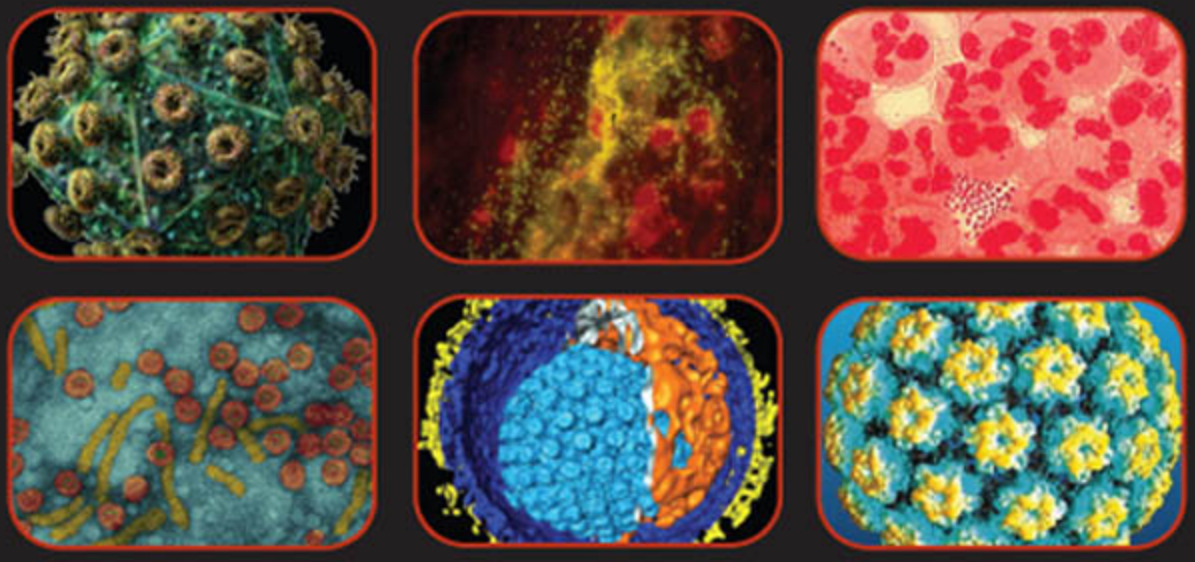
4TH EDITION

SEXUALLY TRANSMITTED DISEASES



KING K. HOLMES • P. FREDERICK SPARLING • WALTER E. STAMM
PETER PIOT • JUDITH N. WASSERHEIT
LAWRENCE COREY • MYRON S. COHEN • D. HEATHER WATTS

Sexually Transmitted Diseases

KING K. HOLMES, MD, PhD
Director, Center for AIDS and STD; William H. Foege Chair, Department of Global Health,
University of Washington; Chief, Infectious Diseases,
Harborview Medical Center, Seattle, Washington

P. FREDERICK SPARLING, MD
Professor Emeritus of Medicine and Microbiology and Immunology, Division of Infectious Diseases,
Department of Medicine, University of North Carolina at Chapel Hill School of Medicine,
Chapel Hill, North Carolina

WALTER E. STAMM, MD
Professor of Medicine, Head, Division of Allergy and Infectious Diseases,
University of Washington,
Seattle, Washington

PETER PIOT, MD, PhD
Executive Director, Joint UN Programme on HIV/AIDS,
Geneva, Switzerland

JUDITH N. WASSERHEIT, MD, MPH
Professor of Global Health and Medicine Vice Chair,
Department of Global Health Schools of Medicine and
Public Health & Community Medicine
University of Washington, Affiliate Investigator
Fred Hutchinson Cancer Research Center
Seattle, Washington

LAWRENCE COREY, MD
Fred Hutchinson Cancer Research Center, Program in Infectious Diseases,
Departments of Medicine and Laboratory Medicine,
University of Washington, Seattle, Washington

MYRON S. COHEN, MD
J. Herbert Bate Distinguished Professor, Medicine, Microbiology, Immunology, Public Health,
Division of Infectious Diseases, Department of Medicine,
University of North Carolina at Chapel Hill, North Carolina

D. HEATHER WATTS, MD
Medical Officer, Pediatric, Adolescent, and Maternal AIDS Branch,
Center for Research on Mothers and Children,
National Institute of Child Health and Human Development/NIH,
Bethesda, Maryland

RONALD A. NELSON
Assistant Editor, Center for AIDS & STD,
University of Washington, Seattle, Washington

Sexually Transmitted Diseases

CONTENTS

CONTRIBUTORS

Miriam J. Alter, PhD (Chapter 29)
Robert E. Shope Professor of Infectious Disease Epidemiology; Director, Infectious Disease Epidemiology Program, Institute for Human Infections and Immunity, The University of Texas Medical Branch at Galveston, Galveston, Texas

Deborah J. Anderson, PhD (Chapter 17)
Professor, Department of Obstetrics and Gynecology, Boston University School of Medicine, Boston Massachusetts

Sevgi O. Aral, PhD, MS, MA (Chapters 5, 89, 92)
Director. of Science, Division of STD Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Akhila Balasubramanian, MPH (Chapter 57)
HPV Research Group, Department of Epidemiology, University of Washington, Seattle, Washington

Ronald C. Ballard, PhD (Chapter 63)
Chief, Laboratory Reference and Research Branch, Division of STD Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Stefan David Baral, MD, MPH, MBA (Chapter 16)
Community Medicine Resident, University of Toronto, Ontario, Canada

Ronald Bayer, PhD (Chapter 107)
Center for the History and Ethics of Public Health, Department of Sociomedical Sciences, Mailman School of Public Health, Columbia University, New York, New York

Stuart M. Berman, MD, ScM (Chapter 11, Appendix B)
Chief, Epidemiology and Surveillance Branch, Division of STD Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Stefano M. Bertozzi, MD, PhD (Chapter 2)
Director Health Economics and Policy, Division of Economics and Policy, Department of Center for Health Systems Research, National Institute of Public Health, Cuernavaca, Morelos, Mexico

Christopher Beyrer, MD, MPH (Chapter 16)
Professor, Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland

James F. Blanchard, MD, MPH, PhD (Chapter 12)
Associate Professor, Department of Community Health Sciences; Canada Research Chair in Epidemiology and Global Public Health, University of Manitoba, Winnipeg, Manitoba, Canada

Magaly M. Blas, MD, MPH (Chapter 108)
Research Professor Unit of STD and HIV, School of Public Health, Universidad Peruana Cayetano Heredia, Peru; Senior Fellow Trainee, School of Public Health, PhD Candidate, University of Washington, Seattle, Washington

William A. Blattner, MD (Chapter 22)
Professor of Medicine, Division of Epidemiology and Prevention, Institute of Human Virology; Professor of Medicine, Division of Geographic Medicine, University of Maryland School of Medicine, Baltimore, Maryland

J. Ties Boerma, MD, PhD (Chapter 98)
Director, Department of Measurement and Health Information Systems, World Health Organization, Geneva, Switzerland

Russell D. Bradford, MD (Chapter 84)
Fellow, Department of Pediatrics, University of Alabama at Birmingham, Birmingham, Alabama

Donald C. Bross, JD, PhD (Chapter 106)
Professor of Pediatrics, University of Colorado School of Medicine; Director of Education and Legal Counsel, Kempe Children's Center, Denver, Colorado

Robert C. Brunham, MD (Chapter 99)
Professor of Medicine, University of British Columbia; Provincial Executive Director and Scientific Director, British Columbia Centre for Disease Control, Vancouver, British Columbia, Canada

Gale R. Burstein, MD, MPH (Chapter 88)
Medical Officer, Division of STD Prevention, Health Services Research and Evaluation Branch, Centers for Disease Control and Prevention, Atlanta, Georgia; Atlanta, Georgia

Anne Buvé, MD, PhD (Chapter 10)
Department of Microbiology, Head, STI/HIV Research and Intervention Unit, Institute of Tropical Medicine Antwerp, Belgium

Michel Caraël, PhD (Chapter 98)
Faculty of Social, Economic, and Political Sciences, Department of Social Sciences, Free University of Brussels, Brussels, Belgium

Alex Carballo-Diéguez, PhD (Chapter 13)
Professor of Clinical Psychology, Department of Psychology, HIV Center for Clinical and Behavioral Studies, Columbia University, New York, New York

Willard Cates, Jr., MD, MPH (Chapters 78, 79, 93, 94)
President, Family Health International, Research Triangle Park, North Carolina

Manhattan E. Charurat, PhD (Chapter 22)
Assistant Professor, Institute of Human Virology, Division of Epidemiology and Prevention University of Maryland School of Medicine, Baltimore, Maryland

Tae-Wook Chun, PhD (Chapter 21)
Staff Scientist, Laboratory of Immunoregulation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland

Thomas J. Coates, PhD (Chapter 53)
Professor of Medicine, David Geffen School of Medicine; Division of Infectious Diseases, Associate Director, UCLA AIDS Institute, University of California, Los Angeles, California

Myron S. Cohen, MD
J. Herbert Bate Distinguished Professor of Medicine, Microbiology and Immunology, and Public Health, Chief, Division of Infectious Diseases, Director, Institute of Global Health and Infectious Diseases, The University of North Carolina, Chapel Hill, North Carolina

Roy Colven, MD (Chapter 62)
Associate Professor, Department of Medicine, Division of Dermatology, University of Washington School of Medicine, Seattle, Washington

Robert W. Coombs, MD, PhD (Chapter 70)
Professor of Laboratory Medicine and Medicine, Harborview Medical Center Research and Training Virology; Director, ACTU Retrovirus Laboratory, University of Washington, Seattle, Washington

Lawrence Corey, MD (Chapters 24, 100)
Fred Hutchinson Cancer Research Center, Program in Infectious Diseases; Professor Medicine, Departments of Medicine and Laboratory Medicine, University of Washington, Seattle, Washington

Patricia A. Cornett, MD (Chapter 76)
Clinical Professor, Department of Medicine, VA Medical Center, San Francisco, California

Mark F. Cotton, MB, ChB, MMed, FCPaed(SA), DCH(SA), DTM&H, PhD (Chapter 86)
Director, KID-CRU (Children's Infectious Diseases Clinical Research Unit), Tygerberg Children's Hospital; Faculty of Health Sciences, Stellenbosch University, Tygerberg, South Africa

Walter H. Curioso, MD, MPH (Chapter 108)
Research Professor, School of Medicine and School of Public Health, Universidad Peruana Cayetano Heredia, Peru; Affiliate Assistant Professor, Medical Education and Biomedical Informatics, University of Washington, Seattle, Washington

Gina A. Dallabetta, MD (Chapter 101)
India AIDS Initiative, Avahan, Bill and Melinda Gates Foundation, New Delhi, India

Catherine F. Decker, MD (Chapter 75)
Division of Infectious Diseases, National Naval Medical Center, Bethesda, Maryland

Don C. Des Jarlais, PhD (Chapter 15)
Chemical Dependency Institute, Beth Israel Medical Center, New York, New York

Samuel W. Dooley, MD (Chapter 72)
Associate Director for Science and Program Integration, Division of HIV/AIDS Prevention, National Center for HIV, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

John M. Douglas, Jr., MD (Chapters 30, 90)
Director, Division of STD Prevention, National Center for HIV, STD and TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Anne Duerr, MD, PhD, MPH (Chapter 100)
HUTN Core Operations, Fred Hutchinson Cancer Research Center, Program in Infectious Diseases, Seattle, Washington

Libby Edwards, MD (Chapter 64)
Clinical Associate Professor, University of North Carolina School of Medicine; Chief, Division of Dermatology, Carolinas Medical Center, Charlotte, North Carolina

Erin M. Egelkrout, PhD (Chapter 27)
Senior Scientist, Applied Biotechnology Institute, Cal Poly State University, San Louis Obispo, California

Jonathan M. Ellen, MD (Chapter 11)
Professor and Vice Chair, Department of Pediatrics, Johns Hopkins School of Medicine; Director, Department of Pediatrics Johns Hopkins Bayview Medical Center, Baltimore, Maryland

Joseph J. Eron, Jr., MD (Chapter 73)
Professor of Medicine, School of Medicine; Division of Infectious Diseases, Director, UNC Center for AIDS Clinical Core, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

David Eschenbach, MD (Chapter 56)
Professor, Women's Health Chair, Department of Obstetrics and Gynecology, University of Washington, Seattle, Washington

Anthony S. Fauci, MD (Chapter 21)
Director, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland

Elisabeth Faxelid, RNM (Chapter 54)
Associate Professor, Division of International Health (IHCAR), Department of Public Health Sciences, Karolinska Institutet, Stockholm, Sweden

Kevin A. Fenton, MD, PhD (Chapter 90)
Director, National Center for HIV/AIDS, Viral Hepatitis, STD and TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Mary Glenn Fowler, MD, MPH (Chapter 86)
Visiting Professor, Department of Pathology, Johns Hopkins School of Medicine; Johns Hopkins Onsite Investigator, Makerere University-Johns Hopkins Research Collaboration, Kampala, Uganda

Denise A. Galloway, PhD (Chapter 27)
Research Professor, Microbiology, Fred Hutchinson Cancer Research Center, University of Washington, Seattle, Washington

Geoff P. Garnett, PhD, MSc, BSc (Chapter 3)
Professor of Microparasite Epidemiology, Division of Epidemiology, Public Health, Imperial College London, United Kingdom

Charlotte A. Gaydos, MS, MPH, DrPH (Chapter 52)
Associate Professor, Division of Infectious Diseases, Department of Medicine, Johns Hopkins University, Baltimore, Maryland

Adam P. Geballe, MD (Chapter 25)
Member, Human Biology Division and Clinical Research Division, Fred Hutchinson Cancer Research Center; Professor, Department of Medicine/Allergy and Infectious Diseases, University of Washington, Seattle, Washington

William M. Geisler, MD, MPH (Chapter 60)
Assistant Professor, Division of Infectious Diseases, Department of Medicine, University of Alabama at Birmingham, Birmingham, Alabama

Amy P. Goldberg, MD (Chapter 105)
Assistant Professor, Department of Pediatrics, Brown Medical School; Providence, Rhode Island

Matthew R. Golden MD, MPH (Chapters 54, 91)
Assistant Professor of Medicine, University of Washington; Director, Public Health—Seattle & King County Sexually Transmitted Diseases Control Program, Harborview Medical Center, Seattle, Washington

Carol E. Golin, MD (Chapter 71)
Research Assistant Professor, Department of Medicine, School of Medicine; Department of Health Behavior and Health Education, School of Public Health; Cecil G. Sheps Center for Health Services Research, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Steven Goodreau, PhD (Chapter 7)
Assistant Professor, Department of Anthropology, University of Washington, Seattle, Washington

Pamina M. Gorbach, MHS, DrPH (Chapter 8)
Associate Professor, Department of Epidemiology, School of Public Health, University of California, Los Angeles

Catherine Gourbin (Chapter 10)
Institut de Démographie, Universite Catholique de Louvain, Louvain-la-Neuve, Belgium

Daniel O. Graney, PhD (Chapters 49, 50)
Professor, Department of Biological Structure, School of Medicine; University of Washington, Seattle, Washington

Ian Grimm, MD (Chapter 66)
Associate Professor of Medicine, Division of Gastroenterology and Hepatology, University of North Carolina School of Medicine; Chapel Hill, North Carolina

Michael Gross, PhD (Chapter 94)
Public Health Consultant, Long Beach, California

Richard L. Guerrant, MD (Chapter 44)
Thomas H. Hunter Professor of International Medicine; Director, Center for Global Health, Division of Infectious Diseases and International Health, University of Virginia School of Medicine, Charlottesville, Virginia

Morgan Hakki, MD (Chapter 25)
Associate in Clinical Research, Fred Hutchinson Cancer Research Center; Acting Instructor Medicine, University of Washington, Seattle, Washington

Colin Hall, MB, ChB (Chapter 77)
Professor and Interim Chairman, Department of Neurology, AIDS Neurological Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Margaret R. Hammerschlag, MD (Chapter 83)
Professor of Medicine and Pediatrics, SUNY Downstate Medical Center, Brooklyn, New York

Edward Handelsman, MD (Chapter 86)
Assistant Professor, Department of Pediatrics, SUNY Downstate and Kings County Hospital Center, Brooklyn, New York

H. Hunter Handsfield, MD (Chapters 35, 51, 67)
Senior Research Leader, Batelle Seattle Center for Public Health Research and Evaluation; Clinical Professor of Medicine, Center for AIDS and STD, University of Washington, Seattle, Washington

Patrick R. Harrington, PhD (Chapter 20)
Postdoctoral Fellow, Lineberger Cancer Center, University of North Carolina at Chapel Hill, North Carolina

Stephen E. Hawes, PhD (Chapter 58)
Assistant Professor, Department of Epidemiology, University of Washington, Seattle, Washington

Bernadine P. Healy, MD (Chapter 37)
Columnist and Health Editor, US News and World Report; Former Director, National Institute of Health (NIH), Bethesda Maryland; Former Dean, College of Medicine and Public Health, Ohio State University, Columbus, Ohio

Zsakeba Henderson, MD (Chapter 88)
Epidemic Intelligence Service Officer, Division of STD Prevention, Health Services Research and Evaluation Branch, Centers for Disease Control and Prevention, Atlanta, Georgia

Sharon L. Hillier, PhD (Chapters 18, 42, 94)
Professor of Obstetrics, Gynecology and Reproductive Sciences and Molecular Genetics and Biochemistry, University of Pittsburgh School of Medicine; Director, Center of Excellence in Women's Health, Magee-Women's Hospital of the University of Pittsburgh Medical Center; Pittsburgh, Pennsylvania

Martin S. Hirsch, MD (Chapter 73)
Professor of Medicine, Harvard Medical School; Professor of Immunology and Infectious Diseases, Harvard School of Public Health; Boston, Massachusetts

Jane Hitti, MD, MPH (Chapter 80)
Associate Professor, Division of Perinatal Medicine, Department of Obstetrics and Gynecology, University of Washington, Seattle, Washington

Marcia M. Hobbs, PhD (Chapter 43)
Associate Professor of Medicine, Microbiology and Immunology, Division of Infectious Diseases, Department of Medicine and Microbiology and Immunology, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Matthew Hogben, PhD (Chapter 92)
Division of STD Prevention, National Center for HIV, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

King K. Holmes, MD, PhD (Chapters 5, 8, 42, 47, 55, 89)
Director, Center for AIDS and STD; William H. Foege Chair, Department of Global Health, University of Washington; Chief, Infectious Diseases, Harborview Medical Center, Seattle, Washington

David R. Holtgrave, PhD (Chapter 95)
Professor and Chair, Department of Health, Behavior and Society, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, Maryland

Edward W. Hook, III, MD (Chapter 35)
Professor of Medicine, Microbiology, and Epidemiology, Division of Infectious Diseases, Department of Medicine, University of Alabama at Birmingham, Birmingham, Alabama

Robert Hornik, PhD (Chapter 96)
Wilbur Schramm Professor of Communication and Health Policy, Annenberg School for Communication, University of Pennsylvania, Philadelphia, Pennsylvania

Kathleen L. Irwin, MD, MPH (Chapter 88)
Chief, Health Services Research and Evaluation Branch, Division of STD Prevention, National Center for HIV, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Nidhi Jain, MD, MPH (Chapter 88)
Medical Officer, Division of STD Prevention, Health Services Research and Evaluation Branch, Centers for Disease Control and Prevention, Atlanta, Georgia; Atlanta, Georgia

Carole Jenny, MD, MBA (Chapter 105)
Professor, Department of Pediatrics, Brown Medical School, Providence, Rhode Island

Jørgen Skov Jensen, MD, PhD (Chapter 41)
Mycoplasma Laboratory, Statens Serum Institut, Copenhagen, Denmark

Mary Kamb, MD, MPH (Chapter 47)
Prevention Services Research Branch, Division of HIV/AIDS Prevention-Surveillance, and Epidemiology National Center for HIV, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Andrew H. Kaplan, MD (Chapter 71)
Departments of Medicine and Microbiology & Immunology; University of North Carolina School of Medicine, Chapel Hill, North Carolina

Jonathan E. Kaplan, MD (Chapter 74)
Chief, HIV Care and Treatment Branch, Global AIDS Program, National Center for HIV, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Jeffrey A. Kelly, PhD (Chapter 95)
Professor of Psychiatry, Behavioral Medicine, and Director, Center for AIDS Intervention Research, Department of Psychiatry and Behavioral Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin

Nancy B. Kiviat, MD (Chapter 58)
Professor, Department of Pathology, University of Washington School of Medicine, Seattle, Washington

Jeffrey D. Klausner, MD, MPH (Chapter 108)
Deputy Health Officer and Director, STD Prevention and Control Services, San Francisco Department of Public Health; Associate Clinical Professor of Medicine, University of California, San Francisco, California

Stephan A. Kohlhoff, MD (Chapter 83)
Professor of Medicine and Pediatrics, SUNY Downstate Medical Center, Brooklyn, New York

Laura A. Koutsky, PhD, MSPH (Chapters 28, 57)
Professor, Epidemiology, School of Public Health & Community Medicine; HPV Research Group, University of Washington, Seattle, Washington

Derek Kreager, PhD (Chapter 6)
Assistant Professor, Department of Sociology, Pennsylvania State University, University Park, Pennsylvania

John N. Krieger, MD (Chapters 50, 60, 61)
Professor, Department of Urology, University of Washington School of Medicine; Chief of Urology, VA Puget Sound Health Care System; Seattle, Washington

Ann E. Kurth, RN, CNM, PhD (Chapters 48, 69, 108)
Assistant Professor, School of Nursing, Department of Biobehavioral Nursing and Health Systems; Adjunct Assistant Professor, School of Public Health and Community Medicine, Department of Epidemiology, University of Washington, Seattle, Washington

Jane Kuypers, PhD (Chapter 52)
Research Scientist, Senior, Department of Laboratory Medicine, Virology University of Washington, Seattle, Washington

Marie Laga, MD, MPH, PhD (Chapters 10, 103)
Department of Microbiology, Head, STI/HIV Research and Intervention Unit, Institute of Tropical Medicine, Antwerp, Belgium

Peter A. Leone, MD (Chapter 46)
Associate Professor of Medicine, University of North Carolina, Chapel Hill; Medical Director, North Carolina HIV/STD Prevention and Care Branch, North Carolina, Chapel Hill, North Carolina

Stanley M. Lemon, MD (Chapters 19, 29)
John Sealy Distinguished University Chair and Director, Institute for Human Infections and Immunity, University of Texas Medical Branch, Galveston, Texas

William C. Levine, MD, MSc (Chapter 97)
Associate Director for Science Global AIDS Program, Centers for Disease Control and Prevention, Atlanta, Georgia

Susan Lightman, FRCOphth, FRCP, PhD, FMedSci, MD (Chapter 65)
Professor of Clinical Ophthalmology, Institute of Ophthalmology, Moorfields Eye Hospital, London, United Kingdom

Anna Lok, MD, FRCP (Chapter 29)
Professor of Internal Medicine; Director of Clinical Hepatology, University of Michigan Medical School, Ann Arbor, Michigan

Nicola Low, MD, MRCP, MFPH (Chapter 54)
Senior Lecturer in Epidemiology and Public Health, Division of Epidemiology and Biostatistics, Department of Social and Preventive Medicine, University of Bern, Bern, Switzerland

Sheila A. Lukehart, PhD (Chapter 36)
Professor, Division of Infectious Diseases, Department of Medicine, University of Washington, Seattle, Washington

William Lynn, MD, FRCP (Chapter 65)
Department of Infectious Diseases, Ealing Hospital, Southall, Middlesex, United Kingdom

David Mabey (Chapter 104)
Professor, London School of Hygiene and Tropical Medicine, Department of Clinical Sciences, Director, Wellcome Trust Bloomsbury Centre, London, United Kingdom

Lisa E. Manhart, MPH, PhD (Chapter 89)
Assistant Professor of Epidemiology, University of Washington; Center for AIDS and STD, University of Washington, Seattle, Washington

Hein Marais (Chapter 4)
Writer, Editor, Journalist, Geneva, Switzerland

Jeanne M. Marrazzo, MD, MPH (Chapters 14, 42)
Associate Professor, Division of Allergy and Infectious Diseases, Department of Medicine, University of Washington, Seattle, Washington

David H. Martin, MD (Chapter 59)
Harry E. Dascomb Professor of Medicine and Professor of Microbiology; Chief, Section of Infectious Diseases, Louisiana State University Health Sciences Center, New Orleans, Louisiana

Henry Masur, MD (Chapters 74, 75)
Chief, Critical Care Medicine Department, Clinical Center, National Institutes of Health, Bethesda, Maryland

Kenneth H. Mayer, MD (Chapter 13)
Professor of Medicine and Community Health, Director, AIDS Program, Brown University, Providence, Rhode Island

Laura J. McGough, PhD (Chapter 1)
Postdoctoral Fellow, School of Medicine, History of Medicine and Infectious Diseases, Johns Hopkins University, Baltimore, Maryland

Matthew T. McKenna, MD, MPH (Chapter 97)
Medical Officer, United States Public Health Service, Director of the Office on Smoking and Health, Centers for Diseases Control and Prevention, Atlanta, Georgia

André Meheus, MD, DPH, PhD (Chapter 38)
Professor Emeritus, Department of Epidemiology and Social Medicine (ESOC), University at Antwerp, Antwerp, Belgium

Lynne M. Mofenson, MD (Chapter 85)
Chief, Pediatric, Adolescent, and maternal AIDS Branch, Center for Research for Mothers and Children, National Institute of Child Health and Human Development, National Institutes of Health, Rockville, Maryland

Susan Moir, PhD (Chapter 21)
Senior Research Fellow, Laboratory of Immunoregulation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland

James Moody, PhD (Chapter 7)
Assistant Professor in Sociology, Department of Sociology, Duke University, Durham, North Carolina

Megan A. Moreno, MD, MS Ed (Chapter 6)
Fellow in Pediatrics, Division of Adolescent Medicine, Children's Hospital and Regional Medical Center (CHRMC), University of Washington, Seattle, Washington

Martina Morris, PhD (Chapter 7)
Professor, Sociology and Statistics; Director, Center for Studies in Demography and Ecology, University of Washington, Seattle, Washington

Charles S. Morrison, PhD (Chapter 78)
Senior Epidemiologist, Clinical Research and Biostastics Divisions, Family Health International, Research Triangle Park, North Carolina

Stephen Moses, MD, MPH (Chapter 12)
Professor, Departments of Medical Microbiology, Medicine and Community Health Sciences, University of Manitoba, Winnipeg, Manitoba, Canada

F. Kevin Murphy, MD, FACP (Chapter 82)
Clinical Associate Professor, Department of Internal Medicine, Southwestern Medical Center, Dallas, Texas

Daniel M. Musher, MD (Chapter 37)
Professor of Medicine, Molecular Virology, Microbiology, Baylor College of Medicine; Chief of Infectious Diseases, Michael E. DeBakey Veterans Affairs Medical Center, Houston, Texas

Francis J. Ndowa, MD (Chapter 38)
Medical Officer, Sexually Transmitted and Reproductive Tract Infections, Reproductive Health and Research, World Health Organization, Geneva, Switzerland

Graham Neilsen, MBBS, MM (Sexual Health) (Chapter 101)
Associate Director, Technical Support, Public Health Programs, Family Health International, Asia Pacific Regional Office, Bangkok, Thailand

Ronald A. Nelson
Assistant Editor, Center for AIDS & STD, University of Washington, Seattle, Washington

Nigel O'Farrell, MS, MD, MRCP (Chapter 40)
Honorary Senior Lecturer, Division of Infectious and Tropical Diseases, London School of Hygiene and Tropical Medicine, London, United Kingdom

Marjorie Opuni, MA (Chapter 2)
PhD Candidate, Department of Population, Family and Reproductive Health, Johns Hopkins University Bloomberg School of Public Health, Baltimore, Maryland

Jorma Paavonen, MD (Chapter 56)
Professor, Department of Obstetrics and Gynecology, University of Helsinki, Finland

Joel M. Palefsky, MD (Chapter 57)
Associate Dean for Clinical and Translational Research, Professor, Laboratory Medicine and Medicine, Division of Infectious Diseases, University of California, San Francisco

Alice K. Pau, PharmD (Appendix A)
Clinical Pharmacy Specialist, Office of Clinical Research, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland

Rosanna W. Peeling, PhD (Chapters 52, 104)
Diagnostics R&D, UNICEF/UNDP/World Bank/WHO Special Programme for Research & Training in Tropical Diseases (TDR), World Health Organization, Geneva, Switzerland

Peter E. Pertel, MD, MPH (Chapter 23)
Medical Director, Clinical Research, Cubist Pharmaceuticals, Lexington, MA; Assistant Clinical Professor of Medicine, Yale University, School of Medicine, New Haven, Connecticut

Peter Piot, MD, PhD
Executive Director, United Nations' Joint Program on HIV/AIDS, Under Secretary-General of the United Nations

Thomas C. Quinn, MD (Chapter 68)
Professor of Medicine, Division of Infectious Diseases, Department of Medicine, Director, Center for Global Health, Johns Hopkins University School of Medicine, Baltimore, Maryland

Justin D. Radolf, MD (Chapter 82)
Professor of Medicine and Center for Microbial Pathogenesis, University of Connecticut Health Center, Farmington, Connecticut

Andrew Ramsay (Chapter 104)
Special Programme for Research & Training in Tropical Diseases, World Health Organization, Geneva, Switzerland

Michael L. Rekart, MD, DTM&H (Chapter 99)
Professor, Division of Infectious Diseases, Department of Medicine, University of British Columbia, Director, Division of STI/HIV Prevention and Control, British Columbia Centre for Disease Control, Vancouver BC, Canada

Peter A. Rice, MD (Chapter 67)
Professor of Medicine, Division of Infectious Diseases and Immunology University of Massachusetts Medical School UMass Memorial Medical Center, Worcester, Massachusetts

Edward P. Richards, JD, MPH (Chapter 106)
Director, Program in Law, Science, and Public Health; Harvey A. Peltier Professor of Law, Paul M. Hebert Law Center, Louisiana State University, Baton Rouge, Louisiana

Kevin Robertson, PhD (Chapter 77)
Professor and Director of Neuropsychology, Department of Neurology, AIDS Neurological Center, University of North Carolina at Chapel Hill, North Carolina

David Taylor-Robinson, MD, FRCP, FRCPath (Chapter 41)
Professor Emeritus, Division of Medicine, Department of Medicine, Imperial College London, St Mary's Hospital, Paddington, London

Anne M. Rompalo, MD, ScM (Chapter 68)
Professor of Medicine, Johns Hopkins Bayview Medical Center, Baltimore, Maryland

Allan Ronald, MD, FRCPC, (Chapter 91)
Distinguished Professor, Emeritus, University of Manitoba, Visiting Professor, Infectious Diseases Institute, Makerere University, Kampala, Uganda

Michael W. Ross, MA, MSt, PhD, MPH, MHPEd, DipSTD (Chapter 9)
Professor of Public Health, University of Texas, Houston, Texas

Zeda F. Rosenberg, ScD (Chapter 94)
Chief Executive Officer, International Partnership for Microbicides, Silver Spring, Maryland

Mark W. Russo, MD, MPH (Chapter 66)
Medical Director of Liver Transplantation, Carolinas Medical Center, Transplant Center, Charlotte, North Carolina

Caroline A. Ryan, MD, MPH (Chapter 47)
Senior Technical Advisor, Prevention, Technical Team Leader, Office of US Global AIDS Coordinator, Washington, DC; Chief, Prevention Branch, Global AIDS Program, Centers for Disease Control, Atlanta, Georgia

Pablo J. Sánchez, MD, MPH (Chapter 82)
Professor of Pediatrics, Department of Pediatrics, University of Texas Southwestern Medical Center at Dallas, Dallas, Texas

Julius Schachter, PhD (Chapter 31)
Professor of Laboratory Medicine, University of California, San Francisco, School of Medicine; San Francisco, California

Mauro Schechter, MD, PhD (Chapter 102)
Professor of Infectious Diseases, Department of Prevention Medicine, University Federal di Rio de Janeiro; Head, AIDS Research Laboratory, Hospital Universitario Clientias Fraga Filho, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Anna Scheyett, MSW, LCSW, CASWCM (Chapter 71)
Associate Professor, School of Social Work, University of North Carolina at Chapel Hill, North Carolina

Kenneth F. Schulz, PhD, MBA (Chapter 82)
Assistant Director for International Activities, Division of STD Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia; Clinical Professor, Department of Obstetrics and Gynecology, University of North Carolina at Chapel Hill, North Carolina

Bernhard Schwartländer, MD, PhD (Chapter 98)
Director, Performance Evaluation and Policy, The Global Fund to Fight AIDS, Tuberculosis and Malaria, Germany

Jane R. Schwebke, MD (Chapter 43)
Professor of Medicine, Division of Infectious Diseases, Department of Medicine, University of Alabama at Birmingham, Alabama

Salaam Semaan, DrPH (Chapter 15)
National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Arlene C. Seña, MD, MPH (Chapter 43)
Associate Professor, Division of Infectious Diseases, Department of Medicine, University of North Carolina at Chapel Hill, North Carolina

Taraneh Shafii, MD, MPH (Chapter 82)
Assistant Professor, Department of Medicine, University of Washington, Seattle, Washington

Kathleen J. Sikkema, PhD (Chapter 95)
Associate Professor, Division of Chronic Disease Epidemiology and Social and Behavioral Sciences Program, Department of Psychology, Yale University, New Haven, Connecticut

John W. Sixbey, MD (Chapter 26)
Professor, Department of Microbiology and Immunology, Louisiana State University Health Sciences Center, Shreveport, Louisiana

William A. Smith, EdD (Chapter 96)
Executive Vice-President, Academy for Educational Development, Washington, DC

Jack D. Sobel, MD (Chapters 45, 55)
Professor, Division of Infectious Diseases, Wayne State University School of Medicine, Detroit, Michigan

P. Frederick Sparling, MD (Chapters 19, 34, 37)
Professor Emeritus of Medicine, Microbiology, Immunology, Division of Infectious Diseases, Department of Medicine, University of North Carolina at Chapel Hill School of Medicine, Chapel Hill, North Carolina

Patricia G. Spear, PhD (Chapter 23)
Professor, Department of Microbiology–Immunology, Feinberg School of Medicine, Northwestern, University, Chicago, Illinois

Freya Spielberg, MD, MPH (Chapters 48, 69)
Assistant Professor, Family Medicine, University of Washington, Seattle, Washington

Stanley M. Spinola, MD (Chapter 39)
David H. Jacobs Professor and Director, Division of Infectious Diseases, Department of Medicine, Microbiology and Immunology, Indiana University School of Medicine, Indianapolis, Indiana

Sergio Stagno, MD (Chapter 84)
Professor and Chair, Department of Pediatrics, University of Alabama at Birmingham, Birmingham, Alabama

Walter E. Stamm, MD (Chapters 32, 33, 55)
Professor of Medicine, Head, Division of Allergy and Infectious Diseases, University of Washington, Seattle, Washington

Karen A. Stanecki, MPH (Chapter 4)
Senior Advisor on Demographics and Related Data, Strategic Information, Policy, Evidence Partnerships, UNAIDS, Geneva, Switzerland

Markus J. Steiner, PhD (Chapter 93)
Senior Epidemiologist, Clinical Research Department, Family Health International, Research Triangle Park, North Carolina

Richard S. Stephens, PhD (Chapter 31)
Professor, Division of Infectious Diseases, School of Public Health, University of California, Berkeley, California

Katherine M. Stone, MD (Chapter 93)
Medical Epidemiologist, Division of STD Prevention, National Center for HIV, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Katherine W. Stovel, PhD (Chapter 6)
Associate Professor, Department of Sociology, University of Washington, Seattle, Washington

Patrick S. Sullivan, DVM, PhD (Chapter 97)
Chief, Behavioral and Clinical Surveillance Branch, Division of HIV/AIDS Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Ronald Swanstrom, PhD (Chapter 20)
Professor, Department of Biochemistry and Biophysics, Lineberger Comprehensive Cancer Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Morton N. Swartz, MD, MACP (Chapter 37)
Jackson Firm Chief, Department of Medicine, Massachusetts General Hospital; Professor of Medicine, Harvard Medical School, Boston, Massachusetts

Heidi Swygard, MD, MPH (Chapter 43)
Assistant Professor of Medicine, Department of Infectious Diseases, Department of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Amanda J. Thomas, MD, MBBS, DCH, MMEDSCI, MA (Chapter 87)
Doctor/Consultant Community Paeditrician, Community Paediatrics, St. James's University Hospital, Leeds, United Kingdom

Mark Thrun, MD (Chapter 72)
Assistant Professor of Clinical Medicine, Division of Infectious Diseases, Department of Internal Medicine, University of Colorado Health Sciences Center; Director, HIV Prevention, Denver Public Health, Denver, Colorado

Rochelle R. Torgerson, MD, PhD (Chapter 64)
Fellow in Advanced Clinical Dermatology, Department of Dermatology, Mayo Clinic College of Medicine, Rochester, Minnesota

Patricia A. Totten, PhD (Chapter 41)
Research Associate Professor, Division of Infectious Diseases, Department of Medicine, University of Washington, Seattle Washington

Paul Volberding, MD (Chapter 76)
Professor and Vice Chair, Department of Medicine, Director of the Center for AIDS Research, University of California, San Francisco

Bea Vuylsteke, MD, MSc (Chapter 103)
Institute of Tropical Medicine, Antwerp, Belgium

Anna Wald, MD, MPH (Chapter 24)
Associate Professor, Department of Medicine, Epidemiology, and Laboratory Medicine; Medical Director, Biology Research Clinic, University of Washington, Seattle, Washington

Lee Warner, PhD, MPH (Chapter 93)
Senior Scientist, Division of Reproductive Health, Centers for Disease Control and Prevention, Atlanta, Georgia

Cirle Alcantara Warren, MD (Chapter 44)
Assistant Professor of Medicine, Division of Infectious Diseases and International Health, Center for Global Health, University of Virginia, Charlottesville, Virginia

Judith N. Wasserheit, MD, MPH (Chapters 92, 100)
Vice Chair & Professor of Global Health, Professor of Medicine, University of Washington, Affiliate Investigator, Program in Infectious Diseases, Fred Hutchinson Cancer Research Center, Seattle, Washington

D. Heather Watts, MD (Chapters 80, 81)
Medical Officer, Pediatric, Adolescent, and Maternal AIDS Branch, Center for Research on Mothers and Children, National Institute of Child Health and Human Development/NIH, Bethesda, Maryland

Hillard Weinstock, MD, MPH (Chapter 97)
Medical Epidemiologist, Centers for Disease Control and Prevention, Atlanta, Georgia

Lars Westrõm†, MD, DMS (Chapter 56)
Associate Professor of Obstetrics and Gynecology, University Hospital, Lund, Sweden

† Deceased

Richard J. Whitley, MD (Chapter 84)
Professor of Pediatrics, Microbiology, Medicine and Neurosurgery, Loeb Eminent Scholar Chair in Pediatrics, Vice-Chair Department of Pediatrics, Director, Division of Pediatric Infectious Diseases, University of Alabama at Birmingham, Birmingham, Alabama

Jimmy Whitworth, MD (Chapter 104)
Head, International Activities, Wellcome Trust, London, United Kingdom

Teodoara Elvira C. Wi, MD (Chapter 101)
Director, STI Capacity Building, Family Health International, Mumbai, India

Hillard Weinstock, MD, MPH (Chapter 97)
Medical Epidemiologist, Epidemiology and Surveillance Branch, Division of STD Prevention, Centers for Disease Control and Prevention, Atlanta, Georgia

Harold C. Wiesenfeld, MD, CM (Chapter 79)
Associate Professor, Department of Obstetrics, Gynecology and Reproductive Sciences, Director, Division of Reproductive Infectious Diseases & Immunology, University of Pittsburgh School of Medicine; Co-Director, Sexually Transmitted Diseases Program, Allegheny County Health Department, Pittsburgh, Pennsylvania

Rachel L. Winer, PhD, MPH (Chapter 28)
Acting Instructor, Epidemiology, School of Public Health & Community Medicine; HPV Research Group, University of Washington, Seattle, Washington

Robin Wood, MD, FRCP (Chapter 102)
Professor of Medicine (Ad hominem), University of Cape Town; Director of Desmond Tutu HIV Centre, Institute of Infectious Disease and Molecular Medicine; Principal Medical Specialist, Department of Medicine, Groote Schuur Hospital; Observatory, South Africa

Kimberly A. Workowski, MD (Appendix B)
Division of STD Prevention, National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention, Atlanta, Georgia

Claire C. Yang, MD (Chapter 49)
Associate Professor, Department of Urology, School of Medicine, University of Washington; Staff physician, Section of Urology, Veterans Administration Puget Sound Health Care System, Seattle, Washington

Jonathan M. Zenilman, MD (Chapter 16)
Professor of Medicine, Infectious Diseases Division, Johns Hopkins Bayview Medical Center, Baltimore, Maryland

INTRODUCTION AND OVERVIEW

CHANGES IN THE FOURTH EDITION

This edition welcomes new editors Myron Cohen, Larry Corey, and Heather Watts, and 119 new authors. The majority of the editors and many of the authors of this book have wide experience both with HIV/AIDS and with other STIs, facilitating our goal of integrating these two fields where possible throughout the text. We are very happy that the fourth edition is now produced in color and will be available online. Table 1 highlights 55 remarkable examples of recent developments—the good, the bad, and the ugly—in the STD/HIV field, during the 8 years since the third edition of this book was published. These and other recent developments in the epidemiology, pathogenesis, diagnosis, treatment, and prevention of STIs are discussed from different perspectives throughout the text. While many other areas of medicine and public health are also developing rapidly, the recent pace of change in the STI/HIV field has been quite remarkable, and perhaps unique. The 8-year gestation since the last edition helps account for the extensive changes required and the overall "weight" of the evidence presented in this fourth edition.

STD PATHOGENS AND SYNDROMES

The total number of distinct sexually transmitted or transmissible pathogens now exceeds 35 (Table 2). Many of these can be further categorized into multiple subtypes that may have differing clinical manifestations. For a few of these pathogens, sexual transmission is not yet well-defined, but seems quite likely on the basis of indirect clinical and epidemiologic evidence. Many of the clinical syndromes caused by infections with these pathogens are summarized in 10 important categories in Table 3. These syndromes can appear in every subspecialty of medicine, in any health-care setting. With the advent of phosphodiesterase-5 inhibitors for treatment of erectile dysfunction, even geriatrics providers can become increasingly involved in this field. The prevalence, of persistent vaginal and cervical infections are remarkably high in young women; and the incidence, and prevalence, of the chronic STIs are exceptionally high in adults, with seroprevalence increasing steadily with advancing age for infections caused by HIV, syphilis, hepatitis B, and especially, HSV-2 and the genital types of HPV. It is therefore, undoubtedly true that a very large proportion of patients seen by clinicians of all disciplines—perhaps the majority of all adults in the world—have one or more STIs.

IMPORTANCE OF STD FOR SPECIALISTS AS WELL AS FOR PRIMARY CARE CLINICIANS

The 25 years since the preparation of the first edition of this book began have seen extraordinary improvements in both the quality and the quantity of new information concerning STDs. The qualifications and enthusiasm of professionals now entering the field are also higher than ever. STD clinical, research, teaching, and service or program activities have been reentering the academic mainstream after a long separation. This "mainstreaming" has been attributable to increasing recognition of both the magnitude and scope of the problems caused by various STDs, including the epidemic of sexually transmitted HIV/AIDS; to the availability of new tools and new disease prevention models to deal more effectively with them; and to the increasing concerns about STD/HIV in the fields of internal medicine (especially disciplines such as oncology, infectious diseases, hepatology and gastroenterology, neurology, dermatology, and rheumatology)and family medicine; reproductive health, gynecology, and urology; and pediatrics and adolescent medicine.

The organization of the academic discipline and of medical services for STD/HIV differ markedly across the world, especially when comparing developing and industrialized countries. Although the role of primary care clinicians in STD care is increasing in industrialized countries, various types of STD specialists see a high proportion of patients, and HIV/AIDS specialists provide care for a very high proportion of persons with HIV infection. In the United Kingdom, consultants in genitourinary medicine deal with STD, ambulatory care for HIV infection, and related genitourinary diseases. In much of Europe, including Eastern Europe, Africa, Latin America, and Asia, a varying proportion (small in Western Europe) of "dermatovenereologists" devote much of their time to clinical care, teaching, and research on STD. Many universities around the world now offer Graduate Certificates, Diplomas, Masters Degrees, predoctoral, or postdoctoral or professional training related to sexual health, and online training in sexual health, STDs, and HIV/AIDS is also now available from a number of programs.

In contrast, in most developing countries, where STDs and HIV are rampant and 90% of the world's STD and HIV infections occur, the primary care clinician has the major role in providing services for STD and HIV care. In many parts of the developing world, nurses, pharmacists, and pharmacy workers or alternative care providers actually provide much of the frontline care, and specialists and physicians tend to see treatment failures or referrals, although special STD clinics may provide efficient care to a large proportion of men with STD and to sex workers in some urban settings and port cities. In developing countries, syndromic management of STDs is customary, supplemented by serologic screening for syphilis, microscopy, and increasingly by use of rapid, cheaper diagnostic tests, such as rapid HIV and syphilis serology.

Clinical management of HIV/AIDS in 2007 in developing countries still emphasizes first and second line antiretroviral

Table 1. Examples of Major Developments in the STI/HIV Field, 2000–2007

- Clinical epidemiology
  - Further globalization of the HIV epidemic, with an estimated 4.3 million new HIV infections in 2006.
  - Outbreaks of extremely drug-resistant TB in HIV-infected persons in South Africa in 2005; XDR-TB now documented on all continents. We need infection control, rapid diagnostics, new drugs for TB treatment.
  - Declining incidence and prevalence of curable STI (gonorrhea, syphilis, chancroid) in several developing countries, likely attributable both to widespread adoption of syndromic management, as well as to AIDS-related mortality and HIV/AIDS-related risk behavior reduction.
  - Reemergence of STD (syphilis, HIV/AIDS, HSV-2, other) in China and former Soviet Union; followed by improving control of syphilis and gonorrhea epidemics in Eastern Europe.
  - Shift from risk-avoidance by men who have sex with men (MSM) in industrialized countries, to serosorting, risk reduction, or sexual disinhibition with the advent of HAART, resulting in resurgent STD (syphilis, gonorrhea, chlamydial infection) in MSM.
  - Reemergence of LGV proctitis and proctocolitis in MSM (many of whom are HIV and/or HCV infected) in Europe, the United Kingdom, North America, Australia.
  - Declining HIV incidence in several countries in Eastern Africa, the Caribbean, Cambodia.
  - Despite earlier declines attributable to control programs, incidence of chlamydial infection appears to be rising in parts of North America and Nordic countries, with increasing rates of reinfection in British Columbia.
  - Global sexual risk reduction in young people.
  - Recent decline in HSV-2 seroprevalence in U.S. adolescents; continuing high prevalence in U.S. African American populations.
  - Rapid emergence of internet use for initiation of high risk sexual partnerships, especially among MSM, and among adolescents and young adults.
  - Rising proportions of newly diagnosed HIV infections in Europe and parts of North America involve immigrants from highly endemic developing countries.
  - Growing evidence that primary infection with HIV accounts for a substantial proportion of all HIV transmission.
  - Growing evidence for importance of sexual concurrency and highly connected sexual networks in promoting population-level transmission of STI.
  - Growing evidence for potential of infections such as malaria, HSV, and possibly TB and helminths to increase HIV viral load and thereby, possibly HIV progression and transmission.
  - Growing evidence that the frequency and severity of malaria are substantially increased in persons with HIV infection.
  - Neurosyphilis resurgence among HIV-infected MSM with early syphilis.
- Etiology and pathogenesis
  - *Mycoplasma genitalium*–recognized as a cause of NGU, and associated with mucopurulent endocervicitis and with upper genital tract disease in women. Quantity of cervical shedding of *M. genitalium* associated with HIV infection.
  - *Ureaplasma urealyticum*–divided into two species (*U. urealyticum* and *U. parvum*); only the former associated with NGU in some recent studies.
  - Bacterial vaginosis–newly recognized BV-associated bacteria identified, several not yet cultivated, including 3 species in the *Clostridiales* order.
  - Identification of the *tpr* gene family in *T. pallidum*. The family includes 12 *tpr* genes, designated *tprA* through *tprK*, belonging

Table 1. *(Continued)*

to subfamilies I, II, and III. *TprK* undergoes genetic variation during natural infection, with potential implications for treponemal adaptation to the immune response, and adaptation to varied microenvironments, and for vaccine development.

- Mechanism of variation in the *MgpB* and putative recombination with *MgPar* sequences discovered and characterized in *M. genitalium*; may also explain persistence through antigenic variation.
- Rapid, severe depletion of CD4 T lymphocytes from gut-associated lymphoid tissue during primary HIV infection.
- Growing evidence for cross-clade and within-clade HIV superinfection in high-risk cohorts: implications for HIV vaccine development?
- Phylogenetic and experimental evidence for coevolution of retroviruses and their primate hosts; the virus evolves rapidly to escape host defense mechanisms, while host resistance evolves over millenia to avoid the virus.

- **Diagnostics**
  - Household-based HIV counseling and testing (HBHCT) programs in Africa, demonstrating high acceptability, and very frequent HIV serodiscordance in affected couples, with major implications for HIV prevention and treatment strategies.
  - Increasing use of nucleic acid amplification tests (NAATs) for detecting *N. gonorrhoeae* and *C. trachomatis* infections.
  - Recognition and proliferation in Nordic countries of *C. trachomatis* strains with deletion of nucleotide target sequences for those NAATs that had been widely used.
  - Recognition that self-obtained vaginal swabs are suitable for detection of *N. gonorrhoeae* and *C. trachomatis* using certain of the currently available NAAT, and can be used for mailed-in specimens.
  - Serologic tests that are relatively specific for HSV-2 are now commercially available (e.g., the Kalon and Focus tests).
  - Rapid serologic tests for syphilis.
  - Emergence of web-based access to STI diagnostic testing
  - PCR testing of pooled sera to screen for acute HIV infection.
  - "Reflex testing" of liquid cervical cytology specimens for oncogenic HPV types by PCR (e.g., when Pap smears show Atypical Squamous Cells of Uncertain Significance [ASCUS]).
  - PCR testing provides more accurate diagnosis of genital herpes, other causes of genital ulcer disease.
- **Therapeutics**
  - Twenty-five antiretroviral drugs available in 2007, including several new ones since 2000 (including tipranovir, darunivir, fuseon, TMC125, and most recently HIV integrase inhibitor, raltegravir), for HIV treatment.
  - Global emergence of fluoroquinolone-resistance in *N. gonorrhoeae*.
  - Suppressive antiherpes therapy decreases HSV-2 transmission to HSV-2-uninfected sex partners.
  - Patient-delivered therapy for partners (i.e., expedited partner therapy or EPT) decreases repeat infection with gonorrhea or chlamydia (http://www.cdc.gov/std/treatment/EPTFinalReport2006.pdf).
  - Single-dose azithromycin effective for treating early syphilis in Africa; however, azithromycin-resistant strains of *T. pallidum* have rapidly emerged in North America and Ireland, attributable to point-mutations in the *23S rRNA* gene. This has usually been seen in MSM , and especially in areas where azithromycin was used widely to control syphilis outbreaks.
  - Suppressive therapy of HSV-2 infection reduces HIV viral load in plasma and mucosal secretions.
  - Comparable clinical and microbiologic responses to inpatient or outpatient therapy with cefoxitin plus doxycycline for PID (the PEACH study).

(continued)

Table 1. *(Continued)*

- 2006 U.S. and Canadian Guidelines for STD Treatment (www.cdc.gov/treatment). (See Appendix B for summary of U.S. CDC Guidelines.)
- Increasing resistance of head lice, and possibly of pubic lice, to pediculocides, including permethrin cream and pyrethrins.

- **Prevention**
  - Three randomized trials of male circumcision in Africa show approximately 60% protection against HIV acquisition. Scale-up of this intervention is a high priority.
  - Quadrivalent HPV vaccine (types 16, 18, 6, and 11) and bivalent HPV vaccine (types 16 and 18) both highly effective vs. infection with the HPV types included in these vaccines and vs. associated cervical and vaginal dysplasia. There is ongoing discussion of cost-effectiveness, policies requiring vaccination (analogous to requirements for HBV vaccine). Efficacy in men being studied.
  - U.S. Advisory Committee on Immunization Practice prohibits new guidelines recommending more aggressive HBV and HAV vaccine use in adults; and recommending HPV vaccine in females aged 9–26 years.
  - Cohort studies demonstrate condom effectiveness against STI acquisition, not only vs. HIV, but also vs. HSV, gonorrhea, and chlamydial and vaginal infections, and specifically against HPV infection–refuting earlier concerns that condoms did *not* prevent HPV acquisition.
  - Randomized clinical trials that did not reduce the risk of HIV acquisition: (a) *behavioral intervention in MSM*–the EXPLORE study did not have a statistically significant sustained impact on HIV acquisition, but did highlight the importance of comorbidities (e.g., depression, alcohol, drug use) as risk factors for HIV acquisition; (b) *vaginal microbicide trials*–cellulose sulphate, like Nonoxynol 9, actually may increase risk of HIV acquisition; SAVVY trial stopped for futility; (c) *HIV vaccines*–GP120-based HIV vaccine trials demonstrated no efficacy in the U.S., the Netherlands, and Thailand; current emphasis is on clinical trials of HIV vaccines designed to produce a cytotoxic T-lymphocyte response; (d) *cervical diaphragm plus lubricating gel*–not associated with decreased risk of HIV acquisition in the MIRA trial; (e) *HSV-2 suppression with daily acyclovir*–did not reduce HIV acquisition in women in a small Tanzanian study with relatively low adherence to acyclovir therapy; (f) *structural intervention*–a microfinance program for women did not reduce HIV acquisition (the IMAGE trial).
  - Community-randomized trials of treatment of curable STIs in Mwanza, Tanzania (adults; school children); Rakai, Uganda; Masaka, Uganda, Manicaland, Zimbabwe have shown varying efficacy in reducing STI and HIV incidence. Comparative analyses suggest that STD treatment interventions have limited or no efficacy in reducing HIV transmission in generalized HIV epidemics where there is low STI incidence, as compared with the significant efficacy observed in the earlier Mwanza study, where the HIV epidemic was less widespread and STI prevalence was higher.
  - Serostatus-based approach to advancing HIV prevention, with greater emphasis on widespread testing, partner notification, and "prevention in positives."
  - "Prevention in positives," an early priority in a few European countries, is now becoming standard of care in North America; new CDC guidelines for "Prevention in Positives;" group level interventions among young minority HIV-infected women showed significant reduction in subsequent acquisition of other STIs (the WILLOW program).
  - A nonrandomized trial, but with comparison groups, found that a long-term school-based social development intervention (beginning in 5th grade) was associated with reduced teen pregnancy, and, in African American youth, with greatly reduced risk of self-reported STIs.

Table 1. *(Continued)*

- And finally, there is emerging consensus on need for multicomponent, integrated biomedical and behavioral effectiveness trials and programs for preventing HIV and other STI. Today, clinicians giving ART use a combination of at least 3 drugs in highly active antiretroviral therapy (HAART) and would not consider using a single drug (Fig. 1A). In contrast, in HIV prevention research and program, workers still tend to work in silos, constrained narrowly by their disciplines, and moral philosophies, advocating abstinence only, etc. (Fig. 1B). The limited impact so far of HIV prevention globally, coupled with growing evidence of the impact of various types of interventions, clearly warrants efforts to study the efficacy and implement and evaluate the effectiveness, of multicomponent preventive interventions, to achieve more highly active retrovirus prevention (HARP) (Fig. 1C). The potential for additive or synergistic effects is related in part to the differing non-duplicative mechanisms of action of various preventive interventions, to the existence of a multiplicity of HIV epidemics with differing characteristics and patterns of behavioral and other risk factors, each potentially presenting unique opportunities for differing preventive interventions.

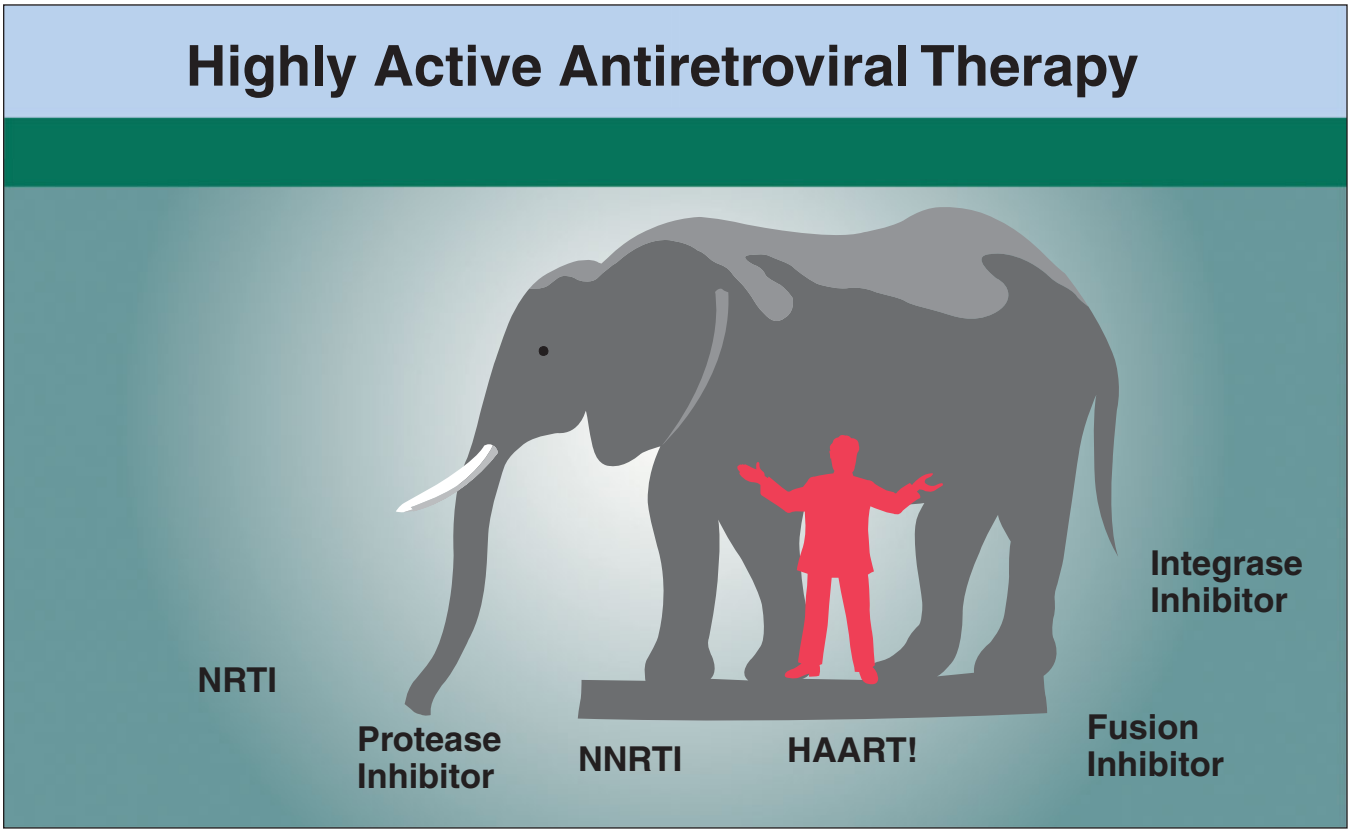

FIGURE 1A

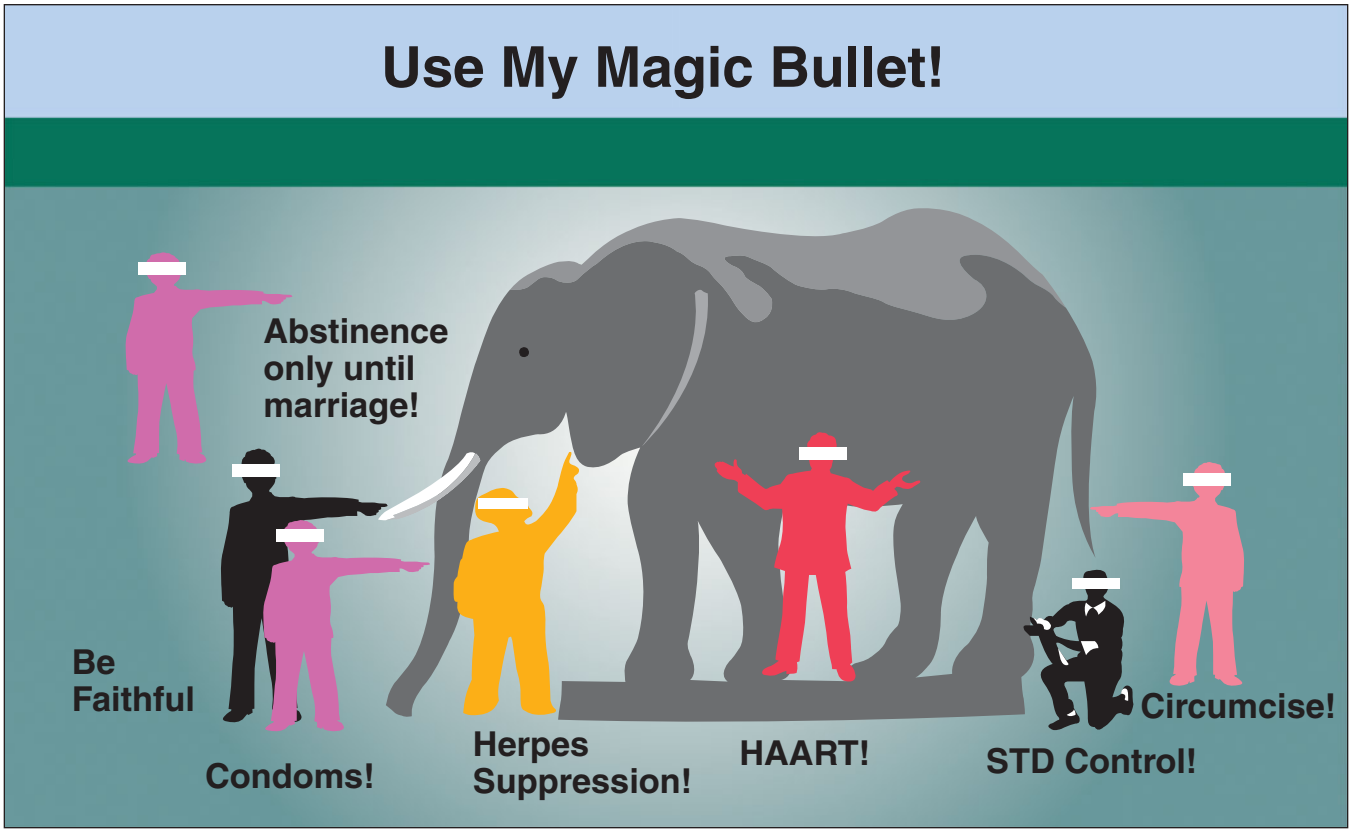

FIGURE 1B

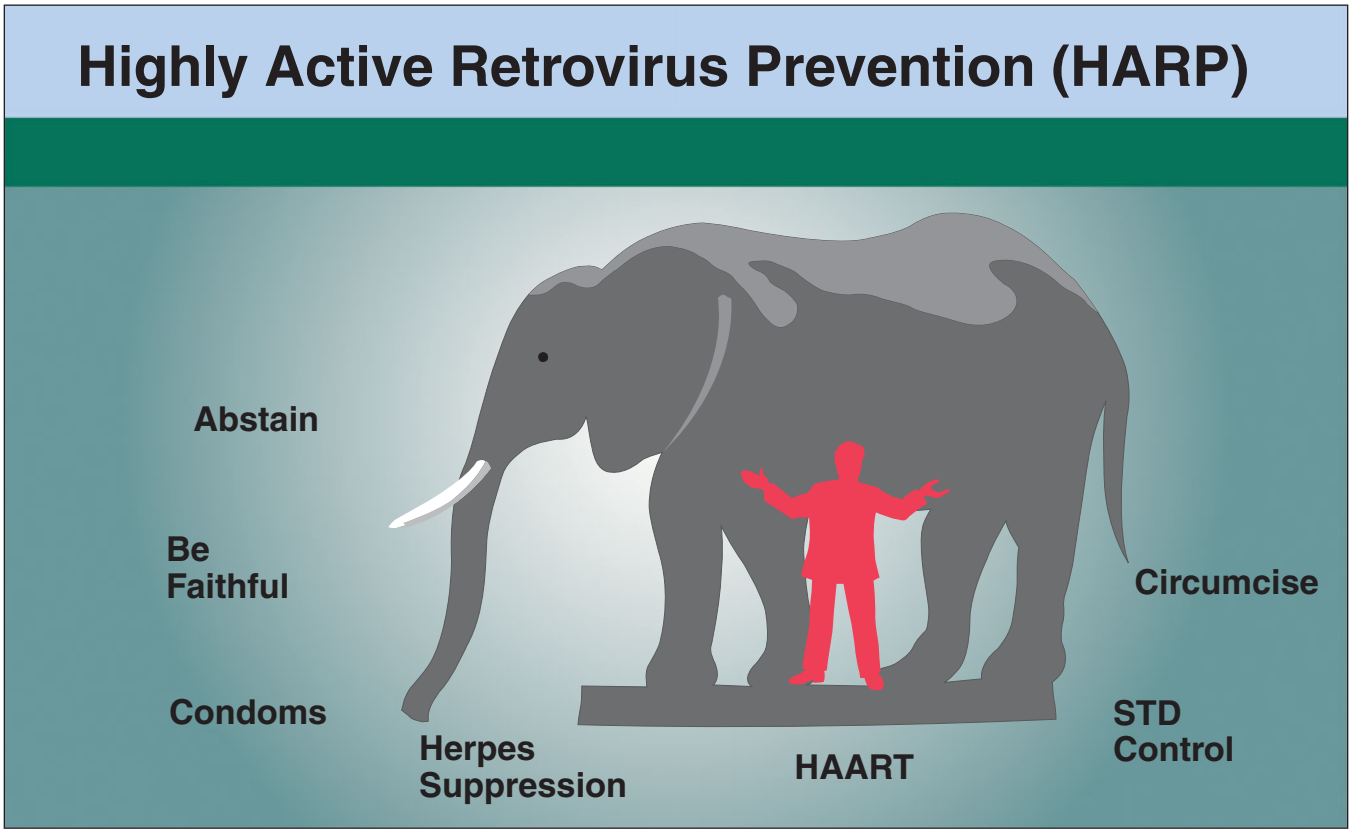

FIGURE 1C

Table 2. Sexually Transmitted and Sexually Transmissible Pathogens

Bacteria	Viruses	Protozoa, Ectoparasites, Fungi
Transmitted in adults predominantly by sexual intercourse		
Neisseria gonorrhoeae	HIV (types 1 and 2)	*Trichomonas vaginalis*
Chlamydia trachomatis	Human T cell lymphotropic virus type I	*Phthirus pubis*
Treponema pallidum		
Haemophilus ducreyi	Herpes simplex virus type 2	
Calymmatobacterium granulomatis	Human papillomavirus (multiple genotypes involved in genital infection)	
Ureaplasma urealyticum		
Ureaplasma parvum	Hepatitis B virus[a]	
	Molluscum contagiosum virus	
Sexual transmission repeatedly described but not well defined or not the predominant mode		
Mycoplasma hominis	Cytomegalovirus	*Candida albicans*
Mycoplasma genitalium	Human T cell lymphotropic virus type II	*Sarcoptes scabiei*
Gardnerella vaginalis and other vaginal bacteria	Hepatitis C, D viruses	
Group B *Streptococcus*	Herpes simplex virus type 1	
Mobiluncus spp.	Epstein-Barr virus	
Helicobacter cinaedi	Human herpesvirus type 8	
Helicobacter fennelliae		
Transmitted by sexual contact involving oral-fecal exposure; of importance in homosexual men		
Shigella spp.	Hepatitis A virus	*Giardia lamblia*
Campylobacter spp.		*Entamoeba histolytica*

[a]Among U.S. patients for whom a risk factor can be ascertained, most hepatitis B virus infections are transmitted sexually or by injection drug use.

therapy (ART), often initiated relatively late as HIV therapy has become available initially only to those with more advanced infection. Opportunistic infections (especially tuberculosis), and the immune reconstitution inflammatory syndrome (IRIS) after initiation of ART are much more common today in clinical practice in developing countries than in industrialized countries. In contrast, in industrialized countries, clinicians must place much greater emphasis on ARV-resistance phenotyping and genotyping, on viral load measurement, and on selection from a wide variety of newer ARVs.

At a policy and practice level, the field of STD has also become a more integral part of efforts to improve reproductive health both in developing countries and in the industrialized world. The explosion of new information on the impact of STD/HIV on reproductive health makes comprehensive knowledge of STD and HIV essential for reproductive health specialists.

Paradoxically, in industrialized countries, as STD has come under better control, and recurrent outbreaks of imported STD emerge as major problems, the relative importance of the STD specialist has increased in public health settings best equipped to contain outbreaks of infection. Similarly, as the HIV epidemic comes under better control, and care has become more complex, the role of the HIV clinical specialist is increasing, even in the context of managed care.

This fourth edition of *Sexually Transmitted Diseases* aims to provide comprehensive and authoritative information on the clinical, microbiological, and public health aspects of STD including HIV infection, as an essential reference for the specialist as well as for the primary health care clinician. Authors of each chapter have been encouraged to address STD/HIV in developing countries as well as in industrialized countries, where appropriate.

EVOLUTION OF TERMINOLOGY: VD, STD, STI, AND RTI

The term *venereal* disease initially referred to the diseases syphilis, chancroid, and gonorrhea, later expanded to include

Table 3. Ten Major Categories of STD Syndromes and Related Sexually Transmitted Microbial Etiologies

Syndrome	Sexually Transmitted Microbial Etiologies
(1) AIDS	HIV types 1 and 2
(2) Genital tract infections: males	
Urethritis: males	*Neisseria gonorrhoeae, Chlamydia trachomatis, Mycoplasma genitalium, Ureaplasma urealyticum, Trichomonas vaginalis,* herpes simplex virus (HSV) types 1 and 2
Epididymitis	*C. trachomatis, N. gonorrhoeae*
(3) Genital tract infections: females	
Cystitis/urethritis	*C. trachomatis, N. gonorrhoeae,* HSV
Mucopurulent cervicitis	*C. trachomatis, N. gonorrhoeae, M. genitalium*
Vulvitis	*Candida albicans,* HSV
Vulvovaginitis	*C. albicans, T. vaginalis*
Bacterial vaginosis (BV)	BV-associated bacteria (see text)
Acute pelvic inflammatory disease	*N. gonorrhoeae, C. trachomatis,* BV-associated bacteria, *M. genitalium,* group B *streptococci*
(4) Reproductive health	
Infertility	*N. gonorrhoeae, C. trachomatis,* BV-associated bacteria
Complications of pregnancy/puerperium	Many STI pathogens have been implicated–especially HIV, HSV, *T. pallidum, N. gonorrhoeae, C. trachomatis,* group B streptococci, BV-associated bacteria.
(5) Hepatology/gastroenterology	
Hepatitis	Hepatitis viruses, *T. pallidum,* CMV, HSV, EBV
Gastritis	*T. pallidum* (secondary syphilis)
Proctitis	*C. trachomatis, N. gonorrhoeae,* HSV, *T. pallidum*
Perihepatitis	*C. trachomatis, N. gonorrhoeae*
Proctocolitis or enterocolitis	*Campylobacter* spp., *Shigella* spp., *Entamoeba histolytica,* other enteric pathogens
Enteritis	*Glardia lamblia*
(6) Acute arthritis with urogenital infection or viremia	*N. gonorrhoeae* (e.g., DGI), *C. trachomatis* (e.g., Reiter's syndrome), hepatitis B virus
(7) Hematology and oncology	
Mononucleosis syndrome	CMV, HIV, EBV
Squamous cell dysplasias and cancers of the cervix, anus, vulva, vagina, or penis	HPV (especially types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66)
Kaposi's sarcoma, body-cavity lymphomas	HHV-8
T-cell leukemia	HTLV-I
Hepatocellular carcinoma	HBV

Table 3. *(Continued)*

(8) Neurologic syndromes	
Myelitis, myelopathy, polyradiculopathy	*T. pallidum,* EBV, CMV, HTLV-I and II, HIV
Meningitis or encephalitis	*T. pallidum,* HIV, HSV, EBV, CMV
Peripheral neuropathy	*T. pallidum,* CMV, HSV, HIV, HTLV-I and II, HCV
Parenchymal mass	*T. pallidum* (gumma), EBV (lymphoma)
(9) Dermatology syndromes	
Ulcerative lesions of the genitalia	HSV-1, HSV-2, *Treponema pallidum, Haemophilus ducreyi, C. trachomatis* (LGV strains), *Calymmatobacterium granulomatis*
Scabies	Sarcoptes scabiei
Pubic lice	*Phthirus pubis*
Rash	*T. pallidum, N. gonorrhoeae* (DGI), *C. trachomatis* (Reiter's syndrome), HBV, EBV, HSV, HIV
Genital and anal warts	Human papillomavirus (90% of warts caused by types 6, 11)
(10) Neonatal syndromes	*T. pallidum,* HSV, CMV, Group B Streptococcus, *N. gonorrhoeae, C. trachomatis*

NOTE: HSV, herpes simplex virus; LGV, *lymphogranuloma venereum*; DGI, disseminated gonococcal infection; HPV, human papillomavirus; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HTLV, human T cell lymphotropic virus; HHV-8, human herpesvirus type 8.

lymphogranuloma venereum and Donovanosis. As the number of diseases recognized to be sexually transmitted gradually grew to include nonspecific urethritis, trichomoniasis, genital herpes, genital warts, hepatitis B, and many others, the term sexually transmitted diseases came into more frequent use. What are the distinctions today between sexually *transmitted* diseases (STD), infections (STI), or pathogens? Between sexually transmitted and sexually *transmissible* diseases, infections, or pathogens? And between STI and reproductive tract infections (RTI, not to be confused with respiratory tract infections, also called RTI by pulmonologists)? All these terms are used throughout this book. Some distinctions are evident: a pathogen causes infection, which may result in disease; a pathogen could be a sexually transmissible even when nonsexual routes of transmission predominate. Viruses like cytomegalovirus (CMV) and hepatitis B virus (HBV) may qualify as predominately sexually transmitted pathogens in adults but not in children. The term RTI is preferred by some in the reproductive health field to encompass conditions like bacterial vaginosis, for which the designation as an STD is debated; and to attempt to destigmatize such conditions.

1 Historical Perspectives on Sexually Transmitted Diseases: Challenges for Prevention and Control

Laura J. McGough

METHODOLOGICAL ISSUES

PROBLEMS IN THE IDENTIFICATION OF DISEASES

Sexually transmitted diseases (STDs) are a broad modern category referring to a variety of pathogens, including viruses, bacteria, fungi, and protozoa, which manifest themselves in an equally wide variety of clinical symptoms (as subsequent chapters in this volume describe). The common factor is the mode of transmission and acquisition: sexual relations between human beings. Many of these pathogens, such as *Chlamydia* and human papillomavirus (HPV), have only been recently identified as part of the late twentieth-century expansion of biomedical research, thereby making the historical study of these pathogens challenging.

The problems that historians face in tracing the history of these diseases are twofold. First, it is difficult to identify modern disease entities based on the written historical record. Influenced by the work of cultural anthropologists, historians recognize that descriptions of disease symptoms are deeply influenced by changing cultural and social perceptions of disease. For example, late fifteenth- and early sixteenth-century Europeans emphasized the religious and moral dimensions of disease, often describing disease as God's punishment for sin. When an epidemic of a new disease was first described in Italy in 1496 after the French invasion and subsequent war on the Italian peninsula, the disease was often symbolically associated with the Biblical figure of Job, who suffered from ugly, incurable skin sores covering his body from head to toe. Italians called the new disease the "French disease" in reference to the French invasion. It is virtually impossible to disentangle the influence of this cultural tradition of interpreting disease according to Biblical traditions from the descriptions of the disease symptoms.[1] Produced during wartime, in a climate of heightened religious expectations of the imminent Second Coming of Christ, fifteenth-century Europeans did not write neutral, scientific accounts of a new disease. What we can learn from these descriptions about the natural history of modern venereal syphilis—the disease that the historical French disease or pox is most commonly assumed to have been—is extremely limited.

Second, it is also difficult to identify specific pathogens from skeletal remains. *Treponema pallidum*, the pathogen responsible for modern venereal syphilis, causes certain distinctive malformations, especially to the central incisors (Hutchinson's teeth) and 6-year molars (mulberry molars), if the disease is acquired early in life, as in the case of congenital syphilis.[2] Other skeletal deformations are similar to those caused by the other treponemal diseases, such as yaws and pinta, thereby making precise identification of venereal syphilis difficult. Paleopathologists have examined skeletal remains from certain sites in both the Americas and Europe prior to the late fifteenth century to see if the pattern of malformations distinctive to venereal syphilis can be found in any of the remains. The implicit assumption is that syphilis, known as the "great imitator" because of its highly variable clinical presentations, exhibited the same pattern of skeletal malformation centuries ago that it does today. Although scientists have found evidence of the distinctive patterns of skeletal destruction associated with modern syphilis in bone remains carbon dated to before the fifteenth century in parts of the New World, specifically the present-day Dominican Republic where Columbus' ships landed in 1492,[3] others will await more definitive proof by new methods in molecular genetics.

Even if scientists do find a method of identifying the pathogens that caused disease centuries ago, it will still be important to place that disease within its historical context in order to explain how people experienced and reacted toward disease. The laboratory revolution of the early twentieth century fundamentally changed the way people understood disease as resulting from a specific, underlying causal agent.[4] When the French disease epidemic broke out in 1496, the disease was regarded as the result of an imbalance of humors in the body, which could be caused by changing climate, atmospheric conditions, diet, and daily habits. By placing descriptions of disease in their historical context, it becomes very clear why contemporary Europeans produced so many theories about the origins of what the majority perceived as a new disease or at least a new epidemic.

STORIES RELATED TO THE ORIGINS OF THE DISEASE

European reactions toward the French disease provide a marvelous case study of how societies react to the psychological, emotional, and societal stress provoked by a major new disease. Both physicians and popular writers produced numerous theories about the ultimate origins of this disease. By the 1530s, the theory that the French disease originated in the New World became popular, especially among the Spanish and those directly associated with the conquest. The Spanish physician, Roderico de Isla, who treated Columbus' sailors and claimed that they suffered from this new disease, did not write his account until 1539. Rather than focusing on whether his and other texts accurately represent a truthful account, it is more useful to examine the themes and symbols deployed in order to find out why this theory had such cultural resonance. Spanish writers described Indians as lascivious and promiscuous. Untouched by Christianity, Indians were portrayed as incestuous savages whose lack of sexual control produced disease. With this theory of disease origins, Spaniards successfully deflected blame for the spread of disease from them and projected it onto a distant people they hoped to conquer.[5]

Different cultures produced different accounts of the origins of syphilis to respond to the unique political, social, and even military conditions they faced. More than 50 years after the invasion of the Italian peninsula, Italian writers continued to locate the origins of the epidemic in the war that had brought the end of independence to most of the Italian city-states. One physician blamed the French army itself, which, as he claimed, resorted to cannibalism and thereby produced disease through this unnatural act[6]; another physician held an extremely beautiful prostitute, who served the French army, responsible for the origins of disease, thereby highlighting the dangers of the female body and the temptation of beauty.[7]

Non-European cultures share this tradition of placing syphilis origin stories within a broader political, economic, and social framework in order to deflect blame from them and toward an external "other." For example, while the city of Shanghai was still under European control during the early twentieth century, Chinese physicians wrote that although gonorrhea had existed in their country since antiquity, syphilis was a foreign import brought by the Portuguese in the sixteenth century.[8] Whether the Chinese physicians' account is true is not the point of this analysis. Instead, it is important to recognize that disease origin stories are often explaining more than a biological event, but also the broader political, economic, and moral conditions that produced the disease. For the Chinese writing during the 1920s, the story of syphilis was a commentary on the evils of European colonialism and European influence, first experienced during the sixteenth century and again during the nineteenth and twentieth centuries. Similarly, modern-day stories of the origin of HIV/AIDS situate the disease within a wider geopolitical framework.[9]

TOWARD A SOCIAL, ECOLOGICAL HISTORY OF DISEASE

The two approaches to the history of disease just outlined—a history of modern pathogens versus a history of perceptions of disease—seem to have little in common. It would be useful, however, to combine the strengths of each approach and therefore produce a richer account of the interactions between human societies and their biological environment. The scientific accounts of *T. pallidum* have often ignored the social and political conditions that produce epidemics. For all of the problems with the sixteenth-century disease origin stories, they did nonetheless highlight the role of the Italian Wars (1494–1530), which brought mercenaries and soldiers from throughout the Europe for long-term liaisons between themselves and local women, in addition to the war's usual impact on rape and prostitution. Similarly, colonial rule brought European soldiers to Asia and Africa; these military units not only frequented local prostitutes, some of them even required that brothels be established in order to serve the sexual demands of European soldiers.[10]

On the other hand, historical accounts of disease perception often ignore the biological dimensions of disease, including their impact on the quality and duration of human life and on the reproductive success of populations. If historical pathogens can be identified, it would be useful to know how easily they were transmitted, how widespread they were, and what impact they had on human life. A social, ecological approach to the history of disease could build on the strengths of different disciplines and yield greater insights into the dynamic relationship between human populations and sexually transmitted pathogens. Although this approach has yet to be fully developed, historical research nonetheless provides many insights for present-day disease control, especially regarding the role of stigma, the problems associated with control of STDs among prostitutes and military personnel, ethical issues in research, the impact of effective medical therapy, and the roles of prevention and surveillance in STD control. This chapter provides a thematic survey of the history of STDs from the late fifteenth century until the early 1980s. Limitations in the availability of archival material for the last 20 years preclude a systematic history of the AIDS epidemic, but this chapter nonetheless provides valuable insights into the challenges of HIV/AIDS control as well as STD control.

STIGMA AND SHAME: ENDURING THEMES

SEXUAL TRANSMISSION AND SOCIAL INEQUALITY

The stigma and shame associated with STDs are one of the most enduring themes in their history. Although diseases such as leprosy had been associated with sexual activity in medieval Europe,[11] the idea of contagion (an ancient Greek

idea reinvigorated during the early sixteenth century by the work of Girolamo Fracastoro), and hence of sexual transmission, was newly accepted.[12] The idea of contagion coexisted with, rather than supplanted, other ideas about disease etiology that emphasized the role of climate, planetary influences, and imbalance of bodily humors. By the mid-sixteenth century, European physicians had reached a consensus that the French disease was a "thing" or "seed" that could be spread person-to-person through sexual activity, acquired at birth through mother's milk, or occasionally transmitted through nonsexual skin-to-skin contact.[1] This expansive definition allowed some discretion to physicians to define "innocent" cases of the French disease.

Reactions to the French disease became closely linked to wider perceptions of sexuality. In sixteenth-century Italy, for example, church and city officials encouraged the "promiscuous" women (defined as a woman who had sexual relations outside of marriage), who contracted the disease, to repent and become nuns, while men were merely offered medical cures and spared the pressure to join a monastery.[7] This sexual double standard persisted for centuries.

Stigma is embedded in wider social processes of power, domination, and social inequality.[13] For example, as European society became more hierarchically differentiated at home during the nineteenth century, prejudices about class began to shape attitudes toward sexuality and venereal diseases (VDs). Throughout Europe, efforts to control VD by regulating prostitution gave widespread authority to police officers to arrest women merely on suspicion of prostitution. As the industrial revolution had produced a new class of factory workers and urban dwellers, who increasingly asserted their political power during the nineteenth century, the upper classes reacted by asserting class-based differences in intellectual and moral capacity. According to the upper classes, their social inferiors were akin to animals, unable to control their sexual impulses. Prostitution was an example of the degeneracy of working-class women, a hereditary vice. Consequently, virtually any working-class woman appearing in public alone was a suspect and could be forcibly detained, subjected to medical inspection, and humiliated in her neighborhood as a result of the arrest.[14,15]

The nineteenth century also witnessed the expansion of European power in Asia and Africa, as well as the development of systematic racist ideologies. In South Africa, for example, white medical officers regarded Africans as incapable of controlling their sexual impulses and therefore unfit for health education about VD or its preventive measures.[16]

REPRODUCTION OF STIGMA THROUGH DISEASE CONTROL PROGRAMS

Historically, stigma has often been reproduced through disease control programs. Even when treatment has been offered to the poor, it has seldom been offered on the same terms of voluntary, confidential treatment as it has been offered to the wealthy. In the eighteenth-century England, for example, a middle-class patient suffering from the "foul disease" could pay for confidential treatment from private physicians, while the poor had to make a public declaration of their disease in order to qualify for charitable treatment.[17] In early twentieth-century Uganda, for example, colonial authorities carried out compulsory mass treatments with mercury injections for entire villages[18]; meanwhile, in Zimbabwe, public health officials had the power to destroy Africans' homes as a disease prevention measure, while whites enjoyed voluntary treatment without punitive measures.[19]

SEXUALLY TRANSMITTED DISEASE AS SYMBOL

The stigma and shame attached to STDs made them powerful symbols in their own right. Because of their ability to evoke sexual immorality and decadence, they were used as metaphors in plays, novels, and poetry from sixteenth century onward.[20] Rather than facing the shame of a public diagnosis and subsequent loss of reputation, some eighteenth-century patients in London, for example, committed suicide.[17] Allegations that certain individuals or groups had syphilis became one more weapon in the political struggles of the eighteenth century. The Enlightenment thinker and satirist Voltaire, for example, skewered the clergy and the nobility in his novel *Candide* with the suggestion that syphilis had been spread via a long line of heterosexual and homosexual contacts between nobility, clergy, and their servants.[21] In an era of increased criticism of the power and privileges of the clergy and nobility, allegations of sexual misconduct and sexual disease were a means of bringing shame and dishonor to these groups. Because STDs were and are such powerful symbols, it is difficult to disentangle allegations about disease from reality, even today.

PROSTITUTION AND THE MILITARY: KEY TARGETS OF INTERVENTIONS

REGULATION VERSUS PROHIBITION OF PROSTITUTION

Public health officials consistently identified prostitution as one of the key problems in the spread of STDs. Policies have swung back and forth between periods of legalization and regulation of prostitution, complete with regular medical checkups for prostitutes, or abolition and criminalization of prostitution, in order to decrease the amount and frequency of commercial sexual relations. During the nineteenth and early twentieth centuries, neither policy was implemented in order to protect women (and men) involved in the sex trade from contracting disease, but rather to protect their clients. Under both systems,

legalization and decriminalization, repression of prostitutes rather than rehabilitation and assistance were the norms.

The French led the way in legalizing and regulating prostitution during the nineteenth century. The engineer who had designed Paris' sewage system tackled the problem of prostitution, which he defined as fundamentally similar. Prostitution was like excrement, unpleasant, but necessary to protect the social body from disease. To prevent the physical and moral contamination of rest of the society, prostitutes should remain under constant, lifelong surveillance, shuttling between brothel, hospital, and refuge, but never free to return to society.[22] Other countries, such as Italy and Russia, adopted the French policies.[14,23] Great Britain briefly experimented with the legalization and regulation of prostitution with the Contagious Diseases Acts of 1864, 1866, and 1869 in order to provide a "sexual outlet" for its army, whose enlisted men were not allowed to marry. As previously mentioned, these Acts gave the police substantial authority to arrest and detain working-class women on spurious grounds, while soldiers were not subjected to medical inspection. This sexual double standard provoked protests from an alliance of working- and middle-class women who succeeded in forcing the repeal of the Contagious Diseases Acts in 1886.[15] World Wars I and II brought increased repression and prosecution of prostitution in Great Britain and in the United States in an effort to protect military personnel from disease.[24]

CHANGING MILITARY POLICY

Closely allied to the control of prostitution is military policy toward STDs. As explained above, part of the reason for the nineteenth-century legalization of prostitution was to provide access to sexual relationships for military personnel, especially those stationed abroad in European-dominated parts of Asia and Africa. This policy provoked criticism abroad as well as at home. In India, for example, the National Congress in 1892 formally objected to state regulation of prostitution as part of its nationalist platform.[25]

Partly under pressure from the social hygiene movement, which emphasized cleanliness and moral reform as bulwarks against disease, military policy in the United States and abroad changed during World War I. Not only did military officials discourage soldiers and sailors from patronizing prostitutes, but also the acquisition of an STD itself became a crime, subject to loss of pay. Medical officers grew concerned that this policy only worsened the health problems of the military forces, since soldiers and sailors avoided treatment as a means of escaping punishment. Political pressure by leading military commanders brought a change in American policy for World War II. Infected military personnel were no longer punished, and prevention and treatment were encouraged.[24]

Before the advent of penicillin, wartime brought significant government attention, as well as increased resources, to STD control. Because STDs affected precisely the demographic group (young men aged 18–25 years) needed to fight wars and caused significant loss of fighting days due to illness, governments changed their policies from peacetime neglect to active, comprehensive STD control. In the United States, Surgeon General Thomas Parran, already interested in reducing syphilis prevalence, seized on World War II as an opportunity to expand both military and civilian disease control efforts. Across the country, residential *rapid treatment centers* were opened for civilians. These centers provided free treatment, in addition to counseling, job training for wartime industries such as sheet metal work and riveting, and job placement following treatment.[26]

The problem with past military approaches to STD control is that they have limited effectiveness as disease control measures for the population as a whole. The military's concern is, of course, with the health of military personnel and the short-term health and manpower needs related to waging war. Even with an unusually powerful public health leader such as Thomas Parran, American wartime STD prevention nonetheless focused on women as vectors of disease and male soldiers as victims. Racy posters of voluptuous scantily clad women with slogans such as "booby trap" disseminated fear-based messages about the dangers of women.[24] Wartime STD control thereby reinforced the idea that women, especially foreign women, spread disease, and it largely ignored the role that the overwhelmingly male military forces played in disease transmission. During the Vietnam War, this trend of blaming the "seductive" foreign female for STDs continued.[27]

RESEARCH AND TREATMENT IN THE TWENTIETH CENTURY

THE TUSKEGEE STUDY

Wartime also provoked the expansion of research into the etiology of diseases and potential therapies. The early twentieth century had witnessed a significant expansion of biomedical research independent of wartime, as germ theory became widely accepted and wealthy philanthropists such as John D. Rockefeller supported research in disease control. During this period, however, some scientists participated in abuses of research ethics, such as the infamous Tuskegee syphilis study.

In 1972, when a journalist exposed the still ongoing 40-year study of untreated syphilis in African Americans in Macon County, AL, the public reacted with shock and outrage. Because many African Americans still cite this study as one of the reasons for their mistrust of the public health system, in particular AIDS prevention and treatment programs,[28] it is worth describing both the historical origins of the study in 1932, as well as its legacy. During the study's 40-year history, the United States Public Health Service

(USPHS) misled the study subjects, 399 poor African American men, that they were receiving treatment for a serious disease when in fact treatment was withheld. Given the current importance of establishing and maintaining ethical research studies in developing countries, the lessons of Tuskegee have relevance to a wider audience than just the American public.

Prior to and during World War II, standards for experimental research differed significantly from what they are today. Although most researchers insisted that research subjects agree voluntarily to their roles, occasional abuses occurred, especially in experiments on soldiers who could be forced to participate by their superiors. More commonly, however, the concept of "voluntary consent" was interpreted much more broadly than today, with fewer protections of subjects' health and safety. A 1915 study on the causes of pellagra, for example, placed healthy male prisoners on a poor diet to determine if they would develop pellagra (and some did). The prisoners consented because they were offered pardons if they followed the diet for 6 months. A few critics argued that prisoners were in an inherently coercive situation in which they could not make independent decisions about participating in research, although the majority of people who knew about the study thought the conditions were fair or even generous. By today's standards, other research studies exploited the economic vulnerability of the poor, especially in the Depression years, when participation in research studies constituted the only available form of employment for some destitute subjects.[29] These studies would not meet today's standards of voluntary, informed consent and freedom from coercion.

Even for its time, however, the Tuskegee study pushed the boundaries of acceptable research ethics, given that the research subjects were under the impression that they were receiving treatment for "bad blood," a vernacular term that covered a variety of conditions, and never told that they had syphilis and were not receiving treatment for this disease. The subjects could not give consent because they were never fully informed of what was happening.

How did this situation arise? Part of the answer lies in the fact that the study was originally conceived in 1929 as a treatment program to show that syphilis could be controlled in rural parts of the South where high disease burden, poverty, and the lack of roads and clinics made public health efforts particularly challenging. If public health officials could conquer syphilis in the rural South, then they thought that they could provide convincing evidence of their ability to control syphilis throughout the country.[30] Treatment at the time consisted of a series of painful intravenous injections of arsphenamine. With a charitable foundation on board to finance this massive treatment program, the initial work of testing blood began in 1930 in five counties in the rural South. By 1932, however, the Great Depression had wiped out the financial reserves of many foundations, thereby making this ambitious treatment program unaffordable. In order to "salvage" the efforts that the USPHS had already directed toward blood testing and developing relationships with black churches and institutions, the USPHS leadership decided to convert the treatment program into a one-county research study, originally conceived as a 6-month to year-long project.[30]

Race and class prejudice also played a role in the development of the study, since the researchers failed to treat their subjects as capable and competent adults. Furthermore, the subjects' inadequate access to health care provided a further justification for research. At the beginning of the trial, medical facilities were so limited that none of the subjects would have been able to obtain treatment. The researchers thought that their study offered an improvement over existing conditions, since they provided hot meals, routine tonics, pain relievers such as aspirin, and $50 toward burial costs. The subjects' poverty served as a partial justification for the study.[31] In a period of particularly brutal race relations characterized by public lynching and a resurgence of Ku Klux Klan activities,[32] the researchers' milder, paternalistic (but nonetheless insidious) form of racial prejudice no doubt seemed less "racist" at the time than the openly genocidal fantasies of some of their contemporaries.[30]

The injustices of the original study were compounded and prolonged as the study was extended in time. Although penicillin became available in 1943, it was never offered to the study subjects. Worse yet, those who would have received penicillin because of their military service were denied treatment. The study was halted only after a journalist reported the story in 1972.[30]

Because this story erupted during the civil rights movement, the Tuskegee study quickly became a symbol of the whole system of racial injustice that African Americans had suffered through during the previous century. African American mistrust of the medical profession and of the white society preceded the 1972 exposure of Tuskegee, based on a long and complex history of systematic racial exploitation. It is therefore important to understand African Americans' reaction to Tuskegee not in terms of a single, isolated event, but in terms of its power to evoke the long, historical experience of injustice and abuse.[33] Because the Tuskegee study evokes such a powerful emotional response in the United States and beyond, it can, however, be used inappropriately to criticize ethical conduct in research studies that does not approximate the ethical abuses of Tuskegee.[34] It is important not to cry "Tuskegee" without carefully analyzing the conditions of a research study.

PENICILLIN REAPPRAISED

Early twentieth-century biomedical research also yielded one of the major triumphs of STD control: the discovery of

penicillin as an effective therapy for the syphilis and gonorrhea in 1943. Although treatment had existed since Paul Ehrlich's discovery of salvarsan (an organic arsenic compound) in 1909 and his development of a less toxic compound known as neosalvarsan in 1912, this treatment was complicated, lengthy, and often produced serious side effects. The outbreak of World War II contributed to the urgency of medical research, since, as previously mentioned, STDs accounted for a substantial amount of lost days of active duty. After finding successful results in the experimental treatment of penicillin on syphilitic rabbits, and then on one human subject, Dr. John Mahoney of USPHS announced the results of his research in September 1943. Within a year, 10,000 patients were being treated for early syphilis, with treatment success rates between 90% and 97%.[24]

Initially, it was difficult to increase the production of penicillin rapidly enough to meet the demand. In the United States, priority of access to penicillin was given to the military to treat a variety of infections including syphilis and gonorrhea. Once the production of penicillin increased to cover military demand, a limited supply of the drug was released for civilian use under the strict control of an expert committee, called the Committee on Chemotherapeutic and Other Agents (COC), to make rationing decisions. The COC restricted access according to the proven efficacy of penicillin against a particular infection (such as staphylococci, sulfonamide-resistant streptococci, and gonococci), to the severity of infection (as long as it was responsive to penicillin), and occasionally to diseases that had research value, such as rare but potentially fatal diseases for which data regarding penicillin's efficacy did not yet exist. However, the need to ration penicillin caused some controversy among civilians. One former congressman complained that a worthy young civilian would die because he did not have access to the drug, while "careless" military personnel who had contracted syphilis or gonorrhea could obtain access to the drug.[35] The media hype about the new "wonder drugs" undoubtedly increased the demand for these medications.

Did the availability of penicillin make people more likely to engage in sexual activities than they would have before, simply because they were no longer afraid of STDs, as some have suggested? Rates of STD infection did in fact increase in Europe, the United States, and Australia between 1945 and 1948. It is difficult, however, to disaggregate the psychological effects of penicillin on behavior from other factors that influenced behavior during the same period. Most importantly, the end of war brought an end to heavy fighting which had been especially rigorous in 1944–1945. Few military personnel had the time or opportunity for sexual relations during the war's final years. During the postwar occupation, however, military personnel had leisure time to spare and disposable income. Meanwhile, occupied countries experienced extreme economic hardship that made casual prostitution or relationships with soldiers one of the few economic opportunities for young women. In occupied postwar Germany, for example, despite an American official ban on fraternization with German citizens, 25% of American GIs spent at least 10 or more hours "talking" with German women every week. Given that few American GIs spoke German and few German women at the time spoke English, it is reasonable to speculate that activities other than talking occurred, especially given that the occupation army in postwar Germany had the highest rate of STDs of any American military unit during 1940s.[36] The situation was the same with Australian and British postwar occupation of Japan, where these troops contracted high rates of STDs.[37]

It is difficult to determine whether soldiers' behavior was a reaction to the end of wartime, which brought expectations for "recreation," or a reaction to the introduction of penicillin, or both. It seems more likely to have been the former, however, because penicillin use was still not the first-line treatment choice for syphilis among British troops,[38] for example, who nonetheless displayed similar behavior to that of the Americans. Furthermore, penicillin was unavailable for civilians in occupied countries for several years after the war. In 1948, when civilians gained access to penicillin in Germany, rates of STDs began to decline.[39] In short, penicillin was introduced at the time of massive social upheaval, increased population mobility of displaced populations and movements of military personnel and civilians, as well as unequal power relations between occupying armies and occupied countries. The combined influences of these factors on sexual behavior and sexual networks make it difficult to attribute increased STD rates between 1945 and 1948 to the penicillin's effects on sexual behavior by itself.

One major effect of the introduction of penicillin, however, was loss of public health interest in STD control. Public spending on STD control declined throughout the world, and these diseases became a low priority.[24] For example, India developed the capacity to manufacture its own penicillin in 1954, after which the state governments of India turned their attention to other health problems.[40]

One significant exception to this trend was China. Partly because the Chinese had blamed STDs on foreign occupation of China and foreign cultural decadence, the Communist government adopted STD control as one of its major policy initiatives immediately after its 1949 political victory. In a campaign that included widespread public relations efforts through plays, radio programs, and small discussion groups, the government undertook a massive screening and treatment program including vocational rehabilitation for former female sex workers. By 1964, the government claimed to have eliminated STDs, a statement that is impossible to verify but widely accepted as a general indication of a very low Chinese prevalence rate. The long-term effects of the campaign are, however, less clear. Because STDs were represented as a social evil and sign of decadence,

Chinese patients tried to avoid public hospitals, which charged STD patients to punish them for their having acquired these diseases. Social stigma became a major problem. Furthermore, the medical specialty of venereology was no longer practiced and taught after 1960s. With the liberalization of employment policies in 1989 and the subsequent development of an enormous migrant labor population (between 50 and 120 million people), rates of STDs began to increase, with insufficient medical resources and ability to respond.[41]

PREVENTION AND SURVEILLANCE

PREVENTION: THE NEGLECTED SCIENCE

Historically, prevention is the neglected aspect of STD control programs. Moral reformers have often asserted their control over prevention efforts by defining STD prevention as a problem of morality. Whether led by church groups themselves or by charitable organizations, these efforts focused on fear-based messages about the consequences of immorality (death, disfigurement, infertility, shame) along with representations of happy family life with abundant, healthy offspring as a consequence of correct moral choices.[24]

This approach seldom focused on the structural factors which influence sexual behavior, such as long-term labor migration which keeps spouses separated, population displacement, and lack of economic opportunities for young females. In some cases, the content of the prevention messages themselves potentially undermined their effectiveness. For example, in 1919 the USPHS collaborated with the Young Men's Christian Association (YMCA) to produce an education campaign about the dangers of VD to present to American boys. Both white and black American boys viewed the same set of posters about the white man's responsibility to "lift up" inferior races by setting an example of moral behavior. It is unlikely that this educational campaign, built on assumptions about a racial hierarchy, was effective among African American boys.[42]

Public health officials deliberately ignored prevention in much of sub-Saharan Africa during colonial rule. Racial prejudice informed these decisions, since whites claimed that the "inferior races" could not control their sexual impulses.[16,18,19] Postcolonial African countries seldom possessed the resources to undertake major prevention efforts.

One of the major limiting factors in developing prevention activities has been the emphasis on medicines and technological interventions.[24] Furthermore, medical science could claim greater victories in disease control than the young field of behavioral sciences, thereby further reinforcing the emphasis on research and development of biomedical rather than behavioral interventions. As late as the 1970s and 1980s, prevention efforts worldwide, from San Francisco to Singapore,[43] focused on disseminating information about STDs on the (incorrect) assumption that information alone could produce behavioral change. Not until the threat of HIV/AIDS emerged during the 1980s, when a fatal STD with no cure threatened the lives of millions, did governments begin to invest substantial resources into systematically studying behavioral science approaches to changing behavior.

SURVEILLANCE: A CENTURY OF CONTROVERSY

However neglected prevention and the behavioral sciences were, the same cannot be said of surveillance efforts, which, along with treatment, have formed the core of the STD control effort in the postantibiotic era, especially in the United States. Certain types of surveillance, such as contact tracing, sparked considerable, longstanding controversy over protection of individual privacy and rights versus protection of public health. During the early twentieth century in the United States, the majority of states treated STD patients differently than those with diseases such as measles and smallpox. Because of the social stigma attached to STDs, most states allowed cases to be reported by a patient's initials or a serial number rather than by full name in order to protect patients' privacy. This "shielded" reporting became standard public health practice until 1946, when efforts to find the "missing million" with syphilis were launched and later when laboratory-based reporting became widespread in the 1960s. Before 1946, public health officials had not known the names of the patients. Afterward, in order to contact patients based on laboratory reports and interview patients for names of sexual contacts, public health officials knew the names and other identifying information of STD patients. In order to protect patient privacy, public health officials did not release the name of the original patient to the contacts they later interviewed. Nonetheless, the definition of confidentiality and privacy had changed dramatically during the century so that after 1960s public health officials had access to information about patients that they had not previously possessed.[44]

The fact that government employees (i.e., public health officials) had access to patients' names may have undermined efforts to build trust, especially with the groups suffering from government persecution. In 1947, for example, the U.S. Park police launched its "Pervert Elimination Campaign" to find and arrest gay men, which was followed by the McCarthy-inspired Federal Loyalty Program in which more than 1000 people lost their jobs because of allegations of homosexuality. Vice squad officers frequented gay bars and clubs, interviewed suspects' coworkers, and compiled the lists of "known" homosexuals.[45] Public health officials frequently complained about homosexual men's unwillingness to cooperate during interviews, but never connected their mistrust to the real risks that homosexual men faced from other local and federal government officials during 1950s and 1960s.

Contact tracing was less common in Europe than in the United States. Even a conservative country such as Scotland,

for example, was reluctant to pursue large-scale contact tracing out of fear that it was illegal under the Scots Laws, which protected citizens from slander or "injury done to feelings." Consequently, only about 10% of patients were followed up for interviews and contact tracing.[46]

Aside from contact tracing, surveillance efforts typically consisted of collecting data about patients who seek STD treatment, rather than more costly population-based screening. Governments have not always made effective use of the data from even limited surveillance efforts. For example, the government of Malaysia conducted a national survey of cases reported to the Ministry of Health in 1976. In response to the information that cases were primarily among young Malaysians (in their 20s), health workers advocated the introduction of an STD education program in schools and efforts to reduce stigma throughout the population. The government balked at what they considered a politically contentious program in a conservative Muslim society. Instead, the government focused screening and control efforts more narrowly on prostitutes than on the wider population of 20–30-year-olds.[47] Although surveillance was a central part of STD control during the late twentieth century, the information generated by surveillance efforts was not always used effectively. STD control programs often developed in response to political pressure rather than to actual trends in STD morbidity.

CONCLUSION: CHALLENGES FOR PREVENTION AND CONTROL

STD morbidity continues to remain a challenge, despite centuries of effort to prevent, treat, and control these diseases. Efforts to combat STD stigma have been rare and therefore remain a potential avenue of exploration. STD stigma needs to be recognized as part of a more complex social process than just its association with illicit sexuality, however, in order to develop an effective public health effort.

With the success of antibiotics, one of the major historical impetuses for STD control programs, wartime no longer activates public or government interest in STDs. The public has remained focused on the control of prostitution, but the historical record shows how difficult it is to create sustainable programs that control disease rather than punish prostitutes and further stigmatize these diseases. Prevention grounded in the behavioral sciences remains a marginal part of STD control programs, partly because these programs have often been separated from HIV/AIDS programs where much of the innovation in prevention occurred.

Although treatment has been the major focus of bacterial STD control programs, the viral STDs present a different story not yet adequately studied by historians. We know little historically about the impact of herpes and the success (or failure) of psychosocial support groups and little about the history of HPV. Furthermore, even a few of the bacterial STDs, notably chlamydia, have been left out of this history. In particular, we do not know what the broader impact of the discovery of new STDs has been on public perceptions, availability of resources, and ability to build coordinated public health programs. The impact of the HIV/AIDS epidemic also demands further exploration, especially as the records of major government agencies during the 1980s and 1990s become available to researchers during the next 10 years. Is the history of these new and newly discovered STDs a history of synergy or of competing resources for new demands?

Finally, we still know little about the history of STDs and STD control outside of Europe and the United States. Most of the historical work on Asia and Africa has focused on the colonial period, while Latin America has been virtually ignored. Some of this historical research has been done, but is not available in English. Pre- and postcolonial histories could elucidate a wider range of public health efforts, as well as contribute to our knowledge about how perceptions of STDs vary according to changing historical conditions in different cultures. Even within the history of Europe and the United States—a history, which fully integrates the biological and social perspectives on STDs—a social, ecological approach has yet to be fully developed. By examining how social and biological conditions interact to facilitate or retard the spread of disease, it may be possible to come up with new ideas to prevent and control STDs.

2 An Economic Perspective on Sexually Transmitted Infections Including HIV in Developing Countries

Stefano M. Bertozzi and Marjorie Opuni

INTRODUCTION

The burden of disease of sexually transmitted infections (STI) is large and it disproportionately affects developing countries.[1] As discussed elsewhere in this volume, the prevalence and incidence of STI other than the human immunodeficiency virus (HIV) are high in much of the developing world. Because diagnosis and treatment are often inaccessible, delayed, or inadequate, complications are common with their attendant high morbidity and mortality, especially affecting women and infants.[1] The morbidity and mortality impacts of these STIs are compounded since they also facilitate the sexual transmission of HIV, which continues its unrelenting spread predominantly in resource-poor settings and above all in sub-Saharan Africa.[2,3] In countries heavily affected by the epidemic, HIV has had dramatic impacts on adult and child morbidity and mortality as well as population and family structure.[4–8]

In many developing countries, the scale of the STI epidemics, including HIV, requires that responses to them be based on multidisciplinary analysis, research, policymaking, and intervention development, which must include, but should not be limited to, the biomedical and epidemiological disciplines. Economics, the *science of choice,* is one discipline that has much to contribute to efforts to address the epidemics of STI/HIV in resource-poor settings. Economists have contributed to the analysis of the determinants of STI/HIV infection and to the impacts of STI/HIV on individuals, their households, their communities, production units and institutions, whole economic sectors, and in some cases entire national economies. These analyses have underscored the need for public intervention in the prevention and treatment of STI/HIV. Economics in conjunction with epidemiology also offers a set of tools that can assist in the evaluation and prioritization of STI/HIV interventions in contexts of limited resources.

The objective of this chapter is to provide an overview of some of the contributions that economists have made regarding STI/HIV in developing countries. We focus on developing countries because, as discussed elsewhere in this volume, the epidemiology of STI epidemics in resource-poor settings and in wealthier countries differs substantially as do the impacts and the resources available for STI/HIV prevention and care. The chapter proceeds as follows: in the next section, we discuss briefly some key socioeconomic determinants of the spread of STI/HIV; we then describe the morbidity, mortality, and fertility impacts of STI/HIV and the economic impacts on individuals and their households that emanate from these, as well as the effects that result on the health sector. Finally, we review existing knowledge on the effectiveness, cost, efficiency, and cost-effectiveness of STI/HIV interventions in resource-poor settings and discuss the policy implications of this research.

SOCIOECONOMIC DETERMINANTS OF STI/HIV INFECTION

STI/HIV are not spread randomly. Unprotected sex with an infected partner is by far the most important risk factor for STI/HIV infection.[1,9] This in turn is influenced by prevalence and distribution of infection in a population, as well as the behavior of an individual and his/her partners.

Economic deprivation, low education, economic inequality, and economically driven migration and mobility have all been found to be associated with the risk of STI/HIV infection.[10–12] With its key premise that the choices that people make are strategic decisions based on maximizing well-being given a set of constraints (e.g., income, education, information) within particular contexts, economics can provide a framework to help understand what underlies the behaviors associated with transmission of STI/HIV.

A number of studies suggest the possibility of a causal link between economic deprivation and risk of STI/HIV infection. This may be because the poor have less access to information about STI/HIV risks and are thus more likely to make their choices in the context of lack of information or

misinformation. Research in Cambodia, for example, shows that the poorest segments of society have much less knowledge of how HIV is transmitted and prevented and are more likely to engage in behaviors that put them at risk of STI/HIV infection.[11] The poor are also more likely to have sex at a younger age, they use condoms less frequently, and they are more likely to end up in activities that put them at high risk of STI/HIV infection.[10] Poor women, for example, are more likely to turn to sex work than women who are better off economically.[11] In some cases, poor women are forced into sex work, into providing sexual favors without compensation or into providing sexual favors in return for money. As studies from Mexico, India, and the Philippines have shown, women in the sex-work industry may be willing to risk infection by not using condoms if they are adequately compensated—if they do not perceive the risk to be more significant than the other problems they face.[13–15]

Related to economic deprivation, several studies have also shown an association between education and STI/HIV. Analysis of household data shows a strong correlation of both wealth and education with knowledge and condom use.[16] Similarly, a recent study in Uganda showed that as the HIV epidemic has progressed, educated persons have been more responsive to prevention information campaigns.[16,17] Education was found to be associated with lower risk of HIV infection.

Economic inequality is also likely to influence STI/HIV transmission.[1] Income inequality has been found to be a strong predictor of STI prevalence, even after controlling for gross national income (GNI) per capita. It is also a strong predictor of STI prevalence among key populations—populations at especially high risk of becoming infected or transmitting an infection, such as sex workers. A possible explanation given is that greater inequality creates more active markets for commercial and casual sex, as higher income men negotiate the sexual services of lower income sex workers.[1] A similar situation applies when tourists often have considerably more resources than local populations and may also be more likely to seek commercial sex away from their home environments.[18] In many places, social inequality underpins this economic inequality. The education status of women is often lower than that of men, for example. They have fewer assets and fewer opportunities for employment.[10]

It should also be noted that processes associated with development such as increases in disposable income and increases in mobility among certain groups and not others are associated with increased risk.[10,18] Professions involving high mobility and extended periods away from families, such as migrant labor, serving in the military, driving trucks, or working as sailors are also associated with augmented risk.

Finally, in many developing countries, inaccessible or low quality STI care services result in unnecessary complications from STI other than HIV and in preventable HIV infections.[1] Also, because of low levels of awareness regarding sexual health and associated stigma, health care seeking is frequently inadequate.[1] The care of opportunistic infections (OI) associated with HIV/AIDS and antiretroviral therapy are beyond the scope of this chapter. But clearly, resource constraints also limit access to health care, to antiretroviral therapy, and to social and legal support to combat discrimination for the millions of people living with HIV in resource-poor settings.

SOCIOECONOMIC IMPACT OF STI/HIV

The primary mechanisms through which STI/HIV affects the economic well-being of individuals and their households, communities, and countries are the impacts of the infections on morbidity and mortality. In countries heavily affected by HIV, this can lead to important changes in average household composition and population structure. Stigma and discrimination constitute a second burden for people living with and affected by STI/HIV and their effect on well-being is also partly mediated through economic mechanisms. Discrimination that limits access to education, employment, and/or housing affects a household's ability to generate income and/or its ability to use its income to purchase improved quality of life. Such "economic discrimination" is especially costly for the poor, exacerbating the impoverishment that results from lost income due to illness and the need to care for ill family members.

IMPACT OF STI OTHER THAN HIV ON MORBIDITY AND MORTALITY

Because diagnosis and treatment of STI other than HIV are often delayed or inadequate in resource-poor settings, the burden of morbidity in these countries is significant, especially among women. The most serious complications of pelvic inflammatory disease (PID), primarily associated with chlamydia and gonorrhea, include chronic pelvic pain and ectopic pregnancy.[19] Complications of herpes simplex virus-2 (HSV-2) include severe primary disease, meningitis, and erythema multiforme. Infection with the human papillomavirus (HPV) is a prerequisite for the great majority of cervical cancers.[20] All of these STIs can have important impacts on the productivity of an affected individual.

STIs are also an important cause of reduced fertility among women and some STIs such as chlamydia can reduce fertility among men.[20,21] This aspect of STI morbidity has not been adequately addressed by the health economics literature. Indeed, if one used a human capital approach to estimate the economic impact of STI-induced infertility, one might easily demonstrate that infertility was associated with greater labor market participation by both men and women, implying that infertility was economically beneficial. A better

approach would attempt to estimate the reduction in quality of life and its economic value, typically done by estimating people's willingness to pay to avoid infertility. However, even this approach is not simple, because only people who desire additional offspring have their quality of life reduced by infertility—after all, at any one time a larger proportion of the population is actively seeking temporary or permanent infertility (through contraception or sterilization) than seeking pregnancy.

STI other than HIV also have significant detrimental effects on the fetus and neonate of an infected woman. Adverse pregnancy outcomes include early abortion, premature births, low birth weight as well as congenital infections. Syphilis left untreated during pregnancy, for example, leads to fetal wastage and congenital syphilis.[22] Most vaginally delivered neonates exposed to *Chlamydia* become infected, with a smaller proportion developing conjunctivitis or pneumonitis.[20] Complications of HSV-2 include neonatal herpes. Without appropriate diagnosis and antiviral therapy, over half of infected babies die and approximately half of surviving babies have lasting neurological complications.[23]

IMPACT OF HIV ON MORBIDITY

As disease progresses in persons infected with HIV, with increasing viral load and decreasing CD4 count, the risk increases for OI such as tuberculosis, wasting syndrome, Kaposi's sarcoma, mucocutaneous HSV infection, cryptosporidial diarrhea, and esophageal candidiasis.[24,25] All of these can also have important impacts on the productivity of an infected individual.

It is now well established that HIV/AIDS also has major impacts on fertility in highly affected countries. Studies in a number of countries in sub-Saharan Africa have shown that with the exception of the youngest age group, HIV-infected women have between 25% and 40% lower fertility than HIV-uninfected women.[26,27]

These lower fertility rates are largely due to lower rates of conception. Women with HIV are more likely to have amenorrhea than are HIV-negative women; there may be repercussions for women's fertility from the decreased production of spermatozoa in their HIV-infected male partners, and there may be reductions in the frequency of sexual intercourse and/or increased contraception use resulting from knowledge or suspicion of own and/or partner infection.[28–31] Another factor causing lower fertility rates among women with HIV is the increased rates of pregnancy loss (part of the increased loss may also be explained by the association between HIV infection and infection with other STI).[28,29,32,33]

In addition, the epidemic is also likely to cause behavior changes in the general population. The HIV/AIDS epidemic appears to cause important changes in contraceptive use in the general population with an increase in the use of condoms and the switching to condom use from other forms of contraception.[27] If condoms are used by couples who did not practice contraception previously, this will result in an overall decline in fertility. However, if they replace more effective methods of contraception with condoms, this will cause a slight increase in fertility. The epidemic is also having an impact on fertility by increasing women's age at first sex.[34–36] Finally, changes in postpartum behavior, including reduction in breastfeeding or shortening of abstinence after the birth of a child to discourage a partner from seeking other partners that may be HIV-infected, would tend to increase fertility.[27]

IMPACT OF HIV ON MORTALITY

The primary mechanism through which STI contribute to mortality is through mortality associated with HIV. And with an estimated median survival time, a little above 9 years from HIV infection to death in developing countries in the absence of antiretroviral therapy, HIV has had a dramatic impact on adult mortality.[25,37] National data from the countries that have been most heavily affected by HIV indicate that mortality levels rose rapidly during the 1990s, and studies with information on the HIV serostatus of study participants in these countries provide evidence that HIV has been the major contributor to this increase in mortality.[7]

Demographic and Health Survey data suggest that in the countries most heavily affected by HIV, the probability of a 15-year old dying before reaching the age of 60 years increased from a range of 10–30% in the mid-1980s to a range of 30–60% at the end of the century.[38] More specifically, the probability of dying between the ages of 15 and 60 years in Kenya increased from 18% in the early 1990s to 28% by the end of the decade; in Malawi, while it was 30% in the early 1980s, it is now over 45%; in Zimbabwe, it increased from 33% for both women and men in 1985 to 50% and 65% for women and men, respectively, by 1997.[4,39]

Several studies conducted in countries heavily affected by HIV with information on the HIV serostatus of study subjects provide evidence that HIV has been the major contributor to this increase in mortality. A recent review of these studies found that in regions with already fairly high background mortality, after standardizing for age, on average, the mortality rates of HIV-infected men were 9–16 times the mortality rates of uninfected men, while the mortality rates of HIV-infected women were 15–25 times those of uninfected women.[7]

Since mother-to-child transmission (MTCT) can occur before, during, and after delivery including during breastfeeding, HIV among children parallels that among women of reproductive age.[6] And since most infected children, in absence of antiretroviral therapy, will develop AIDS and die before their fifth birthday, infant and child mortality increases in high HIV-prevalence countries as a result of AIDS.[40,41]

It has been estimated that by 2002, in sub-Saharan Africa, 20% of all deaths among children under 5 years of age in the region could be attributable to HIV.[6]

ECONOMIC IMPACT OF HIV ON INDIVIDUALS AND THEIR HOUSEHOLDS

HIV/AIDS usually affects prime-age adults (age at which normal levels of morbidity and mortality are usually low) at the peak of their economically productive years and incapacitates them for significant periods of time before causing their death, typically with massively increased health costs compared to noninfected adults of similar age. Important economic impacts are therefore to be expected at the individual and household level. Moreover, though a detailed discussion of these is beyond the scope of this chapter, we should note that economists have also looked at how HIV impacts communities, production units and institutions, whole economic sectors, and in some cases entire national economies.[41–61] However, determination of the macroeconomic impact of HIV/AIDS is extremely difficult since at any given time, one cannot determine how the economy would have functioned in the absence of HIV/AIDS. Numerous factors affect economic performance, and attributing changes in performance to one particular cause is difficult. It is therefore not surprising that predictions of the net macroeconomic impact of AIDS have varied widely and economists continue to debate the issue with some economists questioning the usefulness of placing too much emphasis on such studies and others continuing to place a great deal of emphasis on producing models of macroeconomic impact.

