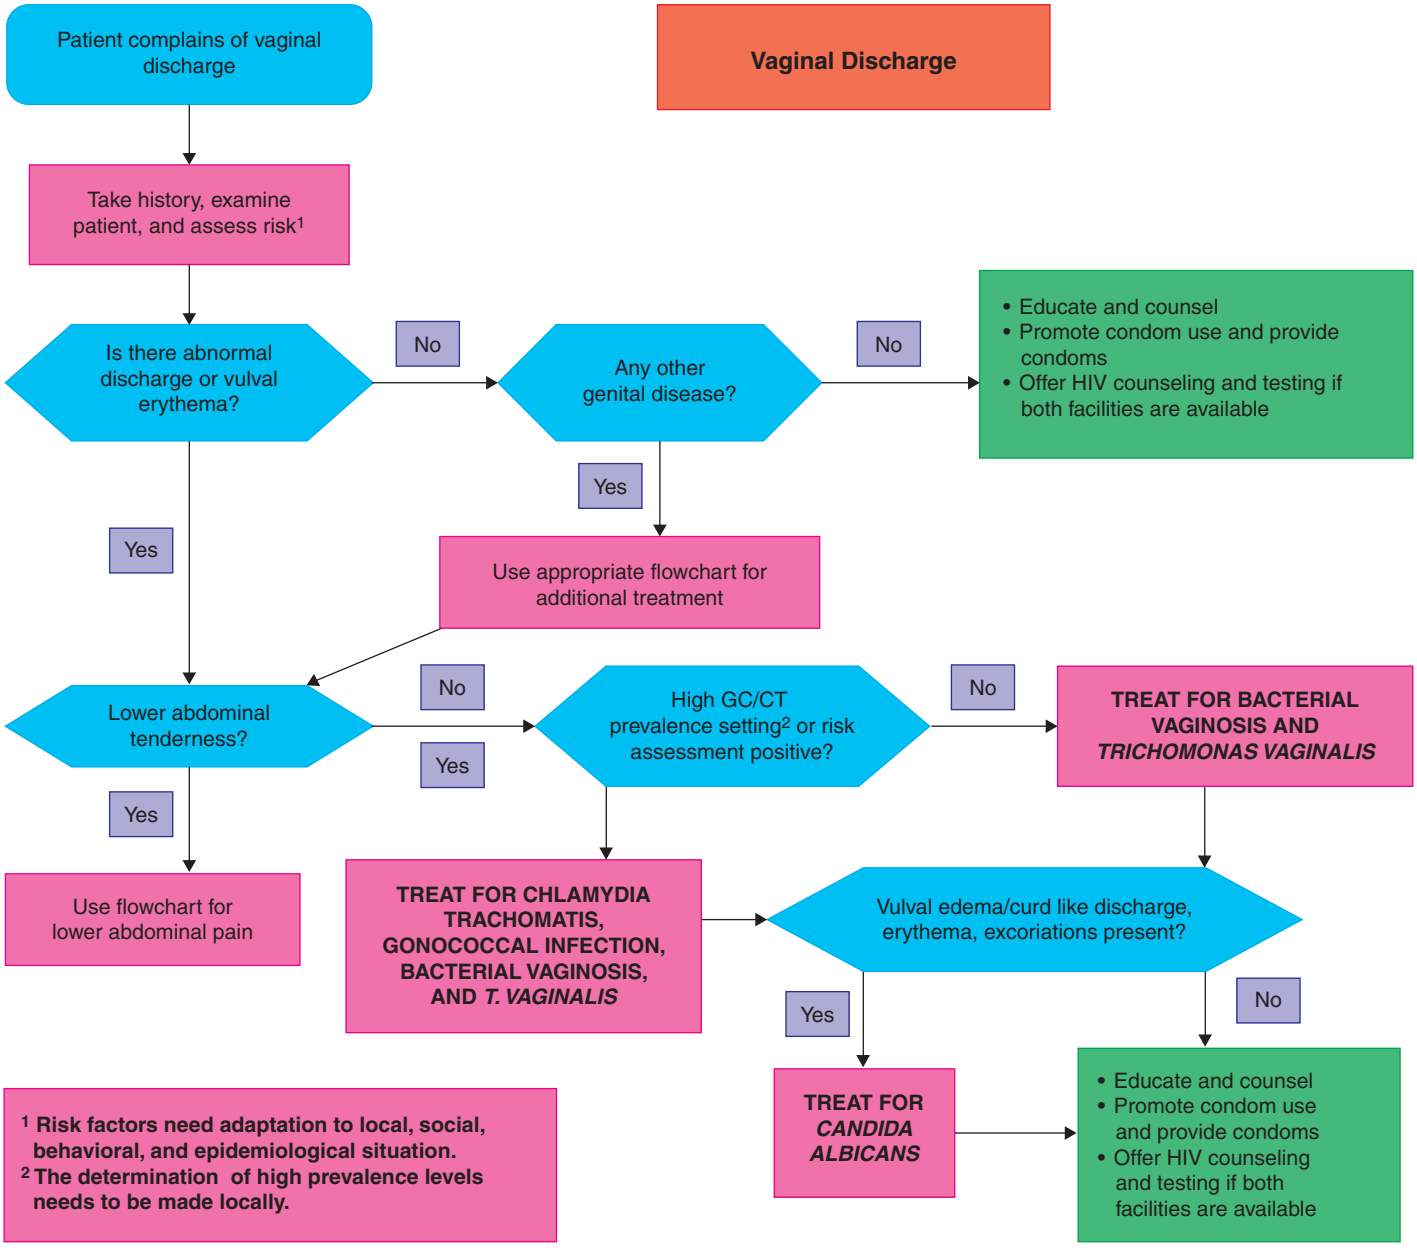

FIGURE 103-5. WHO algorithm for the management of vaginal discharge.[43]

breakthrough for STI control in symptomatic and asymptomatic women in developing countries.

The recommended treatment for vaginal infection is shown in Fig. 103-5. It includes treatment for both candidiasis and trichomoniasis that covers bacterial vaginosis at the same time. Cervical infections should be treated with antibiotics for gonorrhea and chlamydia infection. The observations regarding the resistance to antibiotics for gonorrhea can be applied to treatment for cervicalgonorrhea.

LOWER ABDOMINAL PAIN

Lower abdominal pain is a very common symptom in women attending with STI symptoms. It was among the main complaints in 46%, 48%, and 49% of the women consulting a primary health-care center or STI clinic in Morocco, Kenya, and Malawi, respectively.[100,103,111]

In most cases, the symptom lower abdominal pain is related with cervical infection due to *N. gonorrhoeae* and/or *C. trachomatis*.[100–102] However, when untreated, cervical infections may ascend into the upper reproductive tract and cause PID. The role of gonorrhea and of chlamydia infections in PID in Africa has been well documented.[112,113] The long time sequelae of tubal scarring and occlusion may cause infertility. In Africa, over 85% of infertility in women can be attributed to this infection.[114]

The most important symptom of PID is lower abdominal pain which may or may not be accompanied by clinical signs

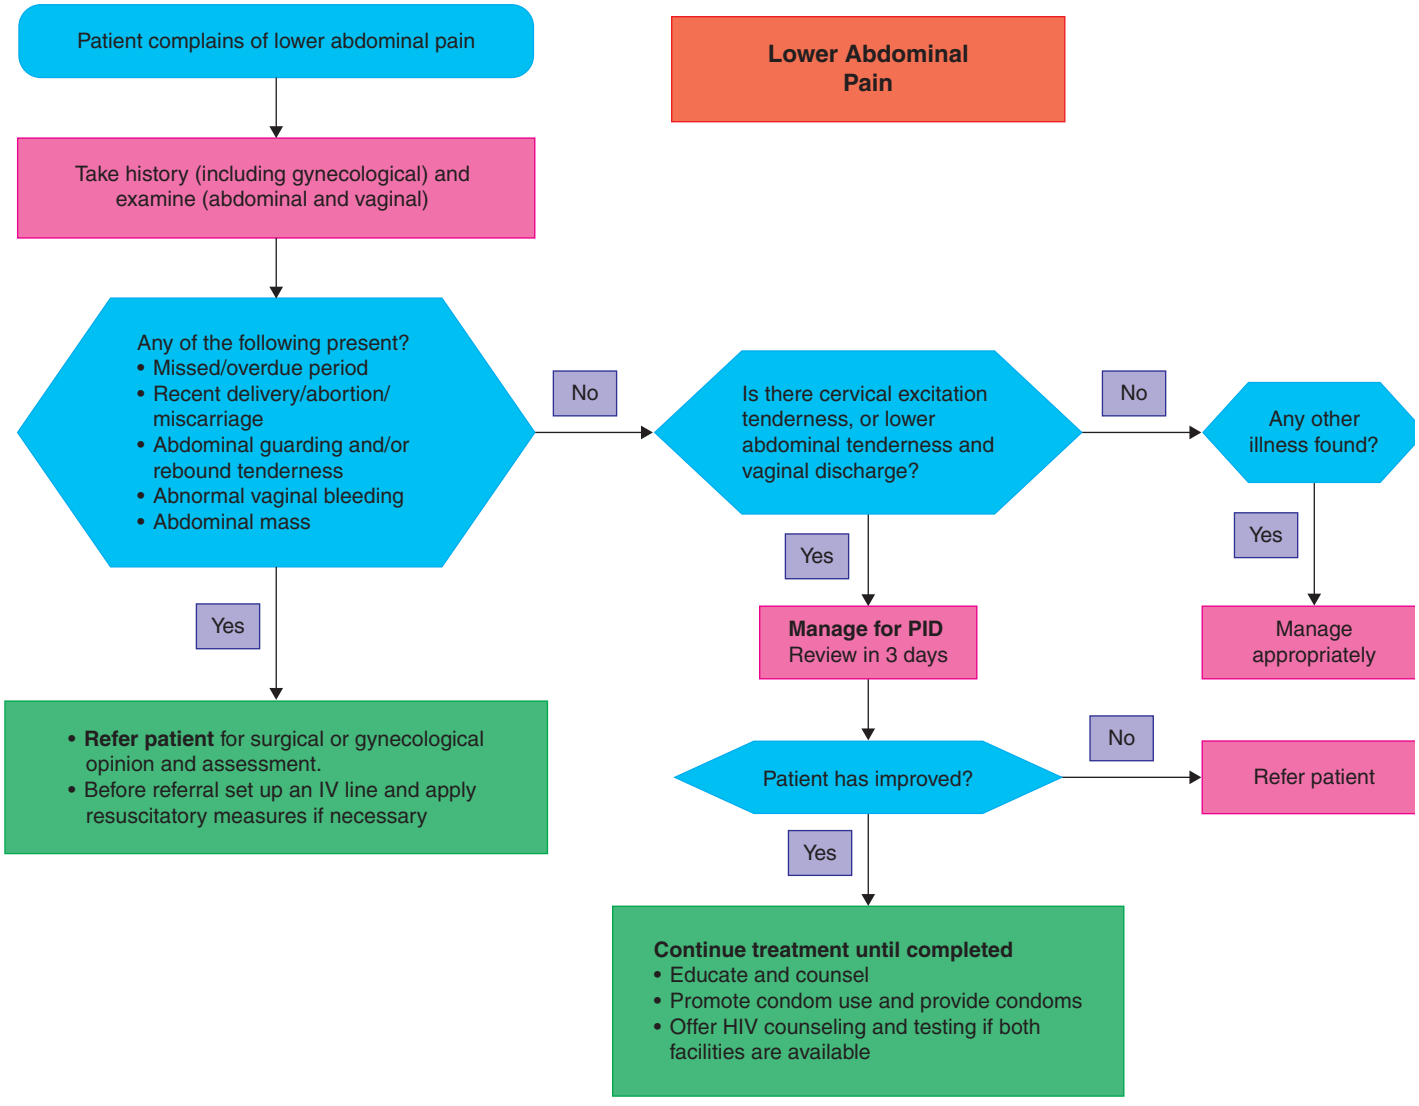

FIGURE 103-6. WHO algorithm for the management of lower abdominal pain.[43]

like fever, cervical motion tenderness, palpable mass, and vaginal discharge.[112,115] See also Fig. 103-6 that shows the WHO algorithm for the management of lower abdominal pain.

Lower abdominal pain in sexually active women can also be a symptom of ectopic pregnancy or of other causes of acute abdomen. These emergencies must be excluded before treating for PID. Recommended treatment regimens and indications for hospitalization are discussed in Chapter X.

NEONATAL CONJUNCTIVITIS

Both gonococcal and chlamydial ophthalmia neonatorum are still common in many developing countries. Although gonococcal ophthalmia tends to be more severe, more purulent and with an earlier onset than ophthalmia caused by chlamydial infection, the etiological cause (gonococcal or chlamydial) cannot be assumed on the basis of clinical signs only.

An example of a diagnostic flowchart for ophthalmia neonatorum is provided in Fig. 103-7. Effective treatment dramatically changes the course and outcome of the disease, usually with noticeable improvement within 24 hours. The eyes of the baby should be washed with frequent saline irrigations. Unfortunately, the availability of recommended drugs such as ceftriaxone IM or spectinomycin IM for pediatric preparations is a problem in many developing countries. Kanamycin (25 mg/kg as a single IM dose) can be given as a suboptimal alternative. Management should also include the treatment of the mother and her partner.

CASE FINDING AND SCREENING FOR STI IN DEVELOPING COUNTRIES

Because of the asymptomatic nature of many infections, particularly in women, and of the serious complications resulting from untreated infections, active case finding or screening for

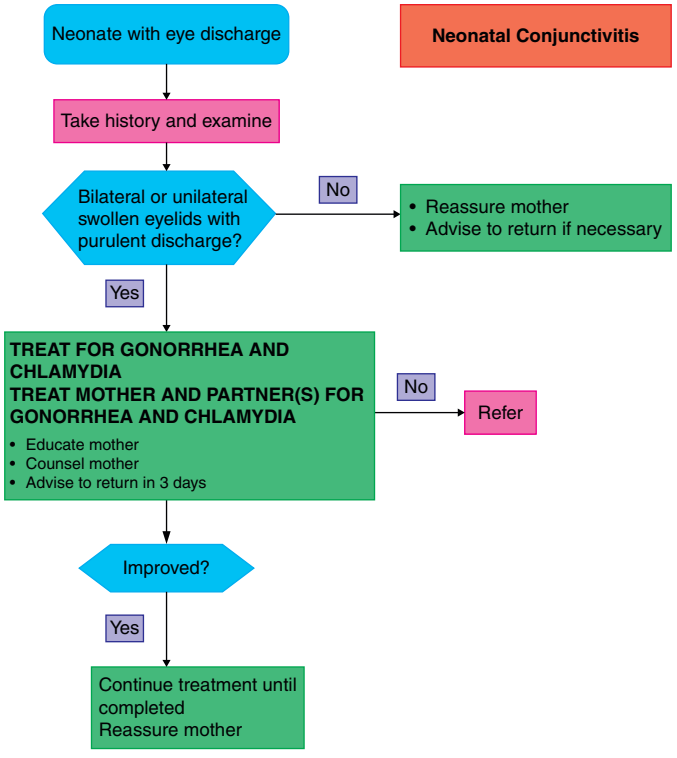

FIGURE 103-7. WHO algorithm for the management of ophthalmia neonatorum.[43]

STIs is an obvious public health strategy. Global strategies for case finding and/or screening may vary according to the target population. If the aim is to reach a maximum coverage, all women of reproductive age should be targeted. It seems logical to integrate STI services in Mother and Child Health services and Family Planning services because these are often women's primary contact with the health-care system. In many developing countries, these services have a good coverage of women of childbearing age. Another strategy is to target particularly vulnerable groups such as sex workers for screening.

STI SCREENING AS PART OF REPRODUCTIVE HEALTH PROGRAMS

The provision of reproductive health, including STI care, was put high on the agenda at the 1994 International Conference on Population and Development (ICPD) in Cairo, and new questions were arising about how to attend reproductive tract infections (RTIs), including asymtomatic STIs in women attending family planning centers or antenatal services.[116]

Syphilis prevalence rates between 3% and 19% have been reported in pregnant women from developing countries, with the highest rates found in southeastern sub-Saharan Africa.[117] Rates of congenital syphilis as high as 3200 per 100,000 live births have been described in Addis Ababa, Ethiopia, and 850 per 100,000 in Lusaka, Zambia.[118,119] In Porto Alegre, Brazil, 2.3% of the newborns had clinical and/or laboratory incidence of congenital syphilis[120] Adverse pregnancy outcome due to syphilis is preventable through routine serological screening by a simple RPR (or equivalent) test and early treatment of both partners. Screening and treating pregnant women for syphilis is known to be a highly cost-effective, inexpensive, and feasible intervention for congenital syphilis, as demonstrated in Nairobi, Kenya,[121] and in Lusaka, Zambia.[117] In the latter study, the cost of preventing an adverse pregnancy outcome due to maternal syphilis was around U.S. $12 at a seroprevalence level of 10%. Even in countries with seroreactivity rates lower than 1 per 1000 syphilis screening in pregnant women was reported to be cost-effective.[122]

For gonococcal and/or chlamydial cervical infections, however, no such simple test is currently readily available. Given the success of the syndromic approach including risk assessment for symptomatic patients, it was appealing to test the validity of the approach for STI screening in asymptomatic women.[93,123,124] However, it soon became evident that the approach has some limitations when used for STI screening in asymptomatic women, especially in low prevalence settings.[93,109] It should be stressed that the syndromic approach was developed as a diagnostic tool in symptomatic patients and it was never meant to be a screening tool.[125] Traditionally, screening tools are used to minimize the number of (more expensive) standard diagnostic tests by identifying a group of people with a higher-than-average prevalence of infection. In the absence of such a test, the risk score approach should not be used as a substitute for standard diagnosis because of its poor discriminative ability. The current picture may change, however, when simple, cheap, and rapid diagnostic tests for *N. gonorrhoeae* and *C. trachomatis* are available in developing countries. The development of such tests is considered by STI control program managers and STI specialists to be an absolute priority in STI research. Major progress has recently been made in this field. A rapid (25 min), cheap (U.S. $0.85) dipstick for chlamydial infection "First burst" has been recently developed and is awaiting FDA approval. Another duplex (*N. gonorrhoeae* and *C. trachomatis*) test is undergoing evaluation.[110] These tests may represent an important breakthrough for STI control in symptomatic and asymptomatic women in developing countries.

STI SCREENING FOR HIGHLY VULNERABLE POPULATIONS, INCLUDING SEX WORKERS

For some specific populations and settings, STI management using the syndromic plus risk assessment approach alone may not be sufficient and alternative strategies are warranted.

Because of high infection rates and large numbers of sexual partners, sex workers have been considered a core group for the transmission of STIs, especially in developing countries.[126]

Standard diagnostic approaches are often not sensitive enough to detect most infections in high-risk groups such as FSWs. In addition, treatment of symptomatic STI alone will not be sufficient for lowering the infection rate in this population. If affordable, regular laboratory screening of sex workers for the common curable STIs using sensitive tests would identify both symptomatic and asymptomatic STIs.[127] These expensive high-tech laboratory tests are not available in most situations and alternative strategies are needed. Such an alternative strategy is presumptive or periodic mass-treatment of STIs in high prevalence populations. Presumptive treatment of individuals or populations with a high likelihood of having disease is dependent not on the presence of symptoms or signs, nor on the results of laboratory tests, but on increased risk of exposure.[127] Because of high prevalence rates and frequent reexposure, sex workers can be treated presumptively for the common curable STI on a one-time or periodic basis. Such an approach may be an effective emergency measure to rapidly reduce high prevalence rates over the short term.[127,128] The Lesedi project started in October 1996 in a South African mining community. FSWs attended a mobile clinic monthly for examination and counseling and were treated presumptively for bacterial STIs with a directly observed 1 g dose of azithromycin. After 9 months of intervention, gonococcal and chlamydial rates decreased from 25% to 10% and from 11% to 6% and genital ulcers decreased from 10% to 4 % and from 6% to 1% among FSW and miners, respectively.[129] By the end of the first year, costs of the periodic presumptive treatment component of the intervention were tracked and a cost-benefit analysis was carried out based on estimates of averted morbidity and mortality. A model was used to estimate the number of HIV infections averted in women using the services and among miners in the area.[130] Hospital costs for inpatient and outpatient care of miners with HIV-related illness were determined from hospital records. The calculated benefit ratios were high, even when only considering the direct medical costs, with estimated annual savings of U.S. $539,000.[131]

Since the end of the first phase, services for women at high risk have been expanded and covered all the high-risk areas in the original town by 2001. Antibiotic resistance studies were conducted in 2000 on samples from the project area and no resistance to azithromycin was found (R. Steen, personal communication).

The prevalence of STI drops quickly among women who are attending services regularly. The difference in infection rate between first-time attendees and returning clients prompted some program managers to design two different strategies. In FSW clinics in Kinshasa (Democratic Republic of Congo) and Sihanoukville (Cambodia), for instance, all first-time attendees are given treatment for cervical infections, whereas returning clients are treated according to a strict algorithm (N. Séguy and F. Crabbé, personal communications). In an FSW clinic in Abidjan, Côte d'Ivoire, women are managed differently if the time since their last visit exceeds 3 months.

Other high-risk male populations who may need special attention regarding STI screening include military personnel, long-distance truck drivers, and in general clients of sex workers. Results from several studies suggest that a significant proportion of men with positive laboratory tests for *N. gonorrhoeae* or *C. trachomatis* are asymptomatic.[132,133] The LED has been proposed as a cheap nonspecific test that could allow the detection of polymorphonuclear cells in asymptomatic men and also be used to confirm symptomatic urethritis.[133–135] In a study among clients of FSW in Benin for instance, the positive predictive value of the LED test for urethritis in asymptomatic clients of sex workers was 37.5%.[135] In another study in Kenya, a positive LED test on urine predicted infection with a sensitivity of 55% and a specificity of 83% in asymptomatic transport workers.[133] These results suggest that LED could be a useful case finding tool for STIs in high-risk asymptomatic men in developing countries.

STI CASE MANAGEMENT AS PART OF STI CONTROL PROGRAMS IN DEVELOPING COUNTRIES

Even if 100% sensitive and 100% specific algorithms or simple inexpensive laboratory tests for STI diagnosis were available, they are not likely to reduce the number of STI infections on their own. Simple and valid diagnostic tools are the cornerstones of effective STI case management, but many other factors play a role in a successful STI control program. A model developed in the sixties to evaluate case finding and treatment in tuberculosis control programs[136] has been adapted to assess the performance of STI case detection and management (Fig. 103-8). It uses a series of steps from number of infected people in the community to number of patients eventually cured by the health system. At every step

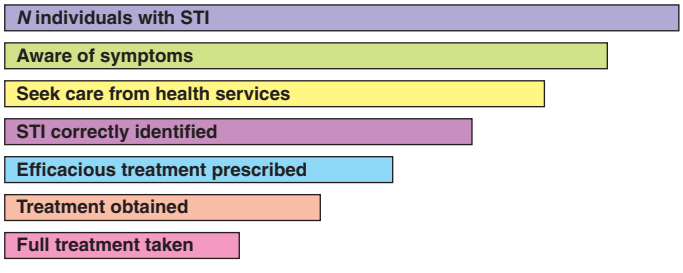

FIGURE 103-8. Operational model to illustrate the different steps involved in STI case detection and treatment. (Adapted from Waaler HT, Piot MA. The use of an epidemiological model for estimating the effectiveness of tuberculosis control measures. Sensitivity of the effectiveness of tuberculosis control measures to the coverage of the population. *Bull World Health Organ* 1969; 41: 75–93; Buvé A, Changalucha J, Mayaud P, et al. How many patients with a sexually transmitted infection are cured by health services ? A study from Mwanza region; Tanzania. *Trop Med Int Health* 2001; 6: 971–979.)

between infection and cure, the number of cases lost to the health services is calculated, in order to identify where interventions might have the greatest impact. This model has helped to illustrate that patients with STI have to overcome several hurdles before they are cured. Issues such as being aware of the STI and become motivated to seek correct and appropriate care are as important in terms of "losses of proportion of STI cured" as correct diagnosis and treatment. This was illustrated by Buvé and colleagues in Mwanza (Tanzania) where this model was applied to a real-life situation.[137]

CURE RATE ACHIEVED BY THE HEALTH SYSTEM

The cure rate not only depends on the diagnostic tools used but also on the correct application of the tools, the availability of efficacious STI drugs, and the patient's compliance with the treatment. During a study in a sex worker clinic in Abidjan, Cote d'Ivoire, for instance, all necessary steps to diagnosis were correctly performed in only 68% of the cases.[138] This shows the importance of training of health-care providers in the correct application of the algorithms, ongoing supervision, and reinforcement after training. In Rwanda, for instance, nurses were able to correctly apply the syndromic STI management guidelines with adequate post-training supervision and a high degree of clinical improvement was achieved.[139]

The accessibility and availability of affordable, effective drugs are further critical conditions for appropriate STI case management. Bulk purchasing by governments and other, more innovative partnerships between multilateral and bilateral agencies, the pharmaceutical industry, and country programs should be put in place urgently.[140] Another step to correct treatment is the patient's compliance with the treatment prescribed. During an observational study in rural Tanzania, for instance, 69% of the returning women said that they took the full treatment.[137]

HEALTH SERVICE DELIVERY

In order to achieve cure through the health system, people with STI have to get in touch with the health system (Fig. 103-8). However, not all men and women who contract an STI are aware of their infection or are worried enough to seek care. Even if they are aware and worried, not all attend a health facility. The literature from developing countries confirms that a substantial proportion of people seek STI treatment in the informal sector from traditional healers, unqualified practitioners, street drug vendors, or pharmacists.[6–8,141] From a study in Mwanza, Tanzania, it was estimated that in the catchment area of health centers offering improved STI services, 51–72% of patients with STI symptoms sought care from those health centers.[137] Reasons for not attending a health center when having an STI include fear of stigmatization and inaccessible and unaffordable services. People may be too frightened to make use of health services because they fear abusive attitudes of health workers and often experience a lack of privacy and confidentiality.[142] A study was performed in South Africa to determine factors associated with delay in seeking healthcare for symptoms of STI. Patients who delayed were those who held misconceptions regarding the STI cause, who perceived STIs not to be serious, whose friends waited before seeking treatment, and who valued personal autonomy in sexual behaviors less.[143]

In ensuring universal access to appropriate STI care programs, it should be recognized that patients seek care from a range of public and private sources. In many countries most STI care is obtained outside the public sector. Planning of a balanced and comprehensive program will need to consider strengthening any health-care providers that are able to provide a quality service.[137]

For vulnerable women such as sex workers, it is even more difficult to access good quality services. Even when they are available, there are a number of reasons for poor utilization of services, such as stigmatization, inconvenient opening hours, and economic, language, or other cultural barriers. Different projects have tried to increase the accessibility of services by promoting sex-worker-only clinics.[126] These clinics could provide them with additional safe and confidential options for sexual health services. In addition, specialized services may offer better opportunities for targeted educational sessions and regular screening activities. A regular visit by the sex worker will enhance the relationship of trust with the health-care workers and provide a forum for prevention messages.

As mentioned previously, the most critical step in effectively implementing STI control programs for youth is reaching the group and convincing individuals of the value of the intervention.[127]

PREVENTION STRATEGIES

Early diagnosis and treatment of STI is an important strategy to reduce the pool of infected people and to prevent secondary infections. In addition, behavioral interventions are designed to prevent the acquisition of infection and disease by promoting abstinence, safer sexual behavior, and the use of condoms for penetrative sexual acts.[20]

Providing STI clinical care offers an important opportunity for health education to persons who are, by definition, at increased risk of infection. A patient's decision to come to the clinic signals a level of concern that may provide the teachable moment. Evidence suggests that people are more willing to learn about a disease when they or someone close to them experiences its symptoms or consequences.[144] Patient education in

STIs can be divided into the categories of preventing future infections and managing the current infection. Preventing future infections requires sustained behavior change or the consistent practice of low-risk sexual behavior. Managing the current infection both prevents further transmission to others and prevents complications in the patient.

Behavior change messages include messages on prevention of STI by reducing the number of partners and promoting the use of condoms but also messages to promote health-seeking behavior.[145] In order to increase their coverage at general community level, behavior change message may be delivered by mass media. Mass media can be used to raise general awareness, but a combination of mass media campaigns and interpersonal communication seems most promising to maintain safe sex behavior or prevent and change unsafe behavior.[146] Wide availability of condoms, e.g., through condom social marketing further supports the preventive components of an STI control program.[147]

104 The Laboratory in the Management of STDs, HIV, and Opportunistic Infections in Developing Countries

Rosanna W. Peeling, David Mabey, Jimmy Whitworth, and Andrew Ramsay

INTRODUCTION

Developing countries bear by far the greatest burden of disease due to HIV and other sexually transmitted infections (STIs). At the same time, the human and material resources at their disposal to control these infections and to provide care for those affected by them are less than in rich countries. In the most severely affected countries, the HIV epidemic has itself had a profound impact on the availability of trained staff in the health sector.

The laboratory is important in the management of STIs, HIV, and opportunistic infection (OI). Its role in the provision of laboratory services in support of patient management and disease control is similar in both developed and developing countries. The main difference is that, in developing countries, the burden of disease is greater but resources are more limited. In the least developed countries, where there is a lack of trained personnel, few resources to buy consumables, old and poorly maintained equipment, and an unreliable electricity supply, there may be few if any fully functioning microbiology laboratories.[1,2] In these circumstances, only the simplest diagnostic tests can be used. On the other hand, even in the poorest countries, there is often a flourishing private market in health care, at least in major cities, although this is often poorly regulated and of variable quality.

Allocation of resources to laboratory services has not been a high priority in developing countries. In resource-limited settings, health service providers have to prioritize their scarce monetary and human resources to accommodate many competing demands. Even where there is political commitment and resources are available, there are often operational and administrative difficulties in delivery of health services due to an inadequate health-care infrastructure plagued by staff shortages, lack of proper training and supervision, inconsistent supply of laboratory reagents and medicines.[3] This has led to demoralization of staff and failure to pay adequate attention to essential aspects of a diagnostic laboratory service: staff training, regular supervision, and quality control. This has affected the quality of results, leading to a lack of confidence in laboratory diagnosis, resulting in a reduced quality of clinical care. It has also fuelled the perception that laboratories are of little value.[2]

In some developing countries such as Malawi, the essential health package developed by the Ministry of Health includes a package of essential medical laboratory services.[4] Such a package includes

- emphasizing the importance of laboratory testing for accurate diagnosis;
- ensuring sufficient financial resources are made available;
- implementation of laboratory training programs;
- regular supervision of laboratory staff;
- routine monitoring of test quality;
- establishing a system for laboratory accreditation;
- evaluation of affordable, rapid diagnostic tests.

This chapter discusses the role of the laboratory in the management of STI, HIV, and OIs and approaches to laboratory diagnosis for these infections according to the resources available. We will focus on public sector services in countries with the greatest burden of disease due to HIV and other STIs, e.g., those in sub-Saharan Africa.

We will discuss the role of the laboratory at three levels of health care:

- peripheral level, such as a health center which serves a number of dispensaries or health posts
- district level, such as district hospitals which serve health centers within a district
- tertiary level, such as regional or referral hospitals

The facilities available at each level will vary from country to country. For the purposes of this chapter, we define them as follows:

At *peripheral* (health center) level, there is unlikely to be a trained microbiology technician, and little likelihood of future staffing with technicians in the short term, nor is there likely to be a member of staff who will be able to interpret and conduct complex investigations appropriately. Tests at the health center level need to be those which will benefit the

Table 104-1. Laboratory Capacity at Different Levels of Health Care

Level of Care	Staff	Equipment	Tests
Peripheral centers	Health worker, nurse	Light microscope at some centers	Rapid tests for STIs and HIV; Smear microscopy for malaria and TB
District hospitals	One or more trained technicians	Light microscope, centrifuge, shaker for syphilis serology, incubator in some facilities	Smear microscopy for malaria and TB; Serological tests for syphilis, HIV; Limited bacterial cultures for tuberculosis and gonorrhea
Tertiary hospitals	Fully functional laboratory with two or more trained technicians	Light microscope, centrifuge, shaker for syphilis serology, incubator	Smear microscopy for malaria; Serological tests for syphilis and HIV, including confirmation; Blood cultures; Antimicrobial susceptibility testing

management of a patient who is not so sick as to need referral to hospital. Testing at these peripheral centers may be useful for protecting therapies from massive overuse or abuse. Laboratory equipment is likely to be restricted to a light microscope.

At *district* level, it is expected that there will be at least one trained technician. Tests performed at this level should be those that will provide clear treatment direction for serious infections. In addition to a light microscope, equipment may include a centrifuge and facilities for simple serological testing and bacterial culture.

At the referral hospital, or *tertiary* level, culture techniques (including blood culture) should be routinely available. If an organism is cultured, then it should be feasible to determine antimicrobial sensitivities. The laboratory at this level should be able to conduct periodic assessment of the etiological cause of common syndromes and of antimicrobial sensitivities of common pathogens to guide syndromic management. The facility and capacity at different levels of health care are summarized in Table 104-1.

Laboratory services need to be organized and quality-assured through a well-defined framework defining roles and responsibilities for STI/HIV laboratory management at different levels of health care. These can include for

tertiary level

1. implementation of national programs and policies;
2. technical support and training for district level laboratory procedures and biosafety issues;
3. providing logistics to ensure the availability of tests, drugs, and other supplies such as needles, reagents, and consumables for diagnostic tests;
4. making recommendations on which tests and equipment to purchase;
5. quality assurance provision and supervision for district and peripheral health centers.

district level

1. technical support and training for peripheral level laboratory procedures and biosafety issues;
2. implementing logistics to ensure the availability of tests, drugs, and other supplies such as needles, reagents, and consumables for diagnostic tests;
3. quality assurance provision and supervision for peripheral health centers.

peripheral level

1. liaise with district regarding program priorities, supply needs and training;
2. performing quality control for rapid tests (if applicable) to ensure test validity.

THE ROLE OF THE LABORATORY IN THE MANAGEMENT OF SEXUALLY TRANSMITTED INFECTIONS

Diagnostic tests for STIs and HIV may be used to improve the clinical management of patients seeking care, to screen asymptomatic individuals at risk of infection, for surveillance, or to screen blood for transfusion. Prompt diagnosis and treatment of infected individuals is a cornerstone of STI control, especially in the case of the curable STIs. In the case of incurable viral STIs (e.g., herpes, HIV infection) diagnosis of infection can help to prevent transmission to sexual partners,

from mother to child, and through blood products, and can allow patients to access effective therapy.

The requirements for test performance may differ depending on the reason for doing the test. For example, in screening blood for case finding or transfusion, high sensitivity is essential, but specificity is less important as confirmatory testing can be performed on those who are positive on the screening test. In voluntary counseling and testing for STI and HIV infection, for psychosocial reasons and to avoid gender-based violence when a woman is wrongly diagnosed with a STI, it is important to avoid a false-positive diagnosis. High specificity is therefore also required.

ROLE OF THE LABORATORY IN THE MANAGEMENT OF SYMPTOMATIC PATIENTS

Three alternative approaches may be used to manage patients presenting with symptoms suggestive of an STI:

- Clinical diagnosis: The health care provider makes a specific diagnosis, e.g., syphilis or gonorrhea, based on clinical findings. Several studies have shown that this method is unreliable even in the hands of experienced physicians.[5]
- Etiological diagnosis: Specimens are sent for laboratory testing to identify the pathogen(s) present and, in some cases, to determine their antimicrobial susceptibility. This is the method of choice but is expensive, and may lead to delay in treatment, resulting in further transmission and development of complications. If those who are tested do not return for their results, they are not treated, resulting in a waste of resources, adverse clinical outcomes, and continued transmission of infection.
- Syndromic management: Patients with well-defined syndromes such as urethral discharge or genital ulcer are treated for all the likely causes of that syndrome.

Syndromic management of STIs is recommended by WHO in settings where access to laboratory services or resources is limited.[6] Flowcharts are available for the management of six syndromes: urethral discharge and scrotal swelling in men, vaginal discharge and lower abdominal pain in women, and genital ulcer and inguinal adenopathy in either sex. The advantages and disadvantages of syndromic management are shown in Table 104-2. The principal disadvantage is that it leads to overtreatment.

The laboratory has two important roles in supporting syndromic management: at the **tertiary level,** studies should be conducted periodically to determine the major causes of the common syndromes and to measure the antimicrobial susceptibility of local isolates of *Neisseria gonorrhoeae* and *Haemophilus ducreyi.* Syndromic management algorithms should be modified according to the results of these studies. At the district or **peripheral level,** simple tests (e.g., microscopy) can reduce the number of patients receiving unnecessary treatment.

Microscopy

- Gram stain for *N. gonorrheae* for patients with urethral discharge (not recommended for vaginal discharge because of poor sensitivity)
- Gram stain for bacterial vaginosis (BV) and candidiasis
- Wet preparation for *Trichomonas vaginalis*

Syphilis Serology

- nontreponemal tests such as the Rapid Plasma Reagin (RPR) or Venereal Disease Reference Laboratory (VDRL) test
- rapid, point-of-care treponemal tests

Use of simple diagnostic tests can increase specificity, and hence reduce overtreatment, as shown in the urethral discharge flowchart (Fig. 104-1 depicts flowchart).[6] Since the sensitivity of a Gram-stained smear of urethral

Table 104-2. Advantages and Disadvantages of Syndromic Management of STIs

Advantages	Disadvantages
• Problem-orientated (responds to patient's symptoms) • Highly sensitive and does not miss mixed infections • Treatment given at first visit • Provides opportunity and time for education and counseling • Avoids expensive laboratory tests • Avoids unnecessary return visit for laboratory results • Curtails referral to specialist centers • Can be implemented at PHC level	• Overdiagnosis and overtreatment with the following consequences: Increased drug costs Possible side effects of multiple drugs Changes in vaginal flora Potential for increased drug resistance Difficulties with partner notification • Requires (re)training of staff

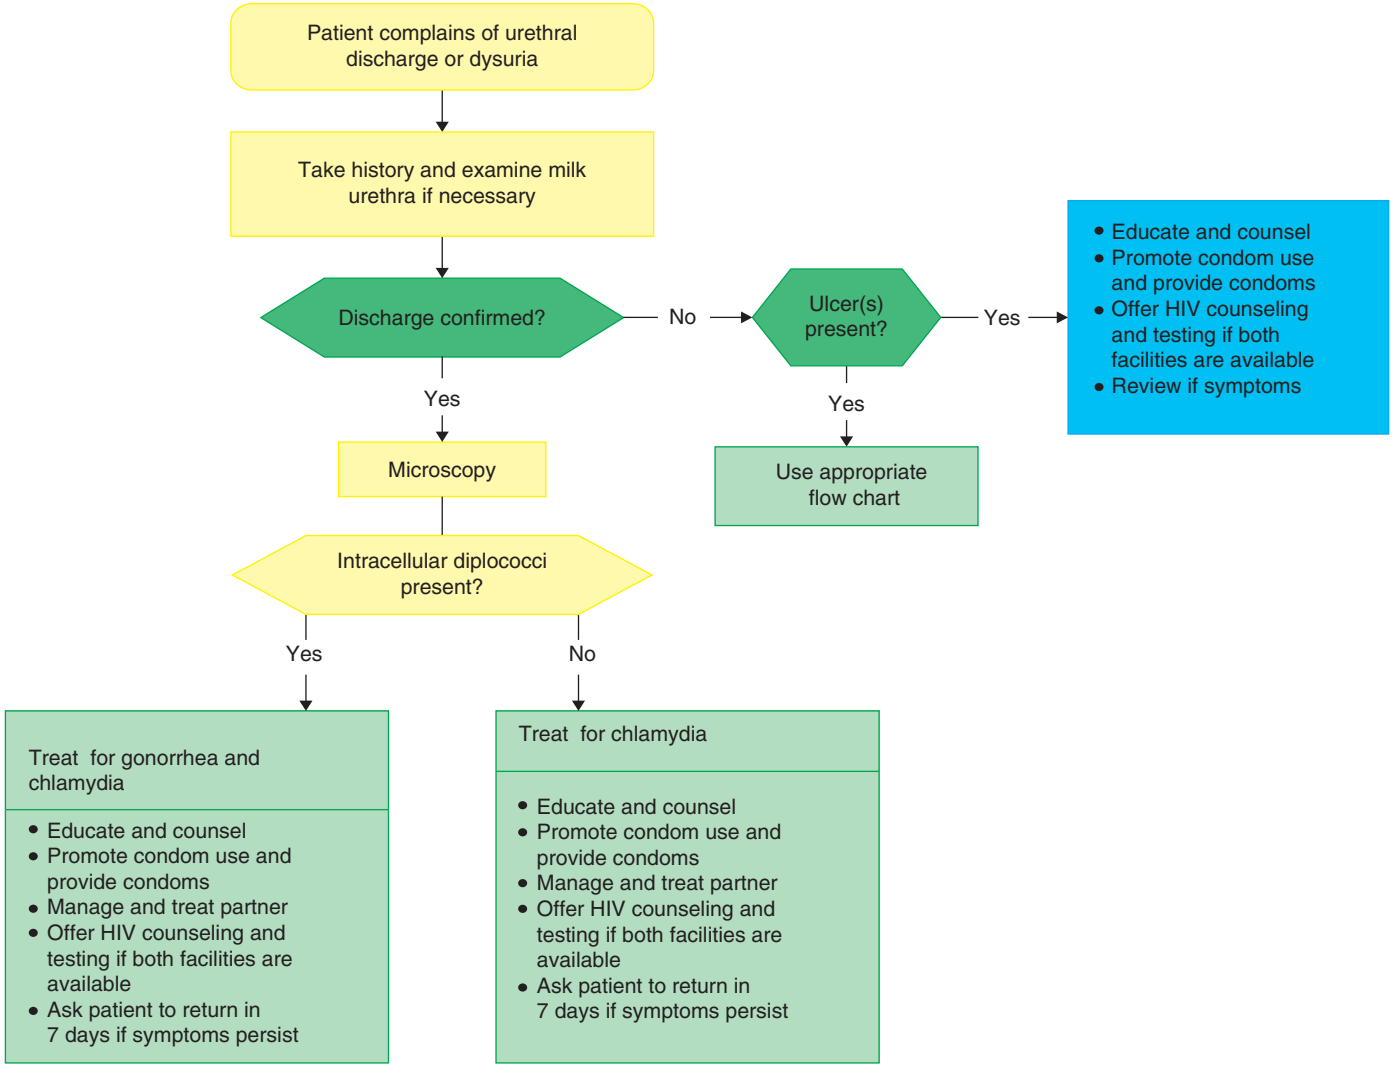

FIGURE 104-1. Flowchart for urethral discharge with microscope.

discharge for the detection of gonococcus is above 90% compared to culture, the use of a microscope in this case avoids unnecessary treatment for gonorrhea in patients who are not infected.

Evaluations of the WHO flowcharts have shown that the algorithm for vaginal discharge lacks both sensitivity and specificity for the identification of women with *Chlamydia trachomatis* and *N. gonorrheae* infection[7,8] (Fig. 104-2 depicts flowchart for vaginal discharge with microscopy).[6] The sensitivity of microscopy for the detection of gonococcus in vaginal discharge is much lower than that for urethral discharge and is therefore not recommended. Most women with this symptom do not have these cervical infections but suffer from vaginal infections (candidiasis, BV, or trichomoniasis). Vaginal infections can be diagnosed microscopically (by Gram stain or wet preparation), but this may not always be required since symptomatic candidiasis can usually be diagnosed clinically by speculum examination and presumptive treatment with metronidazole for both BV and trichomoniasis is safe and inexpensive.

Unfortunately, it is not possible to diagnose gonorrhea or *C. trachomatis* infection in women at peripheral health services in most developing countries since facilities are not available for culture, antigen detection, or nucleic acid amplification tests. Gram stain of an endocervical swab can be used to diagnose gonorrhea, but this technique is at best only about 50% sensitive in specimens from women. In many cases, no infectious cause can be found for the symptom of vaginal discharge, even using the most sensitive diagnostic tests. In these cases, the symptom may be attributable to cultural or psychological factors.[9,10] This leads to problems in both treatment and partner notification. The use of microscopy to exclude vaginal infections can avoid repeated unnecessary treatment in such cases and suggest more appropriate therapeutic interventions.

Whereas presumptive treatment for these infections may be given to women at risk, it is important in all cultures to

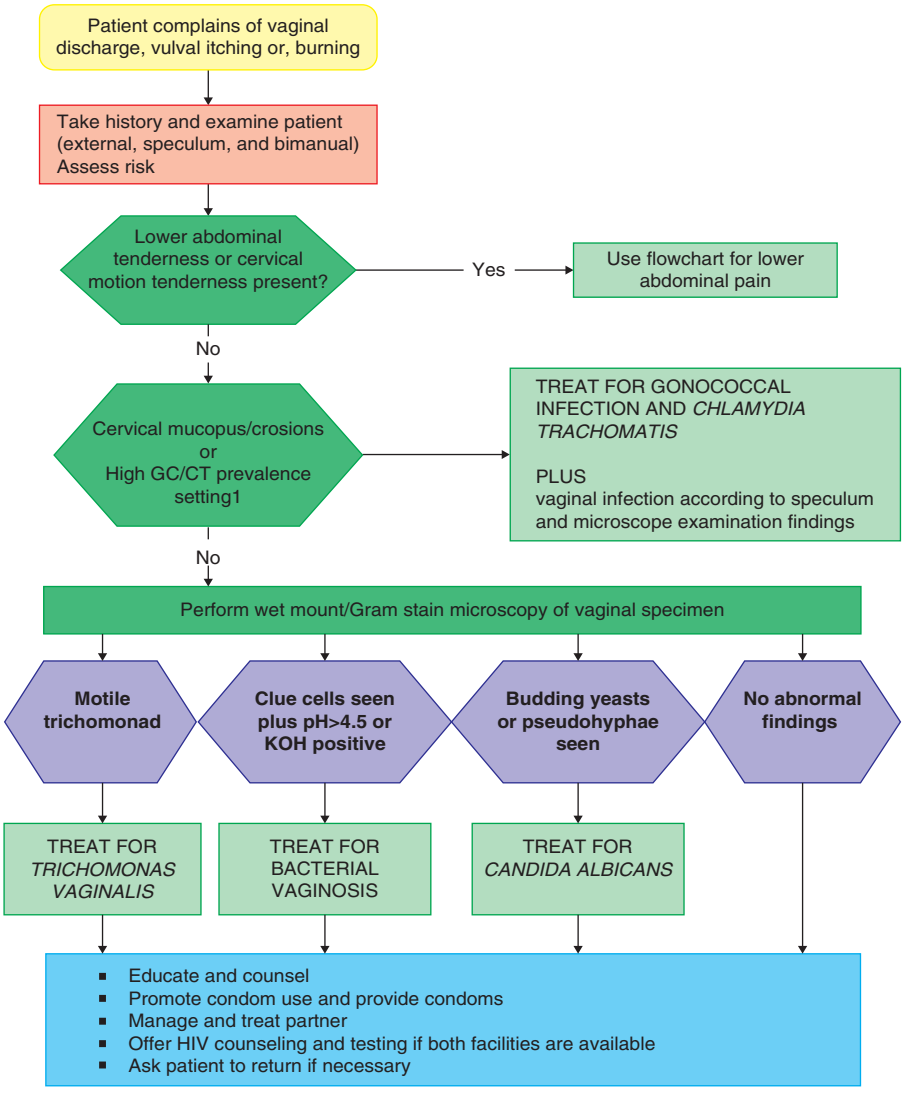

FIGURE 104-2. Flowchart for vaginal discharge with microscope.

avoid informing uninfected women that they should refer their partner for STI treatment. There is a great need for simple, cheap, point-of-care tests for these infections in women.[11,12] These tests should meet the criteria developed by the WHO STD Diagnostics Initiative (SDI) which can be defined by the acronym "ASSURED"(www.who.int/std_diagnostics). They should be Affordable, Sensitive, Specific, User friendly, Robust and Rapid (results available in less than 30 minutes), Equipment-free, and Deliverable to those who need them.

ROLE OF THE LABORATORY IN CASE FINDING AND SCREENING

Case finding

Patients presenting to health facilities with one STI are at increased risk of other STIs, which may be asymptomatic. The laboratory has an important role in identifying such infections in patients seeking STI care. In particular, all STI patients who will not be treated for syphilis through syndromic management should be screened for syphilis. This approach is known as *case finding*.

A range of STI diagnostic tests are available for use at different health-care levels. Most of these tests require a laboratory facility.[13,14] At the peripheral level, patients may be screened with the RPR or VDRL tests for syphilis and treated if positive. At the district level, a positive RPR or VDRL test may be confirmed with a treponemal test such as the *Treponema pallidum* Hemagglutination Assay (TPHA) or *T. pallidum* Particle Agglutination Assay (TPPA) before treatment is given. Culture for gonorrhea and enzyme immunoassays (EIAs) for genital chlamydial infections may be available at district or tertiary level. Rapid tests for chlamydial and gonococcal infections are commercially available but they are costly and their sensitivity is too low to be recommended for use as tools for case finding or screening.[15–17]

Screening

Screening for syphilis and HIV infection is generally offered to pregnant women attending antenatal clinics to prevent transmission of these infections to the fetus or neonate. Screening for other STIs is rarely offered, even to high-risk groups, although screening programs for female sex workers have been successfully implemented in some countries using a combination of clinical findings and simple laboratory tests.[18,19]

Syphilis in pregnancy is a major cause of adverse pregnancy outcome in many developing countries.[20–23] A recent study in Tanzania found that it was responsible for some 50% of all stillbirths.[24] In most countries the RPR is used to screen pregnant women. Women who test positive at peripheral clinics are treated without recourse to a confirmatory treponemal test. Given the importance of early treatment and the efficacy and safety of intramuscular benzathine penicillin, this is a sound strategy, even though it may lead to unnecessary treatment in some cases. Screening and treatment of pregnant women for syphilis remains cost-effective even when the prevalence is low. In Tanzania, where the prevalence of syphilis in pregnant women was found to be approximately 8%, it is among the most cost-effective health interventions available, at less than US $11 per disability-adjusted life year (DALY) saved.[25]

In almost all countries it is official health policy to offer screening for syphilis to all pregnant women. The reality is, unfortunately, rather different. It has been estimated that less than 30% of pregnant women are screened for syphilis in sub-Saharan Africa.[20,26,27] A study in Bolivia showed that although 76% of the study population received antenatal care, only 17% were screened for syphilis during pregnancy.[23] There are many reasons for the low rates of antenatal screening for syphilis, of which a major barrier is that current screening using a nontreponemal test requires a laboratory with

1. trained personnel;
2. refrigeration for storage of reagents;
3. electricity to run equipment: refrigerator, centrifuge to separate serum from whole blood and a shaker to perform the serology.

Since such facilities are generally not available in remote areas, blood or serum samples have to be transported to regional or central facilities for testing. Results are therefore often available only days or weeks after testing. Studies showed that even when this simple policy was followed, only a small proportion of infected women received treatment when RPR testing was performed off site, since many did not return for their results or specimens or results are lost in transit.[28] The delay in obtaining test results not only results in delay in treatment for the patients but also continues transmission of infection until they and their partners are treated. A series of demonstration projects showed that decentralization of syphilis screening followed by immediate treatment can be effective in reducing perinatal mortality.[29–33]

However, in rural areas, there are technical difficulties associated with performing serological tests at primary health care settings. In particular, maintaining trained personnel and assuring quality standards and supplies of tests and treatment are problematic in many settings.[34,35] Where laboratory services are not available, the new, simple, point-of-care treponemal tests provide an important opportunity to improve coverage. Recent evaluations have shown that a number of simple, point-of-care tests for syphilis in a dipstick or cassette format, have sensitivities of 85–99% and specificities of 93–100% compared to laboratory-based treponemal tests.[36–40] The advantage of these tests is that, unlike RPR or VDRL, they can be stored at room temperature in any health facility including mobile clinics, do not require any equipment, and can use whole blood obtained by finger pricks. Field trials showed that they are useful at district or peripheral level.[40] As treponemal antibodies persist for years, treponemal tests cannot be used to distinguish between recent active infection and past treated infection. But given the serious consequences of failure to detect and treat infected pregnant women and the rarity of adverse drug effects, the benefits of a rapid test that is simple to perform and enable immediate treatment clearly outweigh the risks of overtreatment. Their greatest value is likely to be in increasing the coverage of syphilis screening in rural areas of developing countries where access to laboratory services is a problem and in increasing the proportion of cases treated when return rates are low. More information on the performance and operational characteristics of these rapid tests can be found on the SDI website: www.who.int/std_diagnostics.

The role of the tertiary and district level laboratories is critical in assuring the proficiency of the health workers performing the testing and the quality of the rapid tests being stored in conditions where test quality can be compromised by long-term storage in conditions of high heat and humidity.

For large scale screening, enzyme immunoassays have been shown to be highly sensitive and specific compared to standard treponemal tests and are useful for detecting all stages of syphilis.[41] These assays are relatively simple to perform in district or tertiary facilities and have the advantage of automation and high throughput. They are therefore suitable for case-finding and screening.

INTEGRATION OF STI AND HIV LABORATORY SERVICES

STIs have been shown to play a role in increasing the risk of HIV transmission.[42–44] In developing countries, the prevalence of HIV is high in STI clinics. Hence opportunities for integration of STI and HIV screening at all levels of health care must not be missed.[45–47] This approach gives at-risk

populations a single point of access to information and services. For program managers, integrated services are more cost-effective than if the training and quality assurance of testing were provided independently. In particular, rapid syphilis screening can be integrated into rapid HIV testing for prevention of mother-to-child transmission (PMTCT) programs to avoid the tragedy of babies avoiding HIV but dying of syphilis,[47] as was observed in one clinic in Haiti. A mother sought prenatal care at the clinic, accepted HIV voluntary counseling and testing and, after testing HIV-positive, took short course antiretroviral therapy for PMTCT. Postpartum, she gave her baby antiretroviral therapy and provided artificial milk to protect against HIV transmission through breast-feeding. The baby died at 3 weeks from congenital syphilis.

THE ROLE OF THE LABORATORY IN THE DIAGNOSIS AND MANAGEMENT OF HIV INFECTION

Laboratory tests are needed for the diagnosis of HIV infection to determine the need for antiretroviral treatment, to monitor the response to treatment, and to diagnose OIs in HIV-infected patients. When testing is done outside of laboratory settings, the laboratory plays an essential role in providing quality assurance.[48–51]

DIAGNOSIS OF HIV INFECTION

The capacity for HIV serological diagnosis is required at all levels: for laboratory confirmation of suspected HIV-related illness, for screening antenatal clinic attenders to prevent mother-to-child transmission, for voluntary counseling and testing, and for screening of blood for transfusion. HIV screening should also be offered to STD patients and to all clinic and hospital attenders in high HIV prevalence settings (http://data.unaids.org/una-doc/hivtestingpolicy_en.pdf). Because of the serious consequences of an incorrect HIV result, attention to methodological detail is extremely important.

When the number of specimens is small and the staff available are not highly trained, rapid tests are the most attractive option, which makes them suitable at the peripheral level. These tests can use whole blood and are simple to use but they are relatively expensive. Regular supervision is especially important for relatively untrained staff working in health centers. Rapid tests and EIAs are appropriate at district and referral hospital levels where larger numbers of specimens are tested[48] (www.who.int/hiv/amds/diagnostics). Western blot, if used at all, should be done at reference laboratories.

When routinely offering HIV testing, in the voluntary counseling and testing (VCT) setting, in screening pregnant women to prevent vertical transmission (PMTCT programs), or where HIV infection is suspected clinically, a confirmatory test

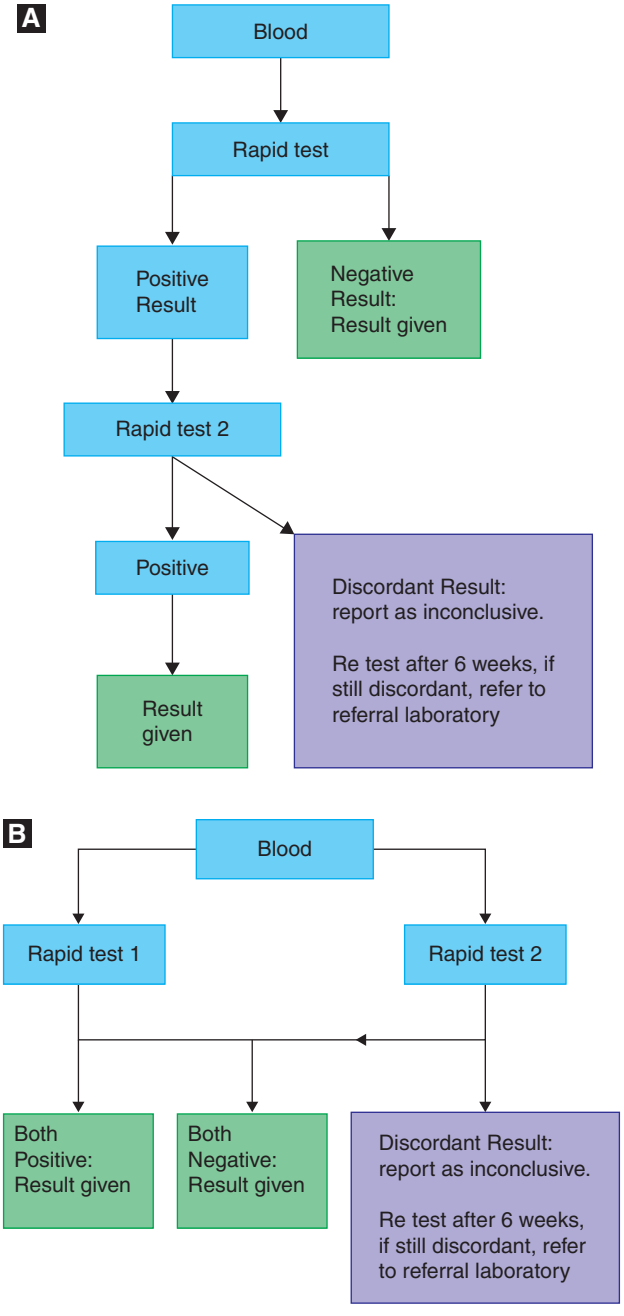

FIGURE 104-3 Schema for parallel versus serial testing for HIV. **A.** Serial testing. **B.** Parallel testing.

should be performed on all positive samples before a patient is informed of his/her result. WHO and CDC have proposed algorithms for parallel testing and sequential testing using two different tests[49–50] (Fig. 104-3). Parallel testing, in which all samples are tested with two assays, is more expensive than sequential testing. Evaluation of different algorithms for testing and confirmation have been studied for a variety of settings.[52–55]

In screening blood for transfusion, a single highly sensitive serological test may be used, if possible after excluding high-risk donors who may be in the "window period" associated with HIV seroconversion. Blood testing positive is discarded and,

unless the donor requests the result, a confirmatory test is not generally required.

THE ROLE OF THE LABORATORY IN HIV TESTING

Diagnosis of HIV infection in people aged >18 months

A positive HIV antibody test (by either a rapid test or EIA) of high sensitivity should be confirmed by a second antibody test (rapid test or EIA) using an antibody test of different operating characteristics with good sensitivity and high specificity.[49–50]

Given the potential for false-positive results in low prevalence populations, in populations with an expected prevalence below 5%, a third HIV-positive antibody test to confirm positive cases from two tests is recommended for clinical purposes.[49–51,56]

The performance of serological tests for HIV infection has been evaluated by WHO using panels of positive and negative sera from different regions of the world. Performance may vary in different populations. Ideally, before being introduced, a new test should be evaluated against a reliable gold standard in the population in which it is to be used. Further technical information on HIV testing by WHO can be found at: www.who.int/hiv/amds/diagnostics.

Diagnosis of HIV infection in children aged <18 months

HIV infection cannot be diagnosed in this age group by the detection of antibodies to HIV since maternal antibodies may be detected even in uninfected babies. Positive reactions for HIV nucleic acid (RNA or DNA) are required, or enhanced HIV p24 antigen in blood on two separate determinations, from specimen(s) taken more than 4 weeks after birth. Where the infant has had antiretroviral prophylaxis HIV RNA nucleic acid testing is not reliable until 4 weeks after cessation of the antiretroviral therapy (ART) used for prophylaxis. Ideally, two separate specimens are required.

The World Health Organization (WHO), as part of efforts to scale up ART treatment for children with HIV/AIDS, particularly in resource-limited settings, has developed simplified standardized recommendations for diagnosis and treatment of HIV that can be used by countries for adaptation and to support development of national treatment recommendations,[57] www.who.int/hiv.

ROLE OF THE LABORATORY IN DETERMINING THE NEED FOR ANTIRETROVIRAL TREATMENT

The need for ART in HIV-infected patients may be determined by clinical stage or by CD4 cell count. The WHO clinical staging system for HIV disease is given in another chapter in this book. The laboratory may play a role in diagnosing stage-defining OIs, including the following: pulmonary or nonpulmonary TB, *pneumocystis carinii* pneumonia (PCP), cryptococcosis, cryptosporidiosis, isosporiasis, disseminated mycosis, pneumococcal bacteremia, recurrent nontyphoid *Salmonella* septicaemia, and visceral leishmaniasis.

The $CD4^+$ lymphocyte count is an important determinant of the need for antiretroviral treatment in HIV-positive individuals. WHO defines advanced HIV infection according to the following laboratory criteria:

- In an adult: CD4 count less than 350/ mm^3.
- In a child: CD4% <35% in those less than 12 months, <25% in those 12–59 months, and <20% in those 5 years or over (subject to review by technical working group).

WHO laboratory criteria for the diagnosis of AIDS are

- in an adult or adolescent >15 years: CD4 count less than 200/mm^3 or CD4% <15%
- in a child: CD4% <25% in those less than 12 months of age; CD4% <20% in those 12–59 months; CD4% <15% or <200/mm^3 in those 5 years or over

Performing a CD4 count is currently technically demanding, although the promise of CD4 counts at district level hospitals may soon be a reality as there has been substantial funding for development and optimization of point-of-care tests for CD4 count.[58–70] Quality control and maintenance of equipment will be important challenges in this setting. The total lymphocyte count has been suggested as a surrogate marker for CD4 cell count, but a recent systematic review found that the correlation between the two was poor, with correlation coefficients varying between 0.23 and 0.74.[71–72]

ROLE OF THE LABORATORY IN MONITORING THE RESPONSE TO ART

ART is likely to fail if adherence to treatment is <95% or if the infecting strain is resistant to one or more of the drugs used. This is best monitored by changes in viral load, which should fall to undetectable levels in those on effective treatment.[73] However, viral load measurement is unlikely to be available outside reference centers (see Table 104-3). CD4 cell counts should rise as the immune system is reconstituted in those taking effective treatment, though this may not be the case in those with very low CD4 levels at the start of treatment. The WHO has established a network for monitoring ART resistance in those who fail treatment, HIV *ResNet*.[74]

THE ROLE OF THE LABORATORY IN THE MANAGEMENT OF OPPORTUNISTIC INFECTIONS in HIV-POSITIVE PATIENTS

In developing countries laboratory facilities are usually limited, such that the scarce resources that are available need to be used to maximum effect. A general problem at all levels with

most microbiology services, including what should be simple microscopy, is a serious lack of trained staff.[2,3] Also, microbiology does require a good supply of quality assured media and reagents, of which there are usually many to consider, and which may be costly.

In many situations, microbiology is not going to affect patient management. Firstly, any microbiological investigation other than microscopy usually takes more than a day to produce a result, by which time the patient might have recovered, died, or simply become untraceable. Secondly, a specific diagnosis might not affect clinical care if there is no treatment available or if the treatment given on clinical grounds is unaffected by the microbiological diagnosis. Microbiological investigation therefore needs to be targeted to situations where a specific diagnosis will lead to effective treatment, or where a diagnosis of an untreatable condition will prevent further fruitless investigation.

A critical factor in a health system is the need for a reference laboratory. In addition to the clinical care aspects required, in a tertiary level hospital, these facilities would form the basis of surveillance systems. Thus, it would be expected that they would intermittently be responsible for performing assessments of blood stream infections (BSIs), identifying common etiologies such as identifying causes of community acquired pneumonia, of diarrhea, and of fevers. This information would be used to provide advice and to modify and support syndromic approaches at more peripheral levels.

There are two main approaches to the management of OIs in HIV-infected individuals in developing countries. These are based on either etiological diagnosis of specific conditions or on investigations of particular syndromes. These two approaches are described in more detail below.

THE ROLE OF THE LABORATORY IN CLINICAL MANAGEMENT OF CASES

The major OIs that need to be identified are tuberculosis, causes of chronic diarrhea, bacteremia caused by *Salmonella* spp. or *Streptococcus pneumoniae,* and cryptococcal disease. In some regions (e.g., Sudan, Kenya and part of the Middle East, and the Indian subcontinent), visceral leishmaniasis should be considered. In Southeast Asia, disseminated penicilliosis is common in advanced HIV infection. In South America, case reports suggest that disseminated

Trypanosoma cruzi infection occurs in advanced HIV infection.

At the peripheral level, microscopy of direct Ziehl-Neelsen (ZN) stained sputum smears might be feasible, though this may not be possible in all health centers. The ZN smear remains the quickest way to detect acid-fast bacilli (AFB); it may be possible to produce a result while the patient waits. The sensitivity of direct sputum microscopy for AFB is known to be low and variable.[75]

At district level, microscopy for sputum and CSF should be available, with the ability to perform Gram, ZN, and Indian ink stains. If a centrifuge is available, the sensitivity of the microscopy techniques can be improved by concentration. Stool microscopy should be feasible and can identify treatable causes of chronic diarrhea such as *Giardia* or *Strongyloides,* which are not considered OIs, and *Cryptosporidium* and *Isospora,* which are. Diagnosis of *Cryptosporidium* or *Isospora* infection defines stage 4 disease, which may have implications for eligibility for ART. Concentrated preparations of stool and staining for *Cryptosporidium* spp. improves the clinical value of stool microscopy but involves the use of formaldehyde and ether. *Cryptococcus neoformans* can be quite easily demonstrated in cerebral spinal fluid (CSF) by direct microscopy with India ink. Cryptococcal antigen testing of CSF or serum may also be valuable at this level.

If culture facilities are available, this should focus on

- blood cultures, to differentiate sepsis due to *Salmonella* spp. and *S. pneumoniae.* This is often impossible clinically, and in regions of high HIV prevalence blind treatment may be unsuccessful or lead to a rapid rise in antimicrobial resistance.
- cultures of pleural effusions, joint fluids, and pericardial fluids. In these cases, other diagnostic tests are often not able to differentiate between TB and bacterial infection.

At the "reference" or tertiary level, it should be possible to culture bacteria (including *Mycobacterium tuberculosis*) and to perform antimicrobial sensitivity testing on a range of clinical specimens—sputum, CSF, blood, pleural fluids, and genital discharge. Mycobacterial susceptibility testing is likely to be highly centralized in a national center.

APPROACHES TO SYNDROMIC MANAGEMENT AND TREATMENT REGIMENS

Investigation of HIV infected patients needs to focus on the major clinical syndromes:

- fever and cough
- fever and headache
- fever with no focus
- diarrhea

It is particularly in these cases that a specific diagnosis will aid clinical management. The three major causes of fever with cough are bacterial (usually pneumococcal) pneumonia, pneumocystis pneumonia, and tuberculosis. Since treatment is different for each, it is important to make an etiological diagnosis. In patients with fever and headache, it is important to exclude meningitis, especially cryptococcal meningitis in immunocompromised patients. In all cases of fever in endemic areas, it is necessary to exclude malaria, which may be more severe in advanced HIV disease.

In patients with fever without an obvious focus, once malaria has been excluded, blood cultures should be taken to identify bacteremia. Ten to twenty percent of febrile admissions are likely to have a BSI. If it is not possible to do blood cultures on all patients, it is nevertheless important to conduct intermittent surveillance of BSI, which can be used to develop clinical algorithms. TB is also high on the list of differential diagnoses. In endemic areas, Giemsa's stain of a buffy coat smear may be used to diagnose visceral leishmaniasis.

The reference laboratory also has important roles to play in response to specific surveillance requests, e.g., identifying causes of community acquired pneumonia, or causes of diarrhea, and in supporting quality assurance for tests performed in health centers and district hospitals. The cause of chronic diarrhea can usually be identified by stool microscopy, especially if concentration techniques are used and a modified ZN stain is used to identify *Cryptosporidium*.

The availability of diagnostic tests to investigate these syndromes is shown in the Table 104-4.

FUTURE OUTLOOK

To increase access to diagnosis and screening for STIs including HIV, ASSURED tests that can be performed outside of laboratory settings have been developed. At present, a number of tests for syphilis and HIV fulfill these criteria and they are available to UN member states from the WHO Bulk Procurement Scheme at negotiated pricing. Improved tests for the diagnosis for genital chlamydial and gonococcal infections will soon be available for evaluation. Investments in development of such tests for monitoring the efficacy of ARTs will soon result in a variety of CD4 tests that can be used at district levels. An important role of the laboratory is in the support of quality control of rapid tests that are being stored and deployed at peripheral sites, often at temperatures above the 30 ∞C limit specified by the manufacturers. Supervisors of laboratories at district levels need to ensure the proficiency of health care workers in performing these tests at peripheral levels.[76,77]

The HIV epidemic has imposed an enormous strain on the already fragile health care infrastructure in many developing countries. The contribution of donor agencies to HIV care and treatment has not been accompanied by sufficient capacity building in countries. This is especially true of laboratory capacity strengthening, as it takes time to build up a workforce with advanced skills to provide timely quality-assured laboratory services. In countries already suffering from severe constraints in their health systems, this scarcity of trained staff is compounded by large numbers of vertical programs and the conflicting agenda of various donor agencies and migration of trained workers for better salaries and benefits.

In many countries there are separate programs for HIV and STI control and prevention even though it has been shown that the two are interrelated in that HIV-infected individuals have a high viral load when they acquire an STI. Testing and treatment are provided at different venues by duplicate sets of staff, adding to the problems of strained human and other resources. The integration of laboratory services for STI, HIV, TB, and OIs at all levels would be an important step forward.

However, in many countries a limited primary health care system has meant poor access to health services for many. In a country already suffering from severe constraints in its health system, the poor integration of programs focused on single diseases within the broader health system further hinders health care delivery at local levels.

An estimated 720,000 infants are born HIV-positive every year. In sub-Saharan Africa, only 30% of pregnant women are screened for syphilis even though the disease is responsible for more than 30% of perinatal deaths. An estimated 492,000 cases of congenital syphilis occur annually in Africa.[20] Observations in many affected countries indicate that the epidemiology and transmission of HIV and syphilis are closely linked and that screening for both infections would lead to better health outcomes. Yet in many parts of the developing world, PMTCT programs do not routinely include syphilis screening. This is a tragedy as congenital syphilis is preventable if infected mothers are identified and treated by the middle of the second trimester of their pregnancy. The tragedy is even more regrettable given that economical,

Table 104-4. The Role of the Laboratory in the Management of Opportunistic Infections in HIV Positive Patients

Syndrome	Pathogen	Peripheral	District	Tertiary

	Bacteremia	–	Microscopy and culture of CSF	Microscopy and culture of CSF
				Microscopy and culture of CSF

simple rapid diagnostic tests and effective treatment for syphilis are available. The story of effective interventions not reaching those in need, heard many times in the developing world, repeats itself.

Increasingly governments are encouraged, in collaboration with nongovernmental organizations, to provide comprehensive care in the scale-up of HIV treatment programs to include tuberculosis and reproductive health and sexually transmitted diseases services in order to avoid the tragedy of babies being saved from HIV but dying of syphilis.

Clearly, future efforts must be focused on using rapid tests to increase access to diagnosis of STI, HIV, and OIs and on effective laboratory systems to provide accurate surveillance information and to monitor the impact of interventions. For each country, such efforts must be informed by more research to determine the feasibility and sustainability of using appropriate tools at different levels of the health care system.

105 Sexual Assault and STD

Carole Jenny and Amy P. Goldberg

The FBI reports that while all other violent crime is decreasing in the United States, the number of forcible rapes is increasing.[1] The prevalence of sexual assault depends on how it is defined. In the United States, the Federal Bureau of Investigation Uniform Crime Reporting Program defines rape as "carnal knowledge" (vaginal coitus) of a female forcibly and against her will. Anal or oral assault and sexual assault of males are not included in the FBI statistics. In 2004, the FBI reported 94, 635 arrests for rape (32.3/100,000 population).[1] The National Institute of Justice's National Violence Against Women Survey used a different definition. Rape was defined as forced vaginal, oral, or anal sex experienced by men or women. This survey, done between November 1995 and May 1996, found that in the United States, 18% of women and 3% of men had experienced rape in their lifetime. In the prior 12 months, 0.3% (203,100) of women and 0.1% (92,700) of men experienced a completed or attempted rape.[2]

Homosexual men may be at increased risk for sexual assault. In one large study, 257 of 930 (27%) gay men reported a history of nonconsensual sex, although only 80 (8.6%) reported assault at age 21 or older.[3]

Sexually transmitted diseases (STDs) are among the most common medical problems complicating sexual assault. STDs diagnosed at the time of a sexual assault can add to the emotional problems experienced by victims, whether or not the disease was acquired as a result of the assault. In addition, victims often express severe anxiety about the possibility of contracting an STD from the assailant. This anxiety can accentuate the emotional trauma they experience, aggravate any posttraumatic stress, and delay their recovery. The possibility of HIV transmission during the sexual assault has further added to the panic and stress related to sexual victimization.[4]

CHARACTERISTICS OF VICTIMS

Factors that increase the risk of rape include major psychiatric diagnoses, homelessness, alcohol or drugs use, and physical disability.[5,6] In adolescents, a history of either initiating intercourse or having an STD at an early age is correlated with experiencing a subsequent rape.[7] One study of women reporting a history of rape showed them to be much more likely to have multiple sexual partners than women not reporting rape.[8]

Many victims of sexual assault neither obtain medical care nor report the event to police agencies. The proportion of "nonreporters" is estimated as 25–46%.[9,10] Victims who are assaulted by strangers are more likely to report than those assaulted by an intimate partner or other person known to them.[9] Men may be more reluctant to report sexual assault than women.[11]

Victims' ages range from adolescence to old age but most victims are younger. In one large emergency department study, one-fourth of victims seeking medical care were younger than 18 years, with a median age of 23 years.[12] In females, the greatest percentage of rapes occurs between ages 11 and 17.[13]

Female victims of domestic violence are at increased risk for sexual assault. McFarlane, et al. studied 148 women seeking protection orders from courts because of domestic violence. Sixty-eight percent of the women also reported being sexually assaulted by their domestic partner.[14]

One of the factors complicating the care of rape victims is the poor rate of compliance with follow-up care.[15] In one study where follow-up care was aggressively promoted, only 31% of victims returned for further care.[16] This increases the importance of prophylactic treatment at the initial visit because a follow-up visit for diagnosis of STD acquired at the time of the rape is not likely to occur.

One of the major risk factors for being sexually assaulted in adulthood is experiencing sexual abuse as a child or young teen.[17] Sexual abuse in childhood puts men and women at risk for depression, low self-esteem, early initiation of sexual behavior, drug and alcohol abuse, and other social ills.[18] These risk factors lead to a decrease in self-protective behaviors (such as condom use) and an increase in risky behaviors such as having multiple sexual partners and trading sex for drugs.[19] After sexual assault in adulthood, victims of childhood

sexual abuse are at increased risk for revictimization as well as STD and high-risk sexual behavior.[7,20,21] The end result is a spiral of risk originating in childhood trauma, leading to a high-risk lifestyle leading to further sexual assault and higher STD risk. This points out the importance of preventing childhood victimization in controlling HIV infection and STDs.[22,23]

CHARACTERISTICS OF ASSAILANTS

Assailants are more likely to be someone known to the victim. In one study, 78% of victims reported assault by a friend, relative, or acquaintance.[24]

Most rapes involve only one assailant. In about 20% of cases, multiple assailants are involved. Rapes of males are more likely to involve multiple assailants than female rapes.[12]

In 1997, the U.S. Bureau of Justice Statistics produced a comprehensive report on convicted sex offenders.[25] On any one day, 234,000 sex offenders are under the care, custody, or control of corrections officers in the United States. About 60% are under supervision in their communities and 40% are incarcerated. Sex offenders account for about 5% of the prison population. Ninety nine percent of convicted rapists are male and 16% are juveniles. When considering all types of sexual offenders (including people committing rape, child molestation, and all other types of sex offenses), 3.8% are female. Among males serving prison time for rape, 64% have a record of a previous conviction for sexual assault. Sex offenders are less likely to be married at the time of their incarceration than other violent offenders. Rapists have other lifestyle risk factors that may increase the likelihood of infection with an STD, including drug use, multiple sexual partners, and history of incarceration.[26]

CHARACTERISTICS OF SEXUAL ASSAULTS

Vaginal assault is the most common type reported by female victims (83%). 25% of females and 43% of males report oral assault. 15% of females and 67% of males report anal assault. One-third of victims report digital penetration, and 3% report assault with an object.[12] Using visual inspection, genital trauma is seen in 53% of female victims. Genital or anal trauma is seen in 36% of male victims.[12] Use of the colposcope to provide magnification increases the percentage of victims noted to have trauma. With colposcopy, 68–87% of vaginally assaulted females show genital trauma and 56% of anally assaulted females show anal trauma.[27,28] Compared to females, a higher proportion of male assault victims will show nongenital trauma.[15]

Rapes of men and women incarcerated in prisons are unfortunately common.[29] Since prison inmates have an increased incidence of STD and HIV infection, victims of prison rape most likely are at higher risk of infection.[30] Prison rapes are rarely reported and until recently, many states have not collected data on the prevalence of rape in their prisons. In 2003, a law was passed in the United States requiring the Bureau of Justice Statistics to collect statistical data on prison rapes. The law also requires yearly public hearings about prisons with the highest and lowest rates of sexual assaults.[31]

The number of victims being given prophylactic antimicrobials varies depending on where they are treated. Some emergency departments report treating as many as 88% of victims.[12] Overall, data from the National Hospital Ambulatory Care Survey from 1992 to 1998 showed that only 49% of U.S. adult sexual assault victims received at least one medication for STD.[32]

CHARACTERISTICS OF THE VICTIM, THE ASSAILANT, AND THE ASSAULT AFFECT THE DIAGNOSIS AND TREATMENT OF STD

Many factors complicate the diagnosis and treatment of STD after sexual assault, including the following:

1. Victims often do not know the STD/HIV status of the assailant, making the calculation of risk of STD/HIV difficult in any particular case.
2. High-risk behaviors leading to sexual assault can also put the victims at risk for STD.
3. Genital and anal injuries (including microtrauma) can increase the victims' likelihood of STD/HIV infection.
4. Many victims are reluctant to come forward for treatment because of shame or fear of reprisals.
5. Medical follow-up is difficult because of the victims' reluctance to return for care.
6. Sex offenders often have been previously incarcerated, increasing their risk for STD/HIV. One study showed a high rate of hepatitis B and C infections in incarcerated sex offenders.[33]
7. An STD identified at the initial visit after sexual assault could be preexisting rather that a result of the assault.[34,35] However, with some organisms, such as herpes simplex virus, hepatitis B virus, or HIV, highly specific serologic tests exist to detect seroconversion in the victim which may indicate whether or not infection was recently acquired.
8. Multiple assailants may increase the risk of STD following rape.
9. The presence of a coexisting STD such as syphilis can increase the risk of HIV.
10. Whether or not the assailant ejaculates can affect the occurrence of STD following rape. However, victims' history of whether or not ejaculation occurred can be

inaccurate. In one study, sperm were found in the vaginal cavity of 44% of rape victims reporting that the assailant did not ejaculate.[36]

11. Studies of sex offenders and reports by victims indicate that during the process of offending, rapists often experience sexual dysfunction, erectile insufficiency, and failure to ejaculate. This could decrease the likelihood of transmitting an STD to the victim.[37,38]

RISK OF ACQUIRING STD FROM SEXUAL ASSAULT

Most sexual assault victims are seen after a single episode of sexual contact. Little is known about the infectivity of most STDs after a single episode of intercourse, although the relative infectivity of some organisms has been determined. Among regular partners of male patients with gonorrhea and *Chlamydia trachomatis* infection, studies employing culture diagnosis found rates of 80% and 45%, respectively.[39] The risk of transmission of *Neisseria gonorrhoeae* from an infected female prostitute in a single sexual exposure has been estimated to be 22–25%.[40] Although equivalent data from a single male to female exposure are not available, the risk would be expected to be at least that high.[40,41] Up to 20–27% of monogamous partners of patients with hepatitis B infection are found to be infected.[42,43] The risk of infection after a single exposure is probably less but is likely to vary with factors such as bleeding during the exposure and presence of hepatitis B antigen in the infected partner. Similarly, 30% of sexual partners of patients with syphilis are found to be infected, but again, the risk of infection after a single exposure, doubtless, varies by stage of syphilis and aspects of the encounter.[44] Risk of transmission of HIV after a single sexual encounter is discussed below (see "HIV and Postexposure Prophylaxis").