Economic research has therefore increasingly focused on assessing the impact of the epidemic on individuals and their households. The illness or death of young adults due to HIV/AIDS can result in changes in household composition; it can result in changed household labor allocations; it can lead to reductions in household income, assets, and savings; it can affect household consumption patterns; and it can affect the health and well-being of other household members.[42]

Before turning to a brief review of key findings on these issues, we note that there are some limitations that characterize the research conducted on the impact of AIDS illness and death on households to date.[43] Much of the information that has been collected has been through anecdotes or through convenience samples, with people affected by HIV/AIDS identified through health centers or nongovernmental support organizations.[44–56] The population-based study conducted by the World Bank in Kagera, Tanzania, is one exception and analysis of these data have provided a great deal of information.[12,57–62] Another population based survey was conducted in Kenya more recently.[63] Economists have also used Demographic and Health Surveys as well as cohort studies in highly affected areas which include economic data although unfortunately, the economic information included in these surveys is often limited.[17,64]

There are also some methodological issues with some of the studies conducted to date. An AIDS death in a household is hypothesized to be a function at least in part of household and individual unobservable characteristics that differ across households and individuals. Moreover, economists are also concerned with the issue of simultaneity or reverse causality. It could be, for example, that it is not the occurrence of an AIDS death in a household that affects household labor allocation and income. Rather, it could be that households that have less stable membership or that include persons who have less stable employment are more likely to include persons that become infected with HIV. If the econometric analyses of the impact of AIDS deaths do not take these issues into account, any resulting estimates will be inconsistent and biased.

AIDS mortality and household composition

An AIDS death within a household clearly changes the composition of the household. In addition, it may also have a direct impact on household size although study results differ on whether such a death leads to an increase or a decrease in household size.[12,65,66] In all studies, the dependency ratio in households affected by HIV/AIDS was higher on average following an adult death.

In the most extreme scenario, the change in household composition that results from a young adult death leads to the dissolution of the household. Analysis of data from rural Tanzania found that the death of a household head can result in household dissolution.[67] In a recent study conducted in KwaZulu-Natal, deaths of young adults were associated with a threefold increased risk of household dissolution compared with households without such a death.[68]

The troubles of orphans and the grandparents caring for them have received a great deal of coverage in the media. This phenomenon does exist. In Kagera, statistically significant changes in household composition were found including a decrease in the percentage of elderly living in three-generation families and an increase in the percentage of living alone or with children only.[61] But research conducted to date in South Africa and Uganda does not support the notion that these households are becoming the norm in areas where young adult mortality is high.[65,69–71]

AIDS mortality and household labor allocations

One of the pathways through which AIDS-related illness and mortality is hypothesized to affect households is through changes in the own labor of other household members with particular concern raised regarding children leaving school to work or to care for the sick.[12] Most of the information on the impact of AIDS-related illness and death on household labor

allocations has consisted of anecdotal evidence or information gathered from convenience samples.[45–47] Analysis of data on farm and chore hours of household members in Kagera, Tanzania, found small and insignificant changes in the labor supply of persons in households experiencing an adult death. This could be because where unemployment rates are high, as in rural Tanzania and other heavily affected countries, those providing care are often those who are themselves unemployed or participating in subsistence production.

AIDS mortality and household income and assets

Related to the issue of how AIDS-related illness and mortality affects the labor allocation of other household members is the issue of how it affects household income. Studies that have looked at the impact of AIDS-related illness and death on household income have generally found that young adult illness and death have a negative impact on income.[44,48,54,63] This is largely due to the loss of income contributions from the ill or dead young adult. Recent analysis of panel data from Kenya found that only the death of a young adult male led to a statistically significant reduction in household off-farm income.[63]

Selling assets, depleting savings, and incurring debt to meet augmented needs are also mechanisms that households have been found to use to cope with the impact of AIDS-related illness and death.[12,44,48,51,55,62,63] For example, households in rural Kenya affected by a young adult death were found to be more likely to sell assets such as small animals and farm equipment to raise cash for medical care and funeral expenditures.[63]

AIDS mortality and household consumption

Studies on the impact of AIDS-related illness and mortality on households have found that households that are affected tend to spend relatively less on certain categories of goods and services and more on other categories than do unaffected households.[12,44,48,51,55,62] Affected households spend less on food, for example, and more on health and funerals. In Kagera, Tanzania, the expenditure on food by the poorest half of households affected by an adult death fell by 32% immediately following the death.[62] Affected households spent one-third less on nonfood items such as clothing, soap, and batteries than did unaffected households. The share of total expenditure that households experiencing an adult death spent on medical care and funerals on average amounted to 16% and 5.4%, respectively, compared with 2.6% and 0.6% in households without an adult death.[62]

However, few studies that have looked at household impact have been able to examine the medium- and long-term effects of such morbidity and mortality. This is likely to lead to two important biases. Household coping behaviors will be expected to compensate for the loss of income and for the change in household composition such that short-term falls in income and consumption will likely be attenuated over time. This is consistent with the results from the Kagera study.[12,62] The short-term impacts measured are likely to underestimate the long-term impact on human capital investments in children in affected households, as discussed below. This result is suggested by both the empirical work done by Gertler et al. in households suffering a non-AIDS-related young adult death in Indonesia as well as the modeling done by Bell et al. for Southern Africa.[72,73]

AIDS mortality and the well-being of household members

Because AIDS deaths occur predominantly among prime-aged adults who are often parents, an estimated 15.2 million children aged 0–17 were estimated to have lost one or both parents at the end of 2005.[3] This demographic trend has resulted in a growing body of research on the impact of young adult death on the well-being of children. Analysis of data from Uganda indicates that the presence of both parents in the household increase the odds of survival by 28%.[74] Analysis of panel data from Indonesia showed that children who had lost their mothers had worse measures of child health and nutritional status than other children.[75] In terms of education, the results of studies have been less consistent. A number of studies have concluded that "the orphan enrollment gap is dwarfed by the gap between children from richer and poorer households."[57,59,60] On the other hand, analysis of Demographic and Health Surveys from sub-Saharan Africa found that orphans were significantly less likely to be enrolled in school.[64] Moreover, analysis of data from Indonesia found that parental mortality doubled school dropout rates.[76]

Though much more limited in scope, some economic analyses have also been conducted on the impact of young adult mortality on the well-being of older adults who often rely on their children and grandchildren for money, food, and other support. Analysis of data from Kagera found that the well-being of older adults as measured by body mass index (BMI) was negatively affected by the death of a prime-aged adult but that their BMI recovered over time and there did not appear to be a long-term association between prime-aged deaths and level of BMI.[58]

ECONOMIC ANALYSIS TO PRIORITIZE INTERVENTIONS

Government and nongovernmental institutions in developing countries face resource constraints and many competing demands. With simply not enough resources to meet all demands, choices must be made and priorities set. Economics offers a set of tools that are useful in the prioritization of interventions.

The classical approach used by economists is to calculate the rate of return on competing interventions and to allocate funds to the investments that yield the highest return, followed by the next highest, until the budget is exhausted. Economists use cost-benefit and cost-effectiveness analyses to compare the benefits and opportunity costs of alternative investments. Cost-benefit analysis compares the benefits of an intervention to its costs with both evaluated in monetary terms. Cost-effectiveness analysis compares interventions using indicators, such as lives saved or disability adjusted life years gained that are not measured in monetary terms and costs that are measured in monetary terms. Many economists prefer cost-benefit analysis to cost-effectiveness analysis. The problem is that many assumptions are required to value the health benefits of an intervention in monetary terms. Because of this, cost-effectiveness analysis has dominated economic analyses in health, including STI/HIV.

In this discussion, we focus on interventions to reduce risk behavior as well as interventions to treat treatable STI. We do not address HIV/AIDS care and treatment interventions and refer readers interested in this issue to recent reviews on the subject.[24,77]

EFFECTIVENESS

Details on the effectiveness of STI interventions are provided elsewhere in this volume. Here we highlight only that there are important differences in the data available regarding the effectiveness of biomedical interventions for STI/HIV prevention and STI treatment on the one hand and STI/HIV prevention interventions aimed at behavior change on the other. Biomedical interventions for STI prevention and treatment benefit form a large accumulated body of rigorous evaluation.[78] Likewise, the effectiveness of biomedical interventions for HIV prevention such as screening of blood for transfusion[79–81] and the prevention of MTCT[29,82–88] is well documented. While there is also an extensive body of literature on the effectiveness of behavior change interventions, that literature suffers from two important disadvantages. First, results of the studies are typically less translatable to different social, cultural, and economic settings. While there is no reason to believe that nevirapine would be more or less effective for MTCT in Guatemala than in Pakistan, there is every reason to question whether an HIV prevention school curriculum would be equally effective. Second, the interventions on average have been much less rigorous, often with insufficient or marginal statistical power, rarely incorporating biological endpoints and with even fewer that measure HIV incidence, something that the trials of biological interventions do routinely.

A number of issues make the evaluation of behavior change interventions particularly complex.[24] Counterfactual models (what would have happened in absence of the intervention) are difficult to estimate both because of the long delay from intervention implementation until a change in prevalence can be observed and because historical controls are of limited utility in describing likely secular behavioral trends into the future. In addition, behavior change interventions are difficult to force into a typology that clearly distinguishes one intervention from another. Also, assessments of behavior change interventions have rarely incorporated well-defined control or comparison groups, in part because of a reluctance in the research community to fund prospective evaluations of large-scale, "real-life" programs rather than small pilot interventions. This absence of data on intervention effectiveness in different settings makes it difficult for policymakers to appropriately tailor packages of prevention interventions to diverse social, economic, and epidemiological settings, and for the varied subpopulations, in which STI/HIV transmission occurs.[89]

Unfortunately, information about the effectiveness of different interventions in different settings/populations is not sufficient. It is also necessary to have information about the epidemiology of risk behavior and STI/HIV infections, as well as the relevant social and cultural characteristics from the countries where prevention programs will be implemented. Thus, the development and maintenance of a sound and reliable public health surveillance system is a prerequisite for an effective prevention response.[84] An understanding of HIV and STI prevalence and trends, as well as the prevalence and distribution of behaviors that contribute to the epidemic's spread, should be supplemented by national monitoring systems that track sources and uses of funding to promote greater accountability. In addition, data are needed to identify and characterize key contextual issues that affect the feasibility and likely effectiveness of interventions.

To the extent that lack of effectiveness data and lack of data on local contexts result in the implementation of ineffective interventions and in the lack of implementation of effective ones, then prevention expenditures are wasteful and people are unnecessarily becoming infected. Without such data it is much more difficult to hold policymakers accountable for bad choices in the allocation of prevention resources, thus perpetuating prevention programs that reflect political expediency or discriminatory attitudes rather than the intent to prevent the maximal number of infections.

COST AND EFFICIENCY

Although the consensus among health economists favors analyses that use a societal perspective that considers all costs and benefits regardless of who incurs them, the most commonly used perspective in cost and cost-effectiveness analyses of STI/HIV interventions is that of the public sector, with the cost of an intervention often defined as total public sector expenditure attributable to that activity.[1] Total expenditure includes that for buildings, durable equipment, skilled and unskilled labor, and materials, including drugs.

The unit cost of an activity is defined as the total expenditure during a stated time period divided by the number of units of output during that same period.[1] Since the same activity can have several outputs, this definition can be ambiguous. While an intermediate output of the delivery of STI treatment services is the patient treated, a more final output is the patient cured. An even more complete measure of total output would include any secondary infections averted due to the cure of the primary infection.

Two reviews have recently been conducted of the literature on the unit costs of STI treatment and of STI/HIV prevention interventions in developing countries.[1,24] This section and the ones following highlight some of the key findings from these reviews.

A partial list of the variables that determine the unit cost of STI treatment can be subdivided into epidemiological characteristics, supply side or provider characteristics, and demand-side or patient/client characteristics.[1] Epidemiological characteristics include prevalence and incidence of disease, transmission efficiency, and epidemic phase. Supply side characteristics include availability of appropriate diagnostic tools and availability of effective treatments with few side effects, the proportion of services delivered in the public versus the private sector, economies of scale, economies of scope, health system characteristics, resource combinations and input prices, incentives to deliver high quality and quantity of services, and discrimination. And finally, population composition and density, income, price, distance, education, perceived stigma, perceived quality of services, and disutility of condom use, are all factors that can constrain demand and thus influence the unit cost of services.

A recent review of available studies in developing countries on the unit cost per cured or effectively managed STI case identified 35 studies.[1] Table 2-1 provides the average and standard deviation for the 42 unit cost estimates that could be interpreted and converted to 2001 US dollars by disease or syndrome and by type of output. The most notable characteristic is the extreme variability in the cost per unit of output across sites; variability that cannot be explained by variability in cost of the primary inputs (labor and drugs). These cost data suggest that very large gains in efficient use of resources stand to be made by more efficient production of services currently being delivered, something not contemplated in most discussions of efficiency in STI/HIV prevention which have typically focused on the relative cost-effectiveness of interventions and perhaps on heterogeneity of risk behavior and prevalence (exposure).

COST-EFFECTIVENESS

Data on cost-effectiveness are extremely limited and a function of the scarcity of both effectiveness and cost data. The best available data are for health facility-based interventions such as syndromic STI management, screening of blood for transfusion, and prevention of MTCT. The data on cost-effectiveness of behavioral, community, and structural interventions are far weaker.

Table 2-1. Average and Standard Deviation of Estimated Cost Per Unit Output, by Disease or Syndrome and by Type of Output

Disease or Syndrome	Treatment	Cure	Total
Syphilis	36.04	–	36.04
	(5.91)		(5.91)
Urethral discharge	14.29	89.07	29.25
	(20.68)	(0)	(37.94)
Genital ulcer	23.16	100.6	48.97
	(21.73)	(83.74)	(59.56)
Venereal disease	25.47	82.65	31.83
	(18.56)	(111.55)	(37.12)
Pelvic inflammatory disease	7.12	–	7.12
	(3.09)		(3.09)
Vaginal discharge	48.23	102.92	81.04
	(0)	(89.63)	(70.1)
Total	24.05	96.1	39.49
	(19.04)	(73.44)	(47.23)

The figures in parenthesis are standard deviations.

Cost-effectiveness of interventions for prevention and care of STI other than HIV

The current state of the art was recently reviewed by Aral and Over in their chapter in the Disease Control Priorities in Developing Countries.[1] Even more so than in the prior review 13 years earlier, the position taken in the current chapter is that estimates of the cost-effectiveness of STI interventions are highly variable, reflecting both the great heterogeneity in environments as well as the great heterogeneity in the efficiency of service delivery:

> The health benefit in terms of numbers of disability-adjusted, discounted, healthy life years saved by curing or preventing a case of syphilis varies from 3 years in a person who has ceased all sexual activity to as many as 161 years in a sex worker with two partners a day. The cost of treating that prostitute for syphilis varies from US$ 5 to US$ 100. Thus the cost per disability adjusted life year (DALY) of syphilis treatment can range from 100/3 or US$ 33 per DALY to 5/161 or less than a US$ 0.05 per DALY. As we learn more about the complexities of delivering STI treatment services and take into account the diversity of risk behavior, the ease with which STI interventions can be ascribed a simple cost-effectiveness ratio has declined. If no easy way to summarize the experience to date with a simple cost effectiveness ratio is available, how should we proceed to analyze economic investments in STI treatment? We believe that the way forward is a better understanding of why STI treatment and other health services vary so much in terms of their efficiency and effectiveness from one setting to another. By studying the determinants of this variation, we should gain an improved understanding of the full costs of high-quality STI service delivery and its place in the health sector investment picture.

Cost-effectiveness of interventions for prevention of HIV

Several authors have recently reviewed estimates of cost-effectiveness for HIV prevention interventions.[90–93] The paucity of studies (Table 2-2) of behavioral interventions is lamentable. The complete absence of studies of contextual and structural interventions or of interventions designed to reduce stigma and discrimination, despite 20 years of calls to action on all of these fronts, is worse than lamentable because it enables ineffectual action. However, the magnitude and growth path of the epidemic demand a massive response

Table 2-2. Cost-Effectiveness of HIV Prevention Interventions by Epidemic Profile

Intervention	Low-Level Epidemic	Concentrated Epidemic	Generalized Low-Level	Generalized High-Level
Blood safety	1 study found[94]	1 study found[94]	4 studies found[79,94–97]	2 studies found[94,96]
ART to reduce MTCT		2 studies found[98,99]	3 studies found[95,100]	3 studies found[101–103]
Sterile injection	1 study found[104]	2 studies found[104]	1 study found[104]	1 study found[104]
VCT		1 study found[99]	2 studies found[105,106]	
Peer–based programs		4 studies found[99,107,108]	4 studies found[95,109]	
STI treatment			3 studies found[95,110,111]	1 study found[112]
School–based education		1 study found[99]		
Harm reduction for IDU		2 studies found[113,114]		
ART for prevention and postexposure prophylaxis		1 study found[115]		
Condom promotion, distribution, and IEC				1 study found[116]
Condom social marketing			1 study found[95]	
Surveillance				
IEC				
Abstinence education				
MTCT, feeding substitution				
Drug substitution for IDU		No cost-effectiveness studies found		
Universal precautions				
Vaccines				
Behavior change for those HIV+

however imperfect the cost and effectiveness data. The suggestions that follow are an attempt to synthesize the available evidence and apply it in the context of the world's very heterogeneous mix of epidemics. It is a far cry from guidance on relative funding levels for different interventions, but it does suggest how the top priority interventions are likely to change across epidemic types.

Prevention studies and national experiences over the past 20 years strongly suggest that prevention strategies are likely to be most effective when they are carefully tailored to the nature and stage of the epidemic in a specific country or community.[24] UNAIDS has developed epidemiological categories for characterizing individual epidemics based on the prevalence of infection in particular subpopulations and in the general population.

As a complement to guidance provided by the epidemic profile, Grassly and colleagues recommend assessing the prevalence of other STI, estimating the extent of mixing between high- and low-risk groups, for example, men who have sex with men who have sexual contact with female partners, and estimating the prevalence of high-risk sexual behaviors in the population, such as lack of condom use with casual partners.[89] They also cite two other critical contextual factors: the capacity of the health service and the social, economic, and legislative context, including social norms and attitudes about sexual and drug use behaviors and the acceptance of breastfeeding. Contextual factors that may play a role in the success of interventions include the status of women, the stigmatization of key populations, and the presence of armed conflict and social upheaval. Together, the epidemic profile and the context in which the epidemic occurs suggest various prevention strategies.

Almost by definition, there is more to be gained by changing the behavior of people with high levels of risk behavior than by changing that of an equivalent number of people with lower levels of risk behavior. However, the difference in the effectiveness between the two falls as epidemics become more generalized, such that in heavily affected countries prevention interventions are likely to become extremely cost-effective even when targeted to individuals with relatively low levels of risk behavior. Consequently, countries with low-level and concentrated epidemics should emphasize interventions that are targeted to individuals at especially high risk of becoming infected or transmitting the virus, whereas countries with generalized epidemics should also invest heavily in interventions that target entire populations or population subgroups. Thus, any determination of the likely effectiveness and cost-effectiveness of specific interventions in particular circumstances requires an accurate understanding of the stage and nature of the national epidemic.

Low-level epidemic. Providing widespread voluntary counseling and testing (VCT), screening for STIs, universal precautions, and postexposure prophylaxis may not be cost-effective in this setting. In a low-level epidemic, as in the Middle East and North Africa, HIV/AIDS control strategies should emphasize

- surveillance and individual-level interventions that target key populations such as sex workers, men who have sex with men, injecting drug users, and people living with HIV/AIDS;
- information, education, and counseling (IEC), including limited education via the mass media and sex education in schools;
- comprehensive prevention programs for people living with HIV/AIDS and harm reduction programs for IDUs;
- VCT that is available to key populations with the highest levels of risk behavior and infection;
- MTCT prevention to mothers known to be infected with HIV;
- screening all blood for transfusions and providing sterile injections;
- addressing market inefficiencies in condom procurement and distribution, including strategies like bulk purchases and incentives;
- addressing community attitudes that impede education and discussion about sexual activity, as these may thwart STI/HIV education efforts.

Concentrated epidemic. In a concentrated epidemic, as in the countries in East Asia and the Pacific, Europe and Central Asia, Latin America and the Caribbean, and South Asia, prevention priorities, in addition to those above, should include

- strengthened surveillance among key populations such as sex workers, men who have sex with men, and injecting drug users;
- subsidized VCT and promotion thereof among key populations;
- HIV screening of pregnant women, guided by individuals' risk profiles;
- peer-based programs for key populations to educate individuals at risk, promote safer behaviors, and distribute condoms;
- harm reduction for IDUs, including needle exchange and drug substitution programs;
- STI screening and treatment for key populations;
- targeted distribution and promotion of condoms to key populations, and condom distribution linked to VCT and STI care.

In addition, contextual factors, such as government rejection of needle exchange programs, the incarceration of drug users, the harassment of sex workers, and illegality of sex among men can be major impediments in the scaling up of effective prevention efforts. As HIV/AIDS is typically concentrated in socially and/or economically marginalized populations in countries with concentrated epidemics, attention to

socioeconomic factors and the stigmatization of key populations will also be vital to an effective response.

Generalized low-level epidemic. In a generalized low-level epidemic, as in many countries in sub-Saharan Africa, the emphasis on targeted interventions must be maintained or even strengthened, but interventions for broader populations must also be aggressively implemented. These prevention priorities should include

- surveillance of STI, risk behaviors, and HIV infections in the entire population, with a particular focus on young people;
- extending mass media IEC beyond basic education;
- routine voluntary and confidential HIV testing and STI screening and treatment promoted beyond key populations;
- subsidized and social marketing of condoms and strengthened distribution to ensure universal access;
- offering HIV screening to all pregnant women;
- broadening peer approaches and targeted IEC to include all populations with higher rates of STI and risk behavior.

Contextual factors remain critical to the success of prevention efforts in generalized low-level epidemics, but population-level factors now have greater priority. The most important of these is likely to be the status of women, especially with regard to their ability to control their sexual interactions, to negotiate condom use and VCT with their partner(s), to be protected from abuse, and to have property rights following the death of a spouse.

Generalized high-level epidemic. In a generalized high-level epidemic, such as in some countries in southern and eastern sub-Saharan Africa, an attack on all fronts is required. Prevention efforts should focus on broadly based population-level interventions that can mobilize an entire society so as to address prevention and care at all levels. Prevention should include

- mapping and surveillance of risk behaviors, STI, and HIV infection;
- routine universal HIV testing and universal promotion of STI screening and treatment;
- condom promotion and free distribution in all possible venues;
- VCT for couples seeking to have children;
- scaling up individual-level approaches to innovative mass strategies with accompanying evaluations of effectiveness;
- utilizing the mass media as a tool for mobilizing society and changing social norms;
- employing other channels to reach large numbers of people efficiently for a range of interventions including workplaces, transit venues, political rallies, schools and universities, and military camps;
- official institutional efforts to alter social norms on infant feeding, and harm reduction for IDUs.

In a generalized high-level epidemic, contextual factors, such as poverty and the fragility of the health care infrastructure, will dramatically affect service provision at every level. The status of women, an important factor in all epidemics, becomes an overriding concern in this setting, requiring priority action to radically alter gender norms and reduce the economic, social, legal, and physical vulnerability of girls and women.

CONCLUSION

The scale of the STI epidemics, including HIV, in many developing countries requires that responses to them be multidisciplinary and economics is one discipline that has much to contribute to efforts to address the epidemics of STI/HIV in resource-poor settings.

We reviewed the contributions made by economists to the analysis of the determinants of STI/HIV infection as well as their contributions to analysis of the impacts of STI/HIV on individuals and their households. Those data that are available underscore the need for public intervention in the prevention and treatment of STI/HIV. The review also highlights the need for additional data that is population-based as well as econometric analysis of these data to better assess the economic impact of young adult deaths on households.

Economics also offers a set of tools that can assist in the evaluation and prioritization of STI/HIV interventions in contexts of limited resources. This review highlights that each country needs data about its risk behaviors, its STI epidemics, and its responses. It also highlights the dearth of information on the effectiveness of interventions in different contexts. Without such data for planning, managing, and evaluation, billions of dollars will continue to be spent and far fewer deaths will be prevented than could be.

3 The Transmission Dynamics of Sexually Transmitted Infections

Geoff P. Garnett

Epidemiology is the study of the patterns of disease and the risks leading to disease. For sexually transmitted disease (STD), in addition to identifying risk factors leading to the acquisition of infection and the development of disease, we can study the spread of infections through populations, i.e., the transmission dynamics of infection. Thus, in STD epidemiology we are concerned with patterns of risk at both the individual and the population level. The change in patterns of infection over time within the population can be described in mathematical models, which provide a framework for the analysis of data, generating testable predictions, and exploring the potential impact of interventions.[1] In this chapter, the key variables contributing to the spread of sexually transmitted infections (STIs) are reviewed within the theoretical framework provided by developing and analyzing mathematical models.

The spread of STIs is directly influenced by a limited number of biological and behavioral variables that could be called "proximate determinants."[2] These in turn are influenced by a range of social, economic, demographic, and cultural factors of the individual and the population, which have to alter the proximate determinants to influence the spread of infection. The pattern of sexual contacts within the population is the same for each STI, but the ability of the infection to exploit these contacts will determine its distribution and depends upon its own biology. That biology is summarized in a description of our assumptions about the natural history of major STIs and the risks of transmission within sexual partnerships.

THE NATURAL HISTORY OF SEXUALLY TRANSMITTED INFECTIONS

The natural history of an infection is the relationship between that infection and disease and associated patterns of infectiousness. In understanding this natural history, individuals can be divided between mutually exclusive categories and the flows between them illustrated schematically in flow diagrams. Figure 3-1 shows the assumptions frequently made about a range of the key STIs in such flow diagrams.

Chlamydia, gonorrhea, syphilis, chancroid, and trichomonas can be thought of as curable STDs, which as a group appear to be short-lived with a high transmission probability. On recovery from infection, either through an acute immune response, mechanical clearance, or treatment, the individual becomes susceptible to reinfection. This lack of acquired immunity maintains the pool of susceptibles facilitating the persistence of infection. Our ability to treat and cure the bacterial STDs and trichomonas provides a means of reducing the duration of infectiousness and controlling the spread of infections.[3–6] Unfortunately, many infections remain asymptomatic, maintaining a reservoir of untreated infection within communities. This is particularly true of chlamydia and trichomonas infections where the majority often remain asymptomatic in women.[5,6] Gonorrhea is also more likely asymptomatic in women than in men with only 5% of infection remaining asymptomatic in men.[4,7] However, in population surveys a greater proportion of prevalent infections in men will be asymptomatic because of the long duration of asymptomatic compared with the more likely treated symptomatic infections.

The duration of infection, and infectiousness, in the absence of treatment determines the epidemiological success of STDs, but it cannot be measured because infections cannot ethically be allowed to continue untreated. Hence, we can only rely on historical records, with attendant problems of unreliable diagnosis and insensitivity to any evolution of the organisms, or on indirect estimates based on the prevalence of the infections and estimates of other parameters. Perhaps the best records are available for syphilis which is caused by slowly replicating spirochete *Treponema pallidum*. The natural history of this infection, which progresses through stages, can be pieced together from historical records of experimental inoculations, the observations of early venereologists, and a prospective observational cohort study in Oslo from the early twentieth century.[8] The primary disease, a chancre at the site of infection emerges after about a month, resolves after around 2 weeks, but is followed about a month later by secondary disease that lasts on average for just under 4 months before resolving, with recurrences in 25% of cases. In

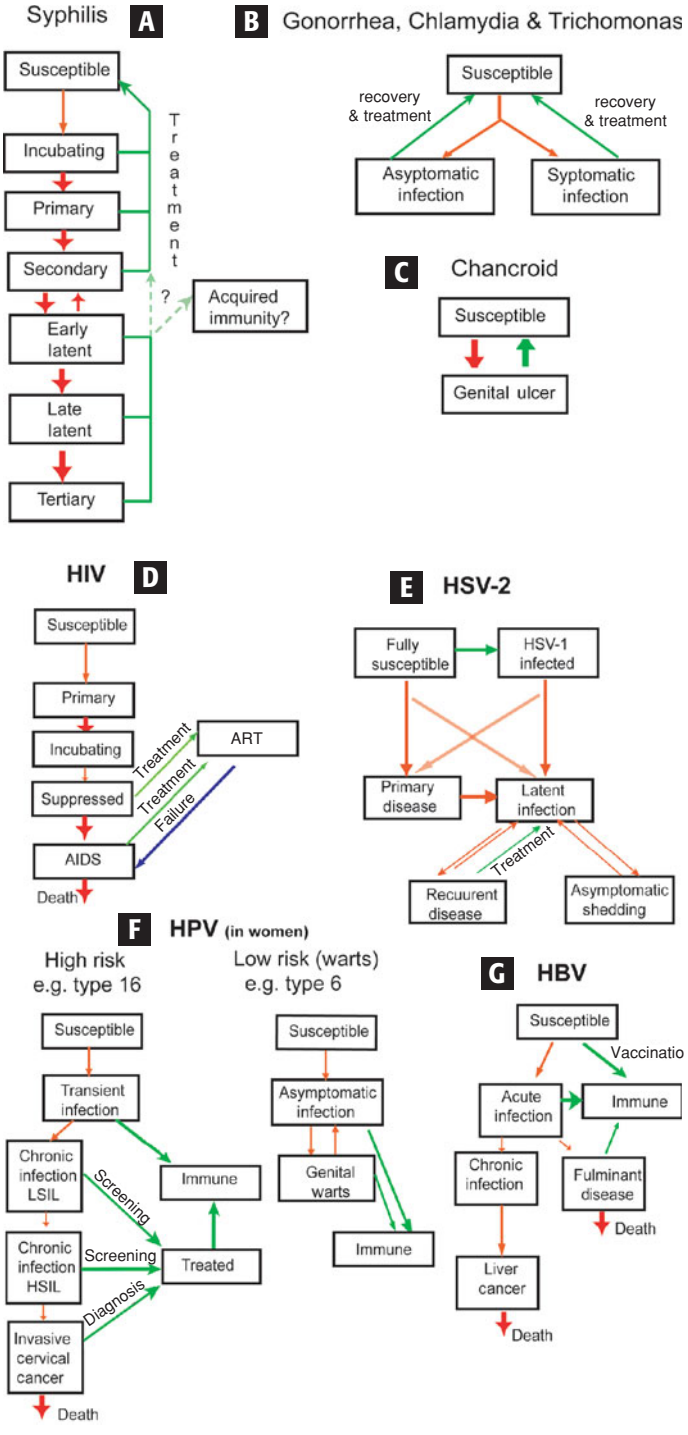

FIGURE 3-1. Flow diagrams illustrating the natural history of the major sexually transmitted infections. **A.** Syphilis; **B.** curable inflammatory STIs including gonorrhea, chlamydia, and trichomonas; **C.** chancroid; **D.** HIV; **E.** herpes simplex virus type 2; **F.** human papilloma virus; **G.** hepatitis B virus.

a follow up of 1940 patients infected between 1890 and 1910, 11% of 694 known deaths were attributable to syphilis, with 9% of men and 5% of women suffering neurosyphilis, 14% of men and 8% of women suffering cardiovascular syphilis, and 16% of men and 20% of women suffering benign late syphilis. Tertiary disease has since been almost eliminated due to the widespread use of antibiotics, but congenital syphilis continues as a severe condition associated with syphilis epidemics.[9] From records it is unclear when exactly syphilis is infectious, although transmission appears to be most closely associated with the early stages. Reinfection following treatment is possible, but there is evidence that long exposure to the bacteria can lead to acquired immunity. Such immunity, either acquired or concomitant in untreated cases provides a simple explanation for the regular cycles of approximately 10 years duration observed in syphilis case reports in the United States[10] and has been invoked to explain increases in incidence following mass syphilis treatment.[11]

The viral STDs appear to be much long-lasting with low transmission probabilities. Infection with genital herpes simplex virus type 2 (HSV-2) infection is more likely to lead to symptoms on infection in someone who has not previously been infected with the related HSV-1.[12] Disease cases take an average of 3 weeks to resolve and then, like initial asymptomatic infections, they enter a latent state from which recurrences of symptomatic lesions and episodes asymptomatic shedding occur with decreasing frequency over time.[13,14] These recurrences create a long infectious period that can expose subsequent sexual partners to infection. A similar long asymptomatic infectious period is associated with HIV infection. Initially there can be symptoms associated with seroconversion, which are generally mild and resolve, then there is a period of on average a decade, before levels of CD4 positive T-helper cells fall to a level where the immune system fails.[15] Treatment prevents viral replication and allows the immune system to recover, but it is not a cure and treatment failure is common.[16] In contrast, human papilloma virus infections and hepatitis B virus infections are normally transient, but for each a fraction of cases become chronic and can progress to cause cancer.[17,18] Human papilloma virus types are separated by a genetic difference of 10% or more and can be categorized as high risk, if they have oncogenic potential, or low risk.[19] Some of the low-risk types, because of their cellular tropisms, are associated with genital warts, with infections sometimes moving repeated from asymptomatic infections to symptomatic lesions and back. HPV infection is a necessary but not sufficient cause of cervical cancer with HPV-16 associated with over 60% of cervical cancer cases.[19] Transient infections become chronic with infections progressing either slowly or rapidly through stages of cytological abnormalities before becoming invasive cancer. It is these precancerous lesions that are detected in cervical cancer screening programs.[20] The illustrated categories of low-grade and high-grade squamous intracellular lesions are those used in the Bethesda System adopted in the United States. Elsewhere, cytological classifications of cervical intraepithelial neoplasias are classified as types 1, 2, and 3. It is questionable whether natural type restricted acquired immunity exists against HPV infections.[21] The likelihood of hepatitis B becoming chronic

depends upon the age of infection, with chronic infection likely at the young ages of infection found when forces of infection are high.[22] This creates a vicious cycle where a high prevalence of chronic and acute infection generates a high force of infection and more chronic cases. Once the force of infection can be lowered slightly increasing the age of infection, chronic infections become rare and the prevalence of hepatitis B should fall dramatically.[23]

The natural history of the STDs determines patterns of disease associated with infection and the duration of infection, it also determines when infected individuals are infectious. Whether this infectiousness is translated into new cases of infection depends upon patterns of sexual contact and the risks of transmission to the contact.

TRANSMISSION OF INFECTION WITHIN SEXUAL PARTNERSHIPS

The relevant contact for the spread of STIs is sexual intercourse. If people distributed their sexual acts randomly through the population then the spread of STIs would likely be great. However, sex generally takes place within the context of sexual partnerships, limiting contacts to particular individuals. Each act of sexual intercourse between someone with an STI and someone susceptible exposes the susceptible to a risk of acquiring infection. Logically, the more sex acts there are, the greater the risk of transmission within the partnership; a relationship which can be described by a binomial model,[24] where the transmission probability per sex partnership (β_p) is a function of the probability per sex act (β_a) and the number of sex acts (n): $\beta_p = 1 - (1-\beta_a)^n$. The explanation of this relationship is illustrated in Fig. 3-2A. Each act between the infectious and susceptible partner carries the risk (β_a) of infection being acquired and ($1-\beta_a$) of it not. At the next sex act only those remaining susceptible can still acquire the infection, so a fraction ($1-\beta_a$). β_a will acquire infection on this second act and ($1-\beta_a$). ($1-\beta_a$) will stay susceptible. This then leaves the cumulative fraction infected equal to one minus the fraction left susceptible.

The relationship saturates to one as the number of sex acts within the partnership increases and is illustrated for a wide range of transmission probabilities per act in Fig. 3-2B. For a high transmission probability per act, the risk of acquiring infection within the partnership soon becomes very high, whereas risk slowly accumulates with a low transmission probability per act. This very simple model relationship has been widely used in illustrating the potential impact of condoms within sexual partnerships[25,26] with modifications to separate out acts with different transmission probabilities where, for example, a fraction f acts are protected by condoms with an efficacy e:

$$\beta_p = 1 - (1 - \beta_a)^{(1-f)n}(1 - (1 - e)\beta_a)^{fn}$$

Graph Figs. 3-2C and 3-2D illustrate for different underlying transmission probabilities the impact of condom use within a partnership where both the consistency and efficacy of condoms are varied. It can be seen that for a high number of acts and a high transmission probability, infrequent or inefficacious condom use has little or no effect. Only when condom use is consistent and efficacious does it reduce the transmission probability within the partnership. In a low transmission probability infection such as HSV-2, condoms can have a marked impact even if they are not consistently used or highly efficacious. The efficacy of condoms against both the bacterial and viral STIs has been demonstrated empirically.[27] Even for human papilloma virus, which can be transmitted without exposure of mucosal surfaces, condoms have been found to reduce the risk of acquisition by 70%.[28]

The above arguments assume that the logically appropriate binomial model for transmission is valid. In the case of gonorrhea transmission from women to men, the model was confirmed in a study in which aircraft carrier personnel were screened for gonorrhea infection before and after shore leave, along with behavioral surveys and prevalence studies amongst women in bars on shore.[29] In contrast, studies of HIV transmission found little impact of number of sex acts on transmission except when small numbers of sex acts are involved.[30] A number of hypotheses are possible to explain this observation, including a large fraction of insusceptible people, a declining risk following initial exposure, possibly due to immunity acquired through exposure, or an extreme heterogeneity in transmission probability between partnerships.[31] The latter (illustrated in Fig. 3-2E) is increasingly supported by data on the relationship between HIV viral load and transmission, which also reflects the course of HIV infection within the infected partner.[32] This should have profound implications for HIV educational messages. The relevant risk of acquiring HIV in a sexual contact with an infectious individual is not the average risk of contact per act (estimated at 1 in a thousand), but more the risk per partnership since the chances of getting infected depend upon the partner's viral load more than the number of sex acts within the partnership. Additionally, condom use needs to be consistent within those partnerships with a high risk of transmission to substantially reduce the transmission probability per partnership.[33]

Data for gonorrhea suggests that the transmission probability of STIs is greater from men to women than from women to men, which is readily explained anatomically.[4] It also appears that the sex difference in prevalence of HSV-2 is a function of an asymmetric transmission probability with women at more risk from an infectious sex partner.[34] Estimates of heterosexual HIV transmission probabilities vary greatly between studies as the likelihood of transmission depends upon the presence of other STIs, the circumcision status of the man, and the stage of HIV infection in the infectious

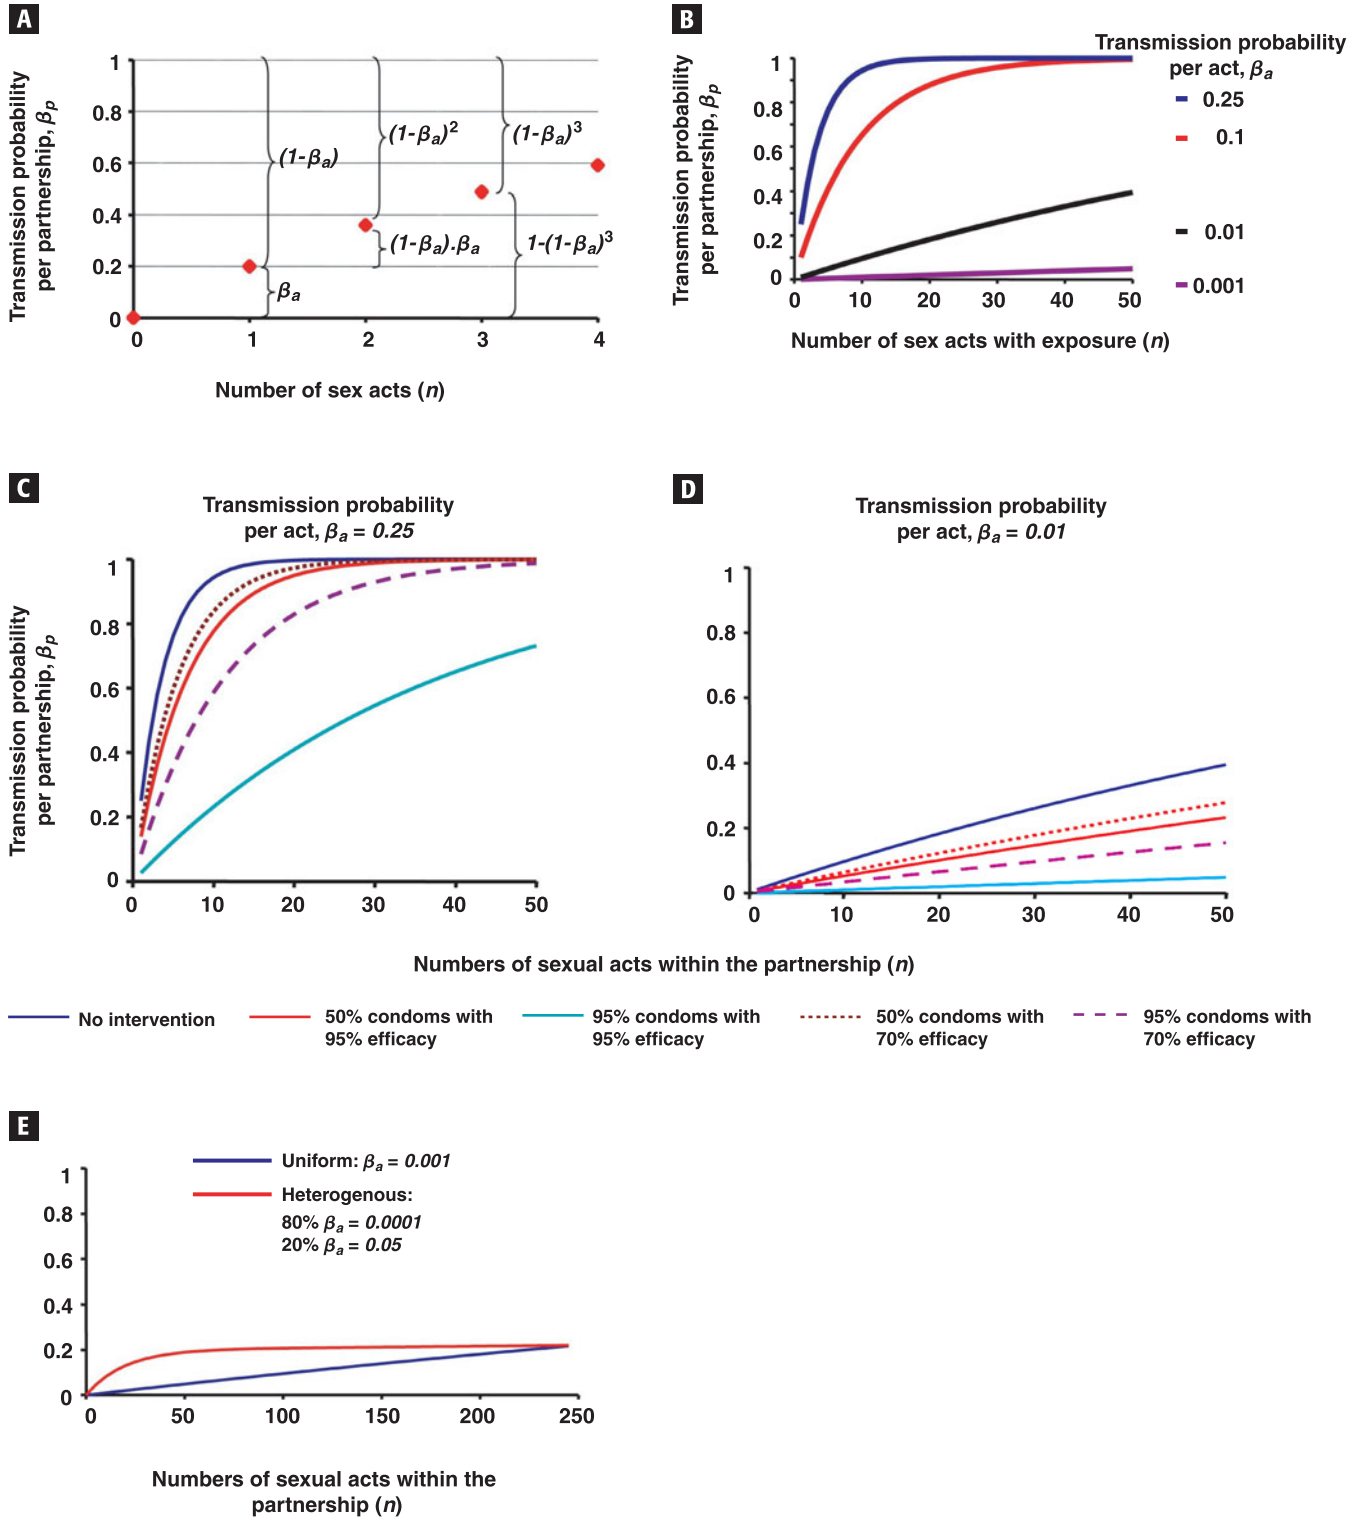

FIGURE 3-2. The transmission probability per sex partnership as a function of the number of sex acts. **A.** For a transmission probability per act (β_a) of 0.2 the probability of staying susceptible after 1 act is 0.8 ($1-\beta_a$); after 2 acts it is 0.64 $(1-\beta_a)^2$; and after 3 acts it is 0.512 $(1-\beta_a)^3$. **B.** The transmission probability per partnership as a function of the number of unprotected sexual acts for a range of transmission probabilities per act. **C.** The influence of condoms on the transmission probability per partnership as a function of the number of sex acts within the partnership with condoms used in 50% or 95% of sex acts with an efficacy of 95% or 70% when the transmission probability per unprotected sex act is 0.25. **D.** When the transmission probability per unprotected sex act is 0.01. **E.** The transmission probability per partnership as a function of number of unprotected sex acts comparing a homogeneous risk of 0.001 with a risk of 0.05 per act in 20% of partnerships and 0.0001 in the remaining 80% of partnerships.

partner. In more detailed studies in the United States and Western Europe, the transmission probability per partnership is around twofold greater from men to women than from women to men.[30,35–37] This difference has not been observed in developing countries.[38–40] The risk of transmission also appears greater amongst men who have sex with men (MSM) than heterosexuals.[41]

ESTIMATING TRANSMISSION PROBABILITIES

The risk of transmission of an STI cannot be estimated by simply determining the proportion of contacts of cases that are infected, as has sometimes been assumed.[42] If we include contacts that were the original source of infection, this will lead to overestimation of the transmission probability. There are a number of ways around this problem. First, if it can be ascertained that the contacts had no other possible source of infection, we can assume that they could only be infected from the case and use the fraction infected as an estimate of the transmission probability.[43] A second method would be to sample all partnerships and determine the fraction where both are infected and where only one partner is infected. This requires a high prevalence, as partnerships have to be sampled randomly, irrespective of whether there is infection within the partnership. If partnerships are chosen on the basis of infection being present, partnerships where both are infected will more likely be sampled leading again to an overestimated transmission probability. In such studies of HIV transmission in sub-Saharan Africa, retrospective analyses have found higher transmission probabilities than observed when discordant couples are followed prospectively.[32] This would be a product of a high early transmission probability associated with a high initial viral load leading to transmission in partnerships before they can be recruited into the study.

The biological characteristics of the STIs determine the relative influence of different sexual behaviors within populations. These behaviors have been explored in studies of those infected and in representative samples of the population as a whole.

RISK BEHAVIORS AND THE ACQUISITION OF STIs

In epidemiology, the normal method for identifying the role of risk behaviors is through comparisons between those with and without infection. However, the risks associated with a particular pattern of behavior depend upon the prevalence of infection within contacts, which in turn depends upon behaviors throughout the population. Thus, while the behaviors of infected individuals provide some indication of their role, we must also develop a theoretical as well as empirical understanding of the contact patterns.

In case control studies, subjects infected with STIs on average report more sexual contacts, but many of those infected can have low-risk behaviors[44,45] (Fig. 3-3). Comparing populations, we might expect those with a higher incidence of STIs to have populations with higher aggregate numbers of sexual contacts. However, such a relationship can easily be confounded, for example, if there are different patterns of

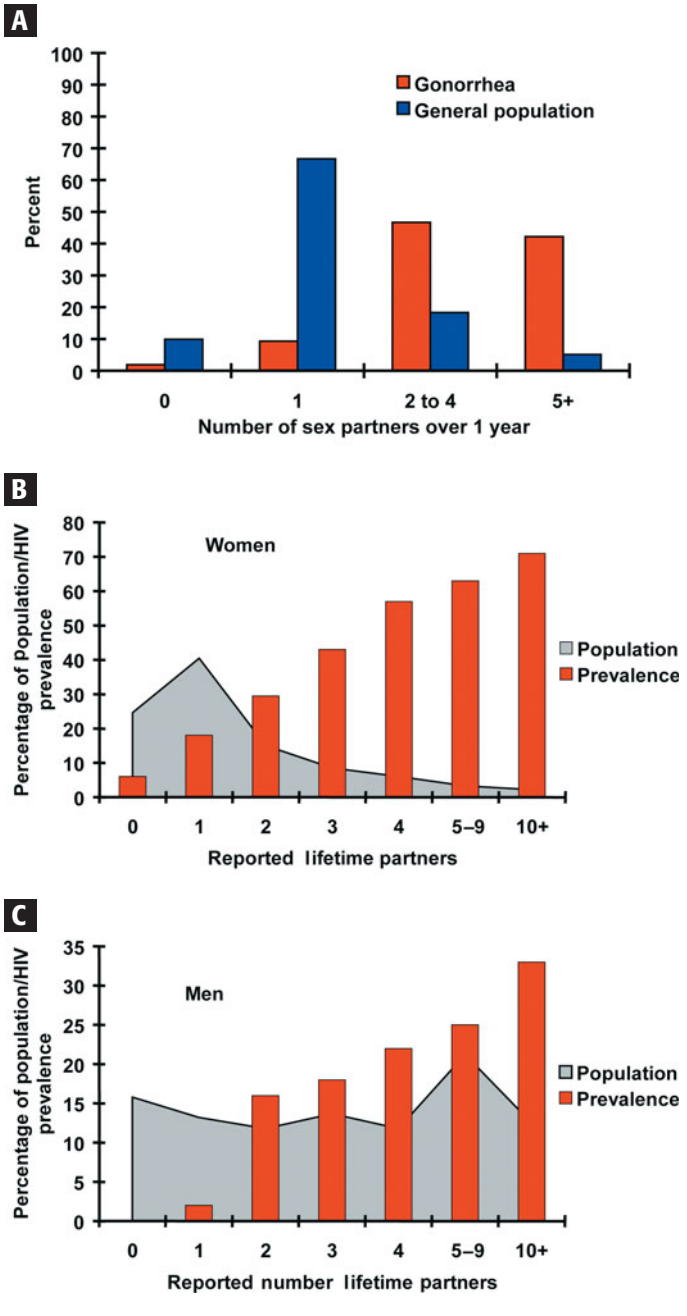

FIGURE 3-3. Reported numbers of sexual partnerships and the distribution of sexually transmitted infections: **A.** The distribution of men reporting a given number of sexual partners over a 1 year period from a household based representative sample in the United States and a sample of men with gonorrhea in Newark, New Jersey, USA.[38] The distribution of men, **B.**, and women, **C.**, reporting a given number of lifetime sex partners in a household based survey in rural Zimbabwe and the prevalence of HIV infection amongst them.[39]

treatment seeking behavior or access to effective treatment, by the timing of an infection being introduced or by errors in reports of risk behavior. Additionally, the distribution of contacts can be as, or more, important than the average behavior. Studies of sexual behavior in representative samples of the population show that the reported number of sexual partners is extremely heterogeneous with some reporting many sexual partners and a minority very many sexual partners[44–47] (Fig. 3-3).

Those with many sexual partners can drive the incidence of an STI in the population and have been described as a "core group".[48] Axiomatically, for a sexually transmitted disease (STD) to exist there must be individuals with sufficient sexual partners to transmit infection to more than one other person.[49] If interventions could reliably prevent infection in these individuals, the STI could be eliminated. Studies of risk behaviors and the distribution of STIs have attempted to identify the characteristics of those within the core group as a target for interventions. This has led to the characterization of neighborhoods, or demographically defined groups, based on the prevalence of infection and those with repeated STIs as a core group.[50] Unfortunately, such grouping will inevitably miss some of those with a high risk, include many who are not at risk and can also lead to stigmatization.[50] Further definitions of the term "core group" have been broader, encompassing those with the social and cultural variables associated with high-risk behavior. This multiplicity of uses has led to confused debate about the role of core groups in the epidemiology of the infections.[51]

The lower the incidence of an STI in a population, the more it will be concentrated in those with higher risk behaviors. If the behaviors placing individuals at risk are similar then those most at risk of one STI would be the same as those most at risk of another infection. We would expect infections with a higher combined transmission probability and duration to not only be more widespread, but to also be found in those with STIs with a lower combined reproductive potential.[52] If this is not the case as has been suggested in some observations,[53] potential explanations include the acquisition of immunity against one infection, different likelihoods of receiving treatment, and different risk behaviors placing individuals at risk. For example, we expect partner numbers over recent time to be more influential in the risk of having a short-lived STI like gonorrhea, and the lifetime number of sex partners to be more influential in the risk of having been infected with HIV.

MIXING PATTERNS

The choice of sexual partners of an individual will have a large influence on whether or not they are exposed to someone infected. The choice of sexual partners will depend upon the contexts in which potential couples meet, for instance, schools, church groups, beer halls, and family gatherings and how they relate. Studies show that individuals tend to choose sexual partners, particularly spouses, who are similar with respect to social and demographic variables such as age, education and income.[47,49] Such a choice will lead to assortative (like-with-like) sexual mixing within the population with respect to the specific variables. If no discrimination is made, mixing will be random, and if partners are chosen to be dissimilar then mixing will be disassortative (like-with-unlike). If individuals are grouped into categories, then a mixing matrix can describe the probabilities that when an individual from one group forms a sexual partnership, it will be with an individual from another group. These mixing matrices can be categorized on the basis of how assortative the mixing is[54–56] (Fig. 3-4A). However, sexual behavior variables determine how likely an individual is to be infected with an STD and mixing according to risk behaviors determines how likely an STI is to spread. Theoretically, we can explore the influence of different patterns of mixing (Fig. 3-4B). Assortative mixing restricts the spread of STIs but helps maintain chains of infection within high-risk groups. Thus if mixing were assortative, an STI would be more likely to invade rapidly and persist within a population but would also be less likely to spread widely. In contrast, random mixing would spread infection from high- to low-risk individuals who are dead ends for the infection. Infection is less likely or slower to invade and persist, but if it did succeed, it would become more widespread.[57] Measuring the pattern of sexual partner formation according to sexual behavior variables is difficult and likely to be biased. If sexual behavior is strongly correlated with social and demographic variables then we would expect mixing to be assortative as similar partners to the individual are chosen on the basis of such variables. The choice of partners of those with high numbers of partners is most influential as it determines how widely an STI will spread through the population. Direct measures of mixing from egocentric data suggest that mixing is near random according to numbers of sexual partners over a short period, but with a few high-risk individuals who tend to have high-risk partners (Fig. 3-4C).[58] This is in agreement with the distribution of reported numbers of sexual partners in those with gonorrhea in the United States where the high proportion with low levels of risk would only be possible if mixing was toward the random end of the spectrum.[44]

Sexual partner network structure: Small worlds, concurrency, and scale-free patterns of contact

The network of sexual contacts through which STIs spread is an example of a social network.[59] Sexual relationships provide the steps in paths linking individuals, with "components" made up of individuals connected through these paths. Recent advances in recording and analyzing social network structure have improved our general understanding of such

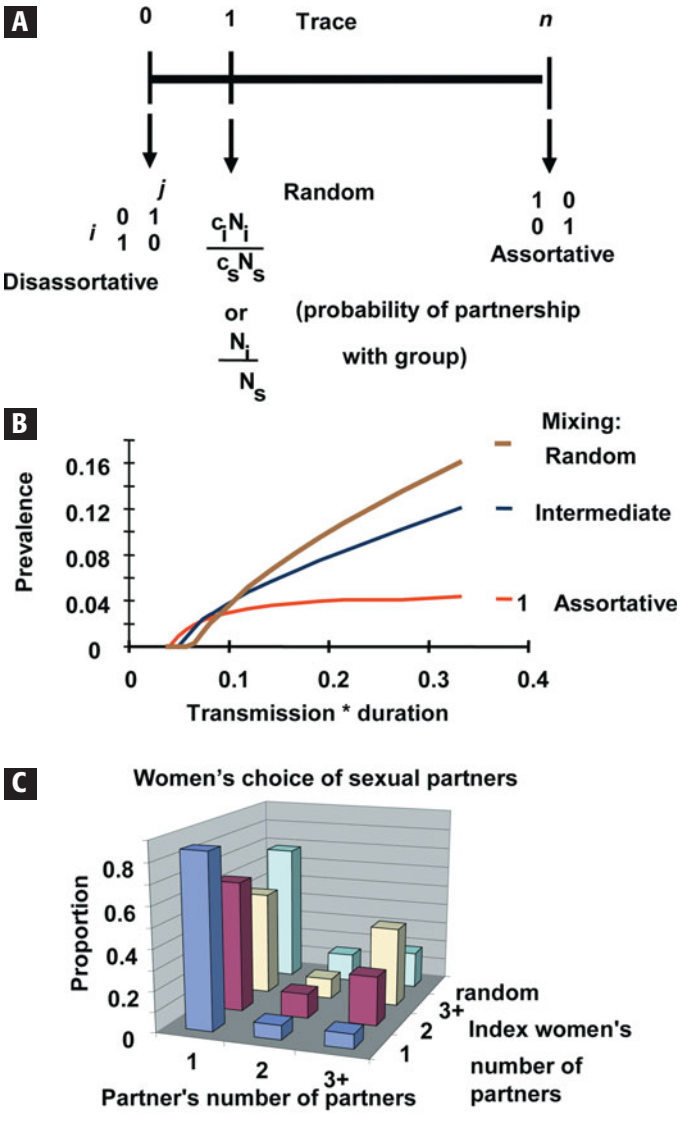

FIGURE 3-4. The influence of patterns of mixing according to sexual activity: **A.** The scale of mixing from fully disassortative through random to fully assortative with associated mixing matrices for two sexual activity groups. The trace is the sum of the values on the diagonal of the matrix which determine like-with-like mixing. Fully disassortative has no like-with-like partnerships, so the diagonal elements of the mixing matrix are zero. For random mixing, each element equals either the number of partnerships supplied by a group as a fraction of all partnerships supplied (where c_j is the rate of sexual partner change of the group j and N_j is the number in that group) or the number of people in the group as a fraction of the population of all potential partners. In both cases, the sum of the values on the diagonal equals 1. In fully assortative mixing, the values on the diagonal are all equal to the number of groups. **B.** The steady state prevalence of a bacterial STI which does not generate immunity in a two activity class model with a mean rate of sex partner change of 2 new partners per year. The prevalence as a function of the combined transmission probability per partnership and the mean duration of infectiousness per partnership is illustrated. Mixing is determined by a single parameter, with results shown for fully assortative, random, and half way between the two. **C.** The reported numbers of partner's partners over 3 months of index women with a bacterial STI as a function of the index women's number of partners from the Harborview STD clinic in Seattle compared with the distribution expected if mixing were random according to the number of partners reportedly "supplied" in household based survey across the United States.[47] Mixing is near random except for a high number of women with 3 or more partners whose partner also had 3 or more partners.

networks with insights often applied by analogy to sexual networks.[60] However, sexual relationships are likely less frequent than many other social contacts and will consequently generate sparser networks. An example is provided by the "small world" phenomena.[61] Here geometric increases in the number of contacts connected through a given number of steps mean that very many people can be connected through a small number of steps. For example, if every new contact had on average 43 other novel contacts then over 6 billion people could be connected in only 6 steps. This assumes that each contact is novel and not already included in the component, which is unrealistic, as contacts are likely to be correlated,i.e., the acquaintances of one individual are also likely acquainted.[61] Such correlations could prevent paths reaching across social and geographic space, except that a few longdistance contacts dramatically reduce path lengths creating a small world, where stepping through the network everyone is closely connected.[61] This has been illustrated through the "6 degrees of separation" example, which has been shown to hold for many social networks, with a few people excluded.[61] Such an extremely small world is unlikely to exist for sexual contacts, since if everyone has on average two partners then only 11 people would be connected to someone over six steps. Even if the average number of partners were increased to 10, this would only increase the maximum number of contacts to 664,299. There is the potential for the cumulative sexual network to be a small world, albeit with more than steps to connect individuals, but this needs to be empirically validated. Nonetheless, the concept of a few sexual partnerships linking sexual networks across social and geographic space is important.

Analysis of social networks tends to assume that networks are static with the network accumulated over time. Over time, sexual relationships form and dissolve creating a cumulative network which could be analyzed. However, the history of a relationship is obviously inadequate for the transmission of an STI where the sexual relationship has to be extant. The most relevant sexual network would be the one accumulated by individuals over the period they are infectious.[62] For a long-lasting infection like HSV-2 (and potentially HIV and HPV), numbers of partners can accumulate over an extended period bringing many people into the network. With a short duration infection such as gonorrhea, the network has little time to build up and concurrent partnerships become important. Concurrent sexual partnerships create network components at one instant in time allowing the rapid spread of infection, both reducing the time before individuals become exposed to infection and negating any requirement for a correct sequence of sexual partnerships moving infection sequentially from infected to susceptible individuals.[63] As the average number of concurrent partnerships across a population increases it can pass a threshold where a giant component of connected individuals is formed, which would

allow the explosive spread of a highly transmissible STI.[64] Populations where this threshold has been passed are extremely vulnerable to STIs and such networks could have played a role in the rapid spread of HIV in sub-Saharan Africa. One study of four populations with different HIV epidemics did not find differences in patterns of concurrency.[65] However, retrospectively identifying the behaviors responsible for the spread of HIV is difficult, with a combination of factors increasing transmission probabilities and the density of contacts likely to matter.

The heterogeneity in the number of sex partners reported by individuals has also created interest amongst network analysts, because it provides an example of a scale-free distribution.[66] The distribution of individuals with respect to reported number of sexual partners does not reach a point with high numbers of partners where it rapidly falls away. This is illustrated for data from the UK in Fig. 3-5 in a log–log plot of the proportion of the population with a higher number of partners than indicated on the x-axis.[67] This illustrates the existence of some individuals reporting very many sex partners, but given the small numbers at the tail of the distribution there is debate over the statistical validity of rejecting non-scale-free distributions.[68] This is called scale free because as we move along the axis for number of partners, the pattern of decline in the fraction reporting a given number does not change. A mechanism called preferential attachment can generate such distributions, where those who already have more sex partners are also more likely to gain additional partners. With such distributions, as population sizes increase, there will always be a small number of people with very high numbers of sex partners and if the falloff in their numbers is slow then there will be no threshold transmission probability below which an STI cannot spread. While this might be theoretically interesting, it is important to note that this scale-free behavior has only been observed over a few orders of magnitude, even when reports are for lifetime numbers of partners.[67] It is likely that if sample sizes increased in studies of sexual behavior, then we would quickly find a limit to the number of sexual partners an individual has.

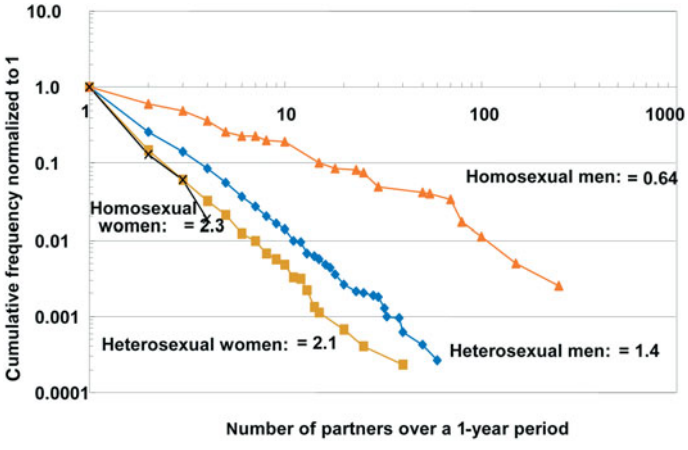

FIGURE 3-5. The distribution of individuals for the British Survey of Sexual Attitudes and Lifestyles from 2000 reporting more than a given number of sexual partners over 1 year logarithmic scales. The exponents show the rate of falloff in numbers which is slower for men, particularly men who have sex with men.

INCIDENCE, PREVALENCE, AND THE COURSE OF AN EPIDEMIC

The basic reproductive number (R_0) is a measure of the potential for the spread of an infection and can be defined for STIs as the average number of infections caused by one infectious individual entering an entirely susceptible population.[69] The key components determining the value of the basic reproductive number are those discussed above: the transmission likelihood (β), the contact rate (c) and the duration of infectiousness (D), with, in a simple, illustrative model, the product of these three being the basic reproductive number: $R_0 = \beta cD$.[69] The value of R_0 determines: the chances of an epidemic when an infection enters a population; the rate of spread of the epidemic; the endemic level of infection, and the effort required to bring the infection under control. An important distinction has to be drawn between the *basic* reproductive number, R_0, which measures the potential for spread in a naive population, and the *effective* reproductive number, R_t, which changes depending on the experience of infection in the population.[70] This effective reproductive number is the number of new infections caused by an average infection at a given time, t, which at time zero equals the basic reproductive number. Once some contacts are already infected or immune, the effective reproductive number is reduced and is the product of the basic reproductive number and the fraction of contacts remaining susceptible. When an infection successfully invades a population its prevalence will initially grow exponentially, until it saturates and the effective reproductive number falls. This is illustrated in Fig. 3-6. In Fig. 3-6A an infection with a long duration is represented, where prevalence will climb even once incidence has fallen, as infections accumulate. However, as infection is lost through death or recovery, prevalence could well fall. Where the prevalence saturates is a function of both the basic reproductive number and the distribution of risks within the population. When risks are evenly spread throughout the population the effective reproductive number is simply the basic reproductive number times the proportion of the population susceptible. At the endemic steady state each new infection on average causes one more infection ($R_t = 1$) and the proportion of the population susceptible is the inverse of the basic reproductive number. Consequently, the greater the value of R_0, the higher predicted prevalence of infection and immunity. In the case of STIs, where there is heterogeneity of risk, contacts are concentrated in a small fraction of the population and infection saturates long before it would in a homogenous population.

In a randomly mixing population with heterogeneous behaviors, a good approximation for the basic reproductive number is the mean plus the variance to mean ratio of rate of sexual partner change.[69] More explicitly, the basic reproductive number for heterogeneous interacting groups can be calculated from a next generation matrix describing the number of new infection caused by the typical infection across the group.[71] There will always be some imprecision in these calculations if individuals with different risk behaviors are included in the same group. More important though is to recognize that the value determines the rate of invasion and does not determine where the infection will saturate. When the value is large an epidemic is likely, as it falls close to one then chance events can prevent epidemics, and when the value is less than one a sustained epidemic is not possible. However, close to the value one moderately large outbreaks can occur infrequently as chains of infection grow by chance before fading away.[72]

The pattern of spread of the epidemic and its subsequent progress to an endemic level depends upon the duration of infection and the role of acquired immunity as illustrated in Fig. 3-6 B. For a short-lived infection with no acquired immunity, such as gonorrhea, we can expect a steady state to be reached quickly. If death or acquired immunity reduces the susceptible pool, the prevalence of infection can fall until the resupply of susceptibles through newly susceptible individuals entering the population either balances the losses or builds up over time to cause new epidemics. The associated declines in prevalence could be confused for the impact of interventions but are the natural course of the epidemic. In the case of syphilis, acquired or concomitant immunity can explain the long-term cycles in incidence observed in US case reports.[10] In the case of HIV, declines in prevalence can reflect earlier declines in incidence caused by saturation.[73]

That a decline in prevalence is expected is not to say that declines in risk behavior do not occur, but that distinguishing between such prevention successes and the natural dynamics of infections requires careful analysis. It is possible to create null models that maximize the natural declines in prevalence expected following a peak in prevalence.[74] For HIV epidemics, the more concentrated the initial high incidence is before saturation, the shorter the period from infection to death, the shorter the average period of high-risk behavior in the life history of individuals and the less recruitment of high-risk individuals compensates for the removal of high-risk individuals through differential mortality, then the greater the postpeak decline in prevalence. Comparing such a null model with observed trends in HIV prevalence from consistently sampled sentinel antenatal clinic sites shows that HIV incidence has declined through changes in risk behavior in Uganda, Thailand, Zimbabwe, and urban Kenya and Haiti.[74]

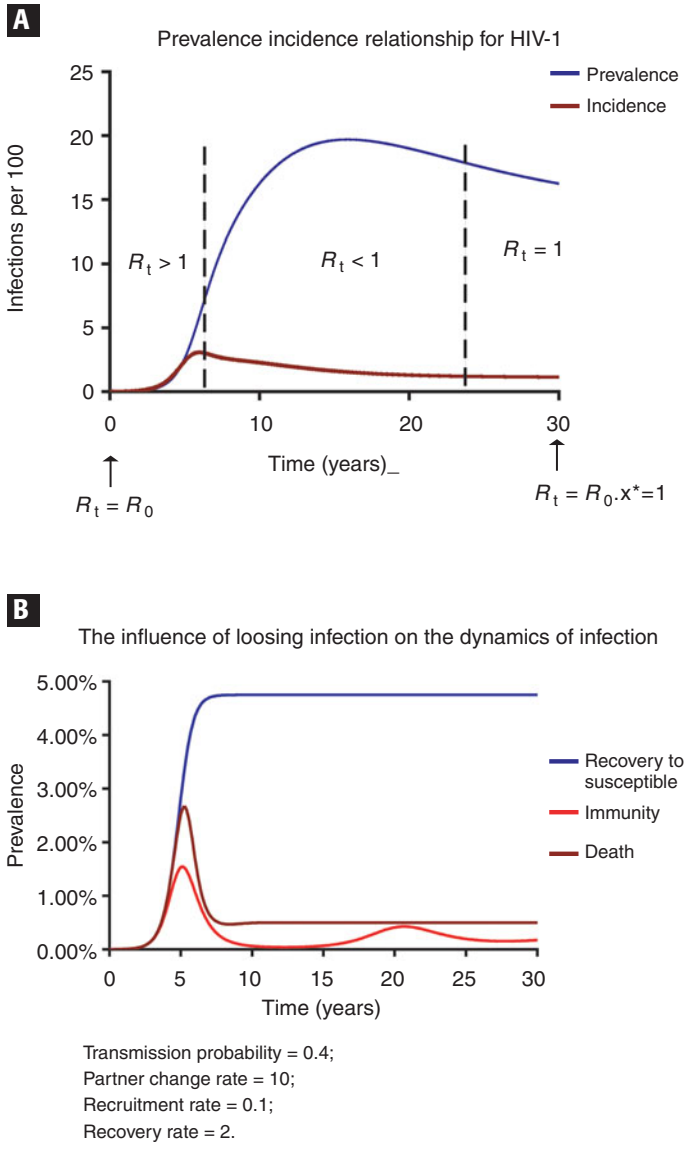

FIGURE 3-6. The predicted pattern of STD epidemics. **A.** The relationship between incidence and prevalence for HIV in a model of the spread of the virus. **B.** The predicted prevalence of an STD over time in a fraction of the population with a high risk of infection. The pattern when recovery is to the susceptible state is compared with recovery to an immune state and with loss of infection through death.

THE IMPACT OF INTERVENTIONS

To reduce the incidence of STI infection interventions must alter the reproductive potential of the infection. Shortening the infectious period, reducing the contact rate, or reducing the transmission probability, all reduce the basic reproductive number of infection, while introducing artificial immunity through vaccination would reduce the proportion of the population susceptible and thereby reduce the effective reproductive number. Reducing the basic reproductive number has a nonlinear impact on the endemic prevalence of infection, with reductions increasing as the threshold value of one is approached.[69] Thus, a small change in risk can have a dramatic

impact near the threshold, while it has very little impact at a high basic reproductive number (Fig. 3-7A). Vaccines on the other hand, if they offer complete protection, which is sometimes called "take" type protection, remove individuals from any risk of infection and linearly decrease prevalence (Fig. 3-7B).[75] If they offer partial protection reducing the risk per contact, termed "degree" type protection, then there is a return to a nonlinear decrease with reductions in exposure needed to reduce infection (Fig. 3-7B). These relationships apply to a homogenous population and might apply to interventions in a high-risk group. However, as we have seen heterogeneity in risk plays a key role in the epidemiology of STIs. In populations with a distribution of risk, small reductions in risk can have a large impact in a lower risk group while having little impact in higher risk groups.[75] Thus, initially interventions can have a large impact, but as their intensity is increased it generates diminishing returns, as infection is removed from low-risk sections of the population and becomes more concentrated. This is illustrated for a model of treatment of symptomatic infections in and for a hypothetical HIV vaccine in (Fig. 3-8).[76]

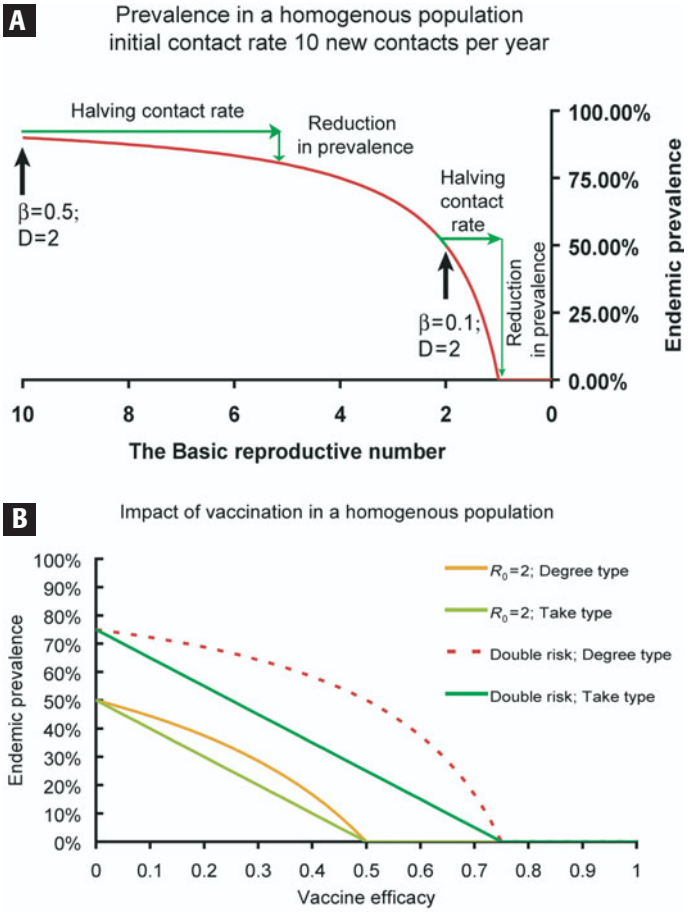

FIGURE 3-7. The predicted impact of interventions in a model of infection in a homogenous population. **A.** The endemic prevalence of infection as a function of the basic reproductive number and the impact of halving the contact rates at different starting points. **B.** The endemic prevalence as a function of vaccine efficacy with complete coverage. Two starting values of the basic reproductive number and two types of vaccine failure are compared. In take type protection, a fraction of individuals are protected, whereas in degree type protection individuals are protected from a fraction of challenges.

The introduction of effective treatment provides an opportunity both to relieve symptoms and reduce the duration of infectiousness of STIs. The impact of introducing rapid treatment of symptoms in a model is illustrated in Fig. 3-8A.[4] The model assumes 40% of infections are asymptomatic which limit the impact of treating symptomatic disease. Screening to identify asymptomatic infections can reduce prevalence further. However, the rate of finding asymptomatic infections will likely be slower than is possible when symptoms lead patients to seek care. This suggests that repeated screening at short intervals is needed, which may be possible with high-risk individuals. The expected bounce back with rounds of screening or mass antimicrobial administration is illustrated in Fig. 3-8B for the same model with periodic rather than continuous screening. Here we see how quickly this short duration high transmission probability infection can regain its original prevalence in the absence of reductions in risk behavior.

Before the introduction of effective antimicrobials the incidence and prevalence of bacterial infections would have been greater. The relative success of different STIs is likely to have changed in response to treatment, with chancroid, syphilis, and gonorrhea becoming relatively less common if their symptoms are more likely to receive attention. Similarly within microbial populations, treatment is likely to provide a selective advantage to organisms that generate negligible symptoms, more so than organisms that have partial drug resistance. Over time, we might expect the pathogenicity of curable STIs to decline unless there is a correlation between symptoms and transmissibility, which is hypothetically likely if disease is associated with larger bacterial colonies and transmission depends upon the infectious dose of bacteria. However, if interventions through screening target both asymptomatic and symptomatic infections, then selection is likely to favor organisms that transmit more readily, with a concomitant shorter duration of infection in the absence of treatment.[77] Similarly, drug resistance becomes a better adaptive strategy if both symptomatic and asymptomatic infections are rapidly treated through active screening.

Although antivirals are now available to treat HIV, HSV, and HBV, these do not provide a cure to these persistent viral infections. Recent advances in the development of vaccines have seen the wide spread use of HBV vaccines and the development of highly effective HPV vaccines, less effective HSV-2 vaccines, and large investment into HIV vaccine development.[73,21,34] The impact of a vaccine against an STI could have a large impact on the prevalence of infection, with the diminishing returns described above illustrated for hypothetical HIV vaccines in a model of the generalized spread of the virus (Fig. 3-8C).

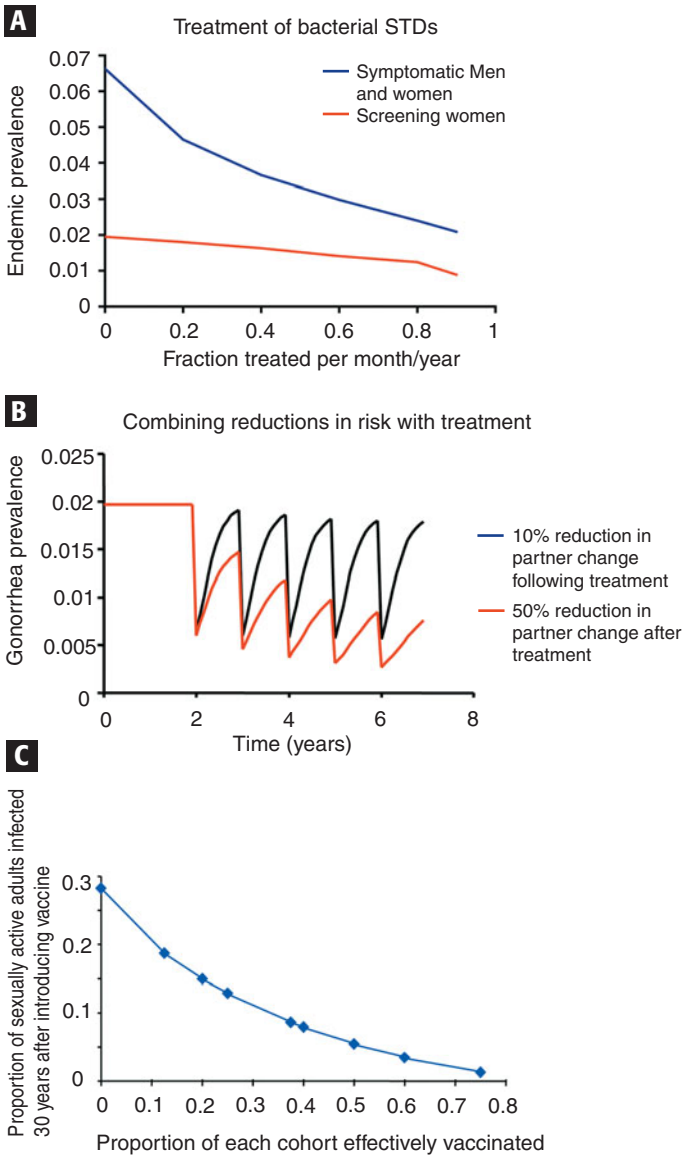

FIGURE 3-8. The population level impact of interventions. **A.** The impact of treatment for bacterial STDs in a model with three sexual activity classes, where 60% of infections lead to symptoms and infection lasts for an average of 6 months in the absence of treatment. One line illustrates the impact of treating 80% of the population for their symptomatic disease with a rate per month of seeking and receiving therapy. The lower line assumes the best symptomatic treatment and then adds screening for asymptomatic infections in 80% of the population. The screening is assumed to be continuous as would be the case with opportunistic screening. **B.** The impact over time of regular screening or mass treatment added to syndromic management of gonorrhea is illustrated, with a reduction in risk of 10% or 50% in those treated. **C.** The impact after 30 years on prevalence of a fully protective HIV vaccination in a sex, age, and sexual activity stratified model of HIV spread.

CONCLUSIONS

The theoretical framework provided by mathematical models allows us to integrate biological and behavioral data in understanding the distribution of STIs. Many aspects of sexual behavior are important in the spread of STIs, the rate of sexual partner change, concurrent partnerships, the pattern of sexual partner choice, and the numbers of sex acts within partnerships all influence the spread of the different STIs. Studies of patterns of behavior have shown how heterogeneous these are within the same population, and understanding the cause of the patterns of behavior is key to understanding the spread of the infections and how to intervene.

Advances in treatments and vaccines have changed the landscape of STI epidemiology, altering the relative importance of the different STIs. However, understanding how to optimize the impact of treatment and change risk behaviors is a subject requiring both empirical and theoretical studies. Mathematical models can predict the impact of interventions, but more work is required to demonstrate at a population level which interventions can have an impact on the incidence of infection and disease. Unfortunately, the few community randomized trials of HIV interventions have been logistically difficult and slow in generating results, and most have shown little impact.[78] Understanding the transmission dynamics of STIs shows that we cannot rely on declines in prevalence alone to indicate intervention successes, but if we can compare observed and predicted declines and use supporting behavior then it is possible to see where interventions are working at a population level.

4 The Global Epidemiology on HIV and AIDS

Karen A. Stanecki and Hein Marais

INTRODUCTION

In 2005, 40.3 million people (36.7–45.3 million) worldwide were living with HIV (Fig. 4-1).[1] That year, an estimated 4.9 million people (4.3–6.6 million) became newly infected with HIV. This is more than in any 1 year before. AIDS killed 3.1 million people (2.8–3.6 million) in 2005. Since the first AIDS case was diagnosed in 1981, more than 25 million people have died of AIDS.

This chapter describes the global epidemic by region, highlighting the changing dynamics of HIV transmission and the diverse patterns of infection found worldwide. The epidemic remains extremely dynamic, growing, and changing character as the virus exploits new opportunities for transmission. Virtually no country in the world remains unaffected. The number of people living with HIV has been rising in every region with the steepest recent increases occurring in East Asia and in Eastern Europe and Central Asia.

The number of AIDS deaths have nearly doubled in East Asia between 2003 and 2005, while a million more people are living with HIV in South and South East Asia in 2005 compared to 2003. In Eastern Europe and Central Asia, where the epidemic of injecting drug use among millions of young people is fuelling HIV transmission, the number of people living with HIV is estimated to be 1.6 million in 2005—a 20-fold increase in less than 10 years.

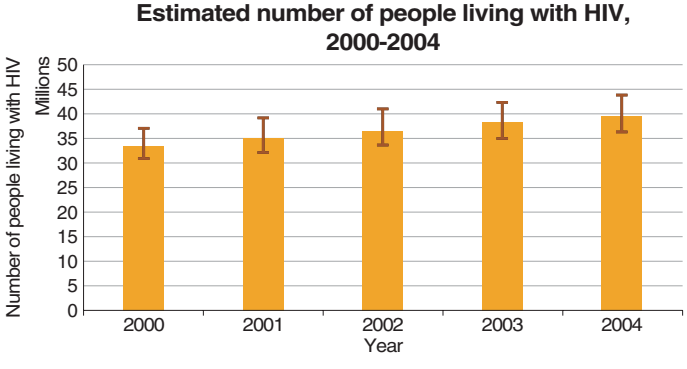

FIGURE 4-1. Estimated number of people living with HIV, 2000–2004.

Some industrialized countries that have let down their guard are seeing a rise in new infections, in part due to a dangerous myth fuelled by widespread access to antiretroviral medicines that AIDS has been defeated. In Asia, epidemics are evolving with the result that even countries that had mounted successful responses are now faced with having to shift gear to readdress emerging epidemics. In sub-Saharan Africa, the overall percentage of adults with HIV infection has remained stable in recent years, but the number of people living with HIV is still growing as populations expand.

The epidemic is not homogeneous within regions; some countries are more affected than others. Even at country level, most often there are wide variations in infection levels between different provinces, states, or districts, and between urban and rural areas. In reality, like the global epidemic, the national picture is made up of a series of epidemics with their own characteristics and dynamics.

SUB-SAHARAN AFRICA

Sub-Saharan Africa has just over 10% of the world's population, but is home to more than 60% of all people living with HIV—some 25.8 million (23.8–28.9 million).[1] In 2005, an estimated 3.2 million (2.8–3.9 million) people in the region became newly infected, while 2.4 million (2.1–2.7 million) died of AIDS. The high HIV prevalence levels in several countries mean that even those that manage to reverse the epidemic's course will have to contend with serious AIDS epidemics for many subsequent years.

The AIDS epidemic in this region is highly varied, both between and within subregions, making it inaccurate to speak of a single, "African" epidemic (Fig. 4-2). Southern Africa, the worst-affected part of the world, shows no sign yet of an overall, national decline. East Africa, though, boasts several examples of gradual, modest declines in median HIV prevalence among pregnant women in urban areas. Meanwhile, in West and Central Africa, infection levels are lower than elsewhere in the region and have stayed relatively stable for several years now.

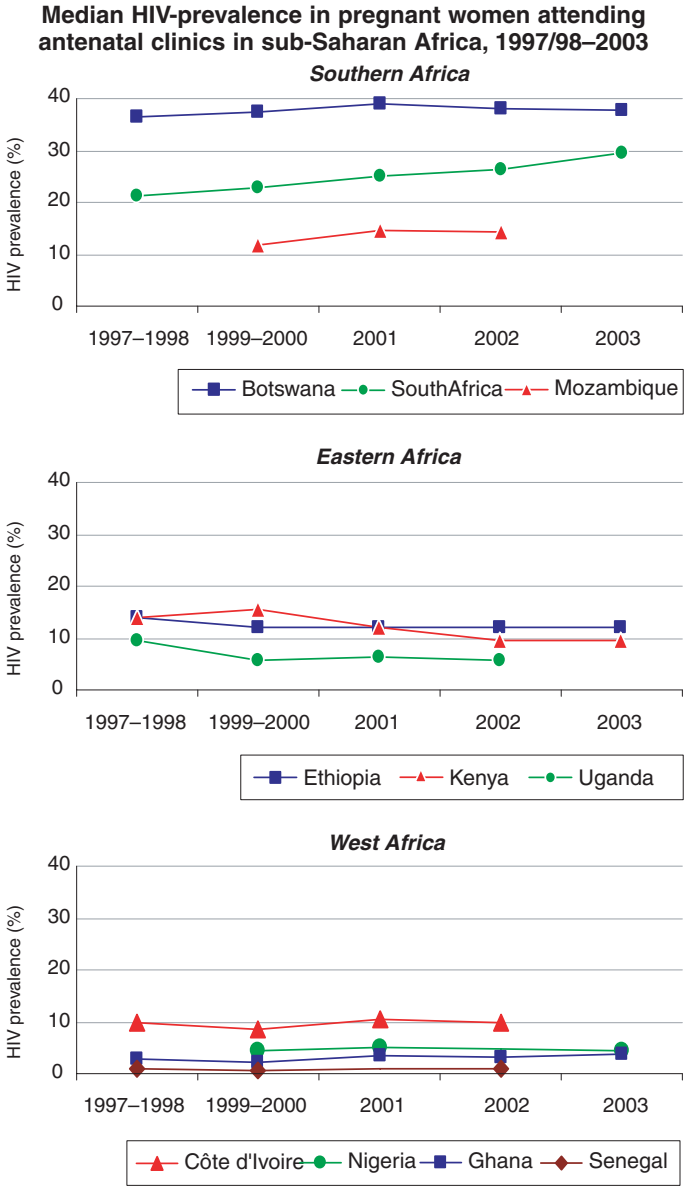

FIGURE 4-2. Median HIV-prevalence in pregnant women attending antenatal clinics in sub-Saharan Africa, 1997/98–2003. (Adapted from Asamoah-Odei E, Garcia-Calleja JM, Boerma T. HIV prevalence and trends in sub-Saharan Africa: No decline and large subregional differences. *Lancet* 2004; 364: 35–40. Data from consistently reporting antenatal clinics.)

Yet there are some striking consistencies, too. Firstly, adult HIV prevalence has been roughly stable in recent years in much of this region. This is not necessarily good news. Stabilization can disguise the worst phases of an epidemic—when roughly equally large numbers of people are being newly infected with HIV and are dying of AIDS. Secondly, throughout the region women are disproportionately affected by HIV, as Fig. 4-3 shows. On average, there are 13 women living with HIV for every 10 infected men and that gap continues to widen. The differences in infection levels between women and men are most evident among young people (aged 15–24 years). Recent population-based studies suggest that there are on average 36 young women living with HIV

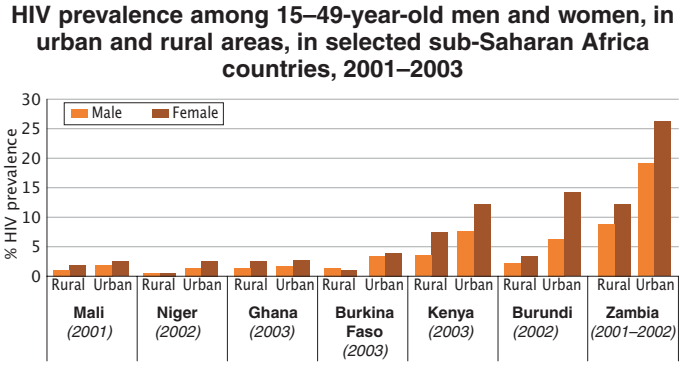

FIGURE 4-3. HIV prevalence among 15–49-year-old men and women, in urban and rural areas, in selected sub-Saharan African countries, 2001–2003. (*Sources*: Burkina Faso, Burkina Faso Enquête Démographique et de Santé 2003, Rapport Préliminaire; Burundi, Enquete Nationale deSeroprevalence de L'Infection pa le VIH au Burundi, Bujumbura, Décembre 2002; Ghana, Ghana Demographic and Health Survey 2003, Preliminary Report; Kenya, Kenya Demographic and Health Survey 2003; Mali, Enquête Démographique et de Santé, Mali 2001; Niger, Enquête Nationale de Séroprévalence de L'Infection par le VIH dans la population générale âgée de 15 à 49 ans au Niger 2002; Zambia, Zambia Demographic and Health Survey 2001–2002.)

for every 10 young men in sub-Saharan Africa. In a study among women in Harare (Zimbabwe) and Durban and Soweto (South Africa), 66% reported having one lifetime partner, 79% had abstained from sex until at least their seventeenth birthday (roughly the average age of first sex in most countries in the world), and 79% said they used a condom. Yet, 40% of the young women were HIV-positive. Many women are being infected despite staying loyal to one partner.[2]

Delayed Pictures

Across sub-Saharan Africa, prevention and treatment efforts have grown manifold in the past 5 years in both scope and scale. HIV incidence data would sketch recent trends and offer clues to the possible impact of those efforts. However, there is no simple and reliable method to assess HIV incidence in sub-Saharan Africa. It is possible to estimate HIV prevalence levels, but these present a delayed picture of the epidemic since they reflect incidence patterns of several years previously. HIV *prevalence* describes the total number of people living with HIV, irrespective of when they were infected, while *incidence* refers to the number of people who became infected over a specific period, usually the previous year. The closest, though imperfect, proxy for HIV incidence would be HIV prevalence in 15–24-year-old pregnant women, most of whom would have been infected relatively recently. This indicator shows infection levels declining in that age group of women in some urban areas of East Africa. In southern Africa, though, it reveals little sign of change with the exception of South Africa, where infection levels have continued to increase in women of that age group.

An estimated 11.7 million (10.8–12.9 million) people are living with HIV in the nine hardest-hit southern African countries. Together those countries have 2% of the world's

population, yet they are home to almost 30% of the global number of people living with HIV.

South Africa continues to have the highest number of people living with HIV in the world. An estimated 5.3 million (4.5–6.2 million) people were living with HIV end-2003 in South Africa, 2.9 million (2.5–3.3 million) of them being women. Unfortunately, there is no sign yet of a decline in its epidemic. Prevalence levels among pregnant women aged 15–24 years, a possible indicator of recent trends in HIV incidence, have continued to rise, reaching 25.0% in 2004. Although levels of HIV prevalence among 15–19-year-olds has stabilized over the past few years, prevalence among 20–24-year old pregnant women continues to increase (Fig. 4-4). Overall HIV prevalence among pregnant women was 29.5% in 2004, compared with 26.5% in 2002 and 25% the year before.[3]

Very high HIV prevalence, often exceeding 30% among pregnant women, is still being recorded in Botswana, Lesotho, Namibia, and Swaziland. There, too, comparisons of prevalence levels at selected antenatal clinics have shown no evidence of a decline. Elsewhere, HIV infections in pregnant women appear to be stabilizing at lower levels—around 18% in Malawi (2003), 16% in Zambia (2003), and 25% in Zimbabwe (2003)—but there is little hint of an impending decline. Angola is an exception in this subregion. Available data suggest that nearly two generations probably slowed the spread of HIV there. Median HIV prevalence of approximately 3% has been measured at antenatal clinics in the capital, Luanda. As normal life resumes for millions of Angolans, there is every reason to fear much more widespread and rapid HIV transmission in their country.

In the Front Line

Effective prevention among young people is essential. Throughout southern Africa, HIV prevalence sharply increases once people reach their twenties. A recent study among young South Africans reports comparatively low HIV prevalence among 15–19-year-olds, at 4.8%.[4] It is in the next age group, among 20–24-year-olds, that HIV prevalence soars, reaching 16.5%, with HIV infections massively concentrated among women. Almost 25% of the women surveyed were HIV-positive, compared to just under 8% of the men. Young women were found to be disproportionately at risk of HIV infection. Sexual aggression is common, with more than one-quarter (28%) of the women saying their first sexual experience was unwanted, and one in ten (10%) saying they had been forced to have sex. Almost half (49%) the young women who had had sex said they had been pregnant at some point, suggesting that condom use was not the norm.

A downward trend in HIV infection levels is most firmly established in Uganda, where national prevalence fell steeply in the mid- and late-1990s and has stayed at 5–6% since then. Kenya is on a similar path. There, median HIV prevalence

HIV prevalence among pregnant women at antenatal clinics in South Africa, by age group, 1991–2004

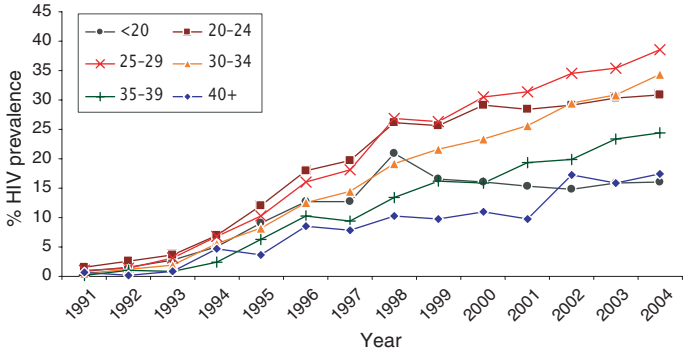

FIGURE 4-4. HIV prevalence among pregnant women at antenatal clinics in South Africa, by age group, 1991–2004. (*Source:* Department of Health, South Africa. *National HIV and Syphilis Antenatal Sero-Prevalence Survey in South Africa* 2004.)

among pregnant women decreased from 13.6% (12.2–27.1%) in 1997–1998 to 9.4% (6.6–14.3%) in 2002 and then stayed roughly the same in 2003. The declining HIV trend among pregnant women in Ethiopia's capital, Addis Ababa, appears to be continuing, while information from Burundi also suggests a drop in HIV prevalence (though this is based on very limited data).[5] It is much too early, though, to regard the declines as irrevocable reversals in these countries' epidemics. Furthermore, the need for treatment, care and support will continue to increase for years to come.

Making a Difference

Although Tanzania shows no signs yet of nationwide HIV prevalence decline, some localities do offer proof that appropriate efforts prevention can make a difference. Mbeya region has been the focus of *intense* prevention work over the past 13 years. Condom use rose and treatment for sexually transmitted infections increased between 1994 and 2000, while a significant delay in age at first sex was also noted. HIV prevalence among 15–24-year-old women fell from 20.5% to 14.6% over the same period. In the urban parts of neighboring Rukwa region, by contrast, only sporadic prevention efforts were mounted. There, HIV prevalence in the same age group rose from 22.5% in 1994 to 30.2% in 1999.[6] The specific kinds of interventions mounted in Mbeya probably helped drive down HIV prevalence there, whereas those in Rukwa did not inhibit the spread of HIV. Other research in Tanzania has revealed a marked lack of behavior change where *low-intensity* HIV prevention programs have been introduced. A standard, district HIV-prevention program operating since the mid-1990s in Mwanza, for example, appears to have made little headway against the epidemic. HIV prevalence rose gradually from 5.9% in 1994–1995 to 6.6% in 1996–1997 and 8.1% in 1999–2000. There was a small increase in condom use and in knowledge about the epidemic, but sexual risk behavior was unchanged and most people felt that they were not at risk of HIV infection.[7] Low-cost, standard district and community-level prevention programs are not sufficient to change the course of the epidemic.

The epidemics in West Africa vary in scale and intensity, but appear to have stabilized in most countries. Median HIV prevalence measured among women in 112 antenatal clinics in the subregion remained at an average 3–4% between 1997 and 2002.[5] Overall, HIV prevalence is lowest in the Sahel countries and highest in Burkina Faso, Côte d'Ivoire, and Nigeria—the latter having the third largest number of people living with HIV in the world (after South Africa and India). Nigeria's 2003 HIV sentinel survey put national HIV prevalence at 5%, a rise from 1.8% found in 1991 but roughly level with the 5.4% recorded in 1999. The apparent stabilization at national level hides significant regional differences in this vast and diverse country, with prevalence ranging from a low of 2.3% in the South West to a high of 7% in the North Central parts. This means that several, more or less distinct epidemics are underway in Nigeria.[8]

Côte d'Ivoire has continued to report the highest level of HIV prevalence in West Africa, although prevalence in the capital Abidjan in 2002 was the lowest it had been in 5 years, at 6.4% compared with 13% in 1999.[5] National adult HIV prevalence in Togo has stayed roughly steady at around 4%[9] while in neighboring Ghana and Benin prevalence is in the 2% to 4% range with little change noted over time.[10] National HIV prevalence in Senegal, long-feted as an HIV success story, remains below 1% but slowly rising HIV levels have been detected among women who sell sex. In the capital, Dakar, prevalence stood at 14% in 2002, while among sex workers in other areas (such as Kaolack and Ziguinchor) it had risen to over 20% by the same year.[11]

Serious epidemics are underway in Central Africa, with Cameroon, Central African Republic, and Gabon worst affected. Here, too, HIV prevalence among pregnant women appears to have stabilized but at high levels (of roughly 10%). In Congo, meanwhile, national adult prevalence has edged below 5%. Two recent rounds of HIV testing among pregnant women in the Democratic Republic of Congo showed prevalence ranging between 4.1% and 4.9%, but HIV levels varied considerably from as low as 1.8% in rural Mikalayi and roughly 3% in urban Bukavu and Bunia, to 6.3% and 7%, respectively, in the cities of Kisangani and Lubumbashi.[5]

LATIN AMERICA AND THE CARIBBEAN

More than 2.1 million (1.6–2.9 million) people are living with HIV in Latin America and the Caribbean, including 230,000 (150,000–440,000) adults and children who acquired the virus in 2005. An estimated 90,000 (68,000–130,000) people died of AIDS in the same year. [1]

CARIBBEAN

With average adult HIV prevalence of 1.6% (1.1–2.7%) the Caribbean is the second worst affected region in the world.[1] As the epidemics in this region evolve, more women are being affected, and the number of new HIV infections among them now outstrips that among men. AIDS claimed an estimated 24,000 (16,000–40,000) lives in 2005 and has become the leading cause of death in the Caribbean among adults aged 15–44 years. On current trends, by 2010 life expectancy in several countries will be significantly lower than it would have been had AIDS not struck (Fig. 4-5).[12]

National adult HIV prevalence exceeds 2% in the Bahamas, Belize, Guyana, and Trinidad and Tobago, but is highest in Haiti which continues to have the largest number of people living with HIV in the Caribbean—some 280,000 at the end of 2003.[13] The most recent data show HIV prevalence among pregnant women varying between 1.8% and almost 7% in different parts of Haiti. Although general AIDS knowledge is widespread, misconceptions about the virus continue to circulate, particularly among women. On the other half of Hispaniola Island, HIV prevalence among 15–24-year-old pregnant women in the Dominican Republic's capital, Santo Domingo, fell from around 3% in 1995 to below 1% in 2003. However, the same trend is not evident in the rest of the country, and HIV prevalence among pregnant women nationally was still higher than 2%.[14]

At an estimated 2.5% at the end of 2003, national adult HIV prevalence in Guyana was the second-highest in the region and there has been a steep rise in the numbers of HIV cases reported since mid-1990s. Jamaica, meanwhile, has the second-highest annual number of AIDS cases and deaths in the region and there is no evidence yet that its HIV epidemic is abating. HIV prevalence among pregnant women stood at 1.4% nationally in 2002 but was considerably higher in some parishes.

Life expectancy at birth with and without AIDS for selected Caribbean countries: 2010

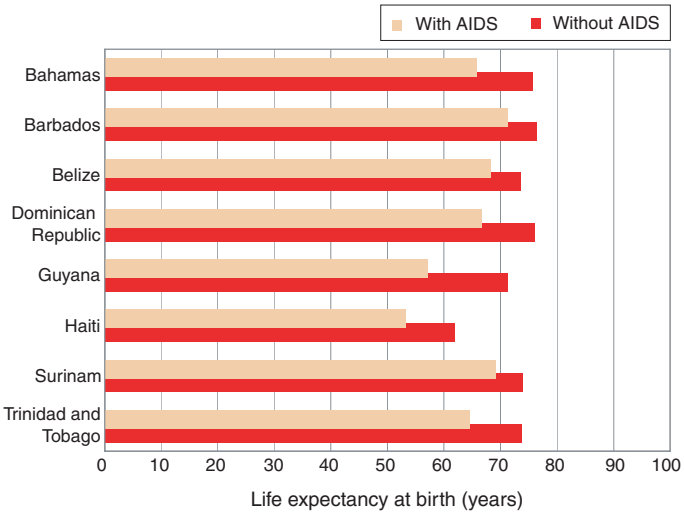

FIGURE 4-5. Life expectancy at birth with and without AIDS for selected Caribbean countries: 2010. *(Source:* U.S. Census Bureau, International Programs Center, International Data Base and unpublished tables.)

On the positive side, both the Bahamas and Barbados show signs that their boosted prevention efforts since the late 1990s could be forcing HIV-infection levels lower. In the Bahamas, HIV prevalence among pregnant women fell from 4.8% in 1993 and 3.6% in 1996 to 3% in the latest round of HIV surveillance in 2002 (Fig. 4-6). HIV levels among pregnant women in Barbados, which has a smaller epidemic, fell from 0.7% to 0.3% in 1999–2003. Mother-to-child transmission of HIV has been reduced since the expansion of voluntary counseling and testing services, and the provision of antiretroviral prevention regimens. In addition, the introduction in 2001 of antiretroviral treatment for people living with HIV halved the annual number of AIDS deaths between 1998 and 2003 and brought about a 42% drop in hospital admissions for treatment of opportunistic infections in the same period.

Cuba has been an exception in the region. Despite an increase in newly reported HIV cases since the late 1990s, HIV prevalence remains extremely low, while universal and free access to antiretroviral therapy has kept the number of AIDS cases and deaths to a minimum.

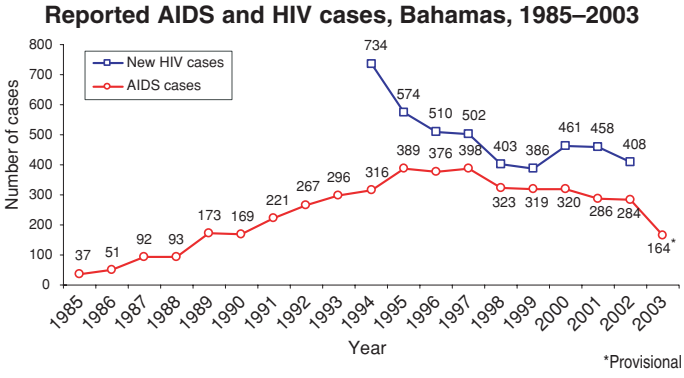

FIGURE 4-6. Reported AIDS and HIV cases, Bahamas, 1985–2003. (*Sources:* Caribbean Epidemiology Centre (CAREC)/PAHO/WHO. *Status and Trends Analysis of the Caribbean HIV/AIDS Epidemic* 1982-2002. Available at: http://www.carec.org)

LATIN AMERICA

HIV prevalence in Latin American countries is lower than in the Caribbean and surpasses 1% in just two countries: Guatemala and Honduras. However, lower prevalence in other countries can hide serious, localized epidemics, for example, in Brazil, which has more than one-third of the people living with HIV in Latin America.[13]

Although national HIV prevalence among pregnant women in Brazil has stayed stable at below 1% for the past 5 years, higher levels have been found in some areas, for example, 3–6% among pregnant women in Rio Grande do Sul state who did not regularly attend antenatal clinics. Injecting drug use still features prominently in Brazil's epidemic, with drug injectors accounting for at least half of the AIDS cases in some regions. Harm reduction programs, though, are making a difference in some cities notably in Salvador where prevalence fell from 50% in 1996 to 7% in 2001. In the south of the country, though, HIV infection levels among injecting drug users remain high, indicating a need for more effective prevention programs.[15]

Several countries illustrate the epidemic's ability to "bridge" between apparently disparate sections of society. In the Andean area, HIV is spreading increasingly to the wives or girlfriends of sex worker clients and men who have sex with men. In Venezuela, which has one of the largest epidemics in the region,[16] HIV is spreading mainly through unsafe sex, much of it between men, a significant proportion of whom also have sex with women. In Uruguay, where most registered HIV cases have been in or around the capital, Montevideo, there has been an alarming increase in the number of people living with HIV who are either injecting drug users or their sex partners.[17] Argentina's epidemic is powered mainly by unsafe drug injecting and is concentrated largely in the urban areas of Buenos Aires, Cordoba, and Santa Fe provinces. Sexual transmission of HIV, however, has become more prominent, with most new infections occurring among the poorest and least-educated urban inhabitants.[18]

In Central America, where the epidemic is also concentrated in urban areas, the numbers of HIV infections have been rising in several countries (including El Salvador, Nicaragua, and Panama) since the late 1990s. HIV prevalence is highest in Guatemala (1.1% at the end of 2003) and Honduras (1.8%).[13] AIDS-related diseases are now estimated to be the second-leading cause of death in Honduras.[19] Overall in Central America, HIV infection levels are highest among men who have sex with men and among female sex workers. To the north in Mexico, national prevalence in the adult population has remained well under 1% but shows some regional variance.[20]

Turning a Blind Eye

Sex between men is a significant factor in most of the epidemics in Latin America and the Caribbean. More than half of Costa Rica's AIDS cases in 1998–2002 were among men who have sex with men, a significant percentage of whom also have sex with women. Studies in several countries have found high HIV levels in groups of men who have sex with men, ranging from 9% to 13% in Guatemala, Honduras, Nicaragua, and Panama to almost 18% in El Salvador. Large proportions of the men in those studies reported also having female sex partners. Therefore, bisexuality constitutes a significant bridge for HIV transmission into the wider population. Yet, widespread homophobia is providing an ideal climate for the spread of HIV, by driving men who have sex with men further away from the information, services, and security that can protect them against HIV. Moreover, particularly in Central America, prevention spending does not yet reflect the prominence of sex between men in countries' epidemics.

On the treatment front, Brazil continues to set an enviable example by offering all people living with HIV access to antiretroviral drugs via its national health system when they need it. As a result, the survival time of AIDS patients has increased dramatically. AIDS cases and AIDS mortality have declined in several other countries including Argentina, Costa Rica, and Panama, after expansion of antiretroviral treatment access.

ASIA

The populations of many Asian countries are so large that even low national HIV prevalence means huge numbers of people are living with HIV. An estimated 8.3 million adults and children (5.4–12.0 million) in Asia were living with HIV at the end of 2005. Approximately 1.1 million (600,000–2.5 million) people acquired HIV in 2005, while 520,000 (330,000–780,000) people died of AIDS in the same year.[1]

The nature, pace, and severity of the epidemics differ across the region. While some countries (notably Thailand and parts of India) were hit early, others (such as Indonesia and Nepal) are only now starting to experience rapidly expanding epidemics, and a few (including Bangladesh and Pakistan) are still seeing extremely low levels of HIV prevalence, even among people at high risk of exposure to HIV, and have golden opportunities to avoid serious outbreaks.[21]

In vast and populous India, serious epidemics are underway in several states, and latest estimates show about 5.1 million (2.5–8.5 million) people were living with HIV at the end of 2003.[13] In each of Andhra Pradesh, Karnataka, Maharashtra, and Nagaland, HIV prevalence has crossed the 1% mark among pregnant women, while infection levels of 50% have been found among sex workers in Tamil Nadu. Manipur's maturing epidemic has already spread from drug injectors to the wider population. At antenatal clinics in the Manipur cities of Imphal and Churachand, HIV prevalence has risen from below 1% to over 5%; many of the women who test positive appear to be the sex partners of male drug injectors. Indeed, injecting drug use seems to be playing a bigger role in India's epidemics than previously thought—and not just in the north. In the southern city of Chennai, for example, 64% of drug injectors were found to be infected with HIV in 2003. The epidemic has ample scope for further growth if prevention efforts do not prevent onward transmission of HIV from drug injectors and the clients of sex workers to their other sex partners.[21]

The most ominous development in this region has been the swift emergence of an AIDS epidemic in the world's most populous country, China. Although moving at a varied pace, HIV has spread to all of China's 31 provinces, autonomous regions, and municipalities.[22]

Much of the current spread of HIV in China is attributable to injecting drug use and paid sex (Fig. 4-7). HIV prevalence among drug injectors was measured at between 18% and 56% in six cities in the southern provinces of Guangdong and Guangxi in 2002, while in Yunnan province some 21% of injectors tested positive for HIV in 2003. Sexual transmission of HIV from injecting drug users to their sex partners looks certain to feature more prominently in China's fast-evolving epidemic. Harm-reduction programs can make a difference, as Sichuan province shows. There, reported reuse of nonsterile needles at last injection fell by almost half in 2002–2003, after the introduction of such programs.

Once HIV becomes well-established in commercial sex circuits, onward spread of the virus could be quite rapid unless current behavior trends alter. In 2003, almost one-quarter of surveyed sex workers in Guangxi said they never used condoms and about one-half used them only occasionally.

Women At Risk

Men who have unprotected sex with HIV-infected sex workers are at risk both of contracting HIV themselves and of passing it on to their other sex partners (including other sex workers). In a study in the southern Chinese city of Guangzhou, 72% of women with sexually transmitted infections said they had only had sex with their husband or regular partner in the previous 6 months–a clear sign that they were put at risk by their partners' behavior, not their own. Expressed in such ways are deeper social inequalities, not least the imbalances in men and women's social power, and the discrimination women face in earning and career opportunities in most countries of Asia (and, indeed, the world). Prevention efforts that neglect these wider dynamics are unlikely to achieve enduring, if any, success.

Recent steep rises in HIV infection among drug injectors have been followed by a rise in HIV among sex workers in parts of China, Indonesia, and Vietnam

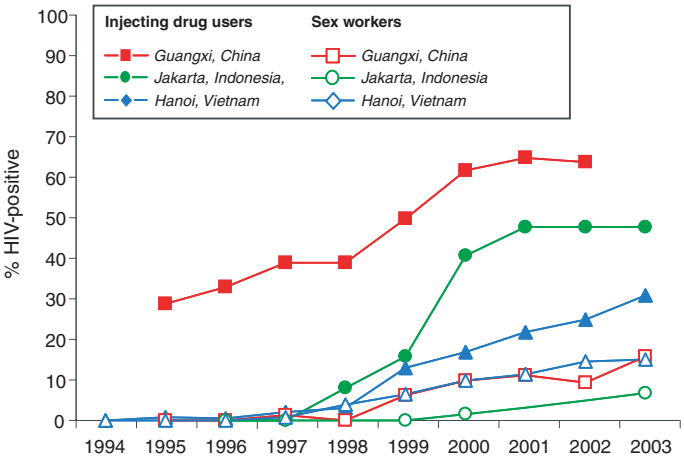

FIGURE 4-7. Recent steep rises in HIV infection among drug injectors have been followed by a rise in HIV among sex workers in parts of China, Indonesia, and Vietnam. (*Sources:* Lao People's Democratic Republic National Committee for the Control of AIDS Bureau 2001; Philippines Department of Health 2002 and national surveillance reports; Bangladesh National AIDS/STD program 2003; Pisani and Dili STI survey team 2004a.)

China can still shape the course of its epidemic, but it will have to act swiftly and with great resolve. Recent efforts to boost public knowledge about HIV appear to be yielding results, but there remains much room for improvement. Two in five Chinese men and women could not name a single way to protect themselves against infection, according to a 2003 survey, for example. In Sichuan province, more than one-third of sex workers (and a similar proportion of their clients) did not know that condoms offer good protection against HIV.

HIV now appears to be spreading freely in some of Vietnam's cities among groups that are at high risk of exposure to HIV. Widespread injecting drug use by sex workers makes Vietnam's epidemic particularly explosive (Fig. 4-7). In Ho Chi Minh City, 38% of almost 1000 surveyed sex workers injected drugs and almost half of those injecting sex workers were infected with HIV (compared with 8% of those who didn't use any drugs).

Wider epidemics are being "kick-started" in Indonesia and Nepal, where the sudden rises in HIV infection among drug injectors are now being followed by subsequent rises in infection among people who do not inject drugs but who have sexual risk behaviors. One in two injecting drug users in Indonesia's capital, Jakarta, now test positive for HIV, while in far-flung cities such as Pontianak (on the island of Borneo) more than 70% of drug injectors who request HIV tests are discovering that they are HIV-positive. Conditions favor HIV spread through sex work, where condom use ranges from irregular to rare.[21]

On the Move

Unsafe injecting drug use is the driving force of Nepal's epidemic, which also highlights the potential links between HIV infection and mobility. Injecting drug users from cities with low prevalence, but who had injected drugs elsewhere, have been found to be two to four times more likely to have acquired HIV than those who had remained in their home cities. Half of the sex workers surveyed in central Nepal and who said they had worked in Mumbai (India) were HIV-infected, compared with 1.2% of those who had never been to India.[21]

In Myanmar's older epidemic, HIV has already filtered from people with the highest-risk behaviors (such as nonsterile drug injection and unprotected commercial sex) to their regular sex partners. Between 45% and 80% of drug injectors have tested positive for HIV infection in sentinel surveillance each year between 1992 and 2003, while prevalence among sex workers leapt from around 5% to 31% over the same period. By 2003, HIV prevalence among pregnant women was above 2% at almost half the sentinel sites and exceeded 7% at one of them.[21]

Such trends can be avoided. Thailand continues to reap the benefits of the prevention effort it focused on sex work in the 1990s, with national adult HIV prevalence still edging lower. However, its epidemic is changing. It is estimated that as many as half of annual, new HIV infections have been occurring among cohabiting couples, as more women are infected by partners who are (or were) drug injectors or clients of sex workers. As a consequence, HIV infection levels among pregnant women are high in parts of the country, including the South (where they exceeded 2% in eight provinces in 2002). In addition, about one-fifth of new infections is occurring through unsafe injecting drug use. In the north, 30% of drug injectors are infected with HIV, while median HIV prevalence as high as 51% has been found in other parts of the country. Yet, scant prevention resources are deployed on that front. A renewed and pragmatic prevention effort is called for.[23]

In Cambodia, large-scale prevention programs have brought reward, reducing sexual risk behavior and pushing HIV levels lower (Fig. 4-8). Fewer men now visit sex workers and more use condoms in commercial sex. The combined effect has been a steep drop in sexually transmitted infections and a steady decline in HIV prevalence.

Some countries still have a rare opportunity to prevent a significant epidemic from taking hold at all if they can provide prevention services to people most at risk of HIV infection. The Philippines, for example, has begun to take up that challenge. By following suit, Malaysia (where HIV infections are concentrated mainly among drug injectors and, possibly, sex workers) could avoid possibly serious HIV outbreaks.

HIV incidence rate among different groups, Cambodia, 1999–2002

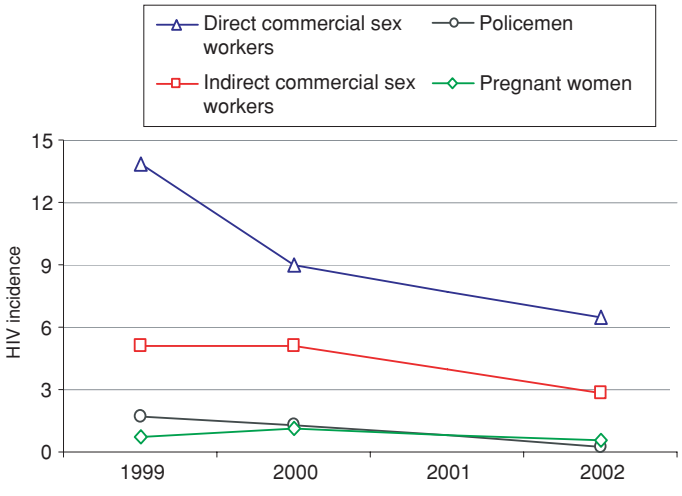

FIGURE 4-8. HIV incidence rate among different groups, Cambodia, 1999–2002. (*Source:* V. Saphon, et al. XV International AIDS Conference, 11–16 July 2004. Abstract No. ThOrC1424.)

Reaching Across Borders

Because AIDS epidemics crisscross national boundaries, joint efforts like the border area needle exchange program run by China and Vietnam since 2002 make sense. The program grew from the realization that the epidemics among injectors in China's Guangxi province and Vietnam's Quang Ninh and Langson provinces were closely linked. Outreach workers collect used syringes from drug injectors for safe disposal and provide them with vouchers that can be used to obtain new needles from participating pharmacies. The program is based on a successful trial that showed a drop in the use of nonsterile injecting equipment in the previous month from 61% to 30% among all injectors in Guangxi.

As the epidemics grow and mature in this region, treatment, care, and support have to move higher up the agenda. A few countries are taking up that challenge, with Thailand possibly on track to reach its target of providing 50,000 people with antiretroviral treatment, while others have committed themselves to drastically expand treatment access, including India (which has pledged free treatment in several states) and Indonesia.

OCEANIA

In the Pacific, Papua New Guinea is home to a potentially explosive epidemic. There, HIV prevalence is higher than anywhere else in this region, with an estimated 0.6% (0.3–1.0%) of adults, roughly 16,000 (7800–28,000) of the 2.5 million adults in the country, living with HIV at the end of 2003.[13] The annual number of new HIV infections detected in Papua New Guinea has been increasing progressively since the mid-1990s, exceeding 1000 in 2003, as Fig. 4-9 shows.[24] In the same year, 1.4% of pregnant women at antenatal clinics in the capital Port Moresby tested HIV-positive, while in Lae, in the central highlands, 2.5% of pregnant women were HIV-infected.

Many questions remain unanswered about Papua New Guinea's epidemic, but available information shows an epidemic that is spreading primarily through heterosexual intercourse, and against a backdrop of widespread violence against women. Urgent action is needed to improve HIV prevention and AIDS care services if Papua New Guinea is to avert a rampant epidemic.

Very low HIV-infection levels are being recorded in other parts of the Pacific, but the data are extremely limited. On remote islands, seafarers and their partners appear to be most at risk; on Kiribati, for example, 9% of seafarers included in a recent study had chlamydia and 3% syphilis, although HIV prevalence was still low (at 0.3%).[25] The high levels of other sexually transmitted infections detected on some other islands, including Vanuatu and Samoa, point to widespread unprotected sex that could enable rapid HIV spread once the virus acquires a presence in these tiny island nations.

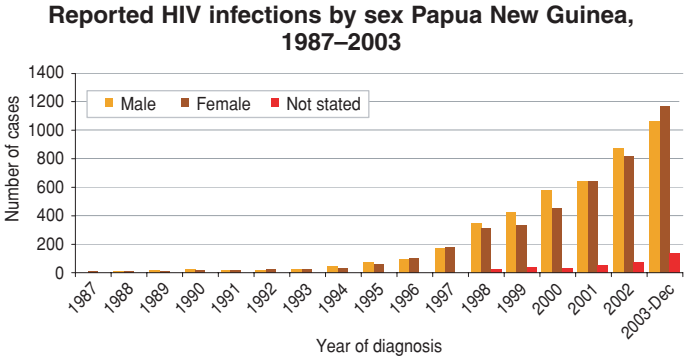

FIGURE 4-9. Reported HIV infections by sex, Papua New Guinea, 1987–2003. (*Source:* National AIDS Council and Department of Health Papua New Guinea. *HIV/AIDS Quarterly Report*. Boroko, Papua New Guinea, 2003.)

Prevention strategies that reduce and treat sexually transmitted infections and that quickly bolster AIDS knowledge among the population at-large are urgently needed.

EASTERN EUROPE AND CENTRAL ASIA

Diverse HIV epidemics are underway in Eastern Europe and Central Asia, where the number of people living with HIV has increased more than 20-fold in 10 years reaching an estimated 1.6 million (990,000–2.3 million) at the end of 2005.[1] The vast majority of them are young; more than 80% of the reported infections are being found among people below the age of 30 years (by comparison, in Western Europe some 30% of people with HIV fall in that age group). Some 270,000 (140,000–610,000) people were newly infected with HIV in 2005, while an estimated 62,000 (39,000–91,000) died of AIDS in the same year.

Research highlights a volatile mix of behaviors that could keep the region's epidemics flaring indefinitely. But most of the epidemics are still in their early stages, which means that timely, effective interventions can halt and reverse them. Arduous social and economic change serves as the context in which extraordinarily large number of young people are injecting drugs in this region. In countries with emerging epidemics, harm reduction programs among young people can prevent larger, more extensive HIV epidemics of the kind now taking hold in Russia and Ukraine. At the same time, sexual transmission of HIV is featuring increasingly in the most seriously affected countries—an indication that the epidemic has established itself in the wider population.

The most serious and firmly established epidemic is in Ukraine, which is experiencing a new surge of infections, while the Russian Federation is home to the largest epidemic in the entire region (indeed in all of Europe) and accounts for some 70% of all HIV infections officially registered in Eastern Europe and Central Asia. An estimated 860,000 (420,000–1.4 million) people were living with HIV in Russia at the end of 2003,[13] fully 80% of them aged 15–29 years and more than one-third of them women. Although present

across the entire country, HIV is unevenly distributed in Russia, with about 60% of all HIV infections to date having been reported in just 10 of its 89 regions.[26] Much scope, therefore, exists for further expansion of Russia's epidemic alongside great opportunities to prevent such an outcome.

At the heart of Russia's epidemic are the extraordinarily large number of young people who inject drugs, many of who are sexually active and risk passing HIV to their partners. Between 1.5 and 3 million Russians are believed to inject drugs (1–2% of the entire population), and an estimated 30–40% of injecting drug users use nonsterile needles or syringes that massively boost the chances of HIV transmission. HIV prevalence among injecting drug users is very high in many parts of Russia. Recent studies have reported an estimated 65% of street drug injectors in Irkutsk were HIV-positive (90% of them still in their teens); in Tver, 55% were infected, in Ekaterinburg the figure was 34%, and in Samara 29%.[27]

Sex and Drugs and HIV

The exchange of sex for drugs, or the use of sex to support drug habits acts functions as an ideal bridge for wider HIV spread. When commercial sex and injecting drug use connect, and when effective HIV-prevention services are absent, the effects can be devastating. In a recent St. Petersburg (Russian Federation) study, 81% of surveyed sex workers said they injected drugs daily, and 48% of the women were HIV-positive; among those aged 20–24 years, 64% were infected.[28]

While some drug injectors buy or sell sex, many also have regular sex partners. According to studies in several Russian cities, upward of 70% drug injectors are sexually active. With safer sex not yet the norm, the epidemic's pattern in Russia has been shifting and the proportion of new, reported HIV infections acquired during heterosexual intercourse has grown dramatically from 5.3% in 2001 to just over 20% in 2003. This means that more women are being infected: the overall proportion of women among people living with the virus has increased to 38% in 2003, compared with 24% in 2001. As a result, more children are being born to HIV-positive mothers, making prevention of mother-to-child transmission an added priority (Fig. 4-10).

A similar trend is underway in Ukraine, where more than 40% of people with HIV infection are women, most of them in their peak reproductive years. There, however, efforts to expand programs to prevent mother-to-child transmission appear to be bearing fruit, with the proportion of HIV-infected babies born to infected mothers shrinking from 27% in 2001 to 12% in 2003.[29]

Ukraine's epidemic continues to expand. Newly registered HIV infections increased by 7% in 2000, 13% in 2001, and 25% in 2002. Just 10 years ago, there were only 183 officially registered HIV cases in Ukraine; by mid-2004 more than 68,000 cases of HIV infection had been officially registered. These figures grossly understate the actual scale of the epidemic since they only measure infections among people who come in direct contact with the authorities and testing facilities.

The deadly combination of HIV and tuberculosis is a serious concern in Ukraine, where 10–15% of TB cases are estimated to be multidrug resistant. Tuberculosis has become the leading cause of death among people living with HIV. This underlines the need for a significant scaling up of access to antiretroviral treatment in Ukraine. Currently, just over 500 of the estimated 45,000 people who need antiretroviral treatment in Ukraine are receiving it, despite the fact that treatment access for all is guaranteed by Ukrainian law.

Hidden Epidemics?

There is a strong chance that HIV could be spreading largely undetected among men who have sex with men in many Eastern European and Central Asian countries. Studies are rare but networks of men who have sex with men have been documented in several countries and scattered surveys of sexual behavior (for example, in the Russian Federation and Ukraine) have pointed to high levels of unprotected sex. Men who have sex with men, like injecting drug users and sex workers, endure routine stigma and discrimination, both at the hands of officialdom and society at large. Reliable sentinel surveillance and appropriate prevention services for men who have sex with men could help limit the epidemic's spread through and beyond their ranks.[30]

In the Baltic states, HIV transmission is occurring at a brisk rate, even if the overall numbers of infections remain low. The total number of HIV diagnoses in Latvia has risen at least fivefold since 1999, reaching more than 2500 in 2003. Just 4 years ago, Estonia reported 12 new HIV cases; in 2003, 840 people were newly diagnosed with the virus. In Lithuania, the 72 new HIV cases detected in 2001 increased more than fivefold the following year. In Belarus (where more than 5000 people had been officially diagnosed with HIV by

Newly registered HIV cases and HIV-seropositive children born to HIV-infected mothers, Ukraine, 1987–2003

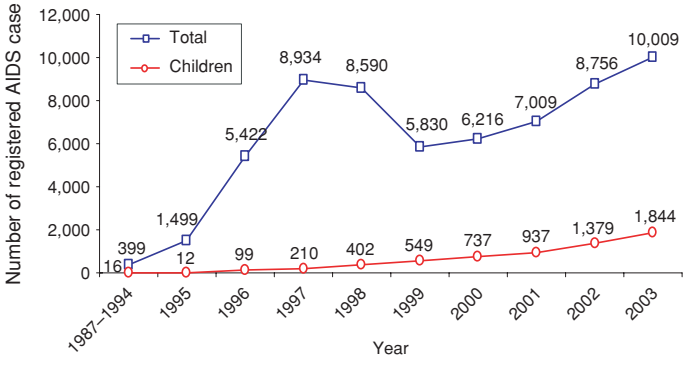

FIGURE 4-10. Newly registered HIV cases and HIV-seropositive children born to HIV-infected mothers, Ukraine, 1987–2003. (*Source:* Ukrainian Centre for HIV Prevention.)

mid-2003) and Moldova (where the figure stood at just under 1800), most infections are occurring among young drug injectors and their sexual partners.)[9]

HIV prevalence remains very low (less than 0.3%) in most of the Central Asian and Caucasian republics, but behavior patterns favor significant spread of the virus and the overall number of registered infections continues to rise formidably in Uzbekistan, which now hosts one of the youngest epidemics in the world (Fig. 4-11). Approximately 90% of all reported infections in Uzbekistan were diagnosed between 2001 and mid-2003, by which point more than 2500 HIV cases had already been reported. A total of 3600 HIV cases had been reported in Kazakhstan by mid-2003. In the Caucuses, significant HIV outbreaks are underway in Azerbaijan, where one in four street drug injectors in the capital, Baku, has been found to be HIV-positive, as were 11% of street-based sex workers).[29]

In parts of south-eastern Europe (notably countries emerging from conflict and difficult transitions) drug injecting and sexual risk behavior appear to be on the increase, and rising numbers of HIV infections could follow. Relatively "young" epidemics such as these can be halted with prevention strategies that concentrate on reaching those who are currently most at risk of exposure to HIV.

There are many opportunities to improve the AIDS response. Surveys show that just 10% of sex workers, less than 8% of injecting drug users, and only 4% of men who have sex with men are being reached with prevention services. Just over 11% of people who need antiretroviral drugs currently are being treated, and for HIV-positive drug injectors, treatment access is still rare to nonexistent in the worst-affected countries. Although Russian law assures free, universal access to antiretroviral drugs for all citizens, current estimates suggest that fewer than 3000 people living with HIV are receiving antiretroviral medication, less than 5% of them injecting drug users in remission. In Ukraine, an estimated 13% of people in need of antiretroviral therapy are getting it, and treatment for drug injectors is not yet supported by substitution therapy.

MIDDLE EAST AND NORTH AFRICA

Latest estimates confirm that the Middle East and North Africa have not eluded the AIDS epidemic's advance. Approximately 58,000 (25,000–145,000) people became infected with HIV in 2005, bringing to 510,000 (230,000–1.4 million) the total number of people living with the virus in this region.[1] AIDS killed an estimated 67,000 (35,000–200,000) people in 2005. With HIV being transmitted along diverse paths in this region, including paid sex, sex between men, and injecting drug use, there is considerable scope for further expansion of the epidemic.

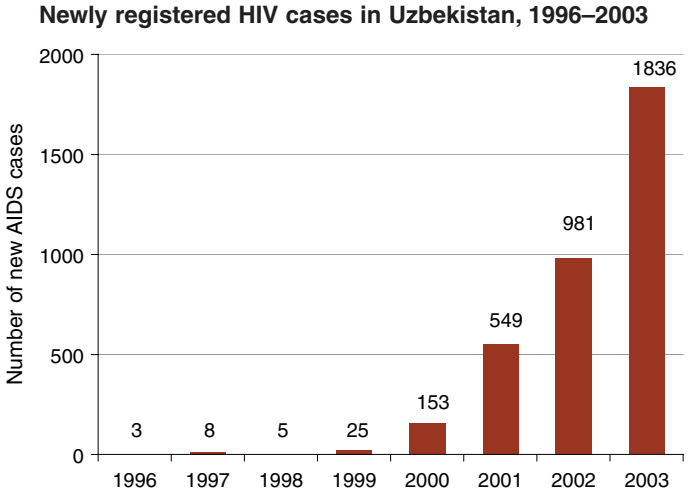

FIGURE 4-11. Newly registered HIV cases in Uzbekistan, 1996–2003. (*Source:* Republican AIDS Centre, 2003.)

Sudan is the region's worst-affected country, with its epidemic concentrated largely in the south. The gradual cessation of conflict in parts of the country could accelerate HIV spread, as people resume their usual patterns of travel and trade.

In most other countries of the region, the epidemics are still in their early stages, which increase the chances that effective prevention efforts can limit the spread of HIV. However, inadequate HIV surveillance data in several countries could mean that significant HIV outbreaks in some populations (including men who have sex with men and injecting drug users) are being missed. Morocco, where the number of annual new HIV diagnoses in 2003 was almost 3 times higher than in 2001, could be a case in point.[13]

Libya's epidemic has also been growing markedly, with almost 90% of its officially reported 5160 HIV infections (at end-2002) having occurred in 2000–2002 alone. Over 90% of those reported HIV cases are attributed to injecting drug use, much of it concentrated in the capital, Tripoli. Injecting drug use appears to be the main driver of HIV transmission in neighboring Tunisia, while a substantial share of HIV infections in Algeria, Bahrain, Kuwait, and Oman has been attributed to injecting drug use, highlighting an urgent need to expand and integrate HIV-prevention and AIDS-care services for drug injectors.

Iran has taken some positive steps in a bid to contain its epidemic, which has been growing in the wake of a dramatic rise in the overall number of people who inject drugs. About 15% of all HIV infections since the start of Iran's epidemic were reported in 2003 alone, most of them among the country's estimated 200,000 drug injectors.[31] Unlike most other countries in the region, Iran has made needles and syringes available over the counter in pharmacies, a move which could be reducing the use of nonsterile needles by half. These moves need to be supplemented with prevention programs

that can limit HIV transmission from injecting drug users to their sex partners, given that research shows about half of drug injectors in Iran are married.

Meanwhile, in Yemen and in parts of Algeria, the epidemic appears to be centered on the sex-work industry. Sentinel surveillance conducted in Algeria in 2004 found 9% of the sex workers tested in Tamanrasset, compared to 1.7% just 4 years earlier.[32] There and elsewhere in the region, more in-depth information is needed about patterns of HIV transmission and the possible role of sex work and sex between men in the epidemic.

Overall, more effective prevention efforts are needed across the region. Even basic steps such as condom promotion are largely absent and steps to defuse the social stigma and institutional discrimination experienced by vulnerable groups remain few and far between; so, too, education and communication to deepen public knowledge of the epidemic.

HIGH-INCOME COUNTRIES

An estimated 1.9 million people (1.3–2.6 million) are living with HIV in North America and in Western and Central Europe.

In high-income countries, where the great majority of people who need antiretroviral treatment do have access to it, people living with HIV are staying healthy and surviving longer than infected people elsewhere. Widespread access to life-extending antiretroviral treatment kept the number of AIDS deaths at between 19,000 and 42,000 in 2005. However, prevention efforts are not keeping pace with the changing epidemics in several countries. Sex between men is the most common route of infection in Australia, Canada, Denmark, Germany, Greece, and the United States. Patterns of HIV transmission are changing with an increasing proportion of people becoming infected through unprotected heterosexual intercourse. In Belgium, Norway, and the UK, the increase in heterosexually transmitted infections is dominated by people from countries with generalized epidemics, predominantly sub-Saharan Africa. In the United States, about half of newly reported infections are among African Americans who represent 12% of the population. Their HIV prevalence is 11 times higher than among whites. In New York City, over 1% of the city's adult population, and almost 2% of Manhattan's, was HIV-positive in 2001.

Drug injecting accounted for more than 10% of all reported HIV infections in Western Europe in 2002 (in Portugal it was responsible for over 50% of cases). In Canada and the United States, about 25% of HIV infections are attributed to drug injecting. Infections transmitted through contaminated injecting equipment are particularly frequent among indigenous people, who are often among the poorest and most marginalized inhabitants of the industrialized world.

5 The Epidemiology of STIs and Their Social and Behavioral Determinants: Industrialized and Developing Countries

Sevgi O. Aral and King K. Holmes

INTRODUCTION

The incidence, prevalence, and population distribution of sexually transmitted infections (STIs) are largely determined by the complex interplay of dynamically changing demographic, economic, social, and behavioral forces and the response of the health system to emergent STI morbidity patterns. Over the past 3 decades, overall incidence and prevalence of bacterial STI, in particular gonorrhea, syphilis, chancroid, and chlamydial infections have declined in the United States, Western Europe, and many developing countries, to their lowest levels since World War II. Declines in bacterial STI in developing countries are attributed to the widespread implementation of syndromic management and to a large-scale shift to safer sexual behaviors in response to the HIV epidemic. Despite such remarkable declines, rates of some bacterial STI are still high and/or increasing in some subpopulations (e.g., adolescent African American women in the United States and homosexual men in Western Europe and the United States); and rates of some bacterial STI (e.g., chlamydial infections) seem to have plateaued. During the past decade prevalences of viral STI, particularly genital herpes infections (HSV), appear to have increased in many countries even though incidence of genital herpes infections has declined remarkably in the United States most recently. The increases in genital herpes and genital warts observed in many countries may be due to increased recognition. Absolute increases in genital herpes in developing countries, particularly in Africa, may be due to increased recurrent herpes caused by immunosuppression due to HIV infection; the relative increase in the proportion of genital ulcer disease (GUD) attributable to herpes also reflects declines in bacterial GUD. Diagnosis, management, and control of viral STIs have changed drastically over the past decade. The introduction of new diagnostic technologies has increased recognition of viral STI, improved sensitivity in identification of bacterial STI, and expanded the repertoire of usable specimens. The use of urine and vaginal swabs has greatly expanded coverage of screening services and has led to the availability of true population-based estimates of the prevalences of STIs.[1] Implementation of integrated behavioral prevention interventions including "abstain," "be faithful," and "use condoms" (the ABC interventions) appears to have resulted in decreased transmission of STI including HIV in some countries like Uganda[2] raising optimistic expectations regarding STI prevention. However, the most recent surveillance data suggest that HIV incidence may again be increasing in Uganda.[3] Introduction of therapeutic and prophylactic vaccines and suppressive therapies raises new behavioral concerns including issues of adherence and the potential for behavioral disinhibition; they also raise issues related to service delivery, technology dissemination, and acceptability. In fact, the simultaneous availability of new preventive and therapeutic interventions, including not only vaccines and suppressive therapy but also male circumcision, and perhaps effective microbicides, renders behavioral disinhibition a central issue. In contrast to overall declines in STI rates in industrialized countries, STIs among homosexual and other men who have sex with men (MSM) are again increasing. These increases further raise concerns about behavioral disinhibition, in this case, disinhibition, which may be related to antiretroviral therapy (ART). The increasing STI rates among MSM are observed consistently across the United States and Western Europe and in light of the global interconnectedness of MSM sexual networks,[4] are expected to expand to other geographic regions.[5] In all societies, for many reasons discussed in this chapter, STIs tend to concentrate in certain populations including urban, poor, and minority populations, with highest rates among sexually active adolescent females followed by adolescent and young adult men. This pattern is particularly pronounced in western industrialized countries where effective prevention and control efforts result in concentrated STI morbidity. During the past decade commercial sex has become an increasingly important factor in STI transmission[6,7] in many areas of the world including the United States and Western Europe. Sex workers tend to include both local and

migrant women and men who move in response to supply and demand conditions and tend to have unstable contact with health-care providers. Social problems such as growing economic inequity between the rich and the poor, political instability, wars (including civil wars), unemployment, low education and low status of women, and globalization[6,8] contribute to the expansion of commercial sex and mobility of sex workers; they also result in behaviors that fuel the hyperendemic transmission of STIs with continuing epidemic spread of HIV infection. Globalization also results in the interconnectedness of all sexual networks, through travel, and particularly of commercial sexual networks due to the mobility of sex workers and their clients.

EVOLVING CONCEPTS IN STI EPIDEMIOLOGY

The three direct determinants of the rate of spread of each sexually transmissible pathogen are: (1) probability of exposure of susceptible to infectious persons; (2) the mean efficiency of sexual transmission when such exposures occur; and (3) the mean duration of infectiousness of individuals who become infected. Efforts to understand the dynamics of transmission focus on the factors that influence these three component determinants of transmission.[9]

EXPOSURE OF SUSCEPTIBLE TO INFECTED PERSONS

National surveys of sexual behavior in a number of countries have revealed that, at any point in time, the great majority of the population does not engage in high-risk sexual behaviors, even though many individuals go through life stages during which they do. A recent review of sexual behavior data from 59 countries suggests substantial diversity in sexual behavior by region and sex.[10] According to these data no recent universal trend toward earlier sexual intercourse has occurred, although the shift toward delayed marriage in most countries resulted in an increase in premarital sex; the prevalence of premarital sex is higher in developed countries compared to developing countries and among men compared to women. In all countries, monogamy is the dominant pattern; having had two or more sex partners in the past year is more common in industrialized compared to nonindustrialized countries and among men compared to women. Reported condom use has increased in most countries; however, rates remain low in many developing countries. Population-based studies including those in San Francisco, Uganda, and Thailand, have indicated, respectively, patterns of sexual mixing to be potential risk factors for HIV infection, concurrent partnerships (as apposed to sequential "serial monogamy") to increase the rate of spread of STIs, and bridge populations to spread infection from high to low prevalence subgroups within a population[11–14] (see Chapter 7).

EFFICIENCY OF TRANSMISSION PER EXPOSURE

Determinants of efficiency of sexual transmission include host susceptibility, the infectious virulence of the pathogen (e.g., the 50% infectious dose, or ID_{50}, assuming host susceptibility is held constant), and the amount or concentration of pathogens shed in semen or genital fluids, which in turn is related to the natural history of infection. The types of sexual exposure (i.e., sexual practices) also indirectly influence susceptibility, operating through host susceptibility, which varies according to the anatomic site exposed. Similarly, the "infectivity" of the infected person operates through the inoculum size delivered and the infectious virulence of the pathogen, both of which may vary in different stages of infection. In addition, recent research has indicated that male circumcision status influences the susceptibility and perhaps the infectivity status of a man.[15]

DURATION OF INFECTIVITY

The duration of infectivity is also based on the natural history of each type of infection, the effectiveness of the host immune response in controlling genital shedding or clearing the infection, as well as on the intrinsic efficacy and use-effectiveness (including population coverage, uptake, and adherence with the required dosage schedule) of antimicrobial therapy or immunity-enhancing approaches to shortening this duration.

Preventive interventions can operate on more than one of the preceding determinants of transmission. For example, vaccines or acquired immunity can produce absolute immunity to infection, thereby decreasing the number of susceptibles in the population and decreasing exposure of susceptibles to infected; can create partial immunity to infection, thereby decreasing the efficiency of transmission, especially for low inoculum exposures; or could simply attenuate infection, allowing infection to occur on exposure, but shortening the duration of infectivity, and perhaps decreasing the inoculum size and efficiency of subsequent transmission to a new partner.

TIMING, INTENSITY, AND TARGETING OF PREVENTIVE INTERVENTIONS

Increasingly, changes in STI rates and their determinants are understood within a framework of time-dependent mutual interaction between the spread of a specific STI and the efforts developed to prevent it. Very small but early beginnings can have large-scale impact both in the spread of STIs and in their prevention. Because the product of the three determinants of transmission must reach a critical threshold before an STI pathogen can spread within a population, even a trivial reduction in one or more of the determinants could, in theory, drop the reproductive rate of spread below that

threshold and ultimately eliminate the pathogen from the population. In the infected individual, the antimicrobial susceptibility of the pathogen, the rate at which the pathogen replicates itself, and the activity and half-life of the antibiotic, determine the choice, dose, and timing of antibiotic therapy. Similarly, in preventing spread of STIs in populations, the mean duration and mean efficiency of transmission of the infection, the density and interconnectedness of affected sexual networks, and the effectiveness of preventive interventions determine the intensity, mix, schedule, and target of preventive interventions required. Cost-effectiveness modeling repeatedly indicates that compared to interventions for the general population, targeted interventions that focus on core groups have greater impact and are most cost-effective.[16–18] (Van Vliet C, et al. unpublished data)

The general inadequacy of STI health-care services in the United States suggests the contribution of inadequate STI services to STI morbidity in populations.[19] Data now accumulating on STI-related health-care seeking indicate the role of health behaviors on duration of infectiousness, and hence, on STI epidemiology (see Chapter 92).

EMERGENT INSIGHTS ABOUT STI EPIDEMIOLOGY AND PREVENTION

Since the late 1990s, when the third version of this chapter was prepared, continued analyses of data from diverse areas have led to emergent insights about STI epidemiology and prevention, as briefly discussed below.

- Populations consist of many diverse subpopulations, and each population-level epidemic trajectory consists of many distinct subpopulation epidemic trajectories.[20] The epidemic trajectories of specific STIs differ depending on when and where the infection was introduced; the structure of sexual networks; the demographic, economic, social, and epidemiological context; and the state of the health system.[1]
- Temporal dimensions are important in relation to STI epidemiology.[21] At the individual level, concurrency of partnerships and short gaps between partnerships are risk factors for the acquisition and transmission of STIs.[22–24] At the population level, investigators have described the evolution of STI epidemics through sometimes predictable phases, characterized by changing patterns in the distribution and transmission of STI pathogens within and between subpopulations.[25,26]
- The timing of high and low levels of infectiousness during the natural history of infection further underscores the importance of the temporal dimension. At the individual level the possibility of infecting sex partners appears to be particularly high early during the natural history of infection, before the immune response begins to reduce genital shedding of STI pathogens; and then again, for HIV, late in the infection when plasma viral load and genital shedding again increase.[27,28] Thus, concurrent partnerships and short gaps happen very early after acquiring an STI and very late during HIV infection; this would be particularly important in spreading disease. Interestingly, people may go through developmental phases of hypersexual mixing activity, (e.g., as steady partnerships dissolve and new partnerships are sought) when they engage in concurrent partnerships and may expose themselves or their partners to infection simultaneously. These developmental phases effectively link hypersexual activity with hyperinfectious, acute infections, creating short periods of heightened risk of transmission, when concordant partnerships and short gaps converge with acute STI and high levels of genital shedding of STI pathogens. As an STI is introduced and spreads through a population, cohorts with acute infections may move together through the stage of high infectiousness plus concurrent partnerships, accentuating increases in STI incidence.
- Sexual networks are important in the transmission dynamics of STIs at the population level, and position in a sexual network is important in the transmission and acquisition of STIs at the individual level[29] (see Chapter 7).
- Trajectories whereby STI epidemics evolve differ for different types of population–pathogen interactions.[30–32] Whereas highly infectious, short duration bacterial STIs—for instance, gonorrhea—depend on the presence of core groups marked by multiple sex partnerships (often of short duration) for their spread, less infectious, long duration viral STIs—for example, herpes simplex virus (HSV) or human papillomavirus (HPV) infections—are less dependent on multiple partnerships of short duration or on short gaps between partnerships. Thus, the pattern of spatial and population distribution of various STIs differs markedly. Syphilis and gonorrhea tend to be concentrated in individuals with multiple partnerships and in populations with highly connected sexual networks; whereas genital chlamydial infections, genital herpes, and genital HPV infections are much more ecumenically, widely distributed across the entire population.[33]
- Interactions among sexually transmitted pathogens affect STI epidemic trajectories at the population level.[34] The inconsistent findings of three landmark randomized community trials evaluating the effect of STI treatment on HIV transmission[35–37] can be accounted for by the phase-specific nature of STI epidemics, with higher prevalences of HIV and declining levels of STI in the two Uganda studies that showed no impact of STI treatment.[38]
- Epidemiologic, behavioral, and social context are highly important in determining the epidemiology of each STI and the potential impact of preventive interventions.

Prevalence, incidence, and distribution of infection(s) and interactions among sexually transmitted pathogens constitute the epidemiological context while the prevalence, incidence, and distribution of each risk and preventive behavior and interactions among distinct risk and preventive behaviors constitute the behavioral context. The impact of a condom use intervention on STI rates depends on the existing prevalence of condom use among high and low risk groups, on whether high or low risk groups receive the intervention, and on the prevalence, incidence, and distribution of infections. Social context includes societal determinants of risk and preventive behaviors and may determine whether or not behaviors can change in response to behavioral interventions. In the context of extreme poverty and/or extreme lack of power and of autonomy, behavioral elasticity (ability to change behaviors) may be close to zero. For example, women in many developing countries who cannot ask their husbands to use condoms, and drug-using sex workers who cannot negotiate condom use with clients for fear of losing them lack behavioral elasticity due to social context. Prevention program planning must be based on a detailed understanding of the local epidemiologic, behavioral, and social context.[20]

- Most recent studies of STI epidemiology highlight the heterogeneity in affected populations, in epidemic trajectories, in social and behavioral contexts, in costs of STIs, and in cost-effectiveness of biomedical and behavioral interventions.[39]
- The most common modality of STI intervention research to date has involved behavior change interventions. Recent reviews provide several insights into such research.[40] First, most evidence is on individual level interventions aimed at reducing STI acquisition, even though individual level interventions may be costly and difficult to sustain. Second, theory-based interventions did not show an effect more frequently than non–theory-based behavioral interventions. Third, behavioral interventions delivered in small group settings were as effective as those delivered to individuals. Fourth, the effect of a particular behavior change on STI risk depended on the type of STI. For example, one review suggested that the number of sex partners may be more predictive of risk for highly infectious STIs than for HIV, and the number of unprotected sex acts may be more predictive of risk for HIV than for highly infectious STI.[41] The one exception to this generalization may be the initial stage of HIV infection—"the acute hyperinfectiousness" stage.[27] Available evidence suggests that during this initial stage of HIV infection (and during the final immunosuppressed stage) behavioral determinants of HIV infection may more closely resemble those of other highly infectious STIs. Finally, a number of intervention trials result in demonstrated declines in risk behavior and yet have no effect on STIs, or even result in increases in STIs. This observation calls into question the use of behavioral outcome measures as indicators of biomedical outcomes.[42]
- Unprecedented increases in travel and communication have had major impact on the global connectedness of sexual networks. Consequently, interconnected STI epidemics are increasingly observed in some populations. Recent outbreaks of syphilis among MSM in many areas of the United States, UK, Western Europe, and Australia are examples of the global connectedness of sexual networks.[4]
- Important methodological advances have taken place in the design, analysis, and interpretation of randomized trials—the gold standard in intervention research. Individual variation in response to medications has implications for the interpretation of individual randomized drug trials.[43,44] The population level variations in cluster-randomized trials (CRTs), which are increasingly used to evaluate the impact of public health interventions have been the subject of considerable discussion. It is now clear that the matching or stratification of clusters and the number and size of the clusters to be randomized can affect the power of a CRT.[45] Moreover, the interdependency of individual outcomes within clusters must be accounted for. The role of cluster-level covariants requires careful consideration in the interpretation of CRT results.[46] An additional methodological advance, not surprisingly involves the increased emphasis on measuring "adherence" to the intervention for the analysis of results of prevention trials. Lack of adherence may be particularly problematic in intent-to-treat analyses.
- Finally, all preventive interventions may have unintended consequences that may modify their net impact. Behavioral disinhibition, the potential increase in unsafe sexual behaviors in response to the introduction of effective preventive and/or therapeutic STI/HIV interventions, is only one type of unintended consequence. Behavioral disinhibition (also euphemistically termed "risk compensation") involves the perception of lowered risk by an individual or society, resulting in lessened perception of need for risk avoidance. Many other unintended consequences of interventions take place at the network and structural levels. For example, police raids to known sex work areas or bathhouses break down existing sexual networks and cause the formation of new networks, with altered probability of exposure between high-risk/infected persons and those who are low-risk/uninfected persons. Interventions that encouraged MSM to learn their HIV serostatus and avoid unprotected sex with serodiscordant partners may have unintentionally caused increases in syphilis incidence by increasing the practice of unprotected sexual intercourse between HIV seroconcordant MSM.[5]

DESCRIPTIVE EPIDEMIOLOGY OF SELECTED STIS AND SEXUALLY TRANSMITTED INFECTIONS

Subsequent chapters of this book describe the epidemiology of various STIs and STI pathogens in detail. This chapter focuses on cross-cutting comparisons that illustrate general or differing aspects of STI epidemiology. Not all STIs are reportable, and even reportable diseases are seldom reported completely or with complete specificity. Data from most of the world are sketchy, occasionally based on prospective cohort studies of incidence, or on serially repeated prevalence surveys but more often based on sporadic prevalence surveys, or solely on anecdotes. Populations sampled in developing societies have most often included sexually transmitted disease (STD) clinic patients or family planning clinic patients, who are not representative of the total population and have less often included prenatal or primary care clinics or other somewhat more representative population samples. Prenatal samples generally best represent sexually active, noncontracepting fertile married women of reproductive age who seek prenatal care, although they often underrepresent the single women who are at highest risk and underrepresent women rendered infertile or subfertile by past or present STIs, including HIV infection and they underrepresent women without access to acceptable hospital-based care. It is interesting that recent comparative assessments of HIV seroprevalence in antenatal women and in random household samples of the general populations in African countries have shown significantly higher HIV prevalences in antenatal women. A detailed review of the descriptive epidemiology of STIs in individual developing countries is beyond the scope of this chapter.

The most recent updated estimates for prevalence and incidence of STIs globally are provided by the WHO.[47] These estimates suggest that of 340 million new cases of gonorrhea, syphilis, chlamydial infection, chancroid, and trichomoniasis STIs in 1999 under 10% occurred in North America and Western Europe; over 90% of new infections were in developing countries (Table 5-1). In 1999, the overall estimated number of new cases of chlamydia, gonorrhea, and syphilis infections among 15–49-year-old men and women totaled over 166 million with close to 92 million cases of chlamydial infection, 62.35 million cases of gonorrhea, and 11.76 million cases of syphilis (Table 5-2). In addition, there were an estimated 173.46 million cases of trichomoniasis.

In developing countries, passive surveillance of STI morbidity is particularly inadequate. However, in recent years the epidemiology of STIs in sub-Saharan Africa is better defined based on large population-based prevalence surveys. The results of these surveys have confirmed the high prevalences of STIs even in rural populations, for example, syphilis (5–10% of adults infected), vaginal trichomoniasis (20–30% of women), and bacterial vaginosis (up to 50% of women). Syphilis has been estimated to cause 490,000 stillbirths and neonatal deaths per year in Africa—a figure similar to the number of children dying of HIV/AIDS worldwide.[48]

During the HIV/AIDS era, in areas where some form of active ongoing STI surveillance has been conducted, the incidence of gonorrhea, chancroid, and syphilis has declined markedly since the mid 1990s. This is likely related to reduction in risk behaviors during the HIV/AIDS era and to widespread promotion of STID syndromic management, especially for the curable bacterial genital ulcers, and for urethritis in men. Mortality among those who were at greatest sexual risk and acquired HIV infection early also likely has contributed. The fact that prospective data on trends in STI were collected predominantly in settings where STI programs were most strongly implemented—e.g., Thailand, Kenya, parts of South Africa and West Africa, the Caribbean—suggests that the available data are not necessarily widely generalizable.

In North America and many countries of Europe, as well as Australia and New Zealand, better data on reported STIs showed steady increases in the incidence of all STIs during the 1960s, with leveling off or decline of most of the bacterial STIs but continual increases in viral STIs and genital chlamydial infections during the 1970s and 1980s. The incidence of the best measured STIs, gonorrhea and syphilis, began to decline at different times, and declined at differing rates, in these industrialized countries but fell more rapidly, especially among MSM during the AIDS era, over the last quarter century. The sex ratio of males to females with bacterial STIs has declined for several decades. During the late 1980s and the 1990s, chlamydial infections began declining in Nordic countries and in the areas of the United States and Canada and wherever chlamydia control programs have been initiated. In contrast, some countries that underwent major political change and opened their borders and/or allowed increasing mobility of their populations and saw rapid social changes, experienced explosive epidemics of bacterial STIs (e.g., China, Mongolia, and Russia and the newly independent states of the former USSR). Many countries in Eastern Europe, Southern Africa, and Asia have continued to experience epidemic increases in HIV infection.[49–51]

Since the mid 1990s a number of the declining trends in the Northern Hemisphere have reversed themselves.[52] Large-scale demographic changes in patterns of fertility, mortality, migration, marriage, and divorce have played an important role in the reemergence of selected STIs (see discussion in the section on the demographic, social, political, and technologic context). In the UK, Ireland, and Sweden diagnoses of gonorrhea more than doubled between 1995 and 2004. Similar increases have been observed in reported syphilis in Belgium, the UK, and Ireland (Table 5-3). Increases in reported gonorrhea and syphilis have been observed in Spain, Denmark, Austria, France, Finland, Netherlands, and Sweden. The increases have been most marked among MSM, since the advent of highly active ART in 1995, and also among young people, residents of major metropolitan areas, and migrant and ethnic minority communities. The reemergence of anorectal lymphogranuloma venereum among MSM after it had virtually disappeared in several European countries and in North America, is another striking example. Factors contributing to increases in incidence of curable STI include high prevalences of infection in countries of origin; higher prevalences of risk behaviors, often associated with increasing recreational drug use in some countries, such as the United

States; and poor access to acceptable prevention and treatment services. Changes in commercial sex patterns and networks (discussed later in the section on demographic social, political, and technologic context) have also contributed to increases in STI incidence.

The WHO categorizes the countries included in the European region into three geographic areas: West, Centre, and East (Table 5-4). Patterns of STI transmission have changed over time and differ markedly between these geographic regions.[53] Although underreporting is common, and reported incidence data do not precisely reflect the numbers of new cases, they provide indicators of trends over time. Particularly noteworthy is the epidemics of syphilis and gonorrhea that spread throughout much of Eastern Europe soon

after the dissolution of the Soviet Union. The reported incidence of both diseases has subsequently declined throughout Eastern Europe, probably reflecting both HIV/AIDS-related behavior change and the intrinsic effectiveness of strengthened public health and clinical programs for control of these two STIs. Data from the WHO European Region Member States and from the United States are the most accessible and comprise the basis of discussions on specific STI below.

GONORRHEA

TRENDS IN INDUSTRIALIZED COUNTRIES

The major bacterial STIs include gonorrhea, chlamydial infection, syphilis, and in many developing countries, chancroid. In most European Union (EU) countries gonorrhea started declining in the 1970s and continued to decline at an accelerated rate during the second half of 1980s. The declines continued into the early 1990s. In many EU states, gonorrhea rates reached their lowest point in 1995. However, increases in reported cases and incidence rates of gonorrhea have been observed since the late 1990s. In Belgium, gonorrhea incidence increased starting in 1997. The incidence in 25–44-year-old men rose from 3 per 100,000 population in 1995 to 3.5 per 100,000 in 1997 and 5 per 100,000 in 1998.[52] Gonorrhea diagnoses more than doubled between 1996 and 2001 in England and Wales and Northern Ireland; 40% of diagnoses among women occurred among those under 20 years of age. In Ireland, there was a 320% increase in reported gonorrhea cases between 1996 and 2001; 75.9% of cases in 2001 were among men. In Austria, the number of reported gonorrhea cases increased from 414 in 2000 to 995 in 2002; the increase was observed among both men and women. Some countries in Europe did report a continued decline in cases of gonorrhea during this period. In Spain, rates of reported gonorrhea declined from 18.6 per 100,000 population to 3.9 per 100,000 population between 1993 and 1999. In Norway, reported cases of gonorrhea decreased from 944 cases in 1990 to 175 in 1995, increased to 223 in 1996 but remained below 200 after 1996. In Sweden, gonorrhea cases increased between 1997 and 2000 but declined in 2001 and 2002 resulting in an infection rate of 5.6 per 100,000 population. However, cases increased during the first half of 2003 compared to the first half of 2002.[52] As noted above, in many countries in the EU gonorrhea incidence is concentrated among the young, MSM, and in socioeconomically deprived communities.[52]

In the United States, the rate of reported gonorrhea declined 74% from 1975 to 1997, then plateaued.[54] In 2005, 339,593 cases of gonorrhea were reported corresponding to a rate of 115.6 per 100,000 population—an increase from 2004 and vastly higher than in other industrialized countries; in fact, the annual incidence of gonorrhea per 100,000 population in the United States approached the total number of cases per country in several EU countries. As earlier, in 2005 the South had the highest gonorrhea rate in the United States. Interestingly, between 2001 and 2005 the gonorrhea rate in the South declined by 17.6% while that in the West has increased by 35.4% from 60.2 cases per 100,000 population to 81.5 cases in 2005. For the fourth year, the gonorrhea rate in women was slightly higher than that among men in 2005; 119.1 per 100,000 population and 111.5 per 100,000 population, respectively. Rates of gonorrhea are highest among 15–19-year-old women and among 20–24-year-old men. Although the gonorrhea rate among 15–19-year-olds has decreased in recent years, this rate increased 3.9% between 2004 and 2005 from 421.9 per 100,000 population to 438.2 per 100,000 population (Fig. 5-1). As before, in 2005, African American 15–19-year-old females had the highest gonorrhea rate among all age and race-ethnicity groups (2814 cases per 100,000 population). Gonorrhea rates among African American men and women did decline from 2001 to 2005 by 19.4% and 16.1%, respectively. Conversely, gonorrhea rates among white men and women increased from 2001 to 2005 by 18.9% and 20.4%, respectively (Figs 5-1 and 5-2).

INFLUENCE OF SOCIODEMOGRAPHIC FACTORS ON GONORRHEA MORBIDITY: MECHANISMS OF ACTION

Both socioeconomic status and racial ethnic background are highly correlated with gonorrhea morbidity in the United States and Western Europe.[9,52,55] In the United States, gonorrhea ranked number one among notifiable diseases; racial disparities were greatest in 2002 with a black/white rate ratio of 24.2.[56] Moreover, racial differences in STIs persist after controlling for indicators of socioeconomic status (SES).[57–59] Recent research has focused increasingly on the reasons for racial, ethnic, and socioeconomic disparities. Sexual mixing patterns are segregated by race and socioeconomic status.[60,61] In addition, minorities are more likely to (sexually) mix with others from other risk groups than their own.[61] The combination

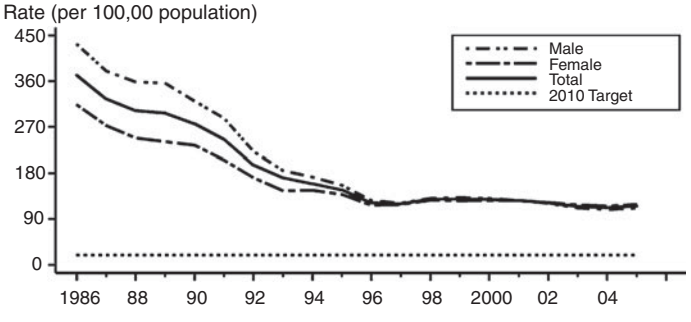

FIGURE 5-1. Gonorrhea rates: total and by sex: United States, 1986–2005 and the healthy people 2010 target. (From Centers for Disease Control and Prevention. *Sexually Transmitted Disease Surveillance, 2005*. Atlanta, GA: US Department of Health and Human Services, Nov 2006.)

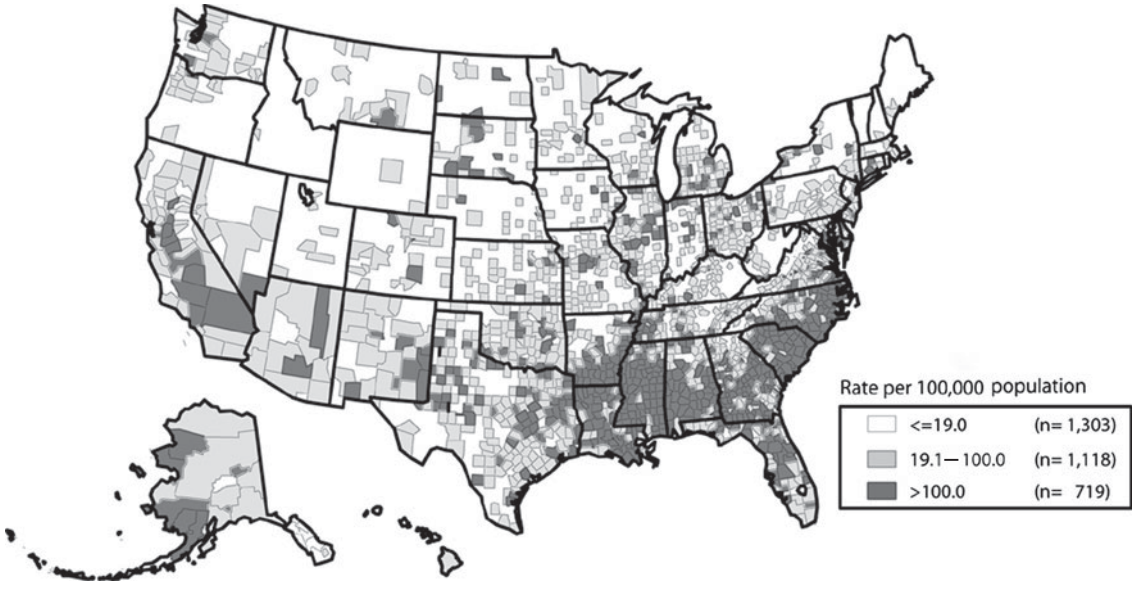

FIGURE 5-2. Gonorrhea rates by county: United States, 2005. (From Centers for Disease Control and Prevention. *Sexually Transmitted Disease Surveillance, 2005*. Atlanta, GA: US Department of Health and Human Services, Nov 2006.)

of assortative mixing by race (and probably socioeconomic status) and disassortative mixing by risk group may contribute to very high rates of all STIs including gonorrhea.[59] Individual behaviors do not account for the disparities; in the United States, while white young adults are at increased STI and HIV risk when they engage in high risk behaviors, black young adults are at high risk even when their behaviors are normative.[59] Interestingly, evidence suggests that socioeconomic status like risk behaviors, may be more strongly associated with STI among white populations compared to African American populations.[58,61]

Residential segregation patterns may also contribute to sociodemographic disparities in gonorrhea and other STIs. In fact, segregation in sexual mixing patterns and residential patterns may interact so as to have a multiplicative impact on racial ethnic disparities in gonorrhea rates and rates of other STIs. The segregation of sexual networks is in part a function of the availability of sexual partners which has a significant geographic component that reflects patterns of social and residential interaction.[62–66] Research that employs "cluster detection analysis" to identify critical STI transmission locations suggests that risks for gonorrhea are associated with definable sociogeographic spaces.[67] Statistically significant geographic clustering of reported gonorrhea cases in Baltimore was observed after adjustment for African American race/ethnicity. These findings suggest that both residential patterns and sex partner preferences may act as macroboundaries to sexual network formation. This pattern may apply to both racial-ethnic and socioeconomic characteristics and may help account for both types of disparities in rates of gonorrhea and other STIs.[67]

Another potential explanation suggested for the strong association of race, ethnicity, and socioeconomic status with gonorrhea is that deteriorated physical conditions of local neighborhoods may increase high-risk behaviors.[68] However, this association may not be causal.

Inadequate treatment can result in preventable onward transmission of gonorrhea, and a recent mathematical model demonstrated the importance of timely delivery of effective health care in preventing onward transmission of gonococcal infection.[69] Inadequate treatment capacity, as observed in the UK, or unacceptable services, as reported by African American men in the United States, can lead to disruptions and delays in the timely delivery of effective health care. This can lead to the establishment of "vicious circles" in the dynamics of further gonorrhea transmission.

As gonorrhea prevalence and incidence became concentrated in particular, separated populations, issues of "elimination, introduction, and reintroduction of infection" become important. Spatial bridging, sexual mixing between distant geographic areas, may represent an important mechanism of introduction and channel of transmission between geographic areas.[70] Since sexual mixing tends to be assortative with respect to race/ethnicity and socioeconomic status, spatial bridging may contribute to sociodemographic disparities in gonorrhea morbidity across local areas.

Increasing globalization, international trade, and travel have become increasingly important in the spread of new variants of sexually transmitted pathogens, such as fluoroquinolone-resistant gonococci. Molecular typing of *Neisseria gonorrhoeae* combined with contact tracing provides a unique and powerful approach to the identification of sexual networks in metropolitan areas,[71] with potential for analyzing spatial and other types of bridging, sexual mixing, and introduction of distinct strains of gonorrhea into specific networks and local areas. Such approaches

could be usefully employed in the future to help understand the different patterns of spread of other communicable disease pathogens, such as specific strains of methicillin-resistant *staphylococcus aureus,* for example.

Gonorrhea incidence among MSM declined remarkably in response to the HIV epidemic during the 1980s but started increasing in discrete local areas in the United States in the early 1990s[9] and subsequently in many European countries. In recent reports 17.4% of all gonorrhea diagnoses in men in England and Wales and Northern Ireland, were acquired through sex between men;[52] 44.8% of the gonorrhea cases in Sweden in 2002 were among MSM; and in Denmark, MSM accounted for a disproportionately large burden of gonorrhea with highest incidence occurring in HIV-infected MSM (483.3 per 100,000 population per year). In Europe, there has been a strong association between gonococcal infection and overseas travel, highlighting the importance of spatial bridging in importing gonorrhea to Europe (with its relatively low rates of gonorrhea) from parts of the world with much higher rates.

Data from several U.S. cities and projects including the Gonococcal Isolate Surveillance Project (GISP) suggest that an increasing proportion of men with urethral gonococcal infection are MSM; and the incidences of syphilis and chlamydial infections involving MSM are also increasing.[72–78] Data from Europe, Canada, United States and Australia suggest a substantial increase in high-risk sexual behaviors among MSM since 1996[79] perhaps leveling off in some cities as of 2006. The increase in STI acquisition appears to result in part from HIV "serosorting," with unprotected sex among HIV seroconcordant men including the increased frequency of HIV seroconcordant sex partner recruitment, for unprotected sex, on the Internet. Serosorting reduces the risk of HIV transmission to uninfected individuals but does not decrease the risk of transmission of other STIs.[79] STDs and many of the sexual behaviors and patterns of sexual mixing associated with acquiring them increase the likelihood of acquiring and transmitting HIV infection; consequently, the rise in STIs among MSM may be associated with an increase in HIV incidence among MSM.[80,81] Prospective data on STIs among MSM in the United States are provided by the MSM Prevalence Monitoring Project which includes data from six public STD clinics and three STD clinics in community-based gay men's health clinics.[82] From 1999 to 2005 the number of gonorrhea tests from all anatomic sites has increased in several cities, while the trend in the number of positive gonorrhea tests from all anatomic sites has varied by city (Fig. 5-3). In 2005, 78% of MSM were tested for urethral gonorrhea, 26% for rectal gonorrhea, and 26% for pharyngeal gonorrhea.[82] In 2005, the median percentage of urethral tests that were positive for *N. gonorrhoeae* in MSM was 11%, median rectal test positivity was 8%, and median pharyngeal test positivity was 7%.

RECENT TRENDS IN ANTIMICROBIAL RESISTANCE OF *N. GONORRHOEAE*

Data on gonococcal antimicrobial resistance across the EU are not comprehensive. Plasmid-mediated resistance to penicillin and tetracycline had increased in Europe during the early 1990s. Sporadic resistance to fluoroquinolones was also documented in the early 1990s, mainly imported from South East Asia.[52] Resistance to third-generation cephalosporins was not observed at that time. By the mid 1990s, high rates of penicillinase-positive *Neisseria gonorrhoeae* (PPNG) were reported in many large metropolitan areas; prevalences were 13% in Sweden, 6% in Finland, 3% in England, 14% in France, and 15–30% in the Netherlands. Recently, increases in fluoroquinolone resistance have been reported in many countries in Europe. In Denmark, the laboratory-confirmed percentage of gonococci with fluoroquinolone resistance increased from 0% to 27% in 1999, 17% of the strains were resistant to both penicillin and fluoroquinolones.[52] In Austria, reported resistance to ofloxacin increased from 0% to 52.3% between 1999 and 2002. The Gonococcal Resistance and Antimicrobials Surveillance Program (GRASP) in England and Wales also demonstrated increases in ciprofloxacin resistance from 2.1% in 2000 to 3.1% in 2001 and 9.8% in 2002. In Scotland, ciprofloxacin resistance increased from 2.8% in 2000 to 4% in 2001 and 11% in 2002.

In the United States, beta-lactamase-producing strains of *N. gonorrhoeae* were first isolated in 1976. Initially, the reported numbers of such strains remained stable at less than 100 cases per year and most cases were linked to overseas travel. In 1980, however, numbers of beta-lactamase-producing isolates started to increase, with reported cases exceeding 4500 by 1982. This may initially have reflected the spread of such strains within developing countries increasing importation into the United States from endemic areas such as Korea, the Philippines, and Africa and then increasing transmission within the United States. Eventually, beta-lactamase-producing gonococci became entrenched in some communities and the number of reported cases began to increase sharply after 1984.[83] This might have also been partly attributable to adaptive stabilization of beta-lactamase-encoding plasmids in *N. gonorrhoeae*. As the incidence of infections with beta-lactamase-producing strains of *N. gonorrhoeae* increased, the epidemiology changed: overseas travel and contact with female sex workers (FSWs) were identified as important risk factors in early outbreaks; but over time the distribution of these strains came to parallel that of endemic, antibiotic-sensitive gonococci, predominantly involving inner-city residents, members of ethnic minority groups, and heterosexuals.[84,85]

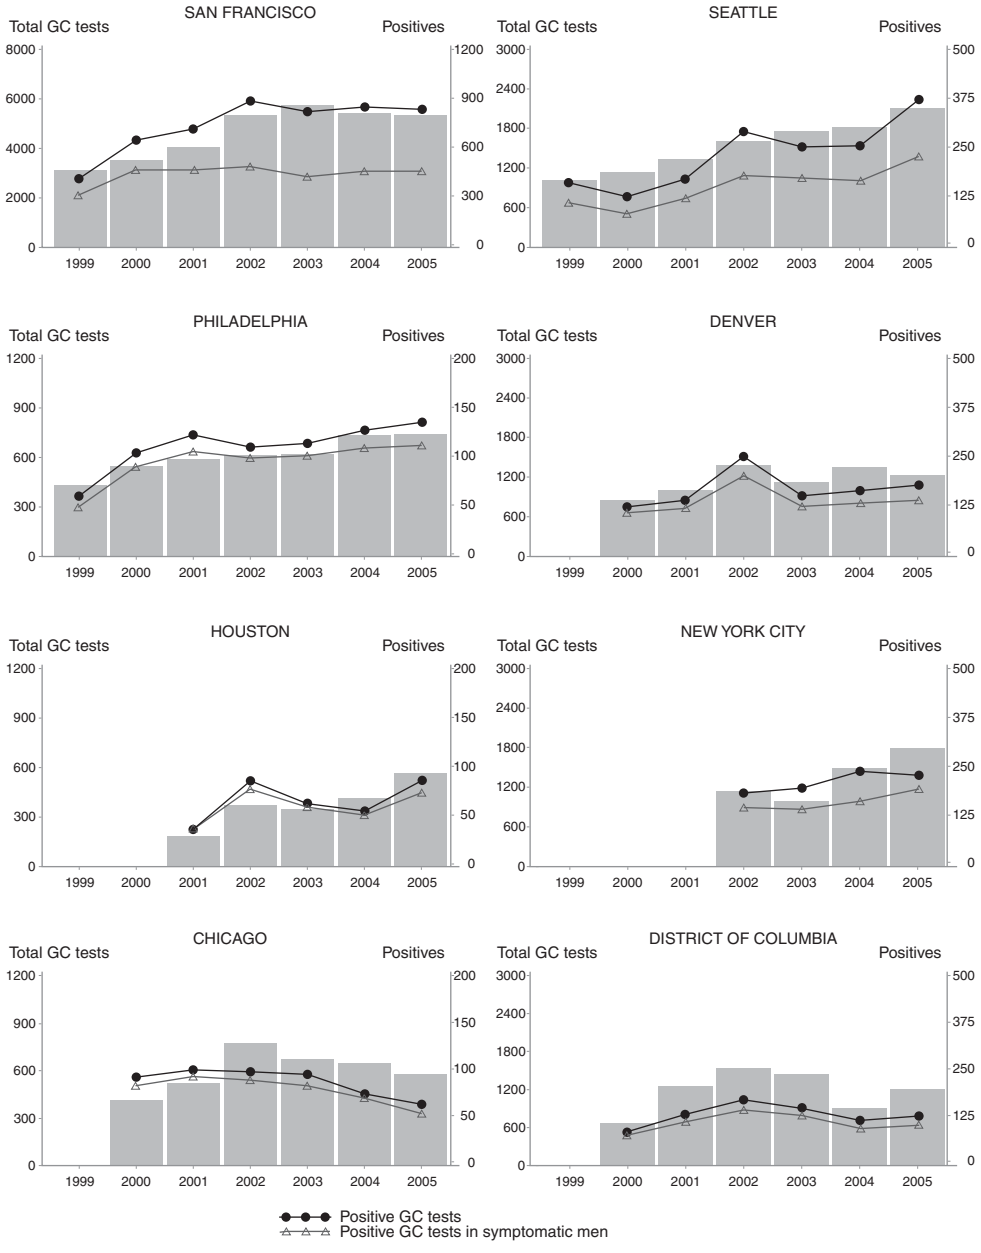

FIGURE 5-3. MSM prevalence monitoring project–number of gonorrhea tests and number of positive tests in men who have sex with men, STD clinics, 1999–2005. (From Centers for Disease Control and Prevention. *Sexually Transmitted Disease Surveillance, 2005*. Atlanta, GA: US Department of Health and Human Services, Nov 2006.)

During the 1990s, levels of gonococcal antimicrobial resistance in the United States were fairly stable, with about one-third of isolates resistant to penicillin or tetracycline, higher than in some other industrialized countries.[32] The more rapid emergence of reduced susceptibility to ciprofloxacin since 1999 has been a concern.

By early 2004, fluoroquinolones were no longer recommended in the United States as first-line treatment for MSM, and by early 2007, were no longer recommended as first-line treatment of gonorrhea in any group.[86] As of 2006, there was considerable geographic variation in the prevalence of fluoroquinolone resistance in the United States for heterosexuals, rates being highest in the west. In the GISP survey, the proportion of isolates that were resistant to ciprofloxacin increased steadily to 29% in MSM, while among heterosexuals the proportion of quinolone resistance *Neisseria gonorrhea* (QRNG) had increased from 2.9% in 2004 to 3.8% in 2005 to 6.7% in 2006. (Figs 5-4 and 5-5) While fluoroquinolone resistant isolates were identified in 25 of the 27 GISP clinics, prevalence was highest in Western States.[54] To date, cephalosporin resistance has not been identified in GISP, and the proportion of GISP isolates demonstrating decreased susceptibility to ceftriaxone or cefixime has remained very low over time.[87,54]

SYPHILIS

TRENDS IN INDUSTRIALIZED AND DEVELOPING COUNTRIES

Globally, an estimated 12 million people are infected every year, and the majority of infections are believed to occur in sub-Saharan Africa and South East Asia.[48] While the majority of transmissions occur through heterosexual intercourse in these settings, vertical transmission remains a concern.[88] Recent estimates suggest that a million pregnancies are affected each year by syphilis.

Syphilis, gonorrhea, and chancroid may fluctuate in incidence somewhat more dramatically than other STIs such as HSV or HPV infections, as sexual behaviors change. In the United States and other industrialized countries, following World War I, the incidence of syphilis fell rapidly, coinciding with the increased availability of improved diagnostic tests and the arsenicals. After a brief rise in incidence during World War II, the incidence fell again, coinciding with the introduction of penicillin. The incidence rose again during the sexual revolution of the early 1960s, and unlike the incidence of gonorrhea, continued to increase after the 1970s, reflecting epidemic spread among MSM until the recognition of AIDS in 1981. During the 1980s and early 1990s, with AIDS-related decreases in risk behaviors, rates of primary and secondary syphilis declined dramactically, particularly among MSM.[9] Primary and secondary syphilis increased in the United States between 1986 and 1990 among minority heterosexual populations, concurrent with the crack cocaine epidemic. In the United States, rates of reported primary and secondary syphilis began to fall again after 1990, with the decreasing use of crack cocaine, and continued to fall until the year 2000, with the lowest incidence[89] of primary and secondary syphilis (since 1941, when reporting began) reached in the year 2000.[54] (Fig. 5-6) The low rate of infectious syphilis and the concentration of most syphilis cases in a very small proportion of geographic areas in the country led to the development of CDC's National plan to Eliminate Syphilis. The plan was first established in 1999 and was revised in 2006.[90]

After implementation of the CDC's syphilis elimination plan, the incidence of primary and secondary syphilis did decline further among women, and among the black population, greatly decreasing the disparity between blacks and other racial-ethnic groups in syphilis incidence (Fig. 5-7). In 1997, the incidence of primary and secondary syphilis among African Americans was 44 times that among

non-Hispanic whites;[9] in 2005, the incidence was 5.4 times higher among blacks than among non-Hispanic whites. However, unfortunately, this has been offset by a large resurgence of syphilis among MSM. In 2005, for the first time in over 10 years, the rate of primary and secondary syphilis among women also increased slightly, from 0.8 cases per 100,000 population in 2003 and 2004 to 0.9 cases per 100,000 population. In 2005, 8724 cases of primary and secondary syphilis were reported to CDC, up from 7980 in 2004, representing an increase of 9.3%; the corresponding incidence of primary and secondary syphilis incidence per 100,000 population increased from 2.7 in 2004 to 3.0 in 2005—an increase of 11.1%. This increase involved most age groups.[54] In 2005, half of the total number of primary and secondary syphilis cases was reported from only 19 counties and two cities; 77.5% of the 3140 counties in the United States reported no cases of primary and secondary syphilis. One caution is that remarkable shift in the type of health-care facilities providing STI care in the United States may influence STI reporting: the proportion of primary and secondary syphilis cases reported from sources other than STD clinics increased from 25.6% in 1990 to 68.7% in 2005.

In 2005, the overall rate of congenital syphilis was 8 per 100,000 population in the United States. Between 1996 and 2005, the average yearly percentage decrease in the congenital syphilis rate was 14.1%.

Throughout much of Europe, following the emergence of HIV/AIDS, rates of infectious syphilis fell to their lowest levels in many countries by the early 1990s (Fig. 5-8A, 5-8B, 5-8C), although following 1990 and the end of the Soviet Union, syphilis increased dramatically in many of the former Soviet States. The declines in Western Europe were accompanied by reductions in the incidence of congenital syphilis and a continued fall in tertiary disease. In 1995 all countries of the EU except Germany, reported fewer than 300 cases of infectious syphilis.[52] Most cases that did occur involved migrants from countries with a high prevalence of syphilis, or locals who were exposed to syphilis outside of Western Europe. In many Northern and Western European countries, syphilis incidence started to increase again in 1996.

Several outbreaks of infectious syphilis in the UK over the past decade[91] have affected MSM, as well as heterosexual men and women, newborns, drug users, and sex workers.[52] France, Belgium, the Netherlands, Denmark, Finland, and Austria all reported outbreaks of syphilis and increases in syphilis incidence. Syphilis incidence began to increase in large metropolitan German cities starting in 2000. Syphilis outbreaks and increased incidence of syphilis, mostly concentrated among MSM, have been reported in Ireland, Norway, and Sweden since 2000.

In Moscow, the prevalence of syphilis among pregnant women increased from 0.02% in 1990 to 1.10% in 1998[91] and the number of babies infected with congenital syphilis in

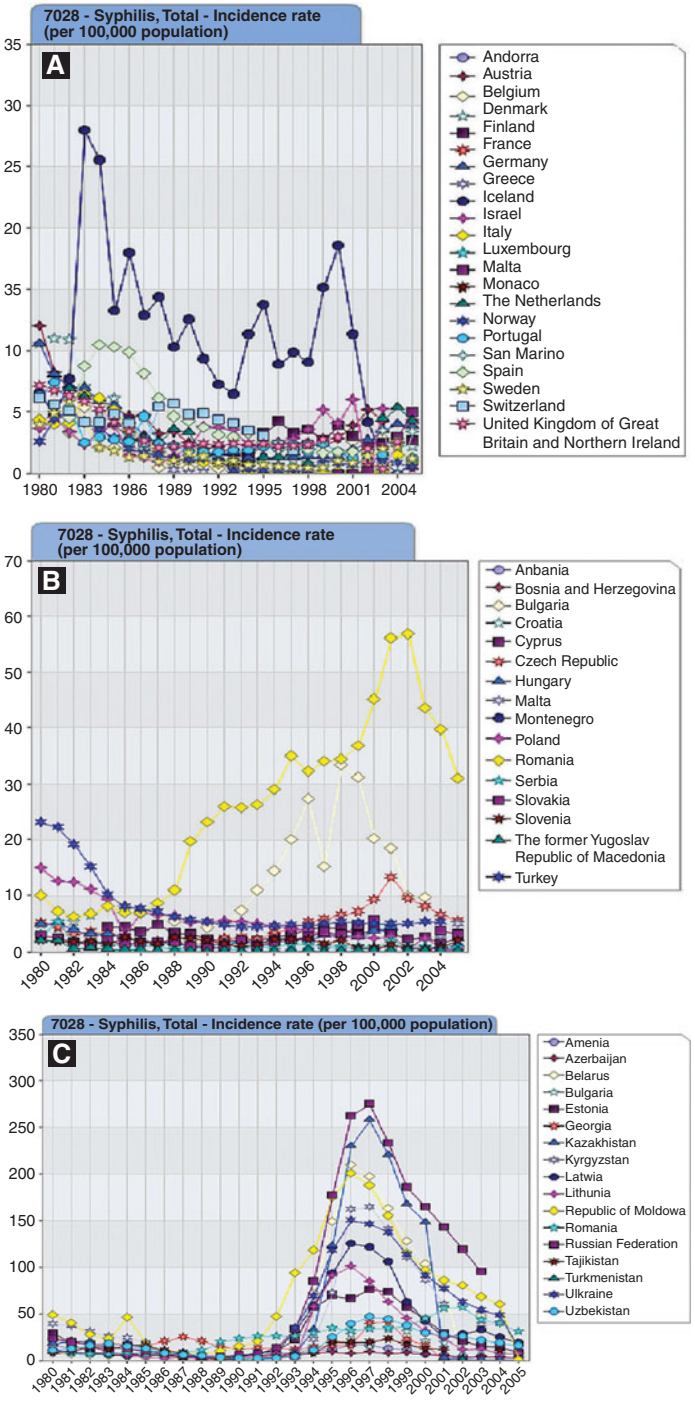

FIGURE 5-8 A. Syphilis, West, 1980–2005. Russia increased from 15 in 1990 to 730 in 1999. The sharp increase in syphilis in former Soviet States during the 1990s, followed by declining incidence of syphilis in these States during the late 1990s and early part of this century,

provides an important case study, not fully explicated as yet, but probably reflecting multiple social and public health factors driving rates up after 1990, as discussed in the next section, followed by increased AIDS and related behavior change plus reinvigorated public health and clinical measures that are proving effective throughout the region.

In many developing countries, syphilis has remained very common, although in many regions where syndromic management of genital ulcers and urethral discharge were implemented, the incidence of syphilis has fallen dramatically. Reported prevalences of syphilis among pregnant women in recent years were 2.4% in Sudan, 3.0% in Morocco, 3.1% in Djibouti, 3.5% in Papua New Guinea, 4% in Cambodia, and 8% in the South Pacific Islands.[92] In sub-Saharan Africa congenital syphilis was the most common cause of perinatal mortality in the 1990s, accounting for around 26% of stillbirths and 11% of neonatal deaths. A survey of 22 sub-Saharan African countries found that although universal screening of pregnant women for syphilis was recommended policy in 17 countries, only 38% of women attending antenatal clinics were actually screened and treated.[93]

The recent history of syphilis epidemiology in China presents a unique pattern.[94,95] After a massive syphilis epidemic during the first half of the twentieth century, syphilis was eliminated in China for 20 years between 1960 and 1980. Recent political and economic changes in Chinese society have been followed by a resurgence of STI epidemics. In 2005, the rate of reported primary and secondary syphilis was 5.7 cases per 100,000 persons compared to only 0.2 cases of all stages of syphilis per 100,000 population in 1993—a 25-fold increased risk.[94,95] The rate of congenital syphilis increased from 0.01 cases per 100,000 live births in 1991 to 19.68 cases per 100,000 live births in 2005; an average yearly increase of 71.9%. Both biological and social factors may have contributed to the resurgence of syphilis in China. The control of syphilis may have created a population which was highly susceptible to infection.[4,96] The country's explosive economic growth which brought with it increased economic inequality, increased internal and external migration and travel, with resurgent commercial sex work. The apparent absence of many STIs over a period of nearly 2 decades led to attrition of public health and clinical infrastructure for prevention and control of STIs, leaving the country ill-prepared to cope with resurgent spread of STIs.

INFLUENCES OF SOCIODEMOGRAPHIC FACTORS ON SYPHILIS MORBIDITY

In Europe, the resurgence of syphilis among MSM has been associated with increasing high-risk sexual behavior with development of new highly connected sexual networks, use of recreational drugs including ecstasy and gamma hydroxybutyrate, sexual activity overseas, and HIV coinfection.[97–99] Among heterosexuals risk factors have included migration from high prevalence countries, sexual activity overseas, contact with sex workers and illegal and recreational drug use.[97]

In the United States, increases in syphilis among MSM have similarly been associated with high risk sexual behavior, recreational drug use, including methamphetamines, and high rates of HIV coinfection.[100–105] Internet-based sex partner recruitment for unprotected sex has emerged as an important risk factor for syphilis transmission among MSM.[106,107] Among heterosexuals, particularly in urban areas and in southern United States, syphilis has been associated with race-ethnicity assortative and risk group dissortative sexual mixing,[61] incarceration,[108] concurrent partnerships,[108,109] and perhaps culturally unacceptable prevention services. Societal parameters associated with syphilis in the past are undergoing worrisome trends. In 2000, 65% of black male high school dropouts in their twenties were jobless (unable to find work, not seeking work or incarcerated). By 2004, 72% of black male high school dropouts in their twenties were jobless compared to 34% of white and 19% of Hispanic dropouts. Incarceration rates have reached historic highs; in 2004, 21% of black men who did not attend college were incarcerated.[110]

THE ROLE OF IMMUNITY

Partial immunity to syphilis may influence trends in syphilis incidence.[4,96,111] Mathematical modeling using data from cities in the United States over 50 years suggests that syphilis incidence may follow a natural cycle that peaks at 8–11 year intervals, possibly related to increasing and declining immunity in populations with particularly high rates of syphilis. The same work also revealed that since the early 1980s, syphilis rates in different cities have risen and fallen at the same time rather than varying independently, as they did earlier. This observation points to the emergence of spatially bridged sexual networks, at least among MSM.

CHLAMYDIA TRACHOMATIS INFECTIONS

Chlamydia trachomatis is still the most prevalent sexually transmitted bacterial infection in North America and Europe.[52,54] It is difficult to describe temporal trends in the incidence of chlamydial infection because of the large proportion of asymptomatic infections; the increasing use of increasingly sensitive diagnostic tests, with expansion of chlamydia screening activities in Europe and the United States; the increased emphasis on case reporting by providers; and the improvements in the information systems for reporting. In many European countries, case reporting of genital chlamydial infections is not mandatory; consequently, relatively little information is available from national surveillance

sources. For example, in Ireland, the reported numbers of cases of chlamydial infection remained stable during the early 1990s at around 200 cases per year. In 1995, there was an increase of 84.2% compared to 1994. During the following 5 years there were an increasing number of cases reported each year reaching 1649 in 2001,[52] still, undoubtedly, far fewer than the total number of new infections actually occurring. In Norway, reported chlamydia cases declined from a peak of 20,000 cases in 1988 to 12,500 cases in 1998. In Sweden, chlamydia incidence per 100,000 declined from 350 in 1989 to 160 per year from 1993 through 1997, then increasing to 276 in 2002—the same level of infection as 10 years earlier. In England, Wales, and Northern Ireland the number of uncomplicated chlamydia diagnoses in Genito Urinary Medicine clinics has risen steadily since the mid 1990s. Increases were also observed in Scotland and Vienna.[52]

In the United States, by 2000, all 50 states and the District of Columbia had regulations requiring the reporting of chlamydia cases. From 1986 through 2005, the rates of reported chlamydia infection increased from 35.2 per 100,000 to 332.5 per 100,000 population. (Fig. 5-9) In 2005, the rate of reported chlamydia infection among women in the United States (496.5 cases per 100,000 women) was over 3 times higher than the rate among men (161.1 cases per 100,000 men) reflecting the greater number of women screened for chlamydia. However, use of nucleic acid amplification tests, particularly on urine, increasingly facilitates the identification of men with asymptomatic infection. From 2001 through 2005, the chlamydia infection incidence in men increased by 43.5% from 112.3 to 161.1 cases per 100,000 males. During the same period, rates per 100,000 women per year increased only by 15.6% from 429.6 to 496.5 cases.[54] Since 1996, chlamydia incidence has increased for all racial-ethnic groups. (Fig. 5-10) In 2005, the incidence of chlamydia among blacks was over 8 times higher than that of whites or Asian-Pacific Islanders; 1247.0 and 152.1 cases per 100,000, respectively. Incidence rates among American Indian/Alaska Natives (748.7 per 100,000) and Hispanics (459.0 per 100,000) were intermediate. In 2005, the highest incidence of reported chlamydia per 100,000 women was among 15–19-year-olds (2796.6) and 20–24-year olds (2,691.1). Age specific incidence per 100,000 men was highest in the 20–24-year age group (804.7). Initiated in 1988 and expanded in 1993, the chlamydia screening and prevalence-monitoring project provides chlamydia test positivity data for all 10 of the U.S. Health and Human Services regions. In 2005, the median state-specific chlamydia test positivity among 15–24-year-old women tested during visits to selected family planning clinics in all states and outlying areas was 6.3%. Chlamydia test positivity has remained stable within regions between 2001 and 2005 even after adjusting to account for use of increasingly sensitive laboratory test methods (Fig. 5-11).

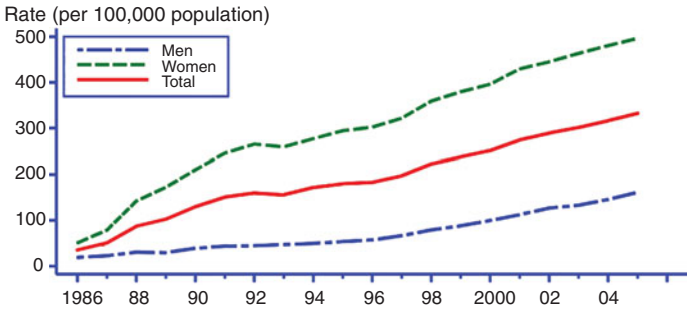

FIGURE 5-9. Chlamydia rates: total and by sex: United States, 1986–2005. (From Centers for Disease Control and Prevention. *Sexually Transmitted Disease Surveillance, 2005*. Atlanta, GA: US Department of Health and Human Services, Nov 2006.)

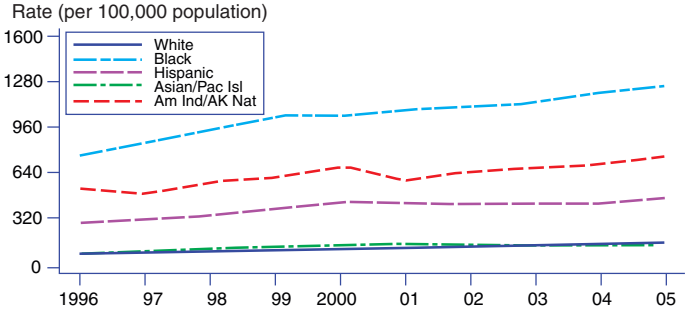

FIGURE 5-10. Chlamydia rates by race/ethnicity: United States, 1996–2005. (From Centers for Disease Control and Prevention. *Sexually Transmitted Disease Surveillance, 2005*. Atlanta, GA: US Department of Health and Human Services, Nov 2006.)

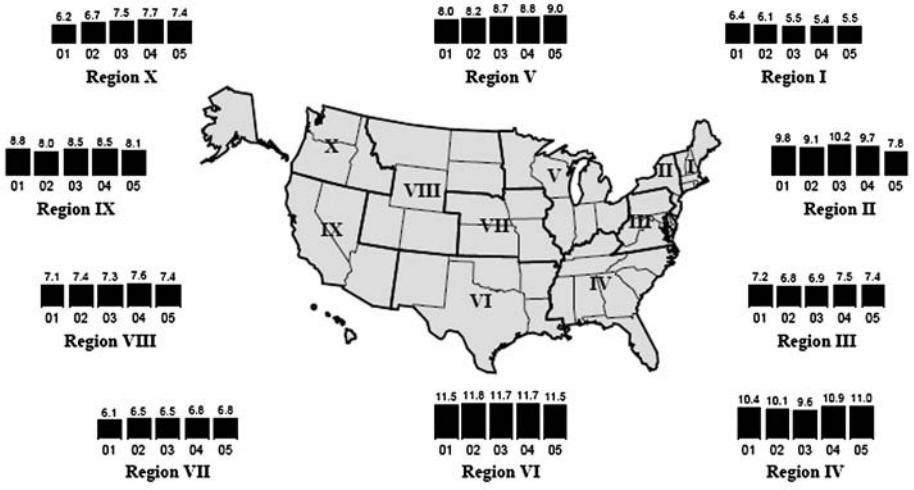
Given the frequently asymptomatic nature of infections, our understanding of chlamydia epidemiology is greatly enhanced by population-based prevalence studies. In Britain in 2000, National Surveys of Sexual Attitudes and Lifestyles (NATSAL 2000) assessed the prevalence of *C. trachomatis* infection detected by urine testing.[112] Among 18–44-year-old men and women, *C. trachomatis* was found in 2.2% of men and 1.5% of women; age specific prevalence was highest among men aged 25–34 (3.1%) and women aged 16–24 years (3.0%). Nonmarried status, age, partner concurrency, or two or more partners in the previous year were independently associated with chlamydial infection. In the United States, data collected between 1999 and 2002 representing the noninstitutionalized civilian population between 14 and 39 years included urine samples tested for chlamydia using the ligase chain reaction assay. The prevalence of chlamydial infection was 2.2% and was similar for men and women. Among women the highest prevalence was among 14–19-year-olds (4.6%); among men the highest prevalence was among 20–29-year-olds (3.2%).[113] Prevalence was higher among non-Hispanic blacks (6.4%) than among non-Hispanic whites (1.5%). Among non-Hispanic blacks 14–19 years of age, the prevalence of chlamydial infection was 11.1%. While overall chlamydia prevalence was similar in the British and



Note: Trends adjusted for changes in laboratory test method and associated increases in test sensitivity.

American samples, the prevalence was higher in men than in women in Britain but not in the United States. In another representative sample of 18–26-year-old U.S. men and women in 2001–2002, chlamydia prevalence was also measured using first-void urine specimens and ligase chain reaction assay.[114] The overall prevalence of chlamydial infection was 4.19%. Women (4.74%) were more likely to be infected than men (3.67%). The prevalence of chlamydial infection was highest among black women (13.95%) and black men (11.12%) and lowest among Asian men (1.14%), white men (1.38%), and white women (2.52%). Prevalence was highest in the south (5.39%) and lowest in the northeast (2.39%).

Recently it has been hypothesized that immunity may play a role in the epidemiology of chlamydial infections[115,116]—as has also been hypothesized for syphilis.[4] In British Columbia, Canada, interventions to control chlamydial infections, including case identification, antibiotic treatment, and contact tracing have been undertaken since 1991. Rates of infection decreased from 1991 to 1996 but started increasing in 1998. In addition, the rate of reinfection with chlamydia has been increasing since 1991. Brunham et al. have suggested that screening and treatment in British Columbia have shortened the duration of chlamydial infections, attenuating the immune response, leading to increasing susceptibility to reinfection at the population level.[115] This argument would be consistent with the stable or upward trend in the proportions of tests for chlamydial infection that are positive (after adjusting for changing test sensitivity) among women tested in the U.S. chlamydia screening project (Fig. 5-11). On the other hand, others argue that stable prevalences of chlamydial infection could reflect trends toward screening of higher risk women. Moreover, there is evidence of inadequate patterns and coverage of screening and treatment delivered to females, not to mention males. Because screening and treatment represent the predominant intervention strategies employed for chlamydia control in the developed world, more direct testing of these hypotheses is very important.[117–120]

CHANCROID

Once endemic in Europe and North America, chancroid began a steady decline early in the twentieth century, before the discovery of antibiotics. Social changes including changes in patterns of commercial sex may have disrupted the conditions necessary to sustain chancroid as an endemic disease. There is evidence that male circumcision reduces the risk of male acquisition of chancroid. Sporadic outbreaks can be easily controlled through effective curative and preventive services provided to sex workers and their clients. More recently, chancroid prevalence has declined in countries like the Philippines, Senegal, and Thailand.[121] In the United States, since 1987, reported cases of chancroid declined steadily until 2001 when 38 cases were reported[54] (Fig. 5-12). In 2005, only 17 cases of chancroid were reported; only 10 states and one outlying area reported one or more cases of chancroid. Because *Haemophilus ducreyi*, the causative agent of chancroid, is difficult to culture and nucleic acid amplification tests for the pathogen are not widely available, chancroid cases may be underdiagnosed.

VAGINAL TRICHOMONIASIS AND OTHER VAGINAL INFECTIONS

Vaginal trichomoniasis and other vaginal infections are not reportable in the United States and Europe. In the United States, trend data are limited to estimates of initial visits to

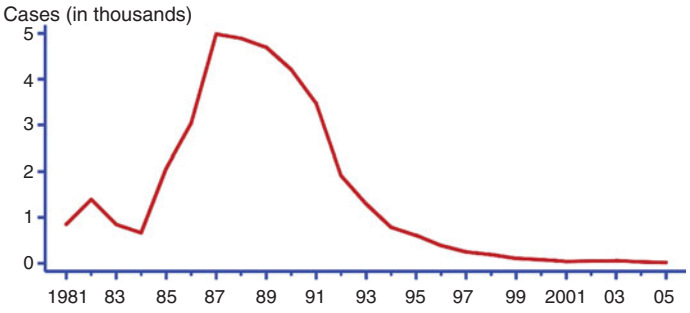

FIGURE 5-12. Chancroid–Reported cases: United States, 1981–2005. (From Centers for Disease Control and Prevention. *Sexually Transmitted Disease Surveillance, 2005*. Atlanta, GA: US Department of Health and Human Services, Nov 2006.)

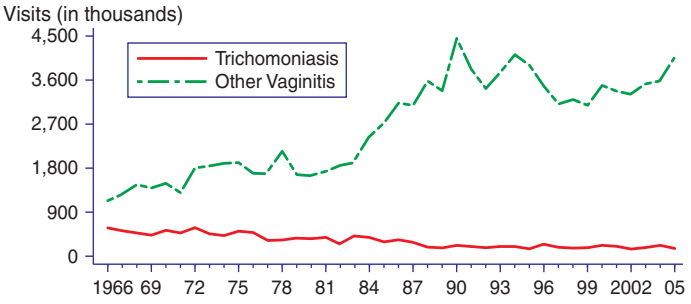

FIGURE 5-13. Trichomoniasis and other vaginal infections in women–Initial visits to physicians' offices: United States, 1966–2005. (From National Disease and Therapeutic Index (IMS Health).)

physicians' offices for these conditions from the National Disease and Therapeutic Index (NDTI).[54] These estimates suggest that incidence of trichomoniasis has declined from an estimated 579,000 in 1996 to 190,000 in 1988 and has remained relatively unchanged since then—there were 165,000 visits in 2005. (Fig. 5-13) These likely represent under estimates of incidence, as discussed below. During the same period initial visits for other vaginal infections of undefined etiology increased from an estimated 1,155,000 in 1966 to 4,474,000 in 1989, declined irregularly to 3,100,000 in 1997 but has been increasing irregularly since then—there were 4,071,000 visits in 2005.[54]

In a recent study,[122] U.S. women aged 14–49 participating in the National Health and Examination Survey (NHANES) cycles 2001–2004 provided self-collected vaginal swabs; vaginal fluids extracted from the swabs were evaluated for *Trichomonas vaginalis* using polymerase chain reaction (PCR). The overall prevalence of *T. vaginalis* was 3.1%; it was highest among non-Hispanic blacks (13.3%) and lower among Mexican Americans (1.8%) and non-Hispanic whites (1.3%). Factors associated with increased risk for *T. vaginalis* in multivariable analyses included non-Hispanic black race-ethnicity, being born in the United States, greater numbers of lifetime sex partners, increasing age, lower educational attainment, poverty, and douching.

Another recent study estimated the prevalence of trichomoniasis in young adults (mean age = 22 years) in the United States by testing urine specimens collected from men and women participating in the National Longitudinal Study of Adolescent Health.[123] In this study, the estimated overall prevalence of trichomoniasis was 2.3%. The prevalence was slightly higher in women (2.8%) than in men (1.7%). The prevalence increased with age and varied by region, with the South having the highest prevalence (2.8%). The prevalence was highest among black women (10.5%) and lowest among white women (1.1%). Among men, prevalence was highest among Native American (4.1%) and black men (3.3%) and lowest among white men (1.3%).[123]

GENITAL HERPES

Viral STIs are not notifiable in most European countries and relatively limited temporal trend data have been published.[52] Genital HSV infection is the most common ulcerative STI in the UK and the United States. However, many patients with genital herpes do not perceive or recognize symptoms of the infection, and clinical case-reports grossly underrepresent the true incidence of genital herpes as reflected by serologic testing for antibody to HSV-2. Increasing case recognition over time does, however, provide one indication of increasing incidence. Between 1972 and 2002, the number of genital HSV diagnoses made at GUM clinics in the UK increased twofold in males and ninefold in females. The number of diagnoses stabilized and fell briefly in the mid-1980s possibly because of changes in sexual behavior following extensive media coverage of AIDS. In 2002, 18,392 new cases were reported in England, Wales, and Northern Ireland. For females and males, highest rates were reported in the 20–24-year olds—2053 per 100,000 population and 93 per 100,000, respectively. In Ireland in 2001, notified cases of genital HSV increased by 23.0% on the previous year. HSV cases increased from 78 (2.2/100,000) in 1989 to 198 (5.5/100,00) in 1995 and 331 (8.5/100,000) in 2001. Between 1995 and 2001, the highest rates per 100,000 population were consistently in females and where age group was known, 20–29 year olds.[52]

Virtually all seroepidemiological studies in Europe, the United States, and elsewhere show that HSV-2 seroprevalence increases with age (reflecting long-term persistence of antibody), and the number of partners during the previous year, and that HSV-2 seroprevalence is substantially higher in females than in males. An increasing proportion of first episodes of genital herpes has been attributed to HSV-1 rather than HSV-2 in several settings.

A recent review of published HSV type-specific seroepidemiologic surveys found striking variations in HSV-2 prevalence in Western Europe.

HSV-2 prevalence appears to be higher in Northern Europe and in North America than in Western and Southern

Europe. The highest prevalence of HSV-2 infection was found among women in Greenland, reaching 57% among 20–26-year olds and 74% in 25–39-year olds. In Scandinavia, HSV-2 prevalence was relatively higher than in other areas of Europe—15–35% among women between 25 and 35 years of age.[124] In Spain, HSV-2 prevalence was low, 2–6% in large samples of men and women between 14 and 45 years of age from different geographic areas. In Italy, HSV-2 prevalence was reportedly even lower; 0.1% in a national sample of male draftees 18–25 years of age and 1.1% among patients attending a hepatitis B immunization center (median age 26 years). In all studies conducted in the UK, HSV-2 seroprevalence was 9% for men and women of all ages.

In the United States, genital HSV infection spread rapidly from the mid-1960s until the onset of the AIDS epidemic. Initial patient consultations with private physicians in office practice for symptomatic genital herpes in the United States have been monitored since 1966 using data from the NDTI—a probability sample of private physician's practices carried out by IMS Health. The annual number of initial visits for genital herpes increased 12.5-fold from 18,000 in 1966, when it was also seen relatively infrequently in STD clinics, to over 235,000 visits in 1991; the annual number has fluctuated since then, with the highest estimated number of initial cases seen in 2004 (269,000 cases) and 2005 (266,000) (Fig. 5-14).

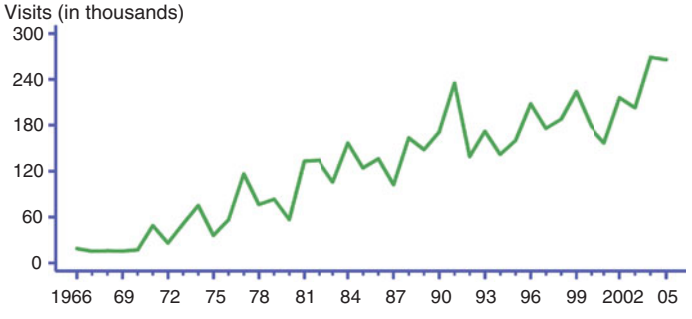

FIGURE 5-14. Genital herpes–Initial visits to physicians' offices: United States, 1966–2005. (From National Disease and Therapeutic Index (IMS Health).)

People 20–29 years of age had more office visits than other age groups. Women outnumbered men in genital herpes-related physician consultations, likely reflecting true gender differentials in genital herpes incidence based upon seroprevalence differences.

During the 1970s and 1980s, media attention may have increased both physicians' and patients' awareness of the signs and symptoms of genital herpes, increasing the proportions of patients with genital herpes who sought physician consultations and received a correct diagnosis.[125] The recent availability of more specific serologic tests for HSV-2 may also be increasing physician diagnoses of genital herpes. However, based on the percentage of adults with serum antibody, the true annual incidence of new HSV-2 infections in the United States clearly exceeds the number of physician consultations for newly diagnosed symptomatic genital infections by several-fold. (Fig. 5-14)

The most recent data on HSV-2 seroprevalence in the United States were collected in a stratified random sample of the United States population through the NHANES during 1988 through 1994 and 1999 through 2004.[126] Persons between ages 14 and 49 were included in the analyses. The overall age-adjusted HSV-2 seroprevalence was to 21.0% in the period 1988–1994, decreasing to 17.0% in 1999–2004, representing a relative decline of 19% between the two surveys. Decreases in HSV-2 seroprevalence were concentrated in persons aged 14–19 years between 1988 and 2004. In adolescents aged 17–19 and in young adults the decreases were significant even after adjusting for changes in sexual behaviors. The seroprevalence of HSV-1 also decreased from 62% to 57.7% between the two surveys—a relative decrease of 6.9%. HSV-2 seroprevalence was higher among women, non-Hispanic blacks, and 40–49-year olds (Fig. 5-15), as well as among the widowed and the divorced, those in greater poverty, those with higher education, those who reported ever using cocaine, and those who reported earlier age at sexual debut. HSV-2

seroprevalence increased with reported number of lifetime sex partners. (Fig. 5-16) These findings may mark a reversal in the trajectory of increasing HSV-2 seroprevalence in the United States.

GENITAL HUMAN PAPILLOMAVIRUS INFECTIONS

The associations between certain types of genital or anal HPV infection and precancerous or invasive lesions of the cervix, vagina, vulva, and penis and anus have been clearly documented. Genital HPV infections are the most prevalent STIs in the United States and in the world. HPV infections other than those causing genital warts (usually types 6 and 11) are nearly always subclinical, not recognized by the infected individual. By screening for HPV DNA every 3 months, using PCR amplification tests, the cumulative incidence of genital HPV infections in one study was 43% over a 3-year period in one study of sexually active female University students[127] and 32% over a 2-year period in another.[128] Serologic tests for antibody to those types of HPV found in the genital tract help further define the epidemiology of genital HPV infection in the same way that serologic tests have elucidated the epidemiology of HSV-2 infection. Based on pooled data from 11 case-control studies of the association between cervical cancer and HPV infection from multiple countries, 15 HPV types have been classified as high risk for development of cervical cancer, three have been classified as probable high risk, 12 have been classified as low risk, and three as undetermined risk.[129] A recent pooled analysis showed the age standardized prevalence of all types of HPV infection to vary 20-fold among different regions of the world.[130] The prevalence of high risk types of the virus was 18% in sub-Saharan Africa, 5% in Asia, 10% in South America, and 4% in Europe. The prevalence of HPV infection is highest among young women and appears to drop-off with increasing age.[131] However, some studies suggest a peak prevalence of HPV infection in women below age 25, a decrease among women between ages 35 and 54, and a second peak after age 55; the increase in the older age group may be attributable to a cohort effect or reactivation of latent virus. Cohort studies which looked at HPV seroprevalence suggest increases in the seroprevalence of some HPV types in Europe over the 1980s and 1990s.[131] Risk factors for HPV infection include increased number of sex partners, increased number of male partners' lifetime partners, a short-time interval between meeting a partner and engaging in sexual intercourse, increased age difference between partners, and current smoking.[128]

Because external genital warts are mostly caused by type 6 or 11 HPV, physician–patient consultations for this condition provide one indicator of trends in the incidence of genital infections by HPV types 6–11. Few European countries collect surveillance data on genital warts.[52]

In the United States, the NDTI survey of physicians in private practice indicates that initial visits to physician offices for genital warts increased from 55, 695 in 1966 to over 351,370 in 1987; declined irregularly from 1987 to 1997, and then increased irregularly to reach an all-time high of 357,000 visits in 2005. (Fig. 5-17) The extent to which this rise and fall represents the natural history of the spread of the epidemic of HPV 6 and 11 through the U.S. population versus changes in health-care seeking or diagnosis versus a rise and fall in risk-taking behaviors, remains undefined.

Among sexually active women, the prevalence of cervical HPV DNA has been highest for teenagers and those in the early twenties, and lower for older women. The natural history of genital HPV infection in men remains largely undefined, although the short-term natural history of incident genital infection by various HPV types has been defined in women by serial cervicovaginal PCR testing, cervical cytology, and by serologic studies[127,128] and is now being studied in men. Type specific serum antibody detectable by current assays develops slowly over several months in the majority of infected women.

The natural history of genital and anal HPV infections is altered by HIV-related immunosuppression and other types of immunosuppression. HIV immunosuppression is associated with increased amount and longer durations of HPV shedding and a related increased risk of cervical and anal high grade squamous intraepithelial lesions.[132,133]

Based on these preliminary findings from cohort studies, and together with data from national surveys of sexual behavior (see the following), it is not unlikely that the majority of adults in the United States, perhaps three-quarters, have been infected with one or more types of genital HPV. With the advent of multitype HPV vaccines that have proven highly effective in preventing HPV infections and cervical neoplasia lesions in women, future studies will be able to examine the impact of such vaccines on preventing HPV acquisition, on whether such vaccines protect men from penile or anal HPV infection, on population-level HPV transmission, and on defining whether there is cross-protection against types of HPV not included in the vaccines.

STIs IN SPECIAL POPULATIONS

Special populations are disproportionately affected by STI morbidity in countries all over the world. In Europe, MSM, migrants, young people, and HIV-positive men are recognized as special populations with high-risk behaviors and high prevalence and incidence of STI.[52] In the United States, sex workers, homeless persons, adolescents and adults in detention, and migrant workers are among special populations with high STI morbidity. The Institute of Medicine report on STIs emphasized the importance of outreach to these special populations for STI control.[134] In general, the prevalence of cervical infection is highest during the first few years after beginning sex work and declines with age and immunity; whereas serologic evidence of past STIs or chronic viral STIs increases with age, time since sexual debut, or increasing duration of sex work, reflecting cumulative acquisition of infection. Consistent condom use protects sex workers against many of these infections, although commercial sex in areas of very high STI endemicity unfortunately leads to high cumulative rates of STIs, including HIV, even among women reporting consistent condom use.[135–137] Among MSM who are sex workers, including transvestites and transsexuals, receptive anal intercourse is customary, carrying particularly high risk of certain STIs, including HIV infection. In industrialized countries, rates of STIs among FSWs and MSM are highest among those using illicit drugs, such as methamphetamines, heroin, and cocaine.

For example, among 227 street-recruited injection drug using MSM in San Francisco, California, between January 2000 and November 2001, 68% reported being paid by another man for sex and HIV prevalence was 12%.[138]

Multiple studies have demonstrated a high prevalence of STIs among persons entering jails and juvenile detention facilities.[139–142] In some locations a substantial proportion of all early syphilis cases are reported from correction facilities.[142] Chlamydia and gonorrhea screening and treatment in jails may lead to reductions of chlamydia and gonorrhea in the community.[143] In 2005, STI screening data from corrections facilities were reported from 32 states for chlamydia, 29 states for gonorrhea, and 13 states for syphilis as part of the Corrections STD Prevalence Monitoring Project.[54] Among adolescent females entering 57 juvenile corrections facilities, the median chlamydia positivity by facility was 14.2%, whereas among adolescent males entering 87 juvenile corrections facilities, the median chlamydia positivity was 6%. Among women entering 38 adult corrections facilities, the median positivity for chlamydia was 7.4%. Among men entering 41 adult corrections facilities, the median chlamydia positivity was 8.1%.

The median prevalence of gonorrhea for females entering 38 juvenile corrections facilities was 4.7% and was 1% for males entering 65 juvenile corrections facilities. The median prevalence of gonorrhea for women entering 33 adult facilities was 2.8%, and for men entering 35 adult corrections facilities, was 2.3%. These high positivity rates suggest that persons entering corrections facilities may comprise an important, special population for STI prevention interventions.

STIs including HIV infection are major health problems among migrant workers.[144,145] Limited access to health care, language and cultural barriers, and limited economic resources, combined with sexual behaviors that expose migrant workers to high-risk partners tend to perpetuate high levels of STI morbidity among this group.[146,147]

Finally, one assessment of STI among homeless adolescents showed the following baseline prevalences of chlamydia, 4.2% for males and 6.3% for females; HSV type 2, 5.73% for males and 12.5% for females; hepatitis B virus, 3.6%; hepatitis C virus 5.0%; and HIV seroprevalence, 0.3%. The annualized incidence of STIs was significantly higher among females (16.7%) than among males (9.8%) and was associated with inconsistent condom use, and for females, with number of partners and sex with older partners. Among females, the incidence of HSV-2 was over 25% and the incidence of chlamydial infection was 12%. Incident hepatitis B virus and hepatitis C virus infection rates were 3.4% and 6.6%, respectively, and both were associated with injection drug use.[148] Another assessment of homeless adolescents in Denver, Colorado, found a chlamydia prevalence of 11.6% and a gonorrhea prevalence of 2.7%. Among first testers, 13% were positive for chlamydia and 3.7% were positive for gonorrhea.[149]

DIRECT AND INDIRECT DETERMINANTS OF POPULATION TRANSMISSION DYNAMICS

Each of the three determinants of the rate of spread of STIs in a population, rate of exposure, efficiency of transmission per exposure, and duration of infectivity, are driven by a complex set of factors.

DETERMINANTS OF EXPOSURE: TRENDS AND PATTERNS OF SEXUAL BEHAVIOR

Our understanding of the relevant components of sexual behavior that influence risk of STIs, including HIV infection, has evolved considerably over the past few decades. A better understanding of the epidemiology of specific STIs, and the greater need for preventive interventions to change sexual behavior in the context of increasing viral STIs, initiated such changes in the early 1980s. The AIDS epidemic has been the single most important factor to both highlight the need for more systematic information on sexual behavior and facilitate an unprecedented increase in infection-related studies of sexual behavior.

The term "sexual behavior" involves many components: sexual experience and activity, age at sexual debut or "coitarche," current and lifetime number of sex partners, frequency of sexual intercourse, consistency of sexual activity, mode of recruitment of sexual partners and duration of sexual unions, and types of sexual practice.[150] Although the conjoint distribution of the component variables in the population determines aggregate exposure to the risk of STIs, the specific relationship between each of these variables and the risk of various STIs with differing natural histories, and the distribution of these variables across population subgroups, have by no means been fully defined.

The population at risk for STIs has often been very simply defined in terms of age groups, often assuming that those between ages 15 and 45 may engage in sexual intercourse with new partners. Further refinements of this concept have included the population at risk, only the sexually experienced, defined as persons who have ever had sexual intercourse.[151] However, current sexual activity, rather than sexual experience per se, is a more accurate measure of current exposure to the risk of STIs.[152]

During the past decade interest in sexual behavior has also focused on special populations, particularly persons who exchange sex for money, drugs, or other goods and services. Sexual services have always functioned as an economic good in human societies. However, the expansion of capitalism and globalization has led to a marked expansion in the volume of commercial sexual transactions.[7] The mobility of goods, services, and capital that accompanies globalization[8] has resulted in large numbers of men and women from distant areas and different cultures exchanging sex in many societies. This presence has important implications for changes in sexual networks and for the ability of the health system to provide coverage to sex workers for preventive, diagnostic, and therapeutic services.

TRENDS IN SEXUAL BEHAVIOR

Overall, sexual attitudes and behaviors became steadily more liberal in the industrialized countries throughout most of the twentieth century—at least until the recognition of the genital herpes epidemic and then of the HIV/AIDS epidemic. With the antibiotic era came less fear of the curable STIs, and with oral contraception in the early 1960s came partial elimination of the double standard of sexual behavior of men and women. The sexual revolution extended to homosexual and bisexual men at the same time. During the 1970s and 1980s, an increasing percentage of young women had premarital intercourse, and recent birth cohorts have had more partners than earlier birth cohorts. During the AIDS era, gay men decreased risky sexual behaviors but some young gay men have since resumed such behaviors.

Globally, sexual behavior data from 59 countries show substantial diversity in sexual behavior by region and sex which highlights the importance of social and economic factors in shaping sexual behavior.[10] Understanding social and economic determinants is essential in the interpretation of sexual behavior data and in the development of effective, high impact interventions. Sexual behavior changes in response to a variety of factors. During the past few decades there have been major socioeconomic changes affecting poverty and income disparities, education, and employment. Demographic changes have taken place in the age structure of populations, timing and frequency of marriage, and in the scale of mobility and migration between and within countries, including seasonal labor, rural-to-urban movement, and social disruption due to war and political instabilities. Many of these changes have affected developed as well as developing countries.

Even among industrialized societies heterogeneity in sexual behavior parameters is remarkable. Proportions of women who had sex before age 15 increased in France, Australia, Britain, Norway, and the United States between the late 1970s and late 1990s. During the same period proportions of men who had sex before age 15 increased in Italy, Switzerland, Britain, and Norway but declined in Australia and the United States.[10] In most developing countries the time between first sexual intercourse and living with a partner is longer for men (3–6 years) than for women (0–2 years). In industrialized countries, the duration of this period is the same for both men and women (about 5 years). Monogamy is the dominant pattern in most regions of the world and most people report only one recent sex partner but the proportion reporting multiple partnerships is generally higher in industrialized countries (Fig. 5-18). Worldwide, more men than women report multiple partnerships except in some industrialized countries, where the proportions of men and women who report multiple partnerships are similar.[10] The mean age difference between married men and women is lower in industrialized countries (1.9 in Australia and 2.2 in United States) than in developing countries; data are not available on age differences between sex partners. According

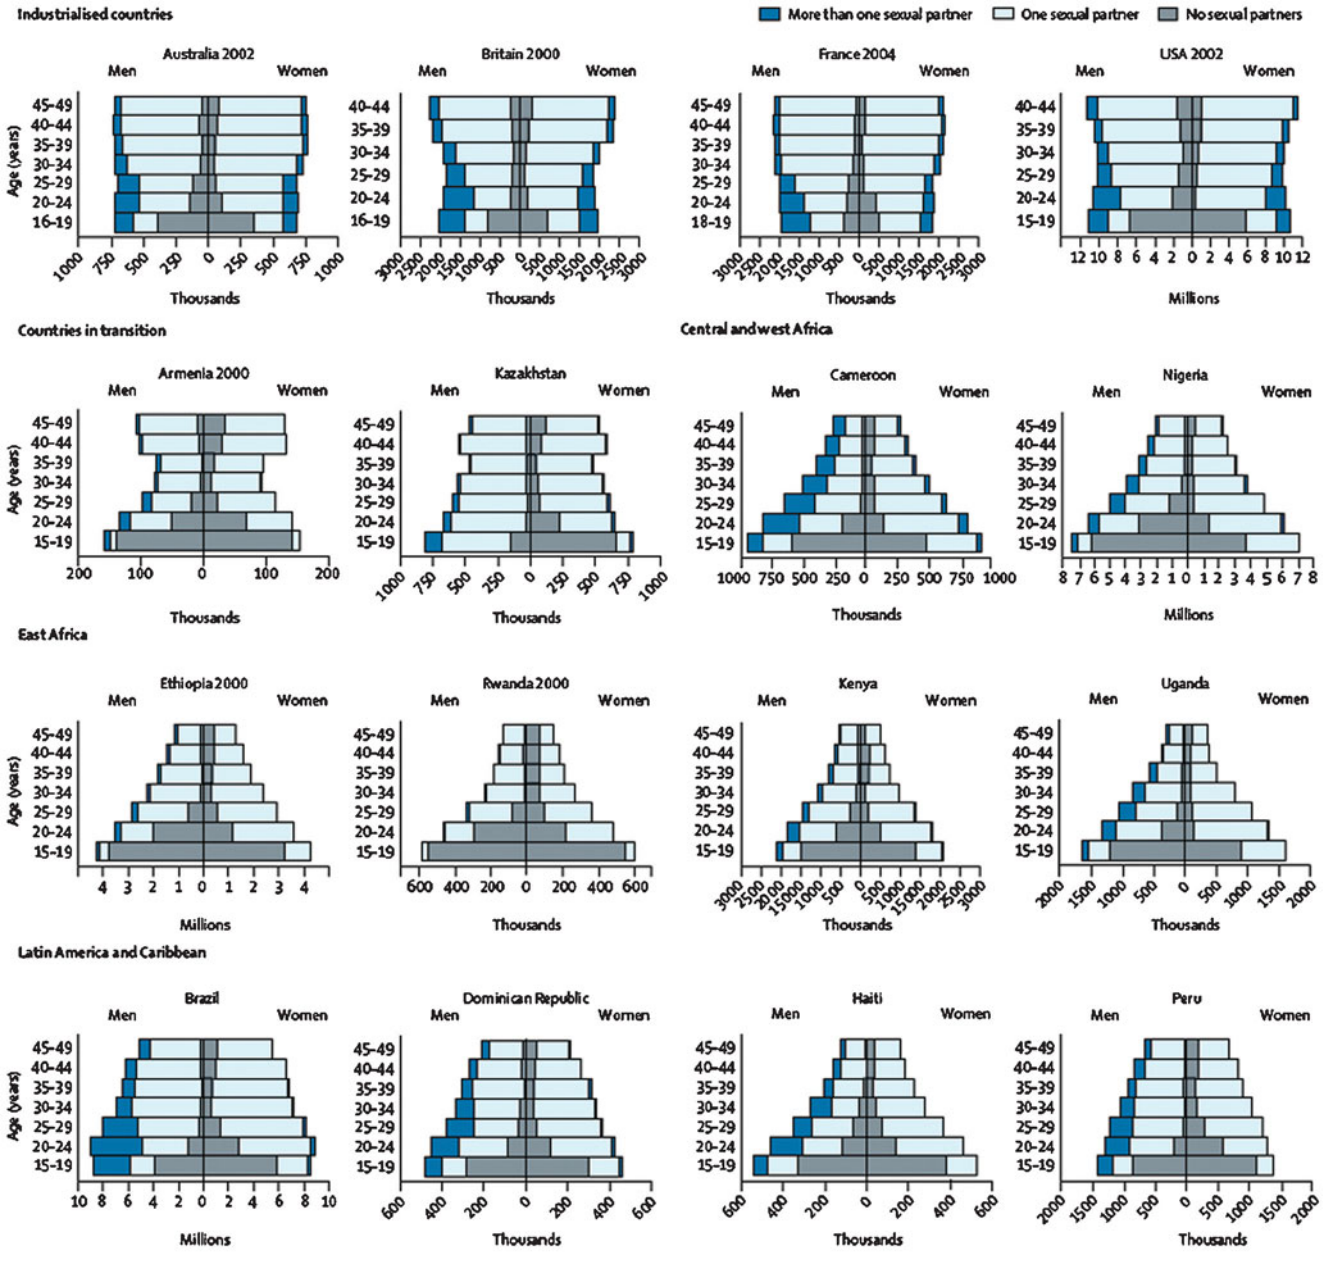

FIGURE 5-18. Population distribution by age and sex and number of sexual partners in the past year. (Reprinted from The Lancet, Vol. 368 (9548), Wellings K, et al. Sexual behaviour in context: a global perspective, pp.1707–1728, Copyright 2006, with permission from Elsevier.

to a recent review[153] of estimates of lifetime, prevalence of men having had sexual intercourse with other men is lower in industrialized countries (6% in the UK and 5% in France) than in most other regions of the world. Rates of condom use are generally higher in industrialized countries than in developing countries, especially in women.[10] The increase in condom use in recent years has also often been more substantial in industrialized countries; the only exception to this pattern is France where women have reported declining condom use in more recent years. Global reviews of exchange of sex for money, drugs, or other goods report difficulties in estimating numbers of men and women who offer sexual services and their clients.[154]

Two nationally representative surveys of sexual attitudes and life styles conducted in 1990–1991[155–157] and 1999–2001[158] provide information on patterns of and temporal trends in sexual behavior of the general population in the UK.[158] The increased reporting of risky behaviors suggested by these data is consistent with changing cohabitation patterns and rising incidences of STIs. The comparison revealed increases over the 1990s in reporting of a wide range of behaviors including numbers of heterosexual partners, homosexual partnerships, concurrent partnerships, heterosexual anal sex, and payment for sex. For many of these parameters the magnitude of observed change was large. The number of heterosexual partners over the lifetime increased

from 8.6 to 12.7 for men and from 3.7 to 6.5 for women. The number of heterosexual partners over the past 5 years increased from 3.0 to 3.8 for men and from 1.7 to 2.4 for women.

The proportion reporting homosexual partnerships increased from 1.5% to 2.6% for men and from 0.8% to 2.6% for women. The proportion reporting concurrent partnerships increased from 11.4% to 14.6% among men and from 5.4% to 9.0% among women. Among men, the proportion reporting having paid for heterosexual or homosexual sex increased from 2.1% to 4.3%. The proportion of MSM who reported receptive anal intercourse in the past year also increased significantly.[158]

In the United States, a survey of the general population in Seattle, WA, showed that between 1995 and 2004 the median number of lifetime sex partners increased from 7 to 8. Similarly, the proportion reporting any anal sex increased from 4.3% to 8.3% and those reporting any anal sex increased from 81.6% to 85.8%.[159] According to the National Survey of Family Growth, a nationally representative survey of sexual and reproductive behaviors, the proportion of 15–19-year-old men and women in the United States who have had sexual intercourse has declined between 1995 and 2002, from 49% to 45% for women and from 55% to 46% for men.[160]

Trends in sexual behaviors of teenagers (15–19) in the United States are difficult to interpret. As of 2002, according to the National Survey of Family Growth, almost one in four teenagers who have *not* had sexual intercourse report having ever engaged in oral sex with an opposite sex partner (24% of males and 22% of females). Compared to published national analyses of oral sex among men in the 1995 National Survey of Adolescent Males,[161] there has been no increase in oral sex practice among never married males aged 15–19 between 1995 and 2002. Overall, in 1995, 39% had ever given oral sex and 49% had ever received oral sex, compared with 38% and 51%, respectively, in 2002. However, in 2002, a greater proportion of never married teen males who had *not* had sexual intercourse reported ever receiving oral sex (21% in 2002 vs. 15% in 1995). Oral sex among never married teen males who had ever had sexual intercourse also increased from 1995 to 2002: 66% had ever given oral sex in 2002, compared with 61% in 1995; 84% had ever received oral sex in 2002, compared with 77% in 1995. Thus, the apparently stable overall trend in oral sex in part reflects the overall decline in the proportion of teenaged men who have had sexual intercourse. Trend data are not available for women.[162] Older teens are more likely to report oral sex than younger teens. Interestingly, non-Hispanic black males are less likely than Hispanic and non-Hispanic white males to have ever given oral sex (21% vs. 37% and 45%). Among females, Hispanics are less likely than non-Hispanic whites to have oral sex experience (47% vs. 58%) and non-Hispanic white females are more likely than Hispanic and non-Hispanic black females to have ever given oral sex (51% versus 34% vs. 25%). Finally, teens whose mothers have less education are less likely to report oral sex experience than those whose mothers have more education. Similarly, teens from families with higher incomes are more likely to report oral sex compared to those whose families have less income.[162] These differences in patterns of oral sex practice by race-ethnicity and socioeconomic status may contribute to disparities in STI rates along these societal parameters. In addition, one in ten adolescent males and females had engaged in heterosexual anal sex.[163] There were no race-ethnicity differentials in this practice. The low prevalence of this practice may suggest that its patterns would not have much impact on sexual transmission at this time.

Oral and anal sex are prevalent among American adults. According to the 2002 National Survey of Family Growth (NSFG), overall, 30% of women and 34% of men had engaged in heterosexual anal sex.[163] The percentage of U.S. inhabitants who have ever had anal sex peaked among 30–34-year olds, with 44% of white women and 50% of African American men reporting that they had anal sex. Approximately, one-third of U.S. inhabitants aged 35–44 years reported having had anal sex; this reflects the fact that younger cohorts are more likely to engage in anal sex. As compared to anal sex, higher percentages of men and women reported ever receiving and giving oral sex—over 75%. Higher percentages of whites (84.8%) compared to Hispanics (64.2%) and non-Hispanic blacks (73.6%) reported ever receiving oral sex. Similarly, a higher proportion of whites (84.3%) compared to Hispanics (60.7%) reported ever giving oral sex. The proportion of non-Hispanic blacks who reported ever giving oral sex was lower (57.4%) compared to the other racial ethnic categories.[163] Only 6% of men and women used a condom at last oral sex; 25% of men and 16% of women reported condom use during last anal sex.