STUDIES OF SPECIFIC DISEASES AFTER SEXUAL ASSAULT

Studies on STD after rape are difficult to interpret. Many factors differ in these studies including age of the subjects, length of time between the assault and the testing for STD, setting of the testing (STD clinic versus emergency department versus other clinic), sex of the victims included in the study, and types of tests used to diagnose STD. Most studies were done retrospectively; i.e., charts of rape victims were reviewed after discharge. Most studies involved many different practitioners obtaining and processing the specimens. And finally, studies have been reported from many different cities and countries, where the underlying rates of STD in the population differ. For these reasons, it is difficult to determine the true incidence of STD resulting from rape. Table 105-1 gives the rates of STD diagnosed after rape in adult victims in studies published since 1990.

STDs AS EVIDENCE IN SEXUAL ASSAULT CASES

STDs are often factors in sexual assault cases tried in courts of law in the United States. They have been recognized by criminal courts as proof that sexual contact has occurred, especially where the victim is a child or young adolescent.[45,46] STD as evidence of sexual assault has been upheld when both the defendant and the victim were infected with the same disease.[47–50]

When an STD is found in the victim and is thought to be the result of sexual contact with the accused, positive cultures or blood tests for antibodies from the defendant can be helpful as corroborative evidence. The collection of those specimens, however, must be done without violating the defendant's rights. Under the modern Federal rules of evidence for criminal proceedings, cultures, blood tests, and physical examinations for STD can be done on the defendant after court hearings are held before a judge to determine "probable cause" that evidence will be recovered. The defendant's fourth amendment rights to protection from unreasonable search and seizure must be respected.[51]

The interpretation of STD evidence requires a thorough knowledge of the epidemiology, natural course of infection, infectivity, and response to treatment of the STD in question. For example, if a victim is found to be infected with an STD at the time of a sexual assault, the accused may not become infected after a single act of intercourse. Negative cultures obtained from the defendant will not necessarily prove he did not commit the crime.

If positive diagnostic studies are obtained from both the victim and the assailant, matching the organisms for various biologic properties could theoretically be useful in linking the assailant to the crime. Matching of victim and assailant strains by serologic typing has been reported.[45] In epidemiologic studies, tests are used to establish the relatedness of strains of *C. trachomatis* and *N. gonorrhoeae* among sexual partners.[52,53] An HIV strain suspected of being transmitted from a dentist to his patients was identified forensically using molecular techniques.[54,55] Such matching can be used if the characteristics studied are stable from generation to generation in in vivo and in vitro systems. In one sexual assault case, HIV gene sequencing using the pol and gag genes (instead of the env gene used in the dental case) was described. This sequence may be even more stable.[56]

Potentially, these techniques could provide very specific matching of organisms to trace the path of transmittal

Table 105-1. Surveys of Sexually Assaulted Women and Men, Published 1990–2005

Numbers under disease categories represent number of patients positive for the disease and numbers within parentheses indicate their percentages.

*NG = *Neisseria gonorrhoeae*; CT = *Chlamydia trachomatis;* TV = *Trichomonas vaginalis*; BV = Bacterial vaginosis; CA = Condyloma accuminata or human papilloma virus infection; TP = *Treponema pallidum*; HSV = Herpes simplex virus; HIV = Human immunodeficiency virus; F/U = Follow-up.

**Infections by patient report. Subjects were assaulted by a domestic partner.

between assailant–victim pairs. Microbial forensic techniques have become standard in other arenas such as bioterrorism research.[57]

TESTING FOR STD AFTER SEXUAL ASSAULT

The CDC's "*Sexually Transmitted Diseases Treatment Guidelines 2002*" recognize that testing for STD and offering prophylactic antimicrobials should be individualized, depending on the circumstances of the victim and the assault.[58] Rape victims may be at risk for preexisting STD, and STD resulting from rape can be psychologically devastating. With this in mind, victims' health will most likely be best served by a careful workup for STD detection. The CDC's recommendations for STD testing after rape are found in Table 105-2. In addition to diagnostic testing, patients should be educated on signs and symptoms of STD and urged to abstain from sexual intercourse until STD prophylaxis has been completed.

Care of the sexual assault victim includes careful medical evaluation, counseling, forensic testing, appropriate reporting, and follow-up for physical or mental complications.

Table 105-2. Recommended Diagnostic Testing for STD After Sexual Assault[58]

Initial examination (preferably within 72 h of assault)

1. Cultures for *N. gonorrhoeae* and *C. Trachomatis* from any sites for penetration or attempted penetration.
2. FDA approved nucleic acid amplification tests can be substituted for cultures. Positive results should be confirmed by a second nucleic acid amplification test that targets a different sequence from the initial test.
3. Wet mount and culture of vaginal swab for *T. vaginalis* infection. If symptomatic, wet mount should also be examined for bacterial vaginosis and candidiasis.
4. Collection of serum for evaluating for HIV, hepatitis B, and syphilis.

Follow-up examination 1–2 wks postassault in patients ***not*** receiving antimicrobial prophylaxis at initial examination

1. Cultures for *N. gonorrhoeae* and *C. Trachomatis* from any sites for penetration or attempted penetration.
2. FDA approved nucleic acid amplification tests can be substituted for cultures. Positive results should be confirmed by a second nucleic acid amplification test that targets a different sequence from the initial test.
3. Wet mount and culture of vaginal swab for *T. vaginalis* infection. If symptomatic, wet mount should also be examined for bacterial vaginosis and candidiasis.

Follow-up examination 1–2 wks postassault in patients who ***received*** antimicrobial prophylaxis at initial examination

1. No follow-up testing is required at 2 wks if patient is asymptomatic.
2. Tailor follow-up workup on symptoms displayed and on antimicrobials received and taken.

Follow-up examination at 6, 12, and 24 wks postassault

1. Repeat serologic testing for HIV and syphilis if initial tests were negative.
2. Repeat testing for HBV if patient is not immunized.

Several publications address recommendations for overall care of victims of sexual assault.[59–63]

ANTIMICROBIAL PROPHYLAXIS AFTER SEXUAL ASSAULT

Rape victims often forego follow-up medical care after an initial evaluation. This increases the urgency of prophylactic treatment of potential STD. If the clinician opts to offer prophylaxis after assault, it is important to explain to the patient the side effects of the drugs and the lack of knowledge about the necessity of prophylaxis after rape. (The special issue of HIV prophylaxis is discussed below.) Table 105-3 lists the CDC's recommendations for STD prophylaxis after sexual assault.[58]

Table 105-3. Recommended Regimen for Antimicrobial Prophylaxis After Sexual Assault[58]

1. Postexposure hepatitis B vaccination (without HBIG [hepatitis B immune globulin]) if the patient is previously unvaccinated. Repeat HBV vaccination should be repeated at 1–2 mo and 4–6 mo after the initial dose.
2. If perpetrator is known to be infected with Hepatitis B, consider administering HBIG.
3. For CT, GC, trichomonas, and BV prophylaxis:
   a. Ceftriaxone 125 mg IM in a single dose; *PLUS,*
   b. Metronidazole 2 g orally in a single does; *PLUS*,
   c. Either azithromycin 1 g orally in a single dose or doxycycline 100 mg twice a day for 7 d.

HIV AND POSTEXPOSURE PROPHYLAXIS

Victims of sexual assault are at risk for acquiring HIV.[64] In January 2005, the CDC issued guidelines recommending the use of postexposure prophylaxis (PEP) for HIV in uninfected patients who sustain high-risk sexual exposures to individuals *known* to be HIV infected and who present for evaluation within 72 hours of exposure.[65] While comprehensive, the guidelines assume knowledge of the source's HIV status. This is rarely the circumstance in sexual assault. Using the recent CDC guidelines as a framework and as an endorsement of nonoccupational PEP, clinicians caring for sexual assault victims must conduct HIV risk assessments and make treatment decisions based on the individual needs of each patient.

One of the justifications for using HIV PEP after sexual assault even if the HIV status of the assailant is unknown is this: The acquisition of a life-threatening and life-changing infection after a forced sexual encounter compounds the trauma inherent in sexual assault and leads to an ongoing violation of the victim's personal integrity and safety.

Chapter 72 discusses the scientific basis for HIV PEP. The risk of HIV transmission resulting from some types of sexual exposure is similar to the risk after needle-stick exposure. Because of the effectiveness of PEP after needle-sticks,[66] several authors have suggested protocols for HIV PEP following sexual assault.[67–70] While previous concerns existed that providing PEP after sexual exposures may increase high-risk sexual behaviors, recent data have not supported this concept.[71] There is no evidence that using HIV PEP after sexual assault would encourage high-risk behaviors.

RISK ASSESSMENT

The assailant's seropositivity (including viral load and clinical status) greatly influences the risk of HIV transmission to the victim.[72] Studies estimate that as many as half of rape victims know their assailants,[73] while less than 2% know the assailant's HIV status.[74] Given these facts, the clinician should ask the victim about what, if anything, is known about the assailant's health and habits and develop a risk profile (history of intravenous drug use, male assailant having sex with men, and a history of current or previous incarceration), if possible. When this information is not available, the seroprevalence of the relevant community where the assault occurred should be considered. For example, the incidence of HIV is 14 times higher in prisoners compared to the general U.S. population.[75] If the assault occurred in an area of high HIV seroprevalence such as a prison, use of PEP may be appropriate.

In addition to quantifying the risk of HIV transmission based on the assailant's seropositivity or risk profile, the clinician can evaluate the level of risk based on the type of sexual exposure. Estimates of risk vary depending on the type of sexual contact that occurred (Table 105-4). In most cases, patients are able to report this information.

Certain factors may increase the risk of HIV transmission during sexual assault compared with consensual sexual activity. Abrasions, mucosal damage, and other physical trauma are more likely to result with forced penetration and may increase the risk of HIV transmission.[15,76] In addition, sexual assault victims and perpetrators may be more likely to be infected with other STDS compared to the general population.[34] These underlying infections increase the victim's susceptibility to HIV.[77] Having multiple assailants may also increase the risk of transmission and should be considered a significant risk factor. Table 105-5 lists suggested categories of risk for HIV to be considered when evaluating sexually assaulted patients for PEP. This risk assessment tool has not been tested clinically.

TREATMENT RECOMMENDATIONS

Sensitive discussion with victims regarding HIV exposure and prophylaxis may alleviate emotional stress for victims. Discussion of avoidance of high-risk sexual behaviors is not appropriate for the initial visit postsexual assault. Follow-up visits, however, can be used to discuss a variety of risk reduction behaviors, including ways to avoid revictimization and assure safety. Many sexual assault victims will have many psychological and social factors in their lives that put them at risk for *both* STD and sexual assault, including prior victimization, poverty, domestic violence, and unsafe living conditions.[7,78,79]

If HIV PEP is prescribed, patients should be educated about risks, benefits, and side effects of therapy. Inform patients about the lack of conclusive data on HIV PEP efficacy. The importance of compliance and follow-up should be stressed. Initial laboratory testing should include HIV testing, a complete blood count, blood urea nitrogen and creatinine, and liver function studies. Careful telephone follow-up frequently throughout the course of treatment may increase patient compliance and successful completion of the course of therapy.[80]

Data on the optimal choice and number of antiretrovirals to prescribe after sexual assault are largely empiric. PEP is recommended only for patients who present within 72 hours of the assault. PEP should be started as soon as possible after exposure and continued for 28 days.[65] All female patients must have a pregnancy test prior to starting therapy, as some regimens are contraindicated in pregnancy.

Table 105.4. Estimated Per-Act Transmission Risk of HIV from Unprotected Exposure to an HIV Infected Person, by Exposure Route

Exposure Route	Risk per 10,000 Exposures to an Infected Source	Reference
Receptive anal intercourse	50	72, 105
Receptive penile-vaginal intercourse	10	72, 105, 106
Insertive anal intercourse	6.5	72, 105
Insertive penile-vaginal intercourse	5	72, 105
Receptive oral intercourse	1	72
Insertive oral intercourse	0.5	72
Percutaneous needle-stick	30	107

Estimate of risk for transmission from sexual exposure assumes no condom use.

From Smith DK, Grohskopf LA, Black RJ, et al. Antiretroviral postexposure prophylaxis after sexual, injection-drug use, or other nonoccupational exposure to HIV in the United States: recommendations from the U.S. Department of Health and Human Services. *MMWR Recomm Rep* 2005; 54(RR-2): 1–20.[65]

Table 105-5. Suggested Categories of Risk to be Considered in Cases of Sexual Assault When Evaluating Patients for HIV Postexposure Prophylaxis

Patients at *high HIV risk* after sexual assault:

- Patients were penetrated vaginally, anally, or orally by a known HIV-positive assailant.
- Assailant's seropositivity is unknown but other factors exist that may modify the risk from the exposure such as
  - anogenital trauma is present;
  - multiple assailants are involved;
  - assailant is known to be from a high-risk population; or,
  - victim has coexisting anogenital infections.

Patients at *moderate risk* after sexual assault:

- Patients were penetrated anally, vaginally, or orally, and the assailant ejaculated, and the seropositivity of the assailant is unknown, but there are no factors that modify or potentially increase the risk of exposure.

Patients at *low risk* after sexual assault:

- Assault involved no anal, vaginal, or oral penetration.
- Assault involved oral penetration without ejaculation.
- Assailant is known to be HIV negative.

The current CDC guidelines endorse a 3-drug regimen for nonoccupational exposures to *known* HIV-infected sources.[65] Favored regimens include a non-nucleoside reverse transcriptase-based regimen such as efavirenz *plus* (lamivudine or emtricitabine) *plus* (zidovudine or tenofovir); or, a protease inhibitor-based regimen such as coformulated lopinavir/ritonavir *plus* (lamivudine or emtricitabine) *plus* zidovudine. While there is no evidence that a 3-drug regimen is more effective than a 2-drug regimen, for patients at *high risk* for exposure (Table 105-5), a 3-drug regimen is recommended.

If the patient is determined to be at *moderate risk* for exposure, the CDC has not offered official recommendations. Other experts have recommended 2-drug regimens because of the decrease in side effects, toxicity, and cost. [67–69,74] These regimens include coformulated zidovudine and lamivudine, zidovudine and emtricitabine, tenofovir and lamivudine, or tenofovir and emtricitabine. Before any regimen is adopted, consultation should be sought from experts in HIV treatment and prevention. For the latest information on doses and side effects of antiretroviral drugs, refer to the U.S. Department of Health and Human Services website, *AIDSinfo* at: http://www.aidsinfo.nih.gov/DrugsNew/Default.aspx?MenuItem=Drugs

Patients at *low risk* for HIV exposure should not be routinely offered PEP. If they are suffering extreme psychological stress related to possible HIV exposure because of sexual assault, they should be counseled, reassured, and referred for follow-up. In the rare case where the patient is unable to accept the provider's recommendation *not* to use HIV PEP, the clinician can reassess prescribing PEP depending on the individual patient's needs.

For patients on PEP, follow-up should include monitoring liver and renal function as well as complete blood count. Whether or not PEP is prescribed, serologic testing for HIV should be repeated at 4–6 weeks, 3 months, and 6 months. Because adherence to PEP medication regimens is especially poor among sexual assault survivors,[81] patients should be warned of the possible risk of developing drug resistant HIV strains with poor compliance. Ideally all patients on PEP should be seen within 72 hours to answer questions and to address side effect from medications should they arise.[80]

OTHER ASPECTS OF TREATMENT OF RAPE VICTIMS

Rape victims are at risk for impaired physical and mental health. In addition to STD, the sequelae of rape include[82]

- physical injuries resulting from assault
- assault-related stress on the immune, endocrinologic, or autonomic systems
- assault-related emotional problems
- increase risk of engaging in high-risk unhealthy behavior postrape, such as unhealthy diet, smoking, excessive alcohol or drug use, and poor sleep
- increase in psychosomatic and physical symptoms resulting from stress and anxiety

Victims commonly experience posttraumatic stress disorder, anxiety disorders, and depression after sexual assault.[83] Health-care facilities caring for rape victims should have counseling and/or referrals available to help mitigate the physical and mental health consequences of sexual assault. Recent work indicates that brief interventions preparing rape victims for their physical examinations and discussing common reactions to rape can reduce exam-related anxiety and may also decrease the development of psychological symptoms postrape.[84]

Rape victims often report "secondary victimization" by police and medical personnel who treat them insensitively.[85]

Many areas have volunteer victims' advocates available who respond to emergency departments and support victims through the medical and legal processes. The presence of victims' advocates during the postrape medical exam has been shown to decrease victims' anxiety and distress.[86] If these services are available, they should be utilized to support victims of sexual assault.

RAPE, HIV, AND VIOLATION OF HUMAN RIGHTS

In many parts of the world where rates of HIV infection are high, women experience sexual inequality, low social status, and little control over their reproductive health. In these societies, violence against women is often rampant. For example, in South Africa, the rate of HIV infection in adults is estimated to be as high as 25%.[87] The rate of sexual assault is unknown but is thought to be among the highest of any country.[88] Human Rights Watch estimates that over 1 million South African women are sexually assaulted each year.[89] Since HIV infection is so common, rape victims face the significant prospect of being infected with HIV as a result of sexual violence.[90]

Gender-based sexual violence is especially a problem during times of armed conflict. During wars in Yugoslavia, Darfur, Rwanda, Somalia, Burma, and many other countries, women have been systematically raped by soldiers as part of 'ethnic cleansing'.[91,92] In Rwanda, reports emerged of HIV-positive soldiers purposely raping large numbers of women to cause illness and death among their enemies.[93] Trafficking of women and children in wartime and peacetime is another human rights violation that threatens the health of the victims and increases risk for STD and AIDS.[94] These complex political/social issues must be addressed worldwide to stop both sexual assault, STD and AIDS from destroying people's lives.

106 Legal and Political Aspects of STI Prevention in the United States: Public Duties and Private Rights

Edward P. Richards and Donald C. Bross

INTRODUCTION

STI prevention is the most legally and politically complex public health problem. STIs involve the most intimate human behaviors and are intertwined with deeply held religious and moral beliefs. In our modern "age of the condom," issues of STI control are easily obscured by the rhetoric of personal protection and responsibility. These are key concepts, but there are populations, such as adolescents, which are difficult to convince to behave responsibly, and others, such as the wives of men who are not faithful, who cannot protect themselves. STI control is also complicated by the legal and moral issues posed by prostitution and illegal drug use.

This chapter focuses on public health law and the control and prevention of STIs in the United States. The U.S. experience is unique for legal, historical, and cultural reasons. The U.S. experience is valuable for those outside the United States because the basic legal and social issues posed by STIs are universal. In many ways, the societal response to STIs is similar in different countries, even though the legal approaches differ.

The defining characteristic of the U.S. legal system is that the United States is divided into 50 state governments. The National Congress can override (preempt) state law in most areas, and the U.S. Constitution is binding on the state as well as the federal government. In some areas of health regulation, such as air and water pollution laws, Congress sets national standards that constrain state action. These standards lead to a uniform national environmental policy. Public health law, however, has been traditionally left to the states. In STI control, this has meant that there are significant differences in basic control laws and enforcement in different states. At the same time, the states depend on the federal government to fund state public health services. Congress uses restrictions on this funding to encourage some public health actions and discourage others. This combination of differing state laws and Congressional overrides means that there is no uniform U.S. STI and HIV control and management policy.

PUBLIC HEALTH LAW BASICS

THE ROOTS OF PUBLIC HEALTH LAW

Public health law is rooted in the fundamental right of a nation to self-defense from external and internal threats. These threats may be military, demographic, economic, or environmental.[1] Historically, the prime environmental threat was disease. The Black Plague ripped the fabric of European society in the Middle Ages. The diseases carried by Western missionaries and sailors did more to destroy indigenous cultures than did their military, religious, and cultural imperialism.[2] Epidemic disease has been resisted with quarantines, embargoes, and limitations on travel since the earliest days of international commerce, making the right to close one's borders to outside threats fundamental to international law.[3] The risk that communicable diseases pose to national security is what justified the broad public health powers traditionally recognized by the United States and most countries.[4] STI control also has a direct history as part of the national security law. Disease control is fundamental to maintaining an army in the field. It has only been in the last 100 years that munitions have outstripped disease as a killer of soldiers. STIs have always followed military campaigns. Even in the United States, the first serious political commitments to controlling gonorrhea and syphilis grew out of a concern with military readiness.[5]

Public health law is part of the larger discipline of administrative law; the law governs the formation and operation of government agencies. Boards of health were among the first governmental agencies and figure in many historic constitutional cases that form the basis for administrative law. As applied to public health actions, administrative law has two major tenets. First, decisions should be made by experts, not by lay judges and juries. Second, agencies must be allowed some flexibility in the development and implementation of policy, i.e., the legislature can give agencies broad powers to address threats to the community.

JUDICIAL DEFERENCE TO PUBLIC HEALTH AGENCIES

Administrative law recognizes that decisions involving technical or scientific information must be made by persons with proper educational training and experience. The agency will be required to show that it has an expert justification for its decision and a procedure to assure that the regulatory process is carried out in a consistent and even-handed manner. The court will defer to the agency's decision unless it finds that it is arbitrary or capricious, i.e., that it did not follow that agency's procedures or that it was not consistent with the agency's rationale. The court will not allow litigants to contest whether the agency made the correct choice from acceptable alternatives.[6]

Public health authority must be broad and flexible to meet the challenges of new diseases and new knowledge about old diseases. Even in the United States, with its suspicion of unconstrained public authority, state laws generally give health officers the authority to do whatever is necessary to protect the public health. Statutes specify the broad outlines of disease control programs, leaving to the discretion of the health officer the specific details on which diseases will be reported, within what time frame, in what form, and how the infected individuals will be managed. The health officer then promulgates regulations to detail the specifics of the disease control strategies. These administrative regulations give notice of a citizen's obligations but may be quickly modified to reflect changes in disease dynamics. Health officer powers are limited to actions rationally related to improving public health, not, for example, supporting a law enforcement effort to reduce pimping that cannot be empirically connected to STI reduction. As another example, courts have struck down laws that used unfounded public health arguments to support discriminatory actions against racial or ethnic groups; but in general, the courts defer to the expertise of local health officers.[7]

The United States Supreme Court has found few limits on the authority of public health officials to take whatever actions are, in their expert opinion, necessary to protect the public health. These have included imposing quarantines on large geographic areas, holding persons infected with communicable diseases in custody to prevent the spread of the disease, the forced treatment of disease carriers, and the seizure and destruction, without compensation, of any property that threatens the public health.[8] Most countries have done the same.

Agency expertise and flexibility depend on the courts' standards of reviewing agency actions. If the courts, whose expertise is in law, not public health, substitute their decisions for the decisions of the agency, it will undermine the effectiveness of expert decision making. If the courts require judicial review of all agency actions, it will be impossible to act quickly, and the cost of the review to the agency will limit the number of actions the agency may take. These transaction costs for decision making are called agency costs. As an example, the Social Security Administration of the United States processes millions of benefits claims each year. If every determination that affected a citizen's rights required court review, the costs of providing a court hearing would be more than many of the claims the agency is asked to pay.[9] It would also increase the cost of making a claim beyond the means of most claimants. In countries without significant judicial review of agency action, interference by politicians without public health expertise can also raise agency costs and make it difficult for agencies to carry out their mission.

Persons who are restricted through public health orders are entitled to have these actions reviewed by an agency appeals panel or the courts, after the health department has acted. This is a critical distinction: most people will cooperate with the public health restrictions and contest it in court. If they want to contest a restriction of their freedom, the U.S. Constitution guarantees them the right to file a writ of habeas corpus to force the agency to show a court the factual basis for their confinement and the legal authority that allows the confinement.[10] If the state requires a hearing before the health department acts, including rights such as appointed counsel paid for by the state, the number of legal proceedings increases dramatically, as does the delay and cost. Most health departments in the United States operate on limited budgets, and some do not have their own attorneys to represent them in court. They must depend on the city, county, or state attorneys to represent them, and these attorneys are often disinterested in public health enforcement. Increasing the due process rights of individuals will reduce the resources that are available to carry out agency functions and force the agency to reduce or limit its enforcement action.

CONSTITUTIONAL LIMITATIONS ON PUBLIC HEALTH POWERS

The major constitutional limit on public health powers is that they may not be used to undermine criminal due process rights. The U.S. Constitution requires that before individuals may be punished, their guilt must be determined by a jury under procedural rules designed to protect their rights. The Constitution does not require that these same protections be provided when the person is being restricted to protect the public health and safety. For example, public health inspectors can enter a private home as part of routine investigations with only limited judicial supervision. In contrast, a police officer looking for evidence of a crime must obtain a warrant from a judge based on a showing that probable cause exists to believe that the evidence is in the home. Since STIs are frequently associated with criminal behavior such as illegal drug use and prostitution, it is important for public health authorities and legislatures to understand this distinction.

The distinction between criminal laws intended to punish and public health laws intended to prevent and ameliorate hazards and behaviors harmful to the public, irrespective of the subjective intent of the individual member of society affected, is crucial in all societies. This was reaffirmed recently by the United States Supreme Court. The case involved pregnant women who were tested for illegal drugs without their consent. This was done as part of their routine prenatal care. The results were used to threaten criminal prosecution if they did not stop using illegal drugs during pregnancy.[11] The court found that while testing pregnant women without their consent would be allowable for a legitimate public health purpose, such as a referral to drug treatment or counseling, it could not be done to collect evidence to be used to justify a criminal prosecution.

Active (infectious) tuberculosis is a good illustration of the difference between public health and criminal laws. Assume that a man has active tuberculosis and is at large in the community under no public health isolation orders. This tuberculosis carrier infects a fellow passenger on a bus, and the passenger eventually dies from the infection. The causation is clear—the bus passenger died because of the actions of the disease carrier. If the man did not know he was infected, or did not know the risks his infection posed to others, this would not be a crime because there was no evil intent or reckless disregard of societal rules. Thus, it would be impermissible to incarcerate the tuberculosis carrier as a punishment for spreading the disease. (If he did know, he could be guilty of recklessly endangering others and might also be liable for damages.) It would be a proper exercise of public health authority to restrict this tuberculosis carrier to prevent the spread of disease.[12] He would have no right to bail because of his danger to the public.[13] When the carrier is successfully cured and rendered noninfectious, the health department's authority to hold him will end.

DISCRIMINATION ISSUES

STIs have always carried a social stigma. One of the categories of the old tort of slander per se, i.e., slander which did not require any proof of harm because the accusation was universally seen as unacceptable, was to be accused of having a loathsome disease. In many of these cases, the loathsome disease was an STI, especially syphilis.[14] At the beginning of the AIDS epidemic in the United States, before HIV was discovered and the epidemiology of the disease was elucidated, there was a fear that this was an easily communicable "gay plague." (This was partially stimulated by the unfortunate first syndromic name—gay related immunodeficiency disease, or GRID.) There were calls to fire gay waiters, gay hairdressers lost customers, and gay men worried, with some cause, about employment and housing discrimination. This was a complex phenomena, at least in the United States, and it has been misunderstood in ways that have hampered HIV control efforts.

First, the level of public fear fell off as it became clear, through the efforts of the U.S. Surgeon General and others throughout the medical and public health world, that AIDS could not be transmitted through casual contact. By the time the HIV test was available in 1985, the initial wave of public fear of AIDS was past. This did not mean that discrimination was no longer an issue, but this discrimination was not just about possible HIV infection but also about homosexuality, which at that time was not well accepted in most parts of the United States. For many employers, the issue was really about gay employees as much as about HIV.

Second, the irrational organization of the U.S. health insurance system created real concerns about the loss of health insurance for persons diagnosed with HIV. Whereas this was real, it was not an HIV phenomenon. A person diagnosed with any serious or chronic illness faces the same issues. If you are not in a group insurance plan, insurance becomes unaffordable if you are sick. If you are in a group plan, your illness will raise the cost to the plan. If it is a small plan, then the costs can rise very quickly and the employer will feel pressure to push the employee out of the plan, i.e., out of the workplace. Persons with liver disease, heart disease, emphysema, and other chronic illnesses faced the same problem, and, to a great extent, still do. The question for public health is not whether there was discrimination against persons with AIDS or other diseases but whether the measures taken to combat the discrimination, and which stymied public health efforts, were needed or even effective and, if they were, are they still needed?

There are two classes of measures to prevent HIV-related discrimination: keeping the disease secret; and laws to prevent discrimination against persons known or suspected to be infected with HIV. Persons wanted to keep their HIV status secret from their employers, their landlords, and their health insurer. This led to restrictions on the handling of HIV information in medical records, special consent forms for HIV testing that discouraged persons from being tested, anonymous HIV testing, and a failure to require HIV to be reported by name to health departments. The problem with these measures is that they did not address the real problems.

Health departments do not report information to employers, health insurers, or landlords. Whether someone is tested at the health department or whether the individual's HIV status is reported to the health department by their health care provider, the information in the public health report is used for public health purposes only. Health departments have an almost perfect record on keeping public health information private. Ironically, the first wave of persons with AIDS were already known to health departments because almost all of them were reported for other STIs and hepatitis B. Had

health departments wanted to do anything sinister with the reporting data, they would have already known who the usual suspects were. Thus, there was no reason to have anonymous testing and no named-reporting—health departments posed no risk of exposure to anyone.

The most problematic issue was keeping information from health insurers. Health and life insurance is not a game where you get a free pass if you can keep your illness secret. Patients have a duty to be truthful about their medical condition, and keeping HIV status secret is fraud on the insurer. Whereas the health department will protect the information about HIV from tests they administer, the patient is defrauding the insurer by withholding this information from the insurer. Whether this is justified or not, it is not an issue of HIV discrimination, it is an issue of the injustice of the health care insurance system and persons with diseases other than HIV were also doing the same thing. Public health officials should have been talking about everyone who has a serious illness and the need for health insurance reform, not supporting special laws for HIV.

The Americans with Disabilities Act of 1990 (ADA)[15] specifically addressed many of the HIV discrimination issues, other than health insurance, which is excluded from the Act. Employers and others are prohibited from discriminating against persons with a disability or against persons who they think have a disability. Employment decisions have to be based on the individual's ability to do the job safely, not on class-based assumptions about what persons with a disability can do. The ADA also limited employers' access to employee health information to prevent employers from using employee health records to identify disabled employees. The United States Supreme Court, interpreting the ADA, found that HIV was a covered disability, even if the infected individual had no signs of the infection other than a positive HIV test result.[16] Whereas individuals may have many valid reasons for hiding their HIV status, the ADA provides them with more protection if their employer knows they are HIV infected.

PRIVATE LAW AND STI CONTROL

The state's role in disease prevention is to prevent the spread of disease, not to compensate those who are infected by others. There is also a private law remedy to compensate persons injured by disease carriers who do not take proper precautions to prevent the spread of their disease. The United States has well articulated liability theories that can be applied to the three types of communicable disease compensation cases: (1) infectees suing infectors; (2) infectees suing physicians for failing to warn them that a patient of the physician was a disease carrier; and (3) patients suing their physicians for medical malpractice. There have been cases awarding compensation for infecting an unsuspecting person with an STI and for malpractice in treating an STI.[17] A physician who fails to report HIV in a state that attempts to warn persons at risk will be sued for negligence per se—the tort remedy for breaking a law.[18] These are difficult lawsuits to defend because the reporting law sets the standard of behavior.

In general, tort law has not been an effective incentive for disease prevention. There has been little litigation over the negligent transmission of STIs because there is no one to pay the compensation and the attorney's fees. Few STI carriers are wealthy enough to pay a court-ordered award, and all insurance policies exclude coverage for STI transmission. There have been a few awards against physicians for failing to take proper disease control measures, but most litigation involving physicians has been over patient privacy issues. These lawsuits generally attempt to limit the access to information about STIs, creating an incentive for physicians to not conduct proper disease reporting, testing, and disease control. Whereas physicians cannot be sued for complying with public health reporting laws, this is not generally known. This should be specifically stated in all public health codes to encourage STI reporting, as this has proven helpful in encouraging reporting of suspected child maltreatment.

Physicians should expect to see more litigation over failing to make a timely diagnosis of HIV as it has become clear that early diagnosis and treatment with antiviral prolongs life and improves its quality. One court has already awarded in excess of $1 million in such a case.[19] Physicians must be especially careful to recommend HIV testing to pregnant women. It is now considered standard of care, and if the woman declines, the physician must be careful to document all the circumstances of the refusal. As cases involving other medical tests have demonstrated, juries tend to assume that patients only refuse simple tests because the physician was negligent in informing the patient of the benefits of the test.[20] With an innocent baby as the plaintiff, and the mother possibly dead by the time of trial, these will be very difficult cases to defend.

APPLYING THE LAW TO STI CONTROL

MANAGING PUBLIC HEALTH INFORMATION

Communicable disease control, including STI control, is driven by epidemiologic information about the medical condition of individuals. Managing this confidential information is a core public health law concern. Medical information occupies a peculiar position in the United States and many other countries. People want information about their medical conditions kept private and worry about it being shared without their knowledge and permission, yet they want access to the best care without delay and they want someone else to pay for it. Since no insurer will pay for care without knowing what it is, and since modern medical care involves many team players, balancing these conflicting expectations is very difficult. The advent of

electronic medical records and widespread electronic transmission of medical information caused the United States and several European countries to enact strict privacy laws controlling the storage, transmission, and sharing of medical information. The United States Department of Health and Human Services has recently promulgated regulations that set a national standard for keeping a patient's medical information private. The law focuses on what it calls Personal Health Information (PHI)—medical information that includes personal identifiers such as the patient name or social security number. These regulations, and all state medical privacy laws, provide exemptions that allow public health personnel access to patient medical records for disease investigation and control programs.[21] Without such exceptions, the health department could not investigate communicable diseases without the permission of the infected person. More generally, all medical care systems should recognize the general principle of patient privacy but also that this must be tempered for public health investigations.

Since PHI must be managed differently from public health information, it is important to distinguish between the two. Public health information is information about an individual's medical condition that is used for epidemiologic purposes such as vital statistics, or disease investigation, or for determining if the person poses a risk to others. Whereas some public health information may come from interviewing the patient or from the patient's medical or laboratory medical records, it may also include information developed by public health investigations. Thus, there is a critical distinction between personal medical records and public health information: patients need access to their PHI to assure ongoing medical care, but they do not need access to public health information held by the health department. Any PHI held by the health department that is not in the patient's ordinary medical record will be investigational data that includes information on others that should be kept confidential.

More generally, PHI with the patient's name or other identifying information held by public health should be kept confidential from the patient and from everyone else who does not have a specific need to know its contents. This means that access to confidential information within the health department should be restricted to persons involved in disease control or epidemiology record keeping. Outsiders should not be told identifying information about the disease carriers unless it is essential, such as telling an employer that an employee is infected with tuberculosis in order to identify all workplace contacts.

Managing public health information is more complex in dual function health departments that provide STI treatment in addition to their STI epidemiology and investigation functions. When a health department is delivering individual medical care, the patient's individual medical care is subject to the same standards as in private medical practice, and the medical records are subject to the same laws as those held by other medical care providers. These include the patient's right of access and access by various financial auditors and medical quality inspectors, as well as all members of the health care team. In the United States, access to and transfer of these records is controlled by comprehensive federal regulations and many other countries have similar restrictions. Public health investigation records must be kept completely separate from the patient care records, and patient care personnel should not have access to them unless the department is so small that the same staff provides both clinical and epidemiological services.

Concerns about the privacy of medical information should not deter disease control efforts, including databases created to facilitate the identification and tracing of infected persons. STIs are a special case in that the carriers of these diseases, particularly the incurable ones such as HIV, have a special responsibility not to spread them to others. A measles or tuberculosis patient, who spreads the disease through ordinary activities, will be isolated to prevent the spread of the disease. STI carriers pose no threat through casual contact and can prevent the spread of the STI by not engaging in risky activity. They are not isolated but in return have an obligation to refrain from risky behavior. As an incurable, deadly communicable disease, HIV is the most serious communicable disease routinely encountered in public health practice. Whereas unnecessary breaches of confidentiality should be avoided, the risk of a breach of confidentiality is more than offset by the importance of making all reasonable efforts to control the spread of HIV.

STI TESTING

Communicable disease epidemiology begins with a diagnosis of the disease. Some diseases—smallpox, Ebola—announce themselves through their severity and visible symptoms. STIs, at least in their initial phases, are silent, or have ambiguous symptoms that are easily confused with other conditions or ignored. Testing is the first step in STI surveillance and epidemiology. Before 1985, when the HIV test became available, there was little controversy over STI testing and clear legal authority to require testing when epidemiologically justified.[22] Most states required pregnant women to be tested for syphilis so that they could be treated to prevent congenital syphilis. STI testing, including syphilis was required for wedding licenses and most hospitals did syphilis screening as part of hospital admission blood work. Many of these requirements were dropped as the decreasing incidence of syphilis made them less cost-effective but not because they were legally questionable. Most states still require syphilis screening for pregnant women without notifying the patient or getting specific consent.[23]

STI testing, other than HIV testing, is done in the same manner as other noninvasive diagnostic testing. The tests are ordered, usually based on "medical suspicion," as part of the

general evaluation of the patient and they are covered by the consent to the medical evaluation. Patients are not asked to consent to individual tests. This consent is usually signed by the patient but may be implied by the patient seeking care and allowing the physician's examination. (Since implied consent would not be adequate for releasing information covered by HIPAA, it is not advisable in the United States.) The physician may or may not tell the patient the specific tests being ordered—the automated analysis performed in many clinics may include 40 or more tests, making it difficult and confusing to present the patient with a list of the tests ordered. The patient is contacted when the results are completed and told the results of tests directly related to the evaluation and any abnormal tests.

State laws that require special consent for HIV testing pose a significant barrier to HIV testing. Another barrier is laws that require post and even pretest counseling. Although such counseling is useful, it limits testing and diagnosis and is not required for other potentially devastating diagnoses, such as cancer or multiple sclerosis. States have also failed to require HIV testing for pregnant women, although they do require testing for syphilis. Since both tests for HIV and syphilis have the same medical justification, preventing the development of congenital infection by treating the mother, there is no scientific justification for putting infants at risk of HIV while trying to protect them from congenital syphilis.

DISEASE REPORTING

The first step in STI surveillance and epidemiology is making the disease known to the public health authorities. This can come from investigations and voluntary reports to the health department, but most communicable disease epidemiology starts with legally mandated reports by medical care providers, clinical laboratories, and persons in other care situations, such as day care centers. Whereas disease reporting has been mandated by law since the colonial period, it was not reviewed by the United States Supreme Court until 1977. This case arose from a state law requiring that narcotic prescriptions be reported to the state. The reports were used to detect inappropriate drug use and illegal prescribing or selling narcotics.[24] The law was challenged by physicians and patients who claimed it was an invasion of their privacy and that it improperly interfered with the physician—patient relationship. This was in the wake of the Roe v. Wade decision that recognized a special status for medical privacy related to abortion.[25]

Rather than extend Roe v. Wade into a general medical privacy law, the United States Supreme Court found the reporting law a constitutional exercise of the state's power to protect the public health. More generally, the Court has rejected special privacy rights in medical care that are not related to abortion and birth control. The Court recognized that the state had a duty to keep the information confidential, but that the state had a right to require the reports and to use them to investigate potential abuses. Despite the fact that a prime purpose of these reports was to identify criminal activity, which merits more constitutional protections than public health investigations, the Court ruled that the state has broad latitude to require disease reports for public health purposes.

Mandatory disease reporting is critical for STIs. Whereas high-quality data on disease epidemiology may be obtained by large-scale surveys of randomly sampled practitioners without requiring routine individual disease reports, such surveys are problematic for STIs. They are expensive and time-consuming, making it virtually impossible to detect short-term changes in disease dynamics. They also depend on the practitioners having the information. Since a major problem with STIs is that physicians do not routinely test for them, especially for HIV where state consent requirements discourage testing, the data is not there for the surveys to reach. Surveys that preserve the anonymity of those surveyed also fail to address the duty to warn, which requires the identification of individual infected patients, and do not allow further investigation of contacts.

Mandatory physician reporting of designated STIs has been a component of STI prevention for more than 60 years in the United States. (Extremely common STIs, such as gonorrhea and chlamydia, are generally not reported by name because they are too common and too easy to treat to justify using limited disease control resources to track.) Unfortunately, epidemiologic information about STIs has been very difficult to collect even with legal persuasion, in part because of the health care providers' concerns with protecting their patients' privacy [26] and also because many physicians do not practice public health responsibilities as a core activity in the practice of medicine.[27]

Statutes and regulations mandating STI reporting should recognize the three functions served by reporting: (1) statistical assessment of disease epidemiology; (2) direct disease control interventions; and (3) discharge of the physician's duty to warn persons at risk of contracting a disease from the patient. The health department must educate physicians about the importance of disease epidemiology and the potential risks they run if they do not comply with reporting laws, thus facilitating the spread of HIV to an innocent third party, especially a newborn.

Public health agencies should also recognize that in modern medical practice, the most important deterrent to physician reporting is time and money. In plain terms, there is no reimbursement code for reporting, and no state health department routinely disciplines physicians for failing to report communicable diseases. For most STIs with a laboratory based diagnostic test, physician reporting is now much less important than laboratory reporting. Laboratories are much more intensively regulated than physician practices, so they are much more likely to comply with reporting laws.

Most laboratories are automated so that reporting can be done automatically as part of the testing and billing process.

The most important barrier to HIV reporting is anonymous testing, which is allowed in most states. This is particularly important because a growing number of women are being infected by male partners who hide their homosexual liaisons.[28] It also creates the dilemma of persons who test positive but never return for their test results and who cannot be contacted for follow-up.

CONTACT TRACING/PARTNER NOTIFICATION

Contact tracing and partner notification is used in the investigation of all communicable diseases. Despite its effectiveness in controlling diseases such as tuberculosis, measles, hepatitis, and bringing persons with curable STIs to treatment, contact tracing is one of the most controversial issues in HIV prevention. It has been criticized because of coercion, because it is not perfectly effective, and because it might increase the chance of violence toward infected women.

The fears of contact tracing are unfounded.[29] First, no jurisdiction in the United States coerces individuals to divulge the names of their contacts. This would not be justified in contact tracing for STIs because effective contact tracing does not depend on perfect reporting.[30] The overlapping sexual networks make it likely that the individuals with the most contacts will be identified by at least one contact. Most people infected with an STI cooperate in identifying their contacts.[31] Although it is a crime to not cooperate with public health investigations, no jurisdiction uses this power in routine disease investigation. (It might be used in an emergency, such as a smallpox outbreak.)

Research showing that contact tracing puts women at risk for domestic violence must be recognized and is troubling, but it is neither new nor limited to HIV. A typical scenario is the woman who is screened as part of her prenatal care and found to be HIV infected. The investigator then notifies her husband, who is often the source of the disease, who assaults his wife for involving him with the public health officers. The best solution, which is used by New York City and some other jurisdictions, is to combine contact tracing with domestic violence services. If the disease investigator believes that the woman (or man) is at risk, they can be referred to domestic violence services as part of the investigation and notification process.

INVOLUNTARY SCREENING, TREATMENT, AND RESTRICTIONS

Informed consent to all medical treatment and testing has become a fundamental tenet of the international medical and bioethics communities. For communicable diseases, as opposed to most noncommunicable diseases, endangerment of others is always a consideration. Courts in the United States uphold orders requiring persons who endanger the public to be isolated unless they agree to treatment that will make them noninfectious. Outside of prisons, it is very unusual for the court to order the use of physical force to overcome the patient's objections to treatment. However, international disease control programs, such as the smallpox eradication program, have found it necessary to use aggressive strategies, including involuntary immunization and bribing villagers to report hidden cases of disease.

What if the patient would be willing to accept the treatment, but for language, educational, cultural, or medical reasons, it is not possible to get a fully informed consent? In these cases it is very important to differentiate between research, and care that is intended to benefit the patient or the community. If the goal of the intervention is solely research, with no potential benefits to the patient, then the international treaties on medical research apply. In these cases, consent is mandatory before testing or treatment.

Isolation and quarantine are venerable techniques in public health. The use of confinement in the case of STIs, however, seems to have little practical use. Unlike many diseases, intimate contact is required for the spread of STIs. In effect, drawing a blood sample or administering an antibiotic under medically indicated circumstances is a less restrictive means of state intervention in the control of STIs than isolation. The fatal and thus far incurable nature of HIV infection may force attention to isolation as a remedy in very rare cases. Depending on the factual situations that arise with HIV infection, for example, associated dementia or an independent mental illness, the courts may well have to consider mental health law and public health law measures for isolating an individual with HIV who is clearly a danger to others or who is gravely disabled and unable to care for himself. Individuals who knowingly expose others to HIV can, and have been, prosecuted under the criminal law and imprisoned.

Given that isolation is a very restrictive approach to STI control, some comparable mechanisms that will ensure participation in examinations and agreements not to expose others are needed. The alternative of health hold orders should be considered. A health hold order means a specific order issued by an authorized public health official to a named individual to cooperate with examination, treatment, or to behave within certain limits necessary to protect the public health.[32] Such an order could be appealed to the courts or higher administrative official in a confidential proceeding. The health hold also might be in the form of a voluntary agreement subject to enforcement by court order and result in a very brief detention for examination or a "show cause" contempt proceeding if the voluntary agreement is not likely to be kept or in fact is not being kept. Health holds might also be administered conveniently to persons detained in institutional settings for alleged sexual crimes. Health authorities can avoid having the health hold used for nonhealth matters, such as to compel cooperation in criminal matters, by

focusing strictly on what is required for individual and epidemiologic treatment of STI.

PRIMARY PREVENTION

Primary prevention of STIs in general, and HIV in specific, is complicated by conflicting political agendas in the United States. Conservative politicians and some religious leaders oppose sex education in general and education about safe sexual practice in particular. This opposition is sufficiently widespread that Congress prevents the use of federal funds to support many effective public health education efforts, including those that target poor and minorities, communities at the highest risk for HIV. Unfortunately, the states depend on federal funding for their public health efforts, so even progressive states that support these efforts must limit their actions because of the limits on the federal grants.

Most politicians want to be seen as tough on crime, so efforts to change Draconian drug laws that merely shift HIV-infected persons into the prison system have failed. Few politicians support needle exchange or other efforts to make illegal IV drug use safer, and there is almost no support for the medicalization of drug addiction.

Ironically, at the same time that conservative politicians and religious leaders oppose programs that try to educate about safer sexual practices, politicians in most major urban centers have prevented the closing of gay bathhouses. This is despite evidence that methamphetamine and Viagra use in the bathhouses threatens to dramatically increase new cases of HIV.[33] HIV treatment, at least in the United States, is seen as so effective that it has reduced the effectiveness of HIV prevention messages.

CONCLUSIONS

Effective laws to prevent STIs are based on accurate understanding of available resources, legal and cultural traditions, and intelligent shaping of legislation to meet sound, and probably narrow, disease prevention goals. Laws to organize the reporting of STIs, the screening of persons at greatest risk, and the tracing of the contacts of disease carriers should be a priority of lawmakers concerned with preventing STIs. Personal privacy and liberty must be protected to the greatest extent possible, consistent with the protection of society from STIs. As demonstrated by the contrast between the magnitude of societal risks for gonorrhea and for HIV infection, the milder the disease, the more it can be tolerated for the sake of preserving personal liberties.

Public and private professionals involved in STI prevention must conform their actions to laws governing diagnosis, treatment, reporting, quarantine, and isolation. Law is an effective device in the prevention of STIs to the extent that it is wielded as one tool in a comprehensive prevention, diagnosis, treatment, and management strategy. Many traditions of public health and legal precedents are valuable standards against which responses to new conditions such as HIV infection must be measured.

107 Ethical Challenges of the Global AIDS Epidemic

Ronald Bayer

In a quite fundamental sense the AIDS epidemic has provided the occasion for the effort to articulate an ethics of public health. Although such an effort drew upon the insights and perspectives of bioethics, it was clear that more was needed. Bioethics had taken root in the United States largely in an effort to redress the balance of power between clinicians and patients and researchers and subjects. Central to that effort was an explicit focus on the rights of the individual. Hence, the protection of autonomy became the core commitment of bioethics. Important as was the protection of the individual, it could not serve as the only or even preeminent principal in the context of public health, where the focus was, by definition, on the protection of the community. Nevertheless, as the ethics of public health took shape in the context of the AIDS epidemic, the critical importance of individual rights—claims of privacy, bodily integrity, freedom from unwarranted restraints—was clear. AIDS, too, provided the context within which the ethics of research in a world characterized by deep inequalities became the subject of contentious discussion. Only during later stages of the epidemic, when therapeutic advances made access to care a critical matter, did questions of justice both within nations and internationally take on greater salience. It was the emerging demand for access to care on the part of the poorest people in nations which bore the brunt of the global epidemic that set the stage for vital questions about the moral duties of the world's richest nations to the poorest.

EXCEPTIONALISM, CIVIL LIBERTIES, HUMAN RIGHTS, AND PUBLIC HEALTH: THE ETHICS OF TESTINGS AND CASE REPORTING

In the early and mid-1980s, at the outset of the encounter with AIDS in the United States and Western Europe, it was necessary to face a set of fundamental questions: Did the history of responses to lethal infectious diseases provide lessons about how best to contain the spread of HIV? Should the policies developed to control sexually transmitted diseases or other communicable conditions be applied to AIDS? If AIDS were not to be so treated, what would justify such differential policies?

To understand the importance of these questions, it is necessary to recall that conventional approaches to public health threats typically provided a warrant, when deemed appropriate, for mandating compulsory examination and screening, breaching the confidentiality of the clinical relationship by reporting to public health registries the names of those diagnosed with "dangerous diseases," imposing treatment, and in the most extreme cases, confining persons through the power of quarantine.[1] To be sure, many aspects of this public health tradition, forged at the outset of the 20th century, had been modulated over the decades, in part because of changes in the patterns of morbidity and mortality.

Nevertheless, it was the specter of the historically coercive aspects of the public health tradition that most concerned proponents of civil liberties and advocates of gay rights and bioethics as they considered the potential direction of public health policy in the presence of AIDS, a disease that so disproportionately affected disfavored groups, gay men, drug users, and the poor in minority communities. Although there were some public health traditionalists in the United States and elsewhere who pressed to have AIDS and HIV infection brought under the broad statutory provisions established to control the spread of sexually transmitted and other communicable diseases, they were in the distinct minority. In place of the conventional approach to public health threats, there emerged an alternative view, broadly defined as exceptionalist,[2] that took as its starting point the need to craft policies that were persuasive rather than coercive that viewed the protection of the rights of those who were infected as integral rather than as antagonistic to the goals of disease prevention. For those who advanced this new perspective, privacy and confidentiality were to be accorded great importance. In all, the goal was to avoid, at all costs, measures and practices that might be counterproductive, which might "drive the epidemic underground" by inspiring fear and distrust rather than fostering engagement between public health officials and those most at risk.

In those nations where the language of civil liberties informed the discourse on rights, it was common to assert that there was no tension between public health and civil liberties. Policies that undermined civil liberties would subvert the goals of AIDS prevention. Policies that effectively advanced the cause of AIDS prevention would protect civil liberties. On a global level, this perspective took the form of claims about the deep connection between health and human rights. Indeed, it was at the WHO's Global Program on AIDS, first directed by Jonathan Mann, that a sustained effort was undertaken to face the synergistic relationship between the protection of human rights and the struggle against AIDS.[3] Central to that mission was the view that HIV was most apt to spread among the socially vulnerable and that the protection of the socially vulnerable from acts of discrimination, stigmatization, and coercion was integral to effective AIDS protection efforts.[4] The specter of the Cuban response to AIDS in the late 1980s haunted the discussion of health and human rights. In that nation, a massive all but mandatory HIV-testing program had identified those who were infected. Following what it took to be established health principles, the Cuban government then quarantined the infected.[5] How the exceptionalist perspective with its commitment to noncoercive approaches to HIV affected the policy is most clearly illustrated in the debates over HIV testing and the reporting of HIV by name to public health registries. From the moment of its introduction in 1985, the HIV test became the subject of intense debate. Fear that those identified as having HIV might be subject to discrimination and stigma; concern about how the diagnosis of HIV infection, in the absence of effective therapy, could produce unbearable psychological burdens; and a belief that testing had little to do with behavioral change, led AIDS activists generally, and gay leaders specifically, to adopt a posture of hostility and/or skepticism regarding the test. On the other hand, many public health officials believed that the identification of infected persons could play a crucial role in fostering behavioral change. Out of their confrontations emerged a broad consensus that, except in a few well-defined circumstances, people should be tested only with their informed, voluntary, and specific consent.[6]

Much of the early discussion of HIV testing occurred in the context of extreme therapeutic limits. And indeed, in the epidemic's early years the primary function of testing was as an adjunct to prevention efforts. As a result of clinical developments—the belief that treatment with zidovudine could delay the onset of symptomatic AIDS and the recognition of the importance of primary prophylaxis against *Pneumocystis carinii* pneumonia—by 1990, the medical significance of identifying those with early HIV disease had become clear. Consequently, the clinical and political context, involving a wide range of constituencies, of the debate about testing underwent a fundamental change.[7] Gay organizations began to urge gay and bisexual men to have their antibody status determined under confidential or anonymous conditions. Physicians pressed for AIDS to be incorporated into the medical mainstream and for the HIV-antibody test to be treated like other blood tests, i.e., given with the presumed consent of the patient. In the face of such pressure, those committed to the protection of the rights of the infected continued to insist that testing only occurs with specific informed consent. Whatever, in fact, occurred in the context of clinical settings, public policy in all economically advanced democratic nations continued to reflect a commitment to the voluntaristic premise of the exceptionalist perspective and the enduring influence of the ethical underpinnings first enunciated in the mid-1980s when medicine was all but impotent.

In the United States, pressure to shift the paradigm of testing away from the exacting standard of informed consent continued to mount. It was especially pronounced in the case of pregnant women and newborns.[8] Diagnostic progress was to make it possible to determine whether HIV-positive newborns were truly infected soon after birth, and the improved prospects of clinical management were to make such determinations for infected infants appear all the more critical. So, it is not surprising that pediatricians became increasingly impatient with the strict regimen of explicit and specific consent that surrounded the testing of newborns for HIV[9]—all the more so because routine and unconsented testing of newborns for inborn errors of metabolism such as phenylketonuria was mandated in virtually every state and had provoked little by way of ethical objection. The 1994 finding that the administration of zidovudine during pregnancy could reduce the rate of vertical transmission by two-thirds[10] only added to the pressure. In June 1996, the American Medical Association's House of Delegates passed a resolution calling for mandatory testing of pregnant women.[11] Even the Institute of Medicine, which early in the epidemic had opposed testing policies that abrogated the privacy rights of pregnant women, was, by the end of the 1990s, to endorse routine testing on the basis of an informed right of refusal, a much less exacting standard that specific informed consent.[12]

In the new millennium, the changes that had occurred in Western nations were to find expression in less developed nations.[13] In 2004, UNAIDS and the WHO issued a policy statement that sought to respond to the fact that "the current reach of HIV-testing services remains poor: in low- and middle-income countries only 10% of those who need voluntary counseling and testing because they may have been exposed to HIV infection have access to it." To face this challenge, the new policy proposed the routine offer of testing in clinics treating STIs, in the context of pregnancy to facilitate antiretroviral prevention of mother-to-child transmission, in settings where HIV is prevalent *and* antiretroviral treatment is available. While maintaining the importance of a human-rights-based approach to HIV testing, the policy significantly suggested that an opt-out approach be relied upon.[14]

Even more expansive was the proposal of Kevin De Cock and colleagues in 2006 which supported "routine testing

wherever *basic* HIV care and prevention are available." Here it was not the possibility of treatment that was to drive the move to extended testing but the prospect of preventing HIV transmission. "The ideal that all citizens of high prevalence countries should know their serologic status and should be tested repeatedly over the course of their lives should become explicit targets of preventative efforts."[15]

Indicative of the changing landscape was the fact that in South Africa, for example, advocates for widescale HIV testing, human rights and treatment activists among them, began to argue that exacting standards of informed consent tended to suppress the uptake of testing. Given the growing prospect of gaining access to antiretroviral treatment, they asserted that testing should be routinized with an opt-out provision. Those who feared the prospect of coercion, no matter how subtle, rejected such suggestions, arguing that only the strict standards of informed consent could protect both the rights and interests of people with HIV.

A course similar to that which occurred with testing characterized the debate surrounding case reporting for HIV infection. Given the profound stigma that surrounded AIDS in the epidemic's first years and the extent to which individuals with or at risk for HIV feared the social consequences of having their diagnoses made public, it is not surprising that confidentiality of AIDS-related information assumed great salience. From the pragmatic perspective of public health officials it was crucial to preserve confidentiality as a way of assuring that those at risk would come forward for testing and counseling.[16] Others objected on grounds of principle. Privacy was a value that should not be lightly set aside.

But, however central were the claims of privacy and the duty to protect confidentiality, they were not absolutes. Among the conventionally accepted limits to those claims occurred when individuals with infectious diseases were reported by name to confidential public health registries. Thus, it was not surprising that despite concerns about privacy, little opposition existed in the epidemic's first years to making AIDS cases reportable by name.[17] AIDS activists appreciated that such reporting was crucial to the understanding of the epidemiology of the new disease. The acceptance of AIDS case reporting requirements was facilitated by the well-established record of health departments in protecting such records from unwarranted disclosure.

With the inception of HIV testing, however, debate emerged about whether the names of all infected persons, regardless of whether they had received an AIDS diagnosis, should be reported. Activists who accepted AIDS case reporting opposed HIV reporting because of heightened concerns about privacy, confidentiality, and discrimination. For them the potential public health benefits of reporting were too limited and the burden on those who would be the subject of reporting too great to justify an abrogation of privacy.

While many public health officials in Western nations opposed HIV reporting because of its potential effect on the willingness of people to seek testing and counseling, some did become strong advocates of such reporting. Their claims sought to underscore the extent to which the public health benefits of HIV reporting would be like those that followed from more broadly conceived reporting requirements, such as those that applied to syphilis, tuberculosis, and AIDS itself.[18]

As therapeutic advances began to emerge in the late 1980s, and as the logic of distinguishing between HIV and AIDS became increasingly difficult to sustain, fissures began to appear in the relatively broad and solid alliance against named HIV reporting in the United States. At the end of November 1990, the U.S. Centers for Disease Control and Prevention declared its support for HIV reporting, which it asserted could "enhance the ability of local, state, and national agencies to project the level of required resources" for care and prevention services.[19] The House of Delegates of the American Medical Association also endorsed the reporting of names as well.[20]

Nothing more tellingly underscores the change that had occurred and the extent to which the claims of public health necessity had trumped the arguments of privacy than an editorial jointly authored by a CDC official, an AIDS activist, and a lawyer-ethicist long involved in AIDS-related work that appeared in the *New England Journal of Medicine* in 1997. "We are at a defining moment of the epidemic of HIV infection and AIDS. With therapy that delays the progression to AIDS, mental illness, and death, HIV infection or AIDS is becoming a complex clinical disease that does not lend itself to monitoring based on end stage illness. Unless we revise our surveillance system, health authorities will not have reliable information about the prevalence of HIV infection. To correct these deficiencies, we propose that all states require HIV case reporting."[21]

At the end of 1999, in the face of lingering opposition from most AIDS activists, the CDC finally proposed that all states put in place an HIV-reporting system. And while it left open the possibility of reliance on unique identifiers that met strict performance criteria, it was clear that the use of names was viewed as preferable.[22] Remarkably, of those states that adopted HIV case surveillance after the publication of the CDC's recommendations, virtually all adopted coded systems. By 2002, only a handful of states had not adopted some form of HIV reporting. In other economically advanced democratic countries, the move to HIV name-based case reporting did not follow the American pattern.

THE ETHICS OF RESEARCH

As was true of public health practice, the first years of the epidemic forced a rethinking of the ethics of human subjects research. Such a rethinking extended beyond the United

States as the debate in the late 1990s broadened to questions of research conducted in poor countries under the sponsorship of wealthy nations.

The ethical analysis of research involving human subjects emerged against a backdrop of torture, abuse, and scandal. From the Nuremberg Code, which sought to set out the basic moral principles for research in the wake of the postwar trial of Nazi doctors, to the establishment of the U.S. National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, created in the wake of the revelations about the infamous Tuskegee syphilis experiment, the need to protect potential subjects captured the attention of those appalled by the practice of science. In 1978 the National Commission issued the Belmont Report, which codified a set of ethical principles that sought to inform and guide the work of researchers.[23] Those principles provided the foundations for regulations subsequently enacted by the Department of Health and Human Services and the Food and Drug Administration. At the core of those guidelines was the radical distinction between research designed to produce socially necessary, generalizable knowledge and therapy designed to benefit individuals. Against the former, the Belmont Report held, individuals, especially those who were socially vulnerable, needed protection against conscription. AIDS forced a reconsideration of this formulation.

The HIV epidemic provided the circumstances for the emergence of a broad and potent political movement that sought to reshape radically the conditions under which research was undertaken. The role of the randomized clinical trial, the importance of placebo controls, the centrality of academic research institutions, the dominance of scientists over subjects, the sharp distinction between research and therapy, and the protectionist ethos of the *Belmont Report* were all brought into question. Although scholars concerned with the methodological demands of sound research and ethicists committed to the protection of research subjects played a crucial role in the ensuing discussions, both as defenders of the received wisdom and as critics, the debate was largely driven by the articulate demands of those most threatened by AIDS.[24] Most prominent were groups such as the People with AIDS Coalition and ACT-UP, organizations made up primarily of white, gay men. They were joined by community-based physicians who identified closely with the plight of their patients.

What was so stunning, disconcerting to some, and exciting to others was the rhythm of challenge and response. Rather than the careful exchange of academic arguments, there was the mobilization of disruptive and effective political protest. Most remarkable was the core demand. As one analyst noted, "The shortage of proven therapeutic alternatives for AIDS and the belief that trials are, in and of themselves, beneficial have led to the claim that people have a right *to be* research subjects. This is the exact opposite of the tradition started with Nuremberg that people have a *right not to be* research subjects."[25] That striking reversal resulted in a rejection of the model of research conducted at remote academic centers, with restrictive (protective) standards of access and strict adherence to the "gold standard" of the randomized clinical trial.

Blurring the distinction between research and treatment, expressed forcefully through the slogan "A Drug Trial Is Health Care Too," those insistent on reform sought to open wide the points of entry to new "therapeutic" agents both within and outside of clinical trials; they demanded that the paternalistic ethical warrant for the protection of the vulnerable from research be replaced by an ethical regime informed by respect for the autonomous choice of potential subjects who could weigh, for themselves, the potential risks and benefits of new treatments for HIV infection. Moreover, the revisionists demanded a basic reconceptualization of the relationship between researchers and subjects. In place of protocols imposed from above, they proposed a more egalitarian and democratic model in which negotiation would replace a scientific authority. Indeed, research "subjects" were now thought of as "participants." Furthermore, the role of the carefully controlled clinical trial as providing protection against the widescale use of drugs whose safety and efficacy had not been proven no longer commanded unquestioned respect.[26]

The new perspective did not go without challenge. Some were concerned that the proposed regime would make the conduct of research, so crucial to the needs of those with HIV/AIDS, all but impossible,[27] others feared that desperate individuals would, in the absence of the now discredited (paternalistic) ethos, be subject to deception.[28]

The AIDS-inspired challenge to the ethics of research was not restricted to issues within the United States. Just as the protective regime surrounding research in the United States was a product of a history of abuse, efforts to enunciate ethical standards for the conduct of research in third world nations were shaped by a history of exploitation, a history characterized by investigations on the poor designed to serve the interests of the privileged. Central to those efforts was the belief that the ethical principles first encountered in industrialized nations had direct bearing on the norms that should govern research in very different settings.[29] Such universalism took as a given the need to assume that insights regarding cultural differences not serve as the basis for moral relativism.

Just as individual informed consent was the first principle of the ethics of research in advanced industrial nations, it was at the heart of the codes designed to guide research in the poorest nations. To preclude exploitation, international consensus also existed on the extent to which it was critical that research be responsive to the health needs and priorities of the community in which it is to be carried out.[30] What would

remain a matter of uncertainty, however, was whether the needs of the poorest and the requirement of responsiveness could justify research that would be unacceptable in the richest nations, whether the principle of universalism could accommodate research in Burundi that would be prohibited in Brooklyn.

That was the issue that would animate a furious international debate occasioned by the 1994 finding that AZT administered to infected women in the second and third trimesters and to their infants for 6 weeks could reduce by two-thirds the rate of vertical transmission.[31] Although superficially a conflict over a technical matter involving research design—the role of placebos—the dispute touched on the deepest questions of what ethical conduct meant in a world characterized by great inequalities and profound inequities.

In 1997, an editorial appeared in the *New England Journal of Medicine* denouncing an international trial designed to determine if it were possible to develop an inexpensive clinical intervention that could provide something approaching what had been attained in wealthy nations in reducing the risk of mother-to-child HIV transmission.[32] Those trials assumed that even if successful, the more affordable interventions would be less effective than was standard in Europe and America.

Given the burden of pediatric AIDS in Africa and Asia, it was a matter of some urgency that trials begin to determine whether cheaper alternatives to the standard regimen could achieve at least some measure of reduced maternal fetal HIV transmission. In June 1994, a special consultation of the WHO considered the challenge and called for the launching of studies to achieve that goal. The consultation made clear its conclusion that placebo-controlled trials "offered the best option for obtaining rapid and scientifically valid results."[33]

There was no question that a placebo-controlled trial would have been considered unethical in the United States or any other advanced industrial nation. No trial that denied access to the effective standard, or to an intervention thought to hold the promise of being at least as effective as, if not more effective than, the prevailing standard of care, would have satisfied the requirements of ethical review. The question posed by the furious controversy that unfolded was whether it was ethical to conduct such a trial in a poor country. The *New England Journal of Medicine* gave its answer unambiguously: "Only when there is no known effective treatment is it ethical to compare a potential new treatment with a placebo. When effective treatment exists, a placebo may not be used. Instead, subjects in the control group of the study must receive the best known treatment."[32] Given this premise, the *Journal* rejected as irrelevant the fact that health care available in most Third World countries provided nothing like health care available in industrialized countries. Citing the Declaration of Helsinki, the international code of research ethics adapted by the World Medical Association in 1964, for authority, the editorial noted that control groups had to be provided with the best current therapy, not simply that which was available locally. "The shift in wording between 'best' and 'local' may be slight but the implications are profound. Acceptance of this ethical relativism could result in widespread exploitation of vulnerable Third World populations for research programs that could not be carried out in the sponsor country."[32]

Those who rejected the *Journal's* viewpoint made clear that placebo-controlled trials were dictated by the urgency of the situation. Only placebo-controlled trials could provide "definitive," "clear," "firm" answers about which interventions worked, thus allowing governments to make "sound judgments about the appropriateness and financial feasibility of providing the intervention." The failure to employ a placebo would have made it difficult to clearly determine whether the affordable but less effective intervention was better than no intervention at all. In short, placebos were crucial to policymakers required to make relatively costly decisions under conditions marked by profound poverty and scarce public health resources.[34]

Paralleling the debates over maternal fetal transmission of HIV were those that surfaced over the ethics of AIDS vaccine trials. In this case, the focus was on those research participants who might become infected with HIV during a trial. On the one hand, there were those who argued that such individuals be provided with optimal care—the retroviral therapy available in the developed countries. On the other hand, there were those who asserted that care should reflect that which was consistent with what was available in the host nation.[35] So divisive was this controversy that UNAIDS could not come to an agreement on the appropriate ethical norm and indeed had to settle for a procedural rather than substantive solution, a solution that focused on how to reach acceptable agreement rather than one that put forth a standard to guide such deliberations.[36]

The controversies ultimately provoked an international effort to reconsider ethical standards of research in the Third World. The World Medical Association undertook a series of consultations on the revision of the Declaration of Helsinki; the Council for International Organizations of Medical Sciences (CIOMS) did so as well. Finally, within the United States, which funded much of the international research that had been subject to scrutiny, the National Bioethics Advisory Committee took up the issue of studies in poor nations.

While those who saw in any effort to craft "flexible" standards that reflected the uniquely pressing context of international poverty and inequality the treacherous embrace of moral relativism, their opponents persisted in arguing that a failure to consider the context of investigation is a failure of moral understanding. Principles could be universal; their application could not be rigid.[37]

How profoundly difficult the issues of research in the context of global poverty were is best demonstrated by conclusions reached by the World Medical Association, the CIOMS, and the National Bioethics Advisory Committee. Despite the fact that each body understood the considerable attention that was focused on their efforts, and the importance of forging a common standard, consensus could not be attained. Only the World Medial Association in its revision of the Declaration of Helsinki adopted the position that once an effective therapy was found it became the standard against which all further interventions had to be measured.[38] Regardless of the cost of the intervention, placebo controlled trials were no longer tolerable. The CIOMS recommendations, on the other hand, concluded that there might be sound scientific and ethical reasons to reject the "best current" method standard, if the failure to use a placebo would make the results inapplicable in the host country where the search for affordable alternatives was essential.[39] That too was the position adopted by the U.S. National Bioethics Advisory Committee.[40]

In the end then, the AIDS-inspired debate over research ethics opened wide the question of whether ethical principles could serve as a universal standard in a world characterized by gross inequality, whether that very inequality made adherence to universal standards morally imperative.

SECURING ACCESS TO CARE

In the first years of the epidemic there was little that medicine could offer those with HIV disease. Indeed, that was the context, as noted, within which AIDS activists struggled to increase access to experimental trials. As the prospects for clinical intervention improved, first with the use of prophylactic treatment to prevent Pneumocystis pneumonia and other opportunistic infections and then with AZT, the first widely prescribed antiretroviral agent, it was inevitable that access would be shaped by the extent to which health-care systems were governed by principles of equity.

In the United States, for example, some who needed treatment had private insurance although they had not infrequently faced efforts on the part of their insurers to deny them coverage for their HIV-related conditions. Those who had very limited resources or who became impoverished because of their disease *could* qualify for Medicaid, the joint federal-state program that covered some of the poor. But many remained unprotected.[41] To meet their needs, special programs were developed. The federal government, through the Ryan White CARE Act, directed significant sums to localities to provide medical services. Among the initiatives under the Act was the AIDS Drug Assistance Program (ADAP), designed to pay for AIDS-related medicines. But the patchwork effort was never adequate and left many without needed protection.[42]

When the protease inhibitors emerged in the mid-1990s and combination antiretroviral therapy became the standard of care, the system was strained to the limits. Medication costs alone for those receiving care could range from $10,000 to $15,000 a year.[43] One review of the dramatically improved therapeutic prospects added the caveat that the new achievements were important "at least for those socioeconomically privileged."[44] ADAP experienced persistent shortfalls in funding. When that was the case, it was necessary to resort to a host of rationing strategies. At one point, nearly half of state ADAP programs limited access to protease inhibitors.[45] The U.S. story with regard to treatment of HIV disease simply reflected the broader failure to adopt a system of health-care delivery that guaranteed access to treatment as a matter of social right. Where principles of social solidarity or egalitarianism defined the basic contours of the health-care system, the inequities that characterized the U.S. situation did not prevail.

On an international plane the prospect of effective but extraordinarily expensive antiretroviral treatment would pose far-reaching ethical challenges. What justification was there for a system of pricing that made the cost of drugs beyond the reach of the desperate? Could markets ever respond to need where effective demand was nil? Could the monopoly confirmed by patent rights be compatible with a response dictated by claims of the dying? Was the treaty on intellectual property rights, incorporated into the WTO's international regime, a barrier to survival in context of the AIDS epidemic? What moral obligation did the wealthiest nations have to the poorest to provide the resources necessary to purchase the new lifesaving agents and build the medical infrastructure necessary for their appropriate administration? Was there any reason to believe that a global community that permitted millions to die each year from treatable and preventable diseases such as tuberculosis and malaria would respond differently in the face of AIDS?

AIDS activists ultimately seized on this issue—Life Over Profits—and began an international campaign to confront the pharmaceutical industry. What might have seemed an utterly quixotic undertaking would, however, ultimately take on worldwide dimensions linking protesters in the United States, France, South Africa, institutional proponents of global health such as the WHO, and a sympathetic public. By the end of the 1990s, the pharmaceutical industry was placed on the defensive, perceived as protecting narrow self-interest when the lives of millions were at stake. Against the claims that high prices were necessary to fuel the engine of research, that patent protections were crucial to spurring investments in drug investigations, those who sought to turn the terms of discourse asserted that urgency demanded that the barriers to drug access tumble. As a leader of the International AIDS Society said in 2001, "This is a war, and when you are in a war as we are worldwide with HIV which will claim more lives

than any other infectious disease in history, the rules of the game have got to change."[46]

In the face of continuing criticism, drug companies argued that at most the price of drugs was a small part of the problem. The issue, they said, was the fundamental limits of the medical infrastructure of poor nations and the inability of the poorest to pay for even heavily discounted drugs. But such arguments, whatever their merits, carried little weight, as long as prices remained high or as long as the offer to negotiate price reductions entailed protracted processes. In early 2001 *The Lancet* thus wrote, "The time has come for the pharmaceutical industry and the governments who represent them in trade disputes to acknowledge that the world is facing an extraordinary challenge."[47]

Ultimately, under pressure from generic drug manufacturers, prices began to tumble, and pharmaceutical firms began to accept the notion of differential or equity pricing.[48]

As drug prices began to fall, it became ever more apparent that challenges posed by the international pharmaceutical industry as it resisted pressure by activists, the generic manufacturers and international public opinion, were not without foundation: Even if drugs were to be provided at cost, even if the principle of equity pricing were to guide sales, even if nations pursued the option of compulsory licensing and parallel imports, the cost of providing antiretroviral therapy was simply beyond the reach of the poorest and most HIV-burdened nations. And even if drugs could be paid for, the necessity of a medical infrastructure that could offer and monitor the use of drugs in a way that was attentive to the needs of individual patients and the risks to public health from drug resistance would require huge investments. This was the context within which a remarkable movement to create a massive funding effort to respond to the threat of AIDS would take shape.

In 2001, a Harvard University group issued a call to the global community. In an era of effective antiretroviral therapy, access to care was a moral imperative.[49] "We believe that on moral, health, social, and economic grounds the international community should provide new scientific and financial leadership for a rapid scaling-up of AIDS treatment in the poorest and hardest hit countries of the world." The goal was to treat one million patients in Africa within 3 years. It was simply untrue that the infrastructural capacity of African health-care systems precluded the provision of treatment. There were limits but they could be overcome with appropriate international assistance.

To those who had asserted that efforts to provide treatment would subvert already fragile prevention programs, a claim made by many of the humanitarian foundations that had funded such efforts, the Harvard group responded directly: "Treatment is necessary to optimize prevention efforts. When treatment is not available, less incentive exists for an individual to take an HIV test since HIV positive status not only is associated with social stigmatization but is tantamount to a death sentence. Ultimately, treatment of infected individuals may become a major tool in AIDS prevention."

Finally, it was argued that the provision of treatment was necessary to preserve the social fabric of societies affected with high levels of infection—"If the current lack of treatment continues, a demographic shift is predicted…such that teenagers will outnumber their elders by 2020. Further, without treatment, millions of adults in the prime of their working lives will die of AIDS and with them skills and knowledge that are necessary for human and economic development."

In assessing the potential costs of such an effort the Harvard group calculated that 1 million Africans could be treated for $1.1 billion a year. Were the program to expand to 3 million individuals, a goal achievable in 5 years, the cost would rise to $3.3 billion a year. (In considering the extension of care to non-Africans who could benefit from inaccessible treatment, it was estimated that approximately $1.4 billion would be needed in the first year and $4.2 billion by year 5.) But even so vast an effort would not cover large numbers of people in need of care. To reach those millions could require significant investments in medical infrastructure that were not calculated. Finally, in addition to the costs of care, it was estimated that for prevention efforts for Africa alone $3 billion was needed annually. Thus, in all, the first year's effort in Africa would require $4 billion. To meet this vast commitment it was proposed that an HIV/AIDS Prevention and Treatment Trust Fund be created. The sum involved, while very large, was not beyond the capacity of the wealthiest nations—0.01% of an aggregate GNP of $23 trillion.

The moral urgency of AIDS treatment was amplified by UN Secretary General Kofi Annan, who called for a global trust fund that would spend $7–10 billion a year over "an extended period" to face the threat to the world's poorest people.[50] Most striking was his assertion that the care which had for so long eluded men, women, and children in the less developed nations was a matter of right. Speaking to Africa's lenders he said, "Even a year ago few people thought that effective treatment could be brought within reach of poor people in developing countries. There has been a worldwide revolt of public opinion. People no longer accept that the sick are dying simply because they are poor. Everyone who is infected should have access to medicine and medical care. Now we know that that is possible, it is surely an ethical imperative."

Strikingly, the idea of a global trust fund not only won the support of editorialists identified with a liberal or social democratic posture but by powerful institutions as well. Within days of Annan's speech the International Monetary Fund and the governing committee of the World Bank endorsed the fund, in principle.[51] The Gates Foundation pledged $100 million to the effort.[52] In less than a year's time, the Global Fund

had been created. By 2005, AIDS funding for developing countries had reached $8 billion but even that vast expansion represents a shortfall given the pressing needs.

The gulf between conviction and action has become all the more stark as prevailing and pervasive international inequality has taken on moral significance: What was the unfortunate has become unfair; inequality has become inequity. In that translation, the possibility of human agency of political action to effect change opened wide the shortfall—the deep moral failure in allocating resources for AIDS care.

CONCLUSION

This chapter began with an analysis of ethical and policy issues that emerged in the United States and other economically advanced nations bounded by the liberal political tradition; it has concluded with a discussion of the profound moral challenge posed by the AIDS epidemic in the poorest nations, focusing on the question of access to care. It is in those nations that the epidemic will take its toll in tens of millions of lives.

No ethical analysis of the challenges posed by AIDS will ever again be sufficient if it is restricted to the challenges faced in wealthy developed nations. Indeed, increasingly the analysis will need to be driven by the complexities of an epidemic in the world's poorest nations. Older concerns rooted in a focus on the need to protect the privacy rights of individuals will inevitably be overshadowed by new concerns about equity. It is not that the older ethics will have no relevance. But with life itself in the balance, unless the material requirements of those who need access to care are given preeminence, little else will matter.

108 Information and Communication Technologies for Prevention and Control of HIV Infection and Other STIs

Walter H. Curioso, Ann E. Kurth, Magaly M. Blas, and Jeffrey D. Klausner

INTRODUCTION

Innovative tools such as the Internet, personal digital assistants, tablet computers, cell phones, and other technologies are a growing arsenal in the effort to prevent and* control HIV and other sexually transmitted infections (STIs). As the price of technology decreases, some of these tools have become more ubiquitous even in resource-constrained settings, and their uses are just beginning to be explored in depth. In this chapter, we review the opportunities and challenges of using information and communication technologies (ICT) for HIV/STI surveillance, diagnosis, partner notification, prevention, clinical management, and provider training, in both resource-rich and resource-constrained settings.

To do this, we conducted a literature review of English-, Spanish-, and Portuguese-language publications and conference proceedings in databases such as MEDLINE (from 1966 to April 2007), the Cochrane Library Database (up to Issue 1, 2007), LILACS (the Latin American and Caribbean Health Science Literature Database; from 1982 to April 2007), as well as the Google search engine. Additional articles were identified from references extracted from relevant articles, reviews, and from experts in the field.