According to the 2002 NSFG, 69% of all reproductive age women reported having one sex partner over the past year; 20.8% reported no partners, 6.1% reported two partners, and 4.1% reported three or more partners. Racial ethnic differences in reported number of sex partners were small (Fig. 5-19).[163]

In this group, 4.6% of Hispanic women, 10% of white women, and 9% of black women have had 15 or more male sex partners in their lifetimes. Among women 30–44 years of age, the median number of male sex partners in their lifetimes was about four.[164]

Among 15–44-year-old men, 63.3% reported having one sex partner over the past year; 21.1% reported no partners; 7.7% reported 2 partners, 3.7% reported 3 partners, and 4.2% reported 4 or more partners (Fig. 5-20).[163] In this group, 18% of Hispanic men, 22% of white men, and 34% of black men have had 15 or more female sex partners in their lifetimes. Men 30–44 years of age reported an average (median) of 6–8 female sex partners in their lifetimes.[164]

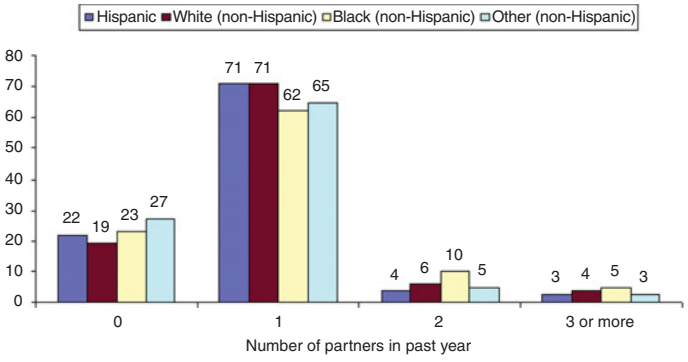

FIGURE 5-19. Number of sex partners in past year for women by ethnicity: 2002. (From Jami Leichliter, Centers for Disease Control and Prevention, Division of STD Prevention, Atlanta GA.)

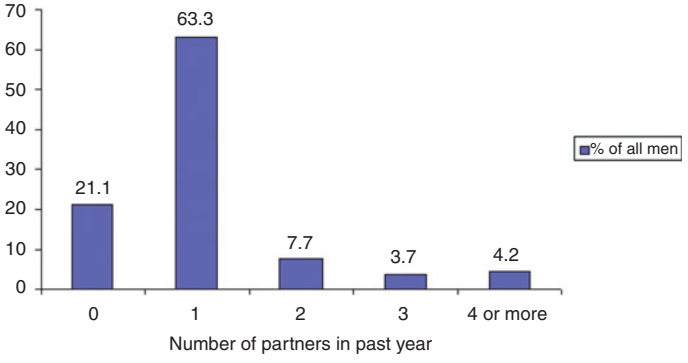

FIGURE 5-20. Percentage of males 15–44 years of age by number of sex partners in past year (overall): 2002. (From Jami Leichliter, Centers for Disease Control and Prevention, Division of STD Prevention, Atlanta GA.)

Preliminary analyses suggest some change in the number of sex partners over the past year reported by 15–44-year-old unmarried U.S. women between 1995 and 2002. The percentage of Hispanic women who reported two or more partners decreased from 13% in 1995 to 11.1% in 2002; percentages of black women who reported two or more partners declined from 23.8% in 1995 to 18.5% in 2002, while the percentage of white women who reported two or more partners increased slightly from 18.4% in 1995 to 19% in 2002. (Jami Leichliter, personal communication February 23, 2007) These findings suggest that except among whites, women may have decreased their number of sex partners while expanding their sexual repertoire.

Among reproductive age women in 2002, 11% reported any sexual activity ever with another female. The proportion of women who had a female sexual partner in the last 12 months was 4.4%; the proportion of women who had only female partners in the last 12 months was 1.3%. Among 15–44-year-old men, 5.7% reported having had oral sex with another male at some point in their lives; 3.7% reported having had anal sex with another male. Overall, 6% reported having had oral or anal sex with another male. Among men 2.9% reported having had a male sex partner over the previous 12 months; 16% had only male sex partners over the previous 12 months. Approximately, 1% of men and 3% of women 15–44 years of age have had both male and female sex partners over the previous 12 months.[164]

Among 15–44-year-old men who had at least one sex partner in the past year, 40% used a condom at their most recent sex; 65% of never married males and 24% of married males; 91% of men who ever had sex with another man and 36% of men who had never had sex with another man reported condom use during last sex.[164]

The role of commercial sex in the epidemiology of STDs and sexual behavior, even though poorly understood, appears to be increasing. One study examined the epidemiology of female commercial sex contacts reported by men in the 1990 and 2000 National Surveys of Sexual Attitudes and Lifestyles (NATSAL) in the UK.[165] The proportion of men who reported paying women for sex in the previous 5 years increased from 2% in 1990 to 4.2% in 2000. Paying for sex was more frequent in men aged between 25 years and 34 years, who were never married, previously married, and lived in London in both surveys. There was no association between paying for sex and ethnicity, social class, homosexual contact, and injecting drug use. Men who paid for sex were more likely to report 10 or more sex partners in the previous 5 years but only 19.3% of their lifetime sex partners were commercial. Men who paid for sex were more likely to meet partners abroad and to report previous STIs. Only 15% among them reported having had an HIV test.[165] Prevalence of this behavior was higher among men attending a sexual health clinic in the UK.[166] A retrospective case note review showed that 10% of the male clinic attendees reported paid sex. The mean age was 34.7 years. The majority reported paying women, with 4.3% paying men for sex. Men reported paying for sex abroad (51%), locally (40%), elsewhere in the UK (11%), with only 1.7% paying for sex both in the UK and abroad. The majority (66%) had paid for sex within the previous 12 months. Almost half the men (43%) paid for sex while in another relationship.

In the United States, data on paid sex from a nationally representative sample are not available. Among a nationally representative U.S. sample of adolescents, 3.5% had ever exchanged sex for drugs or money.[167] In this nationally representative sample, among those who had so exchanged sex, 67.9% were boys. The odds of having ever exchanged sex were higher for African American youth (OR=1.75) and youth whose parents had high school education or less (OR=1.72). The elevated risk for STIs including HIV associated with exchange of sex for drugs or money may result from having more sex partners, riskier partners, and more unprotected sex.[168,169] The exchange of sex for drugs, money, or other goods is observed among adults who use drugs, particularly crack cocaine.[170–172] Among women who use crack cocaine, it is estimated that 70% have exchanged sex for drugs or money.[173] In a study of a nationally representative

sample of youths on the streets and a multicity sample of youths living in shelters in the United States, 28% and 10%, respectively, reported having ever exchanged sex for money or other things.[174]

ROLE OF SEXUAL MIXING, SEXUAL NETWORKS, AND PARTNER CONCURRENCY

Some of the most important developments in our understanding of the role of sexual behavior in determining the probability of exposure between infected and uninfected persons (and thus the rate of spread of STIs in the population) in the 1990s have been in the understanding of patterns of partner mixing, sexual networks, and partner concurrency.[175–181] Deterministic mathematical modeling has been used to describe how patterns of sex partner mixing, such as random, assortative (like with like), or disassortative, can influence the course of an HIV epidemic.[179] Concurrent partnerships, existence of "bridge" persons, who have sex both with members of high-and low-risk groups or with groups specifically found to have high STI prevalence and with groups with low STI prevalence all affect STI spread.[61,182–188] High density sexual networks (i.e., those having a large number of sexual connections among all members of a group), variance in a population's distribution of number of sex partners, and the extent to which so called "core groups" are embedded in the general population are all, in theory, associated with faster spread of STIs in the population, and higher STI rates.[177]

In comparing sexual behaviors of African Americans and white Americans, available data from the National Health & Social Life Survey (NHSLS)[189] indicated infection may spread more extensively among African Americans because the African American core group (defined as those who have had four or more sex partners in the past 12 months, some concurrently) is significantly more likely to have contacts with its adjacent group (defined as those who had one or two partners in the past months, who had concurrent partners or who had been paid for sex, those who had three partners who may have been concurrent or not, and those who had four or more partners, none of whom were concurrent) than the white or Hispanic core groups do with their respective adjacent groups.[189] In addition, the percentage belonging to core and adjacent subgroups is higher for the African American subpopulation, (11 and 25%, respectively) than for the white subpopulation (5 and 14%, respectively). Of three racial/ethnic American subpopulations (white non-Hispanic, Hispanic, and African American), African Americans have the highest levels of assortative mixing, regardless of their level of sexual activity. Whites also express strong self-selection for their own racial/ethnic group, but the strength of this preference is weaker than it is for African Americans. On the other hand, the whites who are more sexually active tend to be more race/ethnicity exclusive in their partner choice. Thus, in terms of transmission of infection, the two racial/ethnic groups tend to be somewhat isolated from each other; Hispanic Americans appear to contribute disproportionately to bridging between them.

The sexual mixing patterns by race/ethnicity and by region also suggest an explanation for the regional pattern of STI morbidity in the United States. The southern region of the United States has the highest rates of STD. According to the NHSLS 1992 data, in the southern region, which includes Arkansas, Tennessee, North Carolina, South Carolina, Georgia, Alabama, Mississippi, and Louisiana, the African American core group, perhaps because of its greater likelihood of rural residence, has a stronger tendency to have sexual partnerships outside of the core group than African American core groups in other census regions.[189]

These developments comprise a paradigm shift in the behavioral epidemiology of STI. Historically, the predominant focus of STI epidemiology has been on the attributes and behaviors of individuals, and on the risk of acquiring, rather than of transmitting infection. This approach is consistent with the approaches of clinical medicine, chronic disease epidemiology, and psychology. However, when considered as the "sole" or "main" focus, it appears to be inconsistent with STI transmission dynamics[190] and it has been increasingly challenged in recent years. The new paradigm includes at least three principles: that one person's health outcome is highly dependent on other person's health outcomes;[191,192] that transmission of infection and its prevention is at least as important and perhaps more important than acquisition of infection and its prevention—thus focusing attention on infected individuals and the role they play in the spread of infection; that characteristics of sex partners and partner selection processes are an important component of risk determination—thereby focusing on behaviors of sex partners as well.[186] Applications of this new paradigm have already been incorporated into the epidemiology of specific STDs.[59,114] For specific examples, please see the earlier discussion on the epidemiology of gonorrhea and chlamydia in this chapter.

DETERMINANTS OF TRANSMISSION EFFICIENCY

Following the emergence of the AIDS epidemic, many studies have focused on the determinants of HIV transmission efficiency. Results of these studies also shed new light on our understanding of transmission efficiency of other STIs.

SUSCEPTIBILITY OF THE UNINFECTED HOST

Host susceptibility to invasive STI pathogens depends on entry of the pathogen into cells through one or more surface

receptors. Factors linked to inflammation or immune activation may influence susceptibility by altering number of susceptible target cells or the receptivity of these cells.[193] Microscopic erosions may allow the pathogen to enter the bloodstream directly. Factors that interfere with or facilitate the survival of the pathogenic organism on the genital skin or the genital, rectal, or oral mucosa may decrease or increase susceptibility. For example, the vaginal pH may affect the survival of HIV under some conditions; vaginal ecology, specifically, the absence of H_2O_2-producing lactobacilli has been associated with vaginal infections, as well as with acquisition of HIV infection.[194,195]

Epidemiologic and molecular biologic data suggest that some hosts may have acquired immunity to HIV-1 infection.[196,197] In addition, mutations or deletions in chemokine receptor genes, which serve as coreceptors (with CD4) for HIV-1, have been associated with inherited resistance to transmission or progression of HIV-1 infection.[198] Various related potential mechanisms for this type of resistance to infection include lack of expression of the abnormal coreceptor on the T-cell surface; in CCR5/CCR5Δ32 heterozygotes, decreased expression of the normal CCR5 receptor on the cell surface; and upregulations of C-C beta chemokines (RANTES, MIP-1α, and MIP-1β), which could inhibit viral attachment.[199] How host genetics plays a role in determining susceptibility to other STIs remains largely undefined.

Pre- or postexposure prophylaxis may potentially decrease susceptibility to STIs. The effect on susceptibility to infection of administering antiviral agents immediately after sexual exposure to HIV is not known although zidovudine administered following needle-stick injuries is associated with decreased risk of HIV infection.[200] Commercial sex workers in many areas use continuous antibiotic therapy as prophylaxis against bacterial STIs. Whether or not this practice reduces susceptibility of the individual, it increases the likelihood of the emergence of resistant gonococci.[201]

Several studies have given evidence that reproductive tract infections with other sexually transmitted pathogens increase both acquisition and transmission of HIV and through similar mechanisms, a given STI may increase susceptibility to other STIs as well. Conversely, prior HSV-1 infection decreases susceptibility to acquisition of HSV-2 infection. Acquired specific immunity to several STI pathogens also occurs. Strain-specific immunity to *C. trachomatis* and *N. gonorrhoeae* may be conferred by prior infection with antigenically related strains.[202,203] Finally, specific immunity to HBV can of course be induced by hepatitis B immunoglobulin and hepatitis B vaccine, specific immunity to HPV by HPV vaccine, and partial protection of women who lack antibody to HSV-1 against HSV-2 by an HSV-2 vaccine not commercially available (see Chapter 24).

ANATOMICAL DETERMINANTS OF EFFICIENCY OF TRANSMISSION: MALE CIRCUMCISION AND CERVICAL ECTOPY

The weight of evidence indicates that male circumcision decreases host susceptibility to several STIs, particularly including chancroid, and HIV.[204] The prevalence of HIV infection is 1.7–8.2 times as high in men with foreskins as in circumcised men and the incidence of infection is 8 times as high. Ecological comparisons have shown a striking geographic association between HIV seroprevalence and usual male circumcision practice in Africa.

A survey based on a national random sample of the U.S. population found no relationship of circumcision to STIs, but evidence for STIs was based only on self-reported history of STIs, rather than proven STIs.[205] Several studies have found a that uncircumcised men have increased risk of chancroid (or of undifferentiated genital ulcers in chancroid-endemic areas). Lack of circumcision has also been held to be a risk factor for penile cancer.[204,206–208]

Biologically plausible hypotheses might explain the associations of STIs and HIV with having a foreskin. The recesses of the preputial sac, the mucosal surface, are less keratinized than the skin of the penis of a circumcised man that might predispose to secondary physical trauma, microbial infection, orbalanitis.[204,209] Similarly, balanitis per se might predispose to invasion by microbial pathogens. The less-keratinized mucosal surface of the prepuce appears to have a high concentration of Langerhans' cells that can serve to attach HIV and then present the virus to susceptible CD4 lymphocytes.[209–211] The preputial sac might serve as a reservoir for STI pathogens acquired during intercourse, from which invasion of the urethra or squamous epithelium might proceed. Clinical manifestations of urethritis, warts, or genital ulcers might go undetected longer in an uncircumcised man, which could increase transmission or complications of STIs.

Over the past decade much attention has been focused on male circumcision as a preventive intervention to decrease HIV acquisition among men. A meta-analysis of data from observational studies suggested a sizable protective effect of male circumcision in the general population (Adj RR = 0.57; CI = 0.47–0.70) and an even greater protective effect (Adj RR=0.31; CI = 0.23–0.42) in high-risk populations.[212] The Uganda discordant couples study also provided evidence of reduced transmission among circumcised heterosexual males especially at low viral loads (RR = 0.41; 95% CI = 0.1–1.1).[213] Three studies looked at the relationship between male circumcision and HIV among MSM; two of these found significant increased risk among uncircumcised men (OR = 2)[214,215] and one found no effect.[216] Male circumcision has also been shown to be associated with chlamydia, chancroid, syphilis, HPV, and HSV.[215,217] Evidence is

particularly strong on the association with HIV, syphilis, and chancroid.[218] Recent studies suggest a possible anatomical explanation for the epidemiologically observed protective effect of male circumcision.[210] Superficial Langerhans' cells on the inner aspect of the foreskin and frenulum are apparently poorly protected by keratin and thus may play an important role in primary male infection. Acceptability studies suggest that circumcision is highly acceptable to both men and women in noncircumcising communities as a preventive intervention.[219] Three randomized controlled trials of male circumcision for the prevention of HIV acquisition found a protective benefit against HIV infection of 50% in South Africa,[220] 53% in Kenya,[221] and 51% in Uganda.[222] A simulation model based on the results of the randomized clinical trials (RCT) conducted in South Africa suggests that male circumcision could substantially reduce the burden of HIV in Africa, particularly in Southern Africa where prevalence of male circumcision is low and prevalence of HIV is high.[223] While there is concern regarding potential risk compensation or behavioral disinhibition following circumcision, there is no strong evidence supporting this concern at this time.

A recent analysis of data from the NHANES suggests that in the United States the overall prevalence of male circumcision is 79% and it varies by race/ethnicity; 88% in non-Hispanic whites, 73% in non-Hispanic blacks, 42% in Mexican Americans, and 50% in others.[224] The prevalence of circumcision peaked among those born in the 1970s (91%) and declined among those born in the 1980s (84%).

Cervical ectopy (the presence on the exposed face of the cervix of a single layer of columnar cells that are typically found inside the os) increases susceptibility to chlamydial infection, perhaps to gonorrhea, and to HIV infection.[204,225,226] Cervical ectopy decreases with increasing age and smoking and increases with hormonal contraceptive use, and may partly mediate the association of early age at sexual debut and hormonal contraceptive use with increased risk for cervical infection, and perhaps the link seen in some studies between early sexual debut and cervical cancer. The increased risk for STIs, including HIV infection in young women because of cervical ectopy represents a powerful rationale for delaying sexual debut and for use of condoms for some time after sexual debut. One recent study found HIV infection not to be associated with cervical ectopy in multivariate analyses,[227] but another found the adjusted odds ratio for cervical ectopy extending over >20% of the cervix was 2.18 (95% CI = 1.01– 4.69).[228]

CONTRACEPTIVES, BARRIER METHODS, AND MICROBICIDES

A number of epidemiologic studies have looked at hormonal contraception as a potential risk factor for HIV infection among women of childbearing age. Study findings are mixed; some studies report a protective effect of hormonal contraception while others find either no association or increased risk.[229,230] A recent study of combined oral contraceptives and depot-medroxyprogesterone acetate found no association between hormonal contraceptive use and HIV acquisition overall.[229] However, in this study, hormonal contraceptive users who were HSV-2 seronegative had increased risk of HIV acquisition—a finding which needs further explanation. The mechanisms by which hormonal contraception might facilitate HIV infection are not known but may involve cervical ectopy associated with combined oral contraceptive use,[231,232] increased cervical chlamydial infection,[231,233,234] and changes in vaginal ecology.[235] Hormonal contraceptive use has also been associated with increased incidence of other STIs including chlamydial and gonococcal infections.[231,233,234]

Use of barrier methods provides protection against the transmission of STIs including HIV. Best studied among the barrier methods is the male condom. Reported correct and consistent use of condoms is associated with protection against transmission of HIV,[236,237] with meta-analysis suggesting 80–95% reduction in risk among HIV serodiscordant couples. Condom use is also protective against gonorrhea, chlamydial infection, and trichomoniasis in women[238]—a 62% reduction in risk of acquiring gonorrhea and a 26% reduction in risk of acquiring chlamydial infection. Consistent condom use is also protective against syphilis transmission,[239] the transmission of HSV-2,[240,241] and the male to female transmission of HPV infection.[242] In a longitudinal study of newly sexually active women, those whose partners used condoms for all instances of vaginal intercourse during the previous 8 months were 70% less likely to acquire a new infection than were women whose partners used condoms less that 5% of the time. Even women whose partners used condoms more than half the time had a 50% risk reduction compared to women whose partners used condoms less than 5% of the time.[242] It is difficult to properly measure the effectiveness of condoms. Overreporting of condom use resulting from social desirability bias may reduce both the point estimate of condom effectiveness and the power of the study to detect a protective effect of condom use.[243] Failure to adjust for the improper use of condoms may also underestimate the effectiveness of proper use.[244] Finally, it is important to restrict condom effectiveness analyses to participants with known exposure to infected partners in order to reduce confounding and obtain a more accurate measure of protective effects of condoms against STI.[245] Efficacy of condoms in reducing STI acquisition and transmission is less of an issue at this point than their use effectiveness. Correct and consistent condom use appears difficult but possible for many to achieve.

During the past decade considerable effort and resources have been invested in the development of microbicides effective in preventing the acquisition of HIV and other STIs among women. However, to date study results have not been

encouraging; nonoxynol-9 has been found to increase HIV acquisition[246] and more recently Phase III trials of cellulose sulfate have been halted after the Data Safety Monitoring Board found, during a routine check, an increased risk of HIV acquisition among women who used cellulose sulfate compared with women who used a placebo gel.[247] Trials of a third topical microbicide, "Savvy," were also recently stopped for futility (i.e., little hope for success). Nonetheless, other candidate products are being evaluated in Phase III trials.

SEXUAL PRACTICES

Clearly, unprotected receptive anorectal sex is a risk for acquiring HIV infection not only for men but also for women and for acquiring hepatitis B virus infection.[248] During vaginal intercourse, women appear to be at somewhat higher risk than men of acquiring HIV infection and several other STIs as well, probably including HSV-2 infection, gonorrhea, chlamydia, and others. Sex during menstruation may increase a woman's risk of acquiring HIV infection.[249] Whether susceptibility to other STIs also increases during menstruation is not known.

INOCULUM SIZE: A DETERMINANT OF THE LEVEL OF INFECTIOUSNESS OF THE INFECTED HOST

From the standpoint of the pathogen, production of epithelial lesions and inflammatory exudates or diarrhea, and initially unfettered growth of the organism to high concentrations in genital fluids, represent strategies for transmission to new hosts and hence for self-propagation and persistence in the population. Thus, infections with HIV, like those with hepatitis B, HSV, *C. trachomatis, N. gonorrhoeae, Treponema pallidum*, and many other STI pathogens are probably most infectious in the early stage of infection, with infectivity increasing as the concentration of the organism in the genital tract increases, and decreasing as the pathogen-specific host immune response suppresses concentrations of the pathogen.[250–252] To the extent that STIs are acquired during periods of rapid partner change, the pathogen benefits by achieving an early peak in transmissibility. Data on higher viral concentration in blood and semen with early HIV infection, on the correlation between an individual's plasma viral load and probability of HIV infection in the partner, all generally support the association between stage of infection and transmission of HIV.[213,253–256]

GENITAL ULCERS, INFLAMMATION, AND OTHER REPRODUCTIVE TRACT INFECTIONS

Inflammation and immune activation may affect the production of virus or bacteria and increase or decrease the level of infectiousness of the infected host. Similarly, factors that inhibit or facilitate survival of the pathogenic organism in or on the oral, genital, or rectal mucosae may affect infectiousness of the infected host. For example, in theory, vaginal ecology may affect the concentration of a pathogen in the vagina of an infected host just as it affects susceptibility among the uninfected. Presence of other STIs increases HIV infectiousness. Seminal leukocytosis,[257] gonococcal urethritis,[258,259] and shedding of cytomegalovirus in semen[260] are associated with increased detection of HIV in semen or urethral swab specimens. Treatment of urethritis diminishes detection of HIV in the urethra and the concentration of HIV in the semen.[258,259] For women data are more limited but consistent with an influence of cervical infection, endometrial inflammation, and abnormal vaginal flora on cervical shedding of HIV.[261–263] Similar data on the impact of genital inflammation or reproductive tract infection on shedding of other STIs are inconclusive.

DETERMINANTS OF DURATION OF INFECTIOUSNESS

As discussed in the preceding text, the primary determinant of duration of infectivity of any specific STI is the natural history of that infection. Access to effective treatment has become the most important factor in reducing the duration of infectiousness (and infection) of bacterial STIs. In some developing countries, inadequate clinical, laboratory, pharmacy, and public health infrastructure allow the duration of infectiousness for even the curable STIs to approach that of the natural history of infection. In the industrialized countries, antiviral therapies now may also influence the level of infectiousness of some of the viral STIs, making this parameter now relevant to both bacterial and viral STIs. Health-care seeking behaviors of the population, behaviors of health-care providers, and properties of the health-care system all influence the duration of infectiousness (and infection).

Even in the United States, the existing infrastructure for provision of STI care is woefully inadequate. The public STD clinics are unable to provide sufficient access to all persons seeking health care, and have generally not made hepatitis B vaccination available to high-risk groups to reduce spread of the first vaccine preventable STIs, or played a major role until recently in diagnostic testing and partner notification for *C. trachomatis* infection. The inadequacy of the STD health service infrastructure and the resulting preventable increment in duration of infectiousness is a major reason why the United States has the highest rates of STIs among developed countries.

PREVENTION TRIALS

Prevention trials targeting particular risk factors for STIs can help confirm the role of the risk factor, as well as guide preventive interventions that directly influence the epidemiology of STIs. The search for conclusive results in the evaluation of interventions to prevent STIs, including

HIV, has resulted in increasing numbers of controlled prevention trials in the past decade. Such trials are generally classified either as behavioral or biomedical intervention trials, although in reality, even those based on a biomedical intervention require supportive behavioral intervention components (e.g., to motivate vaccine acceptance and compliance, and prevent relapse to riskier behaviors by those who might otherwise feel safe after vaccination); and conversely, behavioral interventions benefit from biomedical outcome measures.

BEHAVIORAL PREVENTIVE INTERVENTION TRIALS

In STI and HIV prevention several specific issues need to be considered. First, the behaviors targeted for change (e.g., sexual behaviors) are difficult to measure objectively. Dependence on self-reports of behavior creates additional problems in that interventions may change reports of behavior without changing the behavior itself.[264] Second, individuals who change one risk behavior often change other risk behaviors in a countervailing direction, necessitating use of summary measures that reflect the net effects of these changes.[265] Third, the transmission dynamics of STIs are influenced not only by sexual behavior but also by additional factors, such as phase of the epidemic, population prevalence, transmission probability, duration of infectiousness, and specific characteristics of transmission networks, resulting in different trends in the incidence of various STIs in the same populations.[266,267] Fourth, the nature of the relationship between sexual behavior and STI incidence varies across the phases of the epidemic. At the individual level, the magnitude of risk associated with particular behaviors depends on the infectiousness of the infected partner. Finally, whereas adjustments for confounding factors may be feasible in epidemiologic studies of etiologic factors, bias in adoption of behavior change (or in intervention assignment) is inherently part of the practice of medicine and public health, and the idea that such bias can be simply adjusted away may be wishful thinking.[268] In this context, it is interesting to note that data sets from randomized controlled trials with null findings, when analyzed in the same manner as cohort studies with adjustment for confounding, can misleadingly indicate that the intervention was effective (Ward Cates and Ron Roddy, personal communication). This observation is congruent with earlier conclusions that the many advantages provided by randomization when subgroups are defined by baseline characteristics are lost when follow-up responses are used to define patient subgroups.[269]

In the light of all these considerations, it is obvious that in evaluating behavioral interventions to prevent STIs, and HIV, data from randomized controlled trials are particularly important, the choice of outcome measure is critical, and the outcome measure of choice is the appropriate biomedical measure of the STI or STIs of interest.[264,270]

Most evaluations of behavioral interventions to date have employed less rigorous study designs and behavioral outcome measures. A systematic review of computerized abstracts from International AIDS conferences between 1989 and 1992 showed that only 10 of 15,946 abstracts reported on randomized controlled trials of behavioral interventions.[264] Two subsequent critical reviews of behavioral interventions in general and behavioral interventions for young people reported similar findings.[271,272] These reviews also indicated that many behavioral intervention studies focused only on determinants of behavior such as knowledge, beliefs, and attitudes as outcome measures.

Although the majority of behavioral intervention studies do not employ randomized controlled designs or biomedical outcome measures, some remarkably important studies that do have been completed. Among the most important of these, in terms of public health implications, is Project RESPECT. This project was designed to specifically evaluate the efficacy of individual HIV prevention counseling in changing high-risk behaviors and preventing new STIs. This study of high-risk heterosexuals was among the first randomized trials of HIV/STI preventioncounseling.[273] The study, conducted among HIV negative, heterosexual STD clinic patients enrolled from five United States inner-city STD clinics (Baltimore, Denver, Long Beach, Newark, San Francisco), compared (1) enhanced counseling (a four-session counseling intervention, each session of 1 hour duration) based on theories of behavioral science; social cognitive theory, and the theory of reasoned action, and aimed at changing attitudes, self-efficacy, and perception of risk regarding consistent condom use with all sex partners); (2) client-centered HIV Prevention counseling (two sessions of 20 minutes each), an intervention based on CDC's client-centered counseling model recommended for use with HIV testing, and aimed at increasing clients' perceptions of personal risk, exploring barriers and facilitators around risk reduction, and negotiating an incremental risk reduction plan that emphasized consistent condom use with all sex partners); and (3) HIV education (the control intervention that was purely informational, using two brief, didactic messages about HIV and STIs prevention that encouraged consistent condom use with all sex partners, similar to the type of prevention messages given at most STD clinics). The enhanced counseling and client-centered counseling interventions were significantly more effective than the HIV education intervention at decreasing high-risk behaviors and preventing new STIs. These findings were consistent across study sites and gender. Most of the STI reduction occurred in the first 6 months. At 12 months there were no differences across intervention and control groups in condom use, but a 20% reduction in new STIs for counseling interventions remained significant (although the 12-month difference was attributable to the reductions achieved during the first

6 months). The amount and duration of the effect of counseling in Project RESPECT were modest, but from the population perspective even modest changes in behaviors of high-risk STD clinic patients could have a substantial impact on STI and HIV transmission. Unfortunately, following its publication the RESPECT intervention was not widely implemented.

Another multisite randomized HIV prevention trial, coordinated by the National Institute of Mental Health (NIMH), developed and evaluated a seven-session intervention targeting sexual behavior change among low-income individuals at high-risk for HIV infection.[274,275] Participants were largely recruited from STD clinics, with a smaller number from primary health-care settings. The intervention group experienced significant reductions in reported unprotected sexual exposures and lower rates of gonococcal infection in men (based on chart review), but urine ligase chain reaction (LCR) tests at 12 months showed no difference in prevalence of gonococcal or chlamydial infections. Taken together, Project RESPECT and the NIMH trial suggest an impact on behavior with transient reduction in bacterial STI incidence. The feasibility is lower for widescale implementation in public health settings of the seven-sessions intervention employed in the NIMH trial than for the two-session Project RESPECT intervention.

A third randomized controlled study, a culture and gender-specific risk-reduction intervention targeting African-American and Hispanic STD clinic patients in San Antonio, Texas, reduced reinfection rates with gonorrhea and chlamydia among high-risk minority women and these effects apparently persisted for 12 months.[276] Further work on culture and gender specific behavioral interventions also showed declines in risk behaviors and bacterial STI incidence.[277–279] One study focused on the efficacy of group sessions which emphasized race and gender pride, HIV knowledge, communication and condom skills, and healthy relationships in reducing risky behaviors and bacterial STIs. Significant reductions were reported in risky behaviors.[280] Another study enrolled couples and randomized them to a six-session intervention provided to couples together versus the same intervention provided to the women alone; the results were not different in the two conditions.[281]

Behavioral intervention trials that randomize groups or larger units are fewer in number. A study in Zimbabwe randomized work sites to an HIV-prevention health education intervention, women at the work sites that received the intervention reportedly experienced a subsequent significant reduction in HIV incidence, compared with the control work sites.[282] Persons with STI symptoms in developing countries often first seek treatment at pharmacies. Therefore, another study randomized 14 districts (total population nearly 4 million) in Lima, Peru, to receive either an intervention for pharmacy workers providing training and support for management of STIs or to a control intervention providing training for management of diarrhea. Subsequent visits by simulated patients evaluated training outcome. The pharmacies that received training performed significantly better than control pharmacies in recognition of four STI syndromes, in recommendations for use of condoms, and for treatment of partners ($p < .05$ for 47/48 outcomes measured).[283] In another effort researchers in the UK have conducted a four-school randomized trial to assess the feasibility of a large randomized controlled trial of peer-led sex education in schools.[284] The findings suggest that evaluation of peer-led sex education through a randomized controlled trial is acceptable to schools, pupils, and parents. In general, pupils who received peer-led sex education responded more positively than those in control schools.

In the past 2 decades a number of behavioral intervention trials have been conducted including those mentioned above. Many of these studies showed efficacy in reducing risky behaviors, and a smaller number showed efficacy in reducing incidence of bacterial STI in study subjects. Interestingly, to date, no cluster randomized trial of behavioral interventions (where at least one arm of the study represented a behavioral intervention) has showed significant impact at the population level. Neither the MEMA kwa Vigana project (an adolescent health intervention)[285] nor the behavioral arms of the Mwanza, Rakai, or Masaka trials have had significant outcomes. During an era of important declines in risky sexual behaviors in a number of countries,[286,287] it is remarkable that intervention studies have failed to show statistically significant effects on risk behaviors and/or bacterial STIs. Reasons for this discrepancy need further explanation and may be related to issues of contamination, migration, or coverage/penetration.

BIOMEDICAL PREVENTIVE INTERVENTION TRIALS

A randomized controlled trial provided empirical evidence for the effectiveness of screening for cervical chlamydial infection followed by timely and appropriate treatment. This approach emerged as the key strategy for the prevention of pelvic inflammatory disease. Participants were unmarried female health maintenance organization enrollees 18–34 years of age with risk factors for chlamydial infection. They were randomized to receive chlamydia screening or routine care. In this study, cervical chlamydia screening led to a 56% reduction in the incidence of pelvic inflammatory disease during 1 year of follow-up.[288]

Considerable resources have been invested in the development and evaluation of microbicides that would prevent acquisition of HIV and other STIs. Unfortunately, to date results have not been encouraging. Four randomized trials of microbicides with HIV and STI end points have been stopped for safety concerns.[246,247]

A landmark HIV prevention trial randomized communities to biomedical intervention and control conditions to assess the effect of the community level intervention. This community-randomized trial conducted in the Mwanza region of Tanzania was the first randomized trial to demonstrate an impact of a preventive intervention on HIV incidence in a general population. It showed that improved syndromic management of STIs at the primary health-care level reduced HIV incidence by about 38%.[35] HIV incidence was compared in six intervention communities and six pair-matched comparison communities. A random cohort of 1000 adults, 15–54 years of age, from each community was surveyed at baseline and at follow-up 2 years later. The intervention included establishment of an STD reference clinic, staff training in syndromic management, regular supervisory visits to health facilities, provision of antimicrobials, and general population health education about STIs and health-care seeking for STI symptoms.

A subsequent HIV-prevention trial in the Rakai district of Uganda randomized clusters of villages to mass treatment of STIs every 10 months versus antiparasitic treatment alone. Serologic screening and treatment for syphilis and syndromic management for STIs were offered both to intervention and control villages. The study showed no effect on HIV incidence but significant improvements in pregnancy outcomes.[37] The differences in outcome of the Mwanza and Rakai studies are intriguing. The Mwanza study focused on treatment of symptomatic STIs only, whereas the Rakai study provided antimicrobials to the entire population, some of whom had prevalent STIs. In the Mwanza trial, the intervention villages achieved a lower rate of seroconversion to active syphilis and of symptomatic urethritis in men. The Rakai study offered serologic screening and treatment for syphilis and syndromic management for STIs both in the intervention and the control communities. Thus, at the point the Rakai study was terminated, absolute differences between intervention and control groups in prevalence of STIs (other than trichomoniasis) were small: by the end of the study, there were no significant differences between intervention and control clusters in prevalence of gonorrhea, chlamydial infection, or bacterial vaginosis, or in frequency of reported genital ulcer disease, or in proportion seeking care for STI symptoms. The impact of systemic antimicrobial therapy on normal flora in uninfected individuals (e.g., transient suppression of potentially protective H_2O_2-producing lactobacilli or increasing vulvovaginal candidiasis, both potential risk factors for HIV acquisition), represents possible confounders of any beneficial impact of reduced STI prevalence.[289] Differences in the relative prevalence of STIs and HIV in the Mwanza and Rakai districts (higher prevalence of HIV infection in Rakai) and basic differences in study design and in the nature of the interventions may also account for the differences in outcome. One paper provided a useful methodologic overview of community randomization trials of STI/HIV preventive interventions.[290]

A third community randomized trial conducted in Masaka, Uganda, evaluated the efficacy of information, education, and communication coupled with improved STI case management and found no impact on HIV incidence.[291] Another cluster randomized trial conducted in Manicaland, Zimbabwe, failed to show significant differences between intervention and control communities.[292] The intervention included community-based peer education, free condom distribution, income-generating projects, and clinic-based STI treatment and counseling services.

These findings suggest that population level impact on STI/HIV morbidity is a function of a number of interrelated epidemiologic parameters including incidence and prevalence of infections, incidence and prevalence of risk, and preventive behaviors epidemic potential in the community and epidemic phase. In addition, volume of migration and turnover, penetration of the intervention into the subpopulation being targeted, and coverage of subpopulations that happen to drive the epidemic at a given point in time as well as sensitivity of measurements all affect the power of a study to demonstrate differences between intervention and control communities. These findings also have implications for STI prevention programs; they highlight the importance of strategic planning of programmatic activities including targeting, scale-up, coverage, maintenance, and continuous quality improvement of preventive interventions.

During the past decade remarkable advances were made in individual level biomedical interventions for STI prevention. Single-dose oral azithromycin has improved the treatment of several bacterial STIs.[293] A major recent advance in STI prevention is the early success of a prophylactic, monovalent HPV type 16 vaccine;[294] HPV vaccines may be able to help prevent genital and anal cancers in the foreseeable future. Researchers are evaluating multivalent vaccines for preventing moderate to severe cervical dysplasia as well[295] and the use of suppressive therapy to reduce the transmission of genital herpes to regular partners.[296] In a related development, a prophylactic vaccine against HSV type 2 (HSV-2) has shown limited efficacy in that it has proved partly effective for HSV-seronegative women but not for men or HSV type 1 (HSV-1) seropositive women.[297]

Finally, a recently published randomized, double blind, placebo-controlled trial of HSV suppressive therapy with valacyclovir (500 mg twice daily) among women who were seropositive for HIV-1 and HSV-2 in Burkina Faso showed that HSV suppressive therapy significantly reduces genital and plasma HIV-1 RNA levels in dually infected women.[298] This finding has important implications for HIV control; combined with the results of the male circumcision trials discussed earlier, these findings provide reason for great optimism regarding HIV prevention in the near future.

Randomized controlled trials of HSV-2 suppression to prevent transmission and/or acquisition of HIV infection are ongoing.

ASSESSING EFFECTIVENESS OF POLICY INTERVENTIONS

Randomized controlled intervention trials at individual, group, or community levels provide the best empirical evidence for the effectiveness of preventive measures. However, preventive measures with the greatest impact include so-called structural interventions, often based on policy changes. Use of randomized controlled trials to assess the effects of policy interventions is usually not feasible; more creative approaches are needed for this purpose.

One well-known strategy is to combine information from many sources and check for consistency across data sets. A recent analysis assessing the impact of abstinence education on STI rates compared temporal trends in reported gonorrhea rates between 2001 and 2005 in those states that stressed abstinence education to rates in states which did not have a mandate to cover abstinence education and found no differences.[299]

Another approach has been used in demonstrating the effectiveness of alcohol taxation on reducing STI rates among youth.[300] Between 1982 and 1994 there were 34 instances of a state beer tax increase in the United States. The investigators conducted a nonparametric quasiexperiment comparing the proportional changes in STI rates in states with and without a tax increase over the same period and employed a time series econometric analysis, evaluating the effect of the level of beer taxation on the proportional changes in STI rates, controlling for legal minimum drinking age, per capita income, and state and year differences. The results showed that in 26 (77%) of the states with an increase in beer tax, there was a greater proportional decrease in gonorrhea rates among males in both the 15–19 and the 20–24 age groups as compared to the proportional change among the states without a tax increase. Similar patterns were observed for females. It was estimated that a $0.15 tax increase on a six-pack of beer would reduce gonorrhea incidence rates by roughly 10% among the 15–19 year age group. The feasibility, noninvasive nature, and relatively low cost of this study are remarkable, and of course its findings, not having been based on sample data, are completely generalizable to the study population. Nonobtrusive measures to assess the effectiveness of policy interventions to reduce STIs, including HIV, warrant further evaluation.

As indicated by comparisons of sexual lifestyles in the United States and the UK, the greater dispersion in sexual behavior in the United States than in the UK implies a need for strong public health policy, but that the same dispersion creates strong opinions about inappropriate sexual behavior that make implementation and evaluation of strong health policy decisions difficult.[301]

THE DEMOGRAPHIC, SOCIAL, POLITICAL, AND TECHNOLOGICAL CONTEXT

The trends in STI prevalence and incidence, diagnostic, therapeutic, and vaccine developments and other preventive innovations are all embedded in historical demographic changes. The demographic shifts of the postindustrial era, known as the "second demographic transition," are defined by an unexpected low level of fertility (below replacement); declining population size; and a compensatory trend in migration patterns. The demographic mechanisms of action involved in the second demographic transition are multiple and multidimensional. They include, in addition to large decreases in period and cohort fertility, decreases in the total first marriage rate, strong and large increases in mean age at marriage and childbearing, divorce and union dissolution, cohabitation, proportion of extramarital births, and maternal employment. In the second demographic transition, international migration plays an important role in redistributing population from low-income countries with high population growth to high-income countries with low or negative population growth. Migration into Western Europe and the United States has increased remarkably over the past 2 decades. During the same period the structure of marriage and the family and the values, attitudes, and expectations of men and women also changed.[6] In Europe and the United States, many women choose not to marry; the number of children born to a woman declined; many people now live in a variety of household arrangements including single people with friends and children, gay couples and friends, and step families. Emphasis on values, such as individual autonomy, self-fulfillment, tolerance, democratic decision making, individual freedoms, and individual rights increased. Concurrently, women's roles in society and their expectations also changed. Women are now less likely to endure abusive or unhappy marriages; they assume they have equal rights to education and work outside of the home and they expect an enjoyable sex life with control over their fertility. In industrialized countries, changes of the second demographic transition do not happen uniformly across socioeconomic strata. Changes involving increased freedoms, fulfillment, and autonomy are observed among higher socioeconomic strata while increased divorce and single parenthood are more frequent among lower social strata.[6]

The past few decades have also witnessed major political, technologic, and economic shifts, all of which have the potential to impact sexual behavior, sexual networks, healthcare infrastructure, and health service delivery. Included among these shifts are the breakdown of the Berlin Wall; the opening of China to the rest of the world; the establishment of democracy in South Africa; the demise of the former state socialist economies in Europe; and the information revolution and the emergence of the global economy (the globalization of

capitalism). Processes of globalization are driven by international corporations that move capital, goods, and technology across borders. Some aspects of globalization (e.g., globalization of knowledge, cultural globalization) have been welcomed throughout most of the world; however, economic globalization has created concern and controversy. Economic globalization involved the collapse of national regulatory frameworks; an increase in international trade and investment; increased production for export in developing countries; a decrease in public spending in many developing countries, particularly the poorest ones; and the disappearance of subsistence production. In the globalized system, capital is moved anywhere in the world to find the cheapest production costs. Consequently, in most areas of the world, the secure long-term employment that characterized the era since the second World War declined, job security is reduced markedly, more people work part-time and on temporary contracts, social welfare entitlements have been cut, and economic inequalities have increased.[8] For example, in the United States in early 2005, there were multiple pension system defaults especially in the airline and steel industries and major changes have been proposed for the social security system. Such macrolevel changes in economic and social patterns can have major impact on the structure of sexual partnerships, sexual behaviors, and STD transmission patterns.[21]

Processes of globalization are reflected in the technologies that directly affect the diagnosis, management, and prevention of STI. The new and improved diagnostic tests and therapies, the newly developed vaccines, and medications that enhance sexual functioning such as Viagra and Cialis are researched, developed, and marketed globally, in accordance with the principles of minimized production costs and maximized profits, by increasingly merged global companies.

Processes of globalization are also reflected in the modified face of the sex industry which is an increasingly globally connected, multibillion dollar industry driven by international business concerns that move capital (women, young men, and children) and consumers (through sex tourism) across borders, sometimes illegally. Finally, globalization of capitalism and the market economy have resulted in the creation of new desire for ownership of consumer goods among young people in many developing countries such that they are willing to exchange sex for money in order to purchase consumer goods. Concurrently the market economy increases disposable income among men—a strong correlate of paying for sex. Moreover, there are very effective processes in place that efficiently bring the demand and supply for sexual transactions together. These processes include the flow of information through networks (e.g., sex worker client networks and pedophiliac networks via websites) facilitated by the Internet; travel for business and tourism, sex tourism; economically motivated migrations some of which are for the purpose of buying and selling sex; politically motivated migration; and trafficking of women and children for sex. Natural and man-made disasters such as earthquakes, hurricanes, tsunamis, economic collapse, civil wars, and wars between national states further fuel motivations and processes that govern commercial and quasicommercial sexual transactions.

Technological advances such as the Internet, cell phones, and other instant messaging devices facilitate efficient and low-cost hookups between potential sex partners and between buyers and sellers of sexual services. Numbers of cyber brothels easily accessible through the Internet; supply and demand for pornography, sex with children, sex toys, and sexual networking parties have all increased remarkably. As the volume of commercial sex increases and such transactions penetrate society, attitudes toward nonconventional sexual behavior change. Increased tolerance is associated with increased frequency of riskier sexual behaviors in the general population as observed in the United States and the UK.[6,159]

Thus, the global topology of sexual transactions is changing radically. First, the volume of such transactions is growing. Second, societal acceptance of widely diverse transactions is growing; and third, due to the combined effect of the Internet, increased migration and increased travel, such transactions bring together increasingly diverse individuals—creating sexual network ties among geographically distant populations.

SUMMARY AND CONCLUSIONS

The past decade has been marked by continuing advances in STI/HIV prevention, diagnosis, and treatment. Improved understanding of the epidemiology of STIs including HIV can allow public health workers to make better use of the many available efficacious interventions to help prevent, identify, and treat STI including HIV. At the same time the gestalt of social determinants, public health systems, and risk and preventive behaviors are undergoing rapid transformation in the context of globalization, information technologies, and other social forces. Such transformation suggests that the near future may be marked by a further weakening of public health systems, important increases in risk behaviors, and resultant increases in STIs including HIV globally.

At this juncture, the science of STI/HIV prevention faces new, and perhaps, more difficult challenges. Moving efficacious interventions out of the randomized trial or experimental design context into effective everyday implementation in the community; moving effective interventions through appropriate targeting and scale-up to population level impact; and moving individual level interventions to implementation at the population level require both resources and specialized know-how. Recent experience with STI prevention programs such as screening for chlamydia and STI community randomized trials such as PREVEN and Manicaland suggest a number of new questions for which we

do not yet have answers. These include: How does the point in the epidemic at which an intervention is introduced affect the population level impact of the intervention? How do(es) the group(s) targeted by an intervention affect the population level impact of an epidemic? How do turnover (movement into and out of target groups) and spatial mobility affect coverage achieved during the implementation of an intervention and the resultant population level impact of the intervention? What is the effect of other interventions already being implemented on the population level impact of an intervention? Are there issues of diminishing incremental impact and saturation that need to be considered before implementing interventions? What are synergistic and redundant interactions among interventions that need to be considered in the choice of intervention packages? The current era will probably be marked by increased attention to the interactive dynamics among epidemiologic parameters, among intervention parameters, and the interaction between epidemiology and intervention.

Social and Psychological Dimensions of Sexuality

This page intentionally left blank

6 Social Dimensions of Adolescent Sexuality

Katherine W. Stovel, Derek Kreager, and Megan A. Moreno

OVERVIEW

Most of us recall the awkwardness and immediacy of our early sexual development. With curiosity, excitement, and trepidation, adolescents watch as their bodies undergo the metamorphosis that accompanies puberty. In many ways, it is these changes that awaken adolescents' self-images as sexual beings, providing both the means and the desire for early sexual relationships.[1] But physiological maturation is insufficient for explaining early sexual development. For all youth, sexuality is equally shaped by the images, cues, and interactions that stem from lived environments. It is in negotiating a complex social landscape that adolescents fully come to understand their own sexual identities and subsequently learn to express themselves as sexual adults.

The purpose of this chapter is to explore the social contexts of adolescent sexuality and to present relevant research in this area. Doing so requires an ecological approach to adolescent sexuality and an acknowledgement that many social domains impact early sexual development and behavior. Youth not only have varying rates of physical maturation, but they also come from a multitude of economic, cultural, family, religious, and gendered backgrounds, while participating to varying degrees in age-graded tasks of education, work, peer affiliations, and home life. Therefore, we focus both on sociodemographic characteristics of youth (e.g., age, sex, race) and on various social structures and relationships that shape adolescents' sexual behavior, largely at the expense of the psychological and subjective aspects of adolescents' sexuality. Throughout the chapter, we examine factors that influence the onset and course of adolescents' sexual activities, and the related processes of partnership formation and dissolution. Discerning patterns in this intricate terrain—and relating these patterns to adolescent sexual development—is a challenging task.

For many years, methodological problems plagued research in this area, mainly because of selection effects, limited longitudinal data, small sample sizes, and lack of comparison samples. Recent efforts to understand the social dimensions of adolescent sexuality have been substantially aided by federal investment in a comprehensive, nationally representative data set collected longitudinally since 1995 by the National Longitudinal Study of Adolescent Health (see Bearman[2] for design details). This project, frequently referred to as Add Health, includes survey and biological data from over 20,000 adolescents and young adults residing in 80 communities in the United States, as well as data from their parents and about their schools. Because Add Health was initially a school-based study, adolescents' peers and romantic partners are frequently also study participants—a design feature that allows for much more precise analysis of the multiple influences on adolescent behavior. Studies using Add Health data augment research on teen sexuality that relies on two other large nationally representative samples, the National Longitudinal Study of Youth (NLSY, 1997) and the ongoing National Survey of Family Growth (NSFG). Cumulatively, many published studies that use these data have broadened our understanding of adolescent romantic and sexual behavior; more generally, the availability of these data has reinvigorated this research area and stimulated even more research that seeks to illuminate an often tumultuous developmental stage.

RELATIONAL CONTEXTS OF ADOLESCENT SEXUALITY

PEER INFLUENCE

Peer influence has become the most actively researched area of adolescent sexuality. Interest in peer effects is partially explained by parental fears of children becoming lost to "youth culture." However, it is also clear that the importance of peers increases substantially during the teenage years[3] (see Giordano[4] for a review). Contemporary age-graded societies typically place youth in a protracted period of educational attainment, where contacts with adults are limited and peer contacts greatly increase. This shift toward greater peer involvement fosters the highly complex and stratified

informal peer organizations found in most secondary schools.[5,6] Situating oneself within local peer structures becomes a primary adolescent concern. Moreover, adolescents' lack of economic and political power heightens peer status as a means of attaining individual influence.[7] At home and in school, youth have little control over their lives, but in evaluating and bestowing status on their peers, their power reigns supreme.

Peer relations take several forms, and over the life course different types of peer relations dominate.[8] At the dyadic level are individual friendships or relationships; this type of peer relation first emerges during the toddler years and is frequent through all stages of life. Among adolescents, individual friendships are frequently same-sex, though most adolescents experiment with cross-sex friendships or romantic relationships at some point.

A second type of peer relation is the small group, which may be of same- or mixed sex. Small groups are identifiable among young school aged children, but rise in prominence during late childhood and adolescence. Frequently called cliques, small peer groups are composed of individual friendships of varying strength, duration, and intensity. Characteristically, small peer groups develop identities that distinguish them from other groups of adolescents, and contribute to adolescents' sense of "belonging." Some of these identities are considered prosocial by adults, while others are viewed as problematic or delinquent. However, adolescents who are isolated from these small groups may feel distressed and under some circumstances may engage in antisocial behavior.[9,10]

Finally, a new source of peer group emerges in adolescence: the crowd.[8] Adolescents in industrialized countries frequently become oriented toward large groups of other teens based upon shared interests, backgrounds, or styles. These crowd classifications exist even in the absence of specific relations linking adolescents together. The organization of schools, increased freedom of movement, and adolescents' emerging autonomy all contribute to a new cognitive orientation toward local youth cultures. In terms of relationships and sexual behavior, all three levels of peer influence are important, though scientific studies that disentangle the relative effects of each level are in their infancy.

PEER INFLUENCE ON SEXUAL BEHAVIOR

Peer relations at each level are widely believed to influence adolescent sexual behavior. However, in a recent review of the research literature, Brown and Theobald[11] conclude that peer influence on adolescent sexuality tends to be much more moderate than is often assumed. While parents, educators, and researchers observe a great deal of similarity among pairs or groups of adolescents and frequently interpret this as evidence of peer influence, in some cases adolescents with similar interests or proclivities simply seek one another out. This process of selecting similar others is known as homophily.[12,13] Thus an important concern in studying peer effects is identifying the distinction between the effects of selection and influence;[4] because of these two confounding processes, it is surprisingly difficult to ascertain the extent and significance of peer influence.

Nevertheless, a review of the research suggests that the magnitude of peer influence varies across groups and developmental stages. With respect to age, both Berndt[14] and Brown[3] suggest that peer influence increases dramatically with the transition from childhood to early adolescence and slowly declines thereafter. Other studies document that girls and boys are differentially susceptible to peer influence and that effects differ among racial groups. In a longitudinal study of the effects of friends' sexual behavior on initiation of coitus, Billy and Udry find that peers exert a more powerful influence on whites than on blacks.[15] The same study suggests that white females are more influenced by their male friends than by their female friends; for white males and black females these peer effects are insignificant. However, a recent longitudinal study of adolescents in the Philippines finds that having sexually active friends is associated with earlier sexual debut among both boys and girls, controlling for a variety of social and demographic factors.[16]

Peers are also important as an information source. Peer groups create and enforce group norms of behavior, which are particularly influential for adolescent behavior. Finally, peers may help create opportunities for adolescents, for example, by offering unsupervised venues that can be used to experiment with sexual and other nonnormative behavior.[11]

Peer influence in these different forms may both encourage and discourage sexual risk taking. It is well documented that adolescents who believe that their friends are sexually active are more likely to become sexually active themselves,[17] yet often teenagers must negotiate conflicting influences originating from different subgroups of their peer network (e.g., Haynie,[18] Bearman and Brückner[19]). In this regard, the direction and magnitude of peer effects depend on the level of peer context and whether the friends are male or female. In an analysis of data from students attending high school in the United States, Bearman and Brückner[19] find evidence of protective peer influence, especially among same-sex members of close friendship networks and larger peer groups. In fact, adolescents with no or very few friends are no less likely to become sexually active than are adolescents with average or large peer networks. However, the most popular girls in schools tend to experience sexual debut earlier than their less popular peers. On the other hand, these girls are significantly less likely to become pregnant.

Not surprisingly, the direction of influence depends on the kinds of peers to which an adolescent is connected. Bearman

and Brückner measured the risk status of peers based on a cross-classification of nonnormative behavior and academic orientation.[19] They found that having peers with low risk status is negatively associated with sexual debut and pregnancy, while girls connected to peers who engage in higher-risk activities are at increased odds of both sexual debut and pregnancy. These relationships are illustrated in Table 6-1, which reports odds ratios for sexual debut and pregnancy among a representative sample of American girls aged 12–17 years.

Peer influence, whether via modeling, diffusion of information, norms, or opportunity structures, is not limited to direct peer pressure that flows through social relations between particular teens. Rather, adolescents' influence on one another may occur through intermediaries: friends of friends, or even others more distant. In fact, adolescents may change their behavior or norms as part of an attempt to fit in with a new crowd or to form new friendships.[12] For instance, the proportion of students in a school who are sexually active also strongly predicts sexual debut and pregnancy risk among female adolescents—independent of the behavior of particular friends.[19] It is therefore not a simple matter to identify which peers are most relevant when studying peer effects. Focusing only on best friends or on the most popular peers (the "leading crowds") may under- or overestimate peer effects.[19] On the one hand, selection effects and reciprocity probably limit the influence of best friends, while on the other hand, adolescents may not necessarily like or trust the most popular peers in their school or neighborhood. Powers[20] has demonstrated that the behaviors of peers only indirectly tied to the focal individual (second step ties) influences white female sexual debut. Bearman and Brückner[19] find the strongest and most consistent peer effects at the level of close friends and peer groups; in contrast to the fears of many parents, they find no evidence that the behavior of the most popular crowd in a school influences other adolescents' sexual activities.

These complex patterns of peer influence highlight the role of social networks among adolescents. However, the networks of social relations that underlie the peer influence process are often not readily apparent to adolescents themselves or to their parents and teachers. Studies that rely exclusively on adolescents' reports about their peers may miss significant sources of peer influence and therefore underestimate peer influences that operate through more subtle mechanisms than direct peer pressure. For example, Bearman, Moody, and Stovel used self-report data from all students attending a medium-sized high school in the Midwest to study the actual romantic and sexual network in this city[21] (see Fig. 6-1). Their study found that many adolescents are initiated into romantic relations by partners who themselves have already had at least one romantic attachment. Equally as important, the structure of the overall sexual network was invisible to the students themselves, but provides the context for subsequent partnership formation through the emergence of subtle norms against sexual partnerships that close "short cycles" (i.e., sexual networks in which several sexual linkages occur between relatively small numbers of individuals—see Chapter 7). This apparent prohibition against short cycles among adolescents is important, since short cycles produce dense sexual networks—an important risk factor for the spread of sexually transmitted infection.

In light of these research findings, interventions that move beyond peer pressure resistance training are likely to be most effective at reducing adolescent sexual risk taking. Further, educational interventions that rely on peer leaders should make sure that adolescents chosen as leaders have credibility with their audience. Members of leading crowds or very popular adolescents might make for poor examples if they have high rates of sexual activity. In some cases, adults may actually have more credibility as sources of information.[22]

Table 6-1. Summary of Effects for Peers' Risk Status Across Contexts[19]

	Sexual Debut		Pregnancy	
	Low Risk	High Risk	Low Risk	High Risk
Best male friend	1.09	1.29	0.61	1.36
Close friends (all)	0.63	1.12	0.42	1.26
Close female friends	0.74	1.20	0.50	1.08
Close male friends	0.68	0.73	0.93	2.19
Peer group	1.24	2.73	0.13	0.47

Numbers are odds ratios from logistic regressions, controlling for sociodemographic and individual characteristics.

Data from Bearman PS, Brückner H. *Power in Numbers: Peer Effects on Adolescent Girls' Sexual Debut and Pregnancy.* Washington, DC: National Campaign to Prevent Teen Pregnancy: Research Monographs; 1999.

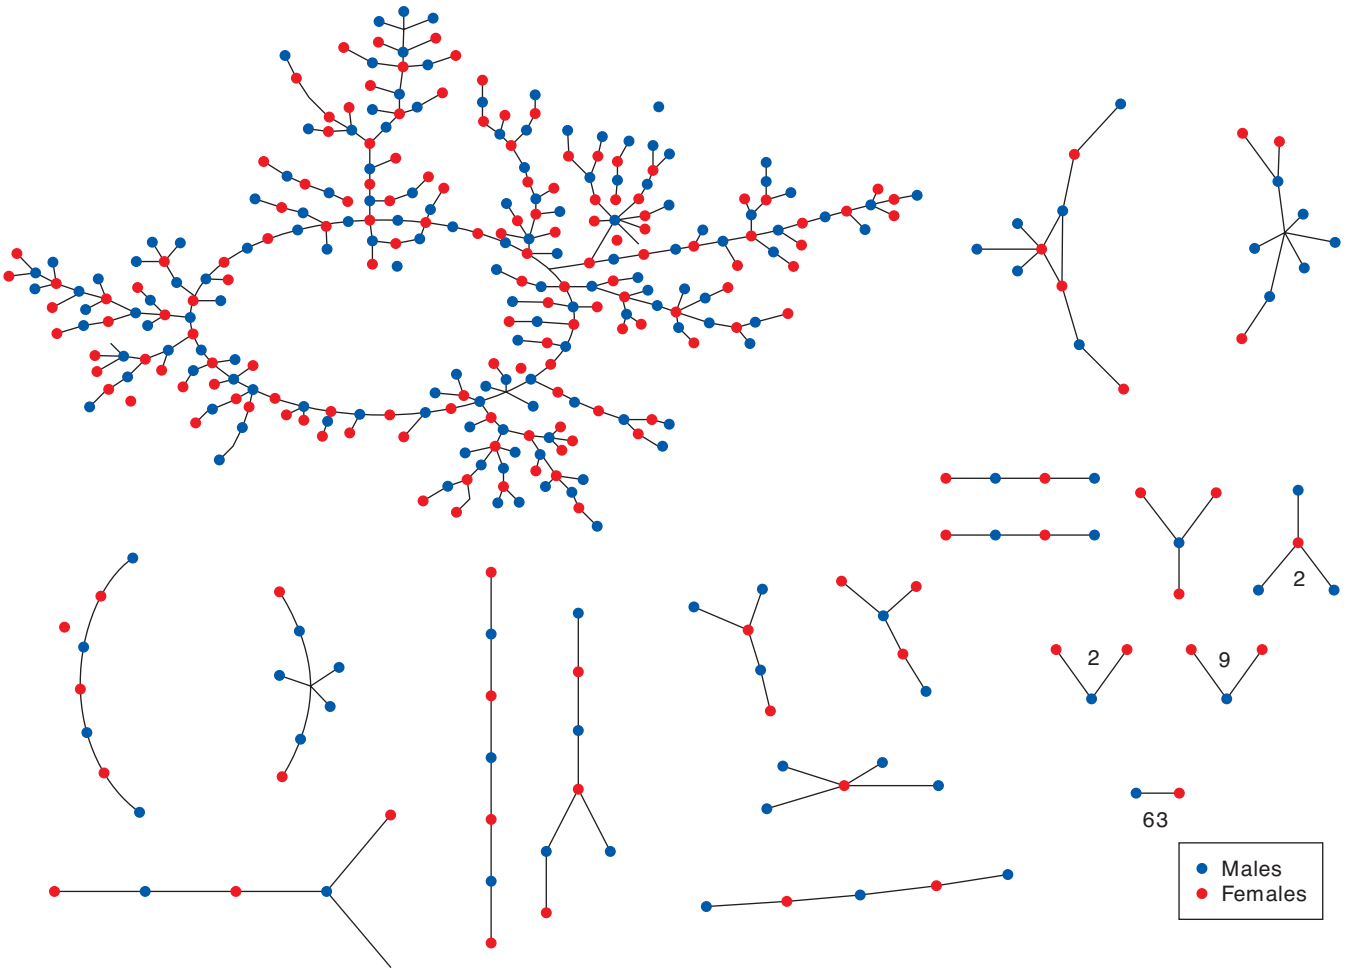

FIGURE 6-1. The structure of romantic and sexual relations at "Jefferson High School." Each circle represents a student and lines connecting students represent romantic relations occurring within the 6 months preceding the interview. Numbers under the figure count the number of times that pattern was observed (i.e., we found 63 pairs unconnected to anyone else). (From Bearman P, Moody J, Stovel K. Chains of affection: The structure of adolescent romantic and sexual networks. *Am J Sociol* 2004; 110(1): 44–99.)

DATING PATTERNS AND SEXUAL BEHAVIOR

As mentioned above, adolescents' opportunities for and interest in sexual relationships develop within a complex and dynamic social milieu. In late childhood, peer groups are predominantly monosexual and opposite-gender contacts are limited. During the middle-school years, boys and girls begin to congregate into group settings and heterosexual pairings emerge.[11] Continued allegiances to same-sex peer groups (along with uncertainties about interacting with the opposite sex) make most early "dating" incursions brief and superficial social displays rather than intimate friendships. Add Health data reveals that teens under age 14 typically report relationship durations of 5 months and teens aged 14–15 years report durations of 8 months.[23] Norms revolving around status symmetry, gender-appropriate behavior, fidelity, and peer valuation add to the scripted nature of early romantic experiences.[10]

As adolescents grow older, peer groups generally become smaller and more gender heterogeneous, making romantic partnerships highly visible structures within peer networks. For most adolescents, these changes correspond to increased intimacy and trust in romantic partnerships, foreshadowing the longer-term relationships associated with adulthood. Accordingly, adolescents over age 16 report typical relationships of almost two years in duration.[23]

The dominant pattern of adolescent relationships is "serial monogamy,"[24] in which teens date (and may be sexually active with) one partner, then select another partner following dissolution of the previous relationship. However, for those who remain embedded in highly gendered peer groups (e.g., athletics, gangs, etc.) or for whom status is a salient aspect of their identities, peer norms may impact these sexual behaviors and developmental trajectories.[25]

For most adolescents, the first sexual experience takes place within the context of a romantic relationship.[26] More than three-quarters of adolescent girls report that their first sexual experience was with a steady boyfriend, a fiancé, a husband, or a cohabitating partner.[27] However, adolescent sexual activity is not always associated with a steady partner. A 1996 study surveyed 75 sexually experienced adolescents about types of sexual relationships and

found that teens classify sexual partners into three distinct groups: steady partners, casual partners/friends, and "one-night stands."[28] Expectations about these relationships, as well as protective behaviors such as condom use, differed between these partnership types. Adolescents had lower expectations about the potential for long-term relationships and higher rates of condom use when they were involved in one-night stands, whereas steady partner relationships carried higher expectations and lowered condom use. These findings show that adolescents are well aware that not all sexual experiences are a part of, or result in, longer-term relationships. This study's findings regarding condom use are also consistent with studies of adults showing that individuals frequently alter their contraceptive behavior depending on their assessment of risk and the future potential of the relationship.

OTHER CORRELATES OF SEXUAL ACTIVITY

AGE

Although peers have been the most studied social correlate of adolescent sexuality, recent research is broadening our understanding of the contexts of early romantic behaviors. Biological explanations are typically used to explain the strong correlation between age and sexual behavior.[1] Explaining variation in the age of sexual onset is one area where social researchers have gained additional insight. While children are physiologically capable of sexual arousal, it is with the onset of puberty that most become more curious and interested in pursuing their sexuality. However, as alluded to above, adolescents' expressions of sexual interest are also functions of the social influences and behaviors of those around them.

National surveys show that a significant proportion of young adolescents (aged 12–14 years) report that they have been on a date or have had a romantic relationship, and approximately one in five adolescents have had sex before their 15th birthday.[29] Younger males are slightly more likely to be sexually active than younger females, though for both young boys and young girls, relationships tend to be short[30] and sex is likely to be sporadic.[29] However, partnerships linking young adolescents with older partners are significantly more likely to be sexual than relationships between young teens.[30]

By late adolescence, the majority of adolescents, both male and female, have had sexual intercourse.[27,31] In addition, most youth begin noninsertive sexual activities prior to first intercourse. Sexual exploration typically occurs in a stepwise fashion, with petting and oral sex commonly preceding vaginal sex. Teens report more "petting" (touching under clothing) and "heavy petting" or fondling (touching each other's genitals) than sexual intercourse, with all behaviors increasing with age.[23] More than three-quarters of teenage males who have had vaginal intercourse report previous experience with masturbation by a female.[32] Moreover, one in five males who had never had vaginal intercourse reported having been masturbated by a female, and one in seven reported having received oral sex. A report from the Guttmacher Institute[27] estimated that 12% of teen males and 10% of teen females had experienced oral but not vaginal intercourse. Further studies of oral sex showed that for males between 15 and 19 years of age, roughly half had received oral sex and 39% had given oral sex.[32] Additional evidence supporting the incremental model of sexual exploration is found in a study reporting that adolescents who intended to become sexually active in the next year had higher rates of petting and oral sex than peers who did not intend to become sexually active.[33] This suggests that teens who hope to have sexual intercourse may be more interested in experiencing other sexual activities as precursors.

Recent data from the National Survey of Family Growth shows that in 2002, the proportion of adolescents who had ever had vaginal intercourse rises steadily from approximately age 15 to 19 years (Fig. 6-2). Comparison with data from previous years shows that rates of sexual activity among younger adolescents have declined over the past decade, though older adolescents continue to become sexually active at comparable rates.[34]

While petting and oral sex are common precursors to vaginal sex, less is known about adolescents' engagement in anal sex. In most studies, adolescents report lower rates of anal sex than other sexual behaviors, though anal sex appears to become more common as adolescents age. In one of the few nationally representative studies of anal sex, Gates and Sonenstein[32] report that 11% of males aged 15–19 years had had anal sex, while a study of college students found that 17% of males and 18% of females had engaged in anal sex.[35]

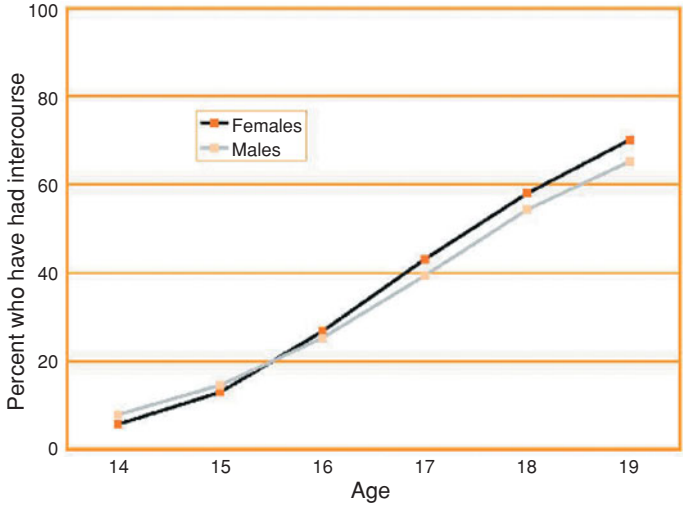

FIGURE 6-2. Percent who had intercourse. (From the Allan Guttmacher Institute, Facts on American Teens' Sexual and Reproductive Health, 2006 (these data are from 2002, i.e., percent of males and females who have had intercourse, by age, 2002).)

Because anal sex is commonly associated with the homosexual male population, stigma surrounding this population may have impeded efforts to learn more about this particular practice among adolescents.[36]

GENDER DIFFERENCES

Although the gender gap is narrowing, recent nationally representative data show that males continue to initiate sex at earlier ages than females[31,37,38] and report that they have significantly more sexual partners than do girls.[31] However, among sexually active adolescents, girls, particularly white girls, are more likely to report that they have had intercourse within the past 3 months.[31]

Some explain the overall decline in teenage sexuality over the last decade in terms of lowered rates of male intercourse.[31,39] Risman and Schwartz[39] argue that increasing numbers of abstaining males result from girls having greater influence in romantic and sexual involvements. Girls are believed to have greater freedom and control over their sexuality within a romantic relationship, while at the same time fewer females are available for male nonromantic sexual activities. This shift in gendered romantic power could then explain lower rates of male sexual activity and level rates of female sexual activity, the latter resulting from offsetting rates of lowered nonromantic sexual activity and higher romantic sexual behavior.

Giordano et al.[40] provide support for Risman and Schwartz's[39] argument using data gathered from the Toledo Adolescent Relationship Study (TARS). They find that boys, more than girls, report that their partners are likely to have more power in a romantic relationship and are more likely to influence their behavior. Moreover, they find that boys are less likely than girls to show confidence in such relationships and are more likely to have difficulty communicating. They argue that their results support symbolic interactionist ideas about individual adaptations to problematic situations. Boys, more than girls, enter heterosexual dating with fewer emotional and social skills in reciprocal relationships. These deficits then leave them at a disadvantage in early romantic involvements. Interestingly, the authors found no significant gender differences in perceptions of "love" in adolescent romantic relationships. Boys were just as likely as girls to report loving feelings in these relationships.

Within gender, variation in biological development may also affect patterns of sexual development, particularly for girls. Girls with early or more advanced pubertal development have been shown to be at greater risk of delinquency[41,42] and early sexual initiation.[43,44] These patterns are typically explained as resulting from early-maturing girls being sought out by older (and likely more risk-taking) males.[42] However, using Add Health, Haynie[41] found that early-maturing girls were not more likely to be embedded in male or older peer groups. Rather, she found that these girls were more likely to be involved in a romantic relationship, embedded in "party" groups, and spend more time with their peers. These results suggest that early development gains girls access to popular peer cliques that are characterized by precocious behavior, including sexual risk taking.

RACIAL DIFFERENCES

Several authors find that the behaviors and meanings of early romantic involvements differ by adolescents' racial characteristics. In a comparison of four nationally representative samples, Santelli et al.[31] find that a higher proportion of African American adolescents aged 15–17 years have had sexual intercourse than white or Hispanic youth, though there is substantial variation in estimates of sexual activity level across surveys.[31] Differences by race are also evident in data describing the proportion of teens that have had four or more lifetime partners: significantly more adolescent African Americans, particularly African American males, report multiple lifetime partners.[31] Moreover, analyzing data from Add Health, Giordano et al.[45] find that even though African American and white youth are equally likely to be involved in a romantic relationship, African Americans are less likely to describe these relationships as intimate and intense. This difference is particularly significant between black and white girls. In addition, African American males are more likely than their white male counterparts to report having intercourse with their partners.

Giordano et al.'s[45] results have greater weight when added to other findings that black youth have lower marriage expectations compared to whites.[46,47] Although the relationships between race, early dating experiences, and subsequent marriage rates are complex, observed patterns suggest important links between these factors.[48] Continued work in this area could distinguish structural, cultural, and developmental processes as they relate to racial dating experiences.

Another research area connecting race and adolescent romance looks at the experiences of young interracial relationships. Adolescent interracial couples are theoretically interesting because prominent racial scholars link interracial marriage rates to the erosion of racial barriers to social mobility.[49,50] Adolescent cross-race relationships may therefore portend a less segregated future.[51] However, even though attitudes toward these relationships are becoming more accommodating, young interracial couples remain infrequent. Looking at Add Health, Vaquera and Kao[52] find that interracial couples are less likely than other daters to publicly and privately show affection. They assert that lower levels of intimacy in interracial romances result from continued social barriers and stigmatization of racially nonnormative relationships. The social isolation of minority communities[53] and the coercive acts of disapproving

peers and parents[54] likely contribute to the difficulties facing interracial couples.

SEXUAL ORIENTATION

For many adolescents, sexual development entails discovering their own sexual orientation. Sexual orientation refers to the direction of an individual's sexuality, usually in relation to the sex of one's preferred partner. Typically, researchers classify sexual orientation into three categories: exclusively heterosexual, predominantly heterosexual with some same-sex experience, and exclusively homosexual.[55] Classification is particularly slippery during adolescence, when the orientation of sexual preferences and sexual behaviors or experiences may not match.

Many studies reveal that adolescents frequently have same-sex romantic or sexual experiences, yet still consider themselves to be heterosexual (while others report having opposite-sex experiences but same-sex attractions). For instance, Add Health data show that the rate of same-sex attraction and behavior in the adolescent population ranges from 1% among younger teens to 15% among older adolescent girls who describe themselves as having a nonheterosexual identity.[56] A separate study of Swiss adolescents showed that 1.5% of girls and 2.5% of boys reported sexual behavior with a person of the same sex; however, 65% of these males and 80% of these females considered themselves to be heterosexual.[57] These data illustrate that sexual orientation cannot be simplified into "gay" and "straight" categories.

Researchers also investigate the life experiences of adolescents who are sexually oriented toward members of their own sex. Cumulatively, these studies show that adolescents with same-sex orientations are at elevated risk for a variety of social, emotional, and mental health problems.[58,59] While some of these negative outcomes can be attributed to an exaggerated form of typical adolescent anxiety and alienation, particularly poor mental health and adverse social experiences may reflect, at least in part, homophobia of parents, teachers, and other adolescents.[60]

SOCIOECONOMIC STATUS

Numerous studies have examined the links between family socioeconomic background and adolescent sexual behavior. By socioeconomic status, we mean the social and economic resources that an individual controls. Social scientists frequently measure socioeconomic status with a composite indicator that captures the highest level of education completed and a measure of income or occupation[61]; when studying adolescents, scholars typically use the socioeconomic status of adults in the household in which the adolescent resides.

Large-scale studies provide mixed results for the association between socioeconomic status and adolescent sexual activity. Some studies find no relationship between family income or occupation and adolescent sexual behavior,[26,62,63] while others find a negative relationship between socioeconomic status and sexual risk taking.[64,65] Much of this divergence may be explained by the conflation of parent education and parent income/occupation in the measurement of family socioeconomic status.

Studies that disaggregate these concepts consistently find strong negative relationships between parent education and early sexual initiation,[62,66,67] contraction of an STD,[68] teenage sexual intercourse,[63] and contraception use,[66,69] but modest or null findings for income or occupation on these same behaviors. These findings suggest that educational opportunities and aspirations, more than financial resources, are important protective factors for adolescent sexual risk taking.

Robust findings that parental education is a protective factor against adolescent sexuality may also help explain socioeconomic status differences in teenage childbearing.[63] Teenage pregnancy and childbirth are strongly associated with poverty.[70] With low expectations for educational success or upward mobility, poor women may welcome young parenthood as a positive identity change and an opportunity to enter into supportive social networks.[71,72] The paradox of parenthood among poor women is that the rewards of becoming a mother contrast sharply with the low likelihood of marriage and the increased risks of school dropout and welfare dependence. In an interview of 162 multiethnic, low-income mothers, Edin and Kefalas[72] found that only 14% had ever been married, approximately 60% did not graduate from high school, and almost 50% were currently unemployed. This strong connection between urbanicity, poverty, and teenage parenthood remains a public health concern and contributes to the reproduction of social inequality.

OTHER RISK-TAKING BEHAVIORS

There is a well-documented association between adolescents' general level of risk taking and the likelihood that they will have sex or engage in risky sexual activities.[73] Most substantially, alcohol and drug use have both been linked to increased risk of having sex, having sex more often and with more partners, and pregnancy. Teens who use drugs are also less likely to use condoms, and more likely to contract an STD.[73] One explanation for these findings is that substance use itself may lower inhibitions and reduce adolescents' abilities to think clearly and take precautions.[73] However, other risk-taking activities, including aggression (such as physical fighting or carrying weapons) and delinquency, are also positively associated with sexual activity.[73]

This pattern of empirical associations suggests that perhaps both risk-taking and unsafe sexual behavior are the result of a common cause—such as risky temperament, low socioeconomic status, or poor school performance.[73]

ADDITIONAL SOURCES OF SOCIAL INFLUENCE

PARENTS

Relationships between parents and children have received substantial research attention (e.g., Youniss and Smollar[74]). Few studies, however, have focused on the association between parenting and adolescent sexual development. This is somewhat surprising, given that a primary motivation for adolescents to date and initiate sexual encounters may be to separate themselves from their parents.[75] Lacking traditional rites of passage, modern adolescents are likely to turn to romantic involvements as assertions of adult status and autonomy from parents.

Even if romantic involvement serves a general developmental function during adolescence, significant variation remains in the timing and social correlates of teenage sexual activity. Some of this variation may be explained by relationships with parents before and during the adolescent period.

Studies consistently find that less cohesive family structures (e.g., single-parent households or families of divorce) are associated with earlier sexual initiation and higher risks of teen pregnancy.[33,76–79] One explanation for this relationship is that disrupted families are less able to monitor children's behavior, increasing the probability that adolescents will deviate from parents' standards. In a longitudinal test of sexual initiation, Longmore et al.[77] found that parent monitoring during late childhood was the most significant parenting effect on the risk of adolescent first intercourse. Another study that measured both mother–child relations and family structure also found that qualities of the maternal relation are more important than family structure per se in predicting sexual initiation—except for adolescent girls in single-parent households.[80]

A different explanation for the relationship between disrupted families and early sexual initiation is that the higher stress in these families results in coercive and authoritarian parenting. Children from overcontrolling families may respond by becoming more involved in unconventional peer groups and increase the risk of early sexual debut.[81] In addition, the hostility associated with authoritarian parenting may influence the quality of adolescent romantic relationships.[75] Coercive and violent parenting, as well as violence in the parents' marital relationship, may be replicated in adolescent peer and romantic relationships.[82,83]

The opposite is true of adolescents who are attached to supportive parents. Individuals from supportive families are more likely to communicate with their parents and share parents' (less permissive) sexual attitudes.[84–86] Teens who live with both parents and enjoy close relationships with them are less likely to have sex or experience adverse sexual outcomes (e.g., pregnancy, STDs) if they do have sex.[73]

The relationship between parenting and adolescent sexual development is also likely to differ by a child's gender. Parents are more likely to monitor daughters' than sons' behaviors,[87,88] and coercive parenting is more likely to apply to boys than girls.[89] These processes may contribute to gender differences in sexual development (see above) and parental responses to children's sexual activities.

NEIGHBORHOOD AND COMMUNITY

Communities provide important sources of informal social control,[90] as well as opportunity structures and normative contexts for early sexual development.[38] In concert with parents, a neighborhood's social networks may provide opportunities for monitoring and sanctioning that are likely to shape early romantic behaviors and prevent risky sexual activities. In addition, neighborhood characteristics may structure an adolescents' access to economic resources or adult role models and therefore affect the type and level of adolescent sexual behavior.[91] Looking at Chicago neighborhoods, Browning et al.[38] recently showed that a community's trust, cohesion, and shared values (e.g., collective efficacy) condition the parental effects on adolescents' sexual debut. This study finds that community networks are particularly salient when parental monitoring is limited; this suggests that youth from disorganized communities who live in households with low levels of parental monitoring are at higher risk of early sexual intercourse.

RELIGION

The public debate over faith-based initiatives has galvanized research on religion and adolescent sexuality. Lowered rates of adolescent sexual intercourse are often attributed to greater adolescent religiosity, particularly among girls. Survey data shows that 44% of adolescent girls report religious or moral reasons for remaining abstinent,[37] while a review of longitudinal studies of the effect of religiosity on sexual initiation concludes that religiosity delays the onset of sexual activity for girls but not for boys.[92]

Although empirical studies typically measure religious beliefs and affiliation at the individual or parent level, theoretical explanations commonly take an ecological approach to the religion–sexuality relationship, viewing religion's effects as occurring at the individual, family, peer, school, and community levels (see Rostosky et al.[92] for a review). Ecological perspectives treat the contexts of religious affiliation as just as important as denominational beliefs and customs. In this vein, Bearman and Brückner[64] recently studied the effects of religiously based virginity pledges on adolescent sexual debut. They found that, net of controls, adolescents who take a virginity pledge initiate sexual intercourse at later ages than their peers. However, they also found that this effect varies substantially by peer context, with the virginity pledge being most effective when there is a minority

of pledgers in a school. They claim that pledging is more meaningful and central to an adolescent's identity when it is unusual and that this motivates adolescents to keep their pledges. When pledging is common, adolescents seem to take it less seriously. As a side note, Bearman and Brückner also found that pledgers who fail to keep their promise are less likely to use contraception than are their nonpledging peers. A follow-up study found that 5 years later, pledgers and nonpledgers had similar rates of STD (measured by nucleic acid amplification testing of urine specimens).[93]

SCHOOL

Schools hold an important place in adolescent sexual development. Education is a primary adolescent task and most contemporary youth go to school for many years before becoming sexually active.[94] The concentrations of similarly aged youth within schools provide an important context for the development of romantic relationships. Moreover, the connection between education and the state makes schools important cites for policy interventions, such as sexual education programs and health clinic access.

Studies consistently find that adolescents who are more invested in school[65,95] or who plan to attend college[96,97] have later ages of sexual initiation and lower frequencies of risky sexual behavior. These findings are commonly explained using Hirschi's[98] social bonding theory of delinquency. For Hirschi,[98] adolescent bonds with schools and school-based adults and peers increase conventional behavior and reduce the risk of deviance, including risky sexual activity. Accordingly, strong bonds to school (1) commit youth to conventional lines of behavior because the cost of unwanted pregnancy or disease contraction could be foregone future opportunities, (2) build belief in a conventional order that discourages early sexual intercourse or childbearing, (3) increase the amount of time spent on conventional activities (e.g., homework, extracurricular activities) and reduce time spent in situations that promote risk taking, and (4) attach students to peers and teachers who encourage abstinence or safe sex.

Schvaneveldt et al.[99] provide a good summary of research connecting academic achievement and adolescent sexual behavior. They emphasize that this relationship may operate in both directions such that high academic aspirations and good grades may reduce sexual risk taking, while risk taking may simultaneously reduce academic aspirations and achievement. In longitudinal analyses using data from the National Survey of Children, they find evidence for both the effects: low educational goals and achievement correspond with lower ages of first sexual intercourse, while early intercourse also is associated with reduced future academic aspirations and achievement.

Although strong school bonds are clearly associated with reduced sexual risk taking among adolescents, evidence for the effectiveness of school-based sex education courses and programs remains inconsistent and methodologically flawed.[100] There are currently no published studies that demonstrate that abstinence-only school programs delay sex.[94] However, Kirby (p. 29) notes that it is too early to judge these programs because "(a) abstinence-only programs are a very heterogeneous group of programs, (b) too few rigorous studies have been completed, and (c) there is some evidence that the abstinence pledge can lead to a delay in sex in some conditions and that one community-wide abstinence media campaign may have delayed sex among young teens."[94]

The few studies that have examined the effects of sex education and HIV education in schools show mixed results, with some studies finding that such education delays sex, while others finding that they lower the age of sexual initiation (see Kirby[94]). With regard to contraceptive use, studies show more consistent results in that sex education increases contraceptive use (see Kirby[94]). Interestingly, the availability of condoms (from health clinics or free handouts) does not appear to increase their use or increase the frequency of adolescent sexual activity.[94] This is broadly consistent with the findings in a pair of longitudinal studies that use Add Health data to examine the consequences of early condom use. Shafii and her colleagues show that adolescents who use a condom at their sexual debut are more likely to use condoms subsequently[101] and that over time, early condom users (1) continue to use condoms at higher rates than nonearly users, (2) have the same number of lifetime partners, and (3) have lower rates of sexually transmitted infections.[102]

MEDIA

Today's adolescents are being raised in a multimedia environment that affects their social, academic, and romantic lives. Many theories describe the role that media can play in shaping people's perceptions and behaviors. Perhaps most salient, the Media Practice Model suggests that adolescents select and react to sexual media diets that speak to an emerging sense of themselves as sexual human beings.[44] Three prominent forms of media have been identified as influencing adolescents' sexual behaviors: music, television, and the Internet.

Though music's influence on teenage sexual behaviors has been suspected since Elvis Presley first swiveled his hips, the empirical evidence on this matter is thin. A recent study[103] interviewed teens between ages 12 and 17 years at baseline, one, and three years later. This survey asked about sexual behaviors and media use, including exposure to sexual content in music and found that even after controlling for multiple other factors, youth who listened to more degrading sexual content were more likely to subsequently initiate intercourse and to progress to more advanced levels of noncoital sexual activity. In contrast, exposure to music with nondegrading sexual content was unrelated to changes in participants' sexual behavior. Though this

study illustrates links between music and sexual activity, it is still somewhat unclear whether the association between sexually aggressive music and sexual activity is spurious.

The evidence with respect to television watching is more robust. For instance, a study using Add Health data found that among adolescents who report strong parental disapproval of sex, the number of hours of television watched is associated with higher rates of sexual activity.[104] However, the mechanism for influence is more complex than a simple exposure to suggestive content: the study found that higher rates of television watching and sexual activity were linked to lower parental monitoring of television watching, and thus the higher levels of sexual activity are—at least in part—a function of parental monitoring rather than simply the result of kids "getting ideas" from TV.

Subsequent studies have found that the relationship between adolescents' television viewing and sexual experiences depends on the type of messages viewed, the sexual outcome considered, and the gender of the viewer.[105] Girls who frequently viewed portrayals of women attracting men by willingly making themselves sexual objects reported less sexual empowerment and had more sexual experience than other girls; girls who saw more portrayals of men shunning commitment in romantic relationships also reported less sexual empowerment. The study found few associations between males and television content. Another study examined four types of media—television, music, magazine, and movies—and found that exposure to sexual content in these forms of media was associated with earlier sexual debut in white, but not black, adolescents.[44]

The evidence in these studies illustrates that the content of the media message is important and that the effects of media on adolescent sexuality may vary by sex and ethnicity. Thus while there is mounting evidence that television has an effect on shaping teen's views and behavior, these effects are complex: program content, gender, and family circumstances all condition the relationship between media and adolescent sexual activity.

Over the past 5 years, the Internet has become a pervasive force in adolescents' social lives. In fact, some observers have suggested that teens displace television watching with Internet-based activities.[106] Regardless, recent data show that that over 90% of American adolescents have Internet access, either at home or at school.[107,108] Teens spend much of their time on the Internet communicating with other people, either through email, instant messaging (IM), or chat rooms.[109–111] Just as the Internet has affected many other domains of life, it has shaped teens' romantic lives by providing a venue for communication with partners and potential partners, as well as a way to seek out and meet new partners. For adolescents who spend a great deal of time online, this may make it easier to transition into, and out of, romantic relationships. Thus it is not surprising that many teens report using the Internet to ask someone out, as well as to break up with a current partner.[112]

Communicating via the Internet allows teens to seek companionship without the social pressure of encounters in person. Some have argued that the Internet provides an alternative venue for higher risk adolescents who have struggled to find satisfying face-to-face relationships.[113] In support of this idea, a study of adolescents who were frequent chat-room users found a disproportionate number of teens who had run away from home, teens who were intrigued by risk, and teens who experimented with drugs and alcohol.[114] This same study found that among ninth graders, those who were frequent Internet users were almost two times as likely to be sexually active than were peers who were not frequent Internet users.[114]

At present, there is evidence suggesting that seeking sexual partners through the Internet has risks. MacFarlane et al.[115] found that young adults who found sexual partners online were at higher risk of acquiring STDs. This association is unlikely the result of the Internet itself triggering high-risk sexual behavior, however. More likely, it is the result of a selection process: since higher risk teens frequently use the Internet to find companionship, high-risk teens may find other high-risk teens on the Internet and share and spread STDs.

COMPARATIVE DATA

Adolescents in developed countries such as Canada, Great Britain, France, Sweden, and the United States have generally similar rates of sexual activity.[70] However, in spite of broad similarities, there are several respects in which American adolescents differ from their Canadian and European counterparts. Specifically, more adolescents in the United States have sexual intercourse before age 15. American teens also tend to have shorter and more sporadic relationships, and more relationship partners, than teens in other developed countries.

In addition to these small differences in relationship patterns, American adolescents experience far more adverse effects associated with their sexuality than do teens in Europe and Canada. Adolescents in the United States have higher rates of pregnancy, childbearing, and abortion than adolescents in other developed countries,[116,117] and higher rates of STDs.[116]

The United States ranks among the top five countries in terms of teenage pregnancy rates.[70] Several factors influence the teen pregnancy rates in the United States, including negative societal attitudes toward teenage sexual relationships, restricted access to and high costs of reproductive health services, ambivalence toward contraceptive methods, and lack of motivation to avoid pregnancy.[70] The relatively high rates of STDs among American teens are associated with increased number of sexual partners, lower levels of condom use, and the structure of adolescents' sexual networks.[116]

Countries with comparable rates of adolescent sexual activity but lower rates of adverse sexual outcomes are frequently described as being more accepting of teenage sexual relationships and more willing to provide access to contraception.[17]

The "pragmatic European approach" to adolescent sexuality[118] refers to a set of interlocking norms and behaviors that support parents, schools, and health-care providers who link positive discussions about sexuality with clear information about how to prevent pregnancy and STDs within relationships.[70] Along these lines, Sweden's success in reducing teenage pregnancy rates followed both improved sexuality education and enhanced provision of contraceptives to adolescents.[119]

SUMMARY

The social dimensions of adolescent sexuality are complex and intriguing. A recent systematic review found that one consistently strong predictor of adolescent sexual activity was the youth's perceptions of social norms about sex.[120] Adolescents' assessments of social norms, in turn, are strongly influenced by peer, partner, school, and parental values about sex. All of these groups influence teens by encouraging beliefs, modeling behaviors, and often by providing opportunities for behaviors to occur (or not to occur). Despite the common view of sexual activity as an intimate and personal topic, the decision to become sexually active is remarkably impacted by social influences.

Ecological approaches to understanding adolescent sexuality are aided by advances in data collection and methodology. Large-scale youth and parent surveys allow researchers to disentangle effects at the individual and contextual levels. With regard to sexual behaviors, these surveys provide clues to the impacts of self-selection, peer pressure, and community contexts on sexual initiation and early dating experiences. Moreover, multiple-school network data and emerging sociometric methods elaborate the structure of romantic ties and place these relationships within broader patterns of peer friendships and school contexts. Taken alongside longitudinal survey and relational data, social networks provide exciting opportunities to observe the development, maintenance, and dissolution of early romantic partnerships and sexual contacts. Such approaches hold the keys to future developmental research and move us past individualized conceptions of clearly social phenomena. By embedding youth in multiple and often overlapping social contexts, we are better able to understand the pushes and pulls that shape early sexual trajectories.

7 Sexual Networks, Concurrency, and STD/HIV

Martina Morris, Steven Goodreau, and James Moody

MOTIVATION

Over the past two decades, the HIV epidemic has challenged the epidemiological community to rethink the framework for understanding infectious disease transmission, both at the individual level and at the level of population transmission dynamics. Research has rapidly converged on the central importance of partnership networks. Systematic patterns in social networks have always served to channel infectious diseases—from the sequence of plagues in Europe and the introduction of European childhood infections into the Native American populations, to the polio epidemics of the early twentieth century and contemporary outbreaks of cholera and typhoid that attend mass movements of refugees.[1] The methodology for network data collection and analysis, however, is only now being developed.

Like other exchangeable goods, the diffusion of pathogens through a human population traces the structure of social networks. The pattern of spread is jointly determined by the biology of the pathogen and the social structure that can support it, so different kinds of diseases travel along different structural routes. The plague, for example, is spread by a mobile vector of rats and fleas. This makes for an efficient, long-lasting infectious vehicle, enabling spread via long-distance transportation and trade routes, so macroeconomic relations help to structure the diffusion path. For influenza and measles, by contrast, transmission requires casual or indirect personal contact in a relatively short period. The spread of these infections is structured by locations for frequent collective activity, like schools and supermarkets today, with transportation networks serving as potential bridges between communities, and sparsely settled or less traveled routes serving as buffers. Finally, there are infections that spread only by intimate or prolonged contact, and sexually transmitted infections (STIs) are a classic example. These diseases travel along the most selective forms of social networks, operating on what is comparatively a very sparse microstructure, with a typically modest duration of infectivity for several STIs. The structure of sexual networks varies within and between societies, governed by local norms, power differentials, and oppositional subcultures. Here, as with other infectious diseases, the transmission network determines the potential for epidemics and the opportunities for prevention.

Network epidemiology offers a comprehensive way of thinking about individual sexual behavior and its consequences for STI. Unlike other health-related behaviors (e.g., smoking and seat belts), behaviors that transmit STI directly involve at least two people, and the links either of these persons might have to others. Understanding this process requires moving beyond the standard, individual-centered research paradigm. This has important implications for the analytic framework, data collection, and intervention planning.

The analytic framework must take a relational approach, integrating individual behavior into partnership contexts, and aggregating partnership configurations into networks. This is a marked departure from the standard approach to "behavioral research" that seeks to link individual attributes to individual outcomes. Data collection and statistical analysis need to be revised accordingly, making the partnership—rather than the individual—the primary sampling unit. While we know a lot about sampling individuals, we know much less about sampling partnerships and networks. Finally, analyzing the network data we collect requires different statistical methods, since the defining property of such data is that the units are not independent. Methods for analyzing dependent data are not unknown—spatial statistics, time series, and multilevel models provide a starting point—but the statistical tools needed to analyze networks have only recently been developed.

Given these difficulties, why bother taking a network approach? Why not simply focus on individual risk factors for acquisition of disease? The answer is that network epidemiology succeeds where more traditional epidemiological approaches have failed: explaining differentials in risk behavior, epidemic potential in low risk populations, and the persistent and substantial prevalence differentials

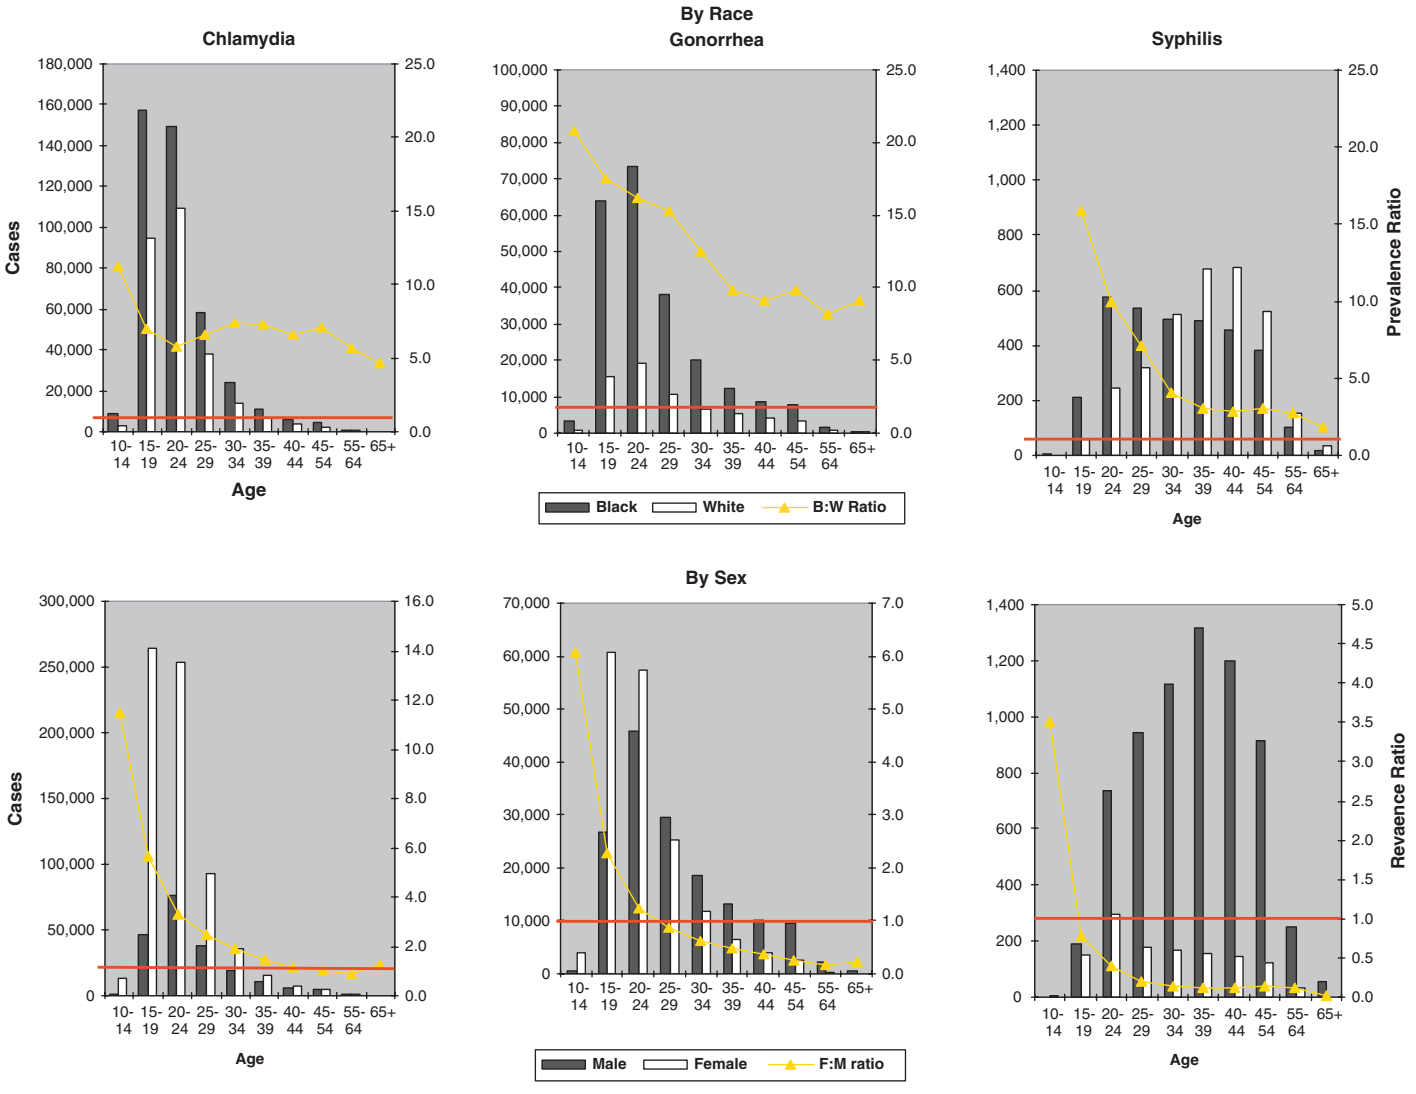

FIGURE 7-1. STI prevalence by age, race, and sex in the United States, 2004. The bars show the number of cases by age and group (on the left axis) and the yellow line shows the per capita prevalence ratio by group (on the right axis). The red line indicates a prevalence ratio of 1 (on the right axis).

across populations. An example of these differentials is the prevalence by age, race, and sex of reportable STI in the United States, shown in Fig. 7-1.

RACIAL DIFFERENTIALS IN STI PREVALENCE IN THE UNITED STATES

In one sense, a network explanation is almost tautological: individuals are infected by their partners, who are in turn infected by their partners—"networks" is just a term that describes this process. But the concept also has explanatory power and prevention implications, as it changes the focus from "what you do" to "whom you do it with." This allows for behaviors to vary within, as well as between persons, and for the same individual behavior to lead to different infection outcomes in different contexts.

As a result, the network perspective changes the way we think about targeting concepts such as "risk groups" and "risk behaviors." The inadequacy of these concepts became clear as HIV prevalence rose among groups that do not engage in individually risky behavior, for example, monogamous married women.[2–5] By the same token, a group of persons with extremely "risky" individual behavior may have little actual risk of STI exposure if their partners are uninfected, and not linked to the rest of the partnership network. It is not only individuals' behaviors that define their risk, it is their partners' behavior and (ultimately) their positions in a network.

The network perspective also changes the way we think about population-level risk factors: the key issue is not simply the mean number of partners but the connectivity of the network, and connectivity can be established even in low density networks. One of the primary ways in which this happens is through concurrent partnerships. Serial monogamy in sexual partnerships creates a highly segmented network with no links between each pair of persons at any moment in time. Relax this constraint, allowing people to have more

than one partner concurrently, and the network can become much more connected. The result is a large increase in the potential spread of STI, even at low levels of partnership formation.

Finally, the network perspective changes the way we think about behavior change. Because the relevant behavior occurs in the context of a partnership, individual knowledge, attitudes, and beliefs do not affect behavior directly. Instead, the impact of these individual-level variables is mediated by the relationship between the partners. A young woman who knows that condoms help prevent the sexual spread of HIV may be unable to convince her male partner to use one. It is not her knowledge that is deficient, but her control over joint behavior.

Networks thus determine the level of individual exposure, the population dynamics of spread, and the interactional context that constrains behavioral change. Taking this seriously represents a paradigm shift in the study of STI.

This chapter is organized into three sections: a brief overview of the origins of social network analysis and its applications to the epidemiology of STI, a review of the primary findings from the last 20 years of network-based STI research, and a discussion of the changes in research methodology needed for network-based studies.

NETWORKS AND EPIDEMIOLOGY: ORIGINS OF THE FIELD

The use of network analysis to understand population structures and their impact on diffusion processes is not new. The analysis of network structures has a relatively long history in the social sciences, which is where the most comprehensive methodology has been developed, and the study of diffusion through structured populations in epidemiology is also longstanding. In recent years, physicists have also begun to work on the epidemiology of diseases on networks.

Social science roots

Social network analysis is an established subfield in the social sciences, with a professional organization The International Network For Social Network Analysis (INSNA) holding an annual meeting (the "Sunbelt" social network conference, now in its 26th year) and a couple of journals (*Social Networks, Connections*). It is an interdisciplinary field, and it has developed a unique set of methodological tools.

What is a social network? The most common definition is a set of relations (links) among persons (nodes) where the relations can range from kinship and exchange, to affection or physical contact. Networks can also be defined on larger units, such as exchange networks among firms, or transportation networks among cities. Another form is the bipartite network (also called two-mode network), in which there are two distinct types of nodes (e.g., persons and places, or men and women), and the links can only occur between types, not within.

The beginnings of the field are traced back to work by the social psychologist Jacob Moreno in the 1930s. Moreno developed the concept of "sociometry" for understanding the ways in which individuals are supported, constrained, and engaged by their network of ties to others. Sociometry became the name of the journal he started, and the name given to network measurement, delineating the nodes and links.

Early network analysts were interested in the social processes that generate networks, and the theories explicitly focused on how individual partner choices, guided by social norms, aggregate up to produce population-level network structures. For example, anthropologists and sociologists focused on how rules governing permissible exchange partners (e.g., gift giving or marriage) cumulate up to determine the overall structure and stability of an exchange system.[6–9] Social psychologists and others explored the population-level impact of the norm of balance for positive and negative affect among three actors, e.g., my friend's friend is my friend, my enemy's friend is my enemy.[10–12] The key findings from this period are that some simple rules of behavior at the local level may lead to overall network structures that display striking regularities, such as linear hierarchies, cliques, and stable cycles of exchange. Other rules do not produce such stable outcomes, and this distinction leads to an evolutionary hypothesis about the differential survival of rules over time.

For the last 25 years, social network analysts have been developing quantitative tools for empirical studies. There are two distinct approaches, defined by the type of data collected. The first is based on a network census—data collected on every node and link for a (typically small) population. This approach is largely descriptive and draws on mathematical graph theory and linear algebra for summary measures of network properties. Despite intense data requirements and unusual methods, this approach became the standard in social network analysis, providing a rich framework for thinking about networks and a wide range of summary measures to represent both the network position occupied by specific nodes and patterns in the overall network structure. Almost all of the classic network measures—paths, cycles, density, centrality, structural equivalence, cliques, blockmodels, role algebras, components, and bicomponents—owe their development to researchers working with these descriptive tools. The current textbooks and computer packages for social network analysis have these methods at their core.[13,14] They have become the common language for network analysis, defining the basic features of networks and helping to develop our intuitions about the complex relational structures we seek to understand. Like linear regression, though, these are descriptive summaries, rather than generative models.

The second approach is based on sampled network data. Since a network census is often impractical, this approach

develops a statistical basis for network estimation and inference from a sample. The most well known of these is the local network (or egocentric) sample design: a sample of the nodes (egos), with a "name generator" in the questionnaire to obtain a roster of their partners (alters), and "name interpreters" to collect information on these partners. The beauty of this simple study design is that no attempt is made to identify or enroll the partners. Local network data collection costs about the same as a standard survey, is relatively easy to implement, and is less intrusive than complete network data collection. Early examples include the Detroit Area Study,[15,16] the Northern California Communities Study,[17] and the core discussion partners network module used in the General Social Survey.[18] More recent methods rely on exponential random graph models that enable both estimation and simulation of networks from locally sampled data.[19,20]

In between these two approaches lies a range of link tracing designs for collecting network data: snowball samples, random walks, and most recently, respondent driven sampling. The absence of methods for analyzing such data previously limited the use of this approach, but new methods are now available and becoming more common.[21–24]

Epidemiology roots

Epidemiologists had a tradition of modeling infectious disease spread through "structured populations" well before the explicit connection was made to social network analysis. The spatial spread of infections was an early focus, with models for the dynamics of childhood disease transmission among families, neighborhoods, schools and playgroups,[25,26] epidemics on islands,[27] and pandemics spreading through the network of airline routes.[28] Models for wildlife disease transmission, especially rabies, were built around small interacting subgroups connected by occasional long jump migrations,[29] anticipating the "small world" models in the recent physics literature.[30]

Simple network-like models for sexually transmitted pathogens began to be developed in the late 1970s and early 1980s when, despite the relative availability of penicillin, gonorrhea and syphilis rates rose rapidly in the United States. Surveys of STI clinic patients in the late 1970s found that repeat cases contributed disproportionately to the total caseload: 3–7% of the infected persons accounted for about 30% of the cases.[31,32] Simulation studies showed that this group can act as a "reservoir," allowing an infection to persist in a population where the average level of activity was otherwise too low to allow for sustained transmission.[33–35] This research led to the "core group" theory: if endemic persistence is due to this small core group, then all cases are caused directly or indirectly by the core. The core group thus came to be seen as the primary driving force in STIs and also as the locus for highly effective intervention targeting.[36–38]

The heuristic of core groups continued to play an important role in early studies of HIV transmission, when the epidemic was concentrated among men who have sex with men (MSM), injection drug users, and commercial sex workers. But concerns began to be raised about the limitations of the core group concept with the emergence of generalized epidemics in the countries of sub-Saharan Africa (see Ref. 39 for a critical review of this concept and literature).

Both the definition and the utility of the original core-group concept depend on high levels of reinfection—persons who contract an STI once are more likely to contract it again, contributing disproportionately to endemic persistence, and making it more cost-effective to rescreen them. In the case of HIV (and most other viral pathogens), there is no cure, and the role of reinfection remains uncertain, so repeat cases do not appear to drive the epidemic (though see Ref. 40). Core group theory explained endemic persistence in an otherwise infection-free population as the result of small highly active subgroups where transmission remained above the epidemic threshold. This model is consistent with the limited HIV spread in the United States and Western Europe but it cannot explain a generalized epidemic. There may be occasional "seeding" of the general population from a core group reservoir, but sustained spread outside the core is not possible since transmission outside the core is below the threshold. With HIV prevalence in some countries rising to 30 or 40%, it is clear that transmission is above the reproductive threshold in a large fraction of the population. Some kind of core group may have played a role in the initial outbreak of HIV here, but core groups are not responsible for generalized spread.

The first explicit link between social network methods and STI dynamics was made by Alden Klovdahl in 1985.[41] The paper was written before the virus that causes AIDS had been identified, and the mechanism of transmission had not been conclusively demonstrated. The paper included a sociogram of an MSM sexual network that linked many of the first known AIDS cases back to a single person ("patient 0"), providing strong evidence that this was an STI.

A large number of theoretical and empirical papers have since followed which use network concepts and methods to help understand the different patterns of HIV spread in different countries, the disparities in infection prevalence within countries, the behaviors that increase exposure risk, and the opportunities for prevention. At their best, network models help us understand the population-level implications of individual behavior—how the choices people make link together and aggregate up to create the partnership network that either inhibits or facilitates transmission.

WHAT HAVE WE LEARNED?

Using network analysis, researchers have identified two basic behavioral patterns that have a large impact on the STI transmission network: selective mixing and partnership timing. Selective mixing is about how we choose partners: the

population comprises several subgroups and the question is how many partnerships form within and between groups. Partnership timing is about the dynamics of relationships: monogamy requires partnerships to be strictly sequential, concurrency allows a new partnership to begin while an existing partnership is still active. Both are guided by norms that influence individual behavior, which in turn create partnership network structures that leave distinctive signatures on transmission dynamics and prevalence.

Partnership networks also have other structural features that can be important for STI spread. One example is closed cycles, e.g., the triangles and odd-numbered cycles that can emerge in same sex networks, and larger even-numbered cycles for heterosexual networks. Closed cycles have the effect of sequestering an infection and preventing further spread outside the cycle. A network with small closed cycles may have less potential for rapid spread if the cycles are not connected by other links. Another example is the "scale-free" model for the distribution for the number of sexual partners. These models use a single parameter to represent the shape of the upper tail in the partnership distribution and its impact on epidemic spread (scale-free models are discussed in a separate section below). The signature statistics from these models are typically employed as descriptive summaries for network structures, rather than generative models that link individual behavior to population level outcomes. But they do have epidemiological implications.

SELECTIVE MIXING

When choosing a sexual partner, people select on the basis of preferences and constraints. "Appropriate" partners are typically defined by attributes such as age, sex, sexual preference, race/ethnicity, social class, and marital status, and availability is dictated by geographic proximity and subgroup size. People also vary in their rates of partner change, and the mixing within and between activity levels is the focus of the classic "core group" model. At the population level, selective mixing can have a strong impact on the speed and direction of epidemic spread. Tight assortative ("like-with-like") mixing can lead to multiple, decoupled epidemics in a population,[42] with sequential waves of infection,[43] while disassortative mixing tends to generate slower-growing but larger epidemics in the long run.[44–46] But the effect also depends on the attributes that define the mixing group boundaries: whether they are stable (like race/ethnicity) or change over time (like marital status), and whether they are correlated to levels of sexual risk behavior (like age). Mixing effects also depend on whether the groups are directly connected (males and females), or whether there are groups with no direct connection but only an indirect connection formed by a "bridge population" (women who are and women who are not commercial sex workers are connected by their shared male partners). Selection thus occurs on many different kinds of attributes, with different but predictable outcomes on prevalence.

Race and ethnicity

This type of mixing is typically assortative and based on fixed attributes. An example is shown in Table 7-1.

This assortative mixing leads to segregated networks which channel infection and can sustain long-term prevalence differentials like the persistent racial differentials in STI morbidity observed in the United States.[47] As shown in Fig. 7-1, this differential peaks among young adults: rates of gonorrhea are 20 times greater among non-Hispanic blacks than among whites, rates of syphilis are 15 times greater,[48] rates of HIV infection are 20 times greater,[49] and chlamydial infection[48] and HSV-2 seropositivity[50] have significant (though smaller) racial disparities.

Race is a proxy for a number of factors that influence risk exposure: discrepancies in health care access, differences in sexual behavior, possible genetic differences, and the structure of partnership networks. But the stability of the race differential persists after controlling for socio-economic status[51] and number of sexual partners[52] remaining strong even among youth who enter juvenile detention facilities[53] and inject drugs.[54] This suggests that, while poverty and behavioral differentials may matter, they alone do not account for the race disparities in prevalence. While there has been some speculation that genetics may play a role, no mechanism by which genetic differences might influence susceptibility or infectivity has been proposed, and the consistent differences across a wide range of sexually transmitted pathogens suggest the transmission network is a more likely explanation.

Note that segregation alone cannot create a prevalence differential unless there is absolutely no direct or indirect contact between the groups. Segregation simply slows the rate of spread between groups. For STI differentials to persist over the long term, it is also necessary to have differential transmission rates within subgroups. This can be induced by different rates of partner change or of concurrency across groups.

AGE

Age mixing is generally assortative, but shows an asymmetry among heterosexual couples, with males typically older than their female partners. Age is also an attribute that changes over time. The net impact on transmission dynamics depends on whether the STI is curable or incurable. For curable STIs, prevalence will typically peak among youth, since rates of partner change are high in this group and partners are typically of similar ages, so the STI circulates rapidly within group. In the United States, for example, about 70% of all chlamydia cases and 60% of all gonorrhea cases are found among persons 15–24 years of age.[48] Age matching will lead

Table 7-1. Mixing by Race/Ethnicity in the National Health and Social Life Survey (NHSLS) and the Add Health Study for Heterosexual Partnerships

	Men				
Women	White[a]	Black[a]	Hispanic	Asian	Other
NHSLS					
White[a]	95.2	1.4	1.7	0.6	1.1
Black[a]	5.4	89.7	2.3		2.7
Hispanic	30.7	2.3	63.8	0.9	2.3
Asian[a]/PI	23.1	–	–	60.0	16.9
Other[a]	37.5	2.1	2.1	2.1	56.3
Add Health Study					
White[a]	84.9	3.6	5.8	1.8	4.0
Black[a]	8.4	80.2	6.0	0.7	4.6
Hispanic	22.4	7.6	63.0	2.6	4.5
Asian/PI	21.1	5.3	9.5	59.4	4.7
Other	34.4	14.4	24.0	5.6	21.6

The cells show the percent of reported partnerships among women in the row group that are with men in the column group

[a]Non-Hispanic

to higher prevalence among youth in this case, as it intensifies the spread within this group. Incurable STI, by contrast, will accumulate with years of exposure, so higher prevalence should be found among older groups for these STIs. For example, in the United States, only 11% of persons living with HIV are in the 15–24-year-old age group.[55] In this case, assortative age mixing will (all else equal) protect youth by lowering their exposure to higher prevalence older partners.[56]

Gender asymmetry in age-matching means that young women will be exposed to older men, and they will get infected earlier than their male age peers. This sex differential in prevalence by age is observed for HIV in many sub-Saharan African countries[57] and in the curable STI in the United States (as seen in Fig. 7-1). Biological mechanisms may contribute to this age differential, specifically cervical ectopy in young women, which gradually disappears as squamous epithelium replaces the ectopic cervical columnar epithelium of young women (see Chapter 55),[58,59] though the evidence is inconsistent for HIV.[60] But young women with older male partners have consistently been found to have higher prevalence than young women with younger partners in empirical studies,[61,62] with odd ratios ranging from 1.04 to 3.2 for age differences of 5 or more years. This suggests the transmission network, rather than some biological mechanism, is responsible. For incurable lifelong infections, where prevalence rises with age, the gender asymmetry in age matching virtually ensures a strong intergenerational chain of transmission: a high-prevalence cohort of older males infects the newly active cohort of young females, who eventually pass it on to their male age-peers, who become the next cohort of older males, and so on.

Age mixing has been shown to influence the dynamics of spread among MSM, where young men with older partners are the leading edge of the epidemic in their cohort.[63,64] An example below comes from the Longitudinal AIDS Impact Project, one of the early surveys of gay men at the beginning of the AIDS epidemic in New York City. The pattern of age matching in partnerships in which unsafe anal sex was reported is shown in the mixing matrix in Table 7-2.

The assortative bias in age-matching is relatively strong: about 40% more partnerships than expected are within group, and there is a steep falloff in partnerships as the age differential increases (stepping off the diagonal). Despite this, the fraction of the young cohorts' contacts that are with older cohorts is relatively high: about 60% of receptive partners are over 25, as are nearly 70% of insertive partners. The potential for spread from the older cohorts to the younger is still strong, though weaker than it would be without the assortative bias.

Table 7-2. Age-Mixing Matrix for Unsafe Anal Sex Partners from the Longitudinal AIDS Impact Project (LAIP), 1990–1991

	Receptive Partner				Pairs	Contact Rate
	18–24	25–34	35–44	45–54		
Insertive Partner						
18–24	6	8	2	1	17	1.04
25–34	9	38	18	6	71	0.95
35–44	3	21	25	7	56	0.91
45–54	1	7	7	5	20	1.08
Pairs	19	74	52	19	164	
Contact rate	1.25	0.97	0.85	1.03		0.96

Observed % within age group	45%
Expected % within age group under proportional mixing	33%
Ratio of observed/expected	1.4

The cells show the number of partnerships reported between insertive partners in the row age group and receptive partners in the column age group.