SURVEILLANCE

As the diversity of HIV/STI epidemics around the world becomes more apparent, existing HIV/STI surveillance systems must be able to flexibly capture data to describe emerging infections or to explain changes over time in mature epidemics. Surveillance systems vary from simple systems that collect data from a single source, to electronic systems that receive data from many sources in multiple formats, to complex surveys. For ongoing systematic reporting, public health agencies increasingly rely on automated electronic laboratory reports of notifiable diseases and Internet-based confidential morbidity reporting from physicians. Other efforts, dubbed "second-generation surveillance systems," collect data among sentinel populations most at risk of becoming newly infected with HIV/STIs, e.g., populations with high levels of risk behavior or young people at the start of their sexual lives.[1]

HIV/STI surveillance often extends beyond case-based reporting to the monitoring of sexual-risk behavior at the population level. Such behavioral surveillance and associated research capture risk factor data, often including sensitive and stigmatized behaviors. This is best done in a way to minimize social desirability, reporting, and other biases.[2,3] Data collection methods that reduce the need for face-to-face acknowledgment of these behaviors, or that ensure anonymity, provide an important means of reducing these biases.[4,5] This may be facilitated by use of computer-assisted self-interviews (CASIs). CASIs with audio, video, or telephone enhancements have been used to assess general risks, patient histories, and a variety of health data, such as psychiatric and other clinical and public health data. In particular, using CASI, HIV/STI risks have been surveyed by researchers among populations including blood donors,[6,7] university students,[8] adolescents,[9,10] injection drug users,[11,12] alcohol users,[12] women at risk of seroconversion,[13,14] and HIV-seropositive individuals.[15,16] CASI studies conducted in STI clinics have shown enhanced reporting of some sensitive or stigmatized behaviors, as compared with face-to-face forms of data collection,[17] though not for all behaviors or equally by sex of the respondents.[18,19] Advantages of CASI-collected data include lower levels of missing data and of data entry errors as well as reduced costs.

In a systematic review of audio computer-assisted self interviews (ACASIs) for assessment of drug use and sexual behavior[20] conducted in 2004, it was found that out of 24 reviewed papers, only 3 described research implemented outside the United States. In the time since that review, the literature on use of ACASI in resource-constrained settings

*This communication was supported by the NIH Fogarty International Center Amauta Health Informatics Research and Training Program Grant Number D43 TW007551 and the CDC Mentored Scientist Award K01 (Kurth).

has grown, showing evidence of usefulness in countries such as Brazil, Vietnam, Thailand, India, Kenya, Zimbabwe, and South Africa, among others.[21–23] The NIMH Collaborative HIV/STI Prevention Trial conducted a feasibility study of ACASI in convenience samples in China, India, Peru, Russia, and Zimbabwe. The results suggested a high-comfort level among participants. The authors reported that despite variable computer experience and literacy, feasibility study participants reported ease in completing ACASI, and preferred a computer to an interviewer for answering sensitive questions, or had no preference.[24]

In clinical practice or research, the use of ACASI in conjunction with electronic health records could ultimately provide high-quality surveillance data linking risk behaviors to HIV/STI prevalence[18] and may also have some advantages in terms of systems efficiency. For example, a touch-screen ACASI blood donor interview system developed for blood banks in the United States was found in one study to increase donor time by 4 minutes but reduced staff time by 5 minutes;[25] the system also generates automated reports to the Food and Drug Administration. Use of an ACASI HIV counseling and testing tool by staff of a community-based mobile HIV testing organization in Seattle resulted in the agency doubling the number of HIV tests offered, with the same staffing level; the automated generation of required reports to the health department also shortened the billing and payment cycle.[26] For busy clinicians, ACASI sexual histories could be a practical tool for identifying persons at increased risk for infection.[18,27] ACASI interviews done prior to the clinician encounter (e.g., while the patient is in the waiting room) could increase the efficiency of the clinical visit,[28] allowing clinicians to triage and tailor counseling messages to the patient's specific situation.[29]

Telephone modalities have been explored for HIV/STI assessment. Computer-assisted telephone interviews (CATI) have been used in several population studies to collect HIV risk data.[30–39] These have been conducted at a population level from centralized call centers,[40] as well as through use of personal digital assistants (PDAs) in venues where higher risk populations may congregate, such as at Gay Pride events.[41] Mobile phone and interactive computer interviewing have been used to measure HIV-related risk behaviors, e.g., in a survey of 2416 adult men returning to Hong Kong from Shenzhen in mainland China during April 1997, who were intercepted at the exit of the checkpoint by systematic sampling.[42]

Cell phones also have been used to collect data and report sentinel events such as medication side effects. Cell-PREVEN Fig. 108-1 is an interactive computer system using cell phones for real-time collection and transmission of adverse events related to metronidazole administration among female sex workers (FSW) in Peru.[43] Curioso et al. developed Cell-PREVEN as an application for cell phones in Spanish, based on a system from Voxiva Inc. Cell phones

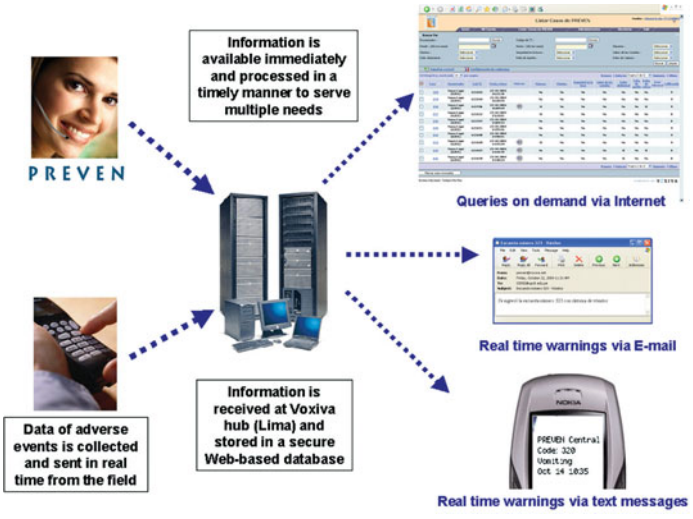

FIGURE 108-1. Description of cell phone and Internet data collection, "Cell PREVEN."

were used successfully as a method of data reporting for tracking adverse events attributable to medicine given to FSW in three communities. Information was stored in an online database, where it could be immediately accessed worldwide and exported over a secure Internet connection. E-mail and text messages sent to mobile devices alerted key personnel to selected symptoms. Both health-care interviewers and FSW were satisfied with cell phones as a method of data collection, and the system led to much earlier and more complete reports of adverse effects.[44]

Other software applications are being developed so that cell phones and PDAs can be used to transfer disease surveillance data, including for HIV infection, via a General Packet Radio Service connection or Short Message Service data channel into a central database, and to allow health workers to order medication, send alerts, and download treatment guidelines.[45]

Handheld CASI is emerging for data collection and intervention delivery due to advantages such as portability, lower cost compared to laptops, and energy efficiency, which could make handheld computers (e.g., PDAs, cell and "smart" phones) ideal for collecting data in the community. Data collection using handheld computers has been shown to be a faster and more accurate method for transferring data than paper-based methods, including scantron forms.[46] A 2004 conference on the use of handhelds in Africa concluded that PDAs were cheaper than paper-based health data collection due to reduced data management costs.[47] One study conducted among adolescents in South Africa to ascertain sexual risk, compared PDA to paper data collection and found reporting was equivalent by modality, but that the PDA format collected more complete data.[48] Data entry via a pen-based PDA may reduce technology anxiety compared to other forms of computer-aided data collection.[49]

Satellife (http://pda.healthnet.org/) are using the cell phone network in Uganda to transfer data to a central site. Local health-care workers collect data on Palm Pilots and then connect to a local, battery-powered server called a "Wide Ray Jack." This server allows data to be sent to and from a central database via a cell phone modem. In Peru, the PREVEN project conducted a cross-sectional field study in 20 cities with an open-source application for PDAs to collect sexual behavior data. The data collected with the PDA application, called PDA-PREVEN, showed very close agreement between paper and PDA responses. The project suggested that PDAs are a feasible alternative to paper forms for field data collection in a developing country.[50]

Computerized data collection for documenting risk behaviors may increase the reliability of sensitive data[51] as well as provide other advantages such as eliminating interviewer bias, ensuring that appropriate questions are asked of respondents, fewer missing data, and reduced data entry costs as compared to paper methods. Resource-constrained countries especially need data collection approaches that are reliable, inexpensive, readily available, and do not require extensive technological expertise to implement or use.[44] Cell-phone-based systems may best fit these requirements.

DIAGNOSIS AND PARTNER NOTIFICATION

Timely HIV/STI diagnosis and partner notification are important actions to initiate treatment and reduce further transmission in the population. Knowledge of an HIV-seropositive status is an important motivator for changing sexual risk practices and seeking medical care.[52,53] Additionally, with the current initiatives to provide universal access to antiretroviral therapy in developing countries, participants diagnosed with HIV will benefit from early entry into the health-care system.[54]

To increase HIV/STI diagnosis and improve partner notification, a variety of informatics tools that include the Internet and cell phones are being used. Use of these tools is appealing when they provide anonymity and convenience for the participants. In this section, we will review new technology approaches for HIV/STI testing and partner notification.

STI SCREENING

For several years, innovative World Wide Web sites to increase STI screening through on-site or self-collected specimens have been created in developed country settings. Some of these Web sites are www.inspot.org, www.STItest.org, and www.iwantthekit.org. InSPOT (see Fig. 108-2), an acronym for Internet Notification Service for Partners or Tricks, started on October 2004 in the city of San Francisco.[55] Although mainly used for partner notification, this Web site also offers information regarding HIV/STI prevention, on-site diagnosis and treatment, as well as locations of STI clinics in the U.S. cities of San Francisco, Chicago, Los Angeles, Philadelphia, and Portland, in the states of California, Colorado, Massachusetts, Indiana as well as the country of Romania (www.inspot.org).

STITest.org is a Web site of the San Francisco City Clinic that provides on-site testing, treatment, and information about a variety of STIs. An interesting component of this Web site is the opportunity for participants to create their laboratory requisition slip and receive their syphilis test online (www.STItest.org). During the first year of launching this program, 218 tests were performed and six patients were diagnosed and treated for a new syphilis infection.[56]

Another Web site used for STI screening is www.iwantthekit.org (Fig. 108-3). This Web site provides an educational Internet-based program to encourage women older than 13 years to request, use, and send back to the laboratory home-sampling kits for self-collection of specimens for *Chlamydia trachomatis* testing. After 1 week, the participants can call to the program and by using their kit's unique ID number and a private password can obtain their results. If the result is positive, the participant is referred to the nearest clinic to receive free treatment. During 7 months, 10% (41/400) of participants were found to be Chlamydia positive and 95.1% received treatment. There was good acceptability of this method: 89.5% of women preferred self-collection and 94% rated collection as easy or very easy. Compared to the community kit pick-up approach, this online program has shown better results: 97.2% of kits were requested by e-mail and 87.5% of kits returned for testing were e-mail requested.[57]

The Internet has been used to advertise kits that involve self-collection of specimens for HIV and STI at home that later are sent to the laboratory for analysis. Frank et al. in 1997 demonstrated that anonymous HIV-1 home specimen collection (HSC) kits with pretest and post-test telephone counseling provided a safe and effective alternative to conventional venous blood HIV-1 antibody testing.[58] Further studies have shown that HSC kits increase HIV testing among persons not previously tested, 60% of all users and 49% of those who tested HIV positive using the kit had never been tested before. Additionally, this way of testing is an acceptable option in the United States for persons with less access such as ethnic minorities or bisexuals.[59]

Only one HSC kit for HIV, The Home Access HIV-1 Test System manufactured by Home Access Health Corporation, has been approved by the U.S. Food and Drug Administration.[60] This kit may be purchased over-the-counter or on the Internet. The blood samples are taken at home by finger prick, and the dried blood spots are mailed to a laboratory for testing using an anonymous personal identification number (PIN). The pretest, and posttest counseling and the results are received through a toll-free telephone number using the PIN.[58]

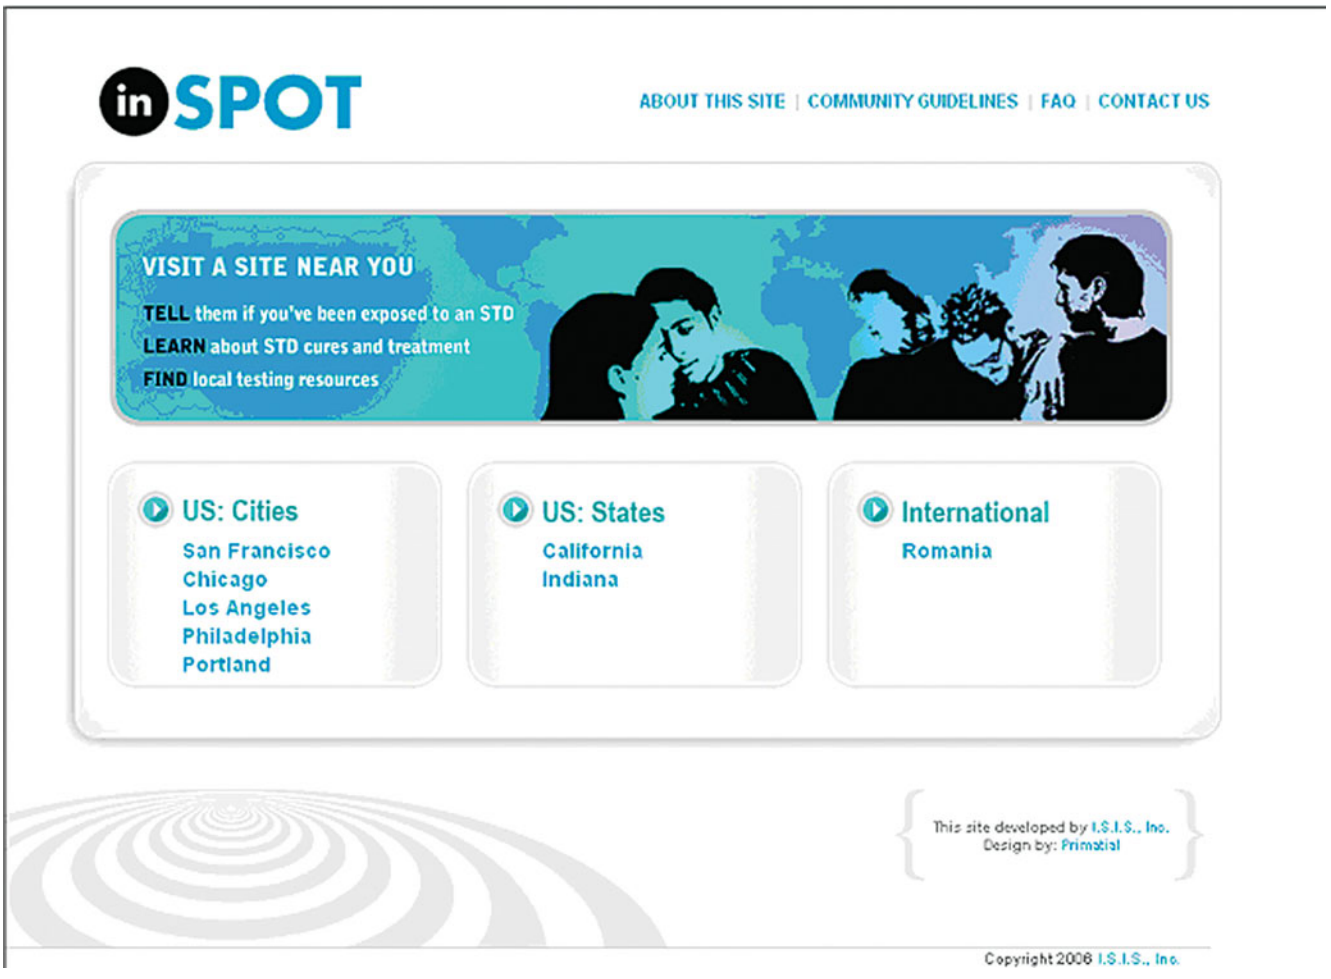

FIGURE 108-2. Screenshot of Internet-facilitated partner notification, "In SPOT" (www.inspot.org).

Evaluation of HIV self-testing is now being studied in the United States; this way of testing requires consumers to collect the sample, run the test, and interpret the results.[60] Although as of mid-2007, there were no FDA cleared home-use test kits, the existence of rapid HIV testing and HSC make its future implementation feasible. Additional research about the acceptability of the test in high-risk populations, feasibility to perform and interpret self-tests correctly, its impact on confirmatory testing, and on risk behaviors still need to be addressed.[61]

PARTNER NOTIFICATION: VIA THE INTERNET, VIA E-MAIL, WHAT ELSE IS COMING?

Partner notification—the process by which sex partners of index cases with HIV/STI are informed of their exposure and the need to receive medical evaluation[62]—traditionally has utilized telephone, mail, or personal contact. Recently, technologies such as cell phones, Internet, email and text messaging have been adopted.[63]

In the first study addressing the use of the Internet for online partner notification, participants of an Internet chat room were notified via e-mail messages about a syphilis cluster and encouraged to seek medical evaluation. As a result, 42% of named partners were notified and tested.[64] Further studies have analyzed different methods to improve partner response rates; some of the recommendations include the involvement of the index patient on the notification, conditional referral of the index patient where he/she is given a distinct time period to notify partners before the provider contacts them, inclusion of personalized messages that reference a specific health matter, the availability of health educators on chat rooms, and the provision of information on STI-testing sites, STIs, and partner referral on Web sites frequently visited by MSM.[65]

The InSPOT Web site was created to allow newly diagnosed patients with an STI/HIV infection the ability to inform anonymously or confidentially their partners through an electronic postcard that they might have been exposed to an STI or HIV. In 2005, this Web site had over 93,000 visitors and approximately 16,000 e-cards were sent to 26,000 recipients; 77% of these e-cards were sent anonymously, 14% notified about Chlamydia, 17% about gonorrhea, and 15% about syphilis.[66]

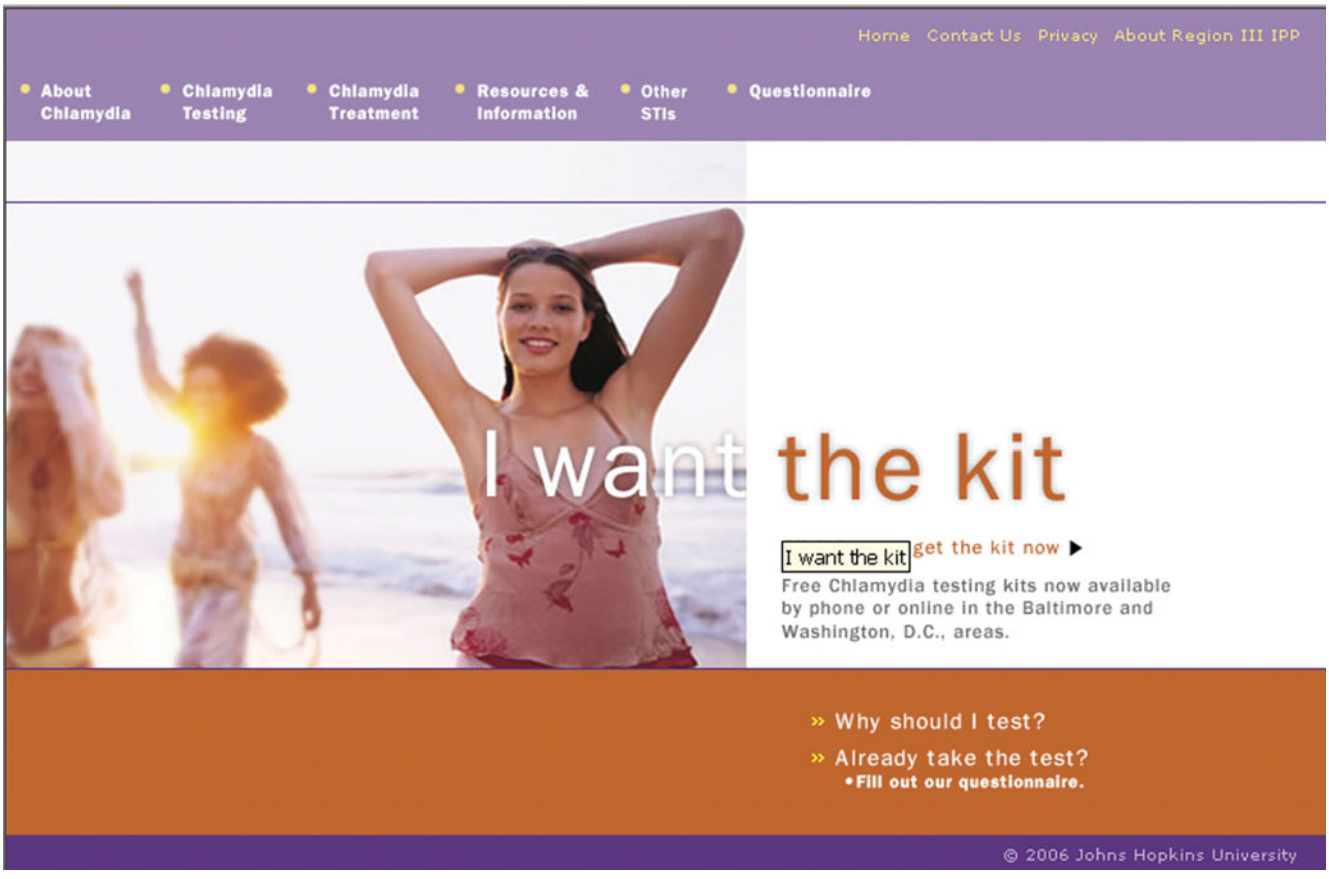

FIGURE 108-3. Screenshot of Internet-facilitated Chlamydia screening, "I Want the Kit" (www.iwantthekit.org).

Other forms of partner notification such as text messaging have been published. A case report of a partner receiving a text message with the diagnosis of trichomoniasis resulted in a timely treatment of this disease.[67]

Future directions for partner notification may involve a text or e-mail message from the health provider's mobile phone or computer to the partner(s) of the index case. The e-mail or text message could have a Web site address specific to each infection that could provide patients with additional information about the disease. In order to protect confidentiality, the Web site could be designed with mechanisms that ensure each page automatically expires when the user moves to another page or alternatively, the partner could be given instructions on how to erase the history of the visit when logging out. A user ID and password could be given to the partner to enter the site; this would not only protect privacy but also could provide an accurate number of contacts visiting the Web site, which can be useful for program evaluation purposes.[63]

While there are multiple benefits to the use of technology for partner notification, it nevertheless also has some risks. Internet and cell phone notification are not always confidential, e-mails can be read by others, mobile phones may be used by more than one person, e-mails and phones can change, and phones can be lost.[63] For these reasons and within the context of each public health effort, it is important to balance the risks and benefits of the use of these technologies before deciding their implementation.

PREVENTION

Effective prevention begins with a foundation of awareness and knowledge about HIV and STIs. One recent effort to promote awareness and increase knowledge and access to education about HIV and STIs using a cell phone short message service is SexTextSF in San Francisco (www.sextextsf.org).[68] This cell phone-based sexual health promotion service was based on a similar service developed by the Brook Charity in the UK. In the San Francisco example, the health department promotes in target communities, the text message "SEXINFO" and the call in number. Users access the discrete service via their text messaging program on their cell phone to reach a variety of topics in sexual health including the following: "What to do about a broken condom?" "If they think they are pregnant?" "Where to go for STI or HIV testing?" The evaluation of that project demonstrated that about 10% of the target population had used the service and use of the service could be associated with increased access to sexual health clinical services.[69]

Brief counseling interventions can reduce incident STIs,[70] yet not all settings have trained staff counselors or sufficient

clinician time to deliver evidence-based risk reduction. Computerized HIV/STI risk assessment and counseling tools may be an effective way to deliver behavioral interventions in busy clinical settings. Computer-delivered counseling interventions for HIV/STI prevention have been developed by several research groups in the last 15 years. Paperny reported in 1997 on a decade of use in Hawaii of a computerized adolescent health assessment and education tool that had been used by over 5000 adolescents.[71] Roberto and colleagues also developed a computerized HIV education tool for adolescents, testing it in two schools.[72] Weinhardt found that STI clinic patients were open to the idea of computer counseling delivered in waiting rooms.[73] Grimley and Annang's computer counseling tool delivered in an STI clinic waiting room was found in a randomized trial among 430 longitudinal enrollees to result in increased condom use at six months (21% increase in the intervention group vs. 13.3% in the control group, $p = 0.03$). Erbelding and colleagues in Baltimore also utilized an ACASI patient assessment designed to provide tailored, theory-based intervention strategies to the medical provider.[74] In a study involving 157 college students randomized either to 3 computerized sessions or to an attention-control arm receiving a nutritional tutorial, Kiene and Barta found a significant increase in self-reported condom use at six-weeks follow-up.[75] Kurth, Spielberg, Fortenberry, and Malotte developed a "Computer-Assisted Risk assessment and Education (CARE) for HIV/STIs" CD-ROM for use in clinical settings[76] to deliver interactive HIV/STI risk reduction counseling and rapid HIV testing administration, in a format that may allow more behavioral reflection on the part of the user.[77] A version of this software designed for use among people living with HIV is described in the "Clinical Management" section.

SEX-SEEKING OVER THE INTERNET: PROS, CONS, AND PROMOTING SEROSORTING

The use of the Internet to seek sex partners has been widely reported in developed and developing countries.[78,79] In some regards, at-risk populations such as men who have sex with men are leading the way in self-directed use of ICT, e.g., using the Internet to seek sex partners,[79,80] or health information. Offline sex that occurs following online solicitation may result in a disproportionately large risk of HIV and STI transmission.[81–83] Individuals who seek sex partners through the Internet may report a higher level of sexual risk behaviors such as higher number of partners, more anal sex, and more sexual exposure to partners known to be HIV positive compared to those who do not use the Internet to find sex partners.[81] Studies of patients at STI clinics found also that among this core group, the Internet has been a common venue for meeting and having sex with partners. In San Francisco, MSM with early syphilis infections reported the Internet as the most common place to meet sex partners, followed by bars, bathhouses, and sex clubs.[84] Having sexual intercourse with partners met online has also been directly linked to syphilis epidemics and HIV transmission. Klausner et al. in 2000 reported a syphilis outbreak among gay men linked to online chat rooms in San Francisco,[64] and Tashima et al. in 2003 reported two cases of acute HIV infection acquired through meeting persons over the Internet.[85]

The Internet does provide an environment where individuals may have open and anonymous discussions about their serostatus, preferences for certain sexual practices and condom use. Carballo-Dieguez et al. in 2006 found that both HIV-negative and HIV-positive MSM were more likely to engage in sexual negotiation and serostatus disclosure on the Internet than in person and that those who negotiate were also more likely to use condoms for anal intercourse.[86]

Among MSM, certain sexual harm reduction practices such as serosorting, strategic positioning, and withdrawal before ejaculation have been described.[87] Serosorting is a process by which individuals discuss their HIV status with potential partners and modify their sexual behavior based on the partner's serostatus.[87] Strategic positioning is a process by which individuals choose certain sexual positions to decrease the risk of transmitting or getting HIV, for example, they may choose to be the receptive instead of the insertive partner if their serostatus is HIV positive.[88]

EDUCATING PATIENTS WITH INFORMATION TECHNOLOGIES

The Internet constitutes an important source of information in health care. Patients can search for information about their diagnosis, seek out health-care providers, explore treatment options, and share opinions about their diseases.[89] The existence of chat rooms that allow real-time communication, forums, and discussion groups where participants can post messages about a specific topic and Web logs where they can comment, post news, or simply talk about their personal lives have changed the way patients interact with each other and has increased enormously the amount of information each participant shares and receives.

Practical criteria to evaluate Web sites are provided by the PILOT mnemonic, developed by Price,[90] to remind people what they should look for a trustworthy medical Web site:

- Purpose: If the site has a mission statement, read it. If not, read the home page and analyze the site's purpose. Does it inform and educate? Or is designed to persuade, sell, outrage, or entertain?
- Information: Truly useful medical Web sites offer valuable information and emphasize facts rather than opinion and testimonials. If the site is selling anything, ask yourself if that influences the content.

- Links: The best sites want to inform you and are happy to recommend additional Web sites to further enhance your knowledge in that topic or related topics. The best sites provide links that are rated or reviewed.
- Originator: Who is responsible for the information? Best bets for sound medical information are medical societies, consumer-advocacy groups, well-known hospitals, and government and university-sponsored sites.
- Timeliness: Medical information is only useful if it is current. Look for sites that update frequently.

The PILOT method has been used by Kalichman et al. to teach HIV-seropositive patients some useful skills for critically evaluating and using health information.[91]

The use of the Internet to provide patient education can be useful to target high-risk populations in developed and developing countries. Bull et al. found in a US study that MSM and persons with a history of STI testing were likely to endorse HIV/STI prevention through chat rooms, e-mails, and Web sites.[80] Alva et al. in 2005 found that among Peruvian HIV-positive persons, who used the Internet to meet sex partners 87.5% also sought information related to HIV, compared to 72.1% of such persons not seeking partners.[79]

Health departments, community-based organizations, and others have long used ICT to reach persons with information about HIV testing, HIV/STI prevention, and advocacy. Rai et al. reported the "Chandigarh AIDS hotline," a computerized telecounseling service in Chandigarh, India, for AIDS prevention and AIDS awareness. It is a 24 hour computerized interactive voice response service, which is accessible on a four-digit number (1097) by telephone.[92] Confidentiality and anonymity of the caller are the hallmarks of this service. The HIV/AIDS hotline is a toll-free service that provides information and counseling on HIV/AIDS related issues in English, Hindi (national language), and Punjabi (regional language).

Web-based health information and education may provide new ways to provide better access to difficult-to-reach populations, cities, and regions. Consider, for example, the great popularity and cheap cost of Internet cafes or "cabinas publicas" in Peru.[44] The unique popularity and low cost of Internet cafes in a growing number of countries open new possibilities to developing future web-based systems to show that effective information management can be possible in poor communities with no modern infrastructure but widespread use of internet cafes.

CLINICAL MANAGEMENT

ELECTRONIC HEALTH RECORDS (EHRS)

Electronic health records are evolving rapidly and are influencing clinical practice[93,94] particularly in chronic disease management. The EHR can provide data that are essential for implementing continuous quality improvement not only at the individual patient level, but also at the clinic or health system level. This will be useful not only for the chronic viral STIs, but will likely also prove essential for optimizing acute care management as well, for example, in management of bacterial STIs.[95,96] Clinicians need to monitor HIV patient status carefully and frequently, and intervene with various therapies. Effective health-care delivery requires innovative methods of disseminating medical knowledge and informing the physician about how to provide and monitor high-quality care. Physicians need easy access to patients' information, simplified reporting, guidelines that improve the quality of care, and methods to facilitate adherence to guidelines. Computer-based patients' records can provide a useful tool for such efforts.[94]

Since 1989, the U.S. Department of Veterans Affairs has maintained a national HIV registry and contains longitudinal data and detailed resource utilization and clinical information. The registry contains data that are electronically extracted from Veteran Affair's computerized comprehensive clinical and administrative databases, called "Veterans Integrated Health Systems Technology and Architecture."[97] In France, NADIS 2000 is an electronic health record program for patients with HIV infection and hepatitis that has been in use in centers of Infectious Diseases in France since November 2000. The tool permitted real-time use by the physicians in outpatient and day-care units and was easily handled by all the practitioners. The developers note that its use was facilitated by having clearly defined the system principles before its application, an intuitive interface simulating a consultation, and providing functions that benefit the physician users (graphical visualization of biological variables, printing of prescriptions and letters).[98]

In the United States, the National Institute of Allergy and Infectious Diseases funds the "Center for AIDS Research Network of Integrated Clinical Systems (CNICS);" a system of EHRs in use across seven HIV clinics. This extensive infrastructure will support basic, translational, and multidisciplinary research, allowing longitudinal tracking of patient outcomes and clinical specimens across sites.

AMPATH, the Academic Model for Prevention and Treatment of HIV/AIDS, is a collaboration of Moi University and the Moi Teaching and Referral Hospital in Eldoret, Kenya and the Indiana University School of Medicine. It was the first organization to offer comprehensive ambulatory HIV/AIDS care in Kenya, enrolling its first patient in November 2001 and by mid-2007 was caring for nearly 45,000 HIV-positive individuals. The AMPATH medical record system (AMRS) is sub-Saharan Africa's first EHR system for the comprehensive management of the clinical care of patients infected with HIV. It was based on an initial "Mosoriot medical record system."[99,100] This system,

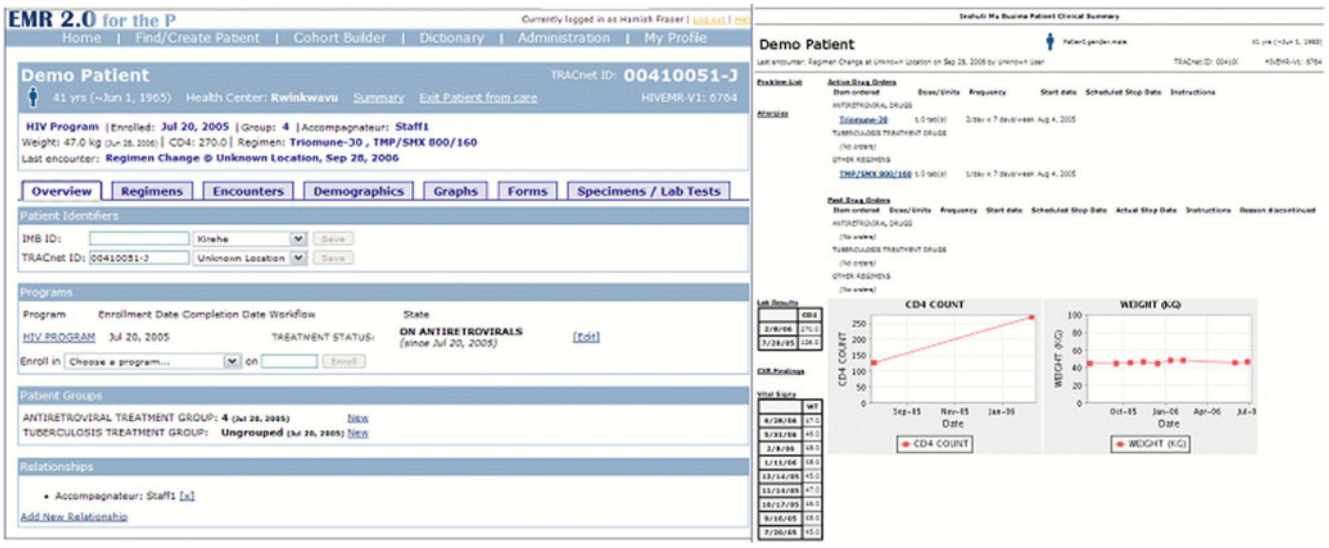

FIGURE 108-4. Example of HIV electronic health record "OpenMRS" architecture.

composed of both paper-based and electronic records, has been found by Siika and colleagues to lead to uniformity in data collection and to facilitate the retrieval of patient data for clinical care and research.[101] The AMRS was explicitly designed to use simple technology, in order to aid in the maintenance and sustainability of the system in resource-constrained environments; the tool is now in use in several countries in eastern Africa and elsewhere.[101] A Wiki (collaborative development) site for the openMRS system is available at http://openmrs.org/wiki/OpenMRS; see Fig. 108-4.

Web-based electronic medical record systems have shown that effective information management is possible in other poor communities without extensive modern infrastructure. In Peru, Fraser et al. described a web-based medical record system to support the management of multidrug resistant tuberculosis.[102] Web-based analyses have been developed to track drug sensitivity test results, patterns of sputum smear, and culture results and time to conversion from positive to negative cultures.[102]

Fraser et al. also described the "HIV-EMR," a prototype electronic medical record system to support treatment of HIV and tuberculosis in remote and impoverished areas in Haiti. This electronic medical record allows physicians to order medicines and laboratory tests, and provides alerts based on clinical status and test results.[103] Partners in health have also used web-based EHRs in Rwanda to support antiretroviral rollout.

Recently, Curioso et al. developed a web-based electronic report system for STI for the PREVEN project in Peru.[44] Interviewers entered their data directly into a single database as they progress through the reports, thereby saving time and costs over having the data entry done after data are collected. The system collects new participants and generates alert reports defined by the number of missed treatments that must be provided by the health-care interviewers. The system has the capability of searching so the interviewers can check past laboratory results and medications. The system allows real-time access of the database (only available for the team leaders) via the web.

DECISION SUPPORT SYSTEMS

The potential for computerization to improve clinical care has been appreciated for some time.[104] Advances in electronic medical record capabilities enable clinical reminders to inform providers when recommended actions are "due" for a patient. Computerized clinical reminders have been advocated as a strategy to improve adherence with established clinical guidelines. With clinical reminders, the software rather than the human initiates the human–machine interaction. Clinical reminders take advantage of preexisting electronic patient information to alert the provider when an action is recommended. In addition, clinical reminders are "real-time" decision aids in that they prompt providers to consider guideline-based advice when a patient record, and ideally the patient, is in front of the provider. As such, they have the potential to improve quality of care, for example, they can result in increased prevention interventions by busy clinicians.

In HIV care, clinical reminders were associated with more timely initiation of recommended practices. For example, Kitahata et al. demonstrated that HIV clinical reminders delivered at the time that HIV care is provided were associated with improvement in adherence to practice guidelines.[105]

Safran et al. demonstrated that when alerts and reminders are linked with a patient's computer-based patient record, adherence to a set of HIV practice guidelines can be improved.[94] Despite evidence that they improve adherence to guidelines, the U.S. Veteran's Health Administration has experienced challenges in having providers consistently use clinical reminders as intended.[106]

Creative utilization of hospital data environments may be an inexpensive route to improved compliance with practice guidelines. Shuter et al. reported that after the initiation of a weekly computer-based Pap smear reminder list in an HIV care clinic, the prevalence of scheduled women with up-to-date Pap smears increased from 61.4% to 73.2% ($p < 0.001$) during 1 year. The improved rate of up-to-date Pap smears showed no sign of attenuation over time.[107]

SUPPORT FOR PEOPLE LIVING WITH HIV

ICTs can help people with chronic diseases such as HIV to self-manage their treatment regimens, as well as to facilitate connection to others for psychological support. Gustafson and colleagues utilized one of the first web-based support sites for people living with HIV, known as the "Comprehensive Health Enhancement Support System."[108] Others have used the web to create virtual support or affinity groups, such as for HIV-positive adolescents.[109]

A randomized trial conducted by Flatley-Brennan et al. involved the use of a home-based computer network connected to the Internet (the ComputerLink) designed for people with AIDS to determine if the program would reduce social isolation and improve confidence and skill in decision making without causing differential decline in health status among people with AIDS. Services available included an online electronic encyclopedia, public and private communication, and a decision support system; a registered nurse coordinated all services. The authors concluded that computer networks provide feasible alternatives for the delivery of health services to homebound individuals. Communication services were used more extensively than other services, suggesting that the primary mechanism of intervention is peer contact. The system use improved confidence, though not skill, in decision making.[110]

VIHrtual Hospital is a telemedicine web system for improving home integral care of chronic HIV patients through the Internet implemented in Spain.[111] Using the videoconference, chat, or messaging tools included in the system, patients can visit their health-care providers (physician, psychologist, nurse, psychiatrist, pharmacist, and social worker), and gain access to the electronic patient record. The system also provides a telepharmacy service that controls treatment adherence and side effects, sending the medication to the patient's home by courier. The system facilitates communication between patients and improves the collaboration between professionals, creating a care plan for each patient. As a complement, there is a virtual library where users can find HIV/AIDS information helping to enhance prevention. This system has been developed using low cost technologies.[111,112]

Garcia et al. designed CREAIDS (Center of Reference for AIDS), a four-module patient-directed interactive software program for improving adherence to antiretroviral therapy.[113] Brock and colleagues have used PDAs to deliver medication adherence education; they found a short-term impact on self-reported adherence.[114]

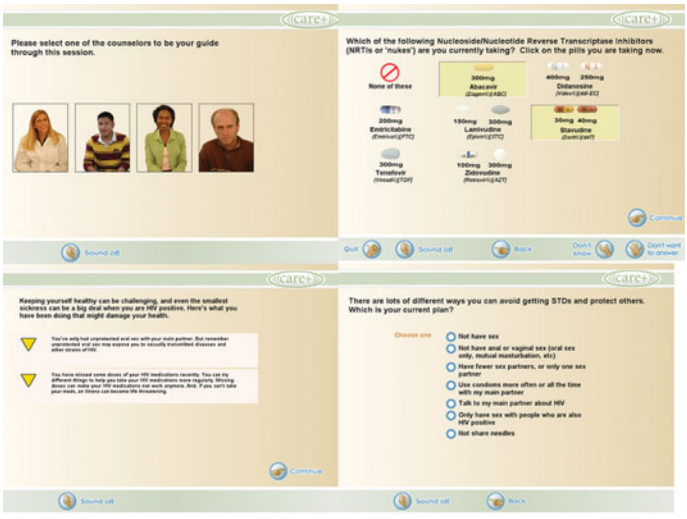

FIGURE 108-5. Screenshots of a computer counseling tool, "CARE +."