The effect of age-matching on individual risk was clear in the pattern of infection. Among those reporting any unsafe receptive sex, seroprevalence was 0 for those who reported no partners outside their own age group, and 44.4% for those who reported at least one partner over age 25. The pattern is the same for insertive anal sex: seroprevalence was 0 for those whose partners were all 25 or younger, and 15.3% for those who reported at least one partner over age 25.[63]

SEXUAL ROLE BEHAVIOR AMONG MSM

For homosexual male anal intercourse, individual men can play either the insertive or receptive role. Some men consistently perform one or the other, while others perform both. This yields three role subgroups of men: insertive, receptive, and versatile as opposed to the two role categories of male and female in heterosexual intercourse. This changes population transmission dynamics, and the impact depends on the prevalence of each role and the relative transmission probabilities of insertive and receptive sex. If the prevalence of versatile role players is low, mixing between the other two role groups will be disassortative, which helps to ensure that the network is well connected. However, if receptive intercourse by an HIV-infected man with a seronegative insertive partner has a much lower probability of HIV transmission than does insertive intercourse with an HIV seronegative partner, spread will still be impeded, as receptives would be less likely to transmit once infected. As the prevalence of versatiles rises, they may either mix with the other two groups or segregate and mix primarily within group. Because they can transmit both ways, there is no biological brake on spread, so the parts of the network that include them will have higher prevalence. Unlike the biologically defined sex difference between men and women, sex roles are not fixed, so if norms change and the prevalence of the versatile role rises, the epidemic potential in the network can rise.

Simulation studies have shown that the effects of role separation on prevalence can be quite large.[65–67] In a recent data-driven simulation, using data from Lima, Peru, Goodreau et al.[68] examined the impact of the prevalence and mixing of versatile men. The survey data showed that 67% of MSM reported segregated roles within their recent male partnerships. The simulation showed that a population of MSM with identical contact rates but complete role versatility would have had twice the HIV prevalence for the epidemic's first three decades. It also showed that versatility, while raising population prevalence, is not necessarily an individual risk factor; versatiles remain less at risk than receptive-only men. This will not be true, however, if versatile men mix assortatively with other versatile men and role segregated men mix selectively (but disassortatively) with role-segregated men. In this case, the epidemic becomes concentrated among the versatiles. Two studies have found higher HIV prevalence for role-versatile than for role-segregated men, which would be consistent with assortative mixing.[69,70]

ACTIVITY LEVEL

Differences in rates of partner change, and mixing between more active and less active groups, was the first form of selective mixing explored by epidemiological modelers[33] and it remains a strong focus.[71,72] Unlike most mixing by demographic attributes (with the notable exception of gender), mixing by activity level varies along the whole continuum from assortative to disassortative, depending on context. Assortative mixing by activity level might be found among gay men who participate in the bathhouse scene, or among younger heterosexuals as a byproduct of age-matching. Disassortative mixing by activity level is typically present in heterosexual partnerships, if norms encourage sexual conquest for men and sexual fidelity for women. Also, unlike demographic attributes, activity levels are not a physically observable feature. This makes it difficult for a person to know the activity levels of a potential or current partner and, therefore, lowers the direct selective impact of this attribute.

Tight assortative mixing by activity level generates the classic core group phenomenon—a reservoir of infection in the core, with limited spread beyond. Disassortative mixing by activity level leads to more generalized epidemics and a decoupling of individual behavior from risk of exposure. The classic example here is the monogamously partnered wife of a man who has had many partners.

GEOGRAPHIC BRIDGING

Sexual networks also have a spatial context, and research suggests that spatially mobile populations have played a key role in the initial spread of HIV, and, in some cases, to higher HIV prevalence. Travel has a wide variety of social origins, from working in the transport industry, seeking education or shopping, to military service, vacations, and involuntary displacement. Migration can be temporary, seasonal, or permanent. In all cases, travel increases the epidemic potential of the network by linking otherwise unconnected populations.

Truck drivers were among the first identified high-risk groups for HIV.[73] Military populations are also spatially mobile, and their tours of duty in both peacetime and war lead to both consensual and forced sexual interactions with sex workers and numerous local resident populations, including partners in their town of origin.[74,75] In Uganda, both the spread of HIV infection in the 1980s and its 1990 spatial pattern, are significantly and positively correlated with ethnic patterns of recruitment into the Ugandan National Liberation Army after the overthrow of Idi Amin some 10 years earlier in 1979.[76] In this, HIV shows the classic association of war and disease.

Seasonal migration of laborers and traders also represents an important continuing vector for HIV transmission.[77,78] Many who leave their homes in search of better employment establish semipermanent homes and sexual relationships at the worksite, while maintaining regular sexual contact with spouses and other partners back home (i.e., concurrency). In a recent study in South Africa,[79] migrant couples were more likely than nonmigrant couples to have one or both partners infected (35 versus 19%) and to be HIV discordant (27 versus 15%). Using simulation based on these data, migrant men were 26 times more likely to be infected from outside their regular relationships than from inside, and nonmigrant men were 10 times more likely to be infected from outside. This pattern is also thought to have played a large role in establishing the high prevalence in countries like South Africa, Botswana, and Zaire.

Longer term international migration streams may also have contributed to the spread of HIV to developed countries but findings have varied by country. In England, HIV infections acquired overseas are mostly among overseas nationals now living in Britain, rather than in British citizens who travel. These imported infections are subsequently channeled by assortative sexual mixing and residential segregation by nationality within the UK, resulting in spread that is geographically and ethnically confined.[80] By contrast, a study in the Netherlands found disassortative sexual mixing by nationality. In one study, 50% of the partnerships reported by migrant men and 26% of those reported by migrant women were between members of different ethnic groups.[81] In this case, bridges apparently exist for the spread of STIs from international travelers to the local population.

ATTRIBUTE-BASED BRIDGING

Selective mixing based on attributes can lead to the complete lack of direct contact between spatially integrated groups. Examples include prostitute and nonprostitute women, or (behaviorally defined) heterosexuals and homosexuals. Indirect exposure may still exist, however, if there is a bridge population that links the two groups.[82–87]

The networks constructed by the sex industry provide a good example. Men who have both commercial and noncommercial sex partners play a critical bridging role for HIV transmission, linking a low prevalence population of female spouses and other noncommercial partners to a high prevalence population of sex workers.[88] A sexual network survey provided a quantitative estimate of the potential impact of this bridge in Thailand in 1993. About 17% of men reported both commercial and noncommercial partners during the past 6 months. As a result, 25 women were potentially exposed in the last 6 months for every 100 sexually active men, and an additional four women were potentially exposed in each successive 6-month interval.[84]

The network approach taken in this study also identified the groups at risk with greater accuracy. While having a wife and a commercial partner was the most common pattern

reported by men, more nonspousal partners were exposed than wives because nonspousal partnerships turn over more rapidly. Younger men were more likely to expose nonspousal partners, and greater numbers of them, so younger unmarried women were at the highest exposure risk. In this case, simple local network data were able to provide substantial detail on the overall network structure, which in turn can help to refocus intervention strategies.

In recent theoretical studies, one of the most effective network structures for spreading infection was found to be the so-called "small world" network—largely separate groups with most of their contacts within group, connected by a small number of links between the groups.[30]

PARTNERSHIP TIMING: MONOGAMY AND CONCURRENCY

The network connectivity that matters for STI transmission is also affected by the duration and sequence of partnerships. Duration affects the likelihood of transmission. Discordant partnerships of longer duration typically result in more sexual contacts and more chances for transmission. Sequence has its impact by changing the effective transmission structure of the network. Under serial monogamy, each partnership ends before the next begins. When this rule is not followed, partnerships can be active concurrently. The difference can be seen in Fig. 7-2.

The figure depicts two hypothetical partnership histories that a person might have. In both cases, the person has four partners over time, and in both cases, the lengths of each partnership are the same. The only difference is the sequence of start and end dates. Under serial monogamy, each partnership must end before the start of the next. With concurrency, more than one partnership can be active at one time.

In the earliest studies of partnership sequencing effects, researchers focused on monogamy and the duration of monogamous partnerships. Long-term monogamous pair formation slows down the rate of disease transmission, as concordant pairs provide no opportunity for spread, and discordant pairs remain together after transmission has occurred. Analytic findings support this intuition: increasing partnership duration raises the number of contacts needed to reach the reproductive threshold, lowers the peak number infected, and increases the time to peak infection.[89–92]

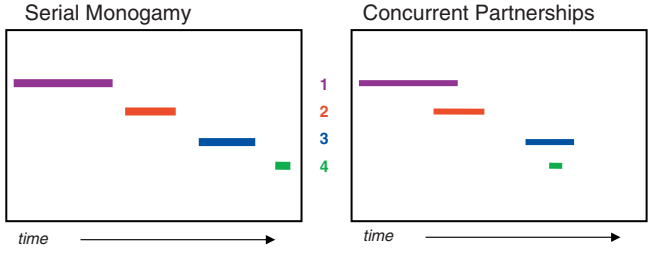

FIGURE 7-2. Definitions of serial monogamy and concurrency. The lines depict partnership intervals over time for a hypothetical person with four partners during the time period reviewed.

Attention then turned to the impact of concurrency, to understand the impact of relaxing the rule of monogamy.[93–95] Concurrency has several consequences that lead to amplified transmission. First, as the earlier research showed, concurrency reduces the time between transmissions: the pathogen is not trapped in a partnership since there is another partner available for immediate subsequent transmission. Second, concurrency removes the protective effect of sequence. Under serial monogamy, earlier partners in the sequence are not exposed to infections that the index case acquires from later partners. Under concurrency, earlier partners lose this protection. In Fig. 7-2, partner 1 is indirectly exposed to partner 2, and partner 3 is exposed to partner 4. Not only does this expose two additional persons, it creates two new potential chains of infection from these persons to others.[96] Third, concurrent partnerships link individuals together to create large connected "components" in a network—if you have more than one partner, then your partner may have more than one partner, and so on. Such connected components function like a well-designed road network—they allow a pathogen to travel rapidly and efficiently to many destinations.

Concurrency increases the speed of STI transmission through a population. In some cases, this can raise transmission above the reproductive threshold: the difference between an infection dying out and sustained epidemic spread. This is particularly likely if the pathogen has a short window of peak infectivity. In this case, concurrency helps to ensure that recently infected hosts have an uninfected partner to transmit to within the constrained time frame.

It is important to note that none of these consequences imply more risk for the index case with concurrent partners; the index case simply has the risk associated with multiple partners, whether sequential or concurrent. Concurrency is instead a risk for the partners of index cases (at the individual level), and it raises the epidemic potential of the network (at the population level). If those with concurrent partners tend to choose partners who also have concurrent partners, then this is a form of assortative mixing. Under these conditions, a prevalence differential can develop, and one will observe a higher risk of infection among those with concurrent partners. This has important implications for empirical studies that seek to quantify the impact of concurrency, as discussed below.

SIMULATION AND ANALYTIC FINDINGS

Even small differences in partnership sequence can have a remarkably large impact on both network connectivity and epidemic spread. Two examples are shown below. In Fig. 7-3,

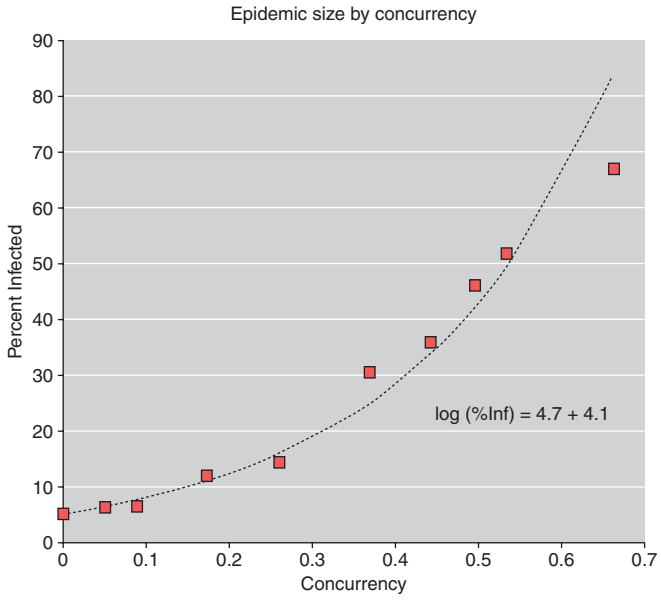

FIGURE 7-3. Impact of concurrency on prevalence. The graph shows the average percent infected at the end of the simulation (*y* axis) as concurrency was increased (*x* axis).

from an early paper in the field by Morris and Kretzschmar,[97] the plot shows the average prevalence of infection after several years (on the *y* axis) as a function of the level of concurrency in the population (on the *x* axis). The results are based on a fully stochastic dynamic simulation, with partnerships that form and dissolve over time, a fixed transmission probability per unit time in discordant partnerships, and no vital dynamics. The points on the graph represent the average of 100 simulations at that level of concurrency. Concurrency is measured as the mean degree of the "line graph" which can be interpreted roughly as the expected number of concurrent partnerships associated with each partnership in the population. In all simulations, the total number of persons and partnerships in the hypothetical population is the same, the infectivity of the pathogen is the same, and the number of years the simulation is run is the same; the only thing that varies is the level of concurrency. As concurrency rises, prevalence rises exponentially: with serial monogamy (concurrency = 0), final prevalence is approximately 5%, and by the time the measure of concurrency is 0.7 (7/10 of a concurrent partner for each partnership in the graph, or 7 out of 10 partnerships having a concurrent partnership), the final prevalence is nearly 70%. Since there is *no increase* in the number of partnerships (or the mean contact rate), the entire rise in prevalence here is due to relaxing the rule that partnerships be monogamous (the editorial that followed the original article was in error on this point[98]). Data from Uganda in the early 1990s suggest that the concurrency measure was about 0.22, which would raise the expected number infected by a factor of 2 or 3 over serial monogamy.[99]

One of the primary mechanisms that explains how concurrency amplifies spread is the increase in network connectivity. The intuition here is simple. Imagine if everyone had only two partners in their lifetime, but had them concurrently. Like a big circle of people holding hands, it is possible for the entire population to be connected, even though the contact rate is very low.

Concurrency can have a large impact on network connectivity, even in populations with low rates of partnership change. This is shown in Fig. 7-4.

Here, everyone in the population is constrained to have no more than three concurrent partners, and the majority have only one or two (we ignore persons with no partners for clarity here, since they do not matter for this example). As the mean of the concurrent partnership distribution rises from 1.68 to 1.84, a difference of less than 0.2 of a partner, the connectivity in the network rises dramatically; the fraction of the population in the largest connected component rises from 2% to over 60%. In addition, we observe the growth of a multiply connected component (the "bicomponent," shown in red), where people are connected by at least two independent paths. Multiply connected components are an important feature of the network because they signal a more robust transmission system. It is harder to disrupt the chain of infection when multiple paths exist.

Concurrency has a number of variations. One is defined by its duration, the length of time that two partnerships overlap. Short overlaps provide less opportunity for transmission and less stable connectivity of the network, so are likely to have less impact on transmission. Another variation is defined by the sequencing of the overlapping partnerships: one partnership interval can be embedded in the other, or the overlap can be transitional, as one partnership ends and another begins. The transmission implications of these sequencing variations are not known but they do represent very different behavioral patterns, so their meaning and importance, culturally and individually, is likely to be quite different.[100]

Formal mathematical analysis has shown that concurrency raises the fundamental measure of epidemic potential, R_0.[101] Other simulation studies show that the impact of concurrency is further amplified by "degree-based" mixing patterns, that is, when concurrency is itself a basis for mixing. Assortative mixing by degree might occur in a bathhouse setting, where those with multiple concurrent partners have sex with other multiply partnered persons, while outside the bathhouse monogamy tends to be mutual. This leads to more rapid short term spread, but lower prevalence in the long run, as the monogamous persons are protected by the segregation in mixing. Disassortative mixing by degree would be typical in heterosexual networks with the gender double standard, where multiply partnered men are paired with monogamously partnered women. This has a slower initial takeoff relative to assortative mixing, but leads to higher prevalence in the long term.[63]

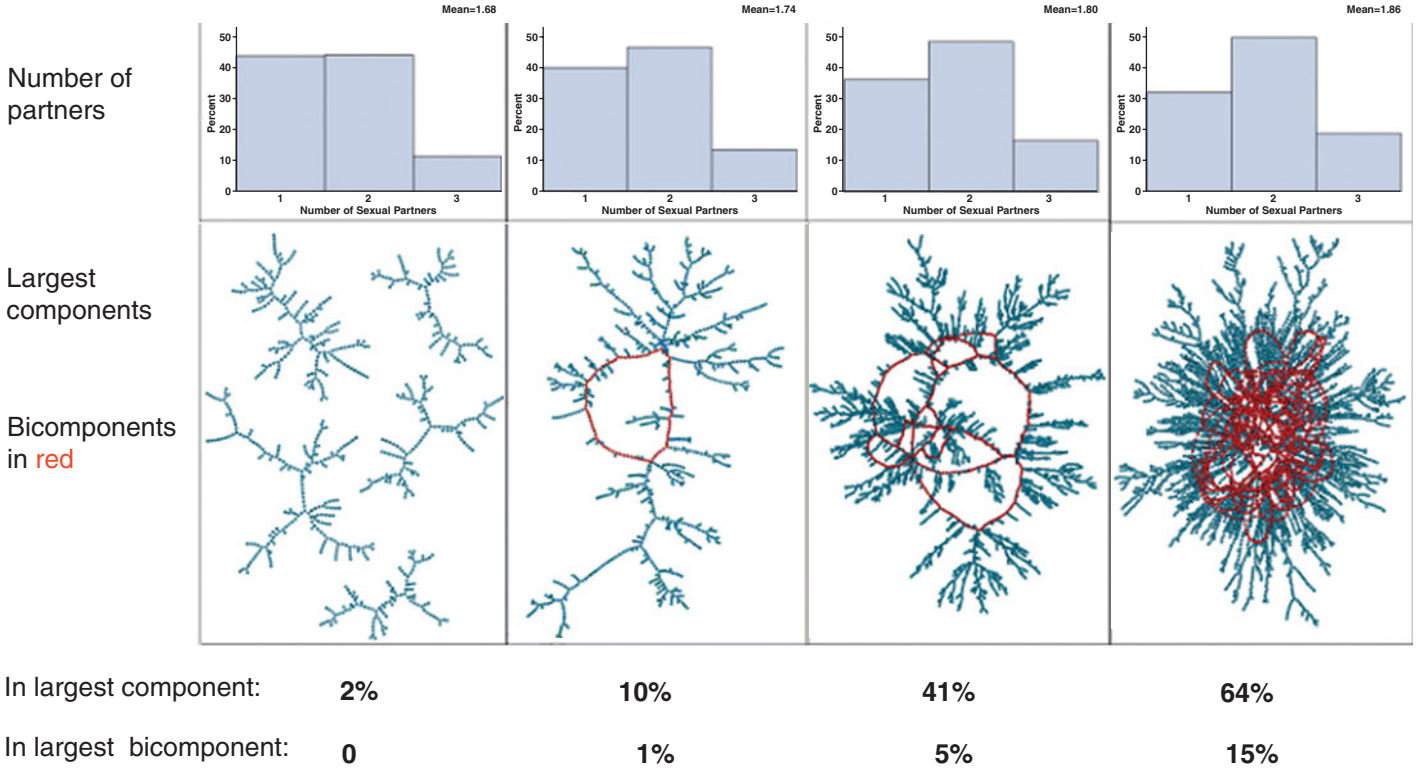

FIGURE 7-4. Impact of concurrency on network connectivity and robustness. The panels in the figure step through small changes in the level of concurrency (shown in the top panels) and its impact on the largest component and bicomponent in the network (in the bottom panels).

EMPIRICAL FINDINGS

Since these simulation studies in the early 1990s, a substantial number of studies have examined concurrency, and in general the findings have confirmed its importance for STI transmission. Empirical verification, however, turns out to be complicated. Concurrency has an impact at both the population level, by changing the network connectivity, and at the individual level, by changing the risk of transmission.

At the individual level the predicted effect of concurrency is to increase the chance of *transmitting* infection, since infection can now be passed to either partner, rather than just the later partner in the sequence, not the chance of *acquiring* infection.[102] From an acquisition standpoint, two partners represent the same risk to the index case whether they are serial or concurrent. This can be seen in Fig. 7-5.

The difficulty is that epidemiological studies are typically designed to measure the risk of acquisition: data are collected on a sample of respondents, and analysis involves predicting the infection status of a respondent as a function of their individual risk factors. To demonstrate the impact of concurrency at the individual level, information on respondents *and* their partners would need to be collected, either by enrolling partners or by asking respondents to report on their partners' behavior. The former is difficult to execute, and the latter is vulnerable to reporting error. Despite this, studies have been done, and the findings generally confirm

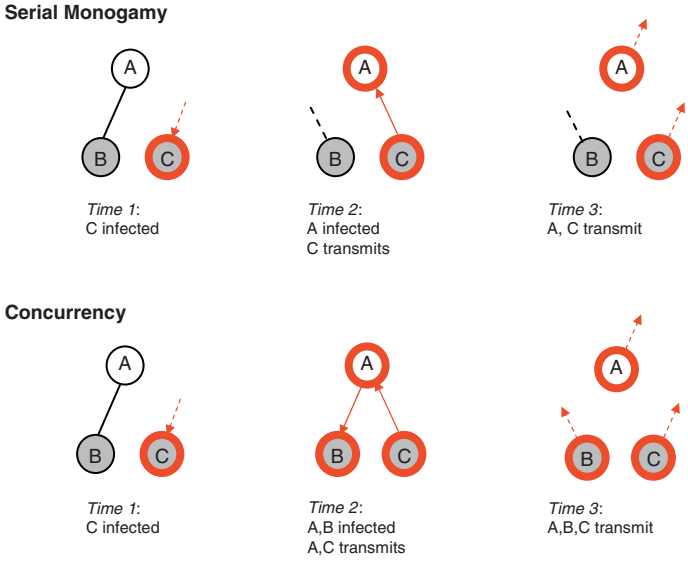

FIGURE 7-5. Concurrency effects at the individual level. The figure tracks an infection originally passed to partner C, under concurrency and serial monogamy. If A is the survey respondent, the effects of concurrency will not be observed in terms of A's infection status, which is the same in both scenarios, but in terms of A's transmission to B in time 2.

the importance of concurrency. The best evidence comes from careful contact tracing studies, which find that the adjusted odds of transmission are over three times higher for index cases with concurrent partnerships for both chlamydia[103] and syphilis.[104] Suggestive evidence comes

from a case-control study of pregnant women in Peru which enrolled the primary partners of the index cases. The HIV infection risk for the women was found to depend primarily on the number of partners their male partners reported.[105] Some studies have also found that respondents who report that their partner has other partners are more likely to be HIV+.[106,107] Despite the fact that concurrency is not a risk for STI acquisition, several studies of clinic populations do find concurrency significantly associated with infection.[108–110] This suggests that concurrency may be a marker for other forms of risk, such as being in a highly connected core of a network (for example, by assortatively choosing partners who also have concurrent partners).

At the population level, establishing the impact of concurrency requires estimates of the prevalence of concurrency and STI prevalence in many different populations. Note that this is not a traditional ecological correlation, since the effect is not hypothesized to operate at the individual level, it is a true population-level effect. But it is subject to the possibility of counfounding, and it is complicated by variations in survey instruments and sampling schemes. A number of observational surveys have found higher rates of concurrency among populations with disproportionately high levels of STI and HIV in the United States.[111–114] And in Uganda, survey data suggest the distribution of the number of partners is not that different from the distribution in the United States, but the rates of concurrency are much higher.[115]

The only exception to the findings linking concurrency to greater spread of STI is a comparative study of HIV based on five African cities.[116] They find no evidence that concurrency influences transmission at the population level. While this is an exemplary survey, since the questionnaires and sampling strategy are largely consistent, the finding is weakened by the small size of the sample ($n = 5$ cities, and city is the relevant unit of analysis here) and timing discrepancies (the concurrency measure is based on reported behavior in the last year while HIV may have been acquired earlier). The city-specific prevalences of acute bacterial STIs do correlate well with the observed levels of concurrency in this study. This study also reported that there was no impact of concurrency at the individual level, but the analytic approach mistakenly sought to correlate concurrency of the index case with the HIV status of the index case, rather than the HIV status of their partners.

OTHER NETWORK PATTERNS

DETAILED NETWORK CONFIGURATIONS

The more fine-grained details of partnership network structure are not captured by selective mixing matrices. These additional details include cycles of transmission caused by closed network loops, the distribution of "component sizes" (components are sets of connected individuals), the distribution of "path lengths" between persons (path lengths are the shortest number of steps between two individuals in a connected component), the centrality of individuals (centrality has several measures, "betweenness" centrality is the number of times an individual is on the shortest path between two other nodes), and the centralization of the overall network (the centralization of a network is the variance centrality of its members). (For an excellent review of network concepts and terminology, cf. Ref. 15.)

The data needed to map out these configurations are more difficult to collect, as they require either contact tracing or a census of the network. However, a number of studies have implemented this approach and the findings have been suggestive. In a comparison of two networks of high-risk persons, in Colorado Springs, CO, and Bushwick, NY, the prevalence differential was associated with the network positions of HIV+ subjects. The HIV+ subjects were found to be located in relatively smaller components of the network in Colorado, linked directly or indirectly to five or six other individuals.[117] In New York City, HIV+ subjects were found to have much more central locations, linked to hundreds of others in a large connected component.[118] Effective interventions in these two different network contexts would probably look quite different. In Colorado Springs, it would be sufficient to target the small, infected components intensively, while monitoring the incidence in the remainder of the network and responding to outbreaks as needed. In New York, the intervention challenge is much greater and would perhaps best be focused on "segmenting" the large, connected component and minimizing the links to newer (hopefully uninfected) users.

"SCALE-FREE" NETWORKS

One of the most well-known features of the partnership distribution is its long upper tail. It is the stuff of legend in U.S. popular culture—recall Wilt Chamberlain's estimate of his 25,000–32,000 lifetime sexual partners—and a topic of serious study in STI epidemiology. An empirical example is shown in Fig. 7-6 based on reports of the number of lifetime sexual partners from a representative national survey of U.S. adults.

A hypothesis put forward in some recent studies with roots in the physics literature is that the long upper tail of the partnership distributions can be described by a "power law."[119,120] Power law distributions have an appealing simple form: the shape is determined by one parameter, which defines the rate at which the upper tail decreases. In mathematical terms, the relation is represented as:

$$p(R = x) \propto x^{-\alpha}$$

Or, the probability that a person's number of partners (R) is equal to x is exponentially falling as x increases, at a rate of α.

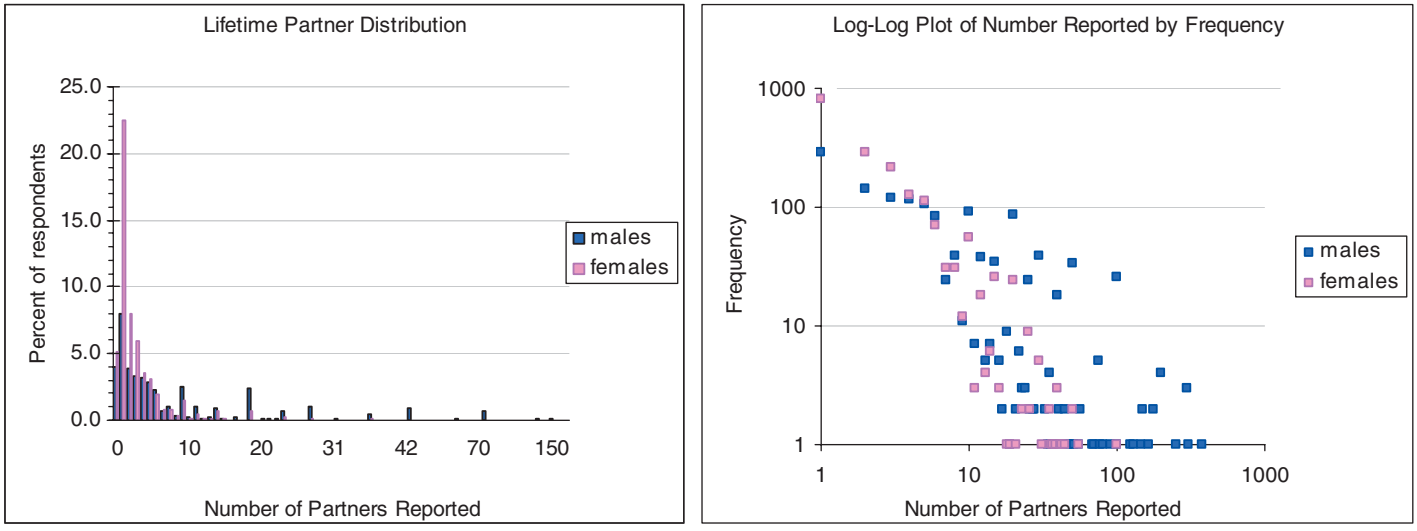

FIGURE 7-6. Distribution of lifetime sexual partners reported in the 1988 General Social Survey. The first plot shows the percent of male and female respondents reporting the number of partners shown on the *x* axis. The second plot shows the relationship between the number of partners reported and frequency of respondents reporting that number on a log–log scale.

A distribution with this property will reveal a linear relationship between the number reported and frequency of reports when plotted on a logarithmic scale. We show this logarithmic plot for our U.S. data in the second panel of Fig. 7-6.

The power law distribution has arisen independently in many scientific fields and is also commonly known as a "Zipf" or "Pareto" distribution.[121] It has been used to represent the distribution of many different phenomena, from income and the frequency of word usage to earthquake magnitudes. In the context of sexual behavior, the power law model defines a distribution where a small number of persons have a very large number of partners. These "superspreaders" serve as hubs in the transmission network.

The epidemiologically interesting behavior of the model occurs when the value of the exponent α is below 3. In this case, the (theoretical) variance of the distribution is infinite, and the R_0 for an infection in such a population would also be infinite. Distributions with this property are sometimes called "scale free." In a scale-free network, the hubs connect such a large fraction of the population that they alone determine the dynamics of epidemic spread. General population interventions that seek to reduce transmissibility will have little impact: there is no transmission threshold, and no critical vaccination fraction or "herd immunity," so the only effective intervention is to remove the hubs.

The most commonly proposed behavioral mechanism that would lead to a power law distribution of contacts at the population level is the "preferential attachment" process.[122] This process implies that people choose sexual partners with a probability proportional to the number of partners that person already has. In some limited contexts, this may be plausible but as a general model of sexual partnership formation, this seems questionable.

Empirically, the support for scale-free networks is not strong. Early studies that claimed to find such evidence were based on simple regression line fits to a log–log plot of the partnership density function, often to the top tail of the data only, making no effort to assess the goodness of fit, or to test alternative models. Where more rigorous statistical methods have been used, the results suggest sexual partnership distributions are not scale free.[123]

While the theoretical implications of this model are striking, its relevance for STI is probably limited to specific settings like commercial sex and bathhouses. The simplicity that makes this model appealing also limits its realism. Partner selection based on the various attributes noted above, race, age, geography, etc., will segment the network and constrain the impact of any particular hub. Concurrency can create connectivity that is robust to the removal of hubs.

In any particular population, a range of different networks structures may be present, arising from the culturally determined mix of behavioral rules that guide partner selection. The epidemic potential of a sexual network determined by the cumulative structural impact of many rules can vary dramatically. There is no one-model-fits-all rule for sexual networks. There are, instead, basic structural regularities that must be assessed empirically.

FUTURE DIRECTIONS

A lot has been learned about the impact of sexual networks on STI transmission, but there have also been some systematic obstacles to progress, especially for empirical research. The major obstacle to the empirical study of networks, in epidemiology as in other fields, has been methodological. The traditional methods of social network analysis required a network census: data on every node and every link in the

population of interest. That approach is clearly infeasible for epidemiological research on sexual networks. What is needed is a statistical framework for sampling networks and for estimating the epidemiologically relevant properties of the network from the sampled data.

Rapid progress is being made now in the development of methodology for network analysis. Methods have been developed to handle networks sampled with egocentric[19,124] and link-tracing designs.[125–128] Statistical theory is being developed for estimation and inference, which is complicated for networks given the dependent data and nonlinear threshold effects.[129,130] The class of models being developed can represent an arbitrarily complex network structure but can also test the goodness of fit of simple parsimonious models to data. A computer package has been released that allows researchers to use these methods for network analysis.[131] It turns out that the algorithm used for network estimation in this package can also be used for simulation. So, for the first time, researchers can simulate networks using models and parameters that have been derived from data and statistically evaluated for goodness of fit.

The promise of these new methods is the potential for parsimony and rapid assessment: explaining the population network structure with a small number of partnership formation rules. If this can be done, it will radically simplify data collection needs and give network analysis a central place in the tools of STI research and intervention.

The research of the previous decade has suggested that mixing and concurrency have a large impact on network structure and transmission dynamics. Now we can ask whether these are the only features that matter. On the one hand, there is a good theoretical basis for this hypothesis. It seems reasonable to presume that people make decisions about which partners to choose based on preferences and norms that operate at the local level. That is, we choose partners because they are the right sex, age, race, and status, and we often care if we (or they) have other partners. It is unlikely that people form partnerships thinking, "if I choose this partner I can increase my eigenvector centrality" or "I'd like to reduce my path length to a randomly chosen person on the west coast." This may seem obvious at one level, but the implications are quite striking. If simple local rules govern partner selection, then these also determine the aggregate structure in the network; what looks like an unfathomably complicated system is, in fact, produced by a few key local organizing principles. By extension, these simple local rules are also, therefore, the key behavioral determinants of disease transmission dynamics on the network.

There are also important practical implications if this is true. Both mixing and concurrency are network properties that can be measured with local (egocentric) network sampling strategies. If it turns out that these two local rules explain most of the variation in network structure that is relevant to disease spread, then we have a simple inexpensive way to rapidly assess network vulnerability for public health surveillance and some simple behavioral rules that people can be taught to recognize and change.

IMPLICATIONS FOR PREVENTION

A number of implications follow from the body of simulation studies and empirical findings on sexual networks and STI transmission that have accumulated since the early 1990s.

First, despite the popular fascination with "superspreaders," it is not necessary to have highly active persons to create the potential for epidemic spread in a network. A modest amount of concurrency can provide the connectivity needed for sustained transmission. This is particularly true for generalized epidemics, which may have started in a traditional core group, but are being sustained in a less active population. In this context there is probably little to be gained by urging people to have fewer partners. Intervention instead should be focused on breaking up the network formed by concurrency. A good intervention message would be: "one partner at a time." Moreover, a good intervention research program would focus on the socioeconomic and cultural roots of concurrent partnerships.

Second, small differences in the pattern of contacts can have huge effects on the transmission network structure. Near the threshold, an average increase of less than 0.2 concurrent partners can be enough to fundamentally change the connectivity of a network and create a robust connected network core. This is important to remember when evaluating the significance of empirical differences in sample survey data. Most samples are not large enough to detect a difference this small as statistically significant, but the difference may still be substantively important.

Finally, persistent prevalence disparities across populations for a wide range of STIs are a signal that the underlying transmission network is probably the cause. A combination of processes may be at work: assortative mixing (which segregates populations), and small variations in concurrent partnerships (which differentially raise the spread in some groups). The disparities that can be sustained in such networks can be surprisingly large, even when the behaviors do not appear to differ much by group. While this may look like a puzzle, it may be an indication that prevention is close at hand. Just as small changes may be enough to push transmission above the epidemic threshold in some groups, small changes may be all that are needed to bring transmission down below that threshold. For this reason, it is important that we have an accurate empirical picture of the key aspects of the transmission network. We need to know who needs to change behavior, what behaviors need to change, and the relevant cultural contexts, so that our intervention efforts can be properly targeted and maximally effective.

8 Sexual Partnership Effects on STIs/HIV Transmission

Pamina M. Gorbach and King K. Holmes

INTRODUCTION

Individuals throughout the world establish and maintain different types of sexual partnerships over their life course. While sexually transmitted infections (STIs) including HIV infection occur for individuals in all types of partnerships, risk of acquisition is determined more by the behaviors practiced with each sex act than by the type of partnership being maintained. The prevalence of STIs as well as relevant risk behaviors such as having a concurrent partner and sex without condoms vary with physical, social, and emotional factors within each partnership. The risk of STI/HIV transmission appears to vary across types of concurrent partnerships according to the differing dynamics within them.[1] Previous research on partnership dynamics has improved our understanding of the multidimensional aspects of sexual partnering, and of how these aspects of sexual partnering interact and increase risks for STIs. Therefore, recognizing within-person variation of sexual behaviors across types of partnerships can enhance the ability of STI practitioners to develop successful counseling approaches and enable public health practitioners to anticipate risk and plan programs to manage the level of disease within a population. Greater understanding of the distribution of different types of risk within populations will also enable program planners to assess the scope and progress of STI epidemics.

In this chapter, we discuss how our understanding of sexual partnerships among heterosexuals and among men who have sex with men (MSM) enhances our understanding of how STIs continue to be propagated through populations. The partnerships of women who have sex with women are not discussed in this chapter not because STIs are not transmitted within such partnerships, but because STI transmission and prevalences in such partnerships are at lower levels than for the partnerships of heterosexuals and MSM. Culture and norms about gender and sexuality play a significant role in determining partnership types and gender-specific sexual behaviors; therefore, this chapter is also limited to discussing partnerships and types within Western countries including the United States and those in Europe. One framework cannot serve all cultures equally; nevertheless, a conceptual framework is developed that reflects how individual and partner characteristics influence partnership dynamics that in turn influence risk behaviors, such as concurrency and not using condoms, and influence associated risks for STIs and HIV. It is hoped that such a framework that includes negotiated safety agreements and discordance of partnership characteristics will be of use to those studying partnerships in other cultural contexts.

DESCRIPTIONS OF PARTNERSHIP TYPES

The types of partnership classifications most often studied in STI/HIV research are "main partner" or "regular partner" versus "casual partner," with few attempts to define what is meant by these types. Even for the clearest designations of a type of partner, the respondents often have some latitude in defining partner type. For example, when asked to describe a "new partner," the length of time that a partner is classified as "new" is not standardized and is often left to be defined by respondents. The benchmark study of sexuality in the United States, the National Health and Social Life Survey (NHSLS), described only four types of sexual partnerships: marriage, cohabitation, the intention of one or both partners to pursue the relationship further, and the explicit view by the partners of the relationship as short term.[2] An expanded list of partnership types allows for a greater variation of types with potential for a more nuanced understanding of differences in behaviors across types. For example, Table 8-1 presents an expanded list of seven different types of partners, for both heterosexuals and MSM, with definitions provided for each. The inclusion of the list in a study of MSM recently infected with HIV revealed a large distribution in the types of partnerships reported[3] and revealed changes in numbers of such partners and in the practice of risk behaviors within these partnerships following the diagnosis of HIV.[4]

Table 8-1. Definitions of Types of Sex Partners for Men Who Have Sex with Men and Heterosexuals[4]

Main: Someone who is your primary sexual partner; this might be your only sex partner or the partner you consider to be most important if you have more than one partner
Regular: Someone who you have sex with on a regular basis but who is not your main partner or primary partner
Friend: Someone you have had sexual contact with more than once, but not on a regular basis, and you normally socialize with
Acquaintance: Someone you have had sexual contact with more than once, but not on a regular basis, and who you don't socialize with
Onetime: Someone you had sexual contact with only one time but could find again if necessary
Unknown: Someone that you had never met before you had had sexual contact and never plan to see again
Trade: Someone who you gave sex to for money or other goods or someone who gave you sex for money or other goods

Data from Gorbach PM, Drumright LN, Daar ES, Little SJ. Transmission behaviors of recently HIV infected men who have sex with men. *J Acquir Immune Defic Syndr*, 2006; 42(1): 80–85.

Most research on partnership types has classified types according to a single aspect of relationships such as duration or exclusivity (or concurrency) and have looked for variations in behaviors by few domains such as emotional closeness (intimacy), communication, and power. Few if any studies have examined these dynamics simultaneously. Scales for measuring dynamics within established couples such as the Dyadic Adjustment Scale[5,6] are not designed for nonmain partnerships. Below we review the literature on three such domains and existing measures for them.

EMOTIONAL CLOSENESS OR INTIMACY

Within some partnerships, increased intimacy can make condom use more likely because it suggests greater comfort in negotiating behaviors. Condom use and partnership factors (mutual partner support and emotional closeness) have been associated with the likelihood that women would attempt to use condoms with main partners; the belief that condoms build trust was also associated with long-term consistent condom use.[7] However, intimacy may also function as a barrier to condom use. For those in ongoing partnerships, nonuse of condoms has been associated with greater perceived relational intimacy[8] and greater commitment has been associated with lower condom use.[9] Among female adolescents, a higher score on a perceived relationship quality scale (a measure of intimacy) of primary partnerships was associated with not using condoms.[10] Clearly, intimacy operates along with other partnership dynamics to influence condom use; however, the relationship between the level of intimacy in a partnership and STI or HIV acquisition is complex.

Partnership discordance by differing intentions to terminate the partnership, another emotional dimension of partnerships, has been associated with STI in heterosexual young adult partners.[11] This might happen when one partner is contemplating termination and the other partner is striving to hold on to the partnership, condoms might not be used to counteract diminishing emotional concordance by enhancing the intimacy during sexual activity. Measurement of emotional discordance in partnerships requires comparison of intentions of each partner to continue the partnership and can benefit from longitudinal assessments of the same partnership.

Measures used to assess emotional closeness or intimacy include the Passionate Love Scale,[12] Miller's Social Intimacy Scale,[13] and the Dyadic Sexual Communication Scale.[14]

COMMUNICATION

Research on communication between partners and risk of STI has focused mostly on communication about condom use but has rarely considered how communication affects other measures of sexual risk. One scale often used to measure communication in partnerships, the Health Protective Communication Scale,[15] has been predictive of condom use and measures partners' discussions of past sexual history in relation to condom use. Higher communication with new partners has been associated with higher condom use among Hispanic women.[16] Communication has been positively associated with consistent condom use among incarcerated adolescents,[17] although no significant difference in levels of reported condom use was found between respondents who reported talking about past sexual histories and those who talked specifically about HIV/AIDS protection.[18] It has also been suggested that belief in one's ability to communicate (communication self-efficacy) may increase the likelihood of condom use.[19] Finally, poor communication in a partnership (both general sexual communication and health-protective communication) has been associated with higher numbers of partners among adolescents.[18] In the studies cited above, communication within partnerships was studied at one point in time and did not consider how communication patterns may evolve as intimacy grows in a partnership or, conversely, as it dissolves. Communication skills, measured

more generally as ability to discuss feelings and concerns within the partnership, need to be considered more fully in relation to other sexual risk behaviors.

POWER DYNAMICS

Power differentials in heterosexual partnerships have been related in part to gender.[20] Physical abuse and economic dependence are related to power dynamics in partnerships and may also decrease an individual's ability to adopt risk avoidance behaviors that protect against STI/HIV. Gender differences in power are thought to increase women's risk for HIV, especially among minorities and women who are economically and socially marginalized. Among Latina women with a primary sexual partner, low relationship power accounted for about half the risk of consistent condom use in one study,[21] and with increased HIV risk behaviors (i.e., having multiple partners, not using condoms with new partners, having partners who may use drugs) in another study.[22]

Because insistence on condom use by economically vulnerable minority women may jeopardize their continued financial support by male partners, their immediate financial needs may outweigh the perceived risk of HIV infection.[23] The threat of domestic violence may also deter women from participating in STI/HIV control efforts such as partner notification.[24] Among young African American women, those in abusive relationships were less likely than others to use condoms, were more fearful of asking their partners to use condoms, worried more about acquiring HIV, felt more isolated, and were more likely to experience verbal abuse, emotional abuse, or threats of physical abuse when they discussed condoms than were the women not in abusive partnerships.[25] Of note, few studies have considered how males' economic dependence on female partners or on other males in homosexual relationships may affect condom use, as the assumption thus far appears to have been that it is females, not males, who are vulnerable to relationship power differentials.

One psychometric instrument used to assess power in partnerships is the Sexual Relationship Power Scale,[21] developed for minority women based on the Theory of Gender and Power[20] and the Social Exchange Theory.[26] This instrument is used for assessing associations between relationship power and consistent condom use. Locus of control has also been used to assess power in relationships.[22]

BEHAVIORS MOST ASSOCIATED WITH RISK OF STI ACQUISITION

CONDOM USE

In general, among U.S. adults, more men than women report using a condom at last intercourse (40% vs. 22% respectively), and condom use is more likely among those who are younger and never married.[27] Condoms are about half as likely to be used with an ongoing or steady partner than with other partners,[28–30] for example, among sexually active U.S. adults, 17.5% of those with an ongoing partner versus 44% with a other sexual partner reported condom use at last sex.[29] Condom negotiation and use are reported more often by individuals with new partners than with ongoing partners; for college students, especially males, perception of positive individual and relational outcomes, such as believing the partner was more deserving of respect, less likely to have an STI, and more caring about them, were reported more often for new partners who insisted on condom use than for those who did not.[8] For those at high risk for STI such as patients in a STD clinic, this pattern holds. For example, in a prospective study of women in STD clinics, condom use was more common with new partners and casual partners than with regular partners; even among women with multiple partners, condoms were still reportedly used more often with new and casual partners than with regular partners.[31]

Within ongoing partnerships, condom use may be less frequent. A population-based survey of U.S. adults found after examining the type of relationship risk (i.e., IDU, MSM, or HIV-infected partner), only 22% of persons at increased risk for HIV used condoms during last intercourse within an ongoing relationship, suggesting a substantial risk of unprotected exposure to HIV.[32] Why condom use is less likely in ongoing partnerships appears influenced by perceptions of the partners' attitudes. Among STD clinic patients, intentions for condom use with casual partners were influenced more by social norms for women and by personal attributes for men, but in steady partnerships, both men and women perceived their steady partners as less likely than casual partners to favor condoms. They seemed more concerned about steady partner's norms concerning condoms than about casual partner's norms.[33] An important consideration is that partners may not agree with each other on the type of partnership they are in. Among 162 partnership pairs at an STD clinic, there was poor agreement between partners on whether their partnership was regular or casual, despite fair agreement on whether the partnership was new.[34]

Condom use patterns within partnerships cannot be assumed to be static because partnerships themselves change over time. It appears that condom use is more likely to lapse than to be adopted as a partnership continues.[35–37] Among the few female STD clinic patients followed prospectively, whose relationship with a new partner evolved to the point where that partner was considered a regular partner, consistency of condom use decreased significantly.[31] Among adolescents, condoms also have been used more often in new than in established partnerships (66% vs. 54%), but among new partnerships, condom use declined rapidly over time, so that within 3 weeks after the establishment of the new

partnership levels of condom use were similar to the levels measured among already established partnerships.[35] Adolescent females have also been found to have increased coital frequency along with less condom use as the duration of their sexual relationships increases, resulting in greater potential risk of acquisition if they are exposed to STIs within the relationship.[36] Therefore, risk of STI acquisition may persist even as partnership duration is prolonged.

CONCURRENCY AND BRIDGING

The concurrent partnership or partner overlap is defined as a sexual partnership in which one or more of the partnership members have other sexual partners while continuing sexual activity with the original partner.[38] Concurrency has been shown to play a fundamental role in potentiating the spread of STIs such as chlamydial infections,[39] gonorrhea,[40] and syphilis,[38] and HIV infection.[28,41,42] Mathematical modeling has indicated that concurrent partnerships are as important multiple partners and cofactor infections in the spread of HIV,[28] not only influencing the rapidity of the spread of HIV in the initial epidemic phase but also the total number of individuals who become infected.[42] Prevalences of reported concurrent partnerships have ranged from 32% to 54% among adolescents[43,44] and 12% to 40% among adults[45–47] in different regions of the United States. In the National Survey of Family Growth, approximately 25% of U.S. women 15–44 years of age who reported a lifetime number of ≥2 partners and 12% of all women, reported concurrent sex partners.[46] Prevalence of concurrency reported by African American women has been higher than that of white and Hispanic women in national surveys.[48] Concurrency has been reported more often by males than by females within the same heterosexual study population.[49]

An individual's practice of having concurrent partners (individual's concurrency) has been associated with higher prevalence of STIs[50] including *Chlamydia trachomatis* in the United States,[51] *Neisseria gonorrhoeae* in Trinidad,[52] and bacterial STIs in adolescents[44] even after adjusting for the individual's number of partners. Essentially having more than one sex partner at one time has appeared more risky than having had the same number of sex partners serially over a somewhat longer period, and has been associated with greater risk of having a bacterial STI at that time. Not surprisingly, among individuals with comparable numbers of recent sex partners, those who have partners with concurrent sexual partners (partner's concurrency) are also at increased risk of acquiring an STI[38,44,49,52] and those whose partners have concurrent partners are also more likely to be transmitters of syphilis (defined as having a partner at an earlier stage of syphilis than oneself) than those who do not report partner's concurrency.[38]

Thus, concurrency has been associated not only with rate of spread and prevalence of STI at the population level but also at the individual and partnership level. Moreover, concurrency and partnership discordance (a difference between members of a partnership with respect to characteristics such as age, ethnicity, geographic residence, or rate of sex partner acquisition) have been found to coexist.[11] Discordance between sexual partners (disassortative mixing) may represent a proxy measure for sexual bridging between two sexual networks, since sexual networks tend to be composed of individuals concordant for geographic residence, age, ethnicity, and sexual activity level.[2,53] This combination of concurrency and bridging may enhance the spread of STI both within and across sexual networks. Bridging alone can bring STI from higher STI prevalence populations to lower STI prevalence populations; and concurrency alone links individuals into clusters of concurrent sexual connections at one point in time,[54] increasing the probability of STI spread to many members of the network within a short period. These two scenarios increase the spread of STI in different ways. Thus if two populations (or networks) were bridged by individuals having concurrent partners, the increase in STI would be at least additive, if not multiplicative in nature. Of course STI transmission within or across networks will only be observed if concurrency or bridging occurs within or across networks in which STI already exists or is introduced. Measuring concurrency and STI prevalences among both members of a partnership, or ideally, among members of sexual networks, would allow for a more complete understanding of the interaction between concurrency and bridging, while quantifying the contribution of both to an individual's risk of STI.[55]

As noted above, sexual bridging between higher-risk and lower-risk sexual networks contributes to the movement of STI/HIV from those with high-risk behaviors to those with lower risks. Among STD patients in the United States who practiced sexual-bridging behaviors, "active bridgers" were defined as those infected with an STI, and "potential bridgers" were defined as those who were uninfected.[56] Concurrent partnerships may involve either assortative mixing (e.g., partners have similar characteristic or behaviors) or disassortative mixing (e.g., sex partners have dissimilar characteristics or behaviors). When a person has concurrent partnerships involving unprotected intercourse with individuals from different sexual networks, that person becomes a particularly efficient bridge for potentially carrying STIs between groups. There are few data on the proportion of concurrent partnerships that involve bridging of networks or on the proportions of potential bridgers who have concurrent partnerships (as opposed to serial partnerships) with members of different sexual networks.[51] Partnerships that involve discordance as described above, as well as concurrent partners, have the potential to rapidly accelerate the spread of STIs/HIV in a population. Such discordance per se may be associated with STI acquisition because it can be a marker for bridging between high and low STI prevalence groups.[2,53,56–59] Partner

discordance for number of recent partners, for example, may represent a connection between high and low STI prevalence populations. When such discordance in partnerships was considered by using data from both individuals in one partnership (i.e., using the partnership as a unit of analysis), partnerships discordant by number of lifetime partners were more likely to have STI than partnerships that were concordant for number of partners, regardless of the actual numbers of partners. Having a sex partner from a network with a level of partner change higher than the level of one's own network presents a greater risk for STI than having a partner from a network with less partner change or similar to one's own network, again emphasizing how an individual's STI risk may not only be a result of an individual's behavior and network but of the partner's behavior and network as well.[11,55]

To the extent ethnicity is associated with STI, partnership discordance by ethnic group may be another proxy for bridging between higher and lower STI prevalence populations, and such discordance has been associated with current STI.[53,57–59] Additionally, ethnic discordance has been shown to be associated with decreased condom use among adolescent partnerships,[59] which may contribute to increased risk of STI in adolescence. Yet, ethnic concordance between partners does not necessarily mean these partners reside in the same sexual networks. For example, among African Americans the smaller population size and high level of assortative mixing by ethnicity among African American women result in African American women having partners who are concordant with them for ethnicity, but these partners are often discordant for sexual activity.[53,58]

A taxonomy of concurrent partnerships among heterosexuals[1] and a longitudinal study assessing the interrelationships between partnership formation and dissolution, condom use, concurrency, and STI incidence within partnerships[11,55] indicate how the efficiency of HIV/STI transmission can vary according to the differing partnership dynamics and patterns of concurrency.

PARTNERSHIP TYPES INVOLVING MSM

Less research has been done on the partnerships of MSM than on those of heterosexuals; research that has been done has tended to focus on the numbers of sexual partners among MSM who acquire or who are at risk for STIs including HIV rather than on partnership types. While many MSM have short-term partnerships, a substantial proportion of which are even anonymous, these types of partnerships have often been lumped into one category termed "casual." The sexual partnerships of MSM are often identified by the venues where men meet partners or have sex, such as circuit parties,[60] or public sex and commercial sex environments,[61] and not by the more substantive or structural features of the partnerships. Partnership type has also come to be identified for MSM by HIV serostatus of the partner, i.e., HIV serostatus concordant positive or negative, or serostatus discordant (one positive, one negative), or serostatus unknown, again ignoring the dynamics within these partnerships. Another characteristic of MSM as individuals and as partners that strongly influences risk of STI/HIV acquisition or transmission is the nature of the sexual behavior, i.e., anorectal insertive, anorectal receptive, or both. Prevalences of such behaviors appear to have differed between countries and regions and have changed over time.

Many MSM establish main or primary partnerships, with 68% of U.S. MSM reporting having a main partner in the past year[62]; and many such partnerships do have long duration. However, a notable characteristic of MSM primary partnerships is the preponderance of nonmonogamy within these partnerships[63] reportedly involving around half of those with main partners in one survey.[64] While nonmonogamy often exists in the context of explicit agreements as to what can be practiced and the need to tell the main partner of the practice, this is not always the case. Moreover, MSM in partnerships they define as monogamous but in which one or more partners report recent nonmonogamy have expressed less satisfaction with their partnerships than those who are openly nonmonogamous or strictly monogamous.[65]

MSM tend to have a variety of different partnership types and continue to accumulate new partners over their life course, and these partnerships are very often concurrent, even though they may have a long-term main or primary partner. Table 8-1 provides illustrative definitions of some of the variety of partner types that exist for MSM and for heterosexuals; these terms and definitions may be useful for sexual behavior research and surveys. It should be noted that while different types of concurrent partnerships have been described for heterosexuals,[1] this remains a topic yet to be tackled for concurrent partnerships of MSM. While sexual behaviors have been compared by partnership type, there is less research examining factors such as communication, power dynamics, and intimacy across partnership types for MSM than for heterosexuals.

HIV INFECTION AS A PARTNERSHIP ISSUE FOR MSM

Given the high prevalence of HIV among MSM in many large cities, averaging about 25% in the United States but ranging by city from 18 to 40%,[66] HIV infection per se has become a very salient issue for MSM partnerships. The likelihood of being in a partnership, albeit of short or long duration, with someone having HIV infection is much more likely for MSM than it is for heterosexuals. This makes discussion of HIV status a particularly important dynamic for MSM within their partnerships. Disclosure of HIV status remains a challenge for HIV-positive MSM; among those

reporting unprotected sex, almost half [67,68] reported not disclosing their HIV status to prospective sex partners prior to having unprotected sex, and even fewer report disclosing within their casual partnerships.[69] Within more intimate partnerships there is a tension between facing fear of rejection from a partner and wanting to share the information with that partner, often resulting in a delay of the discussion.[70] Unprotected intercourse occurs frequently within serodiscordant regular partnerships regardless of whether HIV has been disclosed by the positive partner; as reported above, condoms are less likely to be used with main or regular partners than with other partners. This leads to a higher probability of HIV transmission within such regular partnerships than in nonregular serodiscordant partnerships.[71] Nevertheless, MSM more often report practicing unprotected anal intercourse (UAI) in seroconcordant partnerships than in serodiscordant partnerships, particularly if the seroconcordant partner is also a steady partner.[72] When total numbers of recent sex acts are considered, more than half of those reported by HIV-positive MSM occurred with seroconcordant partners and 82% of those with serodiscordant partners were protected.[73] Not knowing the status of a partner is associated more often with risky sex than when the partner is known to be serodiscordant. For sex with nonmain partners, HIV-positive MSM more often report unprotected sex with partners of unknown serostatus than with HIV-negative partners.[74] There may also be the misguided expectation that the HIV-negative individual should inquire about the HIV status of his partner, and that if that negative individual does not ask, then an HIV-positive partner may either assume that the individual is also positive or does not care about the risk of acquisition.[70] While HIV-positive MSM clearly struggle with disclosure and many do practice unprotected sex with partners of unknown or serodiscordant status, there are many who either use condoms with such partners or avoid sex with them to reduce transmission risks.

Some evidence suggests that after a diagnosis of HIV infection, men seek partners who are also HIV infected (i.e., sorting themselves by serostatus to establish seroconcordant partnerships).[75] Some, but not all, HIV-infected individuals may also intentionally modify their sexual behavior to reduce the risk of transmission to others,[76] but other HIV-positive MSM may continue risky behavior following their HIV diagnoses.[77–80] Comparisons of reported risk behaviors over time have not shown increased risk taking among HIV-positive MSM.[81,82] However, the rising rates of STIs such as gonorrhea, syphilis, and chlamydial infection among MSM, including HIV-positive MSM, may be explained either by increasing risk taking in general or by increasing rates of unprotected sex in HIV-seroconcordant partners, which could offer some protection against acquisition or transmission of HIV but not of other STIs.

USE AND NONUSE OF PROTECTIVE BEHAVIORS

Condom use by MSM has long been promoted as the fundamental way to prevent STI/HIV transmission among MSM, yet is still far from a universal behavior even with partners who are not regular partners. For example, among MSM in 17 U.S. cities, about half reported UAI in the past year, 58% with a main male partner (defined in the study as someone with whom the participant had sex and to whom he felt most committed, e.g., a boyfriend, spouse, significant other, or life partner), and by 36% with a casual male partner (defined as someone with whom the participant had sex but who was not considered a main partner).[62] The pattern is similar for young MSM, with even fewer always using condoms with steady partners than with nonsteady partners.[83] Findings are similar in Britain; in their National Survey of Sexual Attitudes and Lifestyles, 60% of MSM who reported anal intercourse in the past year reported UAI in the same period; condoms were used at last intercourse by about one-third, with either a regular or not regular partner.[84]

Similar to heterosexuals, MSM may practice protected sexual activity (condom use) with new and short-term partners more frequently than with ongoing partners, making longer-term partnerships risky for HIV transmission between serodiscordant partners or nonmonogamous partners. Among HIV-positive MSM more report practicing UAI in stable or main partnerships than in shorter term or less intimate partnerships.[85–87] Moreover, condom use is often discontinued early on (within the first 3 months) and without previous discussion in these partnerships.[88] Such behaviors have been responsible for a substantial proportion of HIV acquisition; an ongoing or primary partner was reported to be the source in 50% of cases of seroconversion in a cohort of young men in Amsterdam.[89] However, no independent confirmation of the source of infection was obtained and many seroconverters reported multiple partners. Seronegative MSM have been found to use condoms significantly less often if they are in a primary relationship with a single partner known or thought to be HIV-seronegative than with other partners[90] whereas seropositive MSM reported significantly less unprotected insertive anal intercourse (IAI) with seronegative partners than with seropositive partners.[91]

"Barebacking" or "raw sex" (slang terms for anal sex without condoms) has been defined as a phenomenon in which some MSM seek unprotected anal sex in spite of and sometimes because of the risk of acquiring HIV.[92] Barebacking has been construed as anal intercourse without condoms with intention, to be contrasted with just the behavior of anal sex without a condom, and that those who bareback share a social identity.[93] Barebacking has been reported more often by HIV-positive MSM than by HIV-negative MSM, who often reported barebacking with seroconcordant partners.[94] Up to one-third of HIV-positive MSM in a survey in two

large cities identified themselves as "barebackers"; among those 42% reported only barebacking other HIV-positive men and were more likely to also have IAI with HIV-positive men than with HIV-negative men or men whose serostatus was unknown.[93] This suggests some reduction in transmission risk that may accompany the barebacking practiced by some HIV-positive MSM. When not considering the intention involved in unprotected sex, studies have reported that HIV-positive MSM continue risk behavior following their diagnoses,[95] and unprotected sex with casual partners has been especially common among MSM on highly active antiretroviral therapy (HAART) although also observed among men with high HIV-1 RNA levels and not receiving HAART.[96] Among MSM in HIV-discordant partnerships[97,98] using condoms can signify lack of closeness and trust.

NEGOTIATED SAFETY

UAI does not always represent risk within a partnership if it occurs within a "negotiated safety" (NS) agreement in which both men are seronegative and comply with an arrangement in which they only have UAI with each other.[99] Such agreements are relatively common, reported by 50% of HIV-negative men in partnerships of ≥6 months duration in one study.[100] However, because compliance with such negotiated agreements is not consistent, e.g., up to 40% of those with NS agreements reporting recent violations of the agreement,[100] risk may not be static and may not remain low.[101] In the San Francisco Men's Health Study, HIV-positive men in a primary relationship were less likely to be monogamous thanHIV-negative men.[102] Management of this risk within the partnership requires both partners knowing and sharing their HIV status with each other; however, many MSM do not know their own or partners' status—even those in primary relationships. In one large study in Switzerland, only 52% of steady partners knew each other's status.[103] Another study found that although the men with primary partners reported higher frequencies of UAI than men without primary partners, only a quarter of those primary partnerships were reported monogamous.[104] Compliance with such negotiated safety agreements may be affected by the same partnership dynamics over time as those described above for heterosexuals.

SEXUAL POSITIONING

The practice in which HIV-positive men report opting to be receptive with HIV-negative or HIV-status unknown partners is known as "selective" or "strategic" positioning.[105] Some HIV-positive MSM report choosing lower-risk sexual positions to avoid disclosing their serostatus.[70] Overall, the evidence to support the intentional practice of sexual positioning by HIV-positive MSM as a method of reducing risk of HIV transmission is mixed. While there is some evidence from Australia that MSM in regular serodiscordant partnerships practice sexual positioning to reduce transmission risk[106] the choice of positions did not seem to be consistent among HIV-positive men with serodiscordant or serostatus unknown partners when studied in two large U.S. cities. Moreover, the latter U.S. study did not find positioning practiced in a consistent manner across partner types, although HIV-positive MSM did report more risk behaviors such as IAI with other HIV-positive partners.[74] Thus, while some HIV-positive MSM report using this approach, this has not yet become a normative behavior.

Among HIV-negative MSM sexual positioning is also a strategy being employed to reduce risk of acquiring HIV. There is some evidence that HIV-negative MSM in the United States practice unprotected IAI slightly more often than receptive anal intercourse (55% vs. 48%).[107] Clearly both for HIV-negative and HIV-positive MSM, there is awareness of sexual positioning as a strategy to reduce transmission, but not for a large majority of MSM. This may be because of the influence of partnership type, and of other factors such as substance use during sexual activity, and also because this alone is likely a much less reliable strategy than consistent condom use. Finally, positioning is not widely promoted by public health authorities as an effective method for preventing HIV transmission among MSM.

A FRAMEWORK

Partnership dynamics have been assessed largely as predictors of condom use and less often as predictors of other risk behaviors, such as having other partners in an ongoing partnership. In Fig. 8-1 we offer a conceptual framework for individual and partner characteristics which influence partnership dynamics, which in turn influence risk behaviors

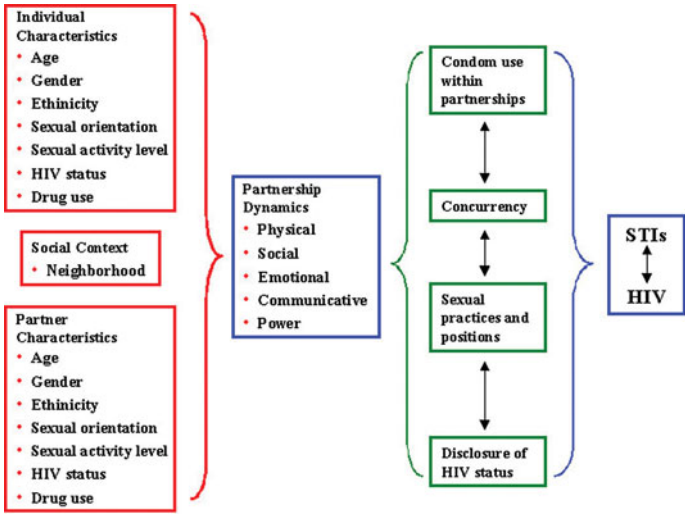

FIGURE 8-1. Expanded framework of how partnership dynamics affect STI/HIV transmission.

such as the practice of certain sexual behaviors and positions (such as anal sex itself or practice of either receptive or insertive anal sex, or both), concurrency and condom use, for all of which there may be explicit agreements in a negotiated safety agreement, and which are all ultimately associated with some risk of HIV and other STIs.

CONCLUSIONS

Measures of sexual risk within partnerships (i.e., amount of sexual contact and sexual practices including condom use) have not been incorporated into sexual network models. Sexual networks are instead usually described by their density, i.e., by the number of partnerships within them and the number of those that are concurrent. Yet just as the differing natural histories of various STIs have received little attention as yet in transmission models, the potential contribution of sexual networks to STI/HIV transmission can also benefit from a further advanced approach; transmission may vary not only by network size but also by other sexual behaviors occurring within the network. Therefore, network studies could be advanced by research that includes in-depth descriptions of partnership types and risk behaviors within networks, while measuring and characterizing numbers of sexual contacts. One example of this is research on "bridge" persons who have sex both with members of high-risk and of low-risk groups, or with individuals from groups that have high and low STI/HIV prevalences, respectively.[108] Transmission in some networks could be accelerated when such bridging occurs within concurrent sex partnerships.

Partnership level analysis can also expand the concept of risk for researchers who focus on individual level analysis in assessing associations between behavior and disease. The individual's risk of acquiring an STI stemming from his or her concurrency resides not only in the individual's own behavior via increased exposure to additional sexual partners over a short period but also particularly in the individual's partner's practice of concurrency. These partners may reside in high STI/HIV prevalence sexual networks thereby drawing an individual unknowingly into further exposure,[54] Risk varies both across partnership types and within partnerships over time; however, the associations between such variation and STI/HIV acquisition have not yet been well defined. To improve the understanding of transmission dynamics driving STI/HIV epidemics, there is a need to move beyond reports of sexual behaviors to include the measures of partnership dynamics cited in Fig. 8-1 such as level of communication, intimacy, and power dynamics as well as concurrency and condom use. To further the understanding of behavioral epidemiology on STI/HIV, we need a better understanding of how partnerships vary within sexual networks, how risk behaviors vary within partnership types, and how the intersection of risky partnership types and sexual networks is associated with disease transmission.

9 Psychological Perspectives on Sexuality and Sexually Transmissible Diseases and HIV Infection

Michael W. Ross

INTRODUCTION

Psychological variables are closely associated with sexually transmissible infections (STIs) in both immediate (social psychology of situational pressures to engage in sex, which may lead to higher risk of infection) and more distant (personality styles or attitudes to sex and sexuality, which may put an individual at greater risk of STI) senses. Psychological aspects of sexuality may affect both risk of STI (precursors of STI risk) and presentation for, and response to, treatment (consequences of STI). Maladaptive or psychopathological responses to infection (or fear of infection) may also occur. However, psychological precursors to STI risk largely operate where power over sexual behavior resides in the individual and not the situation.[1,2] Where the individual is largely powerless to avoid sex or unsafe sex, or would be at risk of consequent violence or discrimination (as in younger age, female gender, sex workers, or other dependent positions), psychological *determinants* of STI risk behaviors (although not psychological *consequences* of STIs and risk behaviors, which may even be exacerbated by powerlessness) may be of minimal importance.

PSYCHOLOGICAL THEORIES OF HUMAN SEXUALITY

Sexual behavior is considered an inborn drive in humans: even infants show signs of sexual behavior. Sex drive may be markedly modified by cultural, social, and interpersonal factors. Freud termed the energy of sex the libido, and believed that along with hostility and aggression it accounted for most of the motivation behind human behavior. Freud postulated that the individual was born potentially able to respond to any individual sexually but that socialization through a series of stages directed the sexual urge toward heterosexual contact. Freud's stages included the oral stage, the anal stage, the genital stage, the latency stage, and the reawakening of sexual impulses at puberty. Major studies of children's sexual thinking[3] show that sexual understanding follows three Piagetian stages of nonsexual, transitional sexual, and fully sexual stages of cognition rather than Freud's psychoanalytic stages, and these depend strongly upon the cultural and educational information on sexuality available to children and adolescents.

There is general agreement that a fundamental propensity to act sexually exists but that it may be modified by learning. Ford and Beach[4] note that cultural conditioning accounts for the extent and type of sexual expression but falls short of accounting for what is biologically possible in humans. The psychological process of moulding sexual expression is through conditioning. Modeling, in which individuals learn roles or behaviors through observing the behavior of others, is also involved.[5] Nevertheless, little is understood about the specific development of heterosexual or homosexual behavior, which probably results from the interaction of biological and social factors. Sexuality has a number of different aspects and meanings depending on variation in person, time, culture, age, and situation. Ross[6] has noted that multiple meanings of sexual expression are learned. These multiple meanings of sexual behavior can include, in addition to reproduction, the symbolism of union, religious meanings, love, release of sexual urges, pleasure, meeting survival or financial needs, as ritual, as experimentation, dominance or ownership, developmental or normative in a particular peer group, dynastic, in the context of mentoring, or the excitement of the forbidden. Some of these meanings may have significance in particular cultural or historical contexts, not necessarily in Western or twenty first century situations. Sexuality is not a unitary phenomenon but part of social interaction and best explained by opportunity and contingencies of reinforcement acting upon a basic biological drive. For people in all cultures, sex is multidetermined but most commonly associated with seeking comfort, finding pleasure, and survival.[7] Racial, ethnic, and cultural groups may be differentiated by a wide range of social, psychological, and demographic factors that influence both STI transmission and reaction to STIs, and it is important to specifically distinguish these rather than to assume that they are "cultural" just because they covary with particular racial or ethnic identities.[8]

PSYCHOLOGICAL VARIABLES ASSOCIATED WITH RISK OF STI

The psychological variables associated with increased risk of contracting STIs include those associated with behaviors that carry an increased risk of infection. In addition to specific behaviors such as high partner numbers, specific sexual practices (including condom use), and the context in which the sex occurs, I generally review the variables that have been associated with STI. Where psychosocial factors are associated with risk of STI, this provides a possibility of modifying such factors to decrease the probability of infection as well as to develop information on which intervention strategies may be based. Psychosocial factors may vary across phases of development and be profoundly influenced by experiences in childhood and adolescence.

DEVELOPMENTAL ASPECTS OF HIV RISK

IMPACT OF SEXUAL ABUSE

In a cross-sectional study of adult African American women, adult rape survivors were 6 times more likely to have reported >10 partners, 3 times more likely to report not using condoms, and 3.3 times more likely to report not using condoms consistently, in the past 3 months.[9] In Australia, Pitzner et al.[10] using STD clinic attendees and a matched (age, gender) community sample reported that abuse was significantly more prevalent in the STD sample, with the effects being stronger in females than males. In a large psychiatric treatment sample in the United States, Brown et al.[11] indicated that abused versus nonabused adolescents were significantly more likely to report higher rates of STIs: also associated with abuse were less condom self-efficacy, less condom use, and less impulse control. In the UK, Petrak et al.[12], studying female STD clinic attendees, found that 26% of women reported sexual childhood abuse, with similar overlapping proportions reporting emotional and physical childhood abuse. Abuse was very significantly associated with multiple previous STIs. While confidence in using condoms with a partner was not associated with a history of abuse, anticipating negative reactions from partners to suggested condom use was. In a sample of native American women, child physical/emotional abuse was associated with a five times greater risk of having had an STI than found in nonabused women. This risk was higher than the risk for a history of sexual abuse.[13] Minority (Mexican- and African American) women with a laboratory-diagnosed STI who reported a history of abuse (sexual, physical, and psychological) were found to report a larger number of measures of psychological distress than a nonabused comparison group.[14] Champion et al.[14] also noted that for a majority this abuse was experienced from a boyfriend or friend/acquaintance, and that in this population an STI diagnosis mandates the inclusion of violence histories in STI treatment and its inclusion in prevention campaigns. In a population of child and adolescent (aged <16) survivors of sexual assaults/rapes in the UK, Kawsar et al.[15] found an STI prevalence of 26%, while one-third gave a history of previous sexual or other abuse. Over 80% gave a history of current psychological problems with a wide range of multiple mental health and social difficulties. Bartholow et al.[16] in a study of over a thousand adult homosexual/bisexual men attending an STD clinic, found that a history of being sexually abused was associated with STI and HIV risk behaviors. Sexual abuse was also found to be associated with mental health problems, psychoactive substance use, and injecting drug use, suggesting that abuse may produce mental health problems which may in turn lead to drug and STI risk behaviors. The data on history of sexual and other abuse in childhood are consistent in predicting later risk for both STI/HIV risk behaviors and mental health problems. Similarly, recent sexual abuse is associated with more immediate risk of STIs and with multiple mental health problems.

ADOLESCENCEZ AND PSYCHOLOGICAL ASPECTS OF STI

Adolescence is a time of discovery of sexuality and often sexual experimentation. Rosenthal et al.[17] looked at coping strategies in adolescent girls but found no differences in coping strategies between those who had had an STI and those who had not (wishful thinking was used by most of the subjects). Subsequently, Rosenthal et al.[18] and Baker and Rosenthal[19] reported that older females were more likely to report STIs, lifetime partner numbers, and less negative feelings about STI acquisition (with feelings of control over fate being associated with level of development and cultural norms). Problem solving was used less often, and self-blame more often, for STI acquisition in girls when compared with a recent interpersonal stressor.[20] In a longitudinal study of predictors of STI/HIV-related sexual-risk behavior in African American adolescent females, DiClemente et al.[21] found that those with psychological distress at baseline were more likely to perceive barriers to condom use, to be fearful of negative consequences of condom use, to have experienced dating violence, and feel less efficacy in condom negotiation with a new partner. These data suggest that even moderate emotional distress in adolescent African American females may be predictive of STI risk and that clinicians should be vigilant for this. In a study of minority females,[22] symptoms of depression, conduct problems, and substance use were associated with younger teens' STI-related risk behaviors, and negative emotional reactions to intercourse (discomfort, feeling bad about or angry after sex) were also associated with STI in young adults. Taken together, these data suggest that lack of control and negative experiences surrounding sex in adolescents and young adults may be associated with lessened power to negotiate sex or safer sex.

PERSONALITY AND ATTITUDINAL VARIABLES

Hart[23] has argued not only that there is increasing recognition of venereal disease as a behavioral disease, but that psychological variables implicated in venereal disease may be primarily related to the personality of the individual. He reported for his heterosexual sample that an increase in extroversion, and to a lesser extent neuroticism as measured by the Eysenck Personality Inventory,[24] were associated with increased STI. Similar findings are reported by other researchers: Eysenck found that extroverts will have intercourse earlier, more frequently, with more different partners and in more different positions than introverts: they will also engage in more varied sexual behavior outside intercourse and engage in longer foreplay.[25] Measuring attitudes on Eysenck's Sexual Attitudes Inventory (ESAI), Fulford et al.[26] found STD clinic subjects to be less interested than Eysenck's controls in physical sex and pornography, to have less sexual excitement, greater prudishness, sexual disgust, and neurotic sexual attitudes; homosexual patients did not differ from heterosexual patients in these respects, and bisexual patients accounted for most of the differences which were found. Familial variables have also been implicated: Hart[27] has reported soldiers coming from large (four or more children) families as significantly more at risk for STI, and Ross[28,29] reported that the extremes of rejecting and overly supportive parental relationships were among the significant predictors of multiple STI infections in the four western countries he studied.

Personality and attitudinal variables may be associated with increased risk of STI in men. Ross[30] found that beliefs about the meaning of sexuality and its social and political implications predicted sexual behaviors in Swedish homosexual men. Eysenck[25] found that high psychoticism scorers (those who tend to be isolated, affectless, and aggressive) were also more sexually curious, more accepting of premarital sex, more promiscuous, and more hostile. Extroverts scored as more promiscuous and less sexually nervous, while high scorers on the neuroticism scale had significantly lower scores on sexual satisfaction and significantly higher scores on excitement, nervousness, sexual hostility, sexual guilt, and sexual inhibition. High neuroticism scores are also closely associated with "venereoneurosis."[23]

Fulford et al.[26] used the ESAI and found that neuroticism correlated positively with syphilis and gonorrhea infections, and extroversion correlated negatively with the diagnosis of syphilis. Ross[30] refactored the ESAI after rewording it to make it appropriate for homosexual men and derived nine interpretable dimensions. He found that, as anticipated, sexual attitudes did underlie sexual behaviors. In fact, six of the nine scales were predictors of partner numbers, five were predictors of particular sexual practices, and six were predictors of places of partner contact. All of these scales were related in a curvilinear rather than a linear fashion to partner numbers, with those with zero and high partner numbers having greater sexual prudishness, fear of sexual relationships and lower interest in pornography, degree of sexual excitability, and sexual permissiveness. Those with higher partner numbers were highest on the scale measuring lack of control of libido.

Sensation seeking has more recently been implicated in STI including HIV-related risk behaviors. Kalichman et al.[31] found that it predicted HIV-risk behavior in homosexual men, and even with substance use controlled for, sexual adventurism and sensation seeking were major predictors of unsafe sexual behavior. This has also been confirmed in heterosexual men: Bogaert and Fisher[32] were able to predict a significant proportion of the variance of partner numbers using sensation-seeking measures. It appears that there is a constellation of disinhibition, including Eysenck's psychoticism and extroversion, and sensation seeking, significantly related both to safety and to partner numbers. Kalichman et al.[33] reported that sensation-seeking was related to engaging in unprotected sex with casual partners, and that it was also associated with expectancies that alcohol would enhance sex. Subsequently, in a prospective cohort of STD clinic attendees, Kalichman and Cain[34] showed that sensation-seeking predicted unprotected intercourse 6 months later, as well as alcohol use in sexual contexts, which in turn also predicted unprotected sex.

ROMANTIC LOVE AND STD ACQUISITION

The association between romantic love, conceptualized as a possibly biologically programmed urge to fall in love, that intellectually blinds the individual, and STD acquisition, is reviewed by Goldmeier and Richardson.[35] They see romantic love as akin to an obsessional condition in which euphoric mental states override the rational aspects of a decision to have sex or safer sex. Goldmeier and Richardson note research[36] shows that people "in love" differed from controls in having reduced serotonin transporter sites (measured in platelets, and perhaps reflecting a putative "altered serotonergic tone,") and that being "in love" is associated with raised cortisol levels until the initial throes of love dissipate in 12–24 months. They argue that these data support the contention that romantic love produces a "deterministic and nonlogical response to have sex and thus acquire an STI" and that biological states produced by being "in love" may drive some STI-related risk behaviors.

PSYCHOSOCIAL VARIABLES

The environmental stresses of war and immigration produce behavior patterns, which many would not otherwise experience.[23,37] During the 1960s in the UK, half of the men with gonorrhea were immigrants. Single migrants may have numerous sexual encounters until they settle into their new cultural backgrounds.[38] This holds for nonwestern societies:

Hart[39] reported that in single laborers and married immigrants in Papua New Guinea, recourse to prostitutes and, to a lesser extent, homosexual behavior, are more common outlets and venereal disease a prominent sequel. STI incidence rates in immigrants and soldiers are increased markedly (in comparison to baseline rates before immigration or war) and instability and insecurity are associated with lack of discrimination and increase in frequency of sexual contacts. Kelus[40] took random samples of STD clinic attenders and inhabitants in a Polish town and found no differences between inhabitants and patients apart from a tendency for patients to be more urbanized and less religious. However, Hooker[41] has suggested that for some, the seeking of sexual contacts is an activity that is isolated from all other aspects of their lives. We cannot assume that psychological factors that influence sexual contacts will be obvious in other areas of the individual's life.

PSYCHOLOGICAL CONCOMITANTS OF PARTNER NUMBERS

Partner numbers are an important determinant of STI, as they can increase (depending on STI prevalence) the probability of infection. If sexual practices that do not transfer body fluids are utilized, partner numbers are immaterial, and if all partners are mutually monogamous and uninfected, there is no risk. Ross[42] found that partner numbers were not invariably associated with risk of STI in homosexual men. Schofield[43] reports that there is little if any evidence that individuals with high partner numbers have personality defects, are emotionally damaged, or come from a less than adequate social milieu. Goode and Troiden[44] found that homosexual men with higher partner numbers tended to prefer emotionally superficial sex and were less well educated. Partner numbers can be depressed during dysphoric mood states (confusion, fatigue, and distress).[30] High partner numbers may also protect from psychological decompensation through their effect on increasing self-esteem. It was reported that depression increased in homosexual men who reduced their risk of contracting HIV,[45] which suggests that there is some association between mood and partner numbers. Beck et al.[46] found that clinical measures of depression were associated with STI-related risk behavior, and depression was itself associated with perceptions of the uncontrollability of risk and perceived lack of control over sexual practices and fidelity.

Bogaert and Fisher[32] found that number of sexual partners of heterosexual men were best predicted by hypermasculinity and sensation-seeking. A personality construct they labeled "disinhibition" (sensation-seeking, hypermasculinity, Eysenck's psychoticism,[25] and erotophilia) accounted for a substantial proportion of variance in partner numbers. In one cross-cultural study, the homosexual male with high partner numbers sees himself as conventionally masculine, prefers a more feminine partner, and has high alcohol consumption. He may have had a more negative parental rearing pattern and be under less stress than men with low partner numbers, be more involved in the homosexual subculture, see his homosexuality as more central to his lifestyle, and have had more STIs.[30] These data illustrate the multifactorial nature of the variables associated with high partner numbers in white, western cultures.

PSYCHOLOGICAL CONCOMITANTS OF PARTICULAR SEXUAL PRACTICES

Practices that involve the transmission of body fluids, including unprotected anal or vaginal intercourse, brachioproctic ("fist fornication") activities, and fellatio may transmit pathogens; mutual masturbation and frottage (rubbing bodies together) will not. Haist and Hewitt[47] noted that homosexual men who preferred the anal insertee role also tended to prefer the oral insertee role in fellatio. However, Hooker[48] reported no relationship between sexual activity preferences and sex role. Preference for inserter and insertee roles in both fellatio and anal intercourse in homosexual men appeared to be strongly related to conventional masculine and feminine sex roles, and activities such as full-body contact and mutual masturbation appear to be nonsex role related.[30] These last two activities appear to occur when there is emphasis on emotional as well as physical closeness and they are associated with decreased frequencies of STI. Ross's data also suggest that sexual socialization into homosexual subcultures and, to a lesser extent, parental and peer models, have a major influence on the type of sexual activities undertaken: increased time and degree of socialization into the homosexual subculture increase preference for specific roles, as does degree of organization of the homosexual subculture within which that socialization occurs. Preference for particular practices does appear to be a function of increasing sexual experience, although the influence of masculine and feminine sex roles is significant. Acculturation to the norms of a subculture, depending on whether they support or reduce safer sex, also influences risk of STD/HIV acquisition.[49] Safe (or safer) sex involves protection by use of male or female condoms. Psychological characteristics associated with use of condoms have included more assertive personality styles and lower depression and dysphoric mood in both cross-sectional and longitudinal studies.[50,51]

PSYCHOLOGICAL CONCOMITANTS OF PARTNER ANONYMITY AND PLACES OF SEXUAL CONTACT

Partner anonymity and place of sexual contact play an important part in STI; the links are threefold. First, the possibility of partner notification of anonymous partners is virtually impossible. Second, in some places of anonymous contact such as gay

bathhouses, there are opportunities for multiple contacts with multiple partners within a short time span. Third, such places may generate their own demands, which may lead to person–situation interactions in which the effect of being in the situation is significant. However, different motives and interests may attract people to similar physical contexts. The now-classic study of Humphreys[52] classified men using public toilets as places for sexual gratification into four groups: "trade," ambisexuals, gays, and closet queens. Humphreys' "trade" group comprised working-class married men. Two-thirds took an inserter role in fellatio in sexual encounters. Ambisexuals were married men with high income: two-thirds of this group were insertees in fellatio and saw themselves as bisexual. The gay group was individuals who were unmarried, had no preference for sexual roles, and who had independent occupations, while the "closet queens" were also unmarried but in lower middle class occupations in which they were dependent on others for employment, and they avoided the homosexual subculture. They preferred to play the inserter role, at least until they lost their attractiveness.

Ross[30] noted few differences between those preferring particular places of meeting sexual partners. Those meeting partners through cruising reported more positive mood states and higher self-esteem than others, and were markedly different from those who frequented bathhouses, who appear to be more depressed and avoided close emotional contacts. It appears that psychological variables, particularly mood states, are strongly associated with the drive for partners and the context in which they are sought, with a relationship between mood and partner-seeking.

PSYCHOLOGICAL CONCOMITANTS OF STD PREVENTION BEHAVIORS

The psychological aspects of response to STI/HIV prevention activities are important in preventing infection. Following indications from national campaigns in which fear was the central principal in HIV prevention[53–55] there has been considerable focus on what constitutes an effective message. In a comprehensive theoretical review, Ruiter et al.[56] noted that implicit assumptions that prevention will be activated or enhanced by fear arousal are not necessarily supported by the scientific literature. Fear may simply increase denial, and while threat perception may be inherent to fear arousal, they are not necessarily linked. Fear appeals, Ruiter et al. show, provide two types of information: first, fear is aroused by presenting a threat (STI or HIV infection); second, a search for safe conditions is prompted by recommending protective action (e.g., condom use). Ruiter et al. indicate the data suggest that people with low self-esteem seem primarily concerned with fear control and turn to danger control only when fear has been reduced. Those with high self-esteem are more likely to act directly on controlling the threat through preventive action. Moderately fearful individuals are only likely to process information about a recommended response if they expect the information to reassure them.

Using multiracial female samples of both STD clinic and community samples, Nyamathi et al.[57] examined the predictive value of recent STI and return for test results. Emotion-based (as opposed to problem-based) coping strategies were associated with increased STI risk and were in turn predicted by lower self-esteem and more perceived social support. They report that emotion-based coping strategies were more common in their sample of African American women than in homeless Latina women. Osbornet al.[58] noted that patients rated by staff as more psychologically disturbed were more likely to return for follow-up, and Pitts et al.[59] monitored STD patients in Australia and found that 19% returned within 2 years with a new infection; however, reattenders did not differ significantly from the remainder of the cohort on demographic, sexual, or psychological variables.

Several studies have noted psychological variables associated with condom use. Personality variables associated with increased condom use in homosexual men include increased scores on the dominance and aggression scales of the adjective check list and decreased scores on the abasement and deference scales.[50] Longitudinally, mood states as measured by the Profile of Mood States that were associated with a move to safer sex included lower depression, anger and hostility, fatigue, confusion, and total dysphoric mood scores[51]. These data suggest that assertiveness and lack of dysphoric mood are both associated with increased condom use. In a comparative study of heterosexual and homosexual men, Treffke et al.[60] found that attitudes toward condoms were strongly associated with both general assertiveness and condom assertiveness in heterosexual men, but that there was no such association in homosexual men. Data on psychological concomitants of condom use may not generalize across sexual orientation, and probably not across gender.

THE PSYCHOLOGY OF STI

The second area of importance in considering psychological aspects of STIs is the psychological aspects of infection as such, such as reactions and abnormal behavior in those infected. This section considers the presentation and management of the psychosocial manifestations and psychopathology of STIs. Psychological sequelae of STI exposure are poorly understood, frequently unrecognized, and inadequately managed despite being among the most common conditions encountered in STD practice.[23] Psychological and psychiatric problems in STD practice may be divided into three categories: the normal range of psychological reactions to STIs; abnormal reactions to STI (or to believe one is infected); and sexual dysfunctions which may become apparent in the course of consultation or present initially to STD clinics.

PSYCHOSOCIAL RESPONSES TO STD INFECTION

Over 40% of patients attending public STD clinics have been classified as having psychiatric problems on the basis of screening tests.[61] A subsequent study noted that the anxiety caused by the presenting problem was probably the cause of such a high figure, since less than 5% had a sufficiently abnormal level of distress to justify calling it psychopathological.[62] Another study reported that less than 5% of STD patients required psychiatric referral,[63] although Barczak et al.[64] reported that 31% had anxiety and depression not affected by the physical symptoms of STIs, and that these were significantly more prevalent in females. Significant life events in the past 6 months were related to presence of physical symptoms, and in the absence of major life events in this time frame, a psychiatric diagnosis was more likely (this relationship may be related to increase in sexual activity following traumatic life events). Osborn et al.[58] studied over 900 STD clinic patients on the Hospital Anxiety and Depression Scale and reported that 51% scored above normal threshold, whereas clinic staff rated 20% of the patients as "having psychological problems." These latter patients were 1.9 times more likely to attend for follow-up. It is therefore important to differentiate the normal range of reactions to STI from psychopathological ones.

Ross[30] has postulated a model of the meaning of STIs to the individual, which explains the beliefs underlying psychological reactions to STIs and the reasons for psychopathology when it occurs. In discussing the meaning of STDs to the individual, there are at least four separate attributions as follows:

1. STIs are a deserved outcome of indiscriminate sexual behavior and punishment for sexual sins.
2. STIs are a consequence of individual inadequacy that leads to sexually indiscriminate behavior.
3. STIs are a consequence of a breakdown in traditional social values and rapid social change.
4. STIs are solely the result of an individual coming into intimate contact with a virulent pathogen and no blame attaches to this.

There is a hierarchy of decreasing blame from attributions 1 to 4, based on the degree to which individuals see themselves responsible for the infection. The degree to which there is a psychological investment in sexual behavior is also important. The meaning of STIs to the patient and to a lesser degree to the attending health professional will affect not only the compliance with treatment but also the psychological sequelae and the subsequent risks of exposure to STIs.

A qualitative study of the experiences of STD clinic attenders who received an STI diagnosis[65] Holgate and Longman, reported that some experienced feelings of anxiety, stigma, and isolation. Providers should ascertain their own positions and make some estimate of the position of their patients before seeking to educate or to modify risky behaviors.

Reactions to STI may arise from any of the four attributions toward STIs noted above, and vary by culture, degree of control, and gender. In Zimbabwe, Pitts et al.[66] Studied psychosocial and gender issues related to multiple STIs within the context of marriage, through in-depth interviews with 60 men and women attending an STD clinic. Major differences between men and women were found, with gender differences in reactions to various STIs (men can discuss it with friends, while women are shamed and isolated by it). Male STI-related risk behaviors may often be seen as a culturally-sanctioned norm toward male promiscuity. Womens' lack of power to negotiate safe sex within marriage, and lack of social support networks for infected women were consistently found.

Reactions to STIs may be further classified into *abnormal illness behavior and venereoneuroses*. Psychotic reactions that are either triggered by STI or have major venereological components are recognizable by such classic psychotic features as delusional thought patterns and the inability of patients to be convinced by rational discussion. Such patients with psychotic reactions will generally also have a history of psychotic illness.

ABNORMAL ILLNESS BEHAVIOR

Abnormal illness behavior has important implications for treatment. In the case of individuals with an erroneous conviction that they have an STI, there is abnormal illness behavior in terms of both general hypochondriasis and a strong disease conviction without demonstrable pathology. There may also be an indication that patients believe they "deserve" the infection, as noted above. Perhaps more common is the refusal to see STI as an illness but perhaps only as a minor nonsignificant risk of a particular lifestyle. In the case of the absence of any illness behavior, patients may frequently compromise treatment by discontinuing medication after symptoms have resolved, continuing sexual activity after symptom resolution but before clearance, or not returning for proof of cure. Thus, both extreme illness behavior and lack of illness behavior can be abnormal and may have implications for the management of STIs.

Ross[67] found that it was the repeated STD clinic attenders rather than the first attenders who displayed the greatest anxiety and hypochondriasis over STI. Those with higher previous numbers of infections also more often tended to deny life

The interaction between patients and physicians who hold conflicting attributions for STIs may lead to tension, anger, transference and countertransference issues, and resistance to taking advice, treatment or prevention, particularly where more divergent attributions are held.

stresses and attribute their problems solely to the episode of illness. Such individuals also displayed significantly higher disease conviction and symptom preoccupation and higher levels of symptom exaggeration. In comparison, first attenders more often tended to deny that an STI was an illness (denial of acquisition of a stigmatizing illness). Compared to other illnesses, in which there may be substantial secondary gain through sympathy, illness behavior would appear to differ for STIs and to develop as a function of repeated infections. STI tends to be seen as a chance event until after several infections when it becomes perceived not only as an illness but also as a result of particular behaviors. Ross also found that there were few differences between heterosexual and homosexual men in illness behavior with STIs, apart from the fact that there is a less negative reaction to STI among gay men. The STD clinic population was closer in illness behavior scores to a psychiatric outpatient population than to a general practice population. It is unclear whether the disturbance was a function of having a stigmatized illness such as an STI or inherent in STD clinic attenders.

Ross[68] also found that acknowledgment of homosexuality in STD clinics varied significantly between countries (20–52% of homosexually active men did not acknowledge being homosexual) although not between private and public clinics. The variables predictive of whether the respondent reveals his homosexual orientation when presenting to an STD clinic or medical practitioner are coherent. Nonrevealers are likely to conceal their homosexuality from most people, to expect the most negative social reaction to their homosexuality from significant others and society in general, and to believe in much more rigid and conservative sex roles for men and women. Compared with those who reveal homosexual contact, nonrevealers are more likely to report themselves as being more bisexual than exclusively homosexual, to have had no previous STI, and to have had poor relationships with their mother during adolescence. They are also more likely to be unassertive.

The lack of previous STIs in nonrevealers suggests that the clinic situation will be a new and potentially frightening one in which condemnation is expected: in subsequent visits to a clinic, the patient will tend to be more open if the clinician's approach has been nonjudgmental. When clinicians take histories in a manner that implies that any sexual contact was a heterosexual one, the patient may not have the courage to make a correction. These data do suggest that there are significant and consistent psychological factors operating to prevent some homosexual men from revealing same-sex contacts in the context of STD clinics. However, these psychological factors will clearly operate in interaction with environmental factors such as the clinic, the clinician, the stigma, and the legal and social climate regarding homosexuality. The imposition of shame and guilt upon sexual interactions by religious and other traditional moralities is the single most important cause of stigma and consequent psychological problems in STI treatment, and if the physician is able to assess and deal with this early in the treatment process, many difficulties may be prevented or minimized. To fail to do so may even introduce or reinforce shame or guilt and produce an iatrogenically strengthened psychopathology. A high index of suspicion for psychosocial problems attendant on having an STI or reported exposure to STI is mandatory to ensure maximal compliance with treatment, partner notification, and preventive education, and the possible contribution of psychosocial factors to relapse or reinfection should not be underestimated.

COMMON RESPONSES TO STIS

There is a large literature on the response to genital herpes infection, reviewed by Longo and Koehn.[69] They note that much of the research on the impact of genital herpes is neither longitudinal in comparing with the premorbid psychological state, nor comparative with other curable STIs. Nevertheless, some elements of response are common across studies. For people who have had genital herpes for less than a year, negative life events, depression, anxiety, anger, and social alienation predict herpes simplex virus (HSV) recurrences; after a year, high levels of depression and low self-esteem are consistently associated with more frequent HSV recurrences. It is important to note that *responses* to infection may lead to these states, thus setting up a cycle of response and recurrence. Stronks et al.[70] compared people with genital herpes both to a control group with gonorrhea and to their reported premorbid adjustment, and found that while there was no difference in outcome for those with HSV or gonorrhea, both had significantly increased anxiety, sexual inhibition, bitterness toward sexual partners, and increased psychological complaints compared to a control group with no STI. There was a significant interaction between premorbid state and morbid change, however, with the HSV group increasing markedly in psychological complaints and the gonorrhea group increasing minimally. Carney et al.,[71] in a longitudinal study, found that the first episode of genital herpes had a substantially negative psychological impact, with over 60% meeting screening criteria for being a psychiatric case as measured by the General Health Questionnaire. However, two-thirds of these became noncases if there were no recurrences of disease: if there were recurrences, the level of psychiatric case classification stayed high. A clinical study[72] found that the majority of people with genital HSV report that infection made them less capable of physical warmth and intimacy, enjoy sex less, and feel less sexually desirable. This extended outside sexual contacts: all reported that work performance was also hampered. A majority reported disturbance of affect, feeling that genital HSV is incompatible with happiness, and feeling pessimistic about the future course of the illness. Depression was also reported by 84%. Sexual dysfunctions including reduced interest, reduced ability to

achieve orgasm, avoidance of intimacy, and reduced enjoyment of sex, as well as feeling repugnant to others (over 30% of Americans said they would not associate with someone who has genital HSV[73]) were reported. Mindel[74] notes that emotional problems in genital herpes patients are worse for patients with first episodes of genital herpes than for other STD clinic attenders, and likely to be more severe in females than males. Mindel also indicates that cognitive coping strategies and social support from a partner appear to be positive predictors of adjustment.

In a longitudinal study of people with no known history of genital herpes, Rosenthal et al.[75] (2005) note that cross-sectional studies suggest that there is transient distress, concerns about relationship implications, and fear of transmitting the virus but no substantial, negative psychological reaction to HSV-2 infection. Their study compared those diagnosed with HSV-2 with matched controls found to be uninfected; reevaluation using a genital herpes quality of life measure 3 months after diagnosis found that the infected reported intrusive emotional thoughts about herpes and concern about infecting others, but little lasting psychological distress. Significant predictors of distress on infection were greater baseline interpersonal sensitivity, lower social support, and lower perceived quality of sex. These data suggest that the pain and discomfort of the disease itself may be one of the most important aspects of psychological sequelae of HSV-2, and that premorbid functioning is one of the best predictors of poorer psychological outcome. These findings emphasize the importance of anticipating and addressing concerns of newly diagnosed patients, and particularly anticipating problems in those whose feelings are easily hurt. In clinical practice, brief probing as to how a patient might react to a positive diagnosis may usefully anticipate subsequent psychological problems when the patient is given a positive diagnosis. The interaction between pain and discomfort and psychological sequelae underscores the interactions between physical and psychological aspects of STIs.

VENEREONEUROSES

Venereoneuroses may be divided into those neuroses that manifest with exposure to infection and include overreaction to infection, and venereophobias and abnormal disease convictions, as well as factitious STIs and AIDS.

Venereal overreaction and hypochondriasis

Hart[23] notes that individuals may be abnormally preoccupied with bodily processes, manifesting as a genitally-focused hypochondriasis. Irrational concern is focused on urethral, anal, or vaginal discharge or the appearance and sensations of the genitalia. There may be an obsessional element to these, or compulsive genital examination that may itself cause irritation or discharge. Acceptance of these symptoms (or the patient's description of these symptoms) without objective evidence of infection or relapse may promote venereoneurosis and aggravation of the neurotic tendencies of the patient. Hart[23] has also reported that penile manipulation to produce discharge (often including their vigorous squeezing of the glans and shaft, in contrast to the more usual cautious manipulation) is a feature of some patients. In other manifestations, abnormal attention may be payed to irregularities in pigmentation or skin surface, skin tags, sebaceous cysts and hair follicles, and pearly penile papules. Demands for treatment, in the absence of demonstrable infection or pathology, are one indication of the presence of venereoneurosis, and Hart believes that such patients tend to be more severely disturbed.

Miller et al.[76] have reported that in the case of HIV infection, individuals will focus on the nonspecific nature of the symptoms of HIV infection, and attend for minor changes in skin pigmentation which they believe is Kaposi's sarcoma, or for minor changes in respiratory function which they believe is indicative of an opportunistic pulmonary infection. In some cases, obsessional palpation of cervical and axillary lymph nodes will lead to local irritation that may be interpreted as lymphadenopathy. Management involves discussing the patient's specific anxieties, and an opportunity to talk about these may in itself provide considerable relief. In the case of concern over AIDS in those who have been infected with HIV, it is important to focus on the patient's specific concerns, including fear of exposure, stigmatization, pain, death, and the uncertainty associated with the diagnosis of HIV infection and likelihood of progression.

Venereophobias

Venereophobias have been recognized for most of this century, with syphilophobia as the earliest manifestation reported.[77] At present, AIDS phobias are more commonly reported,[78] probably because of the increase in publicity surrounding AIDS and the mortality and morbidity associated with it. In syphilo- and AIDS-phobias, individuals at no or low risk of contracting the disease believe that they are infected. While more accurately described as an abnormal disease conviction than a phobia, in some cases there will also be irrational precautions to avoid catching AIDS and fear or avoidance of situations in which there is a perceived risk of catching AIDS. AIDS phobic patients differ from venereoneurotics in that symptoms are not usually genitally focused and often cannot be traced to a specific sexual episode. Ross[78] has also reported that underlying conflicts and life stresses are likely to be major contributors, and that such presentations are usually associated with guilt over sexual behavior (commonly bisexual or homosexual contact or sexual activity outside a primary relationship). The trigger is usually life stresses, often relationship-related, or media publicity on AIDS. The belief in infection may sometimes be near delusional in quality, with patients refusing to believe the results of HIV tests or

going from clinic to clinic in search of a test result that confirms their worst fears.

Management of venereophobias must encompass more than just reassurance of noninfection, which the patient may interpret as not being taken seriously. Excessive physical intervention, beyond that necessary to exclude disease, reinforces the patient's belief in the existence of disease. Taking a brief sexual history, history of current concerns and stresses, and recent conflicts will frequently bring out the underlying issues of guilt or concern over moral self-image or sexual orientation. Brief interpretive counseling focusing on the conflicts underlying the phobia and on the stresses which promote such conflicts, with emphasis on giving the patient a degree of insight into the processes leading them to present with an abnormal disease conviction, will often resolve the problem. However, referral to appropriate mental health professionals should be considered and not delayed if resolution does not occur.

Not all improbable cases will be evidence of psychopathology. Bodsworth et al.[79] examined the medical records of over 30 male and female virgins attending an STD clinic and reported that most attendances represented recognition of STD clinics as appropriate centers for a wide range of genital and sexual problems: only 10% presented with genital symptoms as part of a previously diagnosed psychosis.

Symptoms without objective signs or microbiological evidence of infection in many women presenting at gynecology or STD clinics, those with vaginal symptoms but no signs or microbiologic evidence of bacterial vaginosis or vaginal infection did not differ from women without symptoms or signs or from women with both symptoms and signs with respect to life stress, sex guilt, or global personality function. However, these symptomatic but otherwise normal women indicated significantly lower marital satisfaction and thought that their relationship was less sexually satisfying to their partner. McGuire et al.[80] suggested that preoccupation with vaginal symptomatology might reconcile for these women the difference between the objective and subjective evaluations of their sexual relationships.

Factitious illness

Several cases of factitious AIDS have been reported.[81–83] Individuals may present stating that they have been diagnosed as having AIDS at another center but findings on examination do not accord with this. Immediate professional consultation with the center of previous treatment usually confirms that the claim of illness is incorrect. Individuals confirmed to have factitious AIDS may be either seeking the secondary gain of sympathy and hospitalization, or seeking to come to terms with the death of a significant other from AIDS. In the few cases reported, individuals usually strongly deny the diagnosis of factitious illness ("Munchausen syndrome") and may present in the future with other factitious illnesses with substituted symptoms. Such individuals are frequently quite medically sophisticated and may present plausible histories. Referral for psychiatric assessment is strongly recommended in such cases.

ACQUIRED IMMUNE DEFICIENCY SYNDROME AND HIV INFECTION

Reactions to HIV infection may be more extreme than reactions to other STIs for four reasons. First, the fully developed disease is usually fatal, although HAART (highly active antiretroviral therapy), where available, has somewhat mitigated this concern, especially in more developed countries. Second, in western societies AIDS is commonly associated with stigmatized minority groups (homosexual and bisexual men, illicit injecting drug users, and prostitutes) and a substantial component of attitudes toward AIDS comprises stigmatization, antihomosexual and antiminority beliefs, and attribution of blame.[84] Third, such attitudes may be internalized in those infected and may lead to guilt and self-blame. Fourth, medical attendants may also contribute to stigmatization through overprecautions or avoidance of contact.[85] Consequently, the emotional impact on the patient of informing them they are infected with HIV is not significantly different from the news they have AIDS-related symptoms or full AIDS.[86]

Psychological complications of HIV infection may be exogenous or endogenous. Exogenous complications arise from the psychosocial stresses resulting from negative societal and interpersonal reactions to AIDS. Faulstich[87] notes that the "worried well" (whether infected or not) may exhibit generalized anxiety and panic attacks, along with excessive somatic preoccupation and fear of the disease. On diagnosis of HIV infection or AIDS, individuals may exhibit disbelief and denial, followed by depressive and anxiety symptoms. Emotional distress may commonly lead to adjustment disorders with depressed mood or major depression. Recurrent psychological themes include uncertainty about disease progression, social isolation (imposed or adopted), dealing with terminal illness, and guilt or blame over lifestyle. Suicidal ideation may be present. The advent of HAART may have lowered the intensity of the psychological impact of HIV infection in places where HAART is accessible, as can medical feedback about success or failure of treatment regimens.[88]

Endogenous complications result from the neuropsychiatric sequelae of HIV infection, either from the direct effect of HIV infection, on the central nervous system (CNS), opportunistic CNS infections, or CNS neoplasia. Up to half of patients with AIDS in the absence of HAART may present signs and symptoms of CNS infection, including subacute encephalitis characterized by malaise, social withdrawal, lethargy, and reduced sexual drive (these may also be signs and symptoms of depressed mood, or of systemic disease).

Subsequently, signs of progressive dementia may appear. Neuropsychiatric deficits resulting from HIV may typically involve impaired language, memory and integrative abilities, and occasionally depressed mood, and their insidious onset makes it important to maintain a high index of suspicion that psychological symptoms may indicate onset of CNS involvement. Although rarer, tertiary syphilis may also involve the CNS and include psychological symptoms.

The potential for depressive reactions, sexual acting out, and further discrimination and stigmatization and loss of social supports make informed consent and adequate pre- and post-HIV test counseling mandatory.[89] Where individuals are infected with HIV, frequent psychological support (or referral to appropriate agencies) and attention to patient's genuine fears of exposure, pain, discrimination, abandonment, and death is indicated, rather than general reassurance that may be interpreted as being dismissive. In cases of chronic depressed mood, pharmacotherapy or referral for psychotherapeutic treatment is indicated.

Longer-term psychological adjustment to HIV was studied in a longitudinal cohort of 38 gay men in psychotherapy over a decade.[90] They noted that HIV disease is like many other chronic and terminal illnesses in its emphasis on it being seen as an attack on the self, raising issues of time, and boundaries between chronic and terminal disease, illness and health, and hope and despair. While this study involved HIV in gay men, feelings of persecution, the dilemma of who to disclose to and possible consequent discrimination or rejection, issues of avoiding intimacy, multiple loss (especially in the pre-HAART era), and dilemmas about having sex and its associated risks of (re)infection, with both HIV and STIs may not be unique to this group. Nilsson Schönnesson and Ross[90] found that psychological adaptation occurs but as the disease enters each new phase (asymptomatic, mild symptomatic, severe, and terminal), psychologic symptoms reoccur. Mood states in the asymptomatic and mild symptomatic phase typically included anger, whereas disappointment, sense of violation, and feelings of aloneness characterized the terminal phase, with powerlessness and helplessness being expressed in all phases. They also report that a central psychological issue in HIV disease across time is existential: the need to provide a meaning for the infection. As Sontag[91] notes, "Nothing is more punitive than to give disease a meaning—that meaning being invariably a moralistic one."

PSYCHOSEXUAL PROBLEMS

Studies in Europe and India[61,92] and clinical experience in Africa have noted that sexual dysfunctions may present to STD clinics or be detected in STD clinics. In some countries, the clinical specialty of andrology serves men with STIs, psychosexual problems, as well as infertility and various urological disorders. Over 13% of STD clinic presentations are for sexual dysfunctions in India, compared with only 4% in psychiatric clinics. Of these, over 80% are males with concerns over the effect of masturbation, erectile dysfunction, and premature ejaculation. Generally, presenting dysfunctions in males will include premature ejaculation, retarded ejaculation, and erectile dysfunction ("impotence"); in females, anorgasmia and general dysfunction ("frigidity") and rarely, vaginismus (spasm of the muscles of the vaginal introitus preventing penetration). Psychosexual problems usually occur in STD patients secondary to pain from infection or trauma, or from fear of infection, reinfection, or of infecting others. Patients or clinicians also sometimes may ascribe sexual dysfunction to STI in the absence of objective evidence of STI, and some clinicians offer therapy for a nonexistent STI in an effort to relieve sexual dysfunction.

In the case of mild or transient dysfunctions, the STD clnician can provide reassurance that such transient dysfunctions are not unusual and are often limited to particular partners, situations, and times, and information or education to correct misapprehensions which affect sexual performance is appropriate. However, chronic psychosexual problems which are not a result of physical pathology warrant referral to sex therapists. It is not uncommon to detect psychosexual dysfunctions in the course of history taking or treatment, and for some individuals the STD clinic will be the first point of consultation for this problem. While the majority of sexual dysfunctions are probably mild and transient and may resolve with adequate information and encouragement, the major dysfunctions in males and females listed above require more specific therapy from specialists in psychosexual dysfunctions.

In summary, psychological variables may be determinants of STD infection, and psychological problems are commonly associated with acquisition of STDs. The physician should be aware of the range, nature, and presentations of these disorders that may adversely affect attendance, compliance, and treatment as well as the psychological state of the individual.

PART 3

Profiles of Vulnerable Populations

This page intentionally left blank

10 Gender and Sexually Transmitted Diseases

Anne Buvé, Catherine Gourbin, and Marie Laga

There are important differences in the way sexually transmitted infections (STIs) affect men and women. These differences are not only determined by biological factors ("sex"), such as susceptibility to infections and complications, but also by gender. "Gender" is a social construct distinct from the biological determinism implied by the word "sex" and refers to the socially and culturally prescribed roles of men and women.[1] Gender includes social status, responsibilities, and behavioral patterns of men and women. The different roles men and women have in society result in a hierarchy of positions occupied by men and women, and a power inequality that usually favors men.[2,3]

GENDER DIFFERENCES IN SEXUAL BEHAVIOR

Social norms determine the importance that is attached to virginity and fertility, and the relationships within which sexual intercourse is permitted. As such they determine, to a large extent, the sexual behavior of men and women. Social norms regarding sexuality evolve over time and there are large differences between different populations. But in many, if not most societies, norms regarding appropriate sexual behavior are different for men and women, usually being less restrictive for men than for women. Restrictive norms regarding women's sexuality not only limit women's sexual freedom but also restrict their access to information about sexuality and, as such, undermine their negotiation position in sexual relations. In addition, the power inequality between men and women extends into sexual relationships and lack of economic independence may prevent women from leaving a relationship that puts them at risk of acquiring an STI. In many settings, even in a stable union, wives have little control over marital sexuality, and women's ability to negotiate safer sexual practices, particularly condom use, is practically nil. The lack of control over their own sexuality makes women not only vulnerable to STIs and their complications, but also affects their health-seeking behavior for STIs.

SEXUAL DEBUT, MARRIAGE, AND EXTRAMARITAL RELATIONSHIPS

Sexual debut has always been considered an important step in a person's life, everywhere in the world. Circumstances of first sexual intercourse have a big influence on sexual behavior and sexual health later in life. Young age at first sexual intercourse has been found to be associated with higher number of lifetime sex partners, even when allowing for more years of sexual activity, and higher risk behavior later in life, especially in men.[4] In women, younger age at first sexual intercourse is often associated with younger age at marriage.[4] However, young women are also more often coerced into their first sexual experience than young men,[5] and coercion is associated with a younger age at sexual debut. In addition, forced first sexual intercourse is associated with a large age difference with the male partner, lower use of condom, or other contraceptives and higher risk of STIs.[5–8]

While traditionally first sexual intercourse, especially for women, is closely associated with marriage, in industrialized countries social norms regarding sexuality have relaxed in the latter half of the twentieth century and this has been accompanied by a decrease in age at first sexual intercourse, which was more marked in women than in men.[9] Nowadays there is only a small difference in age at first sex in the younger generation of men and women in most industrialized countries.[9] In contrast, in many developing countries there is a tendency for age at first sexual intercourse to decrease for men and to increase for women; e.g., in sub-Saharan Africa, men born in 1975 started their sexual activity roughly 1 year earlier than men born in 1950, while women born in 1975 had their first sexual intercourse about 0.5 years later than women born in 1950.[10,11] In both men and women age at first marriage is delayed.[10,11] In women, in all regions in the world, delay of marriage is associated with better education.[12] A delay of marriage can increase sexual activity and rate of sex partner change if the time period between first sexual intercourse and marriage is extended.

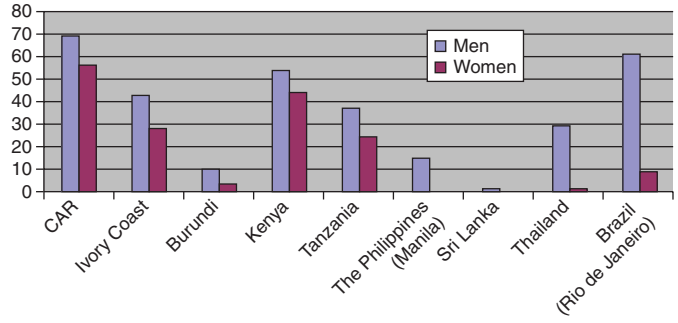

FIGURE 10-1. The proportion of never married men and women 15–19-years-old who reported sexual activity in the previous 12 months. (*Source:* Caraël M. Sexual behaviour. In Cleland J, Ferry B, eds. *Sexual Behaviour and AIDS in the Developing World.* London: Taylor & Francis on behalf of the World Health Organization, 1995: 80).

Premarital sexual activity of women varies from one population to another and is highly dependent on social norms regarding virginity, as is illustrated in (Fig. 10-1).[13] In most industrialized countries and in sub-Saharan Africa, a high proportion of never married young women are sexually active. Other societies maintain strict control over young women's sexual behavior. In these societies, women usually have their first sexual experience with their husband, while men, for whom norms are less strict, often have their first sexual experience with a commercial sex worker. For instance, in many European countries visiting a female sex worker used to be a common way for young men to initiate sexual activity, but since norms on sexuality have relaxed commercial sexual activity has become rather marginal in most European countries.[14] Whether or not women have sexual relations outside marriage has important implications for their exposure to STIs and for prevention interventions. For instance, in populations where the majority of women are only sexually active within a marital relationship, interventions aimed at changing sexual behavior of women in the general population are quite meaningless. Interventions should then rather focus on men and the women with whom they have sex outside marriage, including commercial sex workers.

SEXUAL BEHAVIOR AS REPORTED BY MEN AND BY WOMEN

A major problem when assessing the risk of men and women of contracting an STI, is the differential reporting of sexual behavior between men and women. It is believed that women tend to underreport sexual activity, whereas men tend to overreport. This has been highlighted by studies assessing changes in reported age at first sexual intercourse between successive birth cohorts[15] and by studies that compared the numbers of sex partners reported by men and by women.[10,13,16–18] Several explanations have been put forward for these differences in reporting of sexual activity. Women may only report partnerships that mattered to them and omit relationships that were traumatic. Moreover, social desirability bias may operate in opposite directions for men and women with respect to sexual behavior so that women underreport partners while men overreport.

GENDER AND RISK OF SEXUALLY TRANSMITTED INFECTIONS

PREVALENCE OF STIs IN MEN AND IN WOMEN

There is widespread agreement that women are more frequently and severely affected by STIs than men. However, population-based studies that permit comparison of STI prevalence in men and women are limited. There are several such studies from sub-Saharan Africa and the National Health and Nutrition Examination Surveys (NHANES) in the United States. In the studies in the general population that have assessed the prevalence of gonorrhea, chlamydial infection, and active syphilis, the prevalence was generally higher in women than in men (Table 10-1), with differences in prevalence being more marked in the younger age groups. *Trichomonas vaginalis* is the most common curable STI worldwide,[19] but this STI has been studied primarily in women. In the studies in Table 10–1, for instance, prevalence of trichomoniasis has been assessed in women only, mainly because of the logistical difficulties of obtaining and processing samples for culture for *T. vaginalis* in men. One of the few population-based studies on *T. vaginalis* infection in men has been conducted in the Mwanza region of Tanzania. It found a prevalence of 11% in the age group 15–54 years,[20] whereas in this region the prevalence of trichomoniasis in women was 25.6%.

The difference in prevalence of HSV-2 infection between men and women is much more marked than the difference in prevalence of most curable STIs (Fig. 10-2). HIV infection is also strikingly more prevalent in women than in men in most populations where the predominant mode of transmission is heterosexual intercourse and where the HIV epidemic is mature (Fig. 10-3A). This is particularly apparent in the younger age groups (Fig. 10-3B). In the age group 15–49 years, the ratio of the HIV prevalence in women to the HIV prevalence in men ranges between 1 and 1.5. However, in young people 15–20 years the prevalence in girls may be 5–7 times higher than in boys.

MALE-TO-FEMALE AND FEMALE-TO-MALE STI TRANSMISSION PROBABILITY

Several factors can explain differences in STI prevalence between men and women, including differences in sexual behavior; differences in per sex act transmission probability; and differences in the natural course of the infection and health

Table 10-1. Prevalence of Sexually Transmitted Infections in Women and in Men as Assessed in Population-Based Studies

seeking behavior. It is generally accepted that the male-to-female transmission of STI pathogens is more efficient than female-to-male transmission. The large mucosal surface of the vagina and the cervix compared to the urethral meatus in men makes it biologically plausible that women are more susceptible than men to STIs that infect these sites. In addition, the mucosa of the genital tract of women has more prolonged exposure to infected semen thus increasing probability of infection.

Attempts have been made to assess the male-to-female and female-to-male transmission of gonorrhea and chlamydial infection by studying sexual partners of patients with confirmed gonococcal and/ or chlamydial infection.[21–23] Data from some of those studies do suggest that male-to-female transmission of gonorrhea and chlamydial infection is more efficient than female-to-male transmission.[21,22] However, deriving conclusions about transmission probabilities of STIs from cross-sectional data obtained from contacts of patients with STIs is fraught with problems, as it cannot be established with sufficient certainty who was the infecting partner.[24]

The first data suggestive of a difference in male-to-female and female-to-male transmission probability of HIV-1, also came from studies of partners of HIV-1 infected index cases. These cross-sectional studies strongly suggested that male-to-female

FIGURE 10-3. A. transmission is more efficient than female-to-male transmission.[25–27] Follow-up studies of HIV discordant couples allowed for more direct estimates of the transmission probability of HIV-1. (Table 10-2) summarizes the major prospective studies on HIV-1 discordant couples that allowed comparison of the male-to-female and female-to-male transmission probabilities. Several studies found a higher male-to-female than female-to-male transmission but other studies could not confirm this. There are several possible explanations for these discrepancies. The studies did not all control for the same confounding variables. For instance, in the earlier studies it was not possible to control for viral load of the index patient. Also, many studies did not objectively assess circumcision status of the male partner, which may substantially alter female-to-male transmission rates.[28] Furthermore, not all studies could reliably establish infection within the partnership as opposed to infection by sexual relations outside the regular partnership. This is a problem especially for those studies of discordant couples that have been conducted in high HIV prevalence populations. In the study from the Democratic Republic of Congo, for instance, seronegative men had more extramarital relationships once the positive serostatus of their spouse became known,[29] suggesting that a number of men who seroconverted actually became infected through an extramarital relationship. Lastly, there is mounting evidence for some acquired immunity against HIV-1 infection in individuals who are repeatedly exposed to the virus.[30] At the time of identification, HIV-1 discordant couples already have a history of unprotected sexual intercourse, and discordant couples may have features that distinguish them from HIV-1 concordant couples. Ideally, one would like to recruit HIV-1 discordant couples before they initiate sexual relations but for obvious reason this is not possible.

Data on male-to-female and female-to-male transmission of HSV-2 are also available from prospective studies of HSV-2 discordant couples. In a randomized controlled trial of the effect of suppressive therapy with valacyclovir, 7.4% of female partners of the HSV-2 infected men in the control group became infected with HSV-2, whereas only 1.2% of male partners of HSV-2 infected women seroconverted.[31]

RISK FACTORS FOR GENDER-SPECIFIC DIFFERENTIALS IN HIV PREVALENCE

The difference in prevalence of STIs between men and women is especially marked in young people under the age of 25 (Table 10–1). In industrialized countries also, the incidence of syphilis, gonorrhea, and chlamydial infection is considerably higher in young women aged 15–19 years than in young men.[32] The female-to-male ratio for reported syphilis cases ranged between 0.96 and 3.00; for gonorrhea the ratio was between 0.96 and 3.09 and for chlamydial infection between 3.9 and 69.7. However, the latter high ratios for reported cases of chlamydial infection can, in part, be explained by screening programs that target young women. The discrepancies in prevalence of STIs between young men and young women cannot only be explained by more efficient transmission from men to women than from women to men. The high vulnerability to STIs of young women compared to young men is the result of an interplay between psychological, sociocultural, and biological factors.[33]

Usually, women do not start sexual activity at an earlier age than men, so differences in age at first sexual intercourse cannot explain differences in STI prevalence.[34] Young women do not have more sex partners than young men, but women mostly have partners who are older than themselves, whereas men usually have partners who are younger. As such, young women are more likely to encounter a sex partner who is more experienced and may be infected with an STI. Older age of the sexual partner has indeed been found to increase the risk of HIV-1 infection in young women in Zimbabwe.[35] In addition, the power imbalance between men and women is

Table 10-2. Main Cohort Studies of HIV-1 Discordant Couples

Geographic Area (Ref)	Parameter Used to Assess Transmission	No. of Discordant Couples	Male-to-Female Transmission	Female-to-Male Transmission
Europe[1]	Cumulative rate of seroconversions in couples not using condoms	121	13.4%	11.4%
Haiti[2]	Seroconversions per 100 person years	177	4.8	7.6
DRC[3]	Seroconversions per 100 person years	178	3.7	6.8
Tanzania[4]	Seroconversions per 100 person years	43	10	5
Zambia[5]	Seroconversions per 100 person years	1022	8.9	8.2
Linked infections only			7.8	6.2
Uganda[6]	Seroconversions per 100 person years	121	10.1	5.5
Uganda[7]	Per sex act transmission probability	174	0.0009	0.0013

more marked in relationships between young women and older men. Young women have low social status and may be economically dependent on men. As a result, they find themselves in a weaker position to negotiate safe sex or to refuse sexual intercourse. They may not even have the knowledge and skills to avoid unwanted pregnancies and STIs if prevailing norms about virginity and "proper" sexual behavior of women limit women's access to information.[36]

Biological factors that may explain the high vulnerability of young women to STIs include trauma from defloration, cervical ectopy, and other features of the immature female genital tract. Defloration and the associated trauma have been suggested as a risk factor for heterosexual transmission of HIV.[37] Cervical ectopy, a zone of columnar epithelium on the ectocervix, is a feature of the immature cervix of young adolescents that is replaced by squamous epithelium in adult women. The columnar epithelium is thin, vascularized, and contains target cells for several STIs, including gonorrhea and chlamydial infection. Therefore, ectopy may increase adolescents' vulnerability to STIs. Ectopy, however, disappears with sexual activity and other irritation of the cervix. As such, any inverse association that is found between ectopy and STIs in adolescent girls may be confounded by sexual behavior.[38] The cervical mucus produced during adolescence is more easily penetrable to microorganisms and sperm than the mucus produced by more mature women. Adolescent girls are also immunologically naïve and it is believed that this is an explanation for the higher rates of chlamydial infection found in young women compared to older, more sexually experienced women.[39] Lastly, infection with one or more STIs that go unnoticed may increase susceptibility to another STI, in particular HIV infection. There is, for instance, mounting evidence that HSV-2 infection is an important factor that may explain the high vulnerability to HIV infection of young women.[34] HSV-2 infection has been found to be associated with increased risk of HIV acquisition, and in studies from sub-Saharan Africa prevalence rates of HSV-2 infection in young women aged 15–19 years ranged between 9% and 39%.[40–42]

CHANGES IN STI SUSCEPTIBILITY OVER THE LIFECYCLE

In women, variations in susceptibility to STIs and their complications have been quite well studied in relation to physiological, hormonal, and immunological changes, but less is known about changes in the male genital tract and how they affect risk of STIs. Sexual intercourse during menses has been associated with higher self-reported history of an STI.[43] The risk of upper genital tract infections associated with *Neisseria gonorrhoeae, Chlamydia trachomatis*, and/or bacterial vaginosis has been associated with the woman being in the first week of her menstrual cycle.[44] This is in keeping with the finding that sexual intercourse during menses has been associated with PID.[45] Sexual intercourse during menses, however, does not seem to increase the risk of acquisition of HIV in women, but to increase the risk for the male partner, because of a higher viral load in genital secretions.[26,46,47] Pregnancy appears to be protective against most common STIs. However, gonorrhea and chlamydial infection that remain undetected during pregnancy increase the risk of endometritis after childbirth. Recent evidence suggests that risk of HIV infection may be increased during pregnancy.[48] Also, the period immediately postpartum seems to be a period very vulnerable for women to acquire HIV infection, though it is not clear whether the high incidence is due to increased vulnerability of the vagina and cervix immediately after birth, or due to the fact that many male partners have sex with other women during pregnancy, and with recently acquired HIV, are highly infectious.[49,50]

The effects of contraception on risk of STIs have been extensively studied. Cervical ectopy associated with hormonal contraceptive use has been put forward as a plausible explanation for an increased susceptibility to STIs. Studies on the effects of oral contraceptive use on acquisition of STIs revealed conflicting results.[51] But the evidence for an association between the use of depo-medroxyprogesterone acetate and increased susceptibility to cervical infections, including chlamydial infection and gonorrhea, and HIV infection appeared to be more consistent.[52–55] A large scale multicenter prospective study, however, could not confirm an increase in risk of chlamydial infection, gonorrhea, and HIV infection associated with hormonal contraception in the overall population, though use of hormonal contraception by HSV-2 negative women appeared to increase their risk of HIV acquisition.[56] Hormonal contraception has also been explored as a risk factor for cervical cancer. It appears that use of oral contraception does not increase the risk of infection with human papilloma virus, but that long-term use of oral contraceptives is associated with an increased risk of cervical carcinoma in women who are HPV DNA positive.[57] The possibility that contraception increases the risk of acquiring STIs, especially HIV infection, was a cause for concern for several years, as it could have posed a difficult dilemma between prevention of adverse reproductive health outcomes associated with pregnancies and increased transmission of HIV. Recent evidence suggests that oral contraceptives, as well as IUD, are safe. It is now accepted that the IUD can be inserted safely in women at low risk for an STI, but that women at high risk for an STI should be tested and/or receive a prophylactic antibiotic prior to insertion.

Worldwide, large numbers of older adults are affected by STIs, especially HIV infection. The role older women play in mitigating the impact of the HIV epidemic, as caregivers of patients and/or as guardians of orphaned children, is well documented. But older people also appear to be directly affected by STIs. In the United States, the numbers of AIDS cases in people over age 50 years have quintupled between 1990 and 2001.[58] Part of this increase is due to the longer life expectancy of people living with HIV as a result of highly active antiretroviral treatment. But there is also some evidence to suggest that postmenopausal women are at increased risk of acquiring HIV infection and HTLV-1 infection through sexual intercourse.[59–61] It has been suggested that this may be due to a thinning of the vaginal epithelium in postmenopausal women.[60] In general, however, we know little about the risk of STIs and their complications in older people. Sexual activity decreases with age and unsafe sexual behavior is not expected of older people. Nevertheless, a number of contextual factors have been identified that may increase older women's vulnerability to STIs.[62] Longer life expectancy, widowhood, and divorce may push older women to seek out new sexual partnerships. Postmenopausal women do not have to worry anymore about unwanted pregnancy and they may not think of using a barrier method to protect against STIs. In addition, older women seem less assertive in negotiating safe sex than younger women, and old people in general are less knowledgeable about protective behavior and are less aware about the risks they run. Finally, care providers may be less likely to ask about sexual activity or provide risk reduction counseling to older patients.

GENDER DIFFERENCES IN NATURAL HISTORY AND COMPLICATIONS OF STIs

COMPLICATIONS OF CURABLE STIs

Both men and women are at risk of serious, even life threatening, complications of STIs although the frequency and severity of complications is generally greater in women than in men. Complications of curable STIs, i.e., STIs caused by bacteria or protozoa, can be avoided if infected persons promptly seek care and are managed appropriately. However, a prerequisite to seeking care is that infected persons are aware that they are infected and that they seek treatment.[63] A high

proportion of men and of women infected with *N. gonorrhoeae, C. trachomatis*, or *T. vaginalis*, however, never experience symptoms. Women are asymptomatic more often than men. It has been estimated that 55% of episodes of gonorrhea in men and 86% of episodes in women remain asymptomatic; 89% of men with chlamydial infection remain asymptomatic and 94% of women.[64] For chlamydial infection, it has been well documented that serious complications, including infertility due to tubal occlusion, can occur in the absence of a history of symptoms of pelvic inflammatory disease.[65]

Complications of gonorrhea and of chlamydial infection in men include epididymitis and urethra stricture. Epididymitis can lead to infertility in the extremely rare instances when it is bilateral. Urethra stricture as a complication of gonococcal urethritis was not uncommon in the pre-antiobiotic era, but is considered a very rare complication nowadays, at least in industrialized countries.[66] However, in many parts of the world efficacious treatment of gonorrhea may not be readily accessible and in such contexts severe, incapacitating complications of gonorrhea in men may not be all that uncommon.[67–69]

There is, however, the general consensus that women carry the heaviest burden of complications from curable STIs. The most dramatic complication of gonococcal and chlamydial infection in women is ectopic pregnancy. Not all ectopic pregnancies are due to gonorrhea or chlamydial infection but the most important risk factor is PID associated with STI. Ectopic pregnancy carries a high case fatality rate. In the United States and the UK, the case fatality rate has been estimated at 0.03–0.04%.[70,71] Hospital-based studies from Africa reported much higher case fatality rates, in the range of 1–3%.[72] In the United States, ruptured ectopic pregnancy is the leading cause of maternal mortality in the first trimester of pregnancy and accounts for 10–15% of all maternal deaths.[70] In developing countries, the contribution of ectopic pregnancy to overall maternal mortality is smaller.[72] It was, for instance, responsible for about 1% of maternal deaths in Jamaica in 1993–1995, but the maternal mortality in these countries is much higher than in industrialized countries.[73] As a result, ectopic pregnancy is a nonnegligible cause of mortality among women of reproductive age in developing countries.

The most common, serious complications of bacterial STIs in women are impaired fertility and adverse pregnancy outcomes. In the cohort study of Lund, Sweden, 8% of women who had a single episode of PID subsequently developed tubal infertility. Among women with two and three episodes the prevalence of tubal infertility was between 19.5% and 40%, respectively.[74] A study conducted by WHO among infertile couples in 33 medical centers in different continents, found that the proportion of women with bilateral tubal occlusion ranged between 11% in industrialized countries and 49% in Africa.[75] Psychiatric morbidity associated with fertility problems appears to be more frequent in women than in men, and low self-esteem, guilt, and blame are common.[76,77] In societies where fertility is the principal reason for couple formation, infertility constitutes a major social handicap for men as well as for women and may lead to social isolation for the latter. However, when a couple is infertile, it is usually the woman who is blamed, while male factors are rarely considered. A study from India found that the blame for infertility lies entirely with the female partner.[78] In some societies, infertile women are accused of having had multiple partners and induced abortions.[79] Infertility is associated with marital instability and constitutes a major cause of early dissolution of the marriage.[80] Women lose the support of their family and may even be subjected to physical and psychological violence.[81–83] Infertility may push men and women into sexual relationships outside marriage, hoping for conception and offspring. They may thereby increase their risk of acquiring an STI. Several studies have documented a higher HIV prevalence in women who are infertile compared to women who are fertile, but it cannot always be established with certainty whether the infertility preceded the HIV infection or the other way round.[84]

HUMAN PAPILLOMAVIRUS INFECTION

Anogenital human papilloma virus (HPV) infection is one of the most common STIs. In the United States, it has been estimated that 4.6 million young men and women, aged 15–24 years, became newly infected with HPV in 2000.[85]

The epidemiology and natural history of HPV infection have been well studied in women, but we lack data on the natural history of HPV infection in men. Only a few studies have compared the prevalence and incidence of HPV infection in men and women of the same age and population subgroup. These studies suggest that the prevalence and incidence of HPV infection in men and women are similar, but there is some evidence to suggest that persistence of HPV infection is more common in women than in men.[86] It is well established that morbidity and mortality related to HPV infection are more frequent in women than in men. Persistent infection with oncogenic types of HPV is found in nearly all cases of cervical cancer, the second most common malignancy in women worldwide. In 2002, there were an estimated 493,000 new cases of cervical cancer and 274,000 deaths.[87] The incidence ranged between 5.8 per 100,000 in Western Asia and 42.7 per 100,000 in Eastern Africa. In industrialized countries, the incidence of cervical cancer used to be in the range of the current incidence in developing countries, but since the introduction of screening programs in the 1960s and 1970s, the incidence has decreased to levels below 15 per 100,000.[87] Anal cancer and penile cancer are relatively rare, especially compared to cervical cancer. However, the incidence of anal cancer has been increasing in the United

States since the early 1970s.[88] The increase is more marked in men than in women and is attributed to the HIV epidemic and the increased incidence of anal cancer among men who have sex with men.

In both men and women there is interaction between HIV infection and HPV infection. Prevalence of HPV infection is higher in HIV infected persons than in HIV uninfected men and women. This is partly explained by the fact that both viruses are sexually transmitted, but HPV infection also persists longer in HIV infected individuals, thereby increasing their risk of developing anogenital cancers.[86,89–94]

HIV INFECTION IN MEN AND WOMEN

In industrialized countries, the HIV epidemic initially disproportionately affected men, including homosexual men and intravenous drug users. As a consequence, the first studies on the natural history of HIV infection were in men. When drugs for HIV infection became available, the first trials were also conducted mainly in men, not only because in industrialized countries more men were affected than women but also because there were legitimate concerns about testing novel drugs in women who could become pregnant. Since the early 1990s, studies have been published that addressed sex differences in progression of HIV infection in industrialized countries.[95] Women appear to have lower viral load levels than men even after adjusting for CD4 count and time since seroconversion,[96,97] but it is still not clear whether these sex differences persist throughout infection.[95] Also CD4 counts are higher in women than in men.[95] In the era before highly active antiretroviral treatment (HAART), given equal access to care, progression to AIDS and death was slightly slower in women than in men. This was found in industrialized countries and in one general population cohort in Uganda.[95,98] With HAART there does not seem to be any difference between men and women in response to treatment and outcome, after adjusting for transmission route, initial viral load and CD4 count, and age.[99]

There is no evidence that pregnancy alters the course of HIV infection substantially,[100–102] but the majority of studies have been conducted in industrialized countries and it is not certain whether the results of those studies can be extrapolated to developing countries.[95] HIV infection in pregnant women, however, increases the risk of obstetric complications and pregnancy related mortality.[103–106] Whether HIV epidemics increase maternal mortality at a population level, thereby obliterating gains in maternal health achieved by safe motherhood programs in developing countries, is still unclear. Some studies have found an increase in maternal mortality, whereas other studies did not find evidence for an increase.[107,108] A possible explanation for discrepancies in findings is that increases in pregnancy-related mortality associated with HIV infection may be offset by lower fertility of HIV infected women, especially in the later stages of disease.[109]

In industrialized countries, the proportion of HIV infected women who become pregnant and keep the pregnancy has increased in the 1990s, in part because of improvements in care and access to antiretroviral treatment.[110–113] In many developing countries, women have less control over their lives and are under pressure from relatives and their environment to have children, even if access to prevention of mother-to-child transmission (MTCT) of HIV is not assured.[114] However, women who have access to programs of prevention of MTCT often are not able to make full use of the opportunities offered to them to prevent their newborn baby from becoming HIV infected. In many programs, uptake of voluntary counseling and testing (VCT) at antenatal clinic is low because of the stigma attached to HIV infection and the inability or reluctance of women to disclose their HIV status to their partner and relatives.[115,116] For the same reason, women cannot use bottle feeding if the norm is breastfeeding. In such contexts, the probability is high that the woman bears a child who is HIV infected or becomes HIV infected through breastfeeding. This is not only a cause of grief but may also be associated with feelings of guilt and being inadequate as a wife and mother.[117]

GENDER DIFFERENCES IN CARE AND PREVENTION OF STIs

Just as prompt diagnosis and treatment of curable STIs can interrupt transmission and prevent serious complications, early diagnosis and management of viral STIs, including genital herpes and HIV infection, may interrupt transmission and result in better health outcomes. There are more opportunities for women to be screened for STIs than for men, including family planning clinics and antenatal clinics. In the latter setting, however, the main rationale for STI screening used to be the prevention of adverse pregnancy outcome and infection in the newborn infant, while the health of the woman was a secondary consideration. Because of the high costs of treatment of PID and its sequelae, extensive screening programs for chlamydial infection have been set up in several industrialized countries. In these programs, far more women are screened than men with resulting declines in chlamydial infection and even ectopic pregnancy rates.[118,119] In recent years, however, it was noted that the decline did not continue and this was attributed, at least in part, to lack of screening among men.[118,120]

Stigma and shame associated with STIs are powerful barriers for promptly seeking effective treatment for STIs, for both men and women.[121–123] However, women appear to face more obstacles than men. In general, women in developing countries have more limited access to proper information and health services than men.[124,125] They may not be in a position to decide themselves to seek care but depend on decisions made by the partner and/ or relatives. Female seclusion can

prevent women from utilizing services outside the home unless she is accompanied by a male relative.[126] Furthermore, women may not have the financial means to seek treatment or may be too busy caring for children to attend a health service. In societies where childbearing is highly valued, women may place the health of their children above their own health needs and this can lead to an unequal utilization of health services within the family.[126] Women may also not recognize STI symptoms as serious enough to seek care and may not have sufficient knowledge about their reproductive functions and STI symptoms.[127–129] If societal norms regarding extramarital sexual relations are more restrictive for women than for men, the psychological and social impact of a diagnosis of an STI is felt more strongly by women than by men.[130] Women may feel too embarrassed to seek care for STI-related symptoms if staff attitudes are (perceived to be) discriminatory or moralizing.[122,131] This is a fortiori the case for young, unmarried women.[121] Several studies from developing countries, conducted in the community and in health services, suggest that women less often seek treatment for STIs than men or have symptoms for a longer period before coming for treatment.[127,132–134]

The notification and management of sexual partners of patients diagnosed with an STI, is an essential component of STI control programs.[135] The aim of partner services, including notification of partners, treatment, and counseling, is to prevent reinfection of the index patient and to interrupt transmission to other men or women. Whatever the strategy that is employed to contact sexual partners, provider initiated or patient initiated, partner notification is often a painful process. Patients find it difficult to reveal the identity of their sexual partners and/or to inform their sexual partners, and partner notification may even be a reason for not seeking care in the public health sector.[121] In societies where women have low social status and are economically dependent on men and where communication about sexual matters between partners is poor, women, in particular, face huge difficulties informing their sexual partner(s).[130,136,137] Apart from embarrassment there is also the fear of rejection or, even worse, violence. In settings where the management of STIs relies on syndromic management, the potential negative consequences of partner notification for women have to be considered against the risk of reinfection because syndromic management of discharge syndromes has a very low specificity for the detection of STIs in women.

The establishment of the causal association between HPV infection and cervical cancer has given impetus to the search for a prophylactic vaccine for the prevention of HPV infection. Two vaccines have been tested in phase III trials in young women and have been found to be effective in preventing incident and persistent HPV infection.[138–141] However, there are still a number of questions about the best way to scale up use of the vaccines in programs and the resulting impact on the incidence of anogenital cancers.[142] There are no data on the efficacy of the vaccines in (young) men, but phase III trials are underway. If the results of these trials are positive, the question remains whether vaccination of men will be cost-effective.[142,143] The added benefits of vaccinating young men in the prevention of cervical cancer may be limited, but vaccination would be an important strategy in the prevention of anal cancer, especially in men who have sex with men.

HIV infection used to be a deadly infection and is now a chronic disease, requiring lifelong treatment with antiretroviral drugs. However, the stigma and fear associated with HIV infection continue to be enormous obstacles for care and prevention, especially for women.[144,145] Stigma surrounding HIV infection affects women more than men. In many societies women have low social status and are blamed for the spread of HIV infection, posing enormous challenges for partner notification by HIV infected women. Fear of being abandoned, which may also mean loss of financial support, and of being subjected to domestic violence, prevents many women from informing their partner, even if this partner is the only person who could have transmitted the infection to them.[116,146,147] Without the support of other persons in the household, compliance with antiretroviral treatment becomes nearly impossible. In many prevention of mother-to-child transmission (PMTCT) programs uptake of HIV-test results and prophylactic treatment with antiretroviral drugs remains low, despite the known benefits of testing and treatment during pregnancy.[148,149] Fear of stigma also prevents mothers in developing countries from using formula feeding instead of breast feeding, even if they are aware that they expose their baby to HIV infection via breast milk. Nevertheless six out of 10 HIV infected patients in sub-Saharan Africa who were on HAART in 2004–2005, were women.[150,151] The high proportion of women among patients on HAART reflects the epidemiological reality of HIV infection in Africa where more women are infected than men. But it could also be explained by the fact that women have more opportunities for HIV screening than men, for instance at antenatal clinics.

CONCLUSIONS AND IMPLICATIONS FOR STI CONTROL: IT TAKES TWO TO TANGO

Unsafe sex ranks fifth among global risk factors for mortality and is the second global risk factor for burden of disease. Mortality and disease burden attributable to this risk factor are higher in women than in men.[152] Part of the excess mortality and disease burden attributable to STIs in women is due to biological factors, but the power imbalance between men and women also plays a critical role in increasing women's vulnerability to STIs and their complications. Several interventions that aim to empower women, especially young women,

have been shown to have health benefits for women.[153] These include improved access to education for girls and the creation of economic opportunities for women.

STI control is, par excellence, an issue that affects both men and women. In recent years, the idea that men should be more involved in reproductive health programs has gained ground. For instance, some successes have been reported with interventions that appeal to men's sense of responsibility for the health of their unborn child.[154] It is clear that men and women have a responsibility in preserving each other's reproductive health. As the experience with screening programs for chlamydial infection has demonstrated, interventions to control STIs have to target both sexes. This does not mean, however, that both sexes have to be approached in an identical manner. Intervention programs have to be sensitive to the context of gender relations and the type of risks men and women encounter.

Eventually, however, norms in society have to change. Redressing the power imbalance between men and women will also benefit men. Norms about masculinity may prevent men from seeking information because they are supposed "to know it all," whereas their female sex partners cannot ask questions because they are "not supposed to know." The same norms may put men under pressure to have multiple sex partners and lead to discrimination against gay men. Yet norms concerning female and male roles are part of the collective consciousness of a society dealing with the meaning of masculinity and femininity and the exercise of power by men.[155] Deeply rooted gender norms may also be a factor contributing to sexual coercion in childhood and adolescence.[156] Reproductive health programs may, therefore, lead more significantly to changes in discourse than in behavior. Gender equity and equality, including in sexual education and reproductive health decisions, should be mainstreamed throughout the educational curriculum, starting from primary school. Last but not the least, advocacy among public opinion leaders should be pursued as a complement to individual education.

11 Adolescents and STDs Including HIV Infection

Stuart M. Berman and Jonathan M. Ellen

Making the transition from childhood to being healthy sexual adults is one of the major tasks and challenges faced by young people. A successful transition implies forming intimate relationships while avoiding the acquisition of sexually transmitted diseases (STDs). Yet it is apparent from the current data that around the world, for a combination of reasons involving biology, psychology, ambient culture, and changing mores, adolescents who have had sexual intercourse have the highest rates of STDs—including HIV in some locales—of any age group. As stated by one researcher, "the challenge lies in getting teenagers to view their relationships in a more realistic light without destroying the positive ways in which these (relationships) may also add to their lives."[1] This chapter describes the magnitude of the STD and HIV problem among adolescents, the factors that contribute to their risk of infection, considerations such as sexual network structure that underlie that risk,[2] and the STD/HIV prevention activities which reflect this understanding and are effective among these young people.

EPIDEMIOLOGY OF STDs AND HIV AMONG ADOLESCENTS

Most population-based STD rates underestimate risk for sexually active adolescents because the rate is inappropriately expressed as cases of disease divided by the number of individuals in this age group. Yet only those who have had intercourse are truly at risk for STDs. *For rates to reflect risk among those who are sexually experienced, appropriate denominators should include only the number of individuals in the demographic group who have had sexual intercourse.* In 2002, whereas 87% of 20–24-year-old women had had sexual intercourse, this was true of only 53% of women 15–19-years old.[3,4] This underestimation of rates is greatest among the youngest adolescents, since only a small proportion of them have had sex. In general, when rates are corrected for those who are sexually active, the youngest adolescents have the highest STD rates of any age group.[5]

CHLAMYDIA

Chlamydia trachomatis infection is the STD most strongly associated with adolescents. Early studies in family planning clinics demonstrated that prevalence of cervical chlamydia is greatest among sexually active individuals under 20 years of age, being approximately twice that found among older individuals.[6–8] Such findings are consistent with more recent data and with results from population-based assessments. It is also clear that prevalence of chlamydia among males is also substantial, if somewhat less than prevalence among women.

Population-based prevalence data are available from several sources. As part of the 1999–2002 National Health and Nutrition Examination Survey (NHANES), urine specimens among women 15–39 years of age were tested for chlamydia and almost 5% of those 14–19 years of age were infected; prevalence was under 2% for older women. African American women (with prevalence exceeding 10% among those 14–19 years of age) and women with 12 years of education or less were also at greater risk of infection.[9] Comparable results were obtained in follow-up of the National Longitudinal Study of Adolescent Health (AddHealth) cohort at 18–26 years of age; overall prevalence among females was 4.7% and rates were substantially higher among blacks than whites, but in this survey prevalence varied less by age.[10]

Chlamydia prevalence data among males are available from multiple settings, including clinical facility based,[11–13] detention-based,[13,14] and community-based venues,[15] as well as from schools[16] and population-based surveys.[9,10,17] As would be expected, prevalence among young males is lower in suburban clinical settings (0.9%),[11] and higher in general clinical settings (4%),[12] and among detainees (3.2–8.0%).[14] Data from the 1999–2002 NHANES indicated that just over 2% of males 14–19 years of age and over 3% of those 20–29 years had chlamydia; prevalence was approximately three times greater among African American males than among whites and low among males 30–39 years of age (prevalence under 0.7%).[9] Data from the AddHealth cohort and the National Survey of Adolescent Males were consistent,

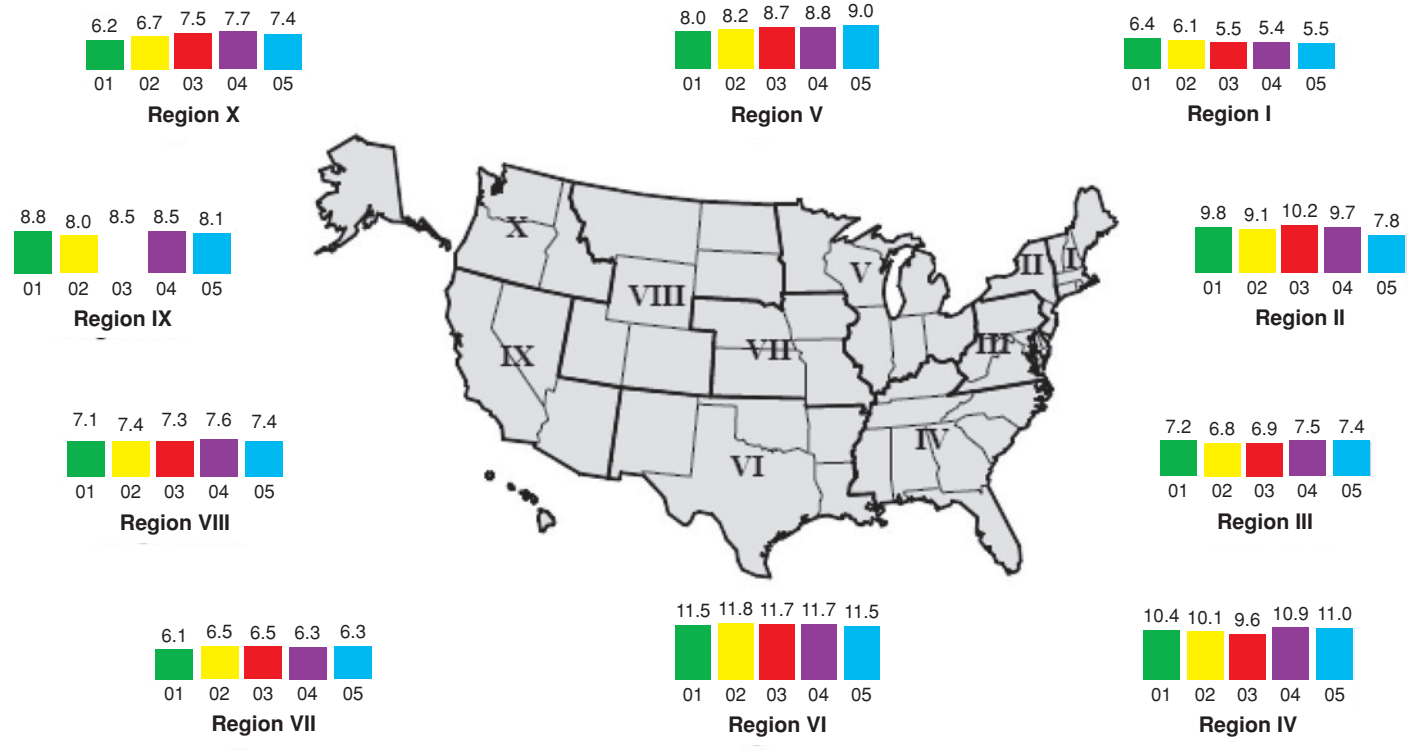
finding a somewhat lower prevalence among adolescent males than that among young adult males[17] and documenting substantial racial disparity.[10] However, these data were not adjusted for sexual activity.

In the United States, CDC first implemented chlamydia screening among family planning attendees in 1988 in the Northwest, and in all 50 states by 1995. Although prevalence among 15–19-year-old women in family planning clinics in the Northwest (Alaska, Idaho, Oregon, and Washington) decreased from 17.8% in 1988 to 5.7% in 1997, prevalence increased to 8.5% by 2005[18] (Fig. 11-1). The increase was not associated with changes in clients' risk profile, or demographics, or explained by use of tests with greater sensitivity (i.e., NAATs).[19] Although elsewhere in the United States, prevalence among 15–19-year-olds in family clinics was essentially unchanged from 2000–2005, increases in chlamydia have been noted in several other countries, such as Finland, Norway, Denmark, Sweden, and Canada.[20–22] In some countries, increased risk behavior has been noted (i.e., Finland), while in other areas low screening coverage is thought responsible (e.g., Sweden),[23] or increases in chlamydia have been accompanied increases in other bacterial STDs.[22] Others believe that the answer is more complicated, and that in areas such as British Columbia, with widespread chlamydia screening, duration of infection was sufficiently shortened to reduce population levels of immunity, allowing an increase in incidence.[24] This is a critical question, requiring ongoing research. Further complicating the issue is the fact that in the United States, from 1998 to 2004, chlamydia prevalence decreased from 11.7% to 10.3% among 16–24-year-old female enrollees in a national training program for disadvantaged and out-of-school youth (formerly the Job Corps).[25] However, the prevalence in this high-risk group remains substantial (see Fig. 11-2).

Chlamydia prevalence among adolescents in other countries has been found to be comparable to that in the United States.[26–32]

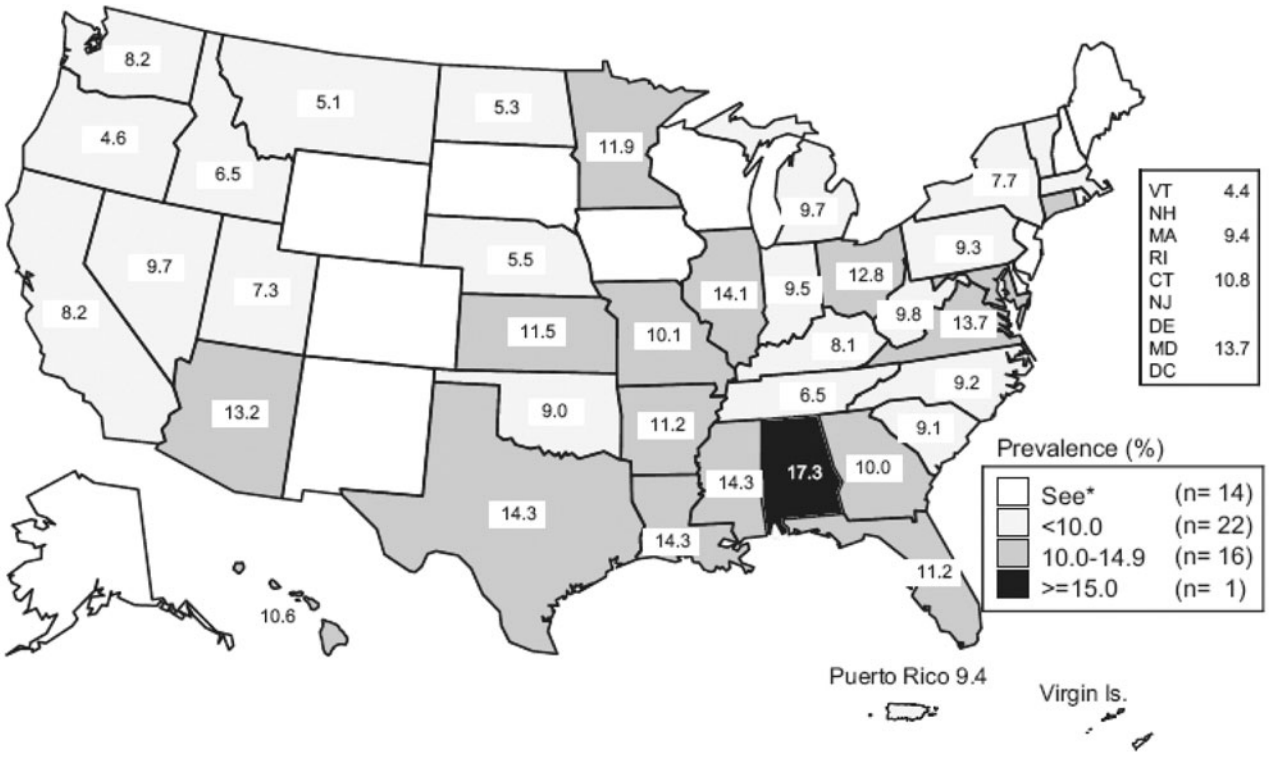
Cumulative risk of chlamydial infection is substantial among adolescents. Among female adolescents tested at least twice in family planning clinics in Washington, Oregon, Idaho, and Alaska from 1988 through 1991, 22% were found to be infected on at least one visit.[33] Similar findings were produced by a population-based study in Umea, Sweden, which evaluated cumulative risk of chlamydia by serologic tests.[34] The prevalence of *C. trachomatis*, identified by culture, among 19-year-old women was 5.5% (3/55).[35] However, 29.1% of these women and 18.0% of 21-year-old women (n = 139) showed serologic evidence of previous chlamydial infection.

Recurrent infection may be particularly worrisome, since such infections may be more likely to be associated with significant damage to the fallopian tubes than is primary



Note: Trends adjusted for changes in laboratory test method and associated increases in test sensitivity.

FIGURE 11-1. Trends in chlamydia positivity among 15–24-year-old women tested in family planning clinics by HHS regions, 2001–2005.[18] (*Source:* Regional Infertility Prevention Projects; Office of Population Affairs; Local and State STD Control Programs; Centers for Disease Control and Prevention.)



*Fewer than 100 women residing in these states/areas and entering the National Job Training Program were screened for chlamydia in 2004.
Note: The overall chlamydia prevalence among female students entering the National Job Training Program in 2004 was 10.3%.

FIGURE 11-2. Chlamydia prevalence among 16–24-year-old women entering the National Job Training Program by state of residence: United States, 2005.[18]

infection. The risk of recurrent infection is higher among adolescents compared with older women,[36–38] with several studies finding that among women treated for chlamydia, at least 10% had infection identified again within 4–6 months after treatment.[37–39] Recurrent or persistent infections have been associated with the continuing presence of an untreated sex partner[40,41] and with treatment failure.[37] Clearly, more information is needed concerning factors responsible for chlamydial persistence after treatment among young women.

GONORRHEA

Gonorrhea rates in the United States fell by almost 75%, from a peak of 467 cases per 100,000 in 1975 to 120 cases per 100,000 in 1997; subsequently, decreases have been smaller and less consistent. Rates among adolescents have also fallen, although not entirely in sync with overall rates. For example, from 1981 to 1991, although the overall gonorrhea rate among males declined by 46%, the rate among 15–19-year-old males did not decline at all. From 1985 to 1995, while the overall rate among females decreased by 53%, rates among 15–19-year-old females decreased by 39%. In contrast, from 1995 to 2005, overall rates of gonorrhea decreased less than 23%, while rates among 15–19-year-olds declined over 34%.[18] Rates among females 15–19 years of age have been the highest of any age group since 1984.

In the United States, as of 2006, rates of reported gonorrhea among African American adolescents are over 17-fold higher than that among their white counterparts.[18] Over the past 10 years, the disparity has decreased somewhat; in 1995 there was a 25-fold difference. These differences are comparable to results of a population-based survey among the cohort enrolled in the AddHealth, which was age 18–26 years at evaluation. Prevalence of gonorrhea among black males and females (approximately 2% for both men and women) was 36 and 14 times greater than that among white men and women, respectively. Reasons for such racial inequalities are beginning to be understood, and involve structural causes[42] as well as sexual mixing patterns.[43]

Gonorrhea screening among sexually active women is a major component of the national prevention program, and recent recommendations acknowledge that women under 25 years of age are at increased risk.[44] However, it is not clear that young age is a sufficient criterion for screening (as it is for chlamydia), since prevalence is so variable across some populations, and closely related to factors such as race[9] and geography[45]; indeed, the median state-specific prevalence of gonorrhea among 15–24-year females attending selected family planning clinics was 0.9%,[18] while that among females admitted to juvenile detention centers was

almost 6%,[14] highlighting the importance of screening in such venues.

Recently, gonorrhea rates have been increasing in several locales and countries (France, Denmark, England, Denver) typically related to increases among MSM,[46–49] but have not appeared to involve adolescents to any extent. However, increases in Sweden[50] and Canada have involved young women,[51] although the reasons for such increases are unclear.

Gonorrhea rates in much of the developing world are still very high, based upon prevalence in antenatal or family planning clinics, or village surveys.[52,53] When age-specific data are reported, prevalence is usually highest among adolescents.[54,55] Population-based prevalence data for gonorrhea from South Africa[26] suggest that approximately 3–4% of young females (15–24 years) and males (20–24 years) were infected; prevalence was lower among younger males (i.e., 15–19 years). Results from elsewhere in Africa (Mwanza, Tanzania, Masaka, and Rakai, Uganda) were comparable, although prevalence among males was somewhat lower than the rates cited above in the two Ugandan locales, as was prevalence among 15–19 females.[56]

SYPHILIS

Adolescents are not a prime risk group for syphilis, and in the United States, with changes in the epidemiology of syphilis, the risk for adolescents has declined. Following decreases throughout the 1990s, syphilis rates have increased during 2000–2005[18] primarily among older MSM,[57] often with high prevalence of HIV coinfection.[58–60] However, rates of P&S syphilis among 15–19-year-olds in the United States declined throughout the 1990s and were stable during the early 2000s. As a result, the rate of P&S syphilis among 15–19-year-olds in 2005 (2.1 per 100,000) was about one-eighth the rate in 1993 (17.0 per 100,000). Of note, although among 15–19-year-olds the rate of syphilis is typically lower among males than females, in 2005, the M:F ratio for P&S rates was above 1 (i.e., 1.3); this is consistent with the national trend of increasing M:F rate ratios (in 2005, over 5:1), reflecting the burden of disease among MSM. The extent of the burden among adolescent MSM is unknown.[18]

Not surprisingly, even among high-risk populations, syphilis seropositivity among adolescents is less than that among older populations; median seropositivity among admittees to juvenile detention facilities (females, 0.7%; males, 0.5%) was less than that among admittees to adult corrections (females, 5.3%; males, 2.7%).[18]

Although syphilis is still quite prevalent in the developing world (2–16% among antenatal attendees),[52,61] adolescents are at substantial, if somewhat lower, risk than older populations. Population-based surveys in Mwanza, Masaka, and Rakai have found that prevalence of syphilis among 15–19-year-old females can be over 5% some places (Mwanza), and 2–4% in the other locales. As expected, prevalence among older populations was consistently greater.[56] Elsewhere, adolescents have not been spared when syphilis has increased; as syphilis exploded in Russia between 1987 and 1998, with rates increasing over 60-fold during that time, rates among adolescents—though lower than that among older individuals—increased proportionately.[62]

HUMAN PAPILLOMAVIRUS

More than 6 million new human papillomavirus infections (HPV) occur each year in the United States,[63] and prevalence is highest among adolescents and young adults.[64] Although there is variation in method of detection and which HPV types were looked for, a large number of clinical studies in a variety of venues[65–67] documented that prevalence among young women was consistently greater than 20–25%, and that most have infection with one of the high-risk types.[68] The prevalence of HPV among males is harder to assess, since there is less agreement about the appropriate method of and site for specimen collection. Nevertheless, prevalence of HPV infection among heterosexual males has ranged from 16% to 45%[68] and is not so clearly associated with young age.[69,70]

These findings are similar to results from analyses of population-based data, obtained from the AddHealth cohort (18–25 years), with HPV prevalence assessed on first catch urine. Overall, almost 27% of women were infected, over 70% of time involving high-risk HPV types. HPV prevalence was highest among those 18–21 years of age (approximately 30%), and then decreased with age.[71]

Risk for HPV acquisition is underestimated by determinations of point prevalence. In a longitudinal study of 15–19-year-old females, cumulative incidence of HPV infection over 5 years was 60%.[72] In other studies, cumulative incidence was as high as 82%.[73]

Although risk of HPV acquisition increases with number of partners,[67,74,75] prevalence of infection is substantial even with limited sexual exposure. Numerous clinic-based studies,[76,77] supported by population-based data, indicate that HPV prevalence typically exceeds 10% among young women with only one or two partners.[71]

In addition, infection appears to be acquired soon after sexual debut. Winer et al. followed college students soon after they became sexually active and found that 20% were infected within 6 months after first intercourse.[78]

Although adolescents and young women are at highest risk for HPV, they appear to clear the infection promptly in the vast majority of instances, since 70% of new HPV infections are no longer detectable within 1 year, and up to 91% within 2 years.[68] Younger women (i.e., ≤25 years) are more likely to clear infection than women who are older.[79] Importantly, persistent cervical infection is a critical predictor of dysplastic changes.[80] Although changes consistent with cervical cancer may not develop for several decades, among young

women with incident HPV infection, dysplasia may appear quite soon; the 36-month cumulative incidence of CIN 2/3 was found to exceed 11%.[78]

Low-grade squamous intraepithelial lesions (LSILs), associated with acute HPV infection, are the findings typically associated with and common among adolescents and young women.[81] In their longitudinal study of college-age women, Winer et al. found that approximately 50% developed cervical LSILs within 3 years from the detection of an incident HPV infection.[78] Such lesions tend to resolve quickly and without need for intervention; Moscicki found, in 36 months follow-up, that 91% of LSILs regressed among an adolescent cohort,[82] findings similar to those of Winer et al. who evaluated college-age women and found that 86% of such lesions cleared in a median of 5.5 months.[78] These findings suggest that incident LSILs among young women have a different natural history than prevalent LSILs among older women, which are more likely to be associated with persistent infection.[78] Of note, an evaluation of prevalent LSILs among adolescents found that 31% had progressed, and only 62% had regressed by 36 months, results similar to those among adult women.[83]

The availability of effective HPV vaccines is expected to have substantial impact on genital warts, cervical cancer, and cancer precursors[84,85] given vaccine effectiveness.[86,87] In June 2006, the FDA licensed a quadrivalent HPV vaccine that protects against types 6/11/16/18 for use among females, ages 9–26 years. (There is another HPV vaccine expected to be licensed during 2008 that protects against types 16/18). In 2006, The Advisory Committee on Immunization Practices (ACIP) recommended that the quadrivalent vaccine be offered to 11–12-year-old females, with catch-up vaccination recommended for females 13–26 years who had not been previously vaccinated. The factors that influenced the recommendation included age distribution of sexual debut (HPV acquisition occurs soon thereafter and immunization should occur prior to exposure); evidence of a vigorous antibody response among preadolescents to vaccination; and age at which adolescents are scheduled to receive other vaccines.[88] Studies have demonstrated that parents and providers are quite accepting of the provision of an STD vaccine to preadolescents,[89–92] although there has been controversy with regard to making HPV vaccination mandatory for young girls.[93] HPV vaccines may also have major impact on cervical cancer screening recommendations for adolescents in the United States; with HPV vaccination against HPV types 16/18, it is more cost-effective to begin screening at 25 years of age than during adolescence (i.e., by 21 years of age), which is when most agencies and organizations (i.e., United States Preventive Task Force, American Cancer Society, American College of Obstetricians-Gynecologists) currently recommend that screening begin.[94]

HERPES SIMPLEX

Few individuals with herpes simplex virus type 2 (HSV-2) infection have recognized symptoms or signs.[95] Population-based serologic data are available from analyses of specimens obtained in 1976–1980, 1988–1994, and 1999–2002 from nationally representative samples of the U.S. population, in the NHANES. Consistent findings from these surveys are that cumulative risk for HSV-2 infection rises with age,[96] that seroprevalence is higher among females than males, and that prevalence is substantially greater among African Americans than whites.[96–98] However, overall seroprevalence fluctuated across these surveys; seroprevalence was 16.0%, 20.8%, and 17.5% in 1976–80, 1988–94, and 1999–2002, respectively. Importantly, both the increases noted from the first to the second survey (i.e., 1976–80 to 1988–94) and the subsequent decreases from the second survey to the third (i.e., from 1988–94 to 1999–02) were concentrated in younger ages.[97,98] Between these last two surveys, HSV-2 seroprevalence among 14–19-year-olds in the United States decreased from 5.8% to 1.7%, essentially returning to the level seen in the 1976–80 survey[8] (Table 11-1). These decreases occurred among males and females and all race/ethnicity groups. The changes may reflect the delay in onset of sexual activity and other behavioral changes reported among adolescents in the last decade.[99]

Although genital herpes is typically associated with HSV-2, there is evidence in several countries (i.e., Australia, Israel, Norway)[100–102] that HSV-1 is responsible for an increasing proportion of genital herpes; one study among students at a U.S. college found that that the proportion of genital herpes that was HSV-1 increased from 31% in 1993 to 78% in 2001.[103] In general, this changing epidemiology affects primarily adolescents and young adults.[103,104] There are several factors that may be contributing to this. For one, it is possible that a greater proportion of adolescents are susceptible to HSV-1 as they become sexually active; with increasing affluence, acquisition of HSV-1 in childhood decreases.[105] In addition, HSV-1 genital herpes has been associated with receptive oral sex,[106] and recent data indicate that over 50% of 15–19-year-olds have received oral sex (49.6% females; 51.5% males).[4]

However, the issue of genital herpes and adolescents may be most critical in the developing world—in particular those areas hardest hit by HIV/AIDS. The evidence that HSV-2 is an important risk factor for HIV acquisition and transmission is extensive.[107–109] Indeed, HSV-2 seroprevalence has been identified as one of the critical factors that may determine HIV population prevalence.[110] This can be seen by looking at HIV prevalence among women 20–24 years, and HSV-2 prevalence among those 15–19 years in four African cities.[111] Compare Cotonou, Benin (HSV 9%, HIV 3.8%), and Yaounde, Cameroon (HSV 14%, HIV 9.3%), with Ndola, Zambia (HSV 41.8%, HIV 23%), and Kisumu, Kenya (HSV 39%, HIV 38.3%).

Table 11-1. HSV-2 Seroprevalence by Age, NHANES II, NHANES III, NHANES 1999–2000, by Race[98]

Non-Hispanic whites			
Age	NHANES II (%) 1976–1980	NHANES III (%) 1988–1994	NHANES (%) 1999–2000
All ages[a]	12	17	14
14–19	1	4	1
20–29	8	15	7
Non-Hispanic blacks

All ages[a]	39	43	42
14–19	7	11	5
20–29	30	33	37

[a]14–49 years; 2000 US Census civilian noninstitutionalized population is standard.

Data from Xu F, Sternberg MR, Kottiri BJ, et al. Trends in herpes simplex virus type 1 and type 2 seroprevalence in the United States. *JAMA* 2006: 23; 296: 964–973.

PELVIC INFLAMMATORY DISEASE

Since pelvic inflammatory disease (PID) is usually caused by either gonorrhea or chlamydia, and since these infections are most prevalent among sexually active adolescent females, this group is also at substantial risk for PID. In 1980, the estimated risk of PID among sexually active 15-year-olds in Sweden was 12.5%, and among sexually active 16-year-olds it was 10%, with progressive decreases with increasing age.[112] The investigators calculated that the risk of developing salpingitis for those with chlamydial infection was approximately 70% greater among women between 15 and 19 than among women between 20 and 24 years old; among those with gonorrhea, the risk for 15–19-year-olds was about 20% less than that among the 20–24-year-olds.[113]

Although monitoring PID is a challenge,[114] available data suggest U.S. rates of PID have been declining overall, and also among adolescents. In the United States, although hospitalization rates for acute PID decreased over the decade of the 1980s, decline was least among 15–19-year-olds.[115] A recent analysis of data for 1985–2001 found overall hospitalization rates for acute PID declining 68% (1985–2001), but rates among adolescents decreasing somewhat less (53%) than rates among either 20–24-(77%), or 25–29-year-old (68%) women.[116] evertheless, when average annual rates of PID for 1995–2001 were analyzed, PID hospitalization rate was lower among women aged 15–19 years than among those 20–25 years, but greater than among women 25–29 years, findings which are comparable to those from England and Wales.[114] In the United States, occurrence of outpatient PID was lower among 15–19-year-old women than among women 20–24 or 25–29 years of age[116]—important to note since hospitalization accounts for less than 10% of diagnosed PID cases.[116,117] However, if rates were based only among those adolescents who had ever had intercourse, the risk for hospitalization with PID among sexually active 15–19-year-olds would be the highest of any age group.

A study in Philadelphia found that adolescent females diagnosed with PID sought care an average of 7.8 days after the onset of symptoms compared with 5.6 days for adults.[118] Such behavior is of particular importance given the finding that the risk of impaired fertility or ectopic pregnancy increases significantly with increasing delay between onset of symptoms and receipt of care.[119] Nevertheless, recent data indicate that women less than 26 years of age are no more likely to suffer chronic pelvic pain after PID than older women; delay of care was not significantly associated with chronic pain.[120]

HUMAN IMMUNODEFICIENCY VIRUS

HIV is a great problem for many of the world's adolescents. It has becomes clear that in several sub-Saharan countries with the highest rates of HIV, the risk of HIV acquisition among women increases dramatically in the adolescent and early adult years. In a recent population-based survey among young people in South Africa, HIV prevalence among 15–19-year-old females was 7.3%, but 2.5% for males of the same age; among those 20–24 years, 24.5% of women were infected, compared with 7.6% of males.[121] Similar results have been noted elsewhere.[122] Overall, 26% of individuals in Kisumu and 28% in Ndola were HIV-positive. In both

sites, HIV prevalence in women was six times that in men among sexually active 15–19-year-olds (with rates as high as 23% in Kisumu)[111] and three times that in men among 20–24-year-olds, but equal to that in men among 25–49-year-olds; young women were at similarly increased risk compared to males in Zimbabwe (age-adjusted odds ratio 4.6).[123] Although several factors, such as cervical immaturity, and increased prevalence of STDs contribute, the major factor associated with the increased risk for young women appears to be having older male partners[123] (Fig. 11-3). While young men typically have sexual relations with partners who are of same age or younger, it is common for young women to have male partners 5–10 years older, as was found in Zimbabwe[123] and elsewhere.[122] Young women prefer older males in large part for economic reasons; unfortunately, they are less likely to use condoms with such partners, who frequently have had relations with commercial sex workers and who view the young women as "safe" and unlikely to be HIV-infected.

In the United States, there have been few recent HIV-prevalence studies among adolescents. Older U.S. studies have demonstrated that prevalence of HIV infection was appreciable in several populations of adolescents. Prevalence exceeding 1% was documented among adolescents seen at STD clinics, among those at shelters for homeless and runaway youth, and among those in correctional facilities. Many of these young people have had sex in exchange for drugs, shelter, or food ("survival sex").[124]

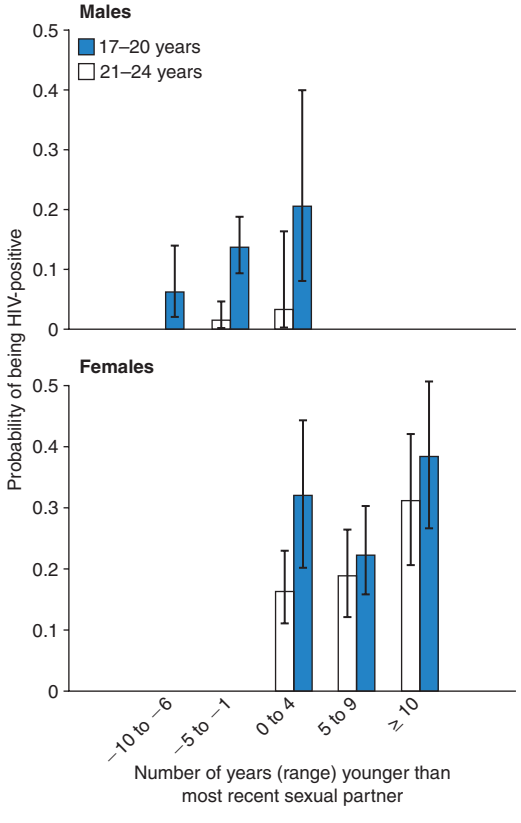

FIGURE 11-3. Probability of being infected with HIV by age and age difference with most recent sexual partner, rural Zimbabwe. (Modified from Gregson S, Nyamukapa CA, Garnett GP, et al. Sexual mixing patterns and sex-differentials in teenage exposure to HIV infection in rural Zimbabwe. *Lancet* 2002; 359: 1896–1903.)

African American youth are disproportionately affected, accounting for 56% of HIV infections reported among those aged 13–24 years.[125]

National HIV surveillance data, using name-based reporting, revealed that, from 1994 to 2003, cases among females 13–24 years of age decreased slightly. A different pattern was seen among males; from 1994 to 1999 male cases decreased substantially, but increased from 1999 to 2004.[126] This increase occurred primarily among 20–24-year-old MSM, and involved all races, with increases greatest among blacks. Such findings are consistent with other reports of high rates of HIV prevalence among young MSM (14% among those 18–24 years).[127] Among those MSM with HIV, young MSM were most likely to have unrecognized infection (79%).

DETERMINANTS OF STD/HIV RISK AMONG ADOLESCENTS

Adolescence is a unique time of life, when societal, biologic, behavioral, and developmental factors all act in concert to increase the likelihood of STD/HIV acquisition.

BIOLOGICAL FACTORS

Several aspects of physical development may be relevant to the high risk of STDs among sexually active adolescents. The histology of the cervix and vagina undergo dramatic changes from childhood through puberty and into adulthood. Newborns show effects of exposure to maternal estrogen, which produces the squamous epithelium lining of the vagina as seen in adults. Soon after birth, these squamous cells are replaced with columnar epithelium. At puberty, estrogen exposure causes the vaginal lining to thicken again with layers of squamous epithelium. Such epithelial changes may be particularly important at the cervix, since the persistence of cervical columnar epithelium in young women appears to significantly increase their vulnerability to STDs. Although cervical columnar epithelium eventually recedes completely, to be replaced with squamous epithelium, this replacement is a gradual process, continuing well into adulthood. Typically, the cervix in the adolescent still displays areas of exposed columnar epithelium,[128] a condition often referred to as *ectopy*. This is significant because *C. trachomatis* infects columnar, not squamous, epithelium and thus ectopy may increase exposure of susceptible mucosa to infection.[129]

The presence of ectopy has repeatedly been associated with chlamydial infection, even after adjusting for sexual behavior and other confounders.[130,131] Although it may be that chlamydial infection causes the appearance of columnar epithelium on the cervix,[128] longitudinal studies have demonstrated that ectopy is associated with increased risk of subsequent infection.[132,133] However, whether ectopy facilitates the detection of chlamydia is still a question.[129]

The presence of ectopy also appears to increase the risk for other STDs and their adverse outcomes. *Neisseria gonorrhoeae* attaches preferentially to columnar epithelium rather than squamous tissue. In addition, there is some evidence that ectopy may contribute to HIV acquisition[134,135] and HIV shedding.[136] The vasculature found with the columnar epithelium associated with ectopy is more superficial and more easily traumatized than that of squamous epithelium, theoretically permitting HIV-infected cellular elements from the circulation to gain access to the mucosal surface, and infected monocytes and lymphocytes to reach the circulation. Ectopy may partially account for the high incidence of HIV among adolescent women by increasing susceptibility; the implications of possibly increased infectivity, associated with HIV shedding, are unknown. However, some studies have not found an association between HIV and ectopy.[137,138] The vaginal flora also changes during puberty. The appearance of *Lactobacillus* spp results in reduction of the high vaginal pH levels of childhood to the more acidic pH associated with adulthood. The higher vaginal pH of early adolescence may be associated with a lower prevalence of hydrogen peroxide-producing organisms. However, causal links between these anatomic or physiologic changes and STD acquisition have not yet been demonstrated.

Changes in mucosal anatomy produce changes in mucus production, which is minimal in childhood. Mucus production is greatly increased in early puberty, but the mucus is thinner than that found in older adolescents or adult women. Thinner mucus may permit organisms to penetrate more easily and to attach to mucosal sites or gain access to the upper tract.

Research has suggested that adolescent females experience a greater decline in IgG levels in cervical secretions during menstrual cycles than adult women,[139] but the implications of such a finding for disease acquisition is unknown. There are many aspects of immune protection of the female reproductive tract, such as expression of chemokines or cytokines, or expressions of CCR5 and CXCR4 receptors, that may function differently among young women, but such differences have not yet been documented and need to be elucidated.

Unfortunately, there is very little information about how development in males affects their risk of STD acquisition or transmission.

PSYCHOLOGICAL AND COGNITIVE DEVELOPMENT

The stages of adolescence have been arbitrarily categorized as "early," "middle," and "late," and have been considered in terms of psychologic, physiologic, and social development (Table 11-2). Development in each of these areas is not necessarily parallel. Individuals are often advanced in some categories, but slower than their age-matched peers in others. Furthermore, growth in some of the cognitive areas is strongly influenced by the quality of teaching or role-modeling individuals' experience.[140] This is particularly relevant for STD prevention, where adults may use indirect methods of educating or rely on "scare tactics" rather than using skills training. Several characteristics of adolescents, particularly in early or middle stages of development, may have important implications for STD risk and prevention. Younger

Table 11-2. Highlights of Adolescent Development Stages[254]

Early Adolescence Females ages 9–13 Males ages 11–15	Middle Adolescence Females ages 12–16 Males ages 14–17	Late Adolescence Females ages 16 and older Males ages 17 and older
• Puberty as hallmark • Adjusting to puberty such as secondary sexual characteristics • Concern with body image • Beginning of separation from family, increased parent-child conflict • Presence of social group cliques • Concentration on relationships with peers • Concrete thinking but beginning of exploration of new ability to abstract	• Increased independence from family • Increased importance of peer group • Experimentation with relationships and sexual behaviors • Increased abstract thinking	• Autonomy nearly secured • Body image and gender role definition nearly secured • Empathetic relationships • Attainment of abstract thinking • Defining of adult roles • Transition to adult roles • Greater intimacy skills • Sexual orientation nearly secured

adolescents frequently use a concrete style of reasoning, focusing on the present time, and until they reach middle or late adolescence are unable to conceptualize the long-term impact that current actions may have. Since some STDs (e.g., HIV or chlamydia) may have adverse effects that are not experienced for a decade or more, it should not be surprising that younger adolescents may not take actions needed to avoid such consequences. Furthermore, adolescents may have difficulty correctly implementing complex tasks (such as condom use) involving a series of steps that must be accomplished in a certain sequence to be effective.

These findings are consistent with ongoing research concerning cognitive development.[141] Significant structural changes in the brain continue into the later teenage years,[142] and the development of an "executive suite" of upper level decision-making functions is a lengthy process, requiring time and experience. Pubertal development and its attendant hormonal milieu appear to fire romantic motivations and an appetite for risk taking, independent of chronological age. However, self-regulation and competent decision making while under emotional stress (i.e., in the throes of adolescent passion) develop slowly and continue well after puberty.[143] The occurrence of puberty at younger ages is, as described by one researcher, like starting a car engine with an inexperienced driver at the wheel.[141] The fact that adolescents are not fully prepared to handle the situations they find themselves in is a reason why it is important to provide appropriate "social scaffolding,"[143] and may explain why parental monitoring appears to be an effective prevention strategy.

Finally, many parents, educators, and health-care workers do not teach about STD risk or even details of pubertal development until long after many adolescents are at risk for STDs. Therefore, these youths do not have even the basic information to make informed choices.

SEXUAL BEHAVIOR

Over the last century, sociocultural and behavioral changes have combined with changes in aspects of the developmental physiology of adolescents to increase the risk of STDs among these young people. Biologically, the average age at menarche has decreased (although it has been stable over the last generation). At the same time, societal changes have resulted in increases in the average age at which young men and women marry. As a result, while 100 years ago young men in the United States spent approximately 7 years between maturation and marriage, more recently the interval was 13 years, and increasing; for young women, the interval between menarche and marriage has increased from 8 years to 14. For this reason alone, it should be expected that premarital sex in the United States has increased[144] (Fig. 11-4).

Changes in sexual behavior have placed adolescents at increased risk of STDs, with the longstanding trend to earlier age at first intercourse occurring worldwide.[145–148] However, in the United States, several ongoing, population-based surveys that provide information about the sexual behavior of adolescents show that during the past decade, the proportion of teenagers that have experienced premarital sexual intercourse has declined.[4,149] This change in behavior reverses the trend seen over the previous several decades in the United States, in which the age of first intercourse had steadily decreased. In 1970, only 5% of women in United States had had premarital intercourse by age 15, whereas in 1988, 26% had engaged in intercourse by this age. However, in 1988, 37% of never married 15–17-year-olds had engaged in intercourse but in 2002, only 30% had. Comparable data from males demonstrated even greater declines—50% of never married 15–17-year-olds reported having had intercourse in 1988, compared with only 31% in 2002[99] (Fig. 11-5). Consistent with these U.S. data, between 1991 and 2000, the pregnancy rate among U.S. females (15–17 years) declined by 33%.[150] Similarly, the percentage of 9–12th grade students who reported having had four or more sexual partners also declined from 19% in 1993 to 14% in 2003.[149] This trend is not universal; no such decline was reported in Sweden.[151]

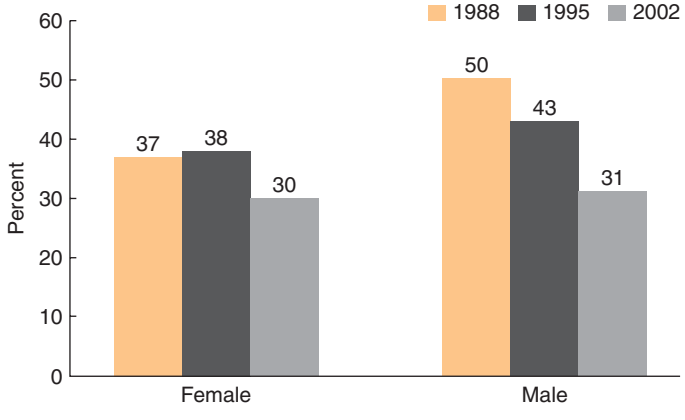

FIGURE 11-5. Percent of never married females and males 15–17 years of age who have ever had sexual intercourse: United States, 1988–2002.[99]

Younger age of sexual "debut" is associated with a greater number of sexual partners—an important determinant of STD risk.[152] In 1988, among American women 15–24 years of age who were sexually active for the same length of time (less than 24 months), over 40% of 15–19-year-olds had had two or more partners, compared with only 26% of women 20 years of age or older.[153] Younger age of sexual debut (below age 18) is also associated with ongoing sexual risk among unmarried women, with an increased likelihood of having two or more recent partners.[154] Adolescent relationships are of shorter duration than those of older individuals. Duration on average is only 15 months, and many relationships are less than 4 months.[155] It is becoming clear that determinants of STD risk at both an individual and population level include other factors such as concurrency[156] and sexual mixing patterns,[43] which involve assessment of sexual network structure[157,158] and should be considered regarding adolescent STD risk. Nevertheless, partner acquisition tends to follow a pattern of serial monogamy, with one study finding that fewer than 10% of sexually active adolescents having more than one partner within a 3-month period.[152] In another study, among adolescents reporting activity in the previous 18 months, over 85% indicated that they had either a single or sequential relationships. However, among serially monogamous females of all ages, adolescents are quicker to acquire a new partner than older women; in a national survey, mean gap between partners was 8 months for serially monogamous 15–19-year-old women, compared with 11 months and 18 months for 20–29- and 30–44-year-old women, respectively.[159] (Some smaller studies among higher risk cohorts of adolescents have found mean interval between old and new partners to be as short as 21 days.[160]) It should be noted, however, that among those adolescents who had more than one partner, concurrency is rather frequent; among adolescents who reported more than one partner in the previous 18 months, over 40% had overlapping sexual relationships.[161]

Although concurrency is expected to have population level effects, implications for individual risk are less clear, since concurrency may[162,163] or may not[45,63] be associated with increased individual STD risk. Furthermore, risk for the individual adolescent may be affected by the likelihood that one's partner has concurrent partners,[45] which appears related to whether one lives in a high-risk community or not.[45]

Recent studies provide some insight into sexual (and romantic) network structures among adolescents. As part of the AddHealth, data were obtained from all students in a large high school and all the romantic and sexual relationships among those students were identified. The relationship structure was described by the researchers as a "spanning tree," similar to "rural phone lines running from a long trunk to individual houses."[164] Such a structure does not reflect random partner selection, but rather a situation in which there are rules about who can be involved with whom. In addition, although there were few "short cycles" (i.e., cyclical pattern which promptly leads back to the same individual), there was a large network component that linked over half of the adolescents involved in romantic relationships (Fig. 11-6). Such a structure would allow efficient spread of an STD across the network, and, as the authors point out, demonstrates that STD risk is not simply

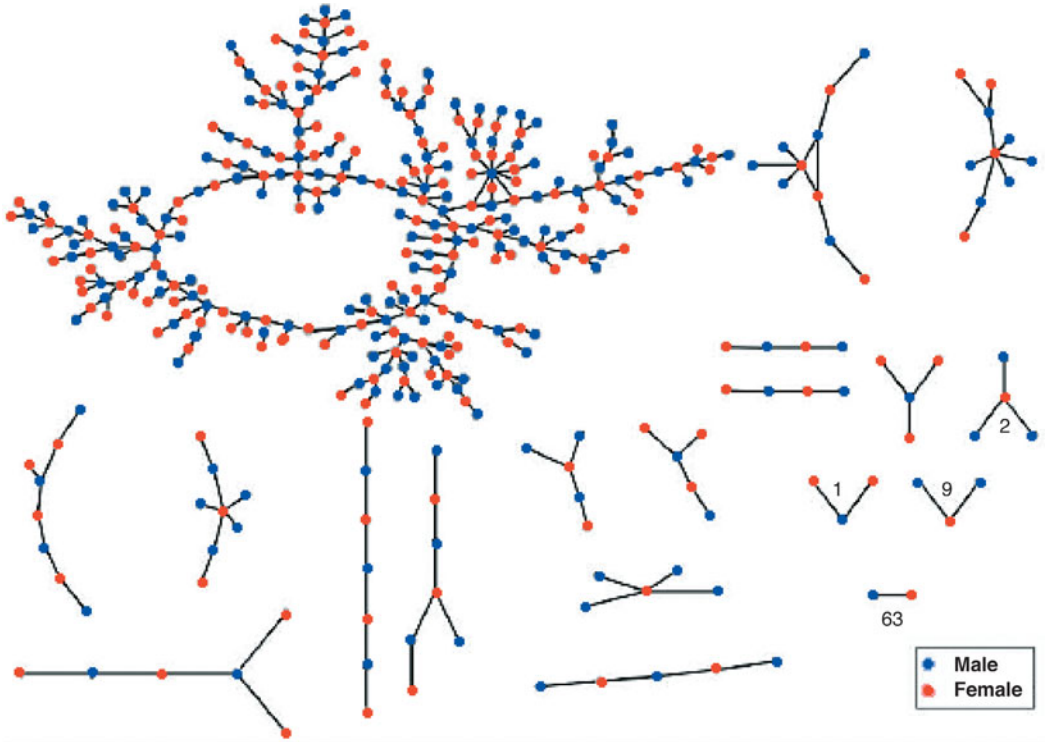

FIGURE 11-6. Direct relationship structure at an American High School. (Modified from Bearman PS, Moody J, Stovel K. Chains of affection: The structure of adolescent romantic and sexual networks. *Am J Sociol* 2004; 110: 44–9111.)

defined by the number of partners. Moreover, the structure has implications for STD prevention. Given the existence of a "spanning tree" network, effective prevention efforts need not target individuals in the "core." A prevention approach that reaches all adolescents—and thus breaks the "spanning tree" into smaller, unconnected clusters—might be even more effective. Of course, this is a single study, performed in a middle-sized town, in the Midwest among working-class population, with limited diversity; and the network analysis did not include individuals who were not high-school attendees; therefore the extent to which its results are generalizable is unknown.

Population-based data demonstrate that condom use has increased substantially in the United States, but that use is not consistent. Surveys indicate that adolescents are more likely to use condoms than older individuals. In 2002, 66% of male teens reported using condoms at last intercourse compared with 53%, 45%, and 29% of males 20–24 years, 25–29 years, and 30–44 years, respectively.[99] In addition, 67% of U.S. women reported condom use at first intercourse if it occurred during 1990–2002, while only 36% of women 15–44 years of age reported condom use at first intercourse that occurred before 1990[4] (see Table 11-3). Condom use among adolescents in general has increased. In 2002, among never married sexually active 15–19-year-old females, 54% used condoms at last intercourse, compared to 38% and 31% in 1995 and 1988, respectively.[4] Similar increases are reported by adolescent males; in 2002, 71% of sexually active, never married 15–19-year-old males reported use of condoms at last intercourse, compared with 64% and 53% in 1995 and 1988, respectively.[4]

However, follow-up data indicate that as males get older and as the duration of the existing relationship increases, condoms are likely to be replaced by forms of contraception that offer less protection against STDs, particularly oral contraceptives.[165] This pattern has also been reported from other countries, such as Australia,[166] Canada,[167] and New Zealand,[168] It is noteworthy that the combined effect of serial monogamy and diminishing use of condoms over the duration of a relationship may be particularly important in exposure to and ongoing transmission of organisms such as HSV-2, chlamydia, HPV, and HIV, which are associated with chronic and often asymptomatic infection.

Although more people are using condoms, few people, including adolescents, use them consistently. Among unmarried U.S. women, 28% of 15–19-year-olds report using condoms consistently (i.e., all the time) over the past 12 months[4]; 48% of 15–19-year-old males report doing so. Not surprisingly, both teenagers and older individuals use condoms less frequently with partners in an ongoing relationship, than in sexual encounters outside that relationship.[169] Furthermore, the young people most at risk for STDs appear to use condoms least.[170] A survey among adolescent males indicated that those who were substance abusers or had paid for sex were among the least likely to have used condoms at last intercourse.[171] Young males were less likely than older males to use condoms at first intercourse with partners they perceived to be at higher STD risk.[165] Among young people with two or more partners, individuals with a greater numbers of partners were less likely to use condoms consistently with either primary or secondary partners.[172] A similar pattern has been observed in other countries.[173]

Table 11-3. Percent of Males and Females Who Used Condoms at First Sexual Intercourse, by Year of First Intercourse, United States[4a]

Year of First Intercourse	% Used Condoms
Males	
1999–2002	73.0
1995–98	70.9
1990–94	58.6
1980–89	44.3
Before 1980	21.7
Females	
1999–2002	67.2
1995–98	61.7
1990–94	58.0
1980–89	38.1
Before 1980	21.7

[a]2002 NSFG.

Use of condoms is a complex behavior, but we can make some generalizations about determinants of condom use upon which to base prevention strategies; most parallel determinants noted among adults. Many studies,[174,175] but not all,[176,177] indicate that use is associated with perceived risk of HIV infection. Youths who think their peers use condoms are more likely to use them,[176,178–180] as are adolescents who feel that their partner would support their use,[170,181,182] and adolescent males who are more able to communicate with their parents and with peers.[183] Adolescents are often mistaken about what their partners believe, however, with females overestimating the resistance and negative attitudes that males have about condom use.[184] In addition, when condoms are used, adolescents frequently experience errors in their use. In one study, among adolescent females who used condoms in the prior 3 months, at least one condom error was reported by 71%.[185] National survey data indicate that misconceptions about condom use (i.e., need for space at tip; use of Vaseline; protection with lambskin vs. latex condoms) are quite prevalent, with up to 50% of adolescents being mistaken about some of these issues.[186]

Studies have noted that self-efficacy, perceived risk, and partner support are important factors in increased condom use.[180,187] However, many young females who feel confident that they could get their partner to use condoms, are not motivated to use them. An important factor appears to be the extent to which young people underestimate their partners' risk of infection. Young homosexual males[188] believe that they are safe if they have sex with younger partners. Heterosexual females often feel that they have little or no risk of acquiring HIV from their male partners and believe their boyfriends' statements of fidelity, often despite having a history of STD themselves.[1] Another major concern is the belief that their partners, particularly their steady partners, would view the request to use a condom as indicating a lack of trust. Conversely, if the request for use is made by the male, the female may assume he is dating outside the relationship. Approaches to reconciling these issues are complex and require skillful and practiced communication, as well as interventions suitable for sexually active adolescents who are in the formative phases of social skill development. Other barriers to condom use that are unique to adolescents include lack of ready availability.[175] Embarrassment about purchasing condoms may be a particular obstacle for girls.[189]

LEGAL AND ETHICAL ISSUES

Adolescents have unique legal status with regard to the provision of health care. Legally they are accorded more rights than children, but in some matters they may have rights that differ from those of adults. These issues are addressed by state minor consent laws that may allow minors to give their own consent for health care. These laws differ by state. However, in all states, adolescents who are at least 14-years-old can be diagnosed and treated for STDs without parental consent or knowledge, and some states have specific provisions regarding testing for and treating HIV infection. Beyond STD diagnosis and treatment, there are some basic issues providers confront in dealing with adolescents[190]:

1. Is the adolescent who is under 14 years of age old enough to have the authority to consent to care without parental involvement? Must the provider request any specific evidence of age?
2. Does the adolescent have the authority to release or prevent release of confidential information (particularly to parents)?
3. Is the adolescent or another source responsible for payment for services rendered? Can adolescents insist that parents not be contacted for health insurance coverage or payments?

In the United States, the answers vary by state[190,191]; however, some generalizations are possible. First, it should be noted that in most states the age of majority is 18, but in three states (Alabama, Nebraska, and Wyoming) it is 19, and elsewhere 21 (Mississippi, and District of Columbia). However, as stated, all states either have specific statues or otherwise permit the diagnosis and treatment of "venereal disease" (the usual terminology) without parental consent.

CONSENT

Although all states and the District of Columbia permit a minor to consent to STD care without parental consent, some states identify an age criterion. In five states (Alabama, California, Delaware, Illinois, and Vermont), minors must be at least 12 years old to consent to STD-related care, and in five states (Hawaii, Idaho, New Hampshire, North Dakota, and Washington) they must be 14-years-old. Laws may also address the extent to which providers can, in "good faith," rely on information provided by the minor about his or her ability to consent. Over a dozen states have such a statement (Alabama, Alaska, Colorado, Delaware, District of Columbia, Indiana, Maine, Massachusetts, Minnesota, Missouri, Oklahoma, Pennsylvania, and Texas).

PARENTAL NOTIFICATION

In general, providers are obligated to maintain confidentiality, although communication with parents is sometimes addressed specifically. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) suggests statutory protection, by indicating that when minors consent to their own care without parental consent, parents do not necessarily have the right to the information related to that care. However, it is state law that determines the specific protections that are applicable (i.e., medical privacy laws, state minor consent laws, etc.).[192] In several states, laws indicate that the information is confidential, and thus parents cannot be informed without the minor's consent (e.g., California, Connecticut, Delaware, Florida, Hawaii, Iowa, Massachusetts), although exceptions are made if life or limb are in danger (Massachusetts), or if the adolescent is found to have HIV (Delaware, Iowa). Other states either permit the provider to notify parents, indicate that providers are not obligated to notify parents, or do not address the issue.

LIABILITY

Most states have not specifically addressed this issue. However, in several states (Connecticut, District of Columbia, Maine, Minnesota, and Oklahoma, and also in the Montana), depending upon ability to pay, the minor who seeks STD care is liable for costs. In many others it is stated that the parents are *not* liable, and therefore cost recovery would not be a reason to contact them.

The specific issue of a minor consenting for care relating to HIV/AIDS has been addressed by a majority of states.[190] Many states have statutes that permit emancipated minors in "special

circumstances"—those who are married, are themselves parents of children, or are living apart from their parents—to consent to care, including diagnosis and treatment of HIV infection. In addition, many states have laws specifically authorizing minors to give consent for HIV testing. Furthermore, several other states indirectly authorize minors to consent to diagnosis and treatment of HIV infection by either (1) stating that HIV/AIDS is an STD and permitting minors to consent to diagnosis and treatment of STDs, or (2) stating that HIV/AIDS is a reportable, infectious, or communicable disease and minors are authorized to give consent for the diagnosis and treatment of such conditions. As a result, adolescents in well over half of the states can consent to diagnosis and treatment of HIV infection, although some laws may limit the care to testing.

Clinicians caring for adolescents should know the laws regarding medical treatment of minors in their locale. Some health-care workers may feel a conflict between the desire to honor a minor's right to confidentiality and the desire to involve a parent or other adult. In addition to being aware of laws supporting an adolescent's right to confidential care for STDs, providers should realize that by disclosing confidential information they may undermine the ability of any provider to care for the adolescent in the future, particularly with regard to these sensitive issues.

HEALTH-CARE UTILIZATION, CONFIDENTIALITY, AND COMPLIANCE

The data suggest that U.S. adolescents obtain health care for all types of problems less often than older or younger individuals. In 1985, U.S. adolescents 10–18 years of age made an average of 1.6 visits to private, office-based physicians, compared with the national average of 2.7 for all ages.[193] Barriers to care relate to adolescents' stage of development. They may wish to arrange care on their own but lack knowledge of or transportation to available services. Since their parents usually have the insurance or Medicaid information, adolescents may be unable to document coverage, and they usually cannot pay for their care themselves. They may be put off by child-oriented waiting rooms or feel unwelcome in facilities that are geared to adults. When adolescents do obtain care, they may be seen by clinicians poorly trained in adolescent issues. From the adolescents' perspective, information about services or the services themselves may be unavailable. As a result, adolescents and young adults have more limited access to health care than other individuals, with 15% of adolescents unable to identify a routine source of care.[194] Obtaining STD-related health care presents even more problems for young people. Over 37% of tenth-grade students did not know where to get treated for STDs and over 40% would be embarrassed to ask a doctor about symptoms related to the genitourinary tract.[195] Adolescents are very concerned about confidentiality and claim that they would not seek care for problems relating to sexuality if they believed their parents would find out.[196] This is particularly true for sensitive issues, such as STDs.[197] In one large national survey, one-quarter of those in middle/high schools indicated they had not sought needed care, and the reason in 35% of cases was that they did not want to tell their parents.[198] In another such survey, one-half of single women less than 18 years of age who were receiving family planning services indicated they would stop using the clinic if their parents were notified about their use of contraception and an additional 12% would not use services such as STD care; however, only 1% indicated they would stop having sex.[199] To some extent, this observation speaks to the anticipated effect of recent attempts to mandate parental notification.[200] Likewise, it is worrisome that over one-third of tenth-graders in a national survey thought that the health department would inform parents about STDs and that most clinics required parental consent to treat STDs.[195] Furthermore, over half of sexually active 15–17-year-olds indicated that they would like more information about where to go to get tested for HIV or other STDs.[201] The general lack of knowledge about STDs among adolescents is a serious concern and undoubtedly influences health-care seeking. In the same survey among sexually active 15–17-year-olds, 20% believed that STDs can only be spread when symptoms are present; 25% did not know that STDs can cause problems with fertility; and of those sexually active teens who had not been tested for STDs, 53% thought they were not at risk and 33% did not know where to go to get tested.[202]

Either because they are not sufficiently trained or they are unaware of or unwilling to address the needs and desires of their young clients, physicians frequently are not useful sources of STD information for adolescents. Although many young people are concerned about STDs[203] and would like more information from their doctors, a survey among college freshmen found that 79% had never received counseling about STDs.[204] A 1997 survey among a school-based sample of adolescent boys and girls found that among those who had made a health-care visit in the past year, 61% wanted to discuss STDs, 65% to discuss drugs, and 59% wanted to discuss smoking and other issues. Unfortunately, a third never discussed any of these topics with the provider.[205]

In many countries STD treatment for females is seen in the most stigmatizing terms,[206] and unmarried young women are too ashamed to access care, such as family planning services, where needed STD treatment can also be obtained. Despite the attention and education concerning HIV infection, adolescents, particularly females, are not informed about STD symptoms. A population-based study in Ethiopia found that 90% of young females had untreated symptoms such as discharge and irritation that warranted care but which the women accepted as normal.[207]

In the United States, improvement in STD and HIV services for adolescents may require that managed care organizations

address the unique situations posed by and facing young people. Fee-for-service providers or primary-care providers who function as the "gateway" to the system may not be well attuned to the needs of adolescents. School-based clinics with a full range of services are among the few sources of accessible, affordable, and comprehensive care for adolescents.[208] Many such clinics provide reproductive health services that include counseling, gynecologic examinations, and the diagnosis and treatment of STDs. However, such clinics are available to only 2% of the nation's students[209] and are threatened by unstable financing.[210]

Contrary to "conventional wisdom," young people and adults adhere to prescribed regimens equally well,[211,212] although compliance with HIV treatment has been a challenge for adolescents.[213] Compliance is often dependent upon provider behavior and can improve when clinicians explain the rationale for treatment. Providers tend to underestimate adolescents' knowledge and the obstacles that adolescents face in implementing medical instructions. Studies suggest that extra efforts on the part of providers can greatly improve compliance.[214]

Advances in STD treatments and diagnosis may be particularly helpful in improving care for adolescents. Convenient, effective treatment regimens such as azithromycin permit single-dose treatment of chlamydia. DNA amplification tests for chlamydia performed on urine or self-collected vaginal swabs expand access for adolescents by allowing specimens to be obtained in street settings,[215] in school clinics,[216] at other community locations,[15] and from general school populations.[16,217] Specimens can even be mailed in.[218,219]

CURRENT AND FUTURE DIRECTIONS TO IMPROVE STD PREVENTION AMONG ADOLESCENTS

In the United States, over the past decade, there has been a trend toward decreased acceptance of teenage sexuality.[220] Fewer high school students have had sex and those who had sex began at a later age and use condoms more consistently,[149] suggesting that changes in societal norms may have had an impact on adolescent sexual behavior.

However, despite these positive behavioral trends, STDs remain endemic among adolescents and young adults, and the arsenal of prevention strategies is limited. Most successful programs have focused on modifying individual behaviors associated with acquiring HIV and have not emphasized factors associated with transmission (i.e., targeting core groups and networks). Similarly, there have been barriers to the dissemination of efficacious programs and limited data on their effectiveness when taken to scale.[221] In addition, few studies have focused on addressing broader structural determinants of risk that exist at the community level such as the lack of economic opportunities and social support for youth who reside in the most affected communities.[222]

In this section, we will describe what has worked, where there are challenges, and promising new approaches in areas of behavior and treatment. We will leave discussion regarding vaccines for the other chapters (see Chapters 99 and 100).

BEHAVIORS

Individual-level cognitive behavioral interventions

Over the past 20 years, several cognitive-behavioral interventions to reduce adolescents sexual risk behaviors have been developed and evaluated. These interventions have focused on outcomes that include delayed onset of sexual intercourse, abstinence, consistent condom use, and the number of sexual partners. Empirical evidence suggests that such programs can achieve their desired behavioral outcome,[223] and recent data indicate that some have been associated with decreased STD incidence.[224,225] Several interventions (but not all[226]), tested in randomized trials, were effective in reducing risk among youth accessed in school, clinic-based settings or in the community,[227–229] and among runaway youth in shelters.[230] Internet and computer programs are now being developed and tested that may more cost-effectively deliver these interventions.[231] Further enhancements to these interventions have included the addition of a component to enhance parental monitoring.[232,233] Parental monitoring has gained attention as an intervention because of its association with delay of sexual onset and discouraging selection of high-risk sex partners. Despite these successes, the dissemination of these efficacious programs has not occurred at the level they merit, perhaps due to costs and competing social values about adolescent sexuality.

In the United States, not only is there a failure to implement and scale-up programs with demonstrable efficacy, but also, as a result of political and cultural forces, so-called "abstinence-only" curricula have been adopted by an increasing number of states and locales. Such curricula lack evidence of effectiveness[234] and have few of the characteristics of those programs that have been shown to be efficacious.[223,235] As a result of the changes in the curricula that have been presented, fewer adolescents in 2002 indicated they had instruction in use of birth control than in 1995.[236] Early analyses from the AddHealth cohort had, in fact, suggested the promise of an abstinence-only approach, since those students who had given "virginity pledges" were more likely to delay onset of sexual activity. However, follow-up evaluation of the cohort indicated that STDs were at least as prevalent among the individuals who had given those pledges as among those who had not. Disturbingly, those who had pledged were also less likely to have tested previously for STDs and were less likely to use condoms when they had initiate intercourse.[237]

Social marketing intervention

The use of mass media has been effective in disseminating information and, in at least one instance, promoting a specific sexual behavior change among young people. In countries such as Zaire and Ghana, mass media campaigns were associated with increases in knowledge and awareness of HIV among adolescents,[238] and a Swiss multimedia campaign significantly increased condom use among adolescents and young adults,[239] although neither the number of partners reported nor the percentage of adolescents who reported being sexually active decreased. To further focus prevention efforts, some health information campaigns addressing HIV prevention among adolescents have used principles from social marketing, and tailored messages to specific audiences; Kennedy et al. demonstrated that increasing adolescents' exposure to STD-related risk reduction messages with a program that included public service announcements, posters, small media, and peer outreach was associated with greater likelihood of condom use with main partners.[240]

Promising new approaches

Youth development interventions. Observational studies have identified those community assets or resources available for youth that are associated with better developmental outcomes. Studies have also shown that youth who feel connected to other individuals, schools, families, or peers have more favorable developmental outcomes.[241] One strategy for STD/HIV prevention, which has been evaluated primarily for pregnancy prevention,[242–244] is to harness the power of the youth development perspective to reduce STD/HIV risk. Potential mechanisms of action could range from less frequent sexual behavior, to safer sexual behavior, to selection of less risky partners. This has also been used in the United States for prevention of adolescent substance abuse.[245]

Structural intervention

School- or community-level policies, practices, or programs can have a profound effect on STD/HIV risk. These structural determinants of risk operate outside the control of the individual, but nonetheless may shape behavior and individual risk. Examples of structural determinants include school policies on condom distribution. Some schools have tried to overcome the barriers adolescents encounter in obtaining condoms. In the United States, over 400 schools have condom availability programs.[246] In this controversial approach,[247,248] most of the schools make condoms available through school personnel, with only a few making condoms available through peers, baskets, bowls, or vending machines—the latter approaches being the more effective in increasing availability.

Partner and networks intervention

Over the past decade, studies have revealed the importance of sexual partners and networks on risk of exposure to STD/HIV. Currently there are no interventions that leverage this information to prevent STDs in adolescents. However, there is no doubt that interventions will be developed that will influence individual partner selection or network structure, composition, and STD prevalence.

EARLY DETECTION AND TREATMENT

The strategies to increase early detection and treatment can be divided into (1) alternative-site STD/HIV testing; (2) increasing adolescent care seeking; and (3) improved quality of care.

Alternative-site testing

The advent of NAAT and their use for urine-based STD screening have made testing in nontraditional settings possible, including schools, jails, street, CBOs, home (with Internet-mediated mail-in), and other social venues.[249] This strategy is particularly useful for asymptomatic infections and especially those in men. The lack of symptoms delays care seeking. Many women may be tested for asymptomatic STDs because they seek care for family planning services. However, men are less likely to seek care and thus alternative-site testing is essential if asymptomatic men are a target.

Care seeking

Studies have shown that many youth fail to access STD services despite their risk of infections. Adolescents are relatively limited in their knowledge about chlamydia and gonorrhea. Although they report that they are infections that can be transmitted sexually, they are often unaware of their asymptomatic nature and their link to infertility.[250] As such, interventions are necessary to increase youths' STD care seeking. One such program, the YUTHE project, was developed, implemented, and evaluated by the San Francisco Department of Public Health and targeted African American youth residing in a high-morbidity area of the city.[251] Peer staff engaged in street-based counseling and referral and distributed informational materials about testing. The evaluation of the intervention showed that exposure to the program was associated with greater likelihood of being tested for STDs.

A critical issue affecting care seeking for adolescents is the perceived confidentiality of services and existence of local laws that permit adolescents to consent for their reproductive- and STD-related care, without parental permission. Adolescents rate privacy and confidentiality as integral to their decisions about when and where to seek care. Adolescent consent laws represent a structural facilitator of care seeking for youth.

Clinical care

Clinic-based services to diagnose and treat STDs can make a significant difference in prevalence of disease. Many providers do not screen at-risk youth because of their discomfort with sexuality, lack of skills with genitourinary examinations, and time constraints. While NAAT tests have increased the acceptability of screening by providers and adolescents by eliminating genitourinary examinations and reducing time, they fail to address the discomfort issues. Training programs are focused on increasing provider comfort with adolescent sexuality. Systems level quality improvement interventions also have greatest promise for increasing STD testing in clinical settings. Shafer et al. conducted a clinical practice improvement intervention designed to increase chlamydia screening using urine-based tests for sexually active adolescent girls during routine checkup visits. They demonstrated that, by 16–18 months, the intervention clinics screened a higher percentage of girls compared to control facilities.[252]

In summary, there are effective strategies which, if coordinated and implemented broadly, should result in healthier behavior and lower rates of STDs among adolescents. Effective health education messages can be provided with consistency across the different levels of social context of adolescents' lives,[253] and educational and health service activities can be systematically linked across schools, media, community organizations, and health-care settings. Clinicians can be trained in effective techniques for communicating with young people and their parents. Providers, together with adolescents, can conduct a meaningful assessment of STD risk with appropriate counseling and treatment. Prevention and care for adolescents must be accessible, affordable, and comprehensive, and it must be provided by professionals who are knowledgeable and committed to caring for young people, in communities and cultures attentive to young people's needs.

12 Female Sex Workers and Their Clients in the Epidemiology and Control of Sexually Transmitted Diseases

James F. Blanchard and Stephen Moses

INTRODUCTION

Sex work entails the provision of sexual services for money or its equivalent, and female sex workers (FSWs) are those women who engage in such work. Clients are those who purchase sex from FSWs. Reducing the transmission of STDs, including HIV, in the context of sex work is a global public health imperative due to the obligation to protect and promote the health of FSWs and clients, and to the strategic importance of interrupting transmission to and from these subpopulations as a means of controlling STD and HIV epidemics.[1–4] Sex workers are generally at high risk of acquiring STDs because they often have many sexual partners [5–13] and many of those partners also have multiple partners.[14–18] Moreover, FSWs are often in highly vulnerable situations or environments that impede their ability to reduce their risk of acquiring STDs and to seek treatment to shorten the duration of STD episodes. Economic needs and the exploitative working environments experienced by many FSWs reduce their freedom to choose the number and types of clients and other sexual partners, and impede their ability to negotiate the use of condoms.[10,19–23] The vulnerability of FSWs is exacerbated by the fact that they are highly stigmatized in many societies, and sex work is criminalized in many countries.[24,25] This often hinders the provision of programs and services and reduces the ability of sex workers to access them.

The strategic importance of STD prevention in the context of female sex work is due to the fact that FSWs and their clients are often at the center of important sexual networks that greatly influence the overall transmission dynamics and epidemiology of STDs. Although the relative epidemiologic importance of sex work interventions in controlling STD epidemics varies according to the pathogen, the prevailing sexual network patterns, and the phase of the epidemic, in many locations these interventions form perhaps the single most important STD control strategy.[26–29]

In this chapter, we provide an overview of the general dimensions and contours of female sex work organization and practice, with an emphasis on the aspects that relate to the epidemiology and control of STDs in the sex work setting. In so doing, we recognize that the complex social, cultural, gender, and public health issues related to STD control in female sex work defy generalization. Moreover, the organization and practice of sex work is highly diverse and in many locations, it is evolving rapidly. Therefore, STD control strategies should be tailored to the local social, cultural, and epidemiological setting.

TYPOLOGY AND SOCIAL CONTEXT OF FEMALE SEX WORK

Sex work, broadly defined, exists in all societies. However, the extent, typology, and organization of sex work are highly variable between and within countries. An assessment of four cities in Africa found that the estimated number of FSWs varied between 10.1 and 19.1 per 1000 men.[30] A high variability in sex work volume was also found in Saratov Oblast, Russia, where the estimated number of sex work contacts in different cities ranged from 32,800 to 730,000 per 100,000 population per year.[31] A recent review article summarized studies estimating the relative size of the FSW population and estimated the proportion of urban adult females engaging in sex work in different global regions as follows: 0.4–4.3% in sub-Saharan Africa cities, 0.2–2.6% in Asia (national estimates), 0.1–1.5% in ex-Russian Federation, 0.4–1.4% in East Europe, 0.1–1.4% in West Europe, and 0.2–7.4% in Latin America.[32] Some variability in these estimates can be attributed to differences in how sex work is defined and on estimation methods.

Different approaches have been used to classify sex work typology.[33,34] At a general level, sex work has been classified as being either "direct" or "indirect."[33] According to this classification, "direct" sex work refers to those circumstances where the exchange of sex for a fee is clearly the primary purpose of the interaction. This includes sex work that occurs at venues which are explicitly maintained for this purpose, such as brothels, and circumstances where solicitation for paid sex occurs in less formal settings, such as on the street, in bars

and pubs, or by telephone contact. For women engaged in indirect sex work, the provision of sex for a fee is generally opportunistic and more often a source of supplemental income than among direct sex workers.[19,35,36] Examples include women who work in massage parlors or as dancers in clubs and will also accept money for sex from some patrons.[19,37] Another classification divides sex work and sex workers into "formal" and "informal" types.[34] In this rubric, "formal" sex work refers to situations wherein FSWs are connected to a formal structure that facilitates the commercial transactions, usually at specific locations such as brothels, lodges, or private homes. In contrast, "informal" sex workers tend to work alone and from nonspecific locations, such as on the street, at market places, and sites where clients can be encountered such as bars, truck stops, and at bus and train stations.[38–42]

While these high-level classifications encompass a broad spectrum of sex work, there is often considerable overlap between categories, and individual FSWs often do not clearly fit into one category or move between these categories periodically. Moreover, such broad classifications do not provide a sufficient basis for understanding the social organization of sex work or the level of vulnerability and risk experienced by sex workers in the local context, which is necessary for planning appropriate programmatic responses. For that purpose, a framework that is structured around the diverse factors that shape the social organization of sex work is helpful. Here we present a conceptual framework that links the various societal, local environmental, and individual characteristics of sex workers to the various ways in which sex work is organized and practised (Fig. 12-1). Societal factors include the broad economic environment, along with social and cultural norms, including gender roles and expectations. These societal level factors influence both the demand for sex work (i.e., proportion of men seeking paid sex) and the supply and characteristics of sex workers. For example, the dramatic changes in the political, social, and economic circumstances in the former Soviet Union and Eastern Europe during the 1990s resulted in an upsurge in the number of FSWs.[31,43,44] Similarly, broad economic and social changes in China, including increasing numbers of mobile and migrant male laborers and the ballooning male:female sex ratio, have influenced the volume and patterns of sex work.[42,45] The local environment in which sex work exists includes the local level of tolerance or suppression, the level of criminalization of sex work, the size and nature of the client population, and the presence of local organizers or controllers of the sex work structure. These factors have a more proximal influence on the individual sociodemographic characteristics of those who enter into sex work and how sex work is organized and controlled locally. For example, longstanding social and cultural traditions and contemporary economic deprivation in parts of rural India have fostered the emergence of a large number

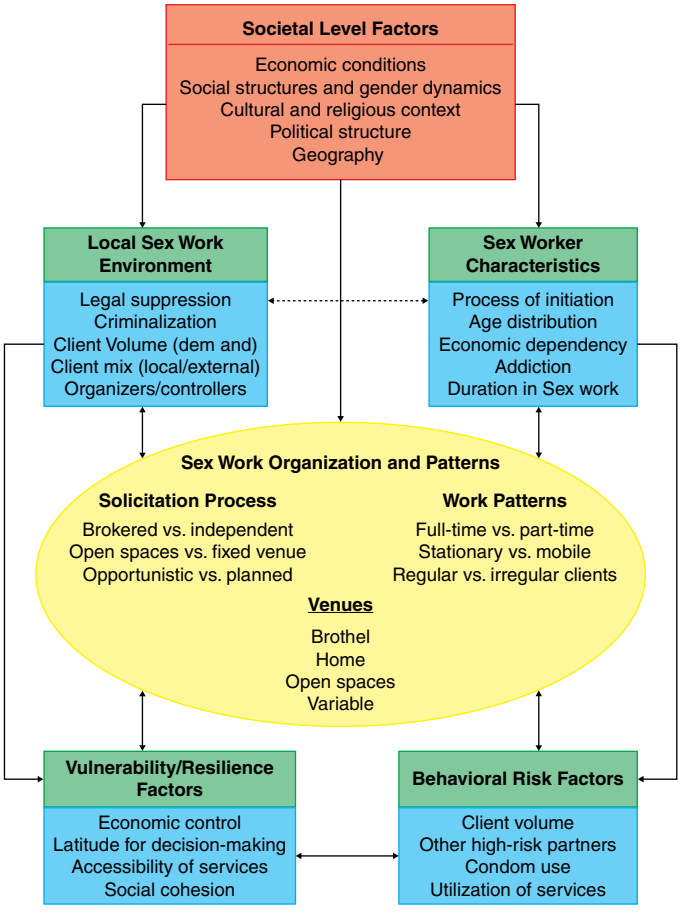

FIGURE 12-1. Conceptual framework for describing the relationship between determinants and patterns of sex work in a population.

of rural FSWs, many of whom migrate to large cities for economic gain.[46,47] Local social and economic factors, including the presence of criminal organizations, have played a major role in shaping the nature of the sex worker population and the organization of sex work in parts of Russia as well.[31,44] At the individual level, the sociodemographic characteristics of FSWs also contribute to the typology and organization of sex work within an area. For example, in some locales, it has been observed that FSWs who have insufficient income from other employment and dependent children are inclined to work as FSWs part-time, and less often work in brothels or other established sex work venues.[35,46]

Together, these factors shape the basic organization and practice of sex work within a particular environment, and are relevant for the STD epidemiology and transmission dynamics and for the design of program responses. There are three important considerations in describing the organization and patterns of sex work. The first is the solicitation process, which describes the way in which FSWs and client populations encounter each other (see Table 12-1 for examples). In some cases, this process is not much under the control of the FSW, but rather is controlled by others such as madams, pimps, or other brokers. In other circumstances, sex workers

Table 12-1. Selected Examples of Different Processes for Client Solicitation

Solicitation Processes	
Brokered	**Independent**
"Falang xiaojie" ("beauty parlour girl") in South China are highly controlled by managers or "pimps" who often determine how many and which clients are to be entertained[48]	"Roadside girls" in Zhengzhou, China, solicit clients independently and entertain them at "mini-motels"[9]
Sex work concentrated in "tochkas" along major thoroughfares in Moscow, Russia, where pimps, guards, and drivers largely determine client–sex worker interactions for clusters of 15–25 sex workers[44]	Individual sex workers, many of whom are drug users, who work as "freelancers" in Balakovo, Russia[31]
Solicit in Open Spaces	**Solicit at Fixed Locations**
Street-based sex workers in Milan, Italy, most of whom are immigrants from other European countries[11]	Brothel-based sex workers in Cotonou, Bénin, with lower income than other sex workers[30]
Street-based sex workers in towns and cities of Andhra Pradesh state of South India, mostly local[8]	Large registered brothel in Daulatdia, Bangladesh[22]
Opportunistic Client Solicitation	**Planned/Organized Solicitation**
Homeless sex workers in Miami, FL, who intermittently sell or trade sex, often to obtain shelter, food, or drugs[10]	Brothel-based sex workers in Kolkata, India, who work in Sonagachi, a large and well-known "red light" area[49]
"Indirect" sex workers in Zhengzhou, China, who work in hair salons and massage parlors and occasionally provide sexual services for clients[9]	Home-based sex workers in rural India, many of whom own and work out of their own home[46]

operate as free agents and largely decide where to find clients and which clients they will choose. Some solicitation occurs in open spaces such as street corners, parks, bus stands, and markets, whereas in other circumstances, the solicitation occurs in a fixed venue such as a brothel or hotel. This is relevant because solicitation that occurs in an open setting can leave FSWs more vulnerable to harassment and intimidation by a variety of individuals, including the police and local "goons." Finally, some solicitation is planned, in the sense that the FSW has a specific intent to seek clients at a particular time and place and can prepare accordingly, including ensuring that she has condoms in case the client does not. In other circumstances, FSWs will be solicited in a more ad hoc way, which can leave them more vulnerable to high-risk sexual encounters. There is also variability in sex work patterns (see Table 12-2 for examples). In some locations, there is a high proportion of part-time FSWs who tend to have fewer clients, whereas in other locations a high proportion of FSWs are full-time and have a high client volume. Many FSWs are highly mobile and therefore often working in unfamiliar surroundings, which can be a source of vulnerability. Some FSWs have a relatively high proportion of their contacts with regular clients, whereas others almost never have repeat clients. There is some evidence that over time, condom use with regular clients decreases, perhaps due to an enhanced level of trust.[54] Altogether, the organization and patterns of sex work interact with the local environmental conditions and the individual FSW characteristics to influence the level of vulnerability and risk experienced by sex workers (Fig. 12-1). For example, FSWs who are in new environments where there is extensive control exerted over client volume and choice have less latitude for decision making and will be more prone to high-risk sexual encounters. Conversely, FSWs who are in a familiar environment with a high degree of social cohesion will be in a much stronger position to choose the number, type, and circumstances of their client encounters, and will also be in a stronger negotiating position if the client is reluctant to use a condom.

SEX WORK AND STD/HIV TRANSMISSION DYNAMICS

Prevention of STD and HIV transmission to and from FSWs is often critical to limiting the establishment and expansion of these epidemics at the population level. The role of sex-worker and client groups in the epidemiology of a particular STD depends upon the frequency and nature of commercial sex transactions and the transmission dynamics of the STD.[55] It has been noted that in the absence of effective treatment and prevention programs, the transmission efficiency and duration of infectivity are relatively stable characteristics of STD pathogens.[56] The frequency of interaction between an

Table 12-2. Selected Examples of Different Work Patterns of Female Sex Workers

Work Patterns	
Part-Time	**Full-Time**
Sex workers in a suburb of Mombasa, Kenya, the majority of whom also earn money from small businesses such as selling foodstuffs[35]	Sex workers in the port city of Diego-Suarez, Madagascar, many of who work full time and are registered with an association of sex workers[50]
"Indirect" sex workers in Nha Trang City, Vietnam, who often work in entertainment venues and are more likely to entertain foreign clients than direct sex workers[5]	
Stationary	**Mobile**
Street-based sex workers in South India, most of whom live in the same district where they solicit clients[46]	Migrant sex workers in Madrid, Spain, many of whom have migrated from South America[51]
Local sex workers in a Ugandan trading town who tend to be impoverished and work in back-street bars serving poor local men[19]	Rajasthani rural traditional FSWs who move from their rural villages to large urban centers, predominantly to Mumbai[47]
Regular Clients	**Irregular Clients**
Some traditional *Devadasi* sex workers in rural parts of Karnataka state in South India who often have one or more regular clients[47]	Sex workers in Cotonou, Bénin, who do not have many repeat clients[3]
Sex workers in Nyanza, Kenya, who often have multiple long-term regular clients[52]	Sex workers at truck stop in KwaZulu-Natal Province, South Africa, who report that many of their clients were truckers from other African countries[53]

infected individual and a new susceptible is therefore the critical determinant of the reproductive rates of STDs. Sex workers and their clients, because of their high rates of partner change, are therefore important in the transmission dynamics of all STDs, including HIV infection. However, it is also important to consider that the centrality of sexual networks involving FSWs will differ according to the STD pathogen. Garnett has pointed out that epidemics of STD pathogens that are highly infectious, but have over a relatively short duration, such as syphilis, gonorrhea, and chancroid, are particularly dependent on subpopulations with high rates of partner change.[57] As STD treatment and prevention programs improve in quality and expand in scope, the duration of infectiousness and perhaps transmission efficiency of the targeted STDs should decrease.[58] As a result, these STDs will increasingly become concentrated in networks where there is a high rate of partner change, including FSWs and their clients. Furthermore, because these groups often experience stigmatization, discrimination, and marginalization, their access to STD-related health care may be limited, resulting in increased durations of infectiousness. Therefore, it is anticipated that control of such epidemics would depend greatly on effective interventions in FSW populations.

FSWs and their clients can also be important for the spread and persistence of HIV infection. However, compared with most curable STDs, HIV is less easily transmitted, but has a longer duration of infectiousness. Therefore, the centrality of subpopulations with high rates of partner change, including FSWs, is less predictable, particularly in more advanced HIV epidemics in which most new infections occur in longer-term, stable partnerships. Mathematical models suggest that an HIV control strategy that achieves condom use in 75% of FSW–client sexual contacts could be sufficient to control the HIV epidemic in India.[28] Similarly, empirical data and mathematical models have shown that the HIV epidemic in Cotonou, Bénin, is still largely dependent on transmission chains that include FSWs.[3] There is also at least anecdotal evidence that programs that achieve a relatively high level of condom use in FSW–client contacts have been associated with a reduction in HIV prevalence in the general population in diverse settings such as Nairobi, Kenya,[59] Kolkata, India,[60] and Thailand.[61] However, the contribution of sexual transmission related to sex work to new HIV infections appears to have changed over time in Kenya and Cambodia.[62] Mathematical modeling has indicated that the introduction of a single intervention that reduced transmission to and from FSW populations, while very effective in controlling HIV in a setting like India, would not have as substantial an impact in Botswana,[28] largely because of the high HIV

prevalence in the general population and the higher frequency of concurrent partnerships outside of sex work. Another study that modeled HIV transmission for a population in rural Uganda showed that transmission in sex work settings was very important early in the epidemic, but declined substantially over time as HIV prevalence in the population rose.[63]

Another key strategic consideration relates to the epidemiologic synergy between HIV and other STD pathogens. Since other STDs, especially those which cause genital ulcers, greatly facilitate the transmission of HIV, reducing the incidence and prevalence of these pathogens in a population is an important component of HIV control.[64] This is particularly true at phases of an HIV epidemic when much of the HIV transmission is occurring in short-duration partnerships. When such circumstances exist, programs that reduce STD transmission in FSW populations are likely to be of critical strategic importance.

In addition to the general importance of sex workers and clients in the transmission of STDs, mathematical modeling suggests that the particular patterns of sex worker–client sexual partnerships also influence the expansion and persistence of STDs in a population. Recent work by Ghani and Aral suggests that STD persistence and prevalence are greater if clients tend to visit different sex workers, rather than repeatedly visiting the same FSWs, since the more random sex worker–client partnership patterns result in denser sexual networks.[29]

SEX WORK AND THE EPIDEMIOLOGY OF SPECIFIC STDs

GONOCOCCAL AND CHLAMYDIAL INFECTIONS

In 1959, Rosenthal and Vandow, finding a decline in the prevalence of gonorrhea among FSWs arrested for soliciting in New York City (from 23.6% in 1946 to 5.2% in 1956), stated that "the prostitute is no longer the major vector of venereal disease" and that "the promiscuous amateur" was filling the role.[65] In fact, the prevalences of *Neisseria gonorrhoeae* and *Chlamydia trachomatis* infection among FSWs have been found to be highly variable and to depend, among other things, upon the frequency and nature of sexual encounters, characteristics of clients, levels of condom use, interactions with HIV infection, and frequency of medical examinations.[1] More recent examples of prevalence levels in a variety of sex worker populations in developing countries are shown in Table 12-3.[35,36,66–73] Lower prevalence of gonorrhea and chlamydial infection is generally reported from developed countries than from developing countries,[25,74,75,76] but this is not always the case. Among sex workers attending clinical services in London, England, the prevalence of gonorrhea declined from 4.5% in 1985–1992 to 1.1% in 1996–2002.[25] During the same time period, the prevalence of chlamydia declined from 10.7% to 4.8%. The relationship with HIV infection is also quite variable. For example, very low rates of gonorrhea and

Table 12-3. Prevalence of *N. gonorrhoeae* and *C. trachomatis* Infections in Populations of Female Sex Workers in Developing Countries

chlamydial infection have been reported from sex worker populations in Zimbabwe[26] and Mombasa, Kenya,[35] where HIV prevalence is very high, and high rates of gonorrhea and chlamydial infection have been reported from sex worker populations in Bangladesh[7] and Indonesia,[70] where HIV rates are very low. The interactions are complex, and each context must be evaluated individually.

The incidence of gonorrhea and chlamydial infection is also variable. Very high incidences have been reported from developing countries in sex workers of lower socioeconomic strata, for example, in Nairobi an 11% weekly incidence of gonococcal cervicitis[77] and in Bangkok 31.7 new gonococcal infections and 43.1 new *C. trachomatis* infections per 100 woman-months of observation.[78] A case-control study among predominantly African American gonorrhea patients in San Francisco in 1988 found that 32% of the female patients and none of the controls had received money or drugs in exchange for sex.[79] In Fresno, California,[80] and Colorado Springs, Colorado,[81] programs of screening or mass treatment for gonococcal infection in FSWs resulted in declines in the incidence of gonococcal infections in the general community. These data suggest that in some areas of the world and in certain subgroups, sizable fractions of gonococcal and chlamydial transmission are attributable to sex workers and their clients. Since, in addition, many non-sex worker acquired infections are likely secondary to sex worker acquired infections, successful intervention in sex worker/client core groups is crucial to the control of gonorrhea and chlamydial infection.

GENITAL ULCER DISEASES

The STDs that cause genital ulceration are particularly important because of their strong association with risk for HIV infection.[64] Syphilis and sex work have long been associated. At the height of the U.S. syphilis epidemic in the early twentieth century, 25% of all cases of syphilis were estimated to have been transmitted through commercial sex.[82] Sex work linked with crack cocaine use has been identified as an important contributor to syphilis transmission in the United States.[83] North American epidemics of syphilis in heterosexuals have been described in Fresno, CA,[80] Winnipeg, MB,[84] Edmonton, AB,[85] Baltimore, MD,[86] and Vancouver, BC.[87] Each of these outbreaks has been associated with sex work in urban core areas. In Amsterdam, FSWs who use "hard" drugs have been identified as being at high risk for syphilis.[88] Since the prevalence of syphilis in the general heterosexual population is extremely low, it seems plausible that a large proportion of the heterosexual transmission of syphilis cases in North America and Europe is attributable to FSWs and their clients.

Syphilis is also highly prevalent among FSWs in developing countries. In studies from Honduras,[89] Senegal,[68] Madagascar,[90] India,[69] Cambodia,[6] and Papua New Guinea,[66] over 18% of sex worker populations sampled were found to have syphilis prevalences of over 18%. These data suggest that in developing countries as well, commercial sex plays an important role in the spread of syphilis.

Chancroid has been highly associated with FSWs and their clients, particularly those in lower socioeconomic strata, in virtually every major North American outbreak that has been reported. In several modern epidemics of chancroid (Winnipeg, MB,[91] Orange County, CA,[92] South Florida,[93] New York City,[94] and New Orleans[95]), sex work has been linked with much of chancroid transmission, often in association with drug use and the sale of sex for drugs. In Nairobi, an area of high chancroid endemicity in the 1980s, 66% of men with chancroid attending an STD clinic reported a paid sex partner as the source contact.[96] In a study among one group of Nairobi sex workers during the same time period, the prevalence of culture-proven chancroid was 13%.[97] However, as STD control programs have improved in developing countries, chancroid rates have declined, and chancroid now represents a much smaller proportion of genital ulcer disease.[98]

The reasons for the association between chancroid and lower-socioeconomic-stratum sex work are not entirely clear. As the epidemiology of chancroid is understood, most female transmitters of *Haemophilus ducreyi* have clinical genital ulceration.[96] It may be that poor women, in need of income and with restricted access to health care, ignore ulcer symptoms rather than forgo income for several days. In addition, because of chancroid's relatively short duration of infectivity (compared to other STDs), chancroid epidemics can only be maintained in populations that have very high rates of partner change,[99] such as those seen typically among lower-socioeconomic-stratum FSWs.