Figure 108-5 shows computer screenshot examples of a computer counseling tool called "CARE+" that was designed to support ART adherence and HIV transmission risk reduction. A randomized controlled trial among 240 adults with HIV in Seattle, WA, found that among those with detectable viral load at baseline ($n = 90$), the CARE+ intervention participants were twice as likely as controls to have undetectable viral load at the 6-month follow-up visit (RR 1.9, 49% vs. 26%; $p = 0.04$). There was a statistically significant reduction in condom use errors in the intervention arm at 6-month follow-up (RR 0.44, exact $p = 0.05$).[115]

Several studies utilizing human staff-delivered and automated text messages delivered to pagers and cell phones have been conducted in the United States, with a range of results.[116] Some have not found a meaningful impact of telephone-delivered support on outcomes of interest such as measures of depression among HIV-positive participants.[117] Others have found that use of interactive voice response-delivered phone calls to HIV-positive problem drinkers resulted in lower drinking levels over time.[118] Another study led by Reynolds for the AIDS Clinical Trials Group, found among 109 newly treated HIV-infected patients, a significantly better overall treatment effect at 64 weeks in the telephone group ($p = 0.023$); calls were associated with a promising but nonsignificantly reduced risk (HR = 0.68; 95% CI 0.38–1.23) for treatment failure.[119] Another randomized trial among HIV-positive patients who smoked found that participants who received a cellular telephone intervention were 3.6 times (95% CI 1.3–9.9) more likely to quit smoking compared with participants who received usual care.[120] Potential benefits of phone interventions (accessibility of delivery, potential cost-effectiveness as compared with

in-person delivery) must be weighed against the need for confidentiality (e.g., determining that the cell phone respondent is the participant/patient), targeting (e.g., actively substance-using patients may do better with face-to-face rather than telephone counseling delivery)[121] and sustainability, as effects may wane over time unless maintained, as was found in one study with HIV-positive adolescents.[122]

Cell phones are being used to support patient medication adherence in resource-constrained settings. In South Africa, the project Cell Life is using cell phones to monitor adherence for the management of HIV disease in patients on antiretroviral therapy. Some of the platforms used by Cell Life include a global system for mobile communications, wireless Internet gateway, and a geographical information system database.[123] A cell phone system in use in Rwanda over the course of 2 years connected 75% of the country's 340 HIV clinics and covered 32,000 people. Patient entry data are transmitted centrally to Kigali, and weekly reports are created to monitor various factors such as clinics' stocks of antiretroviral drugs and any relevant notices to providers.[124] In 2007, Voxiva announced an agreement with the U.S. President's Emergency Plan for AIDS Relief to utilize cell phone systems with HIV patients in 10 African countries.[125] While some have questioned health intervention delivery models that assume individual cell phone ownership,[126] such ownership and cell phone penetration are varied by setting, and also are increasing over time; it is estimated that within a few years, 80% of Africans will live in areas that will have cell phone coverage.

CONSULTATION USING TELEMEDICINE

Telemedicine supports of health-care delivery in remote areas.[127–129] Telemedicine holds the promise of improving access to health care, especially in areas where there are geographical barriers, and of reducing costs.[127] Several studies of telemedicine to support HIV patients are reported in the developed world,[111,112] but data are limited in developing countries.

In rural areas, telemedicine may support access for teleconsultation. TeleMedMail[130] is a software application to facilitate store-and-forward telemedicine by secure e-mail of images from digital cameras. TeleMedMail is written in Java and allows structured text entry, image processing, image and data compression, and data encryption. This web-based telemedicine system is currently under evaluation in South Africa and Peru, and Spanish and English versions are available.

The Internet has the potential to enhance collaboration among researchers by facilitating rapid dispersal of information and the coordination of numerous, complex, real-time interactions. One example of a working group was the Great Lakes Regional Center for AIDS Research. The Great Lakes Regional consortium of scientists at Northwestern University, the University of Minnesota, the University of Michigan, and the University of Wisconsin–Madison consolidated their complementary scientific expertise. Core facilities allowed investigators to join proteomics, genomics, bioinformatics, animal models, and clinical studies into a unified whole.[131] Figure 108-6 summarizes the range of information technology tools that a patient living with HIV might use.

PROVIDER TRAINING

COMPUTER-BASED TRAINING PROGRAMS

Digital resources can potentially serve as a powerful medium for the training of clinicians and other HIV/STI workers, delivered via CD-ROMS,[132] e-mail lists[133], and in recent years via the Internet.[134] Advanced communication technologies can create a cost-effective infrastructure to disseminate new intervention models to service providers worldwide.[134]

Given the necessity to support clinicians in treating patients with antiretroviral therapy, many institutions and organizations are developing computer-training programs for health-care providers working in developing countries.

The International Training and Education Center for HIV (I-TECH), which provides training in 25 countries, offers a wide range of training products tailored to each country's needs to help educate all members of society about HIV/AIDS. I-TECH (www.go2itech.org) has produced a broad spectrum of supportive media products and teaching aids, including videos in multiple languages, CD-ROM toolkit compilations; brochures for patients, and pocket guides and posters for health-care workers. I-TECH has assembled a listserv to include in-country clinicians in the periodic updates e-mailed to the I-TECH Clinical Team. I-TECH posts an electronic library of teaching cases for clinical training on HIV/AIDS care, and treatment with WHO and other partners.

I-Med Exchange, launched in July 2000 by the International Association of Physicians in AIDS Care, is a program directed to physicians and allied health professionals providing HIV/AIDS care in southern African countries—Botswana, Lesotho, Namibia, South Africa, and Swaziland. I-Med Exchange proposed to "bridge the digital divide" between the developing world and the developed world for health information, using information technology. The main, formal activity of physicians enrolled in the program was to participate in interactive online presentations accessed live on the Internet, or viewed as archived seminars either on an I-Med Exchange Web site or CD-ROM.[135]

The Institute of Tropical Medicine, Antwerp set up a computer-aided training program for health-care providers, working in more than 17 developing countries. Expert advice from HIV/AIDS specialists on treatment of HIV infection and

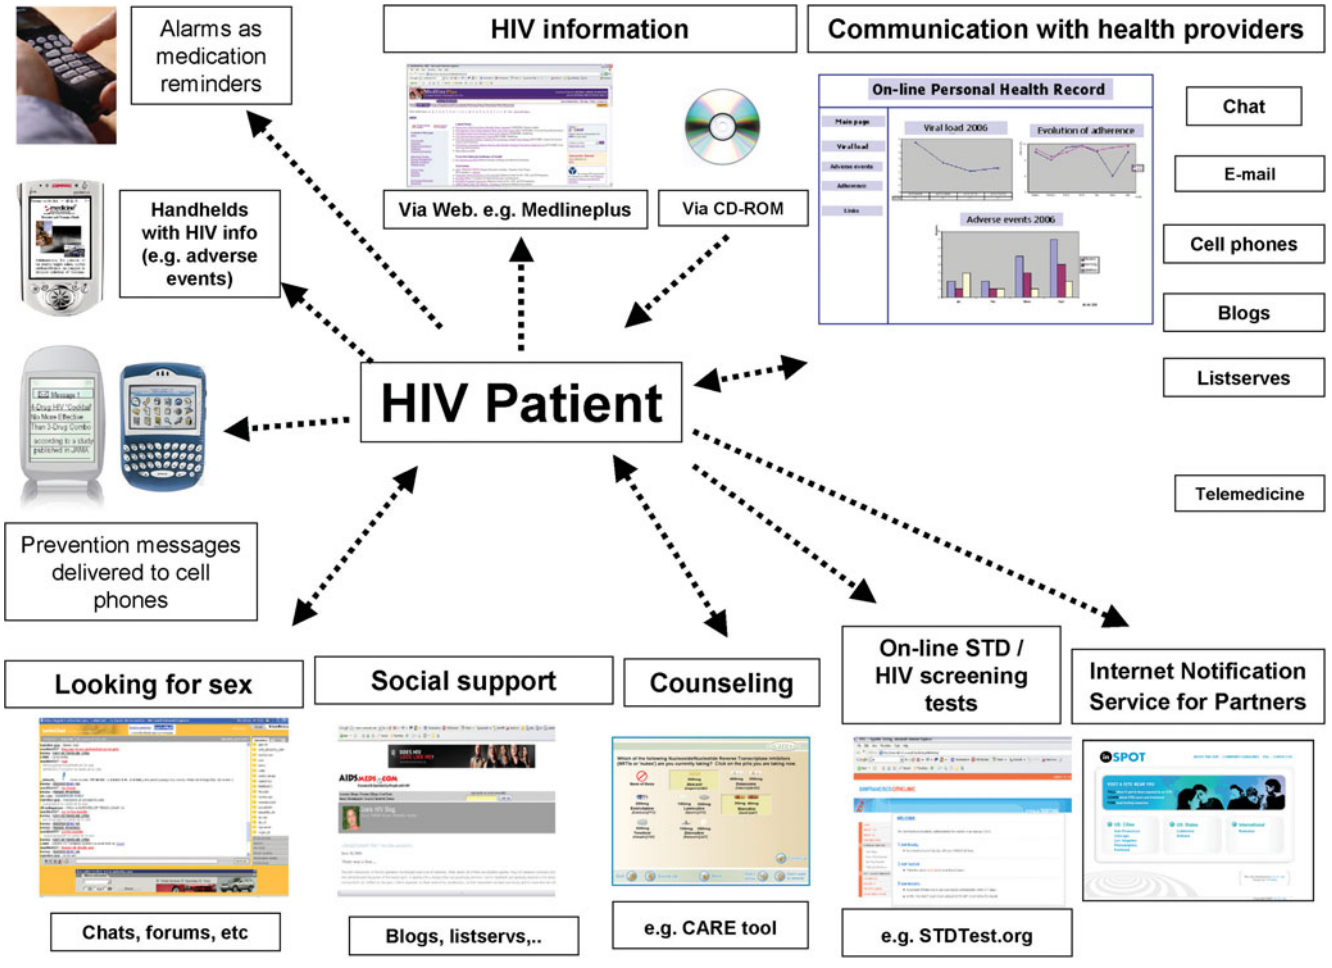

FIGURE 108-6. Overview of information and communication technologies available for HIV patients.

management of opportunistic infections have been offered to colleagues working in different countries. The telemedicine advice was organized initially through an e-mail network on a list server but later, in response to the need of continuous medical education on HIV and treatment, through a discussion forum on a telemedicine Web site (http://telemedicine.itg.be). E-mails have been used for years by the Antwerp Institute as a low cost telemedicine support for colleagues working in low resource countries. By giving the opportunity to trained clinicians to access continuous support and education through a discussion forum and policy documents on the Web site, the idea is to lower the threshold to launch HIV treatment projects in low resource settings.[136]

HIVeDucation is an interactive, HIV clinical management course tailored to the needs of clinicians in those regions of the world that have been hardest hit by the HIV epidemic. The course combines computer-based self-study modules, participatory clinical case studies, e-assisted tutoring, on-site workshops, and the building of peer consultation networks to provide an integrated clinical program. HIVeDucation has continuing education courses that can be completed online or with a jump/thumb drive, uploading pre/post test scores to the Web site: http://www.hiveducation.net.

Cure4Kids (http://www.cure4kids.org) is an Internet learning network that delivers medical education to doctors and nurses on pediatric cancer and AIDS. Cure4Kids also provides web conferencing tools for communication and collaboration.[137]

In China, Tucker et al. developed a HIV/STI training page for the Web site of the Chinese National AIDS Prevention and Control Center (http://www.aids.net.cn).[138]

A number of PDA-based resources are available for the HIV/STI clinician, some of them free of charge. Tice and Bhan reviewed many useful PDA-based resources for the infectious diseases specialist.[139] Additional resources can be found in review articles by Keplar.[140,141]

CONTINUOUS EDUCATION ON THE INTERNET

There is enormous potential to implement web-based continuing education in developing countries through online courses that can train and provide current information to health-care professionals in the management of HIV/STI. Studies have shown that web-based continuing education can improve health-care professionals' practical skills.[142] Technological advances that allow inclusion of interactive

links, video, images, and sounds make it increasingly feasible to illustrate and encourage realistic clinical problem solving.[142] Other advantages of web-based continuing education include absence of geographical barriers, user interaction, real-time interactivity, flexibility and potential low cost, important issues to consider in developing countries.

Most participants who engage in a web-based continued education are satisfied with the experience and find it to be an effective learning format. Barriers to web-based continued education include technical difficulties and lack of computer knowledge.[143]

For any web-based course to succeed, Wong et al. proposed the following 10 overlapping and iterative areas of activity that must be addressed: the market for the course; course aims and intends learning outcomes; choice of software platform; staff training needs; writing high-quality study materials; design features for active learning; technical and administrative challenges; evaluation and quality improvement; mainstreaming the course within the institution; and financial viability.[144]

Table 108-1 summarizes some of the free continuing education courses and activities for doctors and other health-care professionals. Of particular interest are learning tools for STI training available from the CDC STD Prevention Training Centers—e.g., Self-study STD Modules for Clinicians; ready-to-use curriculum for the clinical educators; and STD 101-in-a-box—all available at http://www.cdc.gov/std/training/default.htm.Also available is a comprehensive Web site developed by Drs. Spach and Marrazzo that features interactive case studies covering a broad array of topics related to hepatitis (http://www.hepwebstudy.org).

IMPACT OF INFORMATION TECHNOLOGIES RELATED TO HIV/STI IN RESOURCE-CONSTRAINED SETTINGS

Informatics is particularly useful for electronic health records, telemedicine, clinical decision systems, and improving access to information.[145] Yet, resource-constrained countries that can benefit the most from the use of informatics and telemedicine, are the ones that have the least access to them, and the highest burden of disease. Despite growing interest in telemedicine and medical informatics in these countries, issues of affordability, cost-effectiveness, and sustainability remain to be addressed.

Information systems should be carefully planned and integrated across different programs, especially in resource-constrained settings. Prahalad (2005) has reported that health workers in many developing countries spend as much as 40% of their time filling out paper-based forms, and compiling and copying data from different programs (e.g., tuberculosis, malaria, HIV/AIDS).[146] By choosing the most appropriate information technology, duplication can be avoided and appropriate devices—e.g., cell phones, Internet—can be deployed to report from public health programs. Development and evaluation of practical, low cost clinical information systems should be a priority in rolling out HIV treatment in developing countries.[103]

There is great potential to improve health through the use of ICTs in developing countries. The problems of low Internet diffusion and the digital divide are obstacles that developing countries face in using the Internet for development purposes. In some countries, one user may access the Internet in numerous ways including wireless, Internet cafes, kiosks, home, work, and/or school accounts.[44] Single accounts may be shared by many users. Some users are heavy users and others light users; some started long ago while others started recently. The diffusion of innovation is contingent not only on willingness to adapt to new technologies, but also on the financial and human resource base able to support these tools.

E-health in developing countries is a nascent reality that offers opportunities that need to be explored. Given the widespread access through Internet cafes in Latin America, there is potential to deploy web-based prevention intervention programs as well as educational interventions for HIV/STI, especially to difficult-to-reach populations and higher-risk groups such as men that have sex with men.[147] Those can be delivered at low cost and can be accessed by a great number of participants in innovative ways. In addition, the Internet also can be used to recruit people for randomized trials (for example, hard-to-reach populations like MSM) and to deliver testing and prevention messages.

In many developing countries, health workers have limited access to the Internet in their workplace. They may instead gain access from Internet cafes and other venues. While countries in Africa have the world's lowest Internet penetration (as a percentage of population), the continent also has the largest absolute growth in Internet usage from 2000 to 2007.[148] Moreover, up to 80% of Africans are projected to live within mobile phone coverage areas by 2010, making cell phone delivered data collection and interventions more feasible. The dramatically falling costs of computers suitable for Internet use should go some way to closing the gap between rich and poor. This price drop and accessibility to computers brings a unique opportunity for health-care delivery and research.

The past few years have witnessed several developments that are making access to information for scientists in the developing world more affordable.[149] These include initiatives promoted by scientists, libraries, publishers, academies, and societies. The WHO Sexually Transmitted Diseases Diagnostics Initiative (http://www.who.int/STI_diagnostics/) posts summaries and critical reviews of key articles related to STI screening approaches and technologies on a Web site to enhance access to the STD diagnostics literature in developing countries.[150] The Public Library of Science (http://www.publiclibraryofscience.org) is a nonprofit

Table 108-1. A Selection of Free HIV/STI Continuing Education Resources

Name	Courses, Online Modules
California STI/HIV Prevention Training Center http://www.STIhivtraining.org/	– Online Chlamydia course: The training is designed to increase knowledge of asymptomatic Chlamydia infection, the importance of screening young, sexually active women and the management of Chlamydia infected patients and their partners. During the course, you evaluate and treat two simulated patients. – Online STI case series: Presented by the National Network of STI/HIV Prevention Training Centers & Centers for Disease Control and Prevention (CDC).
CDC training and continuing education online http://www2a.cdc.gov/phtnonline/	– Incorporating HIV prevention into the medical care of persons living with HIV (web on demand). – Prevention with positives: HIV risk reduction strategies for health-care providers (web on demand). – Rapid testing: advances for HIV prevention (web on demand).
Clinical care options Hepatitis http://clinicaloptions.com/Hepatitis.aspx	A series of text-based or case-based interactive activities concerned with aspects of Hepatitis B and Hepatitis C infection.
Clinical care options HIV http://clinicaloptions.com/HIV.aspx	A series of text-based or case-based interactive activities concerned with aspects of HIV/AIDS.
FreeHepatitisInfo http://www.freehepatitisinfo.com/	HepatitisWATCH news is a monthly CE-accredited newsletter that brings updates on new information on the topics of hepatitis and hepatitis/HIV coinfection.
HCV advocate's online education center http://www.hepeducate.org/quizical/login.php (free registration required)	– Diagnosing HCV: Topics covered are the types of tests used to diag nose HCV, antibody tests, HCV viral load tests, the hepatitis C virus and its lifecycle, HCV genotypes and quasispecies, biochemical liver function tests, the significance of ALT levels, liver biopsies, the four histological stages of liver damage.
HIV web study http://depts.washington.edu/hivaids/index.html	Twelve half-hour modules concerning diagnosis and treatment of HIV/AIDS—initial evaluation; dermatologic manifestations; oral mani festations; opportunistic infections: prophylaxis; opportunistic infec tions: treatment; antiretroviral Rx; antiretroviral Rx: resistance; anti retroviral Rx: adverse effects; drug-drug interactions; postexposure prophylaxis; perinatal transmission; special populations.
International AIDS Society USA: cases on the web http://www.iasusa.org/cow/	A series of online continuum education (CE) activities sponsored by the International AIDS Society USA, including – clinical management of treatment-experienced patients presenting with virologic failure. – diagnosis and management of immune reconstitution syndrome in HIV-infected patients. – the importance of viral fitness and drug resistance in chronic and recent HIV infection. – perinatal HIV: special considerations.

(*Continued*)

Table 108-1. (*Continued*)

Name	Courses, Online Modules
Medscape HIV/AIDS http://www.medscape.com/hiv-aidshome	CE activities of special interest to physicians who treat HIV/AIDS. Medscape contains a variety of educational formats: – Conference coverage–Reports of advances presented at major medical conferences; typically includes several tracks with news sto ries, expert interviews, and in-depth topic overviews. – Clinical update–Comprehensive original review article on scientific advances in a clinical topic. – Fast track clinical update–Narrowly focused original review article on scientific advances in a clinical topic. – CE-live–Real-time online events with streaming video, synchronized visuals, and interactive questions and answers; archived for 1 year. – News-CE–Daily reports of major current medical research articles; 0.25 credits each – Journal CE–Articles selected from a wide selection of conference reports and peer-reviewed journals. – Special report CE–Topic-based monthly email newsletter distributed to Medscape's professional member database by specialty. – Interactive patient cases–Original CE activity presented to the physician in an interactive, clinical case-based format. – CE circle: Multimedia content certified by other accredited profe ssional education providers, typically from live symposia or mono graphs, and then posted on Medscape and archived for 1 year.
Medscape infectious disease http://www.medscape.com/infectiousdiseaseshome	CE activities of special interest to infectious disease specialists. Educational formats are similar as "Medscape HIV/AIDS."
MMWR continuing education programs (Centers for disease control) http://www2.cdc.gov/ce/availableactivities.asp	This site contains the PDF versions of several HIV-related articles published in the morbidity and mortality weekly Reports. You down load and read the articles, then submit your quiz answers online.
NNPTC online case series (National Network of STI/HIV Prevention Training Centers) http://www.STIhivtraining.org/nnptc/start.cfm.	The series includes case presentations of common STI-related syndromes. The guided interactive process helps you to evaluate each case, arrive at a diagnosis and provide recommended treatment.
STI/HIV case series (In Spanish). Universidad Peruana Cayetano Heredia/University of Washington. http://cursos.redpreven.org/	An interactive course with clinical cases to train health-care workers in the management of patients with STIs.

Updates can be found at: http://faculty.washington.edu/wcurioso/CE.htm.

organization of scientists committed to making the world's scientific and medical literature freely accessible to scientists and to the public around the world for the benefit of scientific progress, education, and the public good. The Open Archives Initiative (http://www.openarchives.org), supported by the Digital Library Federation and National Science Foundation, has its roots in an effort to enhance access to e-print archives as a means of increasing scholarly

communication. PubMed Central (http://www.pubmedcentral.gov) is a free-and-unrestricted digital archive of life sciences journal literature, developed and managed by the National Center for Biotechnology Information (NCBI) at the U.S. National Library of Medicine (NLM).

Many journals already have online publishing operations, and there is a growing tendency to publish material online only, to the exclusion of print. This literature must be preserved in a form that ensures open access to it over the longer term.[149] A number of journals and archives are now available free on the web. The Open Society Institute (Soros Foundation, http://www.soros.org/openaccess) has supported alternative journals and open archiving initiatives.

There are several nonprofit publishers/distributors of developing country journals and information. These include Bioline International (http://www.bioline.org.br), which hosts electronic versions of many developing country journals (most of them at a modest subscription fee); International Network for the Availability of Scientific Publications, or INASP (www.inasp.info/index.html), a cooperative network of partners whose mission is to enhance the flow of information within and between countries, especially those with less developed systems of publication and dissemination; SciELO (http://www.scielo.org), which hosts multiple journals published in Latin American countries; and African Journals Online or AJOL (http://www.inasp.info/ajol/index.html), which provides free online access to titles and abstracts of multiple African journals and full text on request. HINARI (Health Internet, http://www.healthinternetwork.org), a UN/WHO initiative, aims to provide commercial medical journals free to licensed countries in the developing world. PERI (Programme for the Enhancement of Research Information, http://www.inasp.info/peri/index.html) supports information production, access, and dissemination for research partners in developing and transitional countries utilizing ICTs.

HIF-net, launched in July 2000 by the International Network for the Availability of Scientific Publication and the WHO, is an e-mail discussion list (hif-net@dgroups.org) targeted mainly for providers and users of health information in resource-poor settings. It has more than thousands of subscribers spread over 130 countries. Another global networking health group is the Program for Monitoring Emerging Diseases, ProMEDmail (http://www.promedmail.org). This is an Internet-based reporting system that provides rapid access to information on outbreaks of infectious diseases and acute exposures to toxins.

IMPLICATIONS AND CHALLENGES OF ICTS IN HIV/STI

In this chapter, we have reviewed some of the published literature regarding the use of ICT applications to HIV/STI control. While a variety of ICT tools are in various stages of use for HIV/STI prevention, relatively few areas have accumulated a critical mass of evidence-based data about the most effective approaches. However, some of that evidence is compelling, and the potential for future uses appears large. Application to some areas of practice and research are nascent, the impact on disease incidence and economic evaluation data are still very limited, and evaluation of these tools would benefit from rigorous study designs. Nonetheless, these technologies very likely will become more available and potentially, more integrated, into routine HIV/STI prevention efforts. Appropriately, utilized technologies may improve HIV/STI screening, prevention, surveillance, and care for patients and populations in both resource-constrained and resource-rich settings.

A Appendix

Clinically Significant Drug Interactions with Medications for STDs and HIV

Alice K Pau

Treatment of HIV infection involves use of combinations of medications at the same time. Among the antiretroviral drugs, the protease inhibitors and non-nucleoside reverse transcriptase inhibitors have the greatest propensity of having pharmacokinetic interactions with each other and with other drugs commonly used in the HIV patients, including drugs used for the treatment of other sexually transmitted infections.

The most commonly encountered drug interactions that occur with medications used to treat HIV can be grouped into two major categories: overlapping/additive toxicities and pharmacokinetic interactions. Overlapping/additive toxicities are easily predictable with knowledge of the major side effects caused by each agent. For example, peripheral neuropathy can be a side effect of stavudine, didanosine, and zalcitabine; bone marrow suppression can occur frequently from zidovudine and ganciclovir; when these drugs are used in combination, invariably, increase in frequency and/or intensity of these adverse effects may ensue.

PHARMACOKINETIC INTERACTIONS

These interactions occur when one medication alters the concentrations of another by interfering with its absorption, metabolism, and/or elimination. Not all drug interactions lead to clinically significant events. It is of particular importance for those drugs, which have narrow margin of safety and efficacy. In these cases, increases in drug concentration or exposure may predispose the patient to concentration-related toxicities, whereas reduces in drug concentration may lead to inadequacy of its desired pharmacologic activity. Being able to recognize potentially significant interactions may help the clinicians to avoid these interactions or to manage them accordingly. The table provided in this appendix lists the known interactions and potential management strategies for drugs commonly used in treating HIV and STDs.

CHANGES IN DRUG ABSORPTION

The rate and extent of absorption can be affected by many factors, such as the presence or absence of food, gastric pH, rate of gastric emptying, malabsorption, the presence of metabolic enzymes such as the 3A4 isoenzyme of the cytochrome P450 system (CYP3A4), and efflux proteins such as p-glycoprotein in the gut lumen.

Some drugs may affect the oral absorption of others by alteration of some of the above listed factors. For example, the absorption of the protease inhibitor atazanavir requires an acidic pH. Coadministration of long acting proton pump inhibitors may significantly impair the absorption of atazanavir, resulting in subtherapeutic drug concentrations. On the other hand, the protease inhibitor saquinavir has very poor bioavailability due to the presence of the CYP 3A4 enzyme in the gut lumen, which metabolizes saquinavir before it can be absorbed systemically. Ritonavir given in conjunction with saquinavir can inhibit the CYP3A4 activities in the gut, resulting in substantially improved oral bioavailability. Some of these significant interactions are listed in the table.

CHANGES IN DRUG METABOLISM

Most of the significant drug–drug interactions occur when the hepatic metabolism of one drug is induced (hastened) or inhibited (slowed down) by the presence of another drug which can serve as an inducer or inhibitor of the enzymatic pathway. The cytochrome P450 system is the most important of such hepatic metabolic pathway, responsible for the metabolism of many drug compounds as well as endogenous chemicals such as corticosteroids. The HIV protease inhibitors, non-nucleoside reverse transcriptase inhibitors, azoles, macrolides, and rifamycins are some commonly used antiinfective agents that are metabolized through this pathway and may result in significant interactions when they are used in combination with each other. Careful evaluation of drug interaction potentials each time a new drug is prescribed is critical in order to avoid untoward reactions. The table provides the reader with some initial management strategy, although the clinicians should be cautioned that some interactions are highly variable from patient to patient,

the recommendations in the table do not preclude close clinical monitoring, and further dosage modification or drug discontinuation may be necessary in some patients.

Even though most significant drug–drug interactions may result in negative or undesirable outcome, the recognition of the potent inhibitory effect of ritonavir has led to the exploitation of this unique property to "boost" or "enhance" the systemic exposure of other protease inhibitors. The addition of low dose ritonavir to another protease inhibitor may result in delay in drug clearance, prolong elimination half-life, thus, allowing for less frequent dosing to improve drug adherence. On the other hand, one should be cautious about other drugs the patients may be taking concomitantly with a ritonavir-boosted regimen, as the concentrations of these other medications may be increased if the concomitant drug is a substrate of the CYP system.

CHANGES IN DRUG ELIMINATION

This most commonly occurs when use of a medication that compromises renal function (pentamidine, foscarnet, amphotericin) reduces the kidney's ability to eliminate renally cleared medications (such as penicillin, tenofovir). Drug concentrations may then increase and additional toxicities may develop.

DRUG INTERACTION TABLE

The following table should serve as a guide in helping to predict the outcome of combining medications used to treat HIV infection and sexually transmitted diseases. Because of the narrow therapeutic range of some of these medications it is critical that someone familiar with HIV care evaluates all medications a patient is taking for any possible drug interactions. Unless this is accomplished in a systematic manner a serious toxicity could result or efficacy of the regimen may be compromised and result in incomplete viral suppression and development of resistance. Clinicians are reminded that the absence of data does not always mean that it is safe to combine two drugs. New drug interaction data emerge frequently, significant interactions, which may lead to safety concerns, are often made public through alerts from the Food and Drug Administration and drug manufacturers. Clinicians should be kept abreast of these new information in order to provide the patients the safest possible drug therapy.

Significant Pharmacokinetic Interactions Between Drugs Used for Treatment of Sexually Transmitted Diseases, Including HIV Infection

Primary Drug	Secondary Drug	Interaction Result	Management of Interaction
Antibiotics used for STDs			
Azithromycin	Contraindicated drugs: none		
	Nelfinavir	⇑ Azithromycin level	Monitor for azithromycin toxicities
Cephalosporins	Contraindicated drugs: none		
	Probenecid	⇑ Cephalosporin level by inhibition of renal tubular secretion of cephalosporin	May enhance cephalosporin activity; monitor for toxicities
Ciprofloxacin, Gemifloxacin, levofloxacin, and moxifloxacin	Contraindicated drugs: none		
	Antacids with aluminum or magnesium salts; Calcium-containing products; Didanosine buffered formulation Iron supplements Sucralfate	⇓ Absorption of fluoroquinolones	Fluoroquinolones should be given at least 2 h before or 6 h after these products
	Drugs causing QTc prolongation, e.g., cisapride, Class IA Antiarrhythmics, Class III Antiarrhythmics, Erythromycin, etc.	May have additive effect in QTc prolongation with all fluoroquinolones–less likely with ciprofloxacin	Avoid these combinations if possible, only use if no alternative treatment

(Continued)

Primary Drug	Secondary Drug	Interaction Result	Management of Interaction
Clarithromycin	Contraindicated drugs: astemizole, terfenadine, cisapride, pimozide		
	Atazanavir	⇑ Clarithromycin levels, potential for ⇑ QT prolongation	Reduce clarithromycin dose by 50% & monitor for cardiotoxicity or use azithromycin
	Darunavir/ritonavir	⇑ Clarithromycin levels	Dosage reduction if creatinine clearance <60 mL/min; consider using azithromycin
	Delavirdine	⇑ Clarithromycin levels	Monitor for clarithromycin toxicities or use azithromycin
	Efavirenz	⇓ Clarithromycin levels	Significance unknown, consider using azithromycin
	Fluconazole	⇑ Clarithromycin levels, QT prolongation & torsades de pointes have been reported	Monitor for cardiotoxicity or use azithromycin
	Lopinavir/ritonavir	⇑ Clarithromycin levels	Dosage reduction if creatinine clearance <60 mL/min; consider using azithromycin
	Nevirapine	⇓ Clarithromycin level	Use azithromycin or monitor for clarithromycin efficacy
	Ritonavir	⇑ Clarithromycin levels	Dosage reduction if creatinine clearance <60 mL/min or use azithromycin
	Tipranavir/ritonavir	⇑ Tipranavir levels, ⇑ Clarithromycin levels	Dose reduction if creatinine clearance <60 mL/min, or use azithromycin
Erythromycin	Contraindicated drugs: astemizole, terfenadine, cisapride, pimozide		
	Gemifloxacin, levofloxacin, moxifloxacin	May have additive effect in QTc prolongation	Use this combination with caution, esp. in at-risk patient; possibly use an alternative fluoroquinolone such as ciprofloxacin
Metronidazole	Contraindicated drugs: none		
	Amprenavir oral solution	Potential for propylene glycol toxicity as patients on metronidazole may not adequately metabolize and eliminate propylene glycol–a solvent in amprenavir oral solution	Use amprenavir oral solution only if fosamprenavir cannot be used
	Ritonavir, lopinavir/ritonavir oral solution	Inhibition of alcohol and aldehyde dehydrogenase by metronidazole. Possible disulfiram-like reaction due to alcohol in these preparations	
Penicillin	Contraindicated drugs: none		
	Probenecid	⇑ Penicillin level & half-life by inhibition of renal tubular secretion of cephalosporin	May enhance penicillin activity; monitor for toxicities

(*Continued*)

(Continued)

Primary Drug	Secondary Drug	Interaction Result	Management of Interaction
Tetracycline (mainly doxycycline)	Contraindicated drugs: none		
	Antacids, bismuth, cholestyramine, didanosine buffered formulations, and oral calcium, magnesium, aluminum, and iron products	⇓ Tetracycline absorption	Separate doses by giving tetracyclines at least 2 h before these products
	Atovaquone	May ⇓ atovaquone level	Monitor for atovaquone efficacy
Antifungal drugs used for STD			
Fluconazole	Contraindicated drugs: astemizole, terfenadine, cisapride		
	Clarithromycin	⇑ Clarithromycin levels, QT prolongation & torsades de pointes have been reported	Monitor for cardiotoxicity or use azithromycin
	Nevirapine	May ⇑ Nevirapine level	Monitor for nevirapine-associated toxicities
	Tipranavir/ritonavir	⇓ Tipranavir level	No dosage adjustment of tipranavir/ritonavir recommended; fluconazole dose >200 mg not recommended
Antiretroviral therapy–nucleoside reverse transcriptase inhibitors			
Abacavir	Contraindicated drugs: none		
	Tipranavir/ritonavir	⇓ Abacavir level	No dosage adjustment recommended, monitor antiviral efficacy
Didanosine (ddI)	Contraindicated drugs: none		
buffered formulations	Drugs should not be used with didanosine: Ribavirin (see below), allopurinol, stavudine (during pregnancy–only if benefits outweigh the risk of lactic acidosis/hepatic steatosis/pancreatitis)		
	(Amprenavir/ Fosamprenavir)	Potential for ⇓ amprenavir absorption due to ⇑ in gastric pH	Separate administration by at least 1 h
	Atazanavir	⇓ Atazanavir absorption due to ⇑ in gastric pH	Use enteric coated ddI
	Ciprofloxacin & other fluoroquinolones	⇓ Fluoroquinolone absorption due to chelation from magnesium/aluminium cations	Use enteric coated ddI. If buffered formulation is used, take fluoroquinolones at least 2 h before or 6 h after ddI
	Delavirdine	⇓ Delavirdine–absorption when used with buffered ddI	Use enteric coated ddI or separate administration by at least 1 h
	Ganciclovir (oral and IV)	⇑ Didanosine levels	No dosage adjustment recommended. When used together, monitor for didanosine toxicities (pancreatitis, peripheral neuropathy)
	Indinavir	⇓ Indinavir absorption when buffered ddI is used; not affected by enteric coated ddI	Use enteric coated ddI or take indinavir at least 1 h before ddI
	Lopinavir/ritonavir	⇓ Lopinavir absorption	Take any ddI preparation at least 1 h before or 2 h after lopinavir/ritonavir

(Continued)

Primary Drug	Secondary Drug	Interaction Result	Management of Interaction
	Ribavirin	⇑ intracellular concentration of ddI–increased serious ddI-associated mitochondrial toxicities	Avoid concomitant use
	Tenofovir	⇑ ddI level–for both buffered and enteric coated formulations	⇓ ddI dose to 250 mg/d for pts >60 kg, and to 200 mg/d for pts <60 kg; monitor for ddI-associated toxicities
	Tipranavir/ritonavir + Enteric Coated ddI	⇓ Didanosine level	Clinical relevance unknown, no dosage adjustment recommended. For optimal absorption, give didanosine separate from tipranavir/ritonavir by at least 2 h
Emtricitabine	No significant pharmacokinetic interactions		
Lamivudine	No significant pharmacokinetic interactions		
Stavudine	Contraindicated drugs: none		
	Drugs not recommended to use with stavudine: Zidovudine (antagonistic antiretroviral effect), didanosine (additive toxicities–only if benefits outweigh the risk of lactic acidosis/hepatic steatosis/pancreatitis/additive peripheral neuropathy)		
	No other significant pharmacokinetic interaction		
Tenofovir	Contraindicated drugs: none		
	Atazanavir	⇓ Atazanavir levels	Add ritonavir 100 mg/d; dose atazanavir at 300 mg once daily
	Didanosine	⇑ Didanosine level–for both buffered and enteric coated formulations	⇓ ddI dose to 250 mg/d for pts >60 kg, and to 200 mg/d for pts <60 kg, monitor for didanosine associated toxicities
	Lopinavir/ritonavir	⇑ Tenofovir level	No dosage adjustment necessary
Zidovudine	Contraindicated drug: none		
	Drugs should not be used with zidovudine: Stavudine–antagonistic antiviral effect		
	Probenecid	⇑ Zidovudine levels	Monitor for increase bone marrow suppression
	Rifampin	⇓ Zidovudine levels	Monitor for zidovudine efficacy; consider using rifabutin
	Tipranavir/ritonavir	⇓ Zidovudine levels	Clinical relevance unknown, no dosage adjustment recommended
Antiretroviral therapy–non-nucleoside reverse transcriptase inhibitors			
Delavirdine	Contraindicated drugs: astemizole, terfenadine, cisapride, pimozide, ergot derivatives, alprazolam, triazolam, midazolam		
	Drugs should not be used with delavirdine rifampin, rifabutin, amprenavir, fosamprenavir, carbamazepine, phenytoin, phenobarbital, St. John's Wort, lovastatin, simvastatin		
	Amprenavir and fosamprenavir	⇑ Amprenavir levels, but significant ⇓ in delavirdine level (Cmin ⇓ by 88%)	Do not coadminister. Alternative NNRTI (efavirenz or nevirapine) should be used
	Clarithromycin	⇑ Clarithromycin level	Use azithromycin. If clarithromycin is used, dose reduce if creatinine clearance <60 ML/min

(*Continued*)

(Continued)

Primary Drug	Secondary Drug	Interaction Result	Management of Interaction
	Didanosine (ddI) buffered formulation	⇓ Delavirdine levels	Consider enteric coated ddI; or take delavirdine at least 1 h before buffered ddI
	Indinavir	⇑ Indinavir concentration	No dosage adjustment necessary
	Lopinavir/ritonavir	⇑ Lopinavir level	Doses not established, monitor for lopinavir/ritonavir toxicities
	Nelfinavir	⇑ Nelfinavir level, ⇓ delavirdine level	No dosage adjustment recommended; consider using alternative NNRTI
	Saquinavir	⇑ Saquinavir level	Effect on ritonavir-boosted saquinavir unknown; no dosage adjustment recommended at this point
Efavirenz	Contraindicated drugs: astemizole, cisapride, midazolam, triazolam, ergot derivatives, voriconazole (see below)		
	Atazanavir	⇓ Atazanavir level	Only use with ritonavir boosting
	Clarithromycin	⇓ Clarithromycin level	Significance unknown, consider using azithromycin
	Fosamprenavir	⇓ Amprenavir level	Only use with ritonavir boosting
	Indinavir	⇓ Indinavir levels 30–35%	⇑ Indinavir to 1000 mg Q8H or use with ritonavir boosting
	Lopinavir/ritonavir	⇓ Lopinavir level	⇑ Lopinavir/ritonavir to 600 mg/150 mg (3 tablets) twice daily; once daily lopinavir/ritonavir should not be used with efavirenz
	Ritonavir	⇑ Ritonavir, ⇑ Efavirenz	Monitor for toxicities of both drugs
	Saquinavir	⇓ Saquinavir levels 60%	Use only with ritonavir boosting
	Tipranavir/ritonavir	⇓ Tipranavir level	No dosage adjustment recommended
Nevirapine	Contraindicated drugs: none		
	Atazanavir	May result in ⇓ Atazanavir level	Concomitant use only if atazanavir is boosted with ritonavir
	Clarithromycin	⇓ Clarithromycin level	Use azithromycin or monitor clarithromycin efficacy
	Fluconazole	⇑ Nevirapine level	Avoid concomitant use or monitor for nevirapine toxicities
	Fosamprenavir	May result in ⇓ Amprenavir level	Not recommended unless with ritonavir-boosting
	Indinavir	⇓ Indinavir AUC	⇑ Indinavir dose to 1000 mg q8h or add ritonavir to ⇑ indinavir level
	Lopinavir/ritonavir	⇓ Lopinavir concentration	⇑ Lopinavir/ritonavir to 600 mg/150 mg twice daily; once daily lopinavir/ritonavir should not be used with nevirapine
	Saquinavir	⇓ Saquinavir levels	Saquinavir should not be used with nevirapine without pharmacokinetic boosting (e.g., with ritonavir)

(Continued)

Primary Drug	Secondary Drug	Interaction Result	Management of Interaction
Antiretroviral therapy–protease inhibitors			
Amprenavir (and fosamprenavir)[a]	Contraindicated drugs: cisapride, ergot derivatives, pimozide, midazolam, triazolam		
	Drugs should not be used with amprenavir oral solution or fosamprenavir: bepridil, delavirdine, lovastatin, simvastatin, rifampin, rifapentine, St. John's Wort, tipranavir, ritonavir oral solution (not to be given with amprenavir oral solution–see below)		
	Delavirdine	⇑ Amprenavir level; ⇓ Delavirdine Level	Do not coadminister
	Didanosine buffered formulations	May ⇓ Amprenavir absorption	Separate dosing by at least 1 h
	Efavirenz + Fosamprenavir	⇓ Amprenavir level	Only use with ritonavir boosting; if once daily ritonavir + fosamprenavir is used, an additional 100 mg of ritonavir should be added
	Indinavir	⇑ Amprenavir level; ⇓ Indinavir level	Dosing recommendation not established, monitor for viral efficacy
			Monitor for toxicity of both drugs
	Lopinavir/ritonavir + Fosamprenavir	⇓ Fosamprenavir, ⇓ Lopinavir	Doses not established; increased rate of adverse events seen when use in combination
	Metronidazole (with amprenavir oral solution)	Metronidazole inhibits alcohol & aldehyde dehydrogenase–may lead to propylene glycol toxicity (propylene glycol is solvent in amprenavir oral solution)	Use fosamprenavir oral capsule or other protease inhibitor; or avoid metronidazole
	Nevirapine	May ⇓ Amprenavir level	Consider alternative therapy; or use ritonavir to ⇑ amprenavir level
	Ritonavir oral solution + Amprenavir oral solution	The ethanol in ritonavir oral solution may compete with the propylene glycol in amprenavir oral solution in their metabolic pathway, leading to accumulation of either ethanol or propylene glycol	Concomitant administration of the two products is not recommended
	Ritonavir + Fosamprenavir	⇑ Amprenavir level	Low dose ritonavir (200 mg/d) may be used to boost amprenavir level
	Tipranavir/ritonavir	⇓ Amprenavir level	Do not coadminister
Atazanavir	Contraindicated drugs: cisapride, ergot derivatives, pimozide, midazolam, triazolam		
	Drugs should not be used with atazanavir: bepridil, rifampin, rifapentine, proton pump inhibitors, indinavir, lovastatin, simvastatin, irinotecan, St. John's Wort		
	Clarithromycin	⇑ Clarithromycin level; ⇑ Atazanavir level	⇓ Clarithromycin dose by 50% (to avoid risk of arrhythmia)
			Alternative: Azithromycin
	Didanosine buffered formulations	⇓ Atazanavir absorption due to ⇑ gastric pH	Use enteric coated didanosine

(*Continued*)

(Continued)

Primary Drug	Secondary Drug	Interaction Result	Management of Interaction
	Efavirenz	⇓ Atazanavir level	Only use this combination with ritonavir boosting
	Nevirapine	Not studied; potential for ⇓ Atazanavir level	Not recommended to be used concomitantly; if combined, add ritonavir and consider therapeutic drug monitoring
	Ritonavir	⇑ Atazanavir level	Ritonavir 100 mg/d recommended as pharmacokinetic enhancer
	Saquinavir	⇑ Saquinavir level	Appropriate dose for saquinavir + atazanavir +/- ritonavir has not been established
	Tenofovir	⇓ Atazanavir level	Use the combination only with ritonavir boosting (ritonavir 100 mg + atazanavir 300 mg—both once daily)
Fosamprenavir (Pro-drug of amprenavir)	See drug interaction information under Amprenavir		
Indinavir	Contraindicated Drugs: Astemizole, terfenadine, amiodarone, ergot derivatives, cisapride, midazolam, pimozide		
	Drugs should not be used with Indinavir: Atazanavir, lovastatin, simvastatin, rifampin, rifapentine, St. John's Wort		
	Clarithromycin	⇑ Indinavir level; ⇑ Clarithromycin level	No dosage adjustment
	Delavirdine	⇑ Indinavir level	No dosage adjustment
	Didanosine buffered formulation	⇓ Indinavir level	Use enteric coated didanosine preparation or separate indinavir and didanosine by at least 1 h
	Efavirenz	⇓ Indinavir levels	⇑ Indinavir to 1000 mg every 8 h or add ritonavir to boost indinavir level
	Ketoconazole	⇑ Indinavir level	No dosage adjustment needed
	Nevirapine	⇓ Indinavir level	⇑ Indinavir to 1000 mg every 8 h or add ritonavir to boost indinavir level
	Ritonavir	⇑ Indinavir level	Add ritonavir as pharmacokinetic enhancer—ritonavir 100–200 mg twice daily + indinavir 800 mg twice daily
	Saquinavir	⇑ Saquinavir levels	Dosage for this combination not yet established
Lopinavir/ritonavir	Contraindicated drugs: astemizole, terfenadine, cisapride, pimozide, ergot derivatives, midazolam, triazolam		
	Drugs should not be used with lopinavir/ritonavir: rifampin, rifapentine, lovastatin, simvastatin, St. John's Wort, fluticasone, tipranavir/ritonavir		
	Clarithromycin	⇑ Clarithromycin level	Reduce clarithromycin dose in patients with creatinine clearance <60 mL/min
	Delavirdine	⇑ Lopinavir level	Doses not established, monitor for lopinavir/ritonavir toxicities
	Didanosine	⇓ Lopinavir/ritonavir absorption	Take didanosine at least 1 h before or 2 h after lopinavir/ritonavir
	Efavirenz	⇓ Lopinavir level	⇑ Lopinavir/ritonavir to 533 mg 133 mg twice daily; once daily lopinavir/ritonavir should not be used with efavirenz

(Continued)

Primary Drug	Secondary Drug	Interaction Result	Management of Interaction
	Fosamprenavir	⇓ Fosamprenavir level, ⇓ Lopinavir level	Doses not established; increased rate of adverse events seen when use in combination.
	Metronidazole with lopinavir/ritonavir oral solution	Inhibition of alcohol and aldehyde dehydrogenase by metronidazole. Possible disulfiram-like reaction due to alcohol in lopinavir/ritonavir oral solution	Do not coadminister–may consider oral capsule formulation, at least during concomitant metronidazole therapy
	Nevirapine	⇓ Lopinavir level	⇑ Lopinavir/ritonavir to 600 mg/150 mg twice daily; once daily lopinavir/ritonavir should not be used with efavirenz
	Saquinavir	⇑ Saquinavir level	Reduce saquinavir dose to 800 mg twice daily
	Tenofovir	⇑ Tenofovir level	No dosage adjustment
	Tipranavir/ritonavir	⇓ Lopinavir level	Do not coadminister
Nelfinavir	Contraindicated drugs: amiodarone, quinidine, astemizole, terfenadine, cisapride, ergot derivatives, pimozide, midazolam, triazolam		
	Drugs that should not be coadministered with nelfinavir: Lovastatin, simvastatin, rifampin, St. John's Wort		
	Azithromycin	⇑ Azithromycin level	No dosage adjustment recommended
	Delavirdine	⇑ Nelfinavir level, ⇓ delavirdine level	Dosage has not been established; monitor for nelfinavir toxicities
	Efavirenz	⇑ Nelfinavir	Use standard dose for both
	Indinavir	⇑ Indinavir level and ⇑ nelfinavir level	No dosage established; monitor for excessive toxicities of both drugs
	Saquinavir	⇑ Saquinavir level	⇓ Saquinavir to 1,200 mg twice daily
Ritonavir	Contraindicated drugs: amiodarone, bepridil, flecainide, propafenone, quinidine, astemizole, terfenadine, cisapride, ergot derivatives, pimozide, midazolam, triazolam		
	Drugs not to coadminister with ritonavir: lovastatin, simvastatin, St. John's Wort, fluticasone, alfuzosin, rifapentine, and voriconazole (if ritonavir > 400 mg twice daily is used)		
	Atazanavir	⇑ Atazanavir level	Low dose ritonavir (100 mg/d) may be used to boost atazanavir level; Atazanavir dose: 300 mg once daily
	Clarithromycin	⇑ Clarithromycin level	⇓ Clarithromycin dose in patients with creatinine clearance <60 mL/min
	Fosamprenavir	⇑ Amprenavir level	Low dose ritonavir (200 mg/d) may be used to boost amprenavir level (fosamprenavir 700 mg + ritonavir100 mg) twice daily; or (fosamprenavir 1400 mg + ritonavir 200 mg) once daily
	Indinavir	⇑ Indinavir levels	Low dose ritonavir (200–400 mg/d) may be used to boost indinavir level; Indinavir dose 800 mg twice daily

(*Continued*)

(Continued)

Primary Drug	Secondary Drug	Interaction Result	Management of Interaction
	Metronidazole	Inhibition of alcohol and aldehyde dehydrogenase by metronidazole. Possible disulfiram-like reaction due to alcohol in ritonavir preparations	Use with caution and monitor for disulfiram-like reactions
	Nelfinavir	⇑ Nelfinavir AUC 152%	No dosage recommendation; monitor for nelfinavir toxicities
	Saquinavir	⇑ Saquinavir level to therapeutic concentration	Low dose ritonavir should always be used to boost saquinavir level
Saquinavir	Contraindicated drugs: astemizole, terfenadine, cisapride, pimozide, midazolam, triazolam, ergot derivatives, rifampin, amiodarone, bepridil, flecainide, propafenone, quinidine Drugs should not be use with saquinavir: lovastatin, simvastatin, St. John's Wort, garlic capsules, rifapentine, tipranavir/ritonavir		
	Clarithromycin	⇑ Saquinavir level	No dosage adjustment necessary
	Delavirdine	⇑ Saquinavir level	Appropriate dose of the combination not established
	Efavirenz	⇓ Saquinavir level	Saquinavir should not be used with efavirenz without ritonavir boosting
	Fluconazole	⇑ Saquinavir level	No dosage adjustment necessary
	Indinavir	⇑ Saquinavir levels	Appropriate dosing has not been established
	Lopinavir/ritonavir	⇑ Saquinavir levels	⇑ Saquinavir efficacy
	Nelfinavir	⇑ Saquinavir and ⇑ nelfinavir levels	Saquinavir 1200 mg twice daily; nelfinavir 1250 mg twice daily
	Nevirapine	⇓ Saquinavir levels	Saquinavir should not be used with nevirapine without pharmacokinetic boosting (e.g., with ritonavir)
	Ritonavir	⇑ Saquinavir AUC 20-fold	Low-dose ritonavir should be used to boost saquinavir level
	Tipranavir/ritonavir	⇓ Saquinavir levels	Do not coadminister
Tipranavir/ritonavir	Contraindicated drugs: amiodarone, bepridil, flecainide, propafenone, quinidine, astemizole, terfenadine, ergot derivatives, cisapride, pimozide, midazolam, triazolam Drugs should not be used with tipranavir/ritonavir: Rifampin, St. John's Wort, lovastatin, simvastatin		
	Abacavir	⇓ Abacavir level	Clinical relevance unknown, no dosage adjustment recommended
	Amprenavir/ fosamprenavir	⇓ Amprenavir level	Coadministration is not recommended
	Clarithromycin	⇑ Tipranavir level, ⇑ Clarithromycin level	For creatinine clearance <60 mL/min, clarithromycin dose should be reduced
	Didanosine (enteric coated)	⇓ Didanosine level	Clinical relevance unknown, no dosage adjustment recommended. For optimal absorption, give didanosine separate from tipranavir/ritonavir by at least 2 h
	Efavirenz	⇓ Tipranavir level	No dosage adjustment recommended

(Continued)

Primary Drug	Secondary Drug	Interaction Result	Management of Interaction
	Fluconazole	⇑ Tipranavir level	No dosage adjustment of tipranavir/ritonavir recommended; fluconazole dose >200 mg not recommended
	Lopinavir/ritonavir	⇓ Lopinavir level	Coadministration is not recommended
	Saquinavir	⇓ Saquinavir level	Coadministration is not recommended
	Zidovudine	⇓ Zidovudine level	Clinical relevance unknown, no dosage adjustment recommended
Antiretroviral drugs–fusion inhibitor			
Enfuvirtide	No significant pharmacokinetic interaction		
Antiviral drugs			
Acyclovir/Famciclovir/ Valacyclovir	Contraindicated drugs: none		
	Probenecid	⇑ Acyclovir (for acyclovir & valacyclovir) & Penciclovir (for famciclovir) levels by inhibition of renal tubular secretion	Monitor for toxicities of the antiviral drugs
Cidofovir	Contraindicated drugs: coadministration of drugs with high nephrotoxic potential		
	Probenecid	⇓ Cidofovir nephrotoxicity by blocking uptake of cidofovir by proximal tubular cells	Probenecid given with saline before and after cidofovir dose can reduce incidence of cidofovir-associated nephrotoxicity
	Nephrotoxic drugs (e.g., amphotericin B, cidofovir, pentamidine, aminoglycosides)	May ⇓ Cidofovir renal clearance & ⇑ cidofovir accumulation	Avoid concomitant use; if used, monitor renal function and cidofovir-associated toxicities
Entecavir	No significant drug interaction		
Foscarnet	Contraindicated drugs: none		
	Drugs should be avoided: nephrotoxic drugs		
	Nephrotoxic drugs (e.g., aminoglycosides, amphotericin B, cidofovir, pentamidine, etc.)	May ⇓ Foscarnet renal clearance & ⇑ Foscarnet accumulation	Avoid concomitant use; if used, monitor renal function and foscarnet-associated toxicities
Ganciclovir or Valganciclovir	Contraindicated drugs: none		
	Drugs should not be used with ganciclovir or valganciclovir: Imipenem-cilastatin (reports of generalized seizure, avoid concomitant use unless benefits outweigh the risk)		
	Didanosine	⇑ Didanosine levels	No dosage adjustment recommended. When used together, monitor for didanosine toxicities (pancreatitis, peripheral neuropathy)
	Probenecid	⇑ Ganciclovir level by competition of renal tubular secretion	Monitor for ganciclovir toxicities

(*Continued*)

(Continued)

Primary Drug	Secondary Drug	Interaction Result	Management of Interaction
Interferon alfa (including pegylated formulations)	No significant pharmacokinetic interaction		
Ribavirin	Contraindicated drugs: none		
	Drug should not be used with ribavirin: Didanosine		
	Didanosine	⇑ intracellular concentration of didanosine–increased serious didanosine-associated mitochondrial toxicities	Avoid concomitant use

[a]Amprenavir capsule is no longer in distribution in the United States–the information is primarily pertaining to the effect of interacting drugs on fosamprenavir (prodrug of amprenavir) or amprenavir oral solution.navir (prodrug of amprenavir) or amprenavir oral solution.

B Appendix

Sexually Transmitted Diseases Treatment Guidelines, 2006

Kimberly A. Workowski and Stuart M. Berman

This abbreviated version of the 2006 STD Guidelines focuses on the treatment and counseling of persons with sexually transmitted diseases and does not include discussion of vaccine preventable STDs, screening for cervical dysplasia, management of persons who have been sexually assaulted, and management of less common manifestations; these issues are addressed in detail in the complete guidelines document.

CLINICAL PREVENTION GUIDANCE

The prevention and control of STDs are based on the following five major strategies: (1) education and counseling of persons at risk on ways to avoid STDs through changes in sexual behaviors; (2) identification of asymptomatically infected persons and of symptomatic persons unlikely to seek diagnostic and treatment services; (3) effective diagnosis and treatment of infected persons; (4) evaluation, treatment, and counseling of sex partners of persons who are infected with an STD; and (5) preexposure vaccination of persons at risk for vaccine-preventable STD.

OVERVIEW OF CHANGES IN THE 2006 CDC STD TREATMENT GUIDELINES

For over 30 years, CDC's publication of national guidelines for management of STDs has assisted clinicians with effective guidance on the delivery of optimal STD care. New recommendations in these updated guidelines include the clinical efficacy of azithromycin for chlamydial infections in pregnancy, an expanded diagnostic evaluation for cervicitis and trichomoniasis; a new antimicrobial for trichomoniasis; the role of *Mycoplasma genitalium* and trichomoniasis in urethritis/cervicitis and treatment-related implications; lymphogranuloma venereum (LGV) proctocolitis among men who have sex with men (MSM); revision of the criteria for spinal fluid examination to evaluate for neurosyphilis; the emergence of azithromycin-resistant *Treponema pallidum*; increasing prevalence of quinolone-resistant *Neisseria gonorrhoeae* in MSM; postexposure prophylaxis after sexual assault; and an expanded discussion of STD prevention approaches. A summary of some of these new recommendations is described below. A complete version of the STD Treatment Guidelines is available at www.cdc.gov/std/treatment.

Annual screening for chlamydia in all sexually active women aged ≤25 years ixommended, as is screening of older women with risk factors (e.g., those who have a new sex partner or multiple sex partners). There is insufficient evidence to recommend routine screening for *Chlamydia trachomatis* in sexually active young men, based on feasibility, efficacy, and cost-effectiveness; however, screening should be considered in high prevalence areas (adolescent clinics, correctional facilities, STD clinics). Efficacious therapeutic regimens for chlamydia include azithromycin or doxycycline. Because of the high probability of repeat infection, women should be retested for chlamydial infection 3–4 months after treatment. Clinical experience and limited studies are available to support the efficacy and safety of azithromycin as a recommended regimen in pregnant women.

Selection of appropriate therapy for gonorrhea is guided by a CDC-sponsored surveillance system that has monitored gonococcal antimicrobial susceptibility for the last 20 years (GISP). Ongoing data from GISP demonstrate that fluoroquinolone-resistant gonorrhea is continuing to spread and is widespread in the United States. As a consequence, this class of antibiotics is no longer recommended for the treatment of gonorrhea in the United States (*MMWR*, April 13, 2007). Oral alternatives to fluoroquinolones are limited, as cefixime suspension is the only available formulation. Some evidence suggests that cefpodoxime proxetil 400 mg or cefuroxime axetil 1 g might be reasonable oral alternative regimens.

C. trachomatis, N. gonorrhoeae, Trichomonas vaginalis, and genital herpes are established etiologic agents for cervicitis, and limited data suggest an association with bacterial vaginosis

Adapted from *Morbidity and Mortality Weekly Reports Vol. 55/RR-11 Recommendations and Reports* 1. The material in this report originated in National Center for HIV/AIDS. Viral Hepatitis, STD, and TB Prevention, Kevin A. Fenton, MD. PhD. Director: and the Division of STD Prevention, John M. Douglas. MD. Director.

and *M. genitalium*. However, in the majority of cases of cervicitis no pathogen is identified. The evaluation of cervicitis should include nucleic acid amplification testing on cervical or urine specimens for chlamydia and gonorrhea and examination of vaginal secretions for bacterial vaginosis and trichomoniasis. The decision to provide presumptive therapy for cervicitis (chlamydia or gonorrhea) should include an individual risk assessment, the likelihood of follow-up, and the prevalence of infection in the population. There is limited information on the natural history of cervicitis when neither chlamydia or gonorrhea is present. The value of prolonged administration of antibiotic therapy for cervicitis is unknown, as standard management options are undefined.

Sexually transmitted organisms, especially *C. trachomatis* and *N. gonorrhoeae*, aerobic and anaerobic vaginal flora, and genital mycoplasmas have been associated with PID. There are no differences in short- and long-term clinical and microbiologic response rates between parenteral or oral therapy. If parenteral cephalosporin therapy is not feasible, use of fluoroquinolones (levofloxacin 500 mg orally once daily or ofloxacin 400 mg twice daily for 14 days) with or without metronidazole (500 mg orally twice daily for 14 days) may be considered if the community prevalence and individual risk (see "Gonococcal Infections in Adolescents and Adults" in *Sexually Transmitted Disease Treatment Guidelines*, 2006) of gonorrhea is low. Tests for gonorrhea must be performed prior to instituting therapy and the patient managed as follows if the test is positive:

- If NAAT test is positive, parenteral cephalosporin is recommended.
- If culture for gonorrhea is positive, treatment should be based on results of antimicrobial susceptibility. If isolate is QRNG, or antimicrobial susceptibility can not be assessed, parenteral cephalosporin is recommended.

Although information regarding other outpatient regimens is limited, amoxicillin/clavulanic acid plus doxycycline or azithromycin plus metronidazole has demonstrated short-term clinical cure. No data has been published regarding the use of oral cephalosporins for the treatment of PID.

Metronidazole or tinidazole are the recommended regimens for trichomoniasis treatment. Some strains of *T. vaginalis* can have diminished susceptibility to nitroimidazoles; however, most infections will respond higher doses of metronidazole or tinidazole. In vitro data and limited clinical investigation support the efficacy of tinidazole when treatment with metronidazole fails.

Syphilis remains an important problem due to recent increases in primary and secondary syphilis, especially in MSM, and due to biological interactions, with syphilis facilitating HIV acquisition and transmission. Long-acting preparations of penicillin remain the treatment of choice for all stages of syphilis. Limited data are available on the management of early syphilis in those with penicillin allergy with ceftriaxone or azithromycin and on the appropriate dose and duration of these alternative regimens. However, recent reports have described clinical treatment failure in MSM who received azithromycin for early syphilis. HIV-infected persons who have early syphilis should be managed according to standard treatment recommendations, although there may be an increased risk for neurologic complications and higher rates of treatment failure. The natural history of central nervous treponemal invasion in HIV-infected persons is not well defined, but some investigators have suggested that lumbar puncture be considered in those persons with syphilis who have RPR $\geq$ 1:32 (regardless of stage), especially with concomitant HIV infection with CD4 $\leq$ 350. Abnormalities of the cerebrospinal fluid (pleocytosis or elevated protein) are common in early syphilis and in persons with HIV infection; however, there is no evidence to suggest that these abnormalities reliably predict the need for aggressive treatment regimens.

Suppressive therapy for genital herpes reduces the frequency of recurrences by 70–80% in persons with frequent recurrence (more than six recurrences per year). Treatment with valacyclovir 500 mg daily has been shown to decrease the HSV-2 transmission in discordant heterosexual couples in which the source partner has genital HSV-2 infection. Effective episodic treatment of recurrent genital herpes requires initiation of therapy within 1 day of lesion onset or during the prodrome; new recommendations for episodic therapy include acyclovir 800 mg orally three times daily for 2 days or famciclovir 1 g twice daily for 1 day.

LGV, caused by *C. trachomatis* serovars L1, L2, or L3, most typically presents as a self-limited genital ulcer followed by tender inguinal or femoral adenopathy. However, an increasingly recognized presentation has been recently observed in MSM with proctitis or proctocolitis and a high HIV-coinfection rate. LGV diagnosis should be based on clinical suspicion, local epidemiology, *C. trachomatis* testing, and the exclusion of other etiologies. Genital and lymph node specimens can be tested for *C. trachomatis*, but nucleic acid amplification tests are not FDA cleared for testing rectal specimens, and genotyping (not widely available) is required for differentiating LGV from non-LGV serovars. Chlamydia serology can support the diagnosis in appropriate clinical context, but LGV test interpretation is not standardized; these tests have not been validated for proctitis presentations, and *C. trachomatis* serovars-specific serologic tests are not widely available. Because of the current limitations in LGV diagnostic capabilities (lack of rapid, widely available, standardized

testing), the clinical management of persons with symptoms suggestive of LGV should include presumptive treatment.

Scabies infestation is a common cause of pruritus and skin rash worldwide. Ivermectin represents a new oral therapeutic option for scabies and may hold particular promise in the treatment of severe infestation or in epidemic situations. Lindane should only be used as an alternative therapy due to the risk of neurotoxicity and aplastic anemia. No controlled studies for crusted scabies have been conducted, but combination therapy with ivermectin and topical scabicides may prove to be a useful option. Pediculosis pubis is treated with either permethrin cream or pyrethrins; however, increasing rates of drug resistance to these pediculicides may affect their efficacy in the future. Malathion can be used when treatment failure is believed to have occurred because of resistance.

An important part of STD treatment is the evaluation and treatment of sex partners. Partner management can be provided directly by the provider or with assistance from the health department. The provision of partner services and the specific STDs for which they are offered may vary among providers, agencies, and geographic areas. Expedited partner therapy (EPT) may be an option for management of heterosexual patients with chlamydia or gonorrhea, in which partners of infected patients are treated without medical evaluation or prevention counseling. More information about EPT can be found at http://www.cdc.gov/std/treatment/EPTFinalReport2006.pdf. However, certain operational barriers exist including the lack of clarity about the legal status of EPT in some settings. There is no evidence to support the use of EPT in the management of syphilis or among MSM with chlamydia or gonorrhea.

Table B1. The Five Ps: Partners, Prevention of Pregnancy, Protection from STDs, Practices, Past History of STDs

1. Partners
- "Do you have sex with men, women, or both?"
- "In the past 2 months, how many partners have you had sex with?"
- "In the past 12 months, how many partners have you had sex with?"

2. Prevention of pregnancy
- "Are you or your partner trying to get pregnant?" If no, "What are you doing to prevent pregnancy?"

3. Protection from STDs
- "What do you do to protect yourself from STDs and HIV?"

4. Practices
- "To understand your risks for STDs, I need to understand the kind of sex you have had recently."
- "Have you had vaginal sex, meaning 'penis in vagina sex'"?
- If yes, "Do you use condoms: never, sometimes, or always?"
- "Have you had anal sex, meaning 'penis in rectum/anus sex'"?
- If yes, "Do you use condoms: never, sometimes, or always?"
- "Have you had oral sex, meaning 'mouth on penis/vagina'"?

For condom answers:
- If "never:" "Why don't you use condoms?"
- If "sometimes": "In what situations or with whom, do you not use condoms?"

5. Past history of STDs
- "Have you ever had an STD?"
- "Have any of your partners had an STD?"

Additional questions to identify HIV and hepatitis risk:
- "Have you or any of your partners ever injected drugs?
- "Have any of your partners exchanged money or drugs for sex?"
- "Is there anything else about your sexual practices that I need to know about?"

Table B2. Recommendations for the Proper Use of Male Condoms

- Use a new condom with each sex act (e.g., oral, vaginal, and anal).
- Carefully handle the condom to avoid damaging it with fingernails, teeth, or other sharp objects.
- Put the condom on after the penis is erect and before any genital, oral, or anal contact with the partner.
- Use only water-based lubricants (e.g., K-Y Jelly™, Astroglide™, AquaLube™, and glycerin) with latex condoms. Oil-based lubricants (e.g., petroleum jelly, shortening, mineral oil, massage oils, body lotions, and cooking oil) can weaken latex.
- Ensure adequate lubrication during vaginal and anal sex, which might require the use of water-based lubricants.
- To prevent the condom from slipping off, hold the condom firmly against the base of the penis during withdrawal, and withdraw while the penis is still erect.

Table B3. Recommended Screening Tests for Pregnant Women

- All pregnant women in the United States should be tested for HIV infection as early in pregnancy as possible.
- A serologic test for syphilis should be performed on all pregnant women at the first prenatal visit.
- All pregnant women should be routinely tested for hepatitis B surface antigen (HBsAg) during an early prenatal visit (e.g., first trimester) in each pregnancy, even if they have been previously vaccinated or tested.
- All laboratories that conduct HBsAg tests should use an HBsAg test that is FDA-cleared and should perform testing according to the manufacturer's labeling, including testing of initially reactive specimens with a licensed neutralizing confirmatory test.
- All pregnant women should be routinely tested for *Chlamydia trachomatis* at the first prenatal visit. Women aged <25 years and those at increased risk for chlamydia (i.e., women who have a new or more than one sex partner) should also be retested during the third trimester to prevent maternal postnatal complications and chlamydial infection in the infant.
- All pregnant women at risk for gonorrhea or living in an area in which the prevalence of *Neisseria gonorrhoeae* is high should be tested at the first prenatal visit for *N. gonorrhoeae*. A repeat test should be performed during the third trimester for those at continued risk.
- All pregnant women at high risk for hepatitis C infection should be tested for hepatitis C antibodies at the first prenatal visit.
- Evaluation for bacterial vaginosis (BV) might be conducted during the first prenatal visit for asymptomatic patients who are at high risk for preterm labor (history of previous preterm delivery).
- A Papanicolaou (Pap) smear should be obtained at the first prenatal visit if none has been documented during the preceding year.

Table B4. Recommended Screening for Sexually Active MSM

- HIV serology, if HIV negative or not tested within the previous year.
- Syphilis serology.
- A test for urethral infection with *N. gonorrhoeae* and *C. trachomatis* in men who have had insertive intercourse[a] during the preceding year.
- A test for rectal infection[b] with *N. gonorrhoeae* and *C. trachomatis* in men who have had receptive anal intercourse[a] during the preceding year.
- A test for pharyngeal infection[b] with *N. gonorrhoeae* in men who have acknowledged participation in receptive oral intercourse[a] during the preceding year; testing for *C. trachomatis* pharyngeal infection is not recommended.

These tests should be performed at least annually for sexually active MSM, including men with or without established HIV infection. In addition, some specialists would consider type-specific serologic tests for HSV-2, if infection status is unknown. Routine testing for anal cytologic abnormalities or anal HPV infection is not recommended until more data are available on the reliability of screening methods, the safety of and response to treatment, and programmatic considerations.

[a]Regardless of history of condom use during exposure.

[b]Providers should use a culture or test that has been cleared by the FDA or locally verified in accordance with applicable statutes.

Table B5. Specific Recommendations for Diagnostic Testing for HIV Infection

- HIV screening is recommended for all persons who seek evaluation and treatment for STDs.
- HIV testing must be voluntary.
- Consent for HIV testing should be incorporated into the general consent for care (verbally or in writing) with an opportunity to decline (opt-out screening).
- HIV rapid testing must be considered, especially in clinics where a high proportion of patients do not return for HIV test results.
- Positive screening tests for HIV antibody must be confirmed by a supplemental test (e.g., Western Blot or immunofluorescence assay) before being considered diagnostic of HIV infection.
- Persons with positive HIV test results (screening and confirmatory) must receive initial HIV prevention counseling before leaving the testing site. Such persons should receive a medical evaluation and, if indicated, behavioral and psychological services be referred for these services.
- Providers should be alert to the possibility of acute retroviral syndrome and should perform nucleic acid testing for HIV, if this syndrome is suspected. Patients suspected of having recently acquired HIV infection should be referred for immediate consultation with a specialist.

Table B6. Initial Evaluation of HIV-Positive Persons

- A detailed medical history, including sexual and substance abuse history, vaccination history, previous STDs, and specific HIV-related symptoms or diagnoses.
- A physical examination, including a gynecologic examination for women.
- Testing for *N. gonorrhoeae* and *C. trachomatis* (and for women, a Pap test and wet mount examination of vaginal secretions).
- Complete blood and platelet counts and blood chemistry profile.
- Toxoplasma antibody test.
- Tests for antibodies to HCV; testing for previous or present HAV or HBV infection is recommended if determined to be cost-effective before considering vaccination.
- Syphilis serology.
- A CD4 T-lymphocyte analysis and determination of HIV plasma viral load.
- A tuberculin skin test (sometimes referred to as a purified protein derivative).
- A urinalysis.
- A chest radiograph.
- Some specialists recommend type-specific testing for HSV-2 if herpes infection status is unknown.
- A first dose of hepatitis A and/or hepatitis B vaccination for previously unvaccinated persons for whom vaccine is recommended (see hepatitis A and hepatitis B) should be administered at this first visit.

Table B7. Specific Recommendations for HIV Counseling and Referral

- Persons who test positive for HIV antibody should be counseled, either on site or through referral, concerning the behavioral, psychosocial, and medical implications of HIV infection.
- Health-care providers should be alert for medical or psychosocial conditions that require immediate attention.
- Providers should assess newly diagnosed persons' need for immediate medical care or support and should link them to services in which health-care personnel are experienced in providing care for HIV-infected persons. Such persons might need medical care or services for substance abuse, mental health disorders, emotional distress, reproductive counseling, risk-reduction counseling, and case management. Providers should follow-up to ensure that patients have received the needed services.
- Patients should be educated regarding what to expect in follow-up medical care.

Table B8. Treatment of Chancroid

Recommended regimens[a]

- Azithromycin 1 g orally in a single dose
  or
- Ceftriaxone 250 mg intramuscularly (IM) in a single dose
  or
- Ciprofloxacin 500 mg orally twice a day for 3 days
  or
- Erythromycin base 500 mg orally three times a day for 7 days

Other Management Considerations:

Male patients who are uncircumcised and patients with HIV infection do not respond as well to treatment as those who are circumcised or HIV negative. Patients should be tested for HIV infection at the time chancroid is diagnosed. Patients should be retested for syphilis and HIV 3 months after the diagnosis of chancroid, if the initial test results were negative.

Follow-Up:

Patients should be reexamined 3–7 days after initiation of therapy. If treatment is successful, ulcers usually improve symptomatically within 3 days and objectively within 7 days after therapy. If no clinical improvement is evident, the clinician must consider whether (1) the diagnosis is correct, (2) the patient is coinfected with another STD, (3) the patient is infected with HIV, (4) the treatment was not used as instructed, or (5) the *H. ducreyi* strain causing the infection is resistant to the prescribed antimicrobial. The time required for complete healing depends on the size of the ulcer; large ulcers might require >2 weeks. In addition, healing is slower for some uncircumcised men who have ulcers under the foreskin. Clinical resolution of fluctuant lymphadenopathy is slower than resolution for ulcers and might require needle aspiration or incision and drainage. Although needle aspiration of chancroid buboes is a simple procedure, incision and drainage might be preferred because of a reduced need for repeat drainage procedures.

[a]Ciprofloxacin is contraindicated for pregnant and lactating women. Azithromycin and ceftriaxone offer the advantage of single-dose therapy. Worldwide, several isolates with intermediate resistance to either ciprofloxacin or erythromycin have been reported.

Table B9. Treatment of Genital Herpes

First Clinical Episode of Genital Herpes:

Many persons with first-episode herpes have mild clinical manifestations but later develop severe or prolonged symptoms. Therefore, patients with initial genital herpes should receive antiviral therapy.

Recommended regimens[a]

- Acyclovir 400 mg orally three times a day for 7–10 days
  or
- Acyclovir 200 mg orally five times a day for 7–10 days
  or
- Famciclovir 250 mg orally three times a day for 7–10 days
  or
- Valacyclovir 1 g orally twice a day for 7–10 days

Table B9. *(Continued)*

Suppressive Therapy for Recurrent Genital Herpes:

Suppressive therapy reduces the frequency of genital herpes recurrences by 70–80% in patients who have frequent recurrences (i.e., >6 recurrences per year), and many patients report no symptomatic outbreaks. Treatment also is effective in patients with less frequent recurrences. Safety and efficacy have been documented among patients receiving daily therapy with acyclovir for as long as 6 years and with valacyclovir or famciclovir for 1 year. Periodically during suppressive treatment (e.g., once a year), providers should discuss whether or not to continue therapy with the patient.

Daily treatment with valacyclovir 500 mg daily decreases the rate of HSV-2 transmission in discordant, heterosexual couples in which the source partner has a history of genital HSV-2 infection.

Recommended regimens

- Acyclovir 400 mg orally twice a day
  or
- Famiciclovir 250 mg orally twice a day
  or
- Valacyclovir 500 mg orally once a day[b]
  or
- Valacyclovir 1.0 g orally once a day

Episodic Therapy for Recurrent Genital Herpes:

Effective episodic treatment of recurrent herpes requires initiation of therapy within 1 day of lesion onset or during the prodrome that precedes some outbreaks. The patient should be provided with a supply of drug or a prescription for the medication with instructions to initiate treatment immediately when symptoms begin.

Recommended regimens

- Acyclovir 400 mg orally three times a day for 5 days
  or
- Acyclovir 800 mg orally twice a day for 5 days
  or
- Acyclovir 800 mg orally three times a day for 2 days
  or
- Famciclovir 125 mg orally twice daily for 5 days
  or
- Famciclovir 1000 mg orally twice daily for 1 day
  or
- Valacyclovir 500 mg orally twice a day for 3 days
  or
- Valacyclovir 1.0 g orally once a day for 5 days

[a]Treatment might be extended if healing is incomplete after 10 days of therapy.

[b]Valacyclovir 500 mg once a day might be less effective than other valacyclovir or acyclovir dosing regimens in patients who have very frequent recurrences (i.e., ≥10 episodes per year).

Table B10. Treatment of HSV Infection in Persons Infected with HIV

Recommended regimens for daily suppressive therapy

- Acyclovir 400–800 mg orally twice to three times a day
  or
- Famciclovir 500 mg orally twice a day
  or
- Valacyclovir 500 mg orally twice a day

Recommended regimens for episodic infection

- Acyclovir 400 mg orally three times a day for 5–10 days
  or
- Famiciclovir 500 mg orally twice a day for 5–10 days
  or
- Valacyclovir 1.0 g orally twice a day for 5–10 days

Acyclovir, valacyclovir, and famciclovir are safe for use in immunocompromised patients in the doses recommended for treatment of genital herpes. For severe HSV disease, initiating therapy with acyclovir 5–10 mg/kg body weight IV every 8 hours might be necessary.

If lesions persist or recur in a patient receiving antiviral treatment, HSV resistance should be suspected and a viral isolate should be obtained for sensitivity testing. Such patients should be managed in consultation with an HIV specialist, and alternate therapy should be administered.

Table B11. Treatment for Granuloma Inguinale

A limited number of studies on donovanosis treatment have been published. Treatment halts progression of lesions, although prolonged therapy is usually required to permit granulation and reepithelialization of the ulcers. Healing typically proceeds inward from the ulcer margins. Relapse can occur 6–18 months after apparently effective therapy.

Recommended regimen

- Doxycycline 100 mg orally twice a day for at least 3 weeks and until all lesions have completely healed

Alternative regimens

- Azithromycin 1 g orally once per week for at least 3 weeks and until all lesions have completely healed
  or
- Ciprofloxacin 750 mg orally twice a day for at least 3 weeks and until all lesions have completely healed
  or
- Erythromycin base 500 mg orally four times a day for at least 3 weeks and until all lesions have completely healed
  or
- Trimethoprim-sulfamethoxazole one double-strength (160 mg/800 mg) tablet orally twice a day for at least 3 weeks and until all lesions have completely healed

Some specialists recommend the addition of an aminoglycoside (e.g., gentamicin 1 mg/kg IV every 8 hours) to these regimens if improvement is not evident within the first few days of therapy.