Infection with herpes simplex type 2 (HSV-2) is extremely common among FSWs, and because HSV-2 infection increases the likelihood of both HIV acquisition in HIV-uninfected individuals, and HIV transmission in HIV-infected individuals, HSV-2 infection plays a key role in HIV transmission dynamics.[100] Studies of FSWs in Kenya,[67] South Africa,[101] Tanzania,[36] and Mexico[72] have found HSV-2 prevalences ranging from 70% to over 80%. In a prospective study of HIV seronegative FSWs in Nairobi, Kenya, 72.7% were HSV-2 seropositive at baseline.[67] Over the course of over two years of observation, HIV seroincidence was approximately 4 per 100 person-years, and HSV-2 seropositive FSWs were over six times more likely to acquire HIV infection than women who were HSV-2 seronegative. In a prospective study of HIV seronegative FSWs in Kwazulu Natal, South Africa, 84% were HSV-2 seropositive at baseline.[101] When HSV-2 seroconversion was analyzed as a time-dependent covariate, the risk of HIV seroconversion was six times higher among women with incident HSV-2 infection compared to those with prevalent HSV-2 infection. Ongoing clinical trials will elucidate the role of HSV-2 suppressive therapy in

reducing the risk of both acquisition and transmission of HIV infection.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Human immunodeficiency virus infection is, of course, the most important STD associated with sex work. FSWs and their clients are major groups at risk of acquiring and transmitting HIV. The first evidence that FSWs were at risk for HIV infection came from a study reporting lymphadenopathy and altered T-cell subset ratios among FSWs in New York City.[102] FSWs in Africa were first identified as a risk group for HIV infection in the mid-1980s, when several studies found an extremely high prevalence of HIV infection in women selling sex. The HIV prevalence among FSWs in an early study in Kigali, Rwanda, was 88%.[70] At about the same time in Nairobi, the HIV prevalence was 66% among lower-socioeconomic-stratum FSWs and 31% among higher-socioeconomic-stratum FSWs.[103] Subsequent studies in Uganda and Zaire yielded similar results.[104,105] In the early years of the HIV/AIDS epidemic, high HIV prevalences and incidences were also observed in some Asian countries. In national HIV surveillance conducted in Thailand in 1993, the median HIV prevalence among FSWs was approximately 30%.[106] Annual HIV incidence among FSWs in Thailand was also very high, ranging from 24% to 29%.[107] The high prevalence of other STDs among FSWs, as noted above, is also an important factor facilitating HIV transmission. Genital tract infections and inflammation probably increase HIV shedding in the female genital tract, rendering a woman more infectious to a sexual partner.[108,109] Thus, FSWs are likely more efficient transmitters of HIV because of their high prevalence of genital ulcers and other STDs.[110]

In many developing countries, commercial sex is an important factor in HIV transmission. The concentration of HIV infection in urban areas and along major overland trucking and trade routes has indirectly implicated sex work in the spread of HIV through East Africa.[111,112] In a Kenyan study, male STD clinic patients in Nairobi who reported frequent contact with FSWs, as well as past and current genital ulcer disease (both of which are highly sex work associated), were more likely to be HIV infected.[113] In the same population, an HIV incidence of 8% was estimated to have followed a single sexual encounter with an HIV-infected FSW.[114] More recent data from the state of Karnataka in southern India suggest that HIV prevalence in rural areas is associated with the volume of sex work, both in terms of numbers of identified sex workers and reported contacts by clients.[115] However, as with gonorrhea and chlamydial infection, there is wide variability in reports of HIV prevalence among FSW populations in developing countries. In recent studies, these have ranged from 0% prevalence among FSW populations in Papua New Guinea,[66] Pakistan,[116] and Indonesia[70]; under 1% among FSWs in Madagascar,[117] Colombia,[118] and Mexico[72]; 6–14% in Senegal[68] and the Democratic Republic of the Congo[119]; and 30–68% in Kenya,[35] South Africa,[101] Tanzania,[36] Zimbabwe,[35] Cambodia,[120] and India.[69] Reasons for these wide variations in risk are unclear, but may be due to a variety of factors, including differences in exposure (numbers and types of sexual partners, degree of condom use), as well as differences in rates of other STDs, and perhaps the interplay of other biological factors, such as male circumcision practices.

The prevalence of HIV infection has also been studied in North American and European FSWs. Early studies found relatively low HIV prevalence rates.[121,122,123] The prevalence of HIV infection is higher, however, among intravenous-drug-using sex workers. HIV prevalences of over 50% have been found among intravenous as well as non-intravenous (crack cocaine) drug using FSWs in New York and New Jersey.[124] In Amsterdam, 30% of drug-using FSWs have been found to be infected with HIV, and other STDs were also highly prevalent in this group.[125] In European countries, as well as in North America, FSWs frequently acquire HIV infection through intravenous drug use or from intravenous-drug-using sex partners.[126] In North America, the crack cocaine epidemic, with its accompanying sex-for-drugs phenomenon, is probably also responsible for a large proportion of sex-work-associated HIV infections.[127] The substantial number of FSWs infected with HIV suggests potential for transmission of the virus to the general heterosexual population. That this has not already occurred to a greater extent may be a result of high levels of condom use, the use of nonpenetrative sex, the relative absence of other cofactors such as genital ulcer disease, and sexual mixing patterns.

CLIENTS OF SEX WORKERS

Clients play a large role in determining the volume and organization of sex work and the epidemiology of STDs. However, there has been a relative paucity of research to better understand client behaviors and the epidemiology of STDs in client populations. Surveys in Asia found that 6% of men in the Philippines reported buying sex in the previous 6 months, whereas 7% of men in Myanmar and 16% of men in central Thailand reported buying sex in the previous year.[128] One study found that approximately 75% of men in northern Thailand reported having ever visited a sex worker,[129] but this level of client behavior appears to be uncommon in Asia and elsewhere. A survey in Hong Kong found that 12% of men reported visiting FSWs in the past 6 months.[130] In Africa, estimates of the proportion of men visiting a sex worker in the past 12 months from population-based surveys are highly variable, ranging from 1% to almost 30% of adult males.[131] In Nairobi, Kenya, one study found that almost 15% of a sample of men residing in an urban slum reported having purchased

sex from a FSW at least once during the previous 3 months.[132] However, other focused studies have indicated that there is variability between different regions of Africa. A survey of FSWs in four African cities estimated that the number of client–sex worker contacts varied considerably, ranging from 960 to more than 3300 contacts per 1000 men per year.[30] Surveys in the UK[133] and New Zealand[134] found that approximately 7% of men reported ever paying for sex. A more recent telephone survey in Australia found that almost 16% of men reported having ever paid for sex, with 1.9% reporting that they had paid for sex in the past 12 months.[135] Two national surveys in Britain found that the proportion of men who reported paying women for sex in the previous 5 years increased from 2.0% in 1990 to 4.2% in 2000.[14] A recent review article summarizing the findings of various surveys in different global regions found that the median proportion of men who reported "exchanging gifts or money for sex" in the past 12 months was approximately 9–10%, whereas the proportion of men reporting who engaged in "paid sex" or sex with a sex worker was 2–3%.[136] This review also found that there were substantial regional differences, with the median estimates for proportion of men "exchanging money or gifts for sex" of 13–15% in Central Africa, 10–11% in Eastern and Southern Africa, and 5–7% in Asia and Latin America. For "paid sex," regional estimates ranged from 7% in the South African region to 1% in Asia and West Africa. Interpretation of these estimates and the regional differences is constrained by variability in the definitions of payment for sex, and also the likelihood of differential levels of social desirability biases such that men in some regions might be much less likely to report paying for sex than others. This likelihood is supported by the fact that regional differences in the proportion of men who report paying for sex appear much larger than the variability in regional estimates in the relative size of the FSW population.[32]

As discussed above, in addition to the volume of client–FSW contacts, the pattern by which clients select FSW partners will also affect the transmission dynamics of STDs. In particular, when clients tend to visit the same FSW, or the same type of FSWs, the resulting high-risk sexual networks are less conducive to widespread dissemination of STDs, including HIV. For example, a study in the Netherlands found that almost half of the clients frequented only one type of FSW (club, brothel, window, street, home, or escort), and only 3% of clients reported having unprotected sex with more than one type of sex worker in the past 12 months.[54] In Nyanza, Kenya, clients tended to have more steady FSW partnerships,[52] whereas clients in Cotonou, Bénin, did not tend to visit the same FSW, and 10–20% of clients reported having FSW partners both in Cotonou and outside of the city.[3]

A few client studies have also suggested that sexual risk behaviors depend on the circumstances, location, and type of sex worker being visited. For example, clients from Hong Kong who visited FSWs in mainland China, or both mainland China and other places, reported less consistent condom use than Hong Kong clients who only visited FSWs in Hong Kong.[17] It is not clear whether these differences are due to differences in the characteristics of the client groups, differences in the protective behaviors of FSWs, or both. A study of clients in the Netherlands found that the proportion of client–FSW contacts in which a condom was not used varied by the type of sex work, ranging from 3.7% of brothel-based contacts to 23.6% of contacts with escort FSWs.[54]

There has been a paucity of research into the prevalence of specific STDs among clients of sex workers, but the available evidence indicates that clients have a substantial risk of STDs and HIV. A study in Bénin found a relatively high prevalence of gonorrhea (5.4%) and chlamydial infection (2.7%) among clients of FSWs.[137] HIV prevalence was 8.4%, and approximately 2% of the clients had genital ulcers on physical examination. The prevalences of both HIV and gonorrhea among clients were several-fold higher than that found in a general population-based survey of men. Interestingly, HIV prevalence (16.1%), but not gonorrhea or chlamydia prevalence, was higher among the boyfriends of FSWs than among clients. A study in rural Zimbabwe found that men who reported visiting an FSW were three times more likely to report a genital ulcer in the past 6 months.[27] A study of truckers who visited FSWs at five truck stops in South Africa found that the HIV prevalence was 56%.[53]

STD PREVENTION AND CONTROL PROGRAMS IN SEX WORK

From a strategic perspective, the objectives of STD and HIV prevention and control programs in sex work are the same as in other settings: (1) to reduce the number of high-risk sexual encounters in which STDs and HIV can be transmitted and (2) to shorten the effective duration of infectiousness among those who are infected. There are many examples of successful programs in a variety of settings.[34,49] In many cases, consistent condom use in client–sex worker contacts has increased to more than 80%, and there have been substantial declines in the prevalence of STDs in some sex worker and client populations.[3,59] Given the diverse factors that contribute to the vulnerability of FSWs to STDs and HIV, successful programs cannot focus solely on individual/cognitive interventions for behavior change. Instead, the importance of structural–environmental interventions to complement individual level approaches has been recognized.[138,139,140,141,142] Accordingly, Bourcier et al. have adapted the concept of "risk causation" developed by Sweat and Denison[141] to formulate a framework for sex work program development. In this context, they specify four levels of risk causation in sex work: (1) societal (super structural); (2) community (structural);

(3) institutional (infrastructure/environment); and (4) individual.[34] Similarly, Overs has categorized sex work intervention strategies at three levels: (1) individual/cognitive; (2) participation and empowerment; and (3) structural and environmental.[143] This approach emphasizes the importance of incorporating program elements that address both individual level and structural and environmental factors to reduce the vulnerability of FSWs. A key principle in the development of sex work programs is the empowerment of FSWs to take a leadership role in all aspects of program design, delivery, and monitoring. Doing so promotes the development of programs and services that meet the specific requirements of FSWs in a particular location. Moreover, it often contributes to a reduction in stigma and discrimination that prevent FSWs from accessing needed prevention and treatment services. The following sections give a brief overview of four key elements of STD/HIV prevention and control programs in the context of sex work: peer outreach and education; provision of STD clinical management and other health services; promotion of participation and empowerment; and structural interventions to create an enabling environment.

PEER OUTREACH AND EDUCATION

To reduce the risk of STD and HIV transmission, FSWs require the knowledge and skills to negotiate condom use and lower-risk sexual acts (i.e., nonpenetrative sex) with their clients. Therefore, it is essential that programs ensure that there are mechanisms to reach individual FSWs and provide them with the necessary education and training in risk reduction techniques. To achieve this, a central component of most effective programs is peer-led outreach and education. This entails the training of FSWs as peer educators or guides and giving them the responsibility to reach and educate other FSWs, who are part of their social network or work in similar geographic locations.[49,144,145,147] In addition to providing education and building skills, peers are often responsible for ensuring that FSWs in their sphere of work have an adequate supply of condoms, either through direct distribution or through fixed locations ("condom depots") where FSWs can easily access condoms. Peers also often provide direct education to other FSWs on how to negotiate and use condoms with clients. To be effective, peer outreach programs must be tailored to the local sex work environment. In particular, consideration should be given to the diversity of the social networks of FSWs and the different typologies of sex work in selecting and assigning peers.

PROMOTING PARTICIPATION AND EMPOWERMENT

In addition to individual level interventions, effective programs promote participation and empowerment of FSWs. This entails activities such as the organization of social events that promote social cohesion among FSWs. Other programs have effectively promoted participation and empowerment by addressing some of the broader social needs of FSWs with program components such as literacy classes and skills training for FSWs, and child care for their children.[147] Some programs support FSWs to develop skills to earn money from non-sex work sources as a way of reducing their dependence on sex work income, and thereby increase their latitude for decision making with clients. One such project found that those who earned additional income were more likely to increase their condom use with clients and to reduce their number of clients.[148] Other successful programs have fostered the development of self-help groups and collectives of FSWs. These function as a forum for socialization, a structure for promoting greater economic security through collective savings, and an organization that can take collective action to ensure access to social entitlement programs and protect the rights of FSWs.[49,149] There is some evidence that participation in these collectives results in increased knowledge about STD and HIV prevention, and increased condom usage.[149] Although this association might not be causal, it is reasonable to conclude that enhanced social cohesion and increased access to a wider pool of knowledge and skills render FSWs who participate in such groups less vulnerable than those who are socially isolated.

CLINICAL SERVICES

Many FSWs experience a high degree of marginalization and discrimination by health-care providers and therefore do not have adequate access to health services. Moreover, many FSWs are poor, creating a financial barrier to accessing health care. Therefore, providing access to health services, especially for reproductive health, and including STD treatment, is another cornerstone of effective STD/HIV prevention programs for FSWs. Access to such services can be a key motivator for many FSWs to interact with program staff and to participate in program activities.[147] It is important to ensure that health services, and particularly those for STD management, are configured so that they are easily accessible and acceptable to FSWs. This often means establishing clinics in locations that are convenient and ensuring that they are open at times when FSWs are most able to visit them. In locations where there are diverse types of FSWs, different service configurations might be required. For example, full-time street-based FSWs might prefer a fixed and dedicated clinic site close to where they work, whereas part-time home-based FSWs might prefer the option of visiting clinics that are not exclusively and explicitly for FSWs. Regardless of the type of clinic, it is important to ensure that doctors and other health workers at the clinic are both competent and sensitive to the particular concerns and needs of FSWs.

STRUCTURAL INTERVENTIONS

Structural interventions focus on changing the societal level factors that influence the organization of sex work and the prevailing behavioral norms. Perhaps the most notable examples of this approach are the 100% condom campaign instituted in Thailand[61] and the Sonagachi project in Kolkata, India.[49] The Thailand program focused substantially on changing behavioral norms, largely through a policy of enforcement of condom use in brothels. By so doing, there was less reliance on individual FSWs to use condoms and to convince their clients to do so. Instead, a behavioral norm was established and ultimately 90% or more of brothel-based FSWs consistently used condoms with their clients.[61] In contrast, the Sonagachi project focused substantially on changing the perspectives and actions of those who influence the sex trade in the area, including madams, police, and pimps. In so doing, an enabling environment was created whereby FSWs could take an increasing role in program leadership and in advocating for the rights of FSWs. This empowerment, along with the extensive capacity building of the FSW community, resulted in substantial increases in consistent condom use and stabilization of HIV prevalence among sex workers. It has been noted that such structural interventions have not been as successful when tried elsewhere. It is not clear whether the variations in the results are due to differences in the organization of sex work (i.e., controlling structures) and the prevailing political and economic situation, the social and cultural characteristics of the FSWs, the implementation process, or a combination of these factors.[150,151,152] Nonetheless, it has been observed that the most successful programs for FSWs incorporate a substantial focus on addressing the structural barriers to the empowerment of FSWs and the adoption of safer behaviors.[34]

CLIENT INTERVENTIONS

Despite their centrality in STD/HIV transmission dynamics, clients of FSWs have seldom been the focus of targeted prevention programs.[137,153] In general, client interventions have focused on particular client groups such as truckers[101] and miners.[154] However, in many countries these groups form a small minority of all clients; therefore targeting these specific occupational or sociodemographic groups is not a sufficient strategy. Another approach is to develop specific outreach and education services for men at or near sex work locations, for men who live or work near such locations, or who seek sex there.[137] This approach takes advantage of the fact that sex work often has geographic specificity.[155] To motivate men to engage with the outreach team, on-site STD treatment can be offered after testing with a leukocyte esterase dipstick test. Such approaches hold some promise, but more applied research is required to develop effective strategies for male clients.

MANAGEMENT OF SEXUALLY TRANSMITTED DISEASES

As noted above, it is important for STDs among FSWs to be treated promptly and effectively, both because of the health benefits for the FSW and to reduce STD transmission to clients and other partners. In addition to reducing STD transmission, STD treatment may be important in reducing HIV transmission,[64] although randomized community trials of STD treatment for HIV prevention conducted in Tanzania and Uganda have had conflicting results in this regard.[156,157,158] It may be that STD treatment is more important in reducing HIV infectivity among HIV positive individuals with an STD than in reducing HIV susceptibility among uninfected persons.[67] As indicated in the section above, STD rates are often extremely high among FSWs because of their high levels of exposure, and STD control among FSWs and clients can have considerable impact in reducing STD transmission in the general population.[145] However, because of the stigma associated with sex work, FSWs are often marginalized and have limited access to health care. It is important, therefore, to reach FSWs and clients with effective STD treatment and preventive services, which must be accessible, user-friendly, and available at convenient hours.

A review by Steen and Dallabetta has identified three main specific sexually transmitted infection (STI) treatment strategies involving sex workers[159]: diagnosis of symptomatic sex workers, using either etiologic or clinical/syndromic approaches; regular screening of sex workers (regardless of symptoms) with clinical examination and possibly laboratory tests; and periodic presumptive treatment (PPT). Syndromic case management for STIs is most frequently employed for the treatment of symptomatic infections in developing country settings, ideally using evidence-based treatment guidelines. STI services developed and implemented for FSWs in Madagascar include syphilis screening and treatment; presumptive treatment for gonorrhea, chlamydia, and trichomoniasis/bacterial vaginosis during initial visits, and individual risk-based treatment during follow-up visits; and speculum exams, with treatment for genital ulcers, if present.[117] A program of services for FSWs developed in India follows similar guidelines, but presumptive treatment is provided only for gonorrhea and chlamydia, and vaginal infections are treated only when symptoms are present.[160] A study from Bénin has shown that syndromic diagnosis is preferable to laboratory diagnosis of cervical infections (and much less expensive) in this context, even in the presence of high levels of asymptomatic infection, because of low patient follow-up rates.[161] A study from Ghana has suggested that Gram-stained genital smears in FSWs without clinical symptoms or signs can improve diagnostic accuracy for cervical infections.[162] As FSWs are exposed frequently to STIs, examination and treatment must often be repeated. The frequency with which

examinations should occur is unclear, but 3-month intervals would seem to be a minimum and visits should perhaps be even more frequent. In a program in South Africa, FSWs were offered clinic visits at monthly intervals for examination and counseling, and were provided presumptive treatment with one gram of azithromycin at each visit. Significant declines in the prevalences of gonorrhea, chlamydial infection, and genital ulcer disease were observed over time, both among the women themselves and among miners in the intervention area, who largely formed the client population for the FSWs.[163]

Because the detection of asymptomatic cervical infections in FSWs is problematic, even with the use of risk-based algorithms and simple laboratory tests,[164] increasing interest is being accorded to presumptive treatment, either one-time or PPT. Most commonly, antibiotics (usually azithromycin, at times with the addition of cefixime or other drugs) are provided regularly, often at monthly intervals, for the presumptive treatment of gonococcal and/or chlamydial cervical infection, but PPT has also been used in the context of syphilis and chancroid control. In addition to reducing disease burden among sex workers, PPT should have an impact on the bridging populations that interact with FSWs, such as male clients, but the effectiveness of PPT in reducing STD transmission will depend upon the levels of treatable STDs in the FSW and bridging groups, and the rapidity with which STD prevalence rates are reestablished following treatment. PPT has been used over the past several decades with varying degrees of success to control gonorrhea and chlamydial infections among sex workers in the Philippines, South Africa, Madagascar, Kenya, Bénin, Ghana, and Zimbabwe; and to control syphilis and chancroid infections in Indonesia, United States, Canada, South Africa, and Madagascar.[158,164]

There have been only three reported randomized trials involving PPT in sex worker populations. A trial in Kenya showed significant reductions in gonorrhea and chlamydial infection, as well as trichomoniasis, among FSWs provided a monthly dose of 1 g azithromycin (but no impact on HIV incidence), compared to controls receiving a placebo.[67] A trial in Zimbabwe compared PPT regimens of single doses of 1 g azithromycin and 2 g of metronidazole, with or without 500 mg of ciprofloxacin.[26] Declines were observed in both the groups in the prevalences of gonorrhea, chlamydial infection, and trichomoniasis after 1 month of follow-up among FSWs provided with one dose of PPT, but rates rose to pretreatment levels after 3 months, and the prevalence of gonorrhea and chlamydial infection were both very low in general. A placebo-controlled clinical trial in Bénin and Ghana compared women randomly assigned to receive 1 g azithromycin at month 1 and 500 mg of ciprofloxacin at months 2 and 3 in 3-month cycles. No impact of PPT was found on gonorrhea or chlamydial infection prevalence overall, but there was a decline in gonorrhea prevalence among HIV seronegative FSWs.[165] Thus, PPT administration appears to be associated with reductions in the prevalence of bacterial STDs and trichomoniasis, but not HIV infection. For PPT to be considered as an intervention in sex worker populations, the prevalence of bacterial STDs must be high, and this usually occurs in relatively early stages of STD and HIV epidemics, when preventive and curative services are being established. PPT should be considered where bacterial STD rates are high, and should be integrated with other clinical STD services, such as condom promotion, syndromic case management, risk assessment, and other screening services, such as syphilis screening and HIV voluntary counseling and testing.[166] Important issues that should be studied further include the levels of STD prevalence needed for initiating PPT, the optimum periodicity of PPT, under what circumstances PPT should be discontinued, and what risk groups are most suitable for programs involving PPT.

SUMMARY AND CONCLUSIONS

FSWs and their clients remain central to the transmission dynamics of STDs including HIV in many regions globally. Over the past two decades, much has been learned about how to design and implement programs that are effective in reducing STD and HIV transmission in sex work settings. In fact, adequate programs have almost invariably resulted in substantial increases in safer sex behavior and reduced STD rates among FSWs. However, despite the public health importance and evident success of such programs, there remain unacceptable gaps in the coverage globally so that too many FSWs and their clients still lack the basic information, resources, and services to reduce their risk of STDs. Clearly more resources and greater policy and program focus are required in many countries. But, more resources and determined policy, although necessary, are not likely to be sufficient. The organization and patterns of sex work are already highly complex. Rapid development in many countries and globalization are altering the context and organization of sex work, often more quickly than programs can adapt. Therefore, researchers and those who develop and implement programs from different regions must share, summarize, and analyze their observations so that new strategies can be developed to respond to emerging needs. If widespread control of STDs and HIV can be achieved among sex workers and their clients, that would be a major global public health achievement.

13 Homosexual and Bisexual Behavior in Men in Relation to STDs and HIV Infection

Kenneth H. Mayer and Alex Carballo-Diéguez

INTRODUCTION

Male homosexual behavior has been denounced in the Old Testament and extolled by classical Greek poets like Hesiod, underscoring the longstanding awareness that these behaviors have been commonly expressed since the beginning of human civilization, and demonstrating the ways that diverse cultures have grappled with deviations from the heterosexual norm.[1] Although the Bible recommended that men and women who engaged in homosexual intercourse be put to death, justifying this as a crime against nature, these behaviors were also associated with sacred rituals of local polytheistic cultures, suggesting that neighboring peoples were able to accept homosexuality. Although many famous personalities in history—e.g., Alexander the Great, Tchaikovsky, Walt Whitman—were known to prefer homosexual partners, until the landmark studies of Kinsey and colleagues, very little was known about the natural history and prevalence of male homosexual behavior.[2] Kinsey et al. examined the life histories of more than 6300 males and found that 2/3 had engaged in some homoerotic play as preadolescents, but only 15% of the events involved oral or anal–genital contact. Although the finding that 37% of the males had at least one postpubertal homosexual experience is higher than the rates reported in subsequent studies. The majority of respondents described self-limited experiences, and subsequently identified as heterosexual males for the rest of their lives. The Kinsey group developed a scale from 0 to 6 for the respondents to indicate their sexual preference, with 6 being for those whose sexual attraction was exclusively homosexual. About 18% of the men rated themselves between 3 (equally attracted to both sexes) and 6 for at least 3 consecutive years, but only 4% rated themselves as exclusively homosexual for all of their lives, similar to more recent estimates (see below).

Because of legal and social sanctions against the public expression of homosexuality until the advent of the sexual revolution of the past 40 years, earlier records of sexually transmitted disease (STD) epidemics, such as the spread of syphilis in the late fifteenth century, are generally not enlightening with regard to the extent that male homosexual behavior abetted the spread of specific STD pathogens. However, the increased social acceptance of homosexuality in developed countries in the late 1960s and 1970s was associated with the development of a subculture that accepted intimacy with multiple partners as a normative behavioral pattern.[3] Increased ease of travel also facilitated the spread of STDs through male homosexual behavior, both because of the ability of men to travel widely, contracting infections that could subsequently be efficiently introduced into new settings, and because of the migration of men who wanted sex with men into major metropolitan areas, such as New York and San Francisco, creating "gay ghettos" and the economic environments that could support sexual venues like bath houses, in which sexually transmitted infections could be most readily disseminated.

DEFINITIONS

Current epidemiological reports, especially those dealing with HIV and AIDS, include "men who have sex with men" (MSM) in the breakdown of populations affected by the epidemic. MSM is a nomenclature coined in the mid 1980s in an attempt to find an umbrella term to describe a variety of men who have sex with other men, and thereby may transmit or acquire HIV or other STDs, but do not necessarily share the same sexual orientation, sexual identity, or gender identity. What do these terms mean? Although there is no consensus on specific definitions, there are common uses.

Biological sexuality refers to the genetic determinants of sexual expression. Although the external genitalia are usually considered the most obvious phenotypic indication of biological sex, this is not always unequivocal. Maternal use of estrogens during pregnancy or a variety of endocrine abnormalities may result in children born with underdeveloped external genitals and testis that have not descended, who therefore were thought to be girls and treated as such until adolescence, when suddenly they developed secondary male sexual characteristics. Therefore, chromosomes are the ultimate indicator of biological sex.[3]

Gender refers to the social traits and characteristics associated with each biological sex. The terms "masculine" and "feminine" are generally used to refer to gender, e.g., "the masculine demeanor of Marlon Brando." It should be noted that gender is a social construct and that what is considered masculine or feminine varies significantly from culture to culture. Bolton,[4] in his book *Bravehearts, Men in Skirts*, exemplified this issue by focusing on the clothing men wear in different cultures and signaling that a man wearing a pleated skirt would be considered effeminate in many western societies but not in others—e.g., kilts among the Scots, or skirts worn by the Evzones of the Greek Presidential Guard. Not only dress codes but also behavioral patterns may be judged differently in various cultural milieus—e.g., holding hands among men is considered effeminate in Western nations, but not so in the Arab world.

Biological men who adopt gender traits generally associated with women and vice versa, or individuals who feel they are "trapped in the wrong body," are frequently referred to as transgender persons.

Sexual orientation refers to the erotic and/or affectional disposition to the same and/or opposite sex. "Orientation" rather than "preference" is used because most individuals do not experience having ever had a choice about being attracted to women or men. The terms most commonly employed to refer to sexual orientation are heterosexual, homosexual, and bisexual. This "western" nomenclature is not necessarily shared by all cultures, there being not only different words but also different cultural constructs about what sexual orientation is. For example, whereas in the United States a man who has sex with another man is likely to be labeled homosexual, in many Latin American countries it is not the sex of the partner but the behavior that takes place with that partner that determines such label.[5,6] Thus, a man who always takes the insertive and never the receptive role in anal sex with another man may be considered hypermasculine rather than homosexual.[7] Among Indian men, their roles as husbands and fathers may define men's status much more than the kind of sexual behavior they engage in so that same-sex sexual behavior can occur without necessarily raising the question of sexual orientation for those who engage in the behavior. In some communities in India, male homosexual behavior may be seen as play, a way of dealing with sexual "needs," or maintaining the social norms that restrict sex with women for purposes other than procreation.[8]

Sexual self-identification refers to the way people choose to describe themselves in terms of their sexual orientation. Words like "gay," "lesbian," "straight," and others are used for self-identification. Controversy exists concerning the role culture plays in the reification of such identities, with a school of social criticism, called "queer theory"[9] underscoring the natural sexual plasticity of human beings. Just like gender traits that may not necessarily coincide with genes, sexual orientation, self-identity, and sexual behavior are not always directly related. For example, there are individuals with exclusively same sex orientation and behavior who do not consider themselves gay, and gay-identified individuals who have female sexual partners. Thus, the term MSM is often used to describe male homosexual behavior in a way that is inclusive of the different terms that males may use to identify themselves, while engaging in same-sex practices. The recent phenomenon of African American MSM who do not self-identify as gay, stating that they are "on the down-low," or DL, has been noted in other racial/ethnic communities.[10] This term has been defined as the term referring to men who have sex with other men in secret while maintaining heterosexual relations for public consumption. Williams states that "above all, men on the DL do not think of themselves, much less present themselves to others, as gay."[10]

Distinctions can also be made among behavior, fantasy, and attraction, as famously stated by Kinsey et al.[2]: "Nature rarely deals with discrete categories. Only the human mind invents categories and tries to force facts into separated pigeon-holes. The living world is a continuum in each and every one of its aspects. The sooner we learn this concerning human sexual behavior, the sooner we will reach some understanding of the realities of sex."

PREVALENCE OF MALE HOMOSEXUAL BEHAVIOR

The estimates of the prevalence of same-sex intimate behaviors among men are controversial, fraught with methodological problems, ranging from limitations in the ability to extrapolate from limited (often convenience) samples to disagreements about the appropriateness of inclusion of diverse individuals within a cohort (e.g., men who are situationally homosexual in prison, vs. self-actualized men who are "out," and exclusively homosexual). Laumann and colleagues[11] wrote in their comprehensive monograph, *The National Health and Sexual Life Survey*, "Estimating a single number for the prevalence of homosexuality is a futile exercise because it presupposes assumptions that are patently false, that homosexuality is a uniform attribute across individuals, that it is stable over time, and that it can be easily measured." The prevalence of male homosexual behavior in modern, industrialized societies has been estimated as ranging from 1% to 10%, depending on the sampling interval (e.g., lifetime experience vs. recent contact, or only measuring activities undertaken as an adult) and the behaviors that are considered (e.g., is arousal without physical contact included?).[12,13] Estimates of recent sexual behaviors of adults suggest that 3–7% of men had a homosexual experience within the past year.[14–16]

There are no central repositories that provide comparative data about the prevalence of sexual behaviors in diverse subcultures, and only a handful of countries have comprehensive statistics. Sex research, where it exists, tends to be fertility related, rather than sexuality oriented. Often, even definitions

vary regarding these sensitive topics.[17] In societies where the social expression of homosexuality is more constrained because of the implicit assumption that all men must marry, male homosexual behavior may be common, but difficult to address with Western-oriented prevention messages, based on assumptions of the existence of a coherent subculture. For example, one study in rural India found that 10% of single men and 3% of married men reported anal intercourse with another man within the past year.[18]

ETIOLOGY OF MALE HOMOSEXUAL BEHAVIOR

Two fundamental theories, essentialism and social constructionism, have been posited to explain the etiology of sexual orientation.[19] Essentialism originated with Plato,[20] whose proponents posited that the world is constituted by a finite number of unchanging forms. Modern essentialism implies a belief that certain phenomena are natural, inevitable, universal, and biologically determined. By contrast, social constructionism asserts that reality is ordered by society and everyday reality is shared, with common views of reality becoming institutionalized. Knowledge may be institutionalized at the level of society or within subgroups. *Essentialist theories* underlie many studies that have attempted to find the biological origins of homosexuality.[20] For example, Bailey and Pillard[21] studied identical twin brothers and sisters and found that they have a 52–48% concordance rate of homosexuality; yet, since this observation did not demonstrate 100% concordance, other factors must also be involved. Although LeVay[22] found differences in the size of the hypothalamuses of autopsied homosexual men compared to those of heterosexual men and women, a disproportionate percent of the MSM had died of AIDS, raising methodological concerns.

Studies have found no major hormonal differences between male homosexuals and heterosexuals without endocrine disorders.[23] In congenital adrenal hyperplasia, high levels of androgens are produced. Girls with this disease are genetically female and have female reproductive organs but are born with masculinized external genitalia. When raised as boys, these genetic girls usually adopt a male gender identity and role (showing that the Y chromosome is not necessary for gender development in a male direction). When raised as girls from birth, they develop a female gender identity in spite of their prenatal androgenization. The reverse case is androgen insensitivity syndrome, when tissues do not respond to male sex hormones. Genetic boys have genitals that look like female genitals. If raised like girls, they develop a female gender identity in spite of the presence of the Y chromosome. These studies provide strong evidence that gender roles and sexual identities may be more significantly determined by psychological rather than biological factors. Although hormones may not influence gender identity, they may influence social roles: Girls with congenital adrenal hyperplasia are more likely to be characterized as "tomboys." Money[24] believed that prenatal sex hormones play some part in the development of later sexual orientation, but that whether the individual will be identified as homosexual, heterosexual, or bisexual is strongly dependent on postnatal experience. It is invariably difficult to separate hormonal and environmental influences.[23]

Other studies have focused on birth order, suggesting that gay men are more often born later than their male siblings.[25] According to Cantor et al.,[26] each additional brother increases the odds of homosexuality by approximately 33%. However, only one gay man in seven may have his sexual orientation related to the so-called "fraternal birth effect." One developmental theory that may explain this effect posits that it might be a by product of a biological mechanism that shifts personalities more in the "feminine" (word used by the author) direction in the later born sons, reducing the probability of these sons engaging in unproductive mating competition with each other.[27]

Social Constructionism theorizes that sexuality is not expressed identically in all times and cultures, concluding that sexuality is created by culture that defines some relationships as sexual and creates behavioral scripts.[28] Foucault[29] surmised that sexuality's meaning is derived from how specific behaviors and actors are described. As a consequence of some of these ideas, a whole new area of study appeared, referred to as Queer Theory. It questioned the very idea of identity and its grounds for looking at sexuality and sexual orientation. One of the main characteristics of the gay movement was that it assumed that sexual orientation provided a common ground for a group of people that shared such orientation, as well as other aspects of their personality and lives.[30] One of the main goals of the movement was affirming a presumably stable gay identity, which could be accepted and integrated within mainstream culture, which institutionalized and normalized the establishment of an identity based on (homo)sexual desire. This process created a socially accepted minority status for homosexuals, publicly recognized with rights similar to those of racial or ethnic minority groups. This was done, however, at the expense of excluding marginal manifestations of sexuality. Dissatisfaction with the dominant concept of "gayness" and the emergence of new fractured and dissident kinds of sexual expression led to the development of the idea of "queer," as an alternative. Queer theorists criticized the essentialist idea of the self as a basic and stable entity[9] and posited that sex, gender, and sexual orientation evolve over life. None of these are permanently defined at birth (contradicting the famous Freudian principle according to which "biology is destiny") and can change, be shaped, and evolve, not being constrained by standards of normality imposed by society.[31]

CULTURAL CONTEXT OF HOMOSEXUALITY

Aldrich[32] wrote that ever since the time of ancient Athens and the Biblical Sodom and Gomorrah, organized homosexual activity has been associated with the city. The migration of homosexual men from rural areas to urban centers has been well known for many years, and the appearance of gay neighborhoods in large cities gave rise to the application of the word "ghetto" in the 1970s to such concentrations. Gay ghettos, like Chelsea in New York or the Castro in San Francisco, are distinctive for the visibility of gay men in public spaces and an abundance of establishments that cater to them. Furthermore, some of the men who live in these areas may adopt a common look, from clothes to haircuts to body types, sometimes being referred to derisively as "clones." By contrast, many ethnic minority MSM who live in big cities but not in the gay ghettos may adopt different looks, language, and even lifestyle.[33] Therefore, location, socioeconomic level, ethnicity, and value systems may characterize different groups of MSM. Of course, the boundaries between these groups are not rigid and there is interaction between members of different groups, and some men may move between groups over time. Some MSM who are not city dwellers have found Internet as a very efficient tool to feel less isolated. Recent studies[34] have used the Internet to recruit MSM in rural areas and have started to shed light on this population. The lack of social supports provided by living in an urban environment has often forced rural MSM to be more covert about their sexual orientation, and to feel more isolated, sometimes resulting in substance use and other manifestations of psychosocial distress.

SEXUAL PRACTICES AND STD/HIV TRANSMISSION

MSM may engage in sexual practices that put them at risk for specific STDs, particularly HIV. Because of logistical and ethical issues, the relative efficiency of STD/HIV transmission per discrete sexual act is difficult to define with precision.[34] The majority of studies that document these behaviors tend to follow large cohorts of MSM periodically and infer from participant reports of sexual behaviors the relative transmission risks among the men who become newly infected. Thus, precise estimates of per contact risks are generally not feasible. Unprotected anal intercourse has been generally shown to be most efficient for sexual HIV transmission with an 8.2/1000 contact risk for unprotected receptive anal intercourse with a known HIV-infected partner, and 0.6/1000 contact risk for unprotected insertive anal sex with a known HIV-infected partner.[35] The relative risks of HIV transmission with partners whose status is unknown will reflect the background HIV prevalence in specific communities and cultural milieus.

The relative efficiency of fellatio in transmitting HIV is unclear (partially because of the preponderance of at-risk men also engaging in anal intercourse), but animal data has established biological plausibility.[36] Among 2915 MSM followed in the Multicenter AIDS Cohort Study with 9330 person-years of follow-up, 2 men who only engaged in receptive oral intercourse and no anal intercourse were identified among the 232 seroconverters.[37] Vittinghoff [35] and colleagues estimated the per contact risk of unprotected oral exposure to the ejaculate of HIV-infected or status unknown partners to be 0.4/1000, which was comparable to their estimate of the risk from unprotected insertive anal sex. The role of cofactors may be extremely important in determining the relative efficiency of specific sexual practices for HIV transmission. In a multivariate analysis of factors associated with HIV seroconversion in MSM in a multinational study, Page-Shafer et al.[38] found that although oral sex was modestly, but independently, associated with increased risk of becoming HIV-infected (OR: 1.01), the presence of an intercurrent STD (OR: 3.39) and amphetamine use (OR: 2.55) were much more potent independent predictors for HIV seroconversion.

One of the major variables associated with the efficiency of heterosexual HIV transmission is the plasma HIV RNA level of the infected partner.[39] Although in a study in Uganda, untreated HIV-infected individuals with lower plasma viral loads were less likely than those with higher viral loads to transmit HIV to their discordant partners, suppressing plasma HIV RNA with antiretroviral medications in patients with longstanding HIV infection has not yet been shown to eliminate HIV transmission. In the United States, although the majority of HIV-infected MSM who meet criteria for initiating treatment are on highly active antiretroviral therapy (HAART), USPHS estimates suggest that HIV incidence is increasing in some subgroups of MSM.[40,41] Despite the effects of HAART in lowering HIV concentrations in different compartments, HIV RNA has been detected in the semen,[42] rectal secretions,[43] and pharyngeal samples[43] of MSM on suppressive antiretroviral therapy.[44] Reports of increase in sexually transmitted, drug-resistant HIV[45] also suggest that HAART alone will not necessarily prevent new infections from occurring in MSM. Other cofactors associated with increased HIV transmission among MSM include the use of volatile inhaled nitrates and being uncircumcised.[46]

Other STDs are also efficiently transmitted by anal intercourse, including syphilis, gonorrhea, chlamydia infection, *herpes simplex virus*, and hepatitis B. Many of these pathogens may also be more efficiently transmitted through fellatio than HIV.[47] Human papillomavirus (HPV) is readily transmitted without anal penetration, and may be autoinoculated from the penis to the rectum in sexually active MSM. Other nontraditional STDs may be readily transmitted by specific MSM practices, e.g., enteropathogens like *Shigella* or *Salmonella* may be spread by oral–anal intercourse ("rimming") or digital–anal contact ("fisting") because of the low pathogen inoculum needed to cause infection.

STD TRENDS AMONG MSM

Although the incidence of STDs among MSM initially declined as MSM increasingly practiced safer sex with the advent of the AIDS epidemic,[48] since the late 1990s STD rates have markedly increased in urban epicenters in the United States (Figs. 13-1 to 13-4), as well as other industrialized nations.[49,50] Studies have suggested a combination of factors at play, including the perception, with the widespread availability of HAART that HIV infection is not as dire as at the outset of the AIDS epidemic,[51–53] lack of engagement with current prevention messages, the increasing popularity of different nonprescription drugs (including methamphetamines, volatile nitrates, known as poppers, and erectile dysfunction drugs) in some subgroups,[54] and the coming of age of a generation of young MSM who did not witness the devastation of AIDS in the 1980s.

CDC surveillance studies have suggested that recent increases in sexually transmitted infections have been most pronounced among MSM from communities of color, but the secular trends demonstrate STD increases among all subgroups of MSM, independent of race/ethnicity or geographic location.[55,56] Additional concerns about the increases of STDs in MSM include the potential for epidemiological synergy,[57,58] increasing incidence of new HIV infections among at-risk MSM, and the risks that untreated STDs could compromise the health of HIV-infected MSM. Specific STD trends are reviewed below.

SYPHILIS

Although national syphilis elimination efforts have proven very successful in many communities in recent years,[59] reports of increasing rates of new infections among MSM continue to occur,[60] with disproportionate numbers of newly diagnosed syphilis patients being HIV coinfected.[61] Almost one-quarter (23%) of HIV-infected MSM accessing services at an STD clinic participating in the U.S. Gonorrhea Isolate Surveillance Program (GISP) had a reactive syphilis serology compared to 8% of MSM who were HIV uninfected or whose serostatus was unknown.[56] Overall, seroreactivity ranged from 4% to 11% by clinic location. The male-to-female primary and secondary syphilis rate ratio increased from 1.2 in 1996 to 5.7 in 2005 (Fig. 13-5), primarily due to the resurgence of syphilis among MSM.[55] Futhermore, CDC data reveal almost a tripling in median syphilis seropositivity from 4% in 1999 to 11% in 2005 among MSM visiting the STD clinics participating in the national MSM prevalence monitoring project.[55] However, sustained increases were documented in only 3% of the sites. Syphilis may upregulate HIV expression and replication[62] as well as CCR5 coreceptor prevalence,[63] enhancing HIV transmission to susceptible hosts. The increased prevalence of syphilis in HIV-coinfected MSM may also reflect "serosorting," i.e., careful selection by HIV-infected MSM of other infected partners with whom they can have unprotected sex and/or increased susceptibility to syphilis among HIV-infected patients. Since oropharyngeal chancres may transmit infectious syphilis to insertive partners engaging in oral sex, this practice that is considered safe in relation to HIV transmission may result in new syphilis infections, and safer sex education should take this risk when prevention messages are developed for MSM.

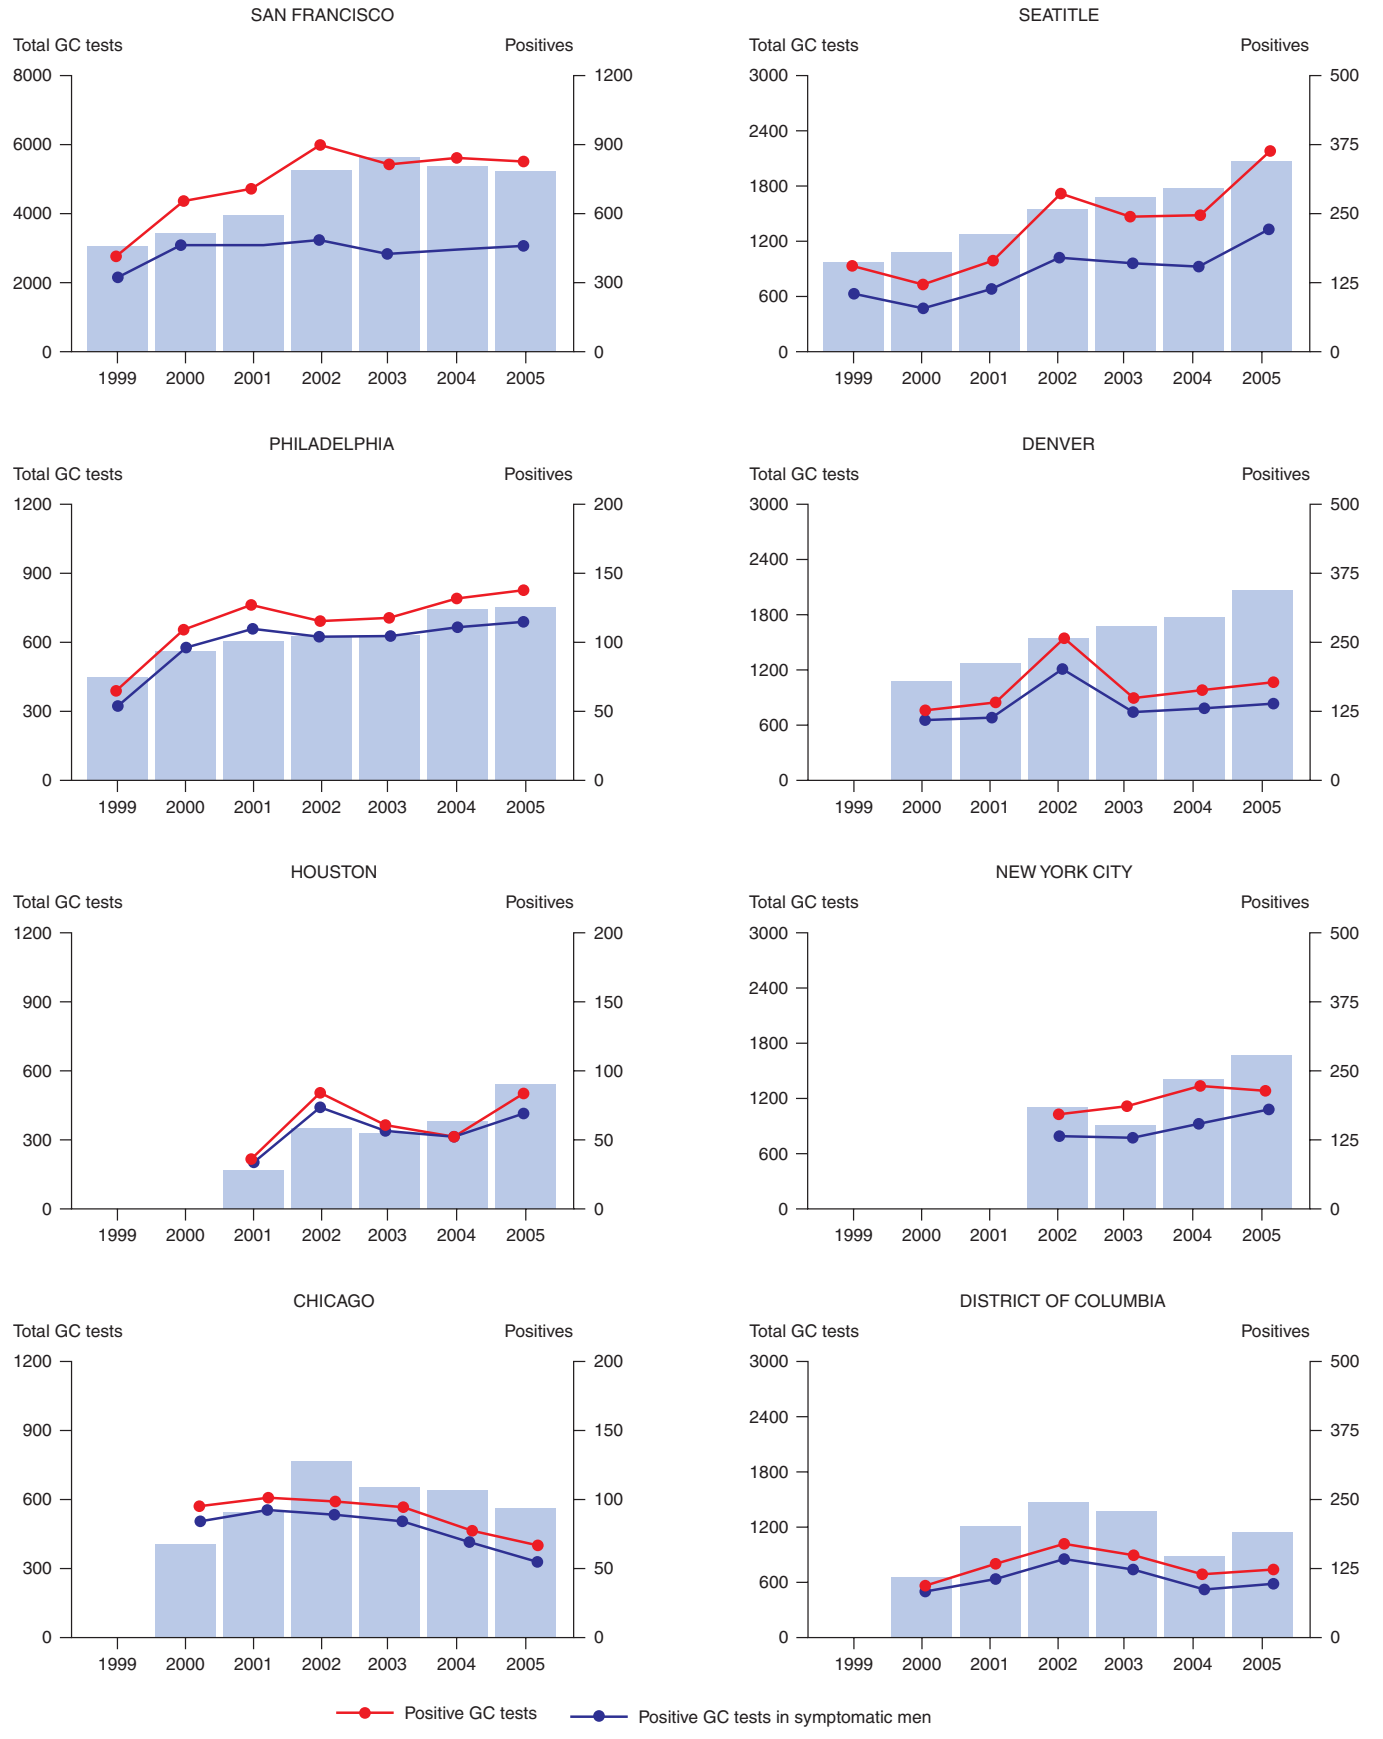
GONORRHEA

Gonorrhea rates have also increased in recent years among urban MSM in developed countries, paralleling the rises seen with syphilis.[64,65] Gonorrhea may be transmitted by fellatio, as well as insertive or receptive anal intercourse, although anal sex is the most efficient means of transmission.[66] According to the GISP, the proportion of positive test results for MSM increased from 4% in 1988 to more than 20% in 2005.[55] Between 1999 and 2005, the overall number of gonorrhea test performed from all anatomical sites for MSM increased at GISP clinics, with the majority being done because of symptomatic complaints.[56] The median clinic test positivity rate was 11% for urethral gonorrhea, 8% for rectal gonorrhea, and 7% for pharyngeal gonorrhea (Fig. 13-6). MSM have accounted for a substantial number of all new gonococcal infections diagnosed at surveillance sites across the country in recent years, particularly on the West Coast (Fig. 13-7).

Increases in unprotected anal intercourse have been paralleled by increases in rectal gonorrhea rates in San Francisco,[67] which have been postulated to be at least partially responsible for the increased HIV incidence noted by the local health department in the years immediately after the introduction of HAART.[68] Although some studies of MSM have suggested that gonococcal infection was associated with increased risk of HIV acquisition,[69] studies from heterosexual cohorts in Africa have not demonstrated such a clear association.[70,71] However, this may be due to the low prevalence of anal intercourse in these populations. In any event, gonococcal urethritis has been demonstrated to increase seminal HIV shedding eightfold in coinfected men, with 0.7 log HIV RNA/mL decreases when men were treated with effective antibiotics.[72] Quinolone-resistant gonococci have been increasingly isolated from MSM, constituting 29% of specimens from MSM in CDC's GISP in 2005 and necessitating the use of expanded spectrum cephalosporins for the treatment of gonococcal infections in MSM, and the recommendation that quinolones no longer be used to treat any gonococcal infection in MSM.[55,73]

CHLAMYDIA INFECTION

Although nongonococcal urethritis (NGU) in MSM may be due to *Trichomonas vaginalis, Ureaplasma urealyticum,* and *Mycoplasma genitalium, Chlamydia trachomatis* is still responsible for the largest number of cases[74,75] and also for most cases of nongonococcal proctitis.[76,77] In 2005, between 5% and 8% of MSM accessing STD services at one of the GISP



Note: The bars represent the number of GC tests at all anatomic sites (pharyngeal, rectal, and urethral) each year. The scales on the left and right axis differ. The bar graphs use the scale on the left. The line graphs use the scale on the right.

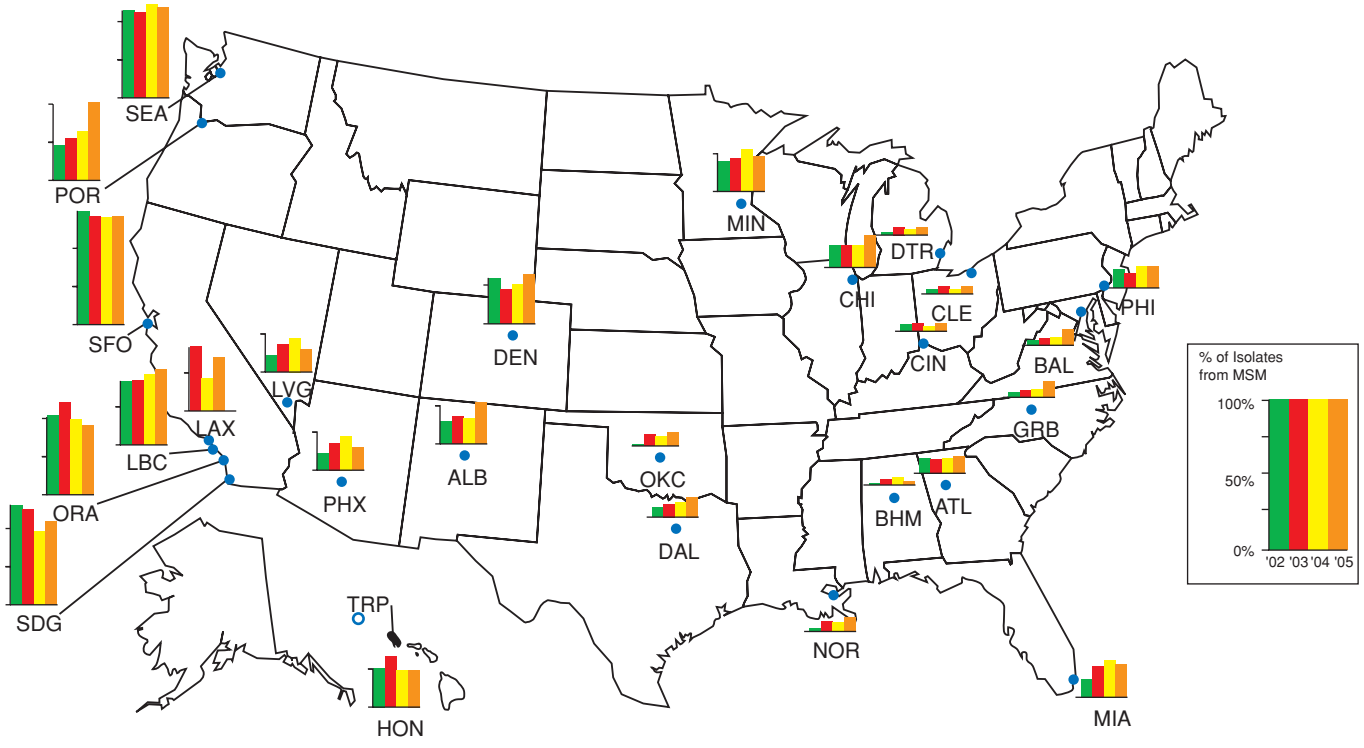
FIGURE 13-6. MSM Prevalence Monitoring Project–Test positivity for gonorrhea, chlamydia, and HIV and seroreactivity to syphilis among MSM, by race/ethnicity, STD clinics, 2005.



Note: Not all clinics participated in GISP for the last 4 years. Clinics include: ALB = Albuquerque, NM; ATL = Atlanta, GA; BAL = Baltimore, MD; BHM = Birmingham, AL; CHI = Chicago, IL; CIN = Cincinnati, OH; CLE = Cleveland, OH; DAL = Dallas, TX; DEN = Denver, CO; DTR = Detroit, MI; HON = Honolulu, HI; LAX = Los Angeles, CA; LBC = Long Beach, CA; LVG = Las Vegas, NV; MIA = Miami, FL; MIN = Minneapolis, MN; GRB = Greensboro, NC; NOR = New Orleans, LA; OKC = Oklahoma City, OK; ORA = Orange County, CA; PHI-Philadelphia, PA; PHX = Phoenix, AZ; POR = Portland, OR; SDG = San Diego, CA; SEA = Seattle, WA; SFO = San Francisco, CA; and TRP = Tripler Army Medical Center, HI (does not provide sexual risk behavior data).

FIGURE 13-7. Gonococcal Isolate Surveillance Project–Percent of *N. gonorrhoeae* isolates obtained from MSM, attending STD clinics, 2002–2005.

clinics tested positive for urethral gonorrhea.[55] NGU has been associated with increased seminal HIV RNA shedding in coinfected men[78,79] and has been associated with increased risk for HIV acquisition in heterosexual cohorts,[70,71] and thus may be reasonably considered a potentiator of HIV transmission and acquisition among MSM. In 2005, the median chlamydia positivity rate among MSM in CDC's MSM prevalence monitoring project was 6% (range 5–8%).[55]

OTHER AGENTS ASSOCIATED WITH NGU

Although the data are scant in MSM, *T. vaginalis* has increasingly been associated with NGU and increased HIV transmission.[80,81] *U. Urealyticum* and *M. genitalium* have also been identified as common causes of NGU.[82–85] The increased prevalence of genital mycoplasmas and ureaplasmas in HIV-infected patients may reflect their increased immunosuppression, or increase sexual activity prior to HIV acquisition, but may also serve to upregulate genital tract HIV and potentiate its transmission.[86]

LYMPHOGRANULOMA VENEREUM

LGV proctitis was first described in MSM more than 60 years ago[87]—a distinctly different syndrome than LGV infection of the genitourinary tract, which has most often been associated with inguinal adenopathy with draining buboes. LGV proctitis was also described just prior to the onset of the AIDS epidemic among U.S. MSM,[88,89] suggesting that the increasing recent recognition of this syndrome[90,91] may reflect the increasing unprotected anal sex among MSM with the wider propagation of an endemic STD pathogen.[92] In a prospective study of rectal swabs of MSM presenting for STD screening in San Francisco, 7% of 205 men had positive nucleic acid amplification tests for chlamydia infection and 36% of those specimens were LGV.[93] Because of the potential for unrecognized LGV to cause ulcerative proctitis with serious sequelae, recommendations have been made for increased surveillance to establish the incidence of LGV among at-risk MSM to inform optimal standards of clinical care.[92]

HERPES SIMPLEX VIRUS TYPE 2

Herpes simplex virus type 2 (HSV-2) is extremely prevalent in the general population worldwide,[94–96] with more than one-fifth of the U.S. population being infected with HSV-2.[97,98] The prevalence is much greater in sexually active MSM, with more than half of any survey of MSM demonstrating seroreactivity.[99] HIV has been readily detected by PCR from HSV-related

male genital ulcers of 70% of a certified cohort in one series,[100] consistent with data supporting its role in potentiating HIV transmission.[101] Large public health trials are underway to assess whether the ongoing use of acyclovir—an HSV-2 thymidine kinase inhibitor—can protect HSV-2-infected, HIV-uninfected high-risk individuals from HIV acquisition, or decrease the likelihood of HIV transmission by HIV-1/HSV-2 coinfected individuals.

HUMAN PAPILLOMAVIRUS

HPV is thought to be the most common STD in the United States and other developed countries,[102] with more than 85% of HIV-infected MSM being HPV coinfected[103–105] and the prevalence of HPV in HIV-uninfected MSM being consistently greater than 50%.[105,106] HPV is primarily spread between male sexual partners through insertive or receptive anal intercourse,[107] but may also be transmitted by oral sex,[108] digital–rectal contact,[109,110] and scrotal contact.[110] Reports of anal cancer in HPV-infected MSM have led to suggestions that routine anal screening for atypia and proactive management of precancerous lesions should be part of the primary care of MSM engaging in anal intercourse.[111,112]

HIV TRENDS AMONG MSM

Since the first cases of AIDS were reported in the United States in 1981, MSM have been disproportionately affected by this epidemic, with about two-third of the men living with AIDS in 2002, having reported male homosexual intercourse as their route of infection,[40] despite MSM comprising less than 10% of adult U.S. males.[15,16] More than half a million MSM in the United States have been diagnosed with AIDS, and more than 200,000 have died since the start of the epidemic.[40] With the advent of HAART, deaths related to AIDS decreased dramatically in the mid 1990s. However, approximately 40,000 Americans continue to be newly infected with HIV every year.[40] HIV incidence had initially increased among MSM in San Francisco, despite wide utilization of HAART, because of increased sexual risk taking and increased rates of STDs.[68] Although rates seem to have subsequently stabilized in Massachusetts, recent figures from the Department of Public Health indicate that 10% of all cases of HIV were newly diagnosed within the past year, and almost half of them were among the MSM.[113]

Because larger numbers of HIV-infected MSM are living longer and feeling healthier on HAART, they may be engaging in risky sexual practices. Their providers need to assist them in developing the skills to negotiate complex social issues, including the development of behavioral changes that will prevent HIV transmission to their sexual partners.[114,115] These secondary prevention efforts are critical for curtailing new infections.[116] Several studies have shown that 20–30% of HIV-infected MSM engage in risky sexual practices frequently and consistently.[117–119] Kalichman and colleagues[120] found that 23% of their sample of HIV-infected MSM reported three or more sexual encounters involving unprotected anal intercourse within the past month. Marks and colleagues[121] found similar results in their large sample of HIV-infected MSM. Twenty percent of their cohort engaged in unprotected anal intercourse within the previous 2 months, representing an increase in unprotected anal intercourse in a comparable cohort of HIV-infected MSM they followed from 1996–2000. Rates of unprotected anal intercourse appeared stable between 1996 and 1998, but then increased nearly 50% between 1998 and 2000 after the advent of HAART. In this study, the cumulative probability of a participant engaging in insertive, unprotected anal intercourse with an HIV-uninfected or unknown partner increased from 13% in 1996 to 25% in 2000. Unprotected anal intercourse also appears to be increasing among HIV-uninfected MSM.[122] In a sample of [13,415] MSM in Seattle, rates of unprotected anal intercourse increased nearly 20% over 3 years, with greater rates of unprotected sex among young men and men of color.

The advent of HAART has not eliminated the AIDS epidemic among MSM. HIV-infected MSM are clearly living longer due to HAART, but the increasing therapeutic armamentarium may result in morbidity for some.[123] Although people with lower plasma HIV RNA concentrations may be less likely to transmit HIV to their partners,[39] HIV can replicate independently in the genital tract. The increasing rates of transmission of drug-resistant HIV to newly infected people[45] suggests that ongoing behavioral research will be needed to optimize biological approaches to HIV prevention. Additional concerns include the possibility of HIV superinfection and viral recombination when HIV concordant couples engage in unprotected intercourse,[124] and therefore prevention messages need to apprise HIV-infected persons of the desirability of safer sex to protect themselves, as well as their partners, independent of HIV status.

FACTORS THAT POTENTIATE TRANSMISSION

Despite a collective understanding and knowledge about the modes of HIV transmission, HIV rates are on the rise. The potential causes are complex and unique to each individual. The conventional wisdom that MSM are optimistic about current HIV treatments or that "prevention fatigue" has caused increased sexual risk taking has yielded mixed results when subject to empirical scrutiny.[125–128] Factors consistently shown to be associated with increased risk taking include a lack of willingness to change one's sexual behaviors,[120] emotional distress,[129] ongoing substance use,[120] past sexual abuse,[130] sex with familiar partners,[131] a diminished sense of sexual control,[132,133] and sexual compulsivity.[134]

Fenton and Imrie[135] attempted to account for recent increases in rates of STDs among MSM in Western Europe and the United States. The authors discuss individual level factors, infectious agents, sociocultural environment, and biomedical environment. Within individual level factors, they mention demographic changes (increases in the proportion of men reporting same-sex experiences and intercourse, increased survival of MSM because of HAART, and increases in HIV-positive MSM populations), sexual risk behaviors (increases in unsafe sex, sex partner change rates, sex partner concurrency, serosorting, and payment for sex), and proximal determinants of sexual risk behavior (recreational drug use, drug abuse, and mental illness). Among the factors related to infectious agents, the authors include resistance and the interaction between STDs (antimicrobial and antiretroviral resistance, interaction between HIV and bacterial STDs, and epidemiologic synergy). Among sociocultural environment factors, the authors list the growth in the sexual marketplace (Internet, sex on premises venues, circuit and sex parties, and sex tourism), socioeconomic status (lower socioeconomic status and lower educational attainment), and changing cultural environments that facilitate high-risk behavior (barebacking, discrimination, homophobia, and HAART optimism). Finally, among factors related to the biomedical environment, they point out the inability of health services to effectively intervene (e.g., MSM seek care in the private sector which may be less amenable or accessible to STD prevention interventions, public health department staff may be less used to dealing with MSM issues or clients, and effectiveness of traditional disease control interventions—e.g., partner notification—with MSM may be reduced because of high proportions of anonymous partners). In sum, there is a wide range of factors that may potentiate each and facilitate sexual risk behavior. This analysis highlights the need to intervene at the personal, interpersonal, community, and structural level if durable decreases in MSM STDs are to be achieved.

INTERVENTIONS TO REDUCE STD/HIV TRANSMISSION IN MSM

Several theoretical models developed in the past two decades have attempted to organize diverse research findings into coherent and comprehensive behavioral models. Some of these have been tested empirically through randomized controlled trials, and for other models, different levels of support were found for their effectiveness in modifying risk behavior.[136] Yet, the studies did not have the statistical power or long-term follow-up required to show intervention effects on HIV incidence, itself. Three of the most common psychosocial models that have been employed to explain HIV risk taking are the health belief model, the theory of reasoned action, and social cognitive theory.[137,138] Health belief models emphasize the role of perceived benefits and barriers to condom use and perceived vulnerability to and consequences of getting HIV infection.[139] In the theory of reasoned action,[140,141] health behavior, such as condom use, is a function of intentions to use condoms and, in turn, intentions to use condoms are a function of variables such as attitudes and norms regarding HIV and condom use. Social cognitive models explain condom use as a function of individuals' knowledge about HIV, their expectations about the outcomes of using condoms (i.e., pleasure reduction vs. disease prevention), and their own self-efficacy or capability to use a condom in different sexual situations.[142,143] These psychosocial models of HIV risk-related behavior have been tested both cross-sectionally and longitudinally in a variety of populations, including HIV-infected individuals.

In a recent meta-analytic review,[144] Herbst et al. searched published and unpublished English language reports of HIV behavioral interventions to reduce sexual risk behavior of MSM. The authors found data from 33 studies described in 65 reports available as of July 2003. After careful comparisons of all reports that offered sufficient data to calculate effect sizes, the authors concluded that there was evidence that the reported interventions were associated with significant decreases in unprotected anal intercourse and number of sexual partners, and with a significant increase in condom use during anal intercourse. Furthermore, the authors found that interventions successful in reducing risky sexual behavior were based on theoretical models, included interpersonal skills training, incorporated several delivery methods, and were delivered over multiple sessions spanning a minimum of 3 weeks. A prior systematic review[145] had also found that interventions that had been evaluated through rigorously controlled trials had shown a reduction in the proportion of men engaging in unprotected anal intercourse. These authors pointed out that the most clearly favorable effects were observed among interventions that promoted interpersonal skills, were delivered in community-level formats, or focused on younger populations or those at higher behavioral risk.

The CDC has compiled a Compendium of HIV Prevention Interventions with Evidence of Effectiveness,[146] which has included five interventions specifically designed for MSM that had been rigorously evaluated and proven effective. Of the community-level interventions, the Popular Opinion Leader program[147] was developed first and conducted in one small city with two other cities used for comparison. The intervention was based on theories of peer influence, social and behavioral norms, and diffusion of innovation and was composed of two parts. The first consisted of a four-session intervention with persons who were popular with others that focused on HIV education and communication strategies. In the second part, these

participants committed to having conversations with 14 peers regarding HIV risk reduction. Before and after this intervention, surveys were conducted among men patronizing gay clubs in the intervention and comparison cities to assess for high-risk sexual behavior. The authors found that the intervention was effective in reducing the proportion of men in those cities who engaged in high-risk activities as well as in increasing the precautions taken by this population. This intervention is currently being evaluated in a multicenter randomized controlled trials involving cities in China, India, Peru, Russia, and Zimbabwe.

The Mpowerment Project,[148] building on the diffusion of innovation components of the POLs intervention, focused on young gay men and was conducted during an 8-month period in Eugene, OR, with Santa Barbara, CA, serving as a comparison city. The intervention had three components: peer outreach aimed at diffusing the safer sex message through the community, small groups of gay men focusing on factors that contributed to unsafe sex among young men, and a publicity campaign which aimed to establish the program in the community and urge the participation of young gay men. A survey assessing sexual behavior, psychosocial factors, and exposure to intervention activities was conducted before and after the intervention to young gay men in both cities. The authors found a significant reduction in the proportion of men in the experimental community reporting unprotected anal intercourse during the previous 2 months, across different types of partners.

The CDC AIDS Community Demonstration Projects[149] tested a community-level intervention aimed at different high-risk groups, including intravenous drug users, their female partners, sex workers, high-risk youth, and non-gay-identified men who have sex with men. The intervention consisted of theoretically based role model stories that were distributed along with condoms and bleach by community members who also encouraged behavior change. The outcome measures focused on movement on the Stages of Change continuum for condom and bleach use, exposure to the intervention, and condom carrying. The authors reported that the intervention led to significant progress in adopting HIV risk-reduction behaviors. However, the assessment of condom use during anal sex with nonmain partners, which was of particular importance in assessing the impact of the intervention among MSM, is still part of an ongoing study.

Results from the two small-group-based interventions were reported in close proximity. The experimental group in the Behavioral Self-management and Assertion Skills intervention received 12 weekly group sessions of 75–90 minute duration which covered the areas of AIDS risk-reduction, behavioral self-management, assertion skills training, relationship skills and social support development, and risk-reduction review.[150] Measures for the study included a risk history, a risk-behavior monitoring journal, self-report inventories, AIDS risk knowledge test, and sexual assertiveness role plays. The intervention produced a reduction in risk behavior among the experimental group that was not replicated in the control group. While not all risk behavior changed, a significant reduction in unprotected anal intercourse among the experimental group was seen. Furthermore, the experimental group experienced increased assertiveness skills in relation to HIV risk behavior, as well as increased AIDS risk knowledge.

In contrast to the other interventions discussed,[151] Valdiserri and colleagues compared the effectiveness of two small group interventions, both providing an educational component, but only one incorporating a skills training component. The outcome variables focused on self-reported sexual behavior, particularly on condom use for insertive and receptive anal intercourse. The educational intervention, which lasted 60–90 minutes, covered HIV transmission and infection, clinical outcomes of HIV infection, risks of specific sexual practices, appropriate use of condoms, importance of "safer sex," and the interpretation of HIV test results. The enhanced intervention, lasting 140 minutes, consisted of this exact educational material plus the use of role plays, psychodrama, and group process as part of skills training aimed at promoting acceptability of safer sex, and facilitate the modification of high-risk behaviors. Participants were randomized into one of the interventions. Results revealed that skills training increased condom use for insertive anal intercourse, but no change was seen in relation to receptive anal intercourse.

Two more recent HIV-prevention interventions focused on MSM are the Project Explore study and the Seropositive Urban Men's Intervention Trial (SUMIT). Blending components of motivational interviewing, the Project Explore information-motivation-behavioral skills model, and social learning theory, the intervention consisted of 10 one-on-one sessions followed with maintenance sessions every 3 months, with the primary outcome being HIV seroconversion.[149,152] The study, carried out in six U.S. cities, enrolled 4295 MSM. The results from Project Explore demonstrated a modest benefit in HIV risk-taking behavior among men in the intervention arm compared to controls, but the difference in HIV incidence rates was small, and suggested that the intervention would not be sufficient to curb the continued HIV epidemic among MSM.[153] The annualized HIV incidence among all study participants was 2.1%, underscoring the need to develop more robust prevention interventions.

SUMIT[154] was based on the findings of the Seropositive Urban Men's Study (SUMS) and was conducted in New York City and San Francisco. HIV-infected MSM participants were randomized into either a single-session educational session or an enhanced six-session intervention,

which included group activities aimed at promoting the adoption of safer sex practices with uninfected partners, and the disclosure of HIV status. Preliminary results indicate that the intervention was not effective in reducing transmission risks over time or in improving rates of HIV disclosure, underscoring the need for more effective interventions in this population, as well.

Interventions for HIV-infected patients in care have shown some efficacy in decreasing HIV risk-taking among MSM.[155,156] The Options Project[155] involved training providers to deliver prevention messages to their patients via a "prevention prescription," while the Partnership for Health involved provider training and the use of diverse printed materials, including posters and educational materials that patients could read in the waiting room or at home. These interventions and other modest steps that providers can use to help promote safer sex among MSM are discussed in recent publications by the CDC.[40,146,157]

Despite the success reported for some interventions in promoting safer sexual practices among MSM, rates of high-risk sexual behavior are increasing among MSM in important urban centers in the developed world. Speculating on why this is the case, Elford and Hart[158] pointed out that it is uncertain whether experimental behavioral interventions shown to be effective in one setting, place, or moment can be generalized to another. They concluded that investigators need to develop programs of research addressing the transferability, sustainability, and effectiveness of sexual health promotion among MSM.

Kippax and Race[159] argued that a successful response to the epidemic among gay men—and drug users as well—is dependent on their being positioned, and positioning themselves, as responsible agents in charge of their own lives and the well being of their communities. They suggested that the medical encounter could be used to augment the prevention efforts and rather than apposing treatments with prevention, treatment can be in entry point for many prevention interventions, both by creating a trusting environment, where prevention education may be readily accepted (an "educable moment") and by enabling the provider to address some of the underlying issues (ranging from depression to active substance use) that enhance the likelihood of persisting risky sexual practices.

PUBLIC HEALTH PRACTICE AND MSM

Several investigators have called attention to the need for structural and environmental interventions to promote safer sexual practices among MSM,[160,161] focusing on economic issues (e.g., poverty); mobility, including migration, seasonal work, and social disruption due to war and political instability; gender inequalities; and the effects of particular governmental and intergovernmental policies in increasing or diminishing HIV vulnerability and transmission. Ameliorating problems that may enhance risk taking (e.g., economic necessity) may help to reduce sexual risk taking in some cases, but innate sexual desires may not be amenable to change despite improvement in standards of living for many MSM.

There are no definitive public health data that demonstrate that specific local structural interventions, such as closing gay bathhouses, have led to reductions in rates of STDs. However, it may be argued that criminalization of homosexual behavior has never eradicated the desire to engage in specific practices. Punitive legal constraints and homophobic social environments could serve to drive such activity underground, making it harder for public health officials to identify sexual contacts. Some have argued for a model of sexual harm reduction, which uses places where risky sexual practices occur, like bathhouses, as sites where STD screening and HIV rapid testing may be performed in for the most appropriate MSM populations.[162,163] Others have suggested that decriminalization of homosexuality and the promotion of stable same-sex relationships through the promulgation of civil unions or homosexual marriage might help to normalize monogamy among MSM and lead to a decrease in STD acquisition and transmission. The governments of several European countries, Canada, and Australia have been able to work with the gay community to create culturally sensitive legal and public-health environments, allowing for the effective detection and treatment of STDs and HIV infection; however, none has seen a diminution in the recent increases in new infections among MSM. It is possible that many of the social changes that allow for the general society to accept homosexual behavior have happened so recently that their effects on community norms and individual behavior will not be discernable for several years. It is also feasible that other societal changes, ranging from the decline in heterosexual marriage, the high rates of divorce, and the advent of meeting partners on the Internet, and other private venues, may mean that for at least a subset of MSM, there will be minimal cultural inducements toward monogamy.

If for the foreseeable future, a subset of MSM continue to engage in risky sexual practices, then optimal public health practice must be to educate them and their providers about the prevalence, signs, symptoms, and clinical consequences of STDs and HIV infection. The U.S. Public Health Service has developed guidelines for routine screening for MSM for STD and HIV (Table 13-1).[164] Interventions to motivate busy providers to pay increased attention to public-health recommendations are needed, as well as intensified efforts in alerting and educating at-risk MSM, if the disturbing trends in high HIV and STD prevalence and incidence among MSM are to be reversed.

Table 13-1. CDC Recommendations for STD Screening for Men Who Have Sex with Men[a]

Annual screening of sexually active MSM for

- HIV serology, if HIV seronegative or not tested within the previous year
- Syphilis serology
- A test for urethral infection with *N. gonorrhoeae* and *C. trachomatis* in men who have engaged in insertive intercourse[a] during the preceding year
- A test for rectal infection[b] with *N. gonorrhoeae* and *C. trachomatis* in men who have had receptive anal intercourse[a] during the preceding year
- A test for pharyngeal infection[b] with *N. gonorrhoeae* and *C. trachomatis* in men who have acknowledged participation in receptive oral intercourse[c] during the preceding year; testing for *C. trachomatis* pharyngeal infection is notrecommended
- Some specialists would consider type-specific serologic tests for HSV-2, if infection status is unknown
- Routine testing for anal cytologic abnormalities or anal HPV infection is not recommended until more data are available on the reliability of screening methods, the safety of and response to treatment, and programmatic considerations
- More frequent STD screening (i.e., at 3–6 month intervals) is indicated for MSM who have multiple or anonymous partners, have sex in conjunction with nonprescription or nonmedically indicated drug use, or whose sex partners participate in these activities

14 Lesbian Sexual Behavior in Relation to STDs and HIV Infection

Jeanne M. Marrazzo

INTRODUCTION

The term "lesbian" derives from the Greek island of Lesbos, home to the famous Greek poetess Sappho (c 600 BC), whose erotic tributes to both male and female lovers continue to undergo fresh translation into the twenty-first century.[1] The Oxford English Dictionary defines the term as both an adjective ("of a woman: homosexual, characterized by a sexual interest in other women. Also, of or pertaining to homosexual relations between women") and a noun ("a female homosexual").[2] Because of the relatively wide implications of these definitions, the use of the term in the scientific literature has given rise to considerable debate and confusion. The term has been used variably, and often carelessly, to convey information about each of three distinct axes of sexuality (orientation, behavior, and identity, discussed further below). Many authors (and readers) assume that use of this term conveys relevant information about all three axes. This confusion has been compounded by a relatively widespread assumption that women who self-identify as lesbian presumably do not have a history of sex with men, and certainly, are not still sexually active with men. Unfortunately, imprecise terminology, assumptions about sexual practices and previous sexual history, and general ignorance of the complexity of women's sexuality have all contributed to the relative lack of sophisticated, long-term data on the sexual practices, preferences, and history of a highly diverse group of women. Moreover, it can be difficult to compare data derived from studying this group over time, as relevant social and sexual mores (for example, acceptance of public discussion of homosexuality in the popular media) can evolve rapidly.[3]

To compound these challenges, the availability of the term "lesbian" has been problematic for researchers seeking a convenient and accurate way to refer to the population of women who report sex with other women. Some investigators have used the term to convey a description of sexual contact between women, leaving aside entirely the question of whether subjects identify as lesbian. Others have simply assumed that self-identification as a lesbian connotes current sexual practice with women. Some authors now use the term *lesbian and bisexual women* to (often vaguely) account for all possibilities, while others have adopted "women who have sex with women (WSW)" for studies that have emphasized outcomes focused on sexual behaviors (as a parallel to men who have sex with men, or MSM). The use of the term WSW has evoked a range of responses in the literature, from perplexity to hostility; some have derided the term for its unwieldiness, "political correctness," or insensitivity to the rich nature of sexual identity.[4,5] Interestingly, no such reaction was reported immediately pursuant to the increasingly widespread use of "MSM."

For ease of reference, in this chapter we use the term *lesbian* as a function of sexual behavior: to define women who have sex with other women. When appropriate, the term "bisexual" will be used to imply sexual behavior with men and women. When referring specifically to the axis of sexual identity, these terms will be prefaced with the phrase "self-identified."

EPIDEMIOLOGY OF LESBIAN AND BISEXUAL BEHAVIOR

Data to describe the population of women who practice sex with other women, whether or not they self-identify as lesbian, are limited for several reasons. The challenges of terminology are noted above. Moreover, while the social stigma associated with disclosure of homosexuality has lessened markedly in the last two decades, many individuals may still be reluctant to disclose these behaviors or feelings, even in the context of a supposedly anonymous or confidential survey, for fear of exposure and negative consequences. This may be particularly true for lesbians who live outside of major urban areas, which have traditionally provided a relative safe haven for gay people. Critically, lesbians have been invisible in the data collected as part of the national disease surveillance systems and major national women's health studies. The Women's Health Initiative did not begin to collect information on same-sex behavior or sexual identity

until 1998, and the Nurses' Health Study began to do so in 1995.[6] These omissions allowed the loss of valuable opportunities to prospectively compare important long-term health outcomes for lesbians and heterosexual women. Critically, among 350 subjects participating in a pilot questionnaire to assess disclosure of sexual orientation and response rates in the Nurses' Health Study II, disclosure rates were similar to the 91,654 subjects participating in the larger cohort study; the investigators concluded that questions on sexual orientation could be added to large studies of women without affecting response rates.[7]

In 2000, the U.S. Census for the first time collected and reported information referent to households in which two unmarried adults reported being the same sex and had a close personal relationship with each other.[8] Although these data do not specifically focus on sexual behavior, they provide an indirect and necessarily incomplete window into the prevalence of females who cohabitate. With data enumerated from 105.5 million households in the United States, 297,061 women indicated that they were unmarried partners living in same-sex households at the time of the survey. Other investigators subsequently indicated that this value may underestimate the total population of lesbians living in same-sex households by as much as 72%.[9] Importantly, 15% of all (male and female) cohabitating same-sex couples who responded to the census resided in rural settings. As noted by O'Hanlon, if one assumes a prevalence of 2% of lesbians among the 146,707,720 adult women estimated to reside in the United States by these census data, the U.S. population of lesbians is approximately 3 million.[10] This number is close to the 2.3 million U.S. women previously estimated to identify as lesbians.[11] Aaron and colleagues employed a methodology used in estimating numbers of rare wildlife species to get at the population estimation problem in a different way.[12] Using identifying data for a county in Pennsylvania and a "capture–recapture" approach with log-linear modeling, they estimated that lesbians comprised 1.87% (95% CI, 1.56–2.28%) of the total county population. Other investigators have used area probability sampling, facilitated by U.S. census tracking, to enhance the proportion of lesbian respondents within the methodologic confines of a population-based approach.[13]

Very few large-scale surveys in which sexual behavior was specifically assessed have reported on the frequency or nature of same-sex behavior among women, or assessed measures of self-identity as lesbian. Those that have done so have employed different recruitment methodologies and, critically, have asked relevant questions in different ways. Directly comparing findings from different surveys is further complicated by the fact that large temporal gaps often exist between them. These gaps may have encompassed major shifts in social norms regarding homosexuality, which significantly impact practices about disclosure. For example, the National Health and Social Life Survey, an area probability sample of 3432 U.S. adults aged 18–59 interviewed in 1992, found that 4.3% of women surveyed reported same-gender sex since puberty and that 8.3% demonstrated at least one of the three components of homosexuality: desire, identity, or behavior.[14] The investigators in that study interviewed subjects face-to-face. More recently, investigators reported findings from the National Survey of Family Growth (NSFG), which collected report of sexual behavior using audio computer-assisted self-interviewing (A-CASI) in a national sample of 12,571 males and females in the household population of the United States.[15] As detailed in Table 14-1, in 2002, among women 15–44 years old, the percentage reporting same-sex behavior during their lifetime was 11% and, during the last year, 4.4%. Interestingly, among women 18–44-years-old, of the 10% who did not think of themselves as heterosexual, the breakdown was 1.3% "homosexual," 2.8% "bisexual," 3.8% "something else," and 1.8% with no answer. The fact that the majority of women who did not classify themselves as heterosexual called themselves "something else," and that this category was cited much less frequently by nonheterosexual male respondents than by the corresponding female group, emphasizes the need for further study regarding research on women's self-defined sexual identity. The NSFG percentages translate to 2.29 million U.S. women 18–44 years of age who self-identify as either homosexual or bisexual.

Findings from a large population-based survey of sexual behavior in adults in the UK have recently been reported.[16] The National Survey of Sexual Attitudes and Lifestyles (NATSAL) 2000 study was a probability sample survey of 11,161 respondents aged 16–44 years who were resident in Britain, with intentional oversampling of London residents.[17] Respondents were interviewed by CASI for the sexual history portion of the assessment, and "WSW" was defined liberally as any woman reporting at least one female sex partner in the past 5 years. Of all female respondents, 4.9% reported any same-sex experience involving genital contact, with 2.8% reporting that this had occurred in the last year. In accord with other surveys, most of the WSW thus defined (98%) reported prior sex with men, with 85% reporting that this had occurred in the past 5 years.

Although the data above are incomplete and do not provide an in-depth picture of the true prevalence of same-sex behavior among women, the most recent estimates are surprisingly consistent, indicating that approximately 2–2.8% of the adult U.S. and UK populations may be lesbian. Apart from the general caveats regarding the conclusions of these surveys, it is important to emphasize that ensuring a representative population-based sample may still not obviate variability in successfully eliciting disclosure of same-sex behavior from women of different cultures and

Table 14-1. Number of Females 15–44 Years of Age and Percentage Reporting any Same-Sex Sexual Contact in the Year Prior to Interview and in Lifetime, by Selected Characteristics: National Survey of Family Growth, U.S., 2002

ethnicities within the larger populations, and from adolescents.[18] The likelihood of reporting sensitive behaviors such as sexual practices could be markedly modified by membership in some of these groups. For example, analysis of eight school-based adolescent health surveys in the United States and Canada from 1986 through 1999 revealed that nonresponse rates for questions about sexual orientation (but not for other comparable variables) were higher for younger students, immigrants, and students with learning disabilities.[19] In a related analysis, self-report of both sexual orientation and sexual behavior revealed significantly higher prevalence of homosexual, bisexual, and unsure responses among 12,978 reservation-based American-Indian adolescents compared to 11,356 Anglo-American adolescents, but the nonresponse rate for these questions was also significantly higher among the former group.[20] Further, no systematically collected data on same-sex behavior are available from women in non-Western or developing countries. Alternative approaches will be required to fully characterize the spectrum of same-sex behavior among women of diverse ethnic backgrounds and geographic regions, particularly because health outcomes themselves are likely adversely affected by "dual" minority status (race and sexual orientation).[21]

SEXUAL IDENTITY, RISK BEHAVIORS, AND PREGNANCY-RELATED OUTCOMES AMONG WSW

In all published studies that have queried lesbians about their lifetime sexual history, the majority of respondents (typically between 80% and 95%) report prior sex with at least one male partner and often report risky sexual behaviors. Diamant and colleagues surveyed 6935 self-identified lesbians solicited through a survey printed in The Advocate, a national news magazine aimed at gay men and lesbians. The majority of women (77.3%) reported one or more lifetime male sex partners, with 17.2% reporting ever having had anal intercourse

and 5.7% reporting having had a male sex partner during the past year.[22] Sexual activity with male partners likely begins in adolescence.[23] Female adolescents who have sex with other females may be especially likely to engage in unprotected sex with both male and female partners or to report sexual abuse.[24,25] Among 182 self-identified bisexual or homosexual adolescents in one study, girls younger than 15 years were more likely than their older counterparts to report an earlier age at onset of sexual intercourse with males.[26] In a subsample of 3816 students who completed the 1987 Minnesota Adolescent Health Survey, bisexual or lesbian respondents were as likely as heterosexual women ever to have had intercourse (33% and 29%, respectively), but reported a significantly higher prevalence of pregnancy (12%) and physical or sexual abuse (19–22%) than heterosexuals or adolescents who were "unsure" about their sexuality.[27] Among sexually experienced respondents, bisexual or lesbian respondents were most likely to have frequent intercourse (22%, compared with 15–17% in the other groups). Among all who were sexually experienced and those who had ever been pregnant, bisexual or lesbian women were the most likely to have engaged in prostitution during the previous year.[27]

Thus, many lesbians report lifetime reproductive outcomes including pregnancy, childbirth, and induced abortion. Lifetime prevalence of reported pregnancy in the few studies that have addressed this issue ranges from 23% to 35%.[28–30] Among participants in the Women's Health Initiative, ever use of oral contraceptives was similar between lesbians and heterosexual women, and 35% reported ever having been pregnant.[29] Among 392 lesbians who participated in the Seattle Lesbian Health Study (1998–2001; median age of all subjects, 28 years), reports of prior pregnancy, oral contraceptive use, and induced abortion were common.[30] Overall, 25% of women had been pregnant at least once and 16% had had an abortion. Over half of all subjects had used oral contraceptives (mean duration, 40 months). The majority of women (63%) who had ever been pregnant had had at least one abortion. One-fifth of the subjects who specifically self-identified as lesbian had been pregnant at least once, 12% had had an induced abortion, and almost half had ever used oral contraceptives. The most common pregnancy outcome for women who became pregnant at age less than 25 years was induced abortion, which occurred in 59% of these pregnancies. Of related importance, the number of reported lifetime male sex partners did not differ by whether women identified as lesbian or bisexual. The overall age-adjusted rate of abortions was comparable to the estimated rate reported for U.S. women overall in the NSFG.[31] The authors concluded that self-identification as lesbian did not consistently preclude prior use of oral contraceptives or pregnancy-related outcomes, with the implication that providers should address these issues with all adult women patients, regardless of stated sexual identity or behavior. These findings may be particularly important for clinics with a traditional "family planning" focus, as these may serve as the primary entry point of care for many lesbians, particularly those with limited resources.

Finally, lesbians who are also currently sexually active with men may, in some settings, demonstrate increased sexual risk-taking behavior.[32] Among women attending STD clinics, reports of sex with women as well as with men has been associated with a markedly increased prevalence of HIV-related risk behaviors, including sex with gay or bisexual men, use of injection drugs and crack cocaine, and exchange of sex for drugs or money.[33–35] In the 1997 College Alcohol Study, comprised of 14,251 randomly selected U.S. college students, women reporting sex with both men and women were more likely to report multiple sex partners than peers with only opposite-sex partners.[36] In a large, cross-sectional, community-based study of sociometric networks among intravenous drug users, Friedman found that a report of same-sex behavior by female respondents was associated with a twofold increase in the likelihood of HIV infection.[37] Koh successfully recruited 1304 lesbians from 33 outpatient primary care settings across the United States.[38] In order to enrich the study population with lesbians, the investigators used a sampling scheme that took into consideration the proportion of lesbian patients (>30% as estimated by lead clinicians) served by contributing sites. They used an extensive questionnaire (98 items) with good response rate (>50%). Respondents were mostly white, highly educated, and had relatively high income. Although most were in a stable relationship (71%), many (23%) reported substance use while having sex or sex with a gay or bisexual man (6%) in the past year. Among women who recently had sex with men ($N = 600$), 51% reported ever using condoms. Bisexual women reported substance use during sex at a higher rate than lesbians or heterosexual women. While lesbians more frequently reported sex with bisexual men and injection drug users, they also reported using condoms more frequently than did bisexual or heterosexual women. Notably, lesbians who participated believed that their risk for HIV infection was high, yet few reported ever having had tests for non-HIV STDs, which are considerably more likely than HIV infection in this group. Why were lesbians employing risk reduction measures? Proximity to the issue of HIV/AIDS in the MSM community may inform this choice (although this might not be consistent with the inverse relationship between age and report of condom use in this subgroup). It could also relate to lesbians' choice of MSM as partners when they do choose to have sex with men. Of great interest is that among women who reported sex with men in the prior year, lesbians reported a higher number of male sex partners than either heterosexual or bisexual women. This finding was modified by age, with younger women tending to report this behavior more commonly. The data collected on heterosexual women's condom use are valuable because of the paucity of data for women whom most primary care providers might categorize

as "low risk"; variations in the frequency of condom use by income and age in heterosexual women deserve further scrutiny.

In the UK some of the findings on risk behaviors from the NATSAL 2000 Study were unexpected.[16] First, two-thirds of female respondents reported only one female partner in the past 5 years and 42% of WSW (as defined in this study, described above) did not report any female partners in the past year. Second, relative to exclusively heterosexual women respondents, WSW reported significantly larger numbers of male partners in the past 5 years (Fig. 14-1), ever, and in the past year (all $P < 0.001$). Third, relative to exclusively heterosexual women, WSW reporting male partners were significantly more likely to report potentially high-risk heterosexual behaviors including anal sex (AOR (age-adjusted odds ratio for WSW relative to women reporting exclusively heterosexual partners) 2.46 [95% CI 1.58–3.85, $P < 0.001$]), most recent partner described as "not regular" (AOR 1.74 [95% CI 1.07–2.82, $P = 0.02$]), initiating sex less than 24 hours after meeting most recent partner (AOR 2.48 [95% CI 1.44–4.27, $P = 0.001$]), and unsafe sex (two or more heterosexual partners in the past 4 weeks with inconsistent condom use; AOR 7.17 [95% CI 3.25–15.8, $P < 0.001$]). WSW respondents were significantly more likely to report seeking care at an STD clinic, getting an HIV test, being diagnosed with any STD, and having had an induced abortion ($P < 0.001$ for each relative to heterosexual respondents). While some of these findings raise questions about the nature of the WSW respondent population, and the generalizability of the study's findings, they do highlight the marked diversity within groups of women who engage in same-sex behavior.

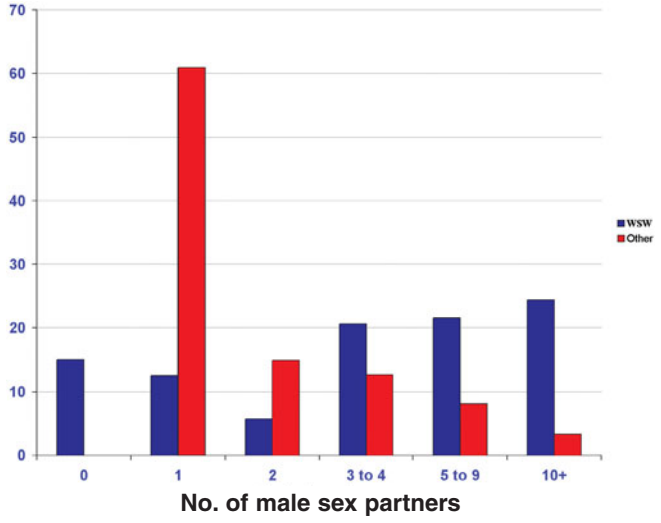

FIGURE 14-1. Number of male sex partners reported in the past 5 years among women who reported sex with other women and among those who reported exclusively male partners. (With permission from Mercer CH, Bailey JV, Johnson AM, et al. Women who report having sex with women: British national probability data on prevalence, sexual behaviors, and health outcomes. *Am J Public Health* 2007; 97:1126–1133.)

Finally, French investigators used data from a national phone survey that focused on domestic violence in France in 2000 to compare female respondents who reported at least one female sex partner ($N = 78$) to heterosexual women ($N = 6332$).[39] Lesbians in this survey reported a younger age at sexual debut, a higher number of lifetime male partners, more frequent report of STD diagnoses and prior HIV testing, and, importantly, more frequently experiencing domestic violence as adults.

EPIDEMIOLOGY OF STDS AND HIV INFECTION AMONG WSW

Despite the considerable numbers of women who engage in same-sex behavior, relatively little data are available on health outcomes related to STD, or to the attributable risk of STDs from sexual practices in which lesbians engage. In its 1999 report "Lesbian Health: Current Assessment and Directions for the Future," the Institute of Medicine emphasized that more data on STDs, Pap smear screening, and risk of cervical cancer in lesbians were needed.[11] Attempts to use national or local surveillance data to estimate the risk of STD transmission between women are limited by the fact that virtually all risk classification schemes have either excluded same-gender sex among women or subsumed it under a hierarchy of other behaviors viewed as higher risk. Moreover, few if any state or local STD reporting systems routinely collect information on same-sex behavior among women. The available data are derived from two sources: small studies that have directly measured the prevalence of common STDs, usually among clinic attendees or self-referred study volunteers, and surveys that have queried lesbians about their self-reported STD history. Many of these studies have also assessed lesbians' self-report of sexual practices. Taken as a whole, these data—limited as they are—indicate that the risk of STD transmission between women depends on two major factors: (1) the specific STD under consideration and (2) the sexual practices in which lesbians engage.

Some sexual practices, including oral–genital sex, vaginal or anal sex using hands, fingers, or penetrative sex toys, and oral–anal sex, are practiced commonly between female sex partners (Table 14-2).[35,40,41] Oral sex, in particular, appears to be extremely common, and is probably practiced more frequently than among heterosexual women. Other sexual practices include digital–vaginal or digital–anal contact, particularly with shared penetrative sex toys. These sexual practices present a plausible means for transmission of infected cervicovaginal secretions, although the frequency of transmission associated with these practices is not well documented. Transmission of common viral STD, especially human papillomavirus (HPV) and herpes simplex virus (HSV), and of *Treponema pallidum,* the causative agent of

Table 14-2. Sexual Practices Among Lesbians: Frequency and Associated STD Risk

Practice	Description & Vernacular Terms	Estimated Frequency[a]	Factors Modifying Risk of STD[b]
Oral–vulvovaginal contact (cunnilingus)	- "Going down" - Top = performing partner - Bottom = receiving partner	Very common (>95%)	- Presence of oral lesions in top partner (herpes, syphilis, possibly gonorrhea) (+) - Use of barriers (plastic wrap, dental dams, condoms)
Digital–vaginal contact	- Range of penetration, from "finger-fucking" to "fisting"	Very common (>85%)	- Sharing of infected cervicovaginal secretions (trichomoniasis, *C. trachomatis,* gonorrhea, HPV, herpes) (+) - Use of gloves (–)
Digital–anal contact	- Range of penetration, from "finger-fucking" to "fisting"	Common (25%)	- Sharing of infected anorectal secretions (hepatitis A, enteric pathogens, gonorrhea, HPV, herpes) (+) - Use of gloves (–)
Insertive sex objects (vagina or anus)	Toys, dildos	Very common vaginally (60%) Common anally (25%)	- Sharing of infected cervicovaginal or anal fluid (trichomoniasis, *C. trachomatis,* gonorrhea, HPV, herpes) (+) - Use of condoms with sex toys (–) - Sharing insertive toys without cleansing prior to use (+)
Oral–anal contact	"Rimming"	(Common 35%)	- Presence of oral infection in performing partner (syphilis, genital herpes) (+) - Presence of anorectal infection in receiving partner (hepatitis A, enteric pathogens) (+) - Use of barriers (–)
Direct genital to genital contact	- Tribadism	Very common (>95%)	- Direct contact of susceptible skin/mucosa (HPV, herpes, syphilis)(+) - May involve use of interposed devices, such as vibrators, which can cause mechanical vulvar irritation
Sadomasochism	Bondage, "BDSM"	Unknown; probably uncommon (<2%)	Sharing of blood (hepatitis B, hepatitis C, HIV) (+)

[a]Refs. 35, 40, and 41.

[b]Plus sign (+) denotes factor likely to enhance risk of STD transmission or acquisition; minus sign (–) denotes factor with probable protective effect.

syphilis, requires only skin to skin or mucosa contact which can easily occur in the context of sex between women. As discussed above, most lesbians (53–99%) have had sex with men, and many (21–30%) continue to do so[22]; they may acquire viral STDs from men and subsequently transmit them to female partners. Among 6146 respondents in the National Lesbian and Bi Women's Health Survey conducted in the early 1990s, women reported contracting an STD from a female partner (including herpes in 135, chlamydia in 102, genital warts in 100, gonorrhea in 16, hepatitis in 9, and HIV

in 1).[42] Although self-report of STD history is often inaccurate (as is attribution of STD to a specific source partner), these data indicate that while transmission of some STDs is relatively inefficient between female sex partners, these respondents sought care for perceived genitourinary abnormalities, and received a diagnosis that indicated the provider had reason to suspect a specific STD.

GENITAL HUMAN PAPILLOMAVIRUS

Genital infection with specific types of HPV causes genital warts and the majority of cervical cancer. In addition to case reports,[43,44] two studies that enrolled self-referred lesbians in Seattle have detected HPV DNA by PCR-based methods in 13–30% of subjects.[40,45] In both of these studies, samples obtained from the cervix, vagina, and vulva all demonstrated HPV DNA and no one anatomic site accounted for the majority of infections. Among 150 women in the earlier of these two studies (1995–1997), HPV DNA was present in 30% of all subjects and in 19% who reported no prior sex with men.[40] In multivariate analysis, current but not prior cigarette smoking was an independent predictor of the presence of HPV DNA (OR 3.4; 95% CI, 1.2, 9.6), as was time to last sex with a male partner ($P = 0.002$). Among all subjects with detectable HPV DNA, 29 (69%) had unclassified types only, 9 (21%) had HPV-31/33/35/39, 8 (19%) had HPV-16, and 1 (2%) had HPV-6/11. Twenty-eight (62%) of these women had HPV DNA detected in the specimens obtained from the cervix, 26 (58%) from the vagina, and 32 (71%) from the vulva; 24 (53%) had HPV DNA in specimens from more than one site. Among the 41 women with HPV DNA who reported prior sex with men, 21 (51%) had not had sex with a male partner in over a year (range, 1–18 years; median, 2 years). In their sexual practices with female partners, women who had detectable HPV DNA did not differ from those who had no detectable HPV DNA. With male partners, women with detectable HPV DNA were more likely to report a history of receptive oral sex ($P = 0.05$). In the subsequent Seattle Lesbian Health Study (1998–2001), HPV DNA was measured in 248 women and detected in 31 (13%), including 7 with HPV type 16 and 15 with other oncogenic types.[45] Twelve (39%) had nononcogenic types (6/11, 40/42/53/54). Among the 28 women with HPV DNA who reported prior sex with men, 14 (50%) had not had sex with a male partner in over a year (range, 1–11 years; median, 2 years).

Capture enzyme-linked immunoabsorbent assay (ELISA) was used in the earlier study to measure type-specific antibodies to HPV and 47% of 133 subjects were seropositive for antibodies to HPV-16 and 62% for HPV-6; 54% had antibodies to both.[40] Among 19 subjects reporting never having had sex with a man, 5 (26%) had antibodies to HPV-16 and 8 (42%) had antibodies to HPV-6. Antibodies to HPV-6 or -16 were detected in 8 (42%) of 19 women reporting no prior sex with men and in 84 (74%) of 114 women reporting prior sex with men. Subjects who were seropositive to either HPV-6 or HPV-16 were older than seronegative subjects (mean age, 34 years vs. 30 years, respectively; $P = 0.01$), but did not differ significantly from seronegative subjects in time to last sex with a male partner, lifetime number of male or female partners, or detection of HPV DNA.

Importantly, both high- and low-grade squamous intraepithelial lesions (SIL) were detected on Pap smear testing in both of these studies, including among women who reported no prior sex with men. In the first study, 13 of the 150 subjects (6% of all subjects) had abnormal Pap smears. Three of these women reported no history of sex with men and three reported having had female sex partners with genital warts. SIL was detected in 2 of 21 women (10%) who had never had sex with men, in 2 (2%) of 93 women who had had sex with a man >1 year previously, and in 2 (6%) of 35 women who reported sex with men during the last year (not significant). HPV DNA was detected in 5 of the 6 women with SIL; HPV type 31/33/35/39 was found in both cases of SIL that occurred in women without a history of sex with men. Among 248 women enrolled in the second study, 7 of the 11 SIL detected occurred in women who reported never having had sex with men, or sex with men >1 year previously. Twenty-five women (10% of all subjects) had abnormal Pap smears. Four women had high-grade and 7 had low-grade SIL detected; 7 of these lesions occurred in women who reported either never having had sex with men or sex with men more than one year prior to testing. HPV DNA was detected in 7 of the 11 women with SIL (HPV-16 in 3 women and other oncogenic types in 4 women). In a large study reporting Pap smear data for lesbians and heterosexual controls in an STD clinic in Melbourne, abnormal Pap smears occurred equally frequently in both groups.[35]

There are fewer data available for the clinical diagnosis of genital warts among lesbians, but this condition has been reported among lesbians who denied prior sex with men in several studies, primarily from STD clinics.[46] In STD clinics that have reported data from lesbian clients, a diagnosis of genital warts was relatively uncommon in London, occurring in 1.6% of 708 lesbians,[47] but more common in Melbourne (8% of 1408 lesbians) (Table 14–3).[35] While genital HPV and associated conditions are most common among women who report increasing numbers of lifetime male sex partners, the data above and the fact that SIL has been observed in women who reported no prior sex with men indicate that high-risk and low-risk genital HPV types are sexually transmitted between women and that lesbians should undergo Pap smear screening using current national guidelines, as recommended in the 2006 Sexually

Table 14-3. Demographics, STD Detected at Clinic Visit, and Risk Behavior Among Lesbians and Heterosexual Control Women at a Sexual Health (STD) Clinic in Melbourne, Australia[a]

[a]Lesbian defined as woman who reported ever having had sex with another woman. Controls defined as women who reported never having had sex with another women. A nested analysis of 283 women reporting sex exclusively with women in the year prior to clinic visit showed that these women were still significantly more likely than controls to report >50 lifetime male sex partners (4% vs. 2%; OR 2.8, *P* = 0.003). The risk behavior profile of this group was otherwise similar to "all" lesbians as depicted in this table. All denominators for percentages are total group numbers as listed at top of column unless otherwise specified. (With permission from Fethers K, Marks C, Mindel A, Estcourt CS. Sexually transmitted infections and risk behaviours in women who have sex with women. *Sex Transm Infect* 2000; 76: 345–349.)

[b]OR, odds ratio for detection of characteristic in lesbian group; CI, confidence interval.

[c]Self-reported history of chlamydia, gonorrhea, bacterial vaginosis, syphilis, genital herpes, or genital warts.

Transmitted Disease Treatment Guidelines from the Centers for Disease Control and Prevention.[48]

GENITAL HERPES

The majority of genital herpes is caused by HSV type-2 (HSV-2), although recent reports indicate a consistent trend towards more HSV-1 related genital disease.[49] Using the Western blot assay to detect type-specific antibodies among 392 women in the Seattle Lesbian Health Study, antibodies to HSV-1 were detected in 46% and to HSV-2 in 8% (Fig. 14-2).[50] HSV-1 seroprevalence increased significantly with increasing number of female partners (Fig. 14-3; also discussed below). Increasing age predicted higher seroprevalence to both HSV types, and HSV-2 seropositivity was associated with a reported history of having had a male partner with genital herpes (but not with prior number of male sex partners). Of 78 women reporting no prior sex with men, 3% were HSV-2 seropositive. Seropositivity to HSV-2 was also associated with report of prior trichomoniasis, gonorrhea, and pelvic

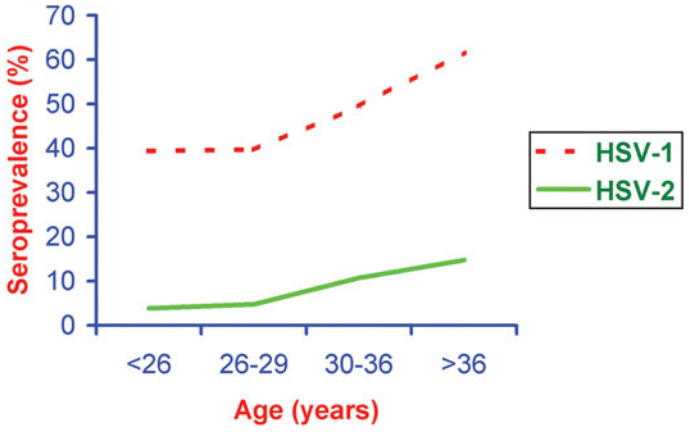

FIGURE 14-2. Age-specific seroprevalence of herpes simplex virus types 1 and 2 among 392 lesbians tested in 1998–2001 by Western Blot. (With permission from Marrazzo JM, Stine K, Wald A. Prevalence and risk factors for infection with herpes simplex virus type-1 and -2 among lesbians. *Sex Transm Dis* 2003; 30: 890–895.)

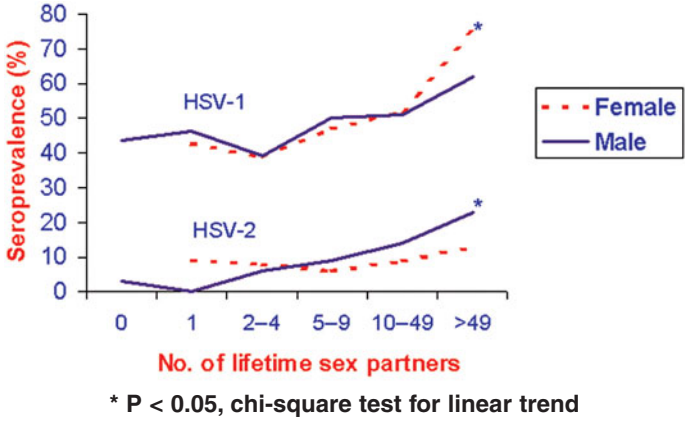

FIGURE 14-3. Seroprevalence of herpes simplex virus type 1 and 2 by number of lifetime sex partners. (With permission from Marrazzo JM, Stine K, Wald A. Prevalence and risk factors for infection with herpes simplex virus type-1 and -2 among lesbians. *Sex Transm Dis* 2003; 30: 890–895.)

inflammatory disease. As has been demonstrated in other studies, most HSV-2 seropositive subjects (71%) reported no history of genital herpes; only 6.1% of all subjects gave such a history. The seroprevalence of HSV-2 among women in this study was approximately half that reported among white women in the National Health and Nutrition Examination Survey (NHANES) study, which tested sera obtained during the years 1999–2004.[51] Data on the sexual orientation of the women in these studies was not reported, but most were presumably heterosexual. In the NHANES population, HSV-2 seroprevalence among women aged 20–29 years old—the subgroup most comparable to the Seattle study population—was 15.6% (95% CI, 13.1–18.5). Possible reasons for the lower HSV-2 seroprevalence among the Seattle lesbian subjects include the potential for less efficient genital transmission of HSV-2 in the absence of penile–vaginal sex, the fact that many subjects were part of monogamous partnerships, frequently of long duration, and subjects' predominantly white race. In all HSV-2 serosurveys performed to date, blacks have been more likely than other racial or ethnic groups to be infected with HSV-2, and also experienced significantly higher rates of new HSV-2 infections in one prospective study.[52] Further, risk factors for infection with HSV-2 may vary across populations studied. In the NHANES study, predictors of HSV-2 infection were race, age, lifetime number of sex partners (gender not specified), and marital status, but fewer years of formal education, income below the poverty level, and ever having used cocaine were also independently associated. Of these characteristics, only increasing age independently predicted higher seroprevalence to HSV-2 in the Seattle Lesbian Health Study.

Many studies have suggested that the incidence of genital infection with HSV-1 is increasing[53–57] and that new genital HSV-1 infections are as common as oropharyngeal HSV-1 infections.[52] Further, report of receptive oral sex in the absence of vaginal intercourse increased the risk of HSV-1 seroconversion among 1207 heterosexual women prospectively assessed in Pittsburgh (9.8 vs. 1.2 cases per 100 woman-years of follow-up; $P = 0.04$).[58] The majority of the subjects (54%) in the Seattle Lesbian Health Study lacked serum antibody to HSV-1, a percentage even lower than that of baseline seroprevalence among women enrolled in the Pittsburgh study (62%). Because genital infection with HSV-1 is most likely acquired during receipt of oral sex,[53] a behavior commonly practiced by lesbians, a substantial proportion of lesbians engaging in receptive oral sex are probably at risk for genital acquisition of HSV-1. In fact, the Seattle data demonstrated a more prominent association between number of lifetime female sex partners and HSV-1 infection than that reported for male sex partners among the women studied in the NHANES III Study.[59] Other investigators have suggested that decreasing HSV-1 seroprevalence among young adults may place these individuals at higher risk for subsequent genital HSV-1 acquisition, and have suggested a need for increased education about the risks of orogenital sex.[56,57] Counseling about susceptibility to genital herpes infection may be enhanced by the recent availability of less expensive, type-specific HSV serologic assays that identify persons at risk.[60]

While no other studies have measured lesbians' HSV seroprevalence, others have assessed lesbians' self-report of genital herpes. Most have used self-referred, volunteer samples and reported a lifetime prevalence of 3.3–7.4%.[22,61,62] However, as noted above, self-reports of genital herpes substantially underestimate prevalence as measured by type-specific HSV serology. Among 27 lesbians seen at an STD clinic in London in the late 1980s, genital herpes was diagnosed by culture in 3 women (11%).[63] More recently, 1.1% of 708 new patients attending a clinic for lesbians in London and 9% of 1408 lesbians seen in a Melbourne (Australia) STD clinic were diagnosed with genital herpes by culture, including women who reported no prior sex with men (Table 14-3).[35,47]

HUMAN IMMUNODEFICIENCY VIRUS

While sexual transmission of HIV between women has been reported,[64–68] the likelihood of transmission in this setting is unknown. It is probably strongly modified by the extent to which female partners share cervicovaginal secretions, particularly if menstrual blood is involved or if activities involving vaginal or anal penetration are vigorous enough to abrade mucosa or cause bleeding. Recently, Kwakwa detailed a convincing case of a 20-year-old woman with documented HIV acquisition during the course of a monogamous relationship with an HIV-infected female partner.[69] The viral strains were genotypically identical, providing strong supporting evidence that the female partner was the source. These women denied having sex during menses, but reported using vaginal sex toys as well as digital penetration, with associated exchange of blood-tinged vaginal fluid. Raiteri followed approximately 18 discordant lesbian couples for HIV transmission over several years without observing any transmission.[70]

In addition to behaviors that transmit these potentially infected secretions, lesbians' participation in sexual networks that involve gay or bisexual men or their own IDU could place them at increased risk of HIV acquisition, but this has not been extensively studied. Chu used national surveillance for reported AIDS cases from 1980 to 1989 to characterize the 79 women who reported sex with another women in these data; 95% also reported IDU.[71] The HIV Epidemiologic Research Study, which required that women report IDU, sex with 5 or more partners in the prior 5 years, prior sex with a male at risk for HIV, or exchange of sex for drugs or money in order to be eligible for enrollment, reported that 67 of 871 subjects (8%) had had sex with a woman during the 3½ years of the prospective follow-up.[72] Most (82%) had a history of IDU. Subjects reported frequent practice of sexual behaviors that could potentially transmit infected secretions without concomitant barrier use, but information on partners' HIV status was not reported. Shotsky examined HIV seroprevalence data from New York state's HIV counseling and testing programs from 1993 to 1994.[73] HIV seroprevalence among the 27,370 women tested was highest among women who reported sex with men and women (4.8%), compared to that among women sexually active exclusively with women (3.0%) or with men (2.9%). Other studies have noted a high prevalence of risky or unprotected sexual behavior with female partners in HIV-infected lesbians who report IDU[74]; however, because of the selection of the populations studied, the generalizability of these data cannot be assured.