Table B12. Treatment for Lymphogranuloma Venereum

Treatment cures infection and prevents ongoing tissue damage, although tissue reaction to the injection can result in scarring. Buboes might require aspiration through intact skin or incision and drainage to prevent the formation of inguinal/femoral ulcerations.

Recommended regimen

- Doxycycline 100 mg orally twice a day for 21 days

Alternative regimen

- Erythromycin base 500 mg orally four times a day for 21 days

Some STD specialists believe that azithromycin 1.0 g orally once weekly for 3 weeks is probably effective, although clinical data are lacking. Clinical followup of persons with LGV in necessary until signs and symptoms have resolved.

Table B13. Treatment of Primary and Secondary Syphilis

Recommended regimen for adults[a]

- Benzathine penicillin G 2.4 million units IM in a single dose

Recommended regimen for children

After the newborn period (aged >1 month), children with syphilis should have a CSF examination to detect asymptomatic neurosyphilis, and birth and maternal medical records should be reviewed to assess whether such children have congenital or acquired syphilis (see Table B18). Children with acquired primary or secondary syphilis should be evaluated (e.g., through consultation with child-protection services) and treated by using the following pediatric regimen.

- Benzathine penicillin G 50,000 units/kg IM, up to the adult dose of 2.4 million units in a single dose

[a]Recommendations for treating HIV-infected persons, pregnant women with syphilis, and sexual assault of children are discussed in the full report.

Table B14. Treatment for Latent Syphilis

The following regimens are recommended for penicillin nonallergic persons who have normal CSF examinations (if performed).

Recommended regimens for adults
Early latent syphilis—Benzathine penicillin G 2.4 million units IM in a single dose
Late latent syphilis or latent syphilis of unknown duration—Benzathine penicillin G 7.2 million units total, administered as three doses of 2.4 million units IM each at 1-week intervals

(*Continued*)

Table B14. *(Continued)*

Management Considerations:

All persons who have latent syphilis should be evaluated clinically for evidence of tertiary disease (e.g., aortitis and gumma) and syphilitic ocular disease (e.g., iritis and uveitis). Patients who have syphilis and who demonstrate any of the following criteria should have a prompt CSF examination:

- neurologic or ophthalmic signs or symptoms,
- evidence of active tertiary syphilis (e.g., aortitis and gumma),
- treatment failure, or
- HIV infection with late latent syphilis or syphilis of unknown duration.

If dictated by circumstances and patient preferences, a CSF examination may be performed for patients who do not meet these criteria. Some specialists recommend performing a CSF examination on all patients who have latent syphilis and a nontreponemal serologic test of >1:32 or if the patient is HIV infected with a serum CD4 count <350. However, the likelihood of neurosyphilis in this circumstance is unknown.

If a CSF examination is performed and the results indicate abnormalities consistent with neurosyphilis, the patient should be treated for neurosyphilis (see Table B16). If a patient misses a dose of penicillin in a course of weekly therapy for late syphilis, the appropriate course of action is unclear. Pharmacologic considerations suggest that an interval of 10–14 days between doses of benzathine penicillin for late syphilis or latent syphilis of unknown duration might be acceptable before restarting the sequence of injections. Missed doses are not acceptable for pregnant patients receiving therapy for late latent syphilis; pregnant women who miss any dose of therapy must repeat the full course of therapy.

Follow-Up. Quantitative nontreponemal serologic tests should be repeated at 6, 12, and 24 months. Patients with a normal CSF examination should be re-treated for latent syphilis if (1) titers increase fourfold, (2) an initially high titer (>1:32) fails to decline at least fourfold (i.e., two dilutions) within 12–24 months of therapy, or (3) signs or symptoms attributable to syphilis develop. In rare instances, despite a negative CSF examination and a repeated course of therapy, serologic titers might still not decline. In these circumstances, the need for additional therapy or repeated CSF examinations is unclear.

Recommended regimens for children

Early latent syphilis—Benzathine penicillin G 50,000 units/kg IM, up to the adult dose of 2.4 million units in a single dose

Late latent syphilis or latent syphilis of unknown duration—Benzathine penicillin G 50,000 units/kg IM, up to the adult dose of 2.4 million units, administered as three doses at 1-week intervals (total 150,000 units/kg up to the adult total dose of 7.2 million units)

After the newborn period, children with syphilis should have a CSF examination to exclude neurosyphilis. In addition, birth and maternal medical records should be reviewed to assess whether children have congenital or acquired syphilis (see Table B18). Older children with acquired latent syphilis should be evaluated as described for adults and treated using the following pediatric regimens. These regimens are for penicillin nonallergic children who have acquired syphilis and who have normal CSF examination results.

Table B15. Treatment of Tertiary Syphilis

Tertiary syphilis refers to gumma and cardiovascular syphilis but not to all neurosyphilis. Patients who are not allergic to penicillin and have no evidence of neurosyphilis should be treated with the following regimen.

Recommended regimen

- Benzathine penicillin G 7.2 million units total, administered as three doses of 2.4 million units IM each at 1-week intervals

Table B16. Treatment for Neurosyphilis

Persons who have neurosyphilis or syphilitic eye disease (e.g., uveitis, neuroretinitis, and optic neuritis) should be treated with the following regimen.

Recommended regimen

- Aqueous crystalline penicillin G 18–24 million units per day, administered as 3–4 million units IV every 4 hours or continuous infusion, for 10–14 days

Alternative regimen

- Procaine penicillin 2.4 million units IM once daily plus
- Probenecid 500 mg orally four times a day, both for 10–14 days

Table B17. Management of Neurosyphilis, Other Management Considerations

Follow-Up:

If CSF pleocytosis was present initially, a CSF examination should be repeated every 6 months until the cell count is normal. Follow-up CSF examinations also can be used to evaluate changes in the VDRL-CSF or CSF protein after therapy; however, changes in these two parameters occur more slowly than cell counts, and persistent abnormalities might be less important. If the cell count has not decreased after 6 months or if the CSF is not normal after 2 years, retreatment should be considered. Recent data on HIV-infected persons with neurosyphilis suggest that CSF abnormalities might persist for extended periods in these persons and close clinical follow-up is warranted.

Penicillin Allergy:

Ceftriaxone can be used as an alternative treatment for patients with neurosyphilis, although the possibility of cross-reactivity between this agent and penicillin exists. Some specialists recommend ceftriaxone 2 g daily either IM or IV for 10–14 days. Other regimens have not been adequately evaluated for treatment of neurosyphilis. Therefore, if concern exists regarding the safety of ceftriaxone for a patient with neurosyphilis, the patient should obtain skin testing to confirm penicillin allergy and, if necessary, be desensitized and managed in consultation with a specialist.

Pregnancy:

Pregnant patients who are allergic to penicillin should be desensitized, if necessary, and treated with penicillin.

Table B18. Treatment of Congenital Syphilis

Effective prevention and detection of congenital syphilis depends on the identification of syphilis in pregnant women and, therefore, on the routine serologic screening of pregnant women during the first prenatal visit. In communities and populations in which the risk for congenital syphilis is high, serologic testing and a sexual history also should be obtained at 28 weeks' gestation and at delivery.

Scenario 1. Infants with proven or highly probable disease and

1. an abnormal physical examination that is consistent with congenital syphilis,
2. a serum quantitative nontreponemal serologic titer that is fourfold higher than the mother's titer,[a] or
3. a positive darkfield or fluorescent antibody test of body fluid(s).

(continued)

Table B18. *(Continued)*

Recommended evaluation

- CSF analysis for VDRL, cell count, and protein[b]
- Complete blood count (CBC) and differential and platelet count
- Other tests as clinically indicated (e.g., long-bone radiographs, chest radiograph, liver-function tests, cranial ultrasound, ophthalmologic examination, and auditory brainstem response)

Recommended regimens

- Aqueous crystalline penicillin G 100,000–150,000 units/kg/day, administered as 50,000 units/kg/dose IV every 12 hours during the first 7 days of life and every 8 hours thereafter for a total of 10 days

  or

- Procaine penicillin G 50,000 units/kg/dose IM in a single daily dose for 10 days

If >1 day of therapy is missed, the entire course should be restarted. Data are insufficient regarding the use of other antimicrobial agents (e.g., ampicillin). When possible, a full 10-day course of penicillin is preferred, even if ampicillin was initially provided for possible sepsis. The use of agents other than penicillin requires close serologic follow-up to assess adequacy of therapy. In all other situations, the maternal history of infection with *T. pallidum* and treatment for syphilis must be considered when evaluating and treating the infant.

Scenario 2. Infants who have a normal physical examination and a serum quantitive nontreponemal serologic titer the same or less than fourfold the maternal titer and the

1. mother was not treated, inadequately treated, or has no documentation of having received treatment;
2. mother was treated with erythromycin or other nonpenicillin regimen;[c] or
3. mother received treatment <4 weeks before delivery.

Recommended evaluation

- CSF analysis for VDRL, cell count, and protein
- CBC and differential and platelet count
- Long-bone radiographs

A complete evaluation is not necessary if 10 days of parenteral therapy is administered. However, such evaluations might be useful; a lumbar puncture might document CSF abnormalities that would prompt close follow-up. Other tests (e.g., CBC, platelet count, and bone radiographs) may be performed to further support a diagnosis of congenital syphilis. If a single dose of benzathine penicillin G is used, then the infant must be fully evaluated (i.e., through CSF examination, long-bone radiographs, and CBC with platelets), the full evaluation must be normal, and follow-up must be certain. If any part of the infant's evaluation is abnormal or not performed or if the CSF analysis is rendered uninterpretable because of contamination with blood, then a 10-day course of penicillin is required.[d]

Recommended regimens

- Aqueous crystalline penicillin G 100,000–150,000 units/kg/day, administered as 50,000 units/kg/dose IV every 12 hours during the first 7 days of life and every 8 hours thereafter for a total of 10 days

  or

- Procaine penicillin G 50,000 units/kg/dose IM in a single daily dose for 10 days

  or

- Benzathine penicillin G 50,000 units/kg/dose IM in a single dose

Some specialists prefer the 10 days of parenteral therapy if the mother has untreated early syphilis at delivery.

Scenario 3. Infants who have a normal physical examination and a serum quantitative nontreponemal serologic titer the same or less than fourfold the maternal titer and the

Table B18. *(Continued)*

1. mother was treated during pregnancy, treatment was appropriate for the stage of infection, and treatment was administered >4 weeks before delivery and
2. mother has no evidence of reinfection or relapse.

Recommended evaluation: No evaluation is required.

Recommended regimen

- Benzathine penicillin G 50,000 units/kg/dose IM in a single dose[e]

Scenario 4. Infants who have a normal physical examination and a serum quantitative nontreponemal serologic titer the same or less than fourfold the maternal titer and the

1. mother's treatment was adequate before pregnancy and
2. mother's nontreponemal serologic titer remained low and stable before and during pregnancy and at delivery (VDRL <1:2; RPR <1:4).

Recommended evaluation: No evaluation is required.
Recommended regimen: No treatment is required; however, some specialists would treat with benzathine penicillin G 50,000 units/kg as a single IM injection, particularly if follow-up is uncertain.

[a]The absence of a fourfold or greater titer for an infant does not exclude congenital syphilis.

[b]CSF test results obtained during the neonatal period can be difficult to interpret; normal values differ by gestational age and are higher in preterm infants. Values as high as 25 white blood cells (WBCs)/mm^3 and/or protein of 150 mg/dL might occur among normal neonates; some specialists, however, recommend that lower values (i.e., 5 WBCs/mm^3 and protein of 40 mg/dL) be considered the upper limits of normal. Other causes of elevated values should be considered when an infant is being evaluated for congenital syphilis.

[c]A woman treated with a regimen other than those recommended in these guidelines for treatment should be considered untreated.

[d]If the infant's nontreponemal test is nonreactive and the likelihood of the infant being infected is low, certain specialists recommend no evaluation but treatment of the infant with a single IM dose of benzathine penicillin G 50,000 units/kg for possible incubating syphilis, after which the infant should receive close serologic follow-up.

[e]Some specialists would not treat the infant but would provide close serologic follow-up in those whose mother's nontreponemal titers decreased fourfold after appropriate therapy for early syphilis or remained stable or low for late syphilis.

Table B19. Evaluation and Treatment of Older Infants and Children for Syphilis

Children who are identified as having reactive serologic tests for syphilis after the neonatal period (i.e., aged >1 month) should have maternal serology and records reviewed to assess whether the child has congenital or acquired syphilis.

Recommended evaluation

- CSF analysis for VDRL, cell count, and protein
- CBC, differential, and platelet count
- Other tests as clinically indicated (e.g., long-bone radiographs, chest radiograph, liver function tests, abdominal ultrasound, ophthalmologic examination, and auditory brain stem response)

Recommended regimen

- Aqueous crystalline penicillin G 200,000–300,000 units/kg/day IV, administered as 50,000 units/kg every 4–6 hours for 10 days

If the child has no clinical manifestations of disease, the CSF examination is normal, and the CSF VDRL test result is negative, some specialists would treat with up to three weekly doses of benzathine penicillin G, 50,000 U/kg IM.

Table B20. Management of Male Patients Who Have Urethritis

Confirmed Urethritis:

Clinicians should document that urethritis is present. Urethritis can be documented on the basis of any of the following signs or laboratory tests:

- Mucopurulent or purulent discharge.
- Gram stain of urethral secretions demonstrating >5 WBC per oil immersion field. The Gram stain is the preferred rapid diagnostic test for evaluating urethritis. It is highly sensitive and specific for documenting both urethritis and the presence or absence of gonococcal infection. Gonococcal infection is established by documenting the presence of WBC containing GNID.

or

- Positive leukocyte esterase test on first-void urine or microscopic examination of first-void urine sediment demonstrating >10 WBC per high power field.

If none of these criteria are present, treatment should be deferred, and the patient should be tested for *N. gonorrhoeae* and *C. trachomatis* and followed closely if test results are negative. If the results demonstrate infection with either *N. gonorrhoeae* or *C. trachomatis*, the appropriate treatment should be given and sex partners referred for evaluation and treatment.

Empiric treatment of symptoms without documentation of urethritis is recommended only for patients at high risk for infection who are unlikely to return for a follow-up evaluation. Such patients should be treated for gonorrhea and chlamydia. Partners of patients treated empirically should be evaluated and treated.

Table B21. Treatment of Nongonococcal Urethritis

Recommended regimens

- Azithromycin 1 g orally in a single dose

or

- Doxycycline 100 mg orally twice a day for 7 days

Alternative regimens

- Erythromycin base 500 mg orally four times a day for 7 days

or

- Erythromycin ethylsuccinate 800 mg orally four times a day for 7 days

or

- Ofloxacin 300 mg orally twice a day for 7 days

or

- Levofloxacin 500 mg orally once daily for 7 days

Recurrent and Persistent Urethritis:

Objective signs of urethritis should be present before initiation of antimicrobial therapy. In persons who have persistent symptoms after treatment without objective signs of urethritis, the value of extending the duration of antimicrobials has not been demonstrated. Persons who have persistent or recurrent urethritis can be retreated with the initial regimen if they did not comply with the treatment regimen or if they were reexposed to an untreated sex partner. Otherwise, a *T. vaginalis* culture should be performed using an intraurethral swab or a first-void urine specimen. Some cases of recurrent urethritis after doxycycline treatment might be caused by tetracycline-resistant *U. urealyticum*. Urologic examinations usually do not reveal a specific etiology. Approximately 50% of men with chronic nonbacterial prostatitis /chronic pelvic pain syndrome

Table B21. *(Continued)*

have evidence of urethral inflammation without any identifiable microbial pathogens. If the patient was compliant with the initial regimen and reexposure can be excluded, the following regimen is recommended.

Recommended regimens

- Metronidazole 2 g orally in a single dose

  or

- Tinidazole 2 g orally in a single dose

  plus

- Azithromycin 1 g orally in a single dose (if not used for initial episode)

Table B22. Management of Cervicitis

Two major diagnostic signs characterize cervicitis: (1) a purulent or mucopurulent endocervical exudate visible in the endocervical canal or on an endocervical swab specimen (commonly referred to as "mucopurulent cervicitis" or cervicitis) and (2) sustained endocervical bleeding easily induced by gentle passage of a cotton swab through the cervical os. Either or both signs might be present. Cervicitis frequently is asymptomatic, but some women complain of an abnormal vaginal discharge and intermenstrual vaginal bleeding (e.g., after sexual intercourse). A finding of leukorrhea (>10 WBC per high power field on microscopic examination of vaginal fluid) has been associated with chlamydial and gonococcal infection of the cervix. In the absence of inflammatory vaginitis, leukorrhea might be a sensitive indicator of cervical inflammation with a high negative predictive value.

Treatment:

Several factors should affect the decision to provide presumptive therapy for cervicitis or to await the results of diagnostic tests. Treatment with antibiotics for *C. trachomatis* should be provided in women at increased risk for this common STD (age <25 years, new or multiple sex partners, and unprotected sex), especially if follow-up cannot be ensured and if a relatively insensitive diagnostic test (not a NAAT) is used. Concurrent therapy for *N. gonorrhoeae* is indicated if the prevalence of this infection is high (>5%) in the patient population (young age and facility prevalence).

Concomitant trichomoniasis or symptomatic BV should also be treated if detected. For women in whom any component of (or all) presumptive therapy is deferred, the results of sensitive tests for *C. trachomatis* and *N. gonorrhoeae* (e.g., nucleic acid amplification tests) should determine the need for treatment subsequent to the initial evaluation.

Recommended regimens for presumptive treatment[a]

- Azithromycin 1 g orally in a single dose

  or

- Doxycycline 100 mg orally twice a day for 7 days

[a]Consider concurrent treatment for gonococcal infection if prevalence of gonorrhea is high in the patient population under assessment.

Table B23. Treatment of Chlamydial Infections

Treating infected persons prevents transmission to sex partners. In addition, treating pregnant women usually prevents transmission of *C. trachomatis* to infants during birth. Treatment of sex partners helps to prevent reinfection of the index patient and infection of other partners.

Coinfection with *C. trachomatis* frequently occurs among persons who have gonococcal infection; therefore, presumptive treatment of such patients for chlamydia is appropriate. The following recommended treatment regimens and alternative regimens cure infection and usually relieve symptoms.

Recommended regimens

- Azithromycin 1 g orally in a single dose

  or

- Doxycycline 100 mg orally twice a day for 7 days

Alternative regimens

- Erythromycin base 500 mg orally four times a day for 7 days

  or

- Erythromycin ethylsuccinate 800 mg orally four times a day for 7 days

  or

- Ofloxacin 300 mg orally twice a day for 7 days

  or

- Levofloxacin 500 mg orally once daily for 7 days

A recent meta-analysis of 12 randomized clinical trials of azithromycin versus doxycycline for the treatment of genital chlamydial infection demonstrated that the treatments were equally efficacious, with microbial cure rates of 97% and 98%, respectively.

Table B24. Treatment of Chlamydial Infections Among Children

Sexual abuse must be considered a cause of chlamydial infection in preadolescent children, although perinatally transmitted *C. trachomatis* infection of the nasopharynx, urogenital tract, and rectum might persist for >1 year.

Recommended Regimens for Children Who Weigh <45 kg

- Erythromycin base or ethylsuccinate 50 mg/kg/day orally divided into four doses daily for 14 days

Recommended Regimen for Children Who Weigh ≥ 45 kg but Who Are Aged <8 Years

- Azithromycin 1 g orally in a single dose

Recommended Regimens for Children Aged ≥8 years

- Azithromycin 1 g orally in a single dose

  or

- Doxycycline 100 mg orally twice a day for 7 days

Table B25. Treatment of Uncomplicated Gonococcal Infections of the Cervix, Urethra, and Rectum

Recommended regimens[a]

- Ceftriaxone 125 mg IM in a single dose

  or

- Cefixime 400 mg orally in a single dose[b]

  plus

Treatment for chlamydia if chlamydial infection is not ruled out

Alternative regimens

- Spectinomycin 2 g in a single IM dose[c]

  or

- Single-dose cephalosporin regimens

Some evidence suggests that cefpodoxime 400 mg and cefuroxime axetil 1 g orally might be additional oral alternatives in the treatment of uncomplicated urogenital gonorrhea; additional information on alternative oral regimens are available at http://www.cdc.gov/std/treatment. Cefpodoxime proxetil 200 mg PO is less active against *N. gonorrhoeae* than is cefixime and also does not quite meet the minimum efficacy criteria (demonstrated efficacy with lower 95% confidence interval [CI] of >95% in summed clinical trials) with cure rates, 96.5% (CI = 94.8–98.9%) for urogenital and rectal infection; efficacy in treating pharyngeal infection is unsatisfactory, 78.9% (CI = 54.5–94%). Clinical studies are being conducted to assess whether cefpodoxime 400 mg PO is an acceptable oral alternative. Treatment with cefuroxime axetil 1 g PO does not quite meet the minimum efficacy criteria for urogenital and rectal infection (95.9%; CI = 94.5–97.3%) and its efficacy in treating pharyngeal infection is unacceptable (56.9%; CI = 42.2–70.7%).

[a]This regimen is recommended for all adults and adolescents, regardless of travel history or sexual behavior.

[b]The tablet formulation is currently not available in the United States.

[c]Spectinomycin is currently not available in the United States

Table B26. Treatment of Uncomplicated Gonococcal Infections of the Pharynx

Gonococcal infections of the pharynx are more difficult to eradicate than infections at urogenital and anorectal sites. Few antimicrobial regimens can reliably cure >90% of gonococcal pharyngeal infections. Although chlamydial coinfection of the pharynx is unusual, coinfection at genital sites sometimes occurs. Therefore, treatment for both gonorrhea and chlamydia is recommended.

Recommended regimens[a]

- Ceftriaxone 125 mg IM in a single dose

  plus

Treatment for chlamydia if chlamydial infection is not ruled out

[a]This regimen is recommended for all adults and adolescents, regardless of travel history or sexual behavior.

Table B27. Gonococcal Conjunctivitis

Recommended regimen

- Ceftriaxone 1 g IM in a single dose

Recommended regimen for disseminated gonococcal infection (DGI)

- Ceftriaxone 1 g IM or IV every 24 hours

Alternative regimens

- Cefotaxime 1 g IV every 8 hours

  or

- Ceftizoxime 1 g IV every 8 hours

  or

- Spectinomycin 2 g IM every 12 hours

  or

- Cefixime 400 mg orally twice daily

Recommended regimen for gonococcal meningitis and endocarditis

- Ceftriaxone 1–2 g IV every 12 hours

Therapy for meningitis should be continued for 10–14 days; therapy for endocarditis should be continued for at least 4 weeks. Treatment of complicated DGI should be undertaken in consultation with a specialist.

Table B28. Recommended Regimen for Ophthalmia Neonatorum Caused by *N. gonorrhoeae*

Recommended regimen

- Ceftriaxone 25–50 mg/kg IV or IM in a single dose, not to exceed 125 mg

Topical antibiotic therapy alone is inadequate and is unnecessary if systemic treatment is administered.

Table B29. Gonococcal Infections Among Children

Recommended regimens for children who weigh >45 kg: Treat with one of the regimens recommended for adults

Recommended regimens for children who weigh ≤ 45 kg and who have uncomplicated gonococcal vulvovaginitis, cervicitis, urethritis, pharyngitis, or proctitis

- Ceftriaxone 125 mg IM in a single dose

Alternative Regimen

Spectinomycin: 40 mg/kg (maximum dose: 2 g) IM in a single dose may be used, but this therapy is unreliable for treatment of pharyngeal infections. Some specialists use cefixime to treat gonococcal infections in children because it can be administered orally; however, no reports have been published concerning the safety or effectiveness of cefixime used for this purpose.

Table B29. *(Continued)*

Recommended regimen for children who weigh ≤ 45 kg and who have bacteremia or arthritis

- Ceftriaxone 50 mg/kg (maximum dose: 1 g) IM or IV in a single dose daily for 7 days

Recommended regimen for children who weigh >45 kg and who have bacteremia or arthritis

- Ceftriaxone 50 mg/kg IM or IV in a single dose daily for 7 days

Table B30. Treatment of Bacterial Vaginosis

Recommended regimens

- Metronidazole 500 mg orally twice a day for 7 days

  or

- Metronidazole gel, 0.75%, one full applicator (5 g) intravaginally, once a day for 5 days

  or

- Clindamycin cream, 2%, one full applicator (5 g) intravaginally at bedtime for 7 days

Persons should be advised to avoid consuming alcohol during treatment with metronidazole and for 24 hours thereafter. Clindamycin cream is oil-based and might weaken latex condoms and diaphragms for 5 days after use. Refer to clindamycin product labeling for additional information. Topical clindamycin preparations should not be used in the second half of pregnancy.

Alternative regimens

- Clindamycin 300 mg orally twice a day for 7 days

  or

Clindamycin ovules 100 mg intravaginally once at bedtime for 3 days

Table B31. Treatment of Trichomoniasis

Recommended regimens

- Metronidazole 2 g orally in a single dose

  or

- Tinidazole 2 g orally in a single dose

Alternative regimen

- Metronidazole 500 mg orally twice a day for 7 days

Persons should be advised to avoid consuming alcohol during treatment with metronidazole or tinidazole. Abstinence from alcohol use should continue for 24 hours after completion of metronidazole or 72 hours after completion of tinidazole.

The nitroimidazoles comprise the only class of drugs useful for the oral or parenteral therapy of trichomoniasis.

Table B32. Vulvovaginal Candidiasis

VVC usually is caused by *C. albicans* but occasionally is caused by other *Candida* sp. or yeasts. On the basis of clinical presentation, microbiology, host factors, and response to therapy, VVC can be classified as either uncomplicated or complicated. Approximately 10–20% of women will have complicated VVC, suggesting diagnostic and therapeutic considerations.

Classification of vulvovaginal candidiasis (VVC)

Uncomplicated VVC

- Sporadic or infrequent VVC
  and
- Mild-to-moderate VVC
  and
- Likely to be *Candida albicans*
  and
- Nonimmunocompromised women

Complicated VVC

- Recurrent VVC
  or
- Severe VVC
  or
- Nonalbicans candidiasis
  or
- Women with uncontrolled diabetes, debilitation, or immunosuppression, or those who are pregnant

Table B33. Treatment of Uncomplicated VVC[a]

Short-course topical formulations (i.e., single dose and regimens of 1--3 days) effectively treat uncomplicated VVC. The topically applied azole drugs are more effective than nystatin. Treatment with azoles results in relief of symptoms and negative cultures in 80–90% of patients who complete therapy.

Recommended regimens

Intravaginal agents:

- Butoconazole 2% cream 5 g intravaginally for 3 days[b]
  or
- Butoconazole 2% cream 5 g (Butaconazole1-sustained release), single intravaginal application
  or
- Clotrimazole 1% cream 5 g intravaginally for 7–14 days[b]
  or
- Clotrimazole 100 mg vaginal tablet for 7 days
  or
- Clotrimazole 100 mg vaginal tablet, two tablets for 3 days
  or
- Miconazole 2% cream 5 g intravaginally for 7 days[b]
  or
- Miconazole 100 mg vaginal suppository, one suppository for 7 days[b]
  or

Table B33. *(Continued)*

- Miconazole 200 mg vaginal suppository, one suppository for 3 days[b]

  or
- Miconazole 1,200 mg vaginal suppository, one suppository for 1 day[b]

  or
- Nystatin 100,000-unit vaginal tablet, one tablet for 14 days

  or
- Tioconazole 6.5% ointment 5 g intravaginally in a single application[b]

  or
- Terconazole 0.4% cream 5 g intravaginally for 7 days

  or
- Terconazole 0.8% cream 5 g intravaginally for 3 days

  or
- Terconazole 80 mg vaginal suppository, one suppository for 3 days

Oral Agent:

- Fluconazole 150 mg oral tablet, one tablet in single dose

[a]For treatment of complicated VVC, see full guidelines report.

[b]Over-the-counter preparations.

Table B34. Treatment of Pelvic Inflammatory Disease

All treatment regimens should be effective against *N. gonorrhoeae* and *C. trachomatis* because negative endocervical screening for these organisms does not rule out upper reproductive tract infection. The need to eradicate anaerobes from women who have PID has not been determined definitively. Anaerobic bacteria have been isolated from the upper reproductive tract of women who have PID, and data from in vitro studies have revealed that some anaerobes (e.g., *Bacteroides fragilis*) can cause tubal and epithelial destruction. In addition, BV also is present in many women who have PID. Until treatment regimens that do not adequately cover these microbes have been demonstrated to prevent long-term sequelae (e.g., infertility and ectopic pregnancy) as successfully as the regimens that are effective against these microbes, the use of regimens with anaerobic activity should be considered.

Recommended parenteral regimen A

- Cefotetan 2 g IV every 12 hours

  or
- Cefoxitin 2 g IV every 6 hours

  plus
- Doxycycline 100 mg orally or IV every 12 hours

Because of the pain associated with infusion, doxycycline should be administered orally when possible, even when the patient is hospitalized. Oral and IV administration of doxycycline provide similar bioavailability.

Parenteral therapy may be discontinued 24 hours after a patient improves clinically, and oral therapy with doxycycline (100 mg twice a day) should continue to complete 14 days of therapy. When tubo-ovarian abscess is present, many healthcare providers use clindamycin or metronidazole with doxycycline for continued therapy, rather than doxycycline alone, because it provides more effective anaerobic coverage. Clinical data are limited regarding the use of other second or third-generation cephalosporins (e.g., ceftizoxime, cefotaxime, and ceftriaxone).

(continued)

Table B34. *(Continued)*

Recommended parenteral regimen B

- Clindamycin 900 mg IV every 8 hours

  plus

- Gentamicin loading dose IV or IM (2 mg/kg of body weight), followed by a maintenance dose (1.5 mg/kg) every 8 hours. Single daily dosing may be substituted.

Alternative parenteral regimens

- Ampicillin/Sulbactam 3 g IV every 6 hours

  plus

- Doxycycline 100 mg orally or IV every 12 hours

Oral therapy can be considered for women with mild-to-moderately severe acute PID, as the clinical outcomes among women treated with oral therapy are similar to those treated with parenteral therapy. Women who do not respond to oral therapy within 72 hours should be reevaluated to confirm the diagnosis and should be administered parenteral therapy on either an outpatient or in-patient basis.

Recommended Oral Regimen
Ceftriaxone 250 mg IM in a single dose
Plus
Doxycycline 100 mg orally twice a day for 14 days
With or without
Metronidazole 500 mg orally twice a day for 14 days

OR

Cefoxitin 2 g IM in a single dose and Probenecid,
1 g orally administered concurrently in a single dose
Plus
Doxycycline 100 mg orally twice a day for 14 days
With or without
Metronidazole 500 mg orally twice a day for 14 days

OR

Other parenteral third-generation cephalosporin
(e.g., ceftizoxime or cefotaxime)
Plus
Doxycycline 100 mg orally twice a day for 14 days
With or without
Metronidazole 500 mg orally twice a day for 14 days

Alternative Oral Regimens

If parenteral cephalosporin therapy is not feasible, use of fluoroquinolones (levofloxacin 500 mg orally once daily or ofloxacin 400 mg twice daily for 14 days) with or without metronidazole (500 mg orally twice daily for 14 days) may be considered if the community prevalence and individual risk (see "Gonococcal Infections in Adolescents and Adults" in *Sexually Transmitted Disease Treatment Guidelines,* 2006) of gonorrhea is low. Tests for gonorrhea must be performed prior to instituting therapy and the patient managed as follows if the test is positive:

- If NAAT test is positive, parenteral cephalosporin is recommended.
- If culture for gonorrhea is positive treatment should be based on results of antimicrobial susceptibility. If isolate is QRNG, or antimicrobial susceptibility can't be assessed, parenteral cephalosporin is recommended.

Although information regarding other outpatient regimens is limited, amoxicillin/clavulanic acid and doxycycline or azithromycin with metronidazole has demonstrated short-term clinical cure. No data have been published regarding the use of oral cephalosporins for the treatment of PID.

Table B35. Recommended Regimens for Treatment of Epididymitis

As empiric therapy is often initiated before laboratory tests are available, it is recommended that all persons receive ceftriaxone plus doxycycline for the initial therapy of epididymitis. Additional therapy may include a quinolone if acute epididymitis is not caused by gonorrhea based on a culture or nucleic acid amplification testing or if the infection is most likely caused by enteric organisms. The goals of treatment of acute epididymitis caused by *C. trachomatis* or *N. gonorrhoeae* are (1) microbiologic cure of infection, (2) improvement of signs and symptoms, (3) prevention of transmission to others, and (4) a decrease in potential complications (e.g., infertility or chronic pain). As an adjunct to therapy, bed rest, scrotal elevation, and analgesics are recommended until fever and local inflammation have subsided.

Recommended regimens

- Ceftriaxone 250 mg IM in a single dose

  plus

- Doxycycline 100 mg orally twice a day for 10 days

For acute epididymitis most likely caused by enteric organisms or with negative gonococcal culture or nucleic acid amplification test

- Ofloxacin 300 mg orally twice a day for 10 days

  or

- Levofloxacin 500 mg orally once daily for 10 days

Table B36. Recommended Regimens for External Genital Warts

Patient applied:

- Podofilox 0.5% solution or gel. Patients should apply podofilox solution with a cotton swab, or podofilox gel with a finger, to visible genital warts twice a day for 3 days, followed by 4 days of no therapy. This cycle may be repeated, as necessary, for up to four cycles. The total wart area treated should not exceed 10 cm2, and the total volume of podofilox should be limited to 0.5 mL per day. If possible, the health-care provider should apply the initial treatment to demonstrate the proper application technique and identify which warts should be treated. The safety of podofilox during pregnancy has not been established.

  or

- Imiquimod 5% cream. Patients should apply imiquimod cream once daily at bedtime, three times a week for up to 16 weeks. The treatment area should be washed with soap and water 6–10 hours after the application. The safety of imiquimod during pregnancy has not been established.

Provider administered:

- Cryotherapy with liquid nitrogen or cryoprobe. Repeat applications every 1–2 weeks.

  or

- Podophyllin resin 10–25% in a compound tincture of benzoin. A small amount should be applied to each wart and allowed to air dry. The treatment can be repeated weekly, if necessary. To avoid the possibility of complications associated with systemic absorption and toxicity, two important guidelines should be followed: (1) application should be limited to <0.5 mL of podophyllin or an area of <10 cm^2 of warts per session and (2) no open lesions or wounds should exist in the area to which treatment is administered. Some specialists suggest that the preparation should be thoroughly washed off 1–4 hours after application to reduce local irritation. The safety of podophyllin during pregnancy has not been established.

  or

(continued)

Table B36. *(Continued)*

- Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80–90%. A small amount should be applied only to the warts and allowed to dry, at which time a white "frosting" develops. If an excess amount of acid is applied, the treated area should be powdered with talc, sodium bicarbonate (i.e., baking soda), or liquid soap preparations to remove unreacted acid. This treatment can be repeated weekly, if necessary.

  or

- Surgical removal either by tangential scissor excision, tangential shave excision, curettage, or electrosurgery

Alternative regimens

- Intralesional interferon

  or

- Laser surgery

Table B37. Recommended Regimens for Cervical Warts

Recommended regimens for cervical warts

- For women who have exophytic cervical warts, high-grade SIL must be excluded before treatment is initiated. Management of exophytic cervical warts should include consultation with a specialist.

Recommended regimens for vaginal warts

- Cryotherapy with liquid nitrogen. The use of a cryoprobe in the vagina is not recommended because of the risk for vaginal perforation and fistula formation.

  or

- TCA or BCA 80–90% applied to warts. A small amount should be applied only to warts and allowed to dry, at which time a white "frosting" develops. If an excess amount of acid is applied, the treated area should be powdered with talc, sodium bicarbonate, or liquid soap preparations to remove unreacted acid. This treatment can be repeated weekly, if necessary.

Recommended regimens for urethral meatus warts

- Cryotherapy with liquid nitrogen

  or

- Podophyllin 10–25% in compound tincture of benzoin. The treatment area must be dry before contact with normal mucosa. This treatment can be repeated weekly, if necessary. The safety of podophyllin during pregnancy has not been established. Although data evaluating the use of podofilox and imiquimod for the treatment of distal meatal warts are limited, some specialists recommend their use in some patients.

Recommended regimens for anal warts

- Cryotherapy with liquid nitrogen

  or

- TCA or BCA 80–90% applied to warts. A small amount should be applied only to warts and allowed to dry, at which time a white "frosting" develops. If an excess amount of acid is applied, the treated area should be powdered with talc, sodium bicarbonate, or liquid soap preparations to remove unreacted acid. This treatment can be repeated weekly, if necessary.

  or

- Surgical removal

Warts on the rectal mucosa should be managed in consultation with a specialist. Many persons with warts on the anal mucosa also have warts on the rectal mucosa and so persons with anal warts can benefit from an inspection of the rectal mucosa by digital examination or anoscopy.

Table B38. Treatment of Acute Proctitis

Acute proctitis of recent onset among persons who have recently practiced receptive anal intercourse is usually sexually acquired. Such patients should be examined by anoscopy and should be evaluated for infection with HSV, *N. gonorrhoeae, C. trachomatis,* and *T. pallidum*. If an anorectal exudate is detected on examination or if polymorphonuclear leukocytes are detected on a Gram-stained smear of anorectal secretions, the following therapy may be prescribed while awaiting additional laboratory tests.

Recommended Regimen
Ceftriaxone 125 mg IM (or another agent effective against rectal and genital gonorrhea)
PLUS
Doxycycline 100 mg orally twice a day for 7 days

Persons with suspected or documented herpes proctitis should be managed in the same manner as those with genital herpes. If painful perianal ulcers are present or mucosal ulcers are detected on anoscopy, presumptive therapy should include a regimen for treating genital herpes. In addition, LGV proctitis should also be considered. Appropriate diagnostic testing for LGV should be conducted in accordance with state or federal guidelines, and doxycycline therapy should be administered 100 mg orally twice daily for 3 weeks.

Table B39. Treatment of Pediculosis Pubis

Recommended regimens

- Permethrin 1% cream rinse applied to affected areas and washed off after 10 minutes

  or

- Pyrethrins with piperonyl butoxide applied to the affected area and washed off after 10 minutes

Alternative Regimens

- Malathion 0.5% lotion applied for 8–12 hours and washed off

  or

- Ivermectin 250 ug/kg repeated in 2 weeks

Reported resistance to pediculcides has been increasing and is widespread. Malathion may be used when treatment failure is believed to have occurred because of resistance. The odor and long duration of application for malathion make it a less attractive alternative than the recommended pediculcides. Ivermectin has been successfully used to treat lice but has only been evaluated in small studies.

Lindane is not recommended as first-line therapy because of toxicity. It should only be used as an alternative because of inability to tolerate other therapies or if other therapies have failed. Lindane toxicity, as indicated by seizure and aplastic anemia, has not been reported when treatment was limited to the recommended 4-minute period. Permethrin has less potential for toxicity than lindane.

Table B40. Recommended Regimens for Treatment of Scabies

- Permethrin cream (5%) applied to all areas of the body from the neck down and washed off after 8–14 hours

  or

- Ivermectin 200 μg/kg orally, repeated in 2 weeks

Alternative Regimens

- Lindane (1%) 1 oz of lotion or 30 g of cream applied in a thin layer to all areas of the body from the neck down and thoroughly washed off after 8 hours

Lindane is not recommended as first-line therapy because of toxicity. It should only be used as an alternative if the patient cannot tolerate other therapies or if other therapies have failed.

Lindane should not be used immediately after a bath or shower, and it should not be used by persons who have extensive dermatitis, women who are pregnant or lactating, or children aged <2 years. Lindane resistance has been reported in some areas of the world, including parts of the United States. Seizures have occurred when lindane was applied after a bath or used by patients who had extensive dermatitis. Aplastic anemia after lindane use also has been reported.

Permethrin is effective and safe and less expensive than ivermectin. One study demonstrated increased mortality among elderly, debilitated persons who received ivermectin, but this observation has not been confirmed in subsequent reports.

Other management considerations:

Bedding and clothing should be decontaminated (i.e., either machine-washed, machine-dried using the hot cycle, or dry cleaned) or removed from body contact for at least 72 hours. Fumigation of living areas is unnecessary.