VIRAL HEPATITIS

No systematically collected data have been reported on sexual transmission of hepatitis B between women, but anecdotal case reports have occurred (J. Hofmann, personal communication). Based on the observation that other blood-borne viruses are transmitted between women, it is reasonable to presume that this occurs, but the frequency is unknown. Transmission of hepatitis A has also been reported among WSW.[75] Notably, in the Melbourne STD Clinic Study comparing lesbians with heterosexual women controls, lesbians' prevalence of hepatitis C was significantly higher (OR 7.7; $P < 0.001$), a finding that probably reflects more frequent report of IDU in this group (Table 14-3).[35]

CHLAMYDIA TRACHOMATIS AND NEISSERIA GONORRHOEAE

Reports of clinically documented *C. trachomatis* and *N. gonorrhoeae* transmission between women are rare. The scant data available derive from clinic-based reports of prevalence among lesbian attendees and from survey respondents' self-report of having received these specific diagnoses. Clinic-based data reported primarily from STD (in the United States and Australia) and sexual health (in the UK) clinics indicate that the prevalence of both of these infections has been very low (typically 3% or less). For example, among 708 new patients attending a clinic for lesbians in London, prevalence of *C. trachomatis* was 0.6% and of gonorrhea was 0.3%.[47] Although a smaller proportion of women who reported sex exclusively with women underwent endocervical culture for *C. trachomatis and N. gonorrhoeae* relative to women who reported sex with men, chlamydial infection was diagnosed in two women reporting sex only with women. In the Melbourne STD Clinic Study, prevalence of *C. trachomatis* was 3%; interestingly, this did not differ from the prevalence among heterosexual control women, which was also quite low.[35] Finally, culture-based data from a Seattle STD clinic revealed *C. trachomatis* among only 2 (1.1%) of 187 women reporting sex only with women in the past 2 months and in 12 (1.9%) of 841 women reporting sex with both men and women during that time frame. Corresponding detection of gonorrhea was 0 of 192 women tested and 14 (2.1%) of 661 tested, respectively.[34] Limitations to generalization of these data include lack of truly universal testing in most settings, as well as relatively small numbers of patients in the U.S. studies. Survey data assessing lesbians' lifetime history of these STDs has been reported principally from the United States, where approximately 3–6% of respondents indicate that a health-care provider had diagnosed chlamydial infection.[42,61]

SYPHILIS

Although *T. pallidum* is relatively uncommon compared to most other STDs, sexual transmission between female partners has been reported.[76] Because some lesbians who choose to have sex with men may be more likely to choose bisexual men for

partners,[33,34] health-care providers should keep in mind that the incidence of early syphilis has markedly increased among men who have sex with men in the last several years.[77]

VAGINITIS, INCLUDING BACTERIAL VAGINOSIS

Bacterial vaginosis (BV), a condition associated with depletion of hydrogen-peroxide-producing *Lactobacillus* species and the most common cause of vaginitis among women of reproductive age, is associated with pelvic inflammatory disease, increased risk of acquiring gonorrhea and HIV, and adverse outcomes of pregnancy.[78] Intriguingly, the prevalence of BV among lesbians is high and vaginal colonization with hydrogen-peroxide-producing lactobacilli is low relative to that of heterosexual women, even when subjects are matched for age and sexual risk behaviors.[35,41,63,79–81] BV prevalence among lesbians in these studies has ranged from 24% to 51%, as compared to 21% for heterosexual STD clinic clients and 9–14% for pregnant women. Recently, BV prevalence was reported for women in the NHANES, which uses a complex, stratified, multistage probability sample design with unequal probabilities of selection to obtain a nationally representative sample of the U.S. civilian noninstitutionalized population.[82] Of over 12,000 women in the 2001–2004 NHANES who supplied a self-collected swab of vaginal secretions for Gram stain analysis by Nugent score, BV prevalence was 45.2% (95% CI, 35.5–57.4) among women who reported having had a female sex partner, compared to overall prevalence of 29.2% (95% CI, 27.2–31.3) ($P = 0.003$). In the single study that has used culture to define the vaginal bacteria present in lesbians with BV, the microbiology of this condition appeared very similar to that in heterosexual women.[41] Although BV is not a classic STD in that a specific microbial precipitant has not been identified, among heterosexual women it is frequently associated with report of a new male sex partner and with unprotected intercourse,[78] and the use of condoms by male partners of women who were successfully treated for BV significantly reduced rates of BV recurrence in these women.[83]

The plausibility of BV being sexually transmitted between women is supported by three general findings. First, Criswell and Gardner successfully transmitted BV from one woman to another by the transfer of vaginal secretions in early studies of "*Hemophilus vaginalis vaginitis.*"[84] Second, limited evidence suggests that female sex partners share identical *Lactobacillus* strains as part of normal vaginal flora. Marrazzo and colleagues used repPCR to characterize vaginal *Lactobacillus* isolates among 30 monogamous (defined within the timeframe of the prior 3 months) female sex partners.[85] Identical strains were detected in 23 of these couples (77%). The likelihood of sharing *Lactobacillus* strains was directly related to report of fewer female sex partners in the prior year and to increasing duration of the current partnership. Paired controls, designated as women not currently in monogamous partnerships and matched for mean age of couple and date closest to visit for each couple, had strains that were not shared. These findings suggest (but do not prove) that women sexually transmit vaginal *Lactobacillus* species. Third, BV is frequently found in both members of monogamous lesbian couples[41,86] and BV concordance within couples has been associated with specific sexual behaviors.[41] In a study of 326 women who reported sex with at least one other woman in the prior year, the prevalence of BV as determined by Nugent criteria was 27%. Factors associated with an increased risk of BV included sexual behaviors that are likely to result in the transfer of vaginal fluid, as well as oral–anal sex (Table 14-4).[41] Moreover, among subjects with BV, 81% had partners with BV, whereas only 4% of those without BV had partners with BV ($P < 0.001$). Bailey reported on a cross-sectional survey of 708 lesbians attending two sexual health clinics in London, among whom BV prevalence as determined by Amsel criteria was 31.4%.[80] The odds of BV were significantly increased among women who reported higher number of female sex partners (OR 1.6 [95% CI, 1.05–2.44] for >11 compared to less than 6 partners) and with current cigarette smoking (OR 1.43 [95% CI, 1.01–2.03]).

These observations have prompted some authors to propose that sexual transmission of some etiologic factor, as yet undefined, is responsible for BV in lesbians.[86] Expanding the spectrum of bacteria specifically associated with BV may help clarify this issue. Several groups have found that *Atopobium vaginae* has relatively high specificity for BV among heterosexual women (in contrast to *G. vaginalis*, which is found in approximately 40% of women with normal vaginal flora).[87,88] In addition to *A. vaginae* and other novel species, Fredricks and colleagues, using 16s rDNA methodology, reported the detection of three previously undefined bacteria in the *Clostridiales* group that were highly specific (95% or greater) for detection of BV in a study that included lesbians.[89] Interestingly, many of the newly identified bacteria associated with BV are anaerobes known to colonize the oral cavity, raising anew the hypothesis that lesbians' relatively frequent practice of orogenital sex may also promote shifts in vaginal bacteria that could precipitate or support BV, a mechanism also postulated in small studies of heterosexual women.[90,91] More research is needed in this area.

Finally, positing that transmission of vaginal fluid is likely during lesbian sex implies that vaginal infection with trichomoniasis should be relatively efficiently transmitted as well. Interestingly, only one detailed case report of this occurrence has been published and described a lesbian couple who had failed standard therapy with metronidazole. Both were

infected with *Trichomonas vaginalis* that was resistant to metronidazole.[92] Among 708 new patients attending a clinic for lesbians in London, trichomoniasis was detected in 1.3%, including lesbians who reported no prior sex with men.[47]

SPECIAL CONSIDERATIONS IN STD/HIV PREVENTION AND CONTROL AMONG WSW

Questions about access to quality health care for lesbians persist.[93] One of the few population-based surveys performed with lesbians as a target audience used a random digit dialing approach to compare the physical and mental health status of 4135 respondents as a function of self-reported sexual orientation.[94] Both lesbians and bisexuals were more likely to report increased rates of poor physical and mental health, as other studies have also noted.[21] Perhaps the most commonly assessed surrogate marker for whether lesbians receive appropriate STD-related preventive care is receipt of Pap smear screening. This is probably performed less frequently among many lesbians than national guidelines advise, even when lesbians accurately perceive themselves to be at risk for cervical cancer.[95–97] In the Seattle Lesbian Health Study, 95% of respondents believed they should receive Pap smears annually or every 2 years after a normal smear, but 36% provided a

reason for not having done so.[45] Reasons most commonly cited were lack of insurance, adverse experience at prior Pap smear screening, and a belief they did not need it because they were not sexually active with men. Ten percent of subjects were told (by physicians in all but one case) that they did not need a Pap smear because they were not sexually active with men. Despite high levels of education and income, women with no prior sex with men were less likely to have ever received a pelvic examination, received their first Pap smear at an older age, and had less frequent Pap smears relative to women who reported prior sex with men. Among the few nationally representative surveys, the Boston Lesbian Health Project used snowball sampling to query a national sample of 1633 lesbians.[98] While overall screening rates approximated the general population, 39% of respondents younger than 20 years and 16% of those 20–29 years had never had a Pap smear and 29% of those 30–39 years had not had one in over 3 years. A multilingual population-based survey in New York City found that WSW were less likely to have had a Pap test in the past 3 years (66 vs. 80%, $P < 0.0001$) or a mammogram in the past 2 years (53 vs. 73%, $P = 0.0009$) than other women. After adjusting for health insurance coverage and other factors, WSW were ten times (adjusted OR 9.8, 95% CI 4.2, 22.9) more likely than non-WSW to have *not* received a timely Pap test. Of interest, subjects' likelihood of having received Pap tests was directly related to whether sexual behavior and self-reported sexual identity were concordant. WSW who identified as lesbians were more likely to have received timely Pap tests (97 vs. 48%, $P < 0.0001$) than those who identified as heterosexual.[99]

What might constitute potential barriers to preventive care by lesbians and how can they explain reduced rates of Pap smear testing or STD-related risk assessment? The first area relates to providers' assessment of and patient's disclosure of sexual behavior and STD-related risk, which are intimately intertwined. Most providers do not routinely perform a sexual history, and thus fail to elicit report of risk behavior.[100] Even if a history is sought, many lesbians (53–72%) may not disclose their sexual behavior to physicians, because disclosures may elicit negative or inappropriate reactions.[101,102] Of note, in a survey of 6935 self-identified lesbians, disclosure of sexual orientation was favorably associated with receipt of appropriate Pap smear screening.[103]

Second, even if behavior is assessed and disclosure of same-sex behavior or lesbian sexual orientation occurs, many healthcare providers lack specific knowledge about STD/HIV prevention and care as they pertain to lesbians. Professional health curricula, including medical schools and residencies, are not mandated to provide education about care of gay and lesbian patients, although some are increasingly doing so.[104–107] Upon eliciting a history from a lesbian patient, providers may assume that STD risk is negligible and, in particular, may fail to obtain a complete sexual history or to do so in a sensitive, nonjudgmental manner. Compounding lack of specific knowledge is the possibility of insensitivity, which may arise from lack of familiarity with gay patients or from frank discomfort dealing with gay people in general.[108–111] For example, one-quarter of 249 Chinese medical students surveyed in 2004 viewed homosexuality as a psychiatric disorder that required therapy, and 25% of family medicine residency directors expressed hesitation in matching openly gay residents in a survey published in 1996.[108,109] Qualitative research has raised serious concerns regarding a lack of sensitive health care that included knowledge specific to lesbian health concerns, and to sexual practices as they relate to risk of STD transmission between women.[102,112] The general invisibility of lesbians in public policy statements and recommendations has compounded this problem; the 2006 CDC STD Treatment Guidelines were the first edition of this widely cited document to include a section on WSW.[48]

Third, many lesbians may perceive themselves to be at low risk for STD acquisition from female partners and for cervical dysplasia. As described in depth in a large study of STD risk perception among lesbians, perceived vulnerability to STD is likely informed by a complex construct of social messages, perceptions of sex partners and their trustworthiness, and stigma.[112] Limited qualitative research has identified several specific misperceptions, notably the perception that the need for STD risk reduction behaviors is primarily a concern for heterosexual women. Participants in focus groups evidenced a very limited knowledge of BV and of the potential for common STDs, including genital herpes and HPV, to be transmitted between women.[102] BV and vulvovaginal candidiasis, in particular, were frequently confused. In another large survey of 1086 lesbians, only 43% of women with the presence of a clear risk factor for HIV perceived themselves to be at risk.[113] Similar assumptions about HPV acquisition from female partners may place lesbians at risk for delayed detection of cervical cancer by infrequent, or no, Pap smear screening, as evidenced by attitudes in several published studies.[45,95–98]

Finally, while lesbians are an economically diverse group, the earnings of lesbian households as a whole are likely less than that of households inhabited by an employed male. Compounding this may be lack of insurance in the absence of domestic partner benefits or unwillingness to disclose sexual orientation to obtain such benefits when they are offered. Moreover, lesbians who do not also have sex with men may not access venues providing hormonal contraception, thus eliminating another "routine" opportunity for STD and Pap smear screening.

FUTURE DIRECTIONS TO IMPROVE STD/HIV PREVENTION AND CONTROL AMONG WSW

Available data—though limited—can help to inform recommendations for STD-related care of WSW. STD transmission risk likely depends on the STD under consideration and

sexual practices involved. Some practices, including oral–genital sex, vaginal or anal sex using hands, fingers, or penetrative sex toys, and oral–anal sex, are practiced commonly. Digital–vaginal or digital–anal contact, particularly with shared penetrative sex toys, could potentially transmit infected cervicovaginal secretions, a risk most directly supported by reports of metronidazole-resistant trichomoniasis and genotype-concordant HIV sexually transmitted between women who reported these behaviors, and by the high prevalence of BV, which frequently occurs in both members of mutually monogamous female partners. Transmission of common viral STDs, especially HPV and HSV, requires only skin to skin or mucosa contact, which frequently occur in this context. Studies have detected HPV DNA by PCR-based methods from the cervix, vagina, and vulva in 13–30% of WSW, including those who reported no prior sex with men. Both high- and low-grade SIL have occurred in WSW who reported no prior sex with men. Importantly, most self-identified lesbians (53–99%) have had sex with men, and many (21–30%) continue to do so. Given this, all WSW should undergo Pap smear screening using current national guidelines. While risk of *C. trachomatis* transmission between women is unknown, WSW who continue to have sex with men are clearly at risk; in the absence of data, WSW should undergo routine screening according to current national guidelines. HSV-2 genital transmission probably occurs with relative inefficiency, but the relatively frequent practice of orogenital sex may place WSW at higher risk of genital infection with HSV-1, a hypothesis supported by the association between HSV-1 seropositivity and lifetime number of female partners. Transmission of syphilis between female sex partners, likely through oral sex, has been reported. Finally, WSW who are also currently sexually active with men may, in some settings, demonstrate increased sexual risk-taking behavior. Among women attending STD clinics, reports of sex with women in addition to sex with men has been associated with markedly increased prevalence of HIV-related risk behaviors, including sex with gay or bisexual men, use of injection drugs and crack cocaine, and exchange of sex for drugs or money. No data on sexual transmission of viral hepatitis are available for WSW, but sexual contact involving menstrual fluid presents a potential exposure.

The relatively limited knowledge of risk-related behaviors among WSW has impeded the development of prevention strategies for this population, including effective behavioral interventions and counseling messages. Although "safe sex" messages pertaining to sex between women are available on the Internet and from some community organizations, none have been specifically tested for acceptability, potential for adherence, or efficacy in reducing STD/HIV transmission between women. An intervention among women with BV aimed at reducing the sexual transfer of vaginal fluid as a means of reducing BV recurrence is currently under study.[102] Such an intervention could conceivably employ one or more of several methods depending on the sexual practices involved. For example, transfer of vaginal fluid during digital–vaginal sex might be reduced by the use of disposable gloves, or by prophylactic use of a topical antimicrobial solution or gel, and a male condom could be used on vaginally inserted sex toys for the same purpose. Because lesbians generally believe that the risk of STD transmitted between women is low, any intervention must include an educational component explaining the evidence that exists to support such a possibility. If this is not adequately conveyed, women may have little motivation to adhere to such an intervention. Qualitative research indicates that lesbians may express a relatively high level of responsibility for not infecting sex partners with an STD or HIV, if they know themselves to be infected.[102,112] Thus, any intervention should incorporate themes of personal responsibility and care for partners' well-being and health. Finally, an intervention would be most likely to succeed if the preventive practice is framed in terms of sexual enjoyment and healthy sexuality rather than in terms of disease, and if respect for one's body and one's sexual choices are emphasized.

A general lack of knowledge about the population of lesbians has been promulgated by omission in many natural history studies of health and disease in women. Research in WSW populations would clearly benefit from inclusion of some measure of same-sex behavior in surveys that have traditionally focused on reproductive health outcomes of women assumed to be exclusively heterosexual; such inclusion is unlikely to adversely affect overall response rates.[7] Other research priorities should include the epidemiology of high-risk HPV types and SIL, conditions that could contribute to infrequent Pap smear screening, and better definition of risk of transmission of specific STDs. The most significant bacterial STD for which more precise data are needed is *C. trachomatis*. Moreover, health-care providers—particularly those in training—would benefit from education to enhance their skills in taking a thorough, sensitive sexual history from all patients, but especially sexual minorities, adolescents, and highly marginalized patient groups, such as HIV-infected lesbians of color.[114–116] Beginning to describe the sexual networks in which lesbians participate—particularly as they involve men at potentially high risk for STDs, including HIV—should provide much-needed data on the sexual and social dynamics of a highly diverse population. The intriguing observation of BV concordance within female sexual partnerships should offer an opportunity to decipher the enigmatic etiology of this common condition. This information could not only contribute to advances in understanding the microbiology and sociology of STDs in general, but more immediately, would inform a cogent approach to counseling lesbians and educating health-care providers about STD-related risk and prevention.

15 HIV and Other Sexually Transmitted Infections in Injection Drug Users and Crack Cocaine Smokers

Don C. Des Jarlais and Salaam Semaan

The burden of HIV and other sexually transmitted infections (STIs) in persons who use illicit, psychoactive drugs, including injection drug users (IDUs) and crack cocaine smokers, is certainly high enough to justify special consideration in a textbook on STIs. Fortunately, the scientific work on parenteral and sexual transmission of HIV infection in IDUs and crack cocaine smokers, has been extensive and includes systematic reviews and meta-analytic work.[1–7] However, limited work exists on the burden of other STIs in IDUs and crack cocaine smokers. Given this imbalance—the extensive HIV literature and the limited literature on other STIs in IDUs and crack cocaine smokers—we present, in this chapter, a comprehensive review of the HIV situation and a more targeted review of three bacterial STIs: chlamydia, gonorrhea, and syphilis, and three viral infections: genital herpes, hepatitis B, and hepatitis C. HIV, hepatitis B, hepatitis C, and syphilis may be transmitted through both parenteral and sexual mechanisms and our review reflects the burden of these infections generated by these two transmission modes. Sexual transmission of hepatitis C is not responsible for the majority of infections. We discuss it in this chapter because the transmission of hepatitis C through injection equipment has been covered extensively elsewhere.[8–12] *Trichomonas vaginalis*,[13–15] bacterial vaginosis,[13] and human papillomavirus[16,17] are not addressed in this chapter because few studies have assessed rates of these STIs in IDUs and crack cocaine smokers. Because there is also an extensive literature on the association between smoking of crack cocaine and infection with syphilis[18–22] and HIV,[23–26] we focus our review on the recent literature on syphilis and other STIs in crack cocaine smokers, as well as in IDUs. The use of methamphetamine, unfortunately an emerging problem for drug users, is covered in other studies.[27] Sexual transmission is the main mechanism of transmission for the bacterial STIs: chlamydia, gonorrhea, and syphilis, and for the viral STI genital herpes; accordingly we cover these four STIs in this chapter.

In this chapter, we focus primarily on the literature published between 1995 and early 2005. We review a comprehensive list of the studies conducted in the United States and an illustrative list of studies conducted in countries other than the United States. We refer to three groups of studies: (1) studies that were conducted exclusively with IDUs, (2) studies that were conducted exclusively with crack cocaine smokers, and (3) studies that included both IDUs and crack cocaine smokers and often presented the results for the combined sample of IDUs and crack users. The IDUs in these studies primarily injected heroin, cocaine, or speedball (heroin and cocaine in combination) and might also have smoked crack cocaine. We use the term IDUs and crack cocaine smokers (or drug users) to refer to samples or to studies of both IDUs and crack cocaine smokers.

In addition to assessing the burden of HIV and other STIs in drug users, we also summarize the public health efforts and successes that have been accomplished to date, as well as gaps in research and program activities. Our goal is to highlight the activities that still need to be addressed in the prevention and control of HIV and other STIs in this important and heterogeneous population.

INJECTION DRUG USE, HIV, AND OTHER STIs

The causal linkages between injection drug use, sexual behavior, and STIs are many and complex. The causal relationships may be mutual and nonlinear, and are often embedded in a variety of contextual and confounding variables. Potential relationships include (1) IDU leading to high rates of unsafe sex behaviors and to high rates of STIs through reducing inhibitions or increasing sexual desire, (2) IDU leading to exchange of sex for drugs or money to purchase drugs, with a possible increase in STIs, and (3) IDU leading to decreased libido or decreased ability to perform (for males) and thus to reduced sexual activity and reduced risk for STIs.

Contextual variables can include the local economic conditions, local prevalence of STIs, local norms regarding different sexual practices (including use of condoms), and social norms governing gender relationships. The majority of the studies reviewed in this chapter suggest that IDUs often

have higher rates of STIs than persons who do not inject illicit drugs. This higher association, however, should not be interpreted as evidence for direct causation. In particular, one should avoid assuming a dose-response relationship that more use of injection drugs will be associated with even higher rates of STIs.

Another aspect of the potential causal relationships between injection drug use (IDU) and STIs is worth noting. Randomized controlled trials (RCTs) are often considered the gold standard for determining causation in behavioral and biomedical research. It would clearly be unethical to randomly assign research subjects to IDU versus no IDU in order to observe changes in rates of STIs as an outcome variable. Indeed, it would be unethical to simply observe increases in IDU without making all reasonable attempts to reduce injection drug use. It is, of course, ethical and practical to randomly assign interventions to reduce IDU by users and then observe changes in rates of STIs. However, in such studies, current ethical standards require that some attempts also be made to reduce IDU and STIs of participants in the control condition. This may be "usual care" or some form of "minimal" or "basic" services for the control group. Just what is provided to the control group can vary greatly across studies. Such variation makes it demanding conceptually and analytically to synthesize results across different studies.[28,29] Thus, while RCTs are usually considered the gold standard for assessing causal relationships in medicine and public health, they are not particularly useful designs for studying potential causal relationships among injection drug use, unsafe sexual behaviors, and STIs.

HIV INFECTION

A number of infectious agents, including HIV, hepatitis B, and syphilis, can be transmitted both through sexual and parenteral routes. HIV is certainly a special case among these pathogens. Both, the very high fatality rate of HIV-infected persons who do not receive antiretroviral treatment and the potential for HIV to reach very high prevalence levels in drug users make HIV by far the most important of the organisms that can be transmitted both sexually and parenterally.

The multiperson use ("sharing") of needles and syringes is a relatively efficient method for transmitting HIV between IDUs. Extremely rapid spread of HIV has been observed in many populations of IDUs, with incidence rates of 10/100 person years up to 50/100 person years. Such rapid transmission has occurred in North America,[30] Western Europe,[31,32] and, more recently, in many areas of Asia and Eastern Europe.[33]

Several factors have been associated with rapid transmission of HIV between IDUs,[34] including lack of awareness about HIV and AIDS, limited availability of sterile needles and syringes, and situations that promote "rapid partner change" of IDUs. The term "rapid partner change" refers to IDUs sharing needles and syringes with large numbers of other IDUs (sharing partners) within short time periods. Examples of injection situations and settings that create rapid partner change include injecting with a "dealer's works" (injection equipment that a drug dealer lends to successive customers) and "shooting galleries" (locations where IDUs rent and use a needle and syringe, and then return them to the gallery operator to be rented to other IDUs). As people tend to be much more infectious in the few months just after they have become infected with HIV,[35] rapid partner change is an important factor in transmission of HIV between IDUs. If the conditions that facilitate rapid transmission of HIV in a population of IDUs are not ameliorated, very high levels of HIV infection can result. Around 80–90% of IDUs in certain areas in China and Myanmar have become infected with HIV,[33] essentially saturating the local IDU population.

At the other extreme, it is quite possible to prevent epidemics of HIV infection in IDUs. Three factors appear to be important in preventing HIV epidemics in IDUs: (1) beginning prevention efforts early, when the number of HIV-infected IDUs is still low; (2) developing trust and communication between health workers and IDUs; and (3) providing very good access to sterile needles and syringes. Community outreach,[36] peer outreach,[36] and syringe exchange programs[37,38] have been the most commonly used programs to prevent epidemics. These prevention programs and strategies have kept HIV infection levels under 5% in many different cities[39] and in several countries, such as the UK[40] and Australia.[41–43]

Prevention of HIV transmission is much more difficult after high HIV seroprevalence levels (20% or higher) have been reached. With both large numbers of infectious IDUs and large numbers of uninfected IDUs at risk for becoming infected, even modest levels of continuing risk behaviors can drive substantial rates of transmission. In such situations, HIV incidence rates of 4/100 person-years to 8/100 person-years have been observed.[31] It does appear, however, that large scale implementation of HIV prevention programs for IDUs over long-time periods (a decade or longer) can lead to eventual declines in HIV incidence in IDU populations.[39,44–49]

Although psychoactive drugs can reduce sexual drive and interfere with sexual performance, data on the number of sex partners and on the proportion of sexually active drug users indicate that drug users are a sexually active group.[50–52] Once HIV prevalence has reached a high level in a population of IDUs (20% or more), sexual transmission between IDUs and from IDUs to sex partners who do not inject drugs becomes a potentially very important problem.[53,54] The great concern is that sexual mixing and transmission in drug users would lead to widespread, self-sustaining, heterosexual transmission of HIV in the local area, where heterosexual transmission would continue

even if all further syringe sharing transmission of HIV were prevented.

The conditions under which high HIV prevalence rates in IDUs will lead to large-scale heterosexual transmission of HIV in persons who do not inject drugs have not been fully identified. Clearly, factors such as the number of HIV-infected IDUs, the scale of commercial sex work, the extent to which male IDUs purchase sex from sex workers, the background prevalence of STIs that facilitate HIV transmission, and the absence or presence of HIV prevention programs are all likely to be important. At present, IDUs are the leading edge of the HIV epidemic in many parts of Southeast Asia and Eastern Europe,[55] including China, Vietnam, Russia, and Estonia.[33,56] The initial HIV epidemics in these areas seem to be developing into "generalized" heterosexual epidemics, with 1% or more of the adult population infected with HIV.

The HIV epidemic in IDUs in New York City has been the largest HIV epidemic of IDUs in the world. It offers useful lessons in both rapid transmission of HIV between IDUs and eventually successful prevention and in combinations of parenteral and sexual transmission of HIV. HIV was introduced into the IDU population during the mid-1970s and it spread very rapidly during the late 1970s and early 1980s. Substantial risk reduction efforts began with IDUs in New York City during the mid-1980s, and HIV prevalence stabilized at approximately 50%.[30,57] The legalization and large-scale expansion of syringe exchange and other HIV prevention services for IDUs in the city, which began in 1992, was associated with drastic reductions in HIV prevalence and incidence in New York IDUs. These declines were seen in multiple studies, including IDUs recruited from drug detoxification programs, methadone maintenance programs, and through street outreach. HIV prevalence declined from approximately 50% in 1990 to the current level of 15–20%,[45] and HIV incidence declined from an estimated 4/100 person years to an estimated 1/100 person years.[48,58] There has also been a decline in HIV incidence among IDUs in the United States as a whole.[59] Declining HIV prevalence among IDUs in cities with relatively good access to sterile syringes has also been observed in Northeastern cities in the United States,[60] and in Europe,[61] particularly in northern Italy.[62]

Sexual transmission of HIV from IDUs to sex partners who do not inject drugs has undoubtedly occurred in New York City since the beginning of the HIV epidemic in IDUs.[53] Initial sexual transmission was primarily from IDUs to the long-term sex partners. The crack cocaine epidemic that occurred in New York during the mid-to-late 1980s involved frequent exchange of drugs for sex and sexual transmission of HIV between persons who used crack.[26] Many IDUs also used crack cocaine[63] and IDUs were a major factor introducing HIV into the crack-for-sex exchange networks. The crack cocaine epidemic in New York and elsewhere has diminished since the 1990s, although there continues to be substantial use of this drug.[64]

Noninjection use of heroin increased greatly in New York City during the late 1980s and early 1990s and continues to the present. This is likely to be the result of both concern about contracting HIV and the reduced price and higher quality of heroin available in the city. Since the mid-1990s, approximately half of heroin users entering publicly funded drug abuse treatment in New York City have reported intranasal use ("sniffing") as their primary route of heroin administration.[65] Noninjection users of heroin often associate with injection users, however, and there is undoubtedly sexual transmission of HIV between injection and non-IDUs.

HIV prevalence has been declining among IDUs in New York City, as mentioned earlier.[45] However, HIV prevalence among noninjection heroin and cocaine users has been increasing, with current prevalence between 10% and 15%.[66] Thus, while injection-related transmission was initially the dominant factor in HIV transmission in IDUs in the city, it now appears that sexual transmission is at least an equally important route of transmission, not only in New York City but also among IDUs in many other cities, including San Francisco and Baltimore.[67,68] Even in areas where injection-related HIV transmission due to IDU is still the predominant mode of HIV transmission among IDUs, such as many parts of Eastern Europe,[55] Central and East Asia,[31] it is important to address sexual transmission among IDUs and from IDUs to sex partners who do not inject drugs. Failure to do so may lead from an HIV epidemic that is concentrated among IDUs to a "generalized" heterosexual epidemic.

MEASUREMENT OF OTHER STIs IN DRUG USERS

STD clinics and the national STD surveillance system do not usually collect or report data by drug use behaviors because drug use behaviors do not represent a direct mode of transmission for most of the non-HIV STIs. Thus, research studies are the primary source of data on the rates of STIs in IDUs and crack cocaine smokers.[69]

In the early part of the 1990s, data on rates of STIs, other than HIV, in IDUs and crack cocaine smokers relied primarily on self-reports of STI diagnoses. In these studies, IDUs and crack cocaine smokers responded to questions such as: "How many times have you been told by a doctor or nurse that you had (hepatitis B, chlamydia, syphilis, gonorrhea, genital warts, or genital herpes?)"[70] Data from these studies were either analyzed for each STI separately or, most often, the data were analyzed for several STIs combined together.[70–73]

In the mid-1990s, investigators working with IDUs and crack cocaine smokers started using biologic markers

(e.g., assays performed in blood or urine samples) to measure STI rates. Data based on biologic markers provide more accurate assessment of the STI burden because these data are not subject to the limitations of self-reported data, which may include underreporting because of (1) a lack of awareness of previous infections, (2) an unwillingness to discuss sensitive subject matter, and (3) an inability to recall disease information provided by a health care provider. However, prevalence rates for self-reported STIs in IDUs and crack cocaine smokers are higher than the rates based on biologic data, probably because self-reported data have most often assessed lifetime experience. Although use of biologic markers is an important step in the assessment of STIs in IDUs and crack cocaine smokers, there are still few such studies. Increased willingness to work with drug users and increased funding for this research will help in assessing the burden of STIs in drug users and in developing relevant prevention and treatment activities. The data that follow on the prevalence and incidence of non-HIV STIs are summarized in Tables 15-1 to 15-3.

CHLAMYDIA

Rates Based on Self-Reported Data: Two studies using self-reported data on lifetime history of chlamydia suggest that approximately one in six IDUs have been infected with chlamydia.[70,74] A chlamydia prevalence of 17% was reported in one study of female IDUs and crack cocaine smokers whose average age was 35 years.[70] Another study reported a prevalence of 15%, (10% among males and 29% among females) in a jail-based sample of IDUs where most participants were older than 30 years.[74]

Chlamydia Rates Based on Biologic Markers: Several studies tested for chlamydial infections in IDUs and crack cocaine smokers using nucleic acid amplification tests. Almost all these studies used the ligase chain reaction test. The overall prevalence ranged from 1% to 5%, with similar rates reported for IDUs and crack cocaine smokers recruited from drug treatment facilities[14,15,75–78] and those who were not.[13,79,80] Drug users recruited from out-of-drug-treatment facilities were younger (18–30 years)[13,79,80] than those recruited from drug treatment facilities (median age of late 30s). The prevalence rates reported for women were higher than those reported for men and were slightly lower in white drug users compared to African Americans or Latinos. Analysis by type of drug-related behavior revealed rates as high as 14% in female crack users and as high as 13% in female IDUs.[80] Chlamydia prevalence was also substantial in those who engaged in the sex trade. For example, prevalence rates of 6% were found in those with a history of selling sex,[75] 8% in female IDUs and crack cocaine smokers who received money for sex,[79] 7% in female IDUs and crack cocaine smokers who received drugs for sex,[79] 12% in male IDUs whose last sexual encounter was with a paying partner,[79] 9% among those with more than five partners in the past 4 weeks,[75] 10% in male IDUs who had ever been forced to have sex,[79] and 11% in male IDUs with more than 10 sex partners in the 6 months prior to data collection.[79]

Chlamydia was common in those who reported that they had had chlamydia or other STIs in the past year. For example, chlamydia prevalence was as high as 33% in male and female IDUs who reported having had genital herpes in the past year, 20% in female IDUs who reported having had genital warts in the past year, and 14% in male IDUs who reported having had chlamydia in the past year.[79]

One study reported incidence rates for chlamydia,[79] with 2% reported in male IDUs and 4% reported in female IDUs at the 6-month follow-up period. Another study examined correlates of prevalent chlamydial infection using regression analysis.[79] This study found that for male IDUs, younger age, younger age of penetrative sex, and African American race were significantly associated with chlamydia. For female IDUs, younger age of penetrative sex and having received money for sex were associated with chlamydia.

Selected International Studies: Studies conducted with drug users outside the United States showed similar rates to those reported in drug users in the United States, with a prevalence of 3% in Quebec city,[81] 2% in Thailand,[82] and 6% in Melbourne, Australia.[83]

Overall Assessment of U.S. Rates: Review of the seroprevalence rates of chlamydia in drug users show that IDUs and crack cocaine smokers have relatively high rates of prevalent and incident infections. However, the 7–33% prevalence range observed among female IDUs and crack cocaine users is higher than the 3–20% (median 6.3%) chlamydia positivity rate seen among 15–24-year-old women screened in family planning clinics.[84] A similar range was observed for the 50 states where 3.1–14% (median 9.2%) state-specific prevalence rate was reported for 16–24-year-old economically disadvantaged women entering the National Job Training Program.[84] Variation in prevalence rates in IDUs and crack cocaine smokers by sociodemographic factors mirrors the variation in rates seen in other populations, with lower rates in older, white, and male drug users. Higher prevalence was seen in subgroups of drug users, especially in female crack cocaine users, female IDUs, and drug users of both genders who are simultaneously at risk for sexual transmission. Higher prevalence rates were found in those who reported having had other STDs including genital warts, genital herpes, and a previous infection with chlamydia.

Table 15-1. Summary of Selected Information on Rates of Bacterial STDs (Seropositivity Rates) in Drug Users in the United States[a]

	Syphilis	Gonorrhea	Chlamydia
Incidence rate	6/1000 person years[86] 26/1000 person years[87]	0% among male IDUs at 6 months follow-up[79] 1% among female IDUs at 6 months follow-up[79]	2% among male IDUs at 6 months follow-up[79] 4% among female IDUs at 6 months follow-up[79]
Prevalence rate	Seropositivity rate: 1–6%[14,76]	Prevalence rate: 1–3%[13,15,77–80]	Prevalence rate: 1–5%[79,86]
Prevalence rates for demographic variables[b]	Higher among African Americans (6–8%)[13,75,87] Mixed results with respect to age 12% among 18–25 IDUs[77] 2% among 20–29 years and 7% among >40 years[76]	Higher (4%) among females[75] Lower (1%) among whites[75] Higher among younger drug users (4% among <20 years old)[75]	Lower among whites (4% among white males and 6% among white females)[79] Lower among older drug users (2% among <25 years old)[13]
Prevalence rates for drug-related variables[b]	Higher (9%) among crack users[80] Higher (13%) among female IDUs[80] Similar for those in- and out- of drug treatment	Higher (11%) among male crack users[80] Higher (13%) among female IDUs[80] Similar for those recruited from in- and from out- of drug treatment drug treatment	Higher (14%) among female crack users[80] Higher (13%) among female IDUs[80] Similar for those recruited from in- and from out- of
Prevalence rates for sex-related variables[b]	Higher (14%) among those with >5 partners past 4 weeks[87]	Higher (5%) among those who exchange sex for money[79]	Higher (8%) among those who trade sex[75] Higher (9%) among those with >5 partners past 4 weeks[13] 4 weeks[13]
Prevalence rates for health-related variables[b]	Higher (33%) among females with previous syphilis infection[90] Higher (42%) among HIV-positive drug users[87]	Higher (4%) among HIV-positive female IDUs[79]	Higher (33%) among those who had genital herpes past year[79] Higher (14%) among male IDUs with previous chlamydial infection[79]
Multivariate correlates of prevalent infection[c]	History of an STD (O.R. = 11.7)[88] Self-report of previous infection with syphilis (O.R. = 10.3)[88]	Among female IDUs: younger age of penetrative sexual debut (O.R. = 1.27)[79] and having received money for sex past 6 months (O.R. = 5.17)[79]	Among male IDUs: younger age (O.R. = 0.89)[79], younger age of penetrative sexual debut (O.R. = 0.91)[79], and being African American (O.R. = 2.92)[79] Among female IDUs: younger age of penetrative sexual debut (O.R. = 1.16)[79] and having received money for sex past 6 months (O.R. = 1.96)[79]
Multivariate correlates of incident infection[c]	Recent initiation into drug use (H.R.) = 4.6)[87]	Not reported in the literature reviewed for this chapter	Not reported in the literature reviewed for this chapter

GONORRHEA

Gonorrhea Rates Based on Self-Reported Data: Few studies provided information on rates of lifetime infection with gonorrhea in IDUs and crack cocaine smokers. An overall rate of past infection of 18% was reported in a jail-based sample of IDUs, most of whom were older than 30 years,[74] with higher rates reported by incarcerated female IDUs than by incarcerated male IDUs (29% vs.15%).[74] History of gonorrhea was reported by 37% of IDUs and crack cocaine smokers recruited in Alaska (average age = 34 years)[85] and by 36% of participants in an 18 site-national sample[85] (average age = 37 years). That same study examined the multivariate correlates of past infection with gonorrhea using regression analysis. It found that in male IDUs and crack cocaine smokers, having ever used cocaine, being African American, younger age, having had illegal income in the past 30 days, and having ever used amphetamines were associated with higher frequency of history of gonorrhea.[85] These predictors were the same correlates found in the sample of male IDUs and crack cocaine smokers recruited in Alaska and in the national sample. For females, the significant predictors in the sample recruited from Alaska were having traded sex for money in the past 30 days, being native American, and having been homeless. The significant predictors in the 18-site national sample were having traded sex in the past 30 days, being native American, and having traded sex for drugs in the past 30 days.[85]

Gonorrhea Rates Based on Biologic Markers: Several studies tested for gonorrhea in IDUs and crack cocaine smokers using nucleic acid amplification tests, mostly using the ligase chain reaction test. The overall prevalence rate, indicating current infection, ranged from 1% to 3% and was similar for those IDUs and crack cocaine smokers recruited from drug treatment facilities[14,15,75,76,78] and those who were not.[13,79,80]

While rates in female IDUs and crack cocaine smokers (ranging across studies from 1% to 13%) were higher than those in male IDUs and crack cocaine smokers, a few studies found little or no gonorrhea in male IDUs and crack cocaine smokers.[13,77,78] A few studies reported gonorrhea rates by race[13,75,79,80] and found that rates in white IDUs and crack cocaine smokers were lower than in IDUs and crack cocaine smokers of other racial or ethnic groups. In terms of drug-related behaviors, gonorrhea rates as high as 11% were found in male crack users and as high as 13% in female IDUs.[80] As with chlamydia, prevalence was substantial among drug users with sexual risk behaviors. Prevalence rates of 5% were found in those with more than five partners in the past 4 weeks versus 2.5% in those who had one to five partners in the past 4 weeks.[75] Prevalence rates of 5% were found in female IDUs who received money for sex versus 1% in those who did not receive money for sex.[79] Prevalence rates of 2% were found in female IDUs who were HIV-positive versus 0% in those who were HIV-negative.[79]

One study examined the incidence rates of gonorrhea in IDUs with 0%–1% reported in males and females, respectively, at the 6-month follow-up period.[79] In that same study, younger age of penetrative sex and having received money for sex were significant correlates of higher prevalent gonorrhea rates in female IDUs.[79]

Selected International Studies: Studies conducted with drug users outside the United States found low prevalence rates for gonorrhea: 0.4% (0 % in males and 1% in females) in Quebec city,[81] 0.4% in Thailand,[82] and 1% in Melbourne, Australia.[83]

Overall Assessment of U.S. Rates: The data on seroprevalence rates of gonorrhea in drug users show that IDUs and crack cocaine smokers have moderate rates of prevalence and incident infections, with lower incidence rates in males. However, the 4–13% prevalence range documented among female IDUs and crack cocaine users reporting ongoing sex risk behaviors is substantially higher than the 1% median positivity rate observed in 15–24 year old women screened in family planning clinics across the United States (range 0–3.8%) or the 2.4% median state-specific positivity rate among 16–24-year-old women entering the National Job Training Program (range 0–6.6%).[84] Variation in prevalence rates by sociodemographic factors again reflects the variation in rates seen in other populations, with lower rates in older, white, and male drug users. Higher prevalence rates were seen in subgroups of drug users, especially in male crack users, female IDUs, those who trade sex, and those with multiple partners. Higher rates of infection with gonorrhea were found in female IDUs infected with HIV.

SYPHILIS

Syphilis Rates Based on Self-Reported data: Self-reported lifetime history of syphilis among drug users was evaluated in the two studies of chlamydia described earlier.[70,74] An overall rate of 6% (2% and 8% in male and female IDUs and crack cocaine smokers, respectively) was reported in one study.[70] The average age of the participants in that study was 39 years for men and 35 years for women. Lower rates were reported in white than in African American IDUs and crack cocaine smokers (in males: 2% vs. 6%; in females: 5% vs. 9%).[70] The second study of incarcerated IDUs, most of whom were older than 30 years,[74] reported a lifetime history of syphilis in 3% of participants, also with higher rates in female than in male IDUs (7% vs. 2%).

Syphilis Rates Based on Biologic Data: A number of studies screened participants for syphilis using a nontreponemal serological test, such as the rapid plasma reagin test.

Reactive results were then confirmed by a treponemal test, such as the microhemagglutination *Treponema pallidum* test. Similar rates of syphilis seropositivity were found in studies with IDUs and crack cocaine smokers recruited from drug-treatment facilities and those recruited from out-of-drug-treatment. Overall prevalence rates (seropositivity rates), ranging from 2 to 6%, were found for in-drug-treatment IDUs and crack cocaine smokers.[14,75,76,86] In three of these studies, the median age of the participants was in the high thirties and age was not reported in the fourth study.[86] Similar overall prevalence rates, ranging from 1 to 6%, were found in recent studies with out-of-drug-treatment IDUs and crack cocaine smokers.[80,87,88] The age range of these study participants was 18–30 years,[88] and 18–24 years,[80] in the first two studies, and a median age of 43 years was reported for the third study.[87] However, earlier studies conducted in the early-to-mid-1990s with out-of-drug-treatment IDUs and crack cocaine smokers found much higher rates ranging from 13% to 20%[89,90] with a median age of 40 years reported for one study[89] and 38 years reported for the other study.[90] These differences may, in part, reflect the 90% decline in primary and secondary syphilis rates that was seen in the United States between 1990 and 2000.[84]

Prevalence rates in female IDUs and crack cocaine smokers as high as 30% and 35% were reported in earlier studies.[89,90] Echoing the epidemiology of syphilis in other U.S. nondrug using populations, rates in African Americans were higher than rates in IDUs and crack cocaine smokers of other racial or ethnic backgrounds.[75,88,90] Rates as high as 12% were reported among 18–25-year-old IDUs in-drug-treatment,[86] but another study with in-drug-treatment IDUs and crack cocaine smokers showed higher rates in those who were older (20–29 years: 2% vs. ≥40 years: 7%).[75] Drug and sexual risk behaviors and STI/HIV history were again associated with higher prevalence rates. Rates as high as 9% were found in crack cocaine smokers[76] and as high as 13% in female IDUs.[80] In terms of sex-related behaviors, rates as high as 14% were found in IDUs and crack cocaine smokers who had more than five sex partners in 4 weeks prior to data collection.[75] Rates as high as 33% were found in female IDUs and crack cocaine smokers who reported having had a previous syphilis infection.[88] Syphilis rates in HIV-positive IDUs and crack cocaine smokers were as high as 42% and were 17% in HIV-negative IDUs and crack cocaine smokers.[90]

Incidence rates were reported in a few studies with IDUs, with an overall incidence rate of 6/1000 person years reported in one study[86] and 26/1000 person years reported in another.[87] In the first study, incidence rates as high as 19/1000 person years were reported in those aged 18–25 years and as high as 16/1000 person-years in those who were paid or paid for sex.[86] Rates as high as 187/1000 person years were found in the subgroup that included male IDUs who had sex with men, bisexuals, and female IDUs who had sex with women.[87]

Studies that examined correlates of syphilis seropositivity rates found that being female,[89,90] being HIV infected,[90] being African American,[90] having had a history of STDs,[75] and having reported a previous diagnosis of syphilis[88] were positively associated with higher rates. In one study,[86] significant correlates of syphilis seroconversion were HIV seroconversion and having multiple sex partners. In another study,[87] significant correlates of syphilis seroconversion were recent initiation into IDU and having multiple sex partners.

Selected International Studies: Studies conducted with drug users outside the United States have found prevalence rates of 2% in Thailand,[82] 5% in Spain,[91] 6% in Jamaica,[92] 12% in St. Petersburg, Russia,[93] (and 7% in syringes obtained from drug users in St. Petersburg).[94] The rates in Bangladesh were 10% in clients of a detox clinic and 23% and 13% in clients of needle exchange programs in the central and northwestern parts of the country.[95]

Overall Assessment of U.S. Rates: The studies of syphilis in drug users show that IDUs and crack cocaine smokers have relatively high seropositivity rates and high incidence rates. Overall seroprevalence rates of 1–6%, and seroprevalence rates of 14–42% in selected subgroups with simultaneous sexual risk behaviors or a history of prior infection with STI or HIV have been reported. Higher seropositivity rates were reported in studies conducted in the 1990s reflecting the syphilis epidemic seen in the United States during that period.[96,97] In more recent studies, variation in seropositivity rates by sociodemographic factors mirrors the variation in rates seen in other populations, with lower rates found in older, white, and male drug users. Higher seropositivity rates were seen in subgroups of drug users, especially in crack cocaine users, those who trade sex, and those with multiple partners. Higher seropositivity rates were found in those who reported a previous episode of syphilis and in those infected with HIV. Higher incidence rates were reported in male IDUs who had sex with men.

GENITAL HERPES

Genital herpes Based on Self-Reported Data: Self-reports of having had genital herpes suggest, rather inaccurately, low rates of this genital ulcer disease among drug users. The rates ranged from 1%[70] reported in out-of-treatment IDUs and crack cocaine smokers (mean age of 35 years) to 5% in a jail-based sample of IDUs most of whom were older than 30 years.[74]

Genital herpes (HSV-2) Based on Biologic Markers: In contrast, the prevalence of herpes simplex virus-type 2 (HSV-2) determined by serological testing was high in IDUs and crack users. Overall, prevalence rates of genital herpes ranged from 38% to 61%.[75,76,88,89] In two studies, the majority of the participants were 25–44-years old,[75,76] and a median age of 40 years was reported in the third study.[89] The fourth study had young participants in the 18–30 years age group.[88] The two studies with in-drug-treatment IDUs[75,76] reported identical rates (44%). Similar (38%)[88] or higher (61%)[89] rates were reported in out-of-drug-treatment IDUs and crack cocaine smokers. Moderate rates (18%) were found in a household sample selected from a high-risk neighborhood.[80] Data on age were not reported for that sample.

Rates were two or three times higher in females than in males. They were as high as 75% for in-treatment female IDUs and crack cocaine smokers[75] and as high as 81% for out-of-treatment female IDUs and crack cocaine smokers.[89] Rates were higher in African American IDUs and crack cocaine smokers than in those of other racial or ethnic backgrounds. In one study with in-drug-treatment IDUs and crack cocaine smokers, the rates in whites, African Americans, Latinos, and others were 37%, 64%, 27%, and 29%, respectively.[75] In a study with out-of-treatment IDUs and crack cocaine smokers, the rates in whites and African Americans were 25% and 57% respectively.[88] Higher rates were reported by older age (20 years: 15% vs. ≥40 years: 57%).[75]

A higher prevalence rate was associated with both sexual and drug-related risk behaviors. High seropositivity was found in those with a history of selling sex versus those without such a history (74% vs. 41%),[75] male drug users who had had sex with men (50%),[88] and women who traded sex (81%).[88] Female sex workers who only smoked crack cocaine had similar rates to female sex workers who smoked crack and also injected drugs (73% vs. 65%).[98] Female IDUs and crack cocaine smokers who had a history of incarceration had higher rates than those who did not report an incarceration history (65% vs. 50%).[88] Higher rates were found in HIV-positive IDUs and crack cocaine smokers than in those who were HIV-negative (females: 93% vs. 56%, males: 78% vs. 20%).[88]

Independent correlates obtained in regression analysis included age over 30 years, female gender, and African American ethnicity.[75] In another study,[88] analysis was conducted by sex. In that study, significant correlates in female IDUs and crack cocaine smokers were being African American, having traded sex in the past 6 months, and having used heroin daily in the past 6 months. In males, the significant correlates were being African American, having had more than 30 lifetime sex partners, being HIV-infected, and ever been incarcerated.

International Studies: We did not find studies on HSV-2 conducted with drug users outside the United States.

Overall Assessment of U.S. Rates: Review of the data on biologic markers of genital herpes reported in four studies conducted with drug users shows that IDUs and crack cocaine smokers have high rates of HSV-2. The overall HSV-2 seroprevalence among IDUs and crack cocaine users of 38–61% contrasts with the 17% seroprevalence rate reported for the general U.S. population.[99] Variation in prevalence rates by sociodemographic factors among IDUs echoes the variation in rates reported for other populations, with lower rates in younger, white, and male drug users. Higher prevalence rates are reported in subgroups of drug users, especially in male drug users who have sex with men, in those who trade sex, in those who have multiple partners, in those who have a history of incarceration, and in those who are HIV-positive.

HEPATITIS B

Hepatitis B virus (HBV) is transmitted both parenterally and sexually. While HBV is transmitted in drug users primarily through the parenteral route,[100] sexual transmission of HBV in drug users is also common.[101] Prevalence of hepatitis B virus (HBV) infection is determined by serologic testing.

Prevalence rates of HBV are high in both in-drug-treatment and out-of-drug-treatment drug users. For in-drug-treatment IDUs and crack cocaine smokers, rates ranged from 11%[78] and 30%[75,76] to as high as 57%[102] and 67%.[103,104] Similar high rates were reported for out-of-drug-treatment IDUs starting from a higher level of around 25%,[8] 30%,[105–107] or 50%,[89] to as high as 80%.[106,108,109] In one study with drug users in the 15–30 years age group, prevalence rates of HBV infection were much higher in IDUs than in non-IDUs (37% vs. 19%), with non-IDU defined as sniffing, smoking, or ingestion of cocaine, crack, or heroin.[107]

Data from several studies show that 50–70% of IDUs become infected with HBV within 5 years of beginning to inject.[110] In HIV-positive IDUs and crack cocaine smokers, incidence rates of acute HBV ranged from 3.5 cases per 100 person years for recent injectors to 1.9 cases per 100 person years for recent users of noninjection drugs.[111]

A low proportion of IDUs (10–25%) perceive themselves to be at risk for HBV infection and, therefore, often do not get vaccinated.[112,113] Studies reported IDU vaccination rates for all 3 doses of hepatitis B vaccine ranging from 10% in primary health care clinics to 86% in drug treatment settings.[114–116] Low rates for hepatitis B vaccination indicate that IDUs and crack cocaine smokers, including recent injectors, and their sex and injection partners are at risk for infection with HBV. This situation of low vaccination rates continues, although an effective HBV vaccine has existed since 1982 and

recommendations for vaccinating IDUs and crack cocaine smokers were first made at that time.[117] Given that IDUs get infected with HBV very early in their injection years, IDUs need to receive vaccination for HBV as soon as they start injecting drugs.

Selected International Studies: Rates of infection with HBV reported in studies conducted with IDUs outside the United States ranged from 33% in Melbourne, Australia,[118] to 60% in Buenos Aires, Argentina,[119] and 48% in St. Petersburg, Russia.[93] A prevalence of 16% was reported in syringes used by drug users in St. Petersburg.[94]

Overall Assessment of U.S. Rates: Review of the data on Hepatitis B shows that IDUs get infected with hepatitis B primarily through injection of drugs, soon after initiation of drug injection. Despite the availability of an effective vaccine, a modest proportion of drug users are vaccinated for hepatitis B and a small proportion understand their risk for infection with HBV. IDUs with HBV infection have a high coinfection rate with HIV and HCV.[8]

IS HEPATITIS C VIRUS AN STI?

IDUs form the largest group of persons infected with hepatitis C virus (HCV), and most new infections occur in IDUs as a result of sharing syringes or injection equipment. Transmission of HCV is estimated to be 10 times more efficient than that of HIV.[120] The prevalence of HCV in IDUs is high and can reach 80%.[8–12,121] Uninfected IDUs generally become infected at rates of 10–20% per year.[12,122–124] Since the introduction of needle exchange and other HIV prevention interventions for IDUs, there is some evidence for decline in the prevalence rate of HCV in IDUs in general, including in recent users of injection drugs, but remains high, at around 50–60%.[121,124]

Although direct use of injection drugs is the most important risk factor for infection with HCV, sexual infection with HCV also deserves attention. Although causality cannot be inferred, for 2003, it was reported that 14% of acute hepatitis C cases were associated with sexual contact with a hepatitis C patient during the 6 weeks to 6 months before illness onset and that 26% of acute hepatitis C cases had more than one sex partner during the same time period.[125] Because transmission of many viruses through blood transfusion has essentially stopped in industrialized countries, some have suggested that evolutionary pressure may select certain strains that are more easily transmitted sexually.[126]

Review of studies that focused on HCV infection of monogamous heterosexual couples[127–129] and of men who have sex with men[130,131] showed that although sexual transmission of HCV is inefficient, it is possible. Recent case studies from Europe showed outbreaks of HCV infection in men who have sex with men.[132–134]

For IDUs, studies have focused primarily on prevalence and incidence rates and on correlates of infection with HCV.[9,106,135–139] Few studies among IDUs found significant correlates with risky sexual behaviors, however, hepatitis B infection was a significant correlate for infection with HCV in two studies,[9,137] and receiving money for sex was a significant correlate in one study.[9]

A relatively high prevalence of HCV is found in non-IDUs ranging from 20% to 40%.[137] Another study found a prevalence of 24% in non-IDUs in an addiction treatment unit in Philadelphia, of whom 65% did not know how HCV is spread.[102] A prevalence of 4% has been reported in noninjection sex partners of IDUs.[138] An additional concern is the high rate of unprotected sexual contact (29% for never injectors and 34% for former injectors) of HCV-infected current non-IDUs of heroin with partners who are either HIV-negative or who use noninjection drugs.[136]

To assess whether HCV gets transmitted sexually in drug users, it is important first to rule out other modes of HCV infection in non-IDUs. Because current noninjectors might have been former injectors who changed route of drug administration to reduce the risk for infection with HIV and might have been infected with HCV during their earlier drug injection days, it is prudent to assess the rate of HCV infection in current non-IDUs by their injection history (i.e., former injectors vs. never-injectors). It is also important to assess how non-IDUs get infected with HCV because there have been reports that in persons who smoke cocaine, transmission of hepatitis C can occur through sharing of smoking equipment.[140]

Review of the data on HCV rates in IDUs and in non-IDUs and of the reports of HCV outbreaks in men who have sex with men shows research gaps about the risk for HCV infection associated with specific sexual practices.[141] In particular, we do not know whether the low HCV heterosexual risk is increased during prolonged vaginal sex under the influence of cocaine (owing to delays in male orgasm) or during sex under the influence of crack (owing to having multiple sex partners in a short time). Similarly, we do not know if traumatic sex (e.g., fisting) and concomitant STDs in male IDUs who have sex with men increase the sexual risk for HCV infection. Although one might assume that sexual activities causing micro tears and abrasions increase the sexual risk for infection with HCV, data about the role of these factors are currently limited. There is also a need to examine the role of HIV and coinfection with other STIs, especially ulcerative STIs, such as syphilis and genital herpes. Collecting data on the characteristics of the sex act (e.g., rough sex, visible or invisible blood-producing sex, fisting) and on the viral load of the HCV-infected partner is important for understanding the sexual risk for HCV infection in drug users. Given the large proportion of HCV-infected IDUs, it is also important to assess the sexual risk of their sex partners for HCV infection.

OVERALL ASSESSMENT OF RATES

The rates of HIV and other STIs in IDUs and crack cocaine smokers deserve public health attention. The evidence-based research and intervention literature on HIV in drug users is, in general, more extensive than the literature on other STIs in drug users. Few studies on bacterial STIs and genital herpes in drug users have been published. Almost all of these studies were conducted as part of HIV research projects.

To the extent that the rates reported in research studies are underestimated because a certain proportion of drug users have been lost to follow-up, the rates could be even higher. In general, the reported rates, when age-adjusted, could be comparable to or higher than those reported in surveys conducted with the general population.[142–144]

The variation in the rates of the bacterial STIs—chlamydia, gonorrhea, and syphilis—in drug users by demographic characteristics, such as age, sex, and race, is similar to those reported in other populations.[69] Higher rates are usually reported in drug users who are younger, of a racial or ethnic background other than white, and in women. Rates of bacterial STIs also differ by drug use and sexual risk behaviors. Higher rates are reported in IDUs who are also crack cocaine users, in those who exchange sex for drugs or money, in those with multiple sex partners, and in those with a history of incarceration. Higher rates are also found in those who reported previous infection with the same STI or with other STIs and in those who were HIV infected.

The variation in bacterial STDs by sociodemographic characteristics is also noted for genital herpes, with the main difference being that higher HSV-2 rates are reported in older drug users because prevalence of this currently incurable STI increases with age. Because drug users are primarily infected with hepatitis B and C through injection drugs, variation in prevalence rates for these two infections is primarily dependent on injection-related history and variables. There is a high coinfection rate of HIV with HBV and HCV.

In general, the magnitude of the burden of STIs, other than HIV, reported in studies conducted with drug users in the United States is not different from the magnitude reported in international studies, although our review of international studies of IDUs and crack cocaine users has been limited. Table 15-3 provides a comparison of the prevalence rates reported in the United States with those reported in selected studies conducted in other countries. Accordingly, it remains important for the public health system to work with drug users to reduce the burden of STIs in this population.

WORKING WITH INJECTION DRUG USERS AND CRACK COCAINE SMOKERS

The problem of drug addiction and the prejudices that drug users face may make IDUs and crack cocaine smokers look as if they are a hard group with whom to work. The fact that HIV transmission has been greatly reduced among IDUs compared to other populations at risk for HIV infection[58,59,145–147] speaks volumes about the intentions and behaviors of IDUs in taking steps to reduce their risk for getting infected and infecting others with HIV.

Addiction: Life pressures can lead people to become addicted to simple pleasures or activities, such as gambling, or to more dangerous activities such as smoking, drinking, or injecting illicit drugs. However, all drug users deserve humane and ethical treatment.[148] From a health and human rights perspective, people addicted to a heavy drug still have the same rights as people addicted to what may seem to be simple pleasures or safer addictions. In addition, societal factors that marginalize people in terms of life opportunities also contribute to the epidemic of drug addiction and STIs, including HIV infection.[149,150]

Research conducted over the past 20 years have demonstrated how substance abuse treatment is associated with reduction in HIV transmission risk behaviors and in increased protection from HIV infection.[151,152] However, for drug treatment to meet its potential, it is important to make drug treatment readily available and accessible to IDUs and crack cocaine smokers[153] and to reduce the use of incarceration to curb drug addiction.[154,155]

Prejudice: IDUs and crack cocaine smokers often report feeling stigmatized and discriminated against by the health care system and by society in general. An awareness of how prejudices develop may help investigators, health care providers, and public health practitioners work with drug users in a humane way to reduce rates of addiction and rates of infection with HIV and other STIs.

A recent study explained how people develop prejudices toward others and identified the different feelings and reasons for these prejudices.[156] Results of this study indicate that different prejudices are associated with different feelings apparently aimed at reducing perceived threats. When IDUs and crack cocaine smokers are seen as posing a threat to physical safety, public health, or moral values, they evoke prejudices characterized by feelings of fear and disgust. However, recognition that societal conditions may lead some people to drug use and addiction may facilitate working with IDUs and crack cocaine smokers in an effective and humane way.

Partnering with IDUs and Crack Cocaine Smokers: Compassion and patience are required to work with IDUs and crack cocaine smokers. In working to control the HIV epidemic in IDUs in many cities in the United States and countries around the world, HIV investigators and their teams of interdisciplinary staff members showed IDUs the respect they deserve as human beings and demonstrated an understanding of how personal and structural determinants influence risk for addiction and for HIV infection.[36]

Similar positive attitudes are needed in working with IDUs and crack cocaine smokers to reduce their risk for infection with other STIs.

A list of 13 principles has been advocated to manage health care relationships with IDUs.[157,158] These principles are (1) developing a professional relationship that shows mutual respect and avoids blame or judgment; (2) educating IDUs and crack cocaine smokers about health care; (3) including IDUs and crack cocaine smokers in decision making; (4) establishing a multidisciplinary and case management team; (5) having a primary care provider who coordinates care needs; (6) developing an agreement on responsibilities; (7) providing a response to behaviors that violate mutual expectations or limits; (8) reducing barriers to accessing the health care system; (9) establishing realistic commitments to more healthful behaviors; (10) emphasizing the importance of risk-reduction measures; (11) acknowledging that success requires several attempts; (12) learning about local resources for IDUs and crack cocaine smokers; and (13) avoiding common pitfalls, such as unrealistic expectations, frustration, anger, moralizing, blame, and withholding therapy.

Despite real and potential difficulties, it is important that the public health system works with IDUs and crack cocaine smokers to reduce their rates of addiction and their rates of infection with HIV and other STIs.

INTERVENTIONS FOR HIV AND OTHER STIs

Efforts to control HIV and other STIs usually aim to interrupt transmission of infection and prevent the development of disease, complications, and sequelae. Primary prevention includes behavioral interventions that focus on information, education, and communication, use of barrier methods, vaccination, screening, testing, and case finding. Treatment strategies include promoting appropriate health-seeking behaviors, syndromic management, partner notification and management, and a supportive health care sector. Targeted interventions include working with those who trade sex for money or drugs, have high rates of sexual partnerships, or are HIV-infected. These subgroups of IDUs and crack cocaine smokers may be more likely to acquire and transmit HIV or STIs, forming a bridge with the general population.

Risk-Reduction Interventions: There is ample evidence in the literature that behavioral, social, and structural interventions have been effective in reducing the sexual risk behaviors of IDUs and crack cocaine smokers.[2,150,159] Several reviews and meta-analyses articles were published recently on the effectiveness of behavioral interventions in reducing the sexual risk behaviors of IDUs and crack cocaine smokers.[2,52,160] These reviews concluded that IDUs and crack cocaine smokers reduced their sexual risk behaviors to avoid becoming infected with HIV and to avoid transmitting HIV infection to others. The sexual risk reduction activities of IDUs and crack cocaine smokers reflected their rational and altruistic response to HIV, which poses a major health threat. In three studies in which the comparison group did not receive an HIV intervention, the average protective odds ratio for risk reduction associated with the behavioral and social interventions provided, was 0.60 (95% CI = 0.43–0.85).[2] When the authors extrapolated this moderate average effect size (an OR of 0.60) to a population with a 72% prevalence of risk behavior, the proportion of IDUs and crack cocaine smokers who reduced their sexual risk behaviors was 12.6% greater in the intervention groups than in the comparison groups.[2] Given the importance of reducing sexual risk behaviors of IDUs and crack cocaine smokers and the likelihood that moderate effects are cost effective,[161] the moderate magnitude of the odds ratio justifies providing intervention programs to IDUs and crack cocaine smokers at risk for the sexual transmission of HIV. In 30 studies in which an HIV intervention was also provided to the comparison group, the average protective odds ratio was 0.91 (95% CI = 0.81–1.03) and was not statistically significant, indicating that participants in both groups reduced their risk behaviors.[2] These results show that IDUs and crack cocaine smokers can reduce their sex-risk behaviors.

Providing evidence-based effective interventions is both superior and ethically responsible when compared to the alternative of providing nothing. Results of the evidence-based literature call for researchers, program providers, and policy makers to work together to make the interventions available to IDUs and crack cocaine smokers and to convert research interventions into materials for use in program settings. As interventions are implemented in different settings, it is important not to let stigmatization of drug use or infection with HIV or other STIs, and concerns about negative consequences of condom use limit effectiveness of interventions. It is equally important to develop and evaluate new interventions that would produce larger reductions in sexual risk behaviors including interventions that address the social roots driving drug addiction and the imbalance in gender relations.

Despite the vast number of behavioral intervention studies that aimed to reduce the sexual risk behaviors of IDUs and crack cocaine smokers, most of these studies focused on reducing the risk of getting infected with HIV.[2] Review articles on interventions that focused on risk reduction and treatment of STIs, other than HIV, do not specifically include IDUs and crack cocaine smokers.[162–164] While information aimed at reducing sexual risk behaviors should work both for HIV and for other STIs, there is a need to assess this assumption by providing specific information for the different bacterial and viral STIs. In one study that randomized IDUs and crack cocaine smokers either to receive risk reduction counseling on HIV and other STIs or to only receive risk reduction counseling on HIV, participants in both groups reduced their sexual and drug risk behaviors.[72]

Informing IDUs and Crack Cocaine Smokers About Safer Practices: Interventions with IDUs and crack cocaine smokers need to provide accurate information on how HIV and other STIs are transmitted sexually and how safer sex practices, including condom use, can reduce the risk for transmission. This information is necessary, though not sufficient, to change behavior. While abstinence prevents the transmission of HIV and other STIs, condoms provide a very effective alternative among sexually active persons in blocking the sexual transmission of HIV and many other STIs. Building on the message about the effectiveness of condoms for HIV prevention, IDUs and crack cocaine smokers need to learn that condoms also offer protection from the skin-to skin and skin-to-sore transmission of STIs such as HPV, genital herpes, and syphilis if the site of infection is covered by the condom.[165] It is also important to inform IDUs and crack cocaine smokers that condoms offer good protection against discharge-related infections such as chlamydia and gonorrhea.[166,167] Making condoms readily available either free or at low cost to IDUs and crack cocaine smokers is important to control the rates of HIV and other STIs. Making condoms publicly available to IDUs and crack cocaine smokers may also facilitate discussions of safer sex behaviors and may help develop peer norms supporting safer sex. IDUs and crack cocaine smokers also need to learn that reducing the number of sex partners and knowing the infectious status of partners is an important strategy in reducing risk of infection with HIV and other STIs.

It is also important to inform IDUs how to protect themselves when there is limited scientific knowledge related to a particular STI.[168] For example, use of condoms is important if other STIs are present or during sex acts that might traumatize the genital or rectal mucosa. HCV-positive individuals who are at risk for STIs and who have multiple sex partners may consider using condoms.[125]

Social Norms: In addition to the provision of accurate information about key aspects of HIV and other STIs, including mechanisms of sexual transmission and symptom recognition, it is also important to influence norms supporting safer behaviors. It is useful for IDUs and crack cocaine smokers to develop peer norms supporting safer sexual behavior, a strategy that is also important for generating social support for reducing sexually risky behavior.[169] It may be helpful if peer leaders or other persons who are respected by IDUs and crack cocaine smokers serve as role models for reducing sexual risk behaviors. Social support, new social norms, and role modeling can reinforce sexual risk reduction in IDUs and crack cocaine smokers.[150,170]

Informing IDUs and Crack Cocaine Smokers About the STIs: it is also important to inform IDUs and crack cocaine smokers about the different symptoms caused by different STIs, as well as the fact that most STIs are asymptomatic. Sharing this information with IDUs and crack cocaine smokers is important so that they are aware that transmission of STIs can occur in the absence of symptoms. For example, IDUs and crack cocaine smokers should be aware that the asymptomatic presentation of gonococcal and chlamydial infections in women perpetuates the transmission of these infections and explains, in part, why exchange of sex for drugs is a contributory factor. Many may not know the basic information such as that most persons with genital herpes are asymptomatic, shedding occurs even in the absence of lesions, and rates of asymptomatic shedding is higher in HIV-infected and immuno-suppressed people. Education and counseling about recognition of symptoms and the importance of seeking medical care and follow-up, including treatment of sex partners, is important. The aim of an educational effort is to reduce the risk of having IDUs and crack cocaine smokers transmit or acquire HIV or other STIs.

Informing IDUs and Crack Cocaine Smokers About the Synergy Between HIV and Other STIs: It is also important for IDUs and crack cocaine smokers to be informed about the synergy between HIV and other STIs and about its implication for prevention and treatment.[171] IDUs and crack cocaine smokers should learn that STI treatment decreases the risk for HIV transmission. They need to know that STIs, particularly those associated with genital ulcers, increase both the efficiency of HIV transmission and the susceptibility to HIV infection and, therefore, recognizing STI symptoms and seeking medical care are essential.

Vaccination for Hepatitis B: One of the healthy people 2010 objectives is to increase HBV vaccine coverage in IDUs and crack cocaine smokers and those with multiple sex partners to 90%.[172] Health care providers need to inform IDUs and crack cocaine smokers about the risk for HBV infection and the seriousness of the disease, and offer them vaccination. A coordinated and well-funded approach at facilities frequented by drug users (e.g., STD clinics, HIV counseling and testing sites, needle exchange programs, drug treatment facilities, corrections facilities) is needed to improve vaccination rates. Cash incentives, outreach efforts, flexible immunization schedules, and coordination between public health practitioners and medical care providers have been useful in improving vaccination rates.[107,173] Attention to issues surrounding reimbursement for vaccination would also help improve vaccination coverage. The use of a combined hepatitis A and B vaccine, with vaccination of drug users for hepatitis A recommended since 1995, would also be useful.[174]

Partner Notification: Reinfection with STIs is common in IDUs and crack cocaine smokers, probably because of inefficient patient–partner notification and because of exposure to new partners. Partner notification should include counseling about behavior change and treatment of the patients and their partners.[175] It is important to teach drug users how to inform their partners about the need for testing and treatment for STIs and how to reduce the potential for violence

or any other unintended negative consequence of partner notification.[176]

Provider-Based Interventions: Screening and testing for HIV and other STIs, including counseling, education, and provision of treatment, are central to acquiring knowledge of one's infectious status, reducing risky behaviors, and treating infected individuals and their sex partners. These services must be provided in a supportive climate that does not stigmatize IDUs and crack cocaine smokers and that keeps their information confidential. Counseling patients about following the medication regimen is important. Taking medications must be seen as a significant commitment on the patient's part, because inconsistent adherence to medications results in development of bacterial or viral resistance. Syndromic case management may be useful with IDUs and crack cocaine smokers especially if treatment is simplified by the use of clinical flow charts and standardized prescriptions and does not rely on IDUs and crack cocaine smokers returning for laboratory results to receive treatment. Investigators and health care providers committed to and experienced in working with drug users have been successful in establishing rapport and improving prevention and control outcomes. Recommended work-up for diagnosis of STDs in IDUs and crack cocaine smokers has been outlined recently.[175] Specific management recommendations for each STD appear in the CDC STD treatment guidelines.[177]

Integration of Services: Integration of prevention and care services for STIs and HIV with drug treatment is an important mechanism to reach IDUs and crack cocaine smokers. Such strategies are possible and have been successful.[15,78,178,179] However, such integration needs to be implemented on a wider scale, including assurance of appropriate funds and training of personnel.

Targeted Interventions: Targeted interventions are relevant because of the different physiologic effects of drugs and the differential effect on sexual behaviors among drug users. The stimulant properties of cocaine and methamphetamine, for example, are associated with increased levels of sexual risk taking. Although heroin has a depressive effect on engaging in sexual activities, recovering heroin addicts find themselves more sexually active and would benefit from safer sex messages, condoms, and other efforts for prevention and treatment of STIs. Those involved in commercial sex work and in informal exchange of sex for drugs or money are at increased risk for HIV and other STIs. HIV-positive IDUs is another subgroup that needs particular attention; for example, they are more likely to have active and severe genital ulcer disease caused by HSV-2.[180] Interventions that aim at identifying core groups will help target screening and management of STIs and may also help modify social, economic, and geographic characteristics that affect the behaviors of IDUs and crack cocaine smokers. Both generic interventions and targeted interventions can be effective with drug users, especially when IDUs and crack cocaine smokers are treated in a humane manner without a judgmental or a stigmatizing attitude.

CONCLUSION

There is no doubt that drug addiction is associated with potentially severe personal and societal consequences, among which are the high rates of HIV and other STIs in drug users. Given that HIV and other STIs have potentially devastating short- and long-term sequelae, it is important to implement effective interventions aimed at prevention and treatment of STIs in this population.

HIV/AIDS is a particularly important infection in drug users. Globally, HIV is responsible for more deaths than all other STIs combined. While there are now drugs for managing HIV infection, there is no cure and no vaccine. HIV can spread very rapidly in IDUs with reported incidence rates of 10/100 person-years to 20/100 person years or higher.[31] Conversely, if effective prevention programs are implemented on a large scale, it is possible to control HIV transmission in populations of IDUs.

Most IDUs are sexually active, so if HIV prevalence rates reach moderate to high levels in a population of IDUs, sexual transmission from IDUs to persons who do not inject drugs can become a substantial problem. This problem can be exacerbated by drugs such as crack cocaine, which is associated with both high rates of unsafe sexual activity and sexual mixing between IDUs and persons who use crack but do not inject drugs. Methamphetamine could potentially play a similar role in facilitating sexual transmission of HIV from injection to non-IDUs.

There are effective programs for reducing sexual risk behaviors in IDUs and crack cocaine users. These include basic education about HIV/AIDS, instructions on condom use, peer support, and voluntary HIV counseling and testing. These prevention efforts, however, have not been as effective as the efforts to reduce unsafe injection behaviors. Thus, to prevent sexual transmission of HIV from IDUs to persons who do not inject drugs, it is important to prevent drug injection-related-transmission in IDUs and initiation of injection drug use.

There are multiple complex relationships between IDU and STIs other than HIV, and between non-IDU and HIV and other STIs. Rates of STIs other than HIV are generally substantially higher in drug users than in an age matched "general household population." There have not, however, been any systematic efforts to control STIs in drug users as a targeted population.

Barriers and facilitators to prevention and control of HIV and other STIs in IDUs and crack cocaine smokers stem from the nature of the specific STI; the characteristics of the IDUs; the role of health care providers and public health

practitioners; and the nature of the health care system. It is critical, however, to work with IDUs and crack cocaine smokers as partners in addressing important public health problems. Collaboration among all those involved in the public health efforts to reduce rates of infection with HIV and other STIs in drug users has great potential. Such collaboration has already led to the success stories seen in the control of HIV in IDUs in many cities in the United States and in several countries throughout the world. Such collaboration has the same power to contribute to many more success stories in prevention of other STIs.

ACKNOWLEDGMENT

The authors thank Ms. Cecile Punzalan for participating in the literature review on the rates of STDs in drug users. Dr. Des Jarlais' effort on this chapter was supported by grants DA 03574 and DA 11041 from the National Institute on Drug Abuse. The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention or the views of the National Institute on Drug Abuse.

16 STDs, HIV/AIDS, and Migrant Populations

Christopher Beyrer, Stefan David Baral, and Jonathan M. Zenilman

INTRODUCTION

Throughout history, infectious diseases of humans have followed population movements. The great drivers of population mobility including migration, economic changes, social change, war, and travel have been associated with disease acquisition and spread at individual and population levels. There have been particularly strong associations of these key modes of population mobility and mixing for sexually transmitted diseases (STDs), including HIV/AIDS.[1] A prominent recent example was the wide array of population level changes that resulted from the dissolution of the former Soviet Union—a collapse with massive social implications and complex economic impacts. Key factors in the health impacts of this transition also included internal population migration, increases in illicit drug trafficking and availability, expansion of commercial sex work, and disintegration of a former functional, albeit punitive, public health system. As a result, there was an enormous epidemic of syphilis and other STDs.[2]

These social-epidemiological associations are more relevant today than ever before, as old forms and patterns of migration change, and as more people move further and more frequently than ever before. Modern wars increasingly target civilians and have forced population mobility and the creation of refugees as a primary conflict goal.[3] Such conflicts have been all too common in our time, particularly across sub-Saharan Africa, the most AIDS affected region globally. And in an interconnected world, the outcomes of seemingly remote events can have far reaching effects. Indeed, the ongoing HIV/AIDS *pandemic* presents the starkest evidence we have of the truly globalized nature of our world, and of the ways in which sexual networks now swiftly span continents and impact even the most remote members of the human family. The interactions of either elective or forced mobility, and STDs, including HIV are complex and multifaceted. Successful interventions and programs for HIV/STD prevention must address emerging modes of mobility and face the challenges of providing both preventive and curative medical and public health services in enormously varied and sometimes challenging settings.

How does human mobility interact with STD and HIV risk? We will present four scenarios and propose intervention strategies for addressing the challenges of service provision and epidemic control. Migration and socioeconomic mobility are primary drivers and will be examined in the light of data on migratory and mobile risk groups including truckers, miners, and migrant sex workers, all of whom have been associated with increased rates of STD and or HIV spread in various settings. War and its multiple and widespread effects on population mobility, mixing, sexual behavior, and sexual violence against women will be discussed as a key factor in the ongoing vulnerability of much of the developing world. Trafficking of persons, predominately women, for the sex industry is a domain of considerable concern from human rights and legal perspectives, and one for which only sparse data on STD and HIV rates and risks exist. Nevertheless, this is an area of emerging concern globally and will be discussed in terms of potential health threats to trafficked women, and programs that might decrease both the frequency and the health risks associated with this grave wrong. Finally, travel medicine is increasingly faced with the challenges of sexual behavior and the STD and HIV exposures associated with global travel and population mixing, with implications for both developing and developed countries. We will address current thinking in management of travel-associated disease, and the need for prevention and counseling for travelers who may be at risk.

MIGRATION, MOBILITY, AND HIV AND STDS

There are currently around 175–200 million people documented as living outside their countries of birth.[3] This number includes both voluntary migrants, people who have chosen to leave their country of origin, and forced migrants, including refugees, trafficked people, and internally displaced people.[4] There are multiple modes of migration, including permanent migration, temporary migration such as "oscillating" migrants who travel for work and return home periodically, if circumstances allow, and seasonal migration, generally for work in agricultural sectors.[5]

Epidemiologists elucidated early in the HIV/AIDS epidemic that there was substantial geographic variability in incidence, as well as different risk factors for disease spread. As researchers better understood the characteristics of HIV transmission, its long incubation time, relatively low infectivity, and chronic disease course, it became clear that mobility of infected persons was a key determinant for further spread to new populations.[6] Indeed, this had already occurred across Africa, Europe, and North and South America before HIV serological assays and diagnostic algorithms were developed in 1984.

In high-prevalence areas, migrants were consistently shown to have higher risk of HIV infection than stable populations. Early research done in Uganda and Senegal demonstrated that when stratifying for age and gender, there was higher HIV seroprevalence in migrant populations compared to their nonmigrant counterparts.[7,8] This work provided early evidence that migration was an independent determinant for HIV infection. Recent work also suggests that migration and mobility are operating at community, national, and even regional levels (Southern Africa) in the dynamics of STI and HIV spread. We will review some of these data here; from sub-Saharan Africa, South Asia, China, the former Soviet Union, and the United States.

SOUTHERN AFRICA

Migration was first identified as an independent determinant in HIV infection in African settings.[7,9–11] Across the continent there were almost invariably higher rates of disease among migrants than their nonmigrant counterparts reported in early studies (Table 16-1). In many African contexts, the majority of migrants do not permanently move; rather, they migrate in an oscillating or "circular" pattern, returning home when circumstances permit.[5] A model that demonstrates this pattern well is the labor migration associated with gold mines in South Africa. In 1997, the gold mines employed 350,000 male workers, of whom 95% were migrants from rural areas in South Africa and neighboring countries including Lesotho, Botswana, and Mozambique, making this a truly regional phenomenon. HIV risk determinants included living situations, high-risk sexual behaviors, and high HIV seroprevalence in the sex workers (SWs) used by miners.[12]

Table 16-1. Risk of HIV Infection Associated with Migration

Association with Migration	Gender	Country	Magnitude	Precision	Reference
Odds of HIV infection among migrants to gold mines	Male	South Africa	OR = 2.4	95% CI = 1.1–5.3	5
Odds of being infected outside of primary relationship compared to inside	Male	South Africa	OR = 26 (migrants) OR = 10 (nonmigrants)	$p < 0.0001$ $p < 0.01$	17
Odds of being infected outside of primary relationship for female partners of migrating men compared to inside	Female	South Africa	OR = 2.0 (partner of migrants) OR = 0.8 (partner of nonmigrant)	$p = 0.1685$ $p = 0.6573$	5
Odds of HIV acquisition associated with >14 occupational travel days per month	Male	Kenya	OR 2.8	95% CI 1.5–5.4	21
Odds of HIV infection for rural to urban migrants	Male	Guinea-Bissau	aOR 2.1	95% CI 1.06–3.99	22
Odds of HIV infection for rural women reporting casual sex in urban settings vs only rural settings.	Female	Guinea-Bissau	aOR 5.61	95% CI 1.56–20.15	22
Odds of HIV infection among Nepalese migrants to India compared to nonmigrants	Male	Nepal	OR = 4.1	95% CI = 0.51–33.5	29

Typically, miners reside adjacent to work areas, whereas their families remain in villages of origin. Miners stay in all male hostels during work periods promoting development of local commercial sex industries resulting in complex networks of sexual relationships extending to nearby urban and rural communities.[13] The combinations of these factors contributed to a dramatic increase in HIV seroprevalence of HIV among these men from 1.3% in 1990 to between 20% and 30% in 1996.[14,15] The end of apartheid era pass laws and restrictions on the free movement of these men doubtless also contributed to the rapid acceleration of this epidemic. This underscores a key point. Population movement and mobility increase disease spread and this may be an outcome of peace and increasing social freedom, as much as an outcome of war and dislocation. Further, established gender roles and high prevalence of gender-based violence in South Africa, also appear to have made the female partners of infected men less likely to refuse sexual intercourse or to negotiate condom use, resulting in increased risks of HIV infection at home.[16]

Studies of groups such as the gold miners have resulted in research on migration as a determinant of HIV infection in South Africa. A cross-sectional study of HIV seroprevalence was completed comparing 196 migrant men and 130 of their rural partners to 64 nonmigrant men and 98 rural women who are partners of nonmigrant men.[5] The results demonstrated a 25.9% HIV seroprevalence in the migrant population compared with 12.7% in their nonmigrant counterparts (OR = 2.4, 95% CI = 1.1–5.3).[5] In a careful assessment of migration as a risk for infection in the (nonmigrating) female partner, migrant couples were more likely to have at least one or both members seropositive for HIV than nonmigrant couples (OR 2.28, $p < 0.03$). In addition, migrant men were 26-fold ($p < 0.01$) more likely to have been infected outside of their primary relationship compared to inside in contrast to a 10-fold ($p < 0.0001$) increase in nonmigrating men. In HIV-serodiscordant couples, there was a trend for female partners of migrants to be more likely to have been infected outside of their primary relationship than female partners of nonmigrant men (RR 2.0 [$p = 0.1685$] versus RR 0.8 [$p = 0.6573$]). This reveals an additional risk in these South African couples; when men are migrating for work, their female partners are more likely to contract HIV from a relationship outside of their primary one.[17] Further research in these regions have concluded that it is not the mix of high- and low-risk settings that resulted in the increased risk of HIV; rather, it is the increased prevalence of high-risk sexual behaviors during migration which explains the higher risk of HIV infection.[18]

In Tanzania, investigators studying the economic and cultural factors resulting in rural to urban migration found higher HIV seroprevalence in trading centers, hosts to predominantly mobile populations, compared to nearby rural villages.[19,20] They propose that prevention strategies, especially in the context of limited resource regions, should focus on these areas, as they may represent epicenters for the spread of disease. The determinants of disease identified among migrant populations in case-control studies have been verified by the few prospective studies that have been conducted. A prospective cohort study was started in 1993 studying seronegative truckers in Kenya to evaluate risk factors in HIV seroconversion. This study found that HIV acquisition during the study was associated with >14 days occupational travel per month (OR 2.8, 95% CI 1.5–5.4), history of sex with SW (OR 1.9, 95% CI 1.0–3.5, $p < 0.05$), and being positive for other STDs such as HSV-2 (OR 2.9, 95% CI 1.2–7.0).[21]

West Africa has an overall HIV seroprevalence rate that is lower than both Southern and Eastern Africa, although recent studies in these countries show that mobility remains very important. A project in rural Senegal and Guinea-Bissau demonstrated that short-term mobility to more urban areas was a risk factor for incidence among men in these communities (aOR 2.06, 95% CI 1.06–3.99). This study also showed that mobile women of rural origin who reported one or more sexual partners in the city during the proceeding 12 months were more likely to be HIV seropositive than women who only reported casual sex in rural settings (aOR 5.61, 95% CI 1.56–20.15).[22] These results further indicate that mobile populations are more likely to exhibit high-risk behaviors and that this population should be targeted for prevention strategies including education.

SOUTH ASIA

In some regions of the world, both permanent and seasonal migration have been an established feature of the social order. In the last quarter century, however, this phenomenon has spread and the absolute number of migrants has dramatically increased. The HIV epidemic in South and Southeast Asia began in earnest in the early 1990s, and because of the large population, it has the potential to become the region with the highest number of infected persons.[23] Migration in South Asia is common, and an estimated 22 million migrants originating in South and Southeast Asia are working throughout the world performing agricultural, construction, and service-sector jobs, especially in the Middle East, or, in many cases, escaping political persecution at home.[24–26]

The landlocked South Asian State of Nepal, with a population of approximately 23 million, sharing long borders with Tibet to the North and India to the South, is a good example. In Nepal, international migration to India increased by 57% within a decade, coincident with an increase in HIV-1 seroprevalence.[27] In the Doti region in far western Nepal, male workers migrate to India in an oscillating annual pattern, functioning predominantly as truck drivers.[28] These individuals generally travel to Mumbai, Punjab, and Chennai, all of which are areas where the HIV prevalence among SWs is high. In 1997, Mumbai SWs were found

to have an HIV seroprevalence of 71%.[28] Regular brothel visits were common among the Nepalese migrants when in India, but condom use was infrequent. Not surprisingly, Doti district male migrants had an HIV seroprevalence of 10.3% (10/97), compared to 2.5% (n = 1/37) in their nonmigrant counterparts, although the results were not statistically significant due to the small sample size.[29]

Upon returning home, migrants pose potential HIV/STD risk to their spouses. In Nepal, while few of these men reported extramarital sex before travel to India, extramarital sex was more common after return, and this appeared to be due to increased financial resources and higher social status of successful migrants.[29] These patterns suggest a pressing need for education, both for risk perception and developing technical skills for using condoms and other protective measures. Very low rates of condom use were reported with the women in villages of origin, as men perceived condoms to be unnecessary with low-risk women, increasing vulnerability to sexual pathogens among these nonmigrant female partners. While migrant men reported high levels of understanding that HIV is an STD, they also believe that it can be contracted by kissing or just socially interacting with an infected person. In addition, few understood the incurability or treatment regimens of HIV or AIDS.[30]

While migration is a risk factor for the Nepali migrants, analyzing male migrant behaviors does little to explore the vulnerability to HIV/STI among rural women from these migrant communities in Nepal. In Kailali, another region of Western Nepal, women partners of migrants were much more vulnerable to HIV infection than women with nonmigrant partners.[31] This was not only because of increased risk-taking behavior of their partners but also because of a variety of gender disparities that operate in Nepalese culture.[31] While men gain increased social and financial standing from work done in India, women reported almost unanimously that their health status had declined compared to before their partners began migrating. This decreased perceived health status appears to be related to heavier workloads and less money to access adequate health care and nutritious food.[32] As of 2001, the overall STI prevalence among women in Kailali district with migrant partners was 30%, suggesting that women's perceptions that health declines when male partners migrate were accurate.[31]

In contrast to Nepal, Myanmar, like South Africa, has huge gem mines that attract significant amount of migrant populations seeking employment, and consequent commercial sex work. This environment synergizes both with the lack of education, the lack of preventive services, and high prevalence of risk-taking behavior.[33] A study of 725 Burmese migrant workers found major gaps in the comprehension of HIV/AIDS and its transmission, high levels of risk-taking behavior, and low rates of condom use.[34] Studies of other occupation-based migrants such as fishermen and other seafarers from South and South-East Asia had similar findings.[35,36]

CHINA

During the Maoist era, STDs had been largely eliminated from China through a combination of enhanced screening and treatment and widespread and punitive public health measures, including the forced rehabilitation of several million former SWs.[37] These measures also included reeducation of persons diagnosed with STDs, and incarceration of persons who refused to identify sex partners.[38] Since the mid-1980s, China has been undergoing significant social change, including rapid urbanization and the movement of an estimated 110 million peasants, the "floating population," off the land—perhaps the largest single migration in human history.[39] This social transformation has had a variety of consequences: economic, political, cultural, and may also be related to sharp increases in the number of drug users and increased level of sex work in a variety of regions of China which, in turn, increased incidence of STD/HIV.[40,41]

Demographic features are poised to fuel migration in China. The Maoist "One Child per Family Policy," combined with traditional preference for male heirs, resulted in a large number of selective female abortions.[39] It is thought that there are currently about 640,000 surplus men, with expected increases to about 8.5 million by 2020. The male-to-female ratio in the reproductive age group is anticipated to be as high as 1.18. This is unprecedented in human history and will result in large numbers of unattached and unmarried men. These men, in comparison to their married counterparts, are poor, unemployed, minimally educated, and are anticipated to constitute a significant portion of the urban lower classes.[42] It is also anticipated that commercial SWs from neighboring, more impoverished countries, will migrate to China to provide sexual services to these unattached men. The female SWs, too, are generally a rural-to-urban migrant population of young, unmarried women with limited education.[43]

STDs and HIV are high among rural-to-urban migrants in China.[43,44] A recent study among such migrants in Beijing showed that higher prevalence of STD was associated with increased usage of SW, multiple sex partners in the previous month, and less regular usage of condoms.[43,44] In addition, risk-taking behavior is common among female SWs in China with few using condoms due to lack of willingness of their customers and many SWs reporting substance use.[45,46] Studies done in Beijing and Nanjing showed that only 28% of female SWs used condoms in their last three episodes of intercourse.[45] Behaviors such as these appear to be driving sexual spread in many regions of China, and national prevalence rates were estimated to be increasing annually by 30%

by 2002.[47] China presents a "dual-risk" example of the intersection of two migrant groups, surplus men and female SWs, both at risk for STDs, including HIV.

RUSSIA AND THE FORMER SOVIET UNION

Before 1990, Russia and the other states of the former Soviet Union were largely spared from the HIV/AIDS pandemic. Although some believed that this was due to concealment and underreporting, it was also likely due to the tight restrictions on population movement and contact with foreigners present in the former Soviet Union.[48] After the collapse of the Soviet Union, these social and structural impediments to transmission abruptly ended, resulting in sharply increased population mobility, mixing, migration, and consequent epidemics of infectious diseases such as syphilis and HIV-1.[2,48] In 2006, the population prevalence of HIV was estimated at approximately 1% in reproductive age adults, with over 80% infections in persons under the age of 30.[49] Key determinants of spread include injection drug use (IDU), increase in commercial sex work, lack of STD control and education, and social transition and economic crisis.[50]

There has been a sharp increase in both internal and external migration of SWs across the former Soviet Union, with increasing involvement of organized criminal syndicates.[51] Sex workers are believed to play important roles in the emerging sexual risk component of the former Soviet Union epidemics, but the data are sparse and research in this area is fraught with logistical and human subjects protections challenges.[51] In the former Soviet Union, because of the preexisting strong education system but dismal economy, migrant SWs often have at least a high school education, infrequently have drug abuse problems, and often anticipate remitting funds to their family of origin. They are, nonetheless, highly susceptible to being trafficked.[52,53] Trafficked women are often unable to implement safer sex practices, even if they desire, because of fear or actual retaliation from the trafficker. A study of SWs in Vilnius, Lithuania, evaluated both STD prevalence and social characteristics among these women.[54] Most had been trafficked and their countries or area of origin included Poland, Russia, and more rural areas of Lithuania. Only one-third regularly used condoms and almost all (34/35 studied) were infected with at least one STD at the time of interview.[54] In Ukraine, the HIV seroprevalence rate of 1.4% is the highest in all of the former Soviet Union.[55] Initially, this outbreak was predominantly due to IDU risks, but it appears to have transitioned to sexual modes of spread, with migrant SWs playing a key role.[56] A St. Petersburg study found that female SWs regularly worked along transportation routes and targeted mobile populations by selling sex at train stations, along highways, and in hotels.[57,58]

Clients of SWs in Russia may be either local residents, or migrants themselves, who pose additional risks for disease transmission, underscoring the reach and complexity of these migrant networks.[57,59] In the St. Petersburg study, male migrant clients included members of the military, *militia*, and migrant workers from Belarus and Ukraine. STD seroprevalence rates in the SWs are high. In Moscow, disenfranchised populations, such as homeless women and female SWs at a remand centre, were at higher risk of being seropositive for STDs and had a 30- to 120-fold increase in HIV seroprevalence compared with the general population.[50] These results from across the whole former Soviet bloc suggest that STD/HIV among migrant populations has become a regional challenge to prevention and control.

NORTH AMERICA

Migrant populations from all over the world congregate in the United States; some originating from countries with higher HIV seroprevalence rates and some from lower. One group of migrants that has been extensively studied is migrant and seasonal farm workers (MSFW) who are mostly of Hispanic origin, predominantly from Mexico.[60,61] Determinants of increased risk in these migrants include poverty, limited education, constant mobility, feeling isolated, and living in a more open society.[62] Migrants from Mexico to the United States tend to have more sexual partners, use condoms more regularly, and are more likely to inject drugs than otherwise similar nonmigrating populations in Mexico.[62,63] Studies have also evaluated urban Latino migrant laborers as an at-risk population for STD. A study of 292 members of this population in San Francisco showed them to have a higher prevalence of syphilis and chlamydia compared to an equivalent population of nonmigrant men living in San Francisco.[64] The determinants of increased risk included limited education, high-risk sexual behaviors, and low levels of condom usage.

WAR, CONFLICT, AND INCREASED VULNERABILITY

Political instability, social disruption, and the kinds of chaos seen during wars and their aftermaths have been long known to have adverse effects on population health.[65–67] In conflict settings, there is often in-migration of military or paramilitary personnel and out-migration of local residents. Military and paramilitaries are often purchasers of commercial sex, and in undisciplined settings, may be perpetrators of sexual violence against vulnerable populations. Out-migration often results in disruption of local sexual and social networks, separations of family members, and economic dislocation that in turn may increase the attractiveness of sex work as a potential source of income. Recent examples of the interaction of infectious diseases and civil conflict include increases in visceral leishmaniasis in conflict areas of Sudan, and increases in HIV/AIDS associated with civil conflicts and/or their aftermaths in

Cambodia, Myanmar, El Salvador, Pakistan, Rwanda, and DR Congo.[33,68–74] These associations make understanding more about infectious disease spread, and STDs in particular, in the contexts of conflict and instability, a global health priority.[75]

The interaction of war, armies, and civilian populations with STDs is ancient but remains highly relevant in the current global context. Modern wars bring militaries into direct conflict with civilian populations, mixing young armed men and vulnerable women in an extreme, but common form of gender inequity that has been particularly important in the HIV/AIDS epidemic in Africa, where mass rape has accompanied conflicts in Rwanda, Burundi, northern Uganda, Sierra Leone, Sudan, Chad, and the DR Congo.[76] Indeed, Hankins et al. recently reviewed what is known about transmission and prevention of HIV and other STDs in war settings.[77] They reported on evidence implicating sexual risks, including sexual coercion and rape, in increasing HIV prevalence in the civil conflicts in Uganda, Rwanda, and Sierra Leone. Sexual risks, including increases in rates of partner change and changes in sexual network patterns have also been described among young adults in the conflict in Bosnia–Herzegovina.[78] An important caveat to these associations has been pointed out by Spiegel, who reported that not all conflicts lead to HIV/STD increases, since some may be associated with decreased population mobility and mixing.[67] Clearly, in several prominent cases, postconflict scenarios have posed greater social risks for disease spread.

An extreme, but still relevant example of conflict, sexual behavior, and HIV risks can be seen in the situation of women who survived the Rwandan genocide of 1994 and its aftermath. An estimated 800,000 persons were murdered by the Rwanda army and Hutu extremist militias in the 100-day genocide, and an estimated 250,000 women were raped.[79] This extreme example of gender-based violence led to tens of thousands of Rwanda women becoming HIV infected in a few short months.[79] While an array of NGOs and programs are attempting to provide services for these survivors, the unmet needs remain enormous.[80] Cohen et al. have suggested that provision of care to these survivors requires integrating medical care with psychosocial support and addressing barriers to care, including poverty and lack of empowerment.[80]

An important element of modern civil conflicts has been the deployment of peacekeeping forces in conflict zones, and the increasing trend toward use of regional peacekeeping approaches.[81,82] Tripodi and Patel have reviewed the HIV/STD associations for regional peacekeeping in African crisis settings and suggest several mechanisms by which disease spread may be exacerbated by peacekeepers.[82] First, HIV rates in many African militaries are substantially higher than among civilians. Second, soldiers from high prevalence militaries may act as vectors of disease spread on deployment. And third, soldiers returning from deployment in high HIV/STD settings may act as vectors for their home communities upon return. For example, of 1885 Dutch marines deployed to Cambodia in 1992–93, all received intensive STD education prior to deployment and condoms were available; 842 (45%) reported sexual contact during deployment, 301 (36%) had 1–3 contacts, and 541 (64%) had four or more contacts.[83] Sexual activity was associated with being younger and not having a steady sexual partner at home. Inconsistent condom use was higher in older men. The overall unadjusted attack rates (including nonsexually active soldiers in the denominator) was 3.5%; no cases were reported in consistent condom users. Recognizing these realities, the United Nations in 2001 implemented an HIV/STD policy for peacekeeping forces, which encourages all military personnel to undergo HIV voluntary counseling and testing, receive sexual health education, and be given 5–6 condoms per week while on deployment.[84] Nevertheless, concerns continue that peacekeeping forces may be vectors of sexual risk and disease spread in some settings.

TRAFFICKING IN PERSONS

Trafficking in persons has been called a modern form of slavery. Trafficking of women, girls, and children for sexual exploitation and work in sex industries is a small subset of the global illicit trade in labor and in persons, but is a particularly grievous form of the practice, and one with potentially important, though understudied, associations with STD and HIV risks, vulnerabilities, and global spread. In 2004, the United Nations estimated that 4 million persons per year were forced, sold, or coerced into trafficked work.[85] The proportion of these millions of persons in sex work is unknown. The U.S. State Department estimates that sex trafficked persons in the United States include 18–20,000 persons per year, mostly women—again, a small minority of overall trafficked persons in the United States.[86] Trafficking is a crime in virtually all UN member states. Trafficking in children for sex is a violation of the UN Convention on the Rights of the Child, the most widely ratified of all UN human rights conventions (all UN members except Somalia and the United States are signatories).[85] In addition to being a severe human rights violation, sex trafficking may have important health consequences in the AIDS era through mechanisms including the wide geographic movement of vulnerable persons, but it has proven to be a difficult domain for research, surveillance, and prevention.

Sex trafficking is usually an outgrowth of a poor economic environment. Countries involved in sex trafficking are generally divided into "Source" countries and "Destination" countries. The typical sex trafficking scheme involves women who are forced or enslaved into commercial sex work.[51] Women are typically recruited in the source countries by recruiters associated with criminal syndicates. Although they are often recruited under false pretenses, for example, as

domestic help, in up to a third of cases, the women are aware of the prostitution-related potential.[51] In qualitative studies, these latter women clearly indicate that this decision is driven by desperate economic circumstances.[87]

Trafficked women are smuggled into destination countries, either through ports of entry under false travel documents or visas, or smuggled over dangerous remote border areas. Once inside the destination country, these women are often sold to brothel owners, and are expected to generate a specified income. Because of their migrant, oppressed, and illegal status, health service delivery, even in countries where health services are easily available, is poor or nonexistent.

Source countries where sex trafficking is known to be important include South East Asia, West Africa, Eastern Europe and the Balkans (Former Yugoslav Republics), Russia, and the Commonwealth of Independent States (including particularly Ukraine, Moldova, Belarus, and Uzbekistan). Destination countries include the Middle East (Lebanon, Israel, and the Gulf States), North Asia (Japan), and North America; making this little understood health threat a truly global phenomenon.[51] Migration to the Middle East presents an example of the routes used and the ability of traffickers to circumvent tightly controlled borders. In 2000, trafficked women in Tel Aviv represented the majority of the estimated 2500 commercial SWs.[88] Most were from Eastern Europe, primarily from Ukraine and Moldova. After recruitment, they travel to Egypt, where entry occurs either at Cairo or Alexandria, and they are then transported across the Sinai desert by subcontracted Bedouin tribesmen. Crossing into Israel occurs at night, at remote locations along the border, where they are then handed over to collaborating traffickers, provided with false documentation, and auctioned to brothel owners. At each stage, the women are at risk for physical and sexual abuse.

Western European States are also destination countries for SWs. A recent study from Spain reports on HIV-1 subtypes among SWs in Madrid.[89] This group identified 1119 non-Spanish SWs in one city, of whom 70% were from Sub-Saharan Africa, 23% from South America, and 7% from Eastern Europe. Non-B clade HIV infections were common and included CRF02_a/G, A, and G. The highest rates of infection were found in women from Liberia (11.4%), Ecuador (7%), and Nigeria (5%). A very high HIV rate was also found among transgender SWs from Ecuador, 18%. This study did not report what proportion of SWs had been trafficked into Spain—a common occurrence in this emerging area of study.

What associations of STD and HIV are known with sex trafficking? Few studies have been done in this difficult area, and most have been hindered by small sample sizes and limited ability to directly assess biological outcomes and exposures from persons who often cannot provide consent or seek medical services. A recent large, multiyear effort of the European Union to investigate sex trafficking into Western Europe was able to enroll and interview only 28 trafficked women.[51] Nevertheless, for those women trafficked into sex work, the risks associated with prostitution are generally thought to apply and to be aggravated by the coerced nature of the work. These include high rates of exposure to STD/HIV where these infections are common in the male client pool. For example, a study of over 350 trafficked women in Tel Aviv found high rates of pharyngeal gonorrhea (8%), and these women had high rates of antimicrobial resistant gonococcal infection.[88] Sexual and physical trauma appear to be a nearly universal experience among trafficked women wherever they work, as are markedly limited access to health care and health information and mental health threats including depression, substance abuse, high rates of posttraumatic stress disorder (PTSD), and more complex psychological burdens associated with rape, slavery, exploitation, and fear.

Defining sex trafficking, as opposed to the wider category of sex work, or immigrant sex work, has been a challenge. The International Organization for Migration of the United Nations has developed a convention, *The Palermo Protocol against the Smuggling of Migrants by Land, Sea and Air*, which became UN enforceable policy in January, 2004. The Palermo Protocol is an important step in international efforts to deal with trafficking since it spells out a clear definition of trafficking in persons. "The recruitment, transportation, transfer, harboring or receipt of persons, by means of the threat or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or of a position of vulnerability or of the giving or receiving of payments or benefits to achieve the consent of a person having control over another person, for purpose of exploitation," which includes prostitution or other forms of sexual exploitation.

Palermo also asserts that "...the consent of a victim of trafficking shall be irrelevant." This is an important element since previous attempts at defining trafficking, and specifically trafficking related to sex work, had often floundered on debates about whether sex work was voluntary or coerced, and whether the trafficked person had given knowing consent to enter sex work. For Palermo, this is irrelevant, and what matters in the law is the exploitative nature of the sex work.[90]

Recognizing that persons trafficked into the United States should not be punished for illegal entry and were deserving of special protection and consideration, the United States passed into law in 2000 the "Victims of Trafficking Protection Act." The law provides legal protection and limited health benefits, including STD services, for adults and children trafficked into the United States for sex services; however, it penalizes traffickers and owners/managers of sex venues. It provides 6 months of health insurance coverage to adult victims, and health benefits to age 18 for minors, as well as protection from incarceration and other punitive measures. Unfortunately, in

the first 3 years since its passage, the act appears to have reached far fewer trafficked SWs than expected and, hence, has generally been seen as well intentioned but less effective than its advocates had hoped.

Other components of the Victims Protection Act legislation include stratification of countries by their response to trafficking, with potential impact on foreign aid. This has been particularly effective in the Middle East, where the State Department, cooperating with local NGOs, has been able to prompt increased provision of medical services and increased prosecution of traffickers. Using the Israeli example cited above, by 2005, the number of trafficked SWs was reduced to approximately 1000, there were over 50 brothel closures in Tel Aviv, a large number of prosecutions, and the establishment of STD clinics specifically targeting vulnerable persons.

SEX TRAFFICKING IN SOUTHEAST ASIA

Southeast Asia has long been one of the world's prime regions for trafficking, due, in part, to its large commercial sex industries.[26] The region has both source and destination countries for women and girls, and several states that are involved in both aspects of the trade. As the most HIV/AIDS affected region after Africa, with an estimated 7.4 million persons living with HIV/AIDS at the end of 2004, this is also a key region for global spread of HIV.[49] Known source countries for trafficked women in the region include Myanmar, Thailand, Vietnam, Russia, Uzbekistan, Nepal, Laos, China, and the Philippines. Destination states for women from the region include Thailand, China, Cambodia, Malaysia, Japan, India, Russia, Sweden, Italy, the Netherlands, the UK, and the United States. Southeast Asian states with internal trafficking include Thailand, Myanmar, Cambodia, and China.[91] It should be noted that trafficking in persons is illegal in all these states and that sex work, itself, is illegal in Myanmar, Thailand, and China.[91] Nevertheless, the sex industries of these states continue to support extensive trafficking.

Some of the better data come from Thailand, where sex worker usage by Thai men was a clear driver of an explosive heterosexual HIV epidemic and where condom campaigns targeting the sex industry had important impacts on control of epidemic HIV.[92–94] While prevention efforts through the early 1990s provide evidence for the success of this approach, the nature of the sex industry in Thailand changed over this period. Data from several studies suggest a shift in the demographic profile of SWs in Thailand.[95] Fewer Thai women were working in the industry by 1995, and since then, increasing numbers have been from Myanmar, China, and Laos, and from ethnic minority and tribal populations much more vulnerable to trafficking.[96] Few of these women can speak Thai, illiteracy rates have been high, and a number of trafficking related factors increase STD/HIV vulnerability. These factors include illegal status as SWs and as illegal aliens; lack of documentation and identity documents; lack of access to care in host country settings, and in some home country settings, language and cultural barriers and exploitation by authorities, police, border guards, prison guards, and others.[97] Taken together, these factors suggest that trafficking has the potential to undermine Thailand's success in HIV prevention.

Trafficking and sexual slavery are severe rights abuses absent increased risks for HIV or STD. In considering global spread of STD and HIV, trafficking is arguably an important and understudied area. Available data suggest that risk factors relevant to sex work are compounded for trafficked persons, and that these women have a range of special medical and mental health needs.

STD, HIV, AND TRAVELERS

Each year about 700 million people travel internationally with an estimated 50 million originating in developed countries traveling to developing ones.[98] International travel can be temporary, permanent, or episodic, and for recreational or occupational reasons, with most travel being both temporary and recreational.[98] Throughout this chapter we have discussed populations migrating in search of financial and/or personal security and associated STD and HIV vulnerabilities; while these populations differ significantly from the recreational traveler, they may share some determinants of infection risk. A number of behavioral and epidemiologic studies have shown that travelers can be less socially constrained during travel and frequently engage in more sexual activities with local inhabitants or newly met fellow travelers.[99–102]

What are the behavioral and risk-taking associations with travel? The recent outbreaks of lymphogranuloma venereum among men who have sex with men (MSM) in Western Europe and the United States suggest that risk-taking patterns among some MSM subgroups may play important roles.[103] But travels risks are certainly not related to MSM alone: a study done in a genitourinary medicine clinic in Glasgow among heterosexual men and MSM reported an increase in sexual encounters from 0.1 to 0.25 per week ($p < 0.0001$).[99] In this study, only about 50% of people interviewed reporting condom usage. Low rates of condom usage among travelers have been reported in several other studies: a study of tourists traveling in Copenhagen showed that while 21% of males and 6% of females ($n = 1225$, mean age 22.5 years) had a condom while traveling, less than 50% of men and 0% of women who had engaged in sexual intercourse actually used one.[104] These and other studies suggest that travelers not only engage in more sexual activity while traveling abroad, they may be more likely to do so unsafely (Table 16-2). This may be true among groups well educated about the risks of unprotected sex. A study of Canadian HIV-1 positive people traveling internationally showed that 23.3% (31/133) had sexual activity but

Table 16-2. Prevalence of Condom Use Among Travelers

Population	Sample Size	Condom Usage if They Had Sexual Intercourse	Country of Origin	Reference
HIV-positive individuals	31	58%	Canada	105
Medical students	27	56%	UK	100
Peace Corp volunteers	432	30%	USA	101
Travelers (mean age = 22.5)	165	49% of men 0% of women	Denmark	104

only 58.1% (18/31) of these reported always using a condom.[105] In this study, among 119 HIV-positive persons on antiretroviral therapy, 29.4% (35/119) either discontinued treatment or were poorly compliant while traveling, underscoring the travel and disease risk associations.[105] A study of medical students done in England showed that 32% reported sexual activity with a new partner on their last trip abroad and only 56% reported always using a condom.[100] This increase in sexual activity is not limited to short-term travelers; rather, long-term travelers such as volunteers in underdeveloped and developing countries, military personnel, and other groups of expatriates generally have reported higher rates of sexual activity while abroad.[101] A study done in 1080 American Peace Corps volunteers showed that 60% reported at least one new partner with 40% of those being local inhabitants and a total of 30% usage of condoms.[101]

These increased risk-taking behaviors would be expected to result in higher disease rates of STD among travelers. However, this has been notoriously difficult to demonstrate. One report from the UK showed that 5.7% of returning travelers acquired an STD while traveling.[106] However, this same group working at the Hospital for Tropical Diseases in London could only attribute 12% of the incidence of STD to sex while traveling.[107] There are certain biological markers that can be used to prove that certain STIs are imported. Strains of fluoroquinolone-resistant *Neisseria gonorrhoea* (QRNG) are increasing in prevalence in certain parts of the United States in the MSM population. This drug-resistant strain has arrived in the United States and other developed countries from travelers returning from Philippines and other regions of Asia.[108–110] This example of the spread of drug-resistant strains of *N. gonorrhoea* illustrates not only the importance of prevention strategies on an individual level but also because these strains may become epidemic in developed countries, the potential to undermine our ability to treat this disease as a whole. QNRG is one example of many STDs, including HIV, that have been carried to other populations by travelers. This highlights the need to target STD control programs at these populations.

A significant amount of research has examined characteristics that predict high-risk sexual behavior while abroad. A study done in the UK showed that variables associated with reporting new sexual contacts abroad were being male ($p < 0.01$) and traveling with friends ($p < 0.01$); factors associated with reporting four or more sexual exposures were being female ($p < 0.05$), being a solitary traveler ($p < 0.01$), being from a higher Socio-economic Status (SES) ($p < 0.05$), and previous attendance at an STD clinic ($p < 0.05$).[111] Furthermore, people who practiced unsafe sex in their home country were more likely to practice unsafe sex when traveling ($p < 0.01$).[111] Another study done in Cuzco, Peru, a popular international destination in part due to its proximity to the Inca Trail, confirmed that factors associated with casual sex during travel included being male, unmarried, and between the ages of 15–35.[112,113] Furthermore, MSM and bisexual travelers had multiple sexual partners more frequently than heterosexual travelers (OR = 6.17, 95% CI 1.16–33.5).[113] A group that represents potentially the highest risk travel group is the sex-tourist. This is a population of people who not only have the expectation of having sexual activity during the course of the trip; it is the purpose the trip, itself. They tend to be an older group, single, and originating in a higher SES.[98] As this group generally interacts with the group with the highest seroprevalence of STD in their destination countries, SWs, they are at very high risk and also historically have not used condoms frequently.[114,115]

As many travelers will seek medical advice before departing, there should be an emphasis in the travel clinic setting on sexual health education, education regarding endemic STDs, in region of travel, and the promotion of safer sex behaviors during these sessions.[116,117] Travelers and those counseling travelers should emphasize that if there is even a remote possibility of sexual relations, the traveler should ensure that condoms are available and easily accessible. Counseling must be nonjudgmental and should identify "triggers" or "risk situations" for the traveler. The best example is the expatriate who does not anticipate being sexually active but does so because of an unforeseen opportunity, often associated with alcohol use. Counseling to anticipate and prepare for these settings is critical.

A study done of travel health brochures showed that only 11% contained any sexual health information at all with only 3% being in a prominent position.[118] From the studies included, it is clear that a sexual history will help elucidate which subgroups of travelers are the most at-risk and where special care should be placed to vaccinate when possible, and promote low-risk behavior while abroad, particularly among young single men and MSM, the highest risk groups in most studies.[117] In addition, travelers should be advised to seek medical care upon return for further testing and treatment, and clearly, travel histories should routinely include taking of travel sexual histories. These prevention strategies have the potential to simultaneously protect the individual and his/her steady partner from chronic sequelae of an acquired STI, and the host population from a new epidemic.

CONCLUSIONS

Mobility, forced and unforced, for work, survival, and leisure, is a reality of our time. The expansion of sexually-acquired HIV from presumed early foci in West and Central Africa to virtually the entire human community tells us that today's sexual networks are indeed globalized and interconnected. The drivers of population mobility and mixing, including labor migration, war, travel, and trafficking are unlikely to decrease in the future. Hence HIV and STD prevention and control programs will increasingly have to focus on these complex domains to achieve control, mitigate impacts, and address the needs of people on the move.

PART 4

Host Immunity and Molecular Pathogenesis and STD

This page intentionally left blank

17 Genitourinary Immune Defense

Deborah J. Anderson

INTRODUCTION

Sexually transmitted pathogens face formidable challenges when attempting to infect cells and tissues of the genital tract. The host's first line of defense is the epithelial layer that delineates the boundary between body and environment. To cross the epidermal layer covering the external ("dry") surfaces of the genital organs, pathogens must penetrate a tough keratinized epithelial layer. To infect the interior mucosal ("wet") epithelial surfaces, they must navigate epithelial barriers that are covered by a thick mucus coat inhabited by commensal microflora and laden with a host of antimicrobial molecules. The second line of defense is the innate immune system, a rapid response system of which epithelial and other resident cells in both skin and mucosal epithelia are active participants. The third level of host defense is the adaptive immune system mediated by lymphocytes and antigen presenting cells, slower to initiate but highly specific, long-lived, and effective. The genital tract mucosal epithelium is a component of the mucosal immune system, an integrated network of specialized cells and tissues that employs specialized immune defense mechanisms at mucosal surfaces. Mediators of systemic immunity also penetrate into genital tract tissues and secretions to fortify the local mucosal immune response. Successful pathogens that cause sexually transmitted diseases (STDs) have devised strategies to overcome or circumvent many of these obstacles.

This chapter will review (1) genital tract epithelial barriers; (2) innate immune defenses at genital mucosal surfaces; and (3) adaptive (humoral and cellular) immunity at mucosal surfaces, with emphasis on specializations of the genital mucosal immune compartment. Since both male and female genital tracts comprise several distinct regions, immunological microenvironments at each of these sites will be delineated, with emphasis on the lower genital tract, where primary exposure to STD pathogens occurs. This information provides a foundation for the development of vaccines, adjuvants, and topical microbicides for the prevention of STDs.

Two other related topics that were covered in the earlier version of this chapter: STD vaccine development, and mechanisms of immune evasion by sexually transmitted bacteria and viruses are now covered in detail in other chapters in this book.

FIRST LINE OF DEFENSE: GENITAL TRACT EPITHELIAL BARRIERS

STRUCTURE OF GENITAL TRACT EPITHELIA

Epithelial surfaces vary in structure depending on their location and function. The skin covering the scrotum, foreskin, penis, and meatus in men, and labia, vulva, and introitus in women, is a keratinizing stratified squamous epithelium. This transitions to a mucosal nonkeratinizing stratified squamous epithelium lining the fossa navicularis in men and the vagina and ectocervix in women. Both keratinizing and nonkeratinizing stratified squamous epithelia are multilayered structures (up to 45 cells thick) consisting of a layer of basal germinative cells resting on a basal lamina (a 20–100 nm layer of extracellular material), which separates the epithelium from the underlying vascular connective tissue called the lamina propria (Fig. 17-1A). As the basal cells undergo mitosis and migrate toward the apical surface, they flatten and extrude their nuclei (a process termed cornification) and, in the keratinizing epithelium, further differentiate to form an interlocking layer of dead stratum corneum cells with an exterior lipid envelop that makes the surface tough and impermeable. Cadherins and other membrane adhesion molecules and numerous intercellular desmosomes tightly bind the epithelial cells within the cornified layer to one another. Gap junctions permit exchange of low molecular weight molecules (i.e., ions, cAMP, and cGMP) between cells enabling rapid intercellular communication and coordinated cellular functions.

As one ascends the interior genital tract, the stratified squamous epithelium transitions to a simple columnar epithelium, a single layer of polarized epithelial cells with apical tight junctions (Fig. 17-1B). In women, this transition

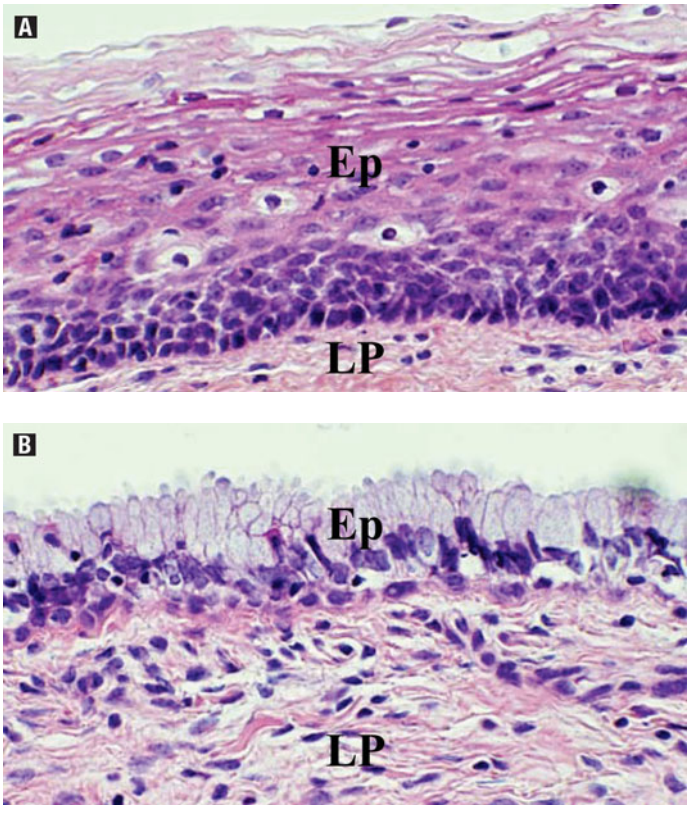

FIGURE 17-1. A. Stratified squamous epithelium lining the human ectocervix. **B.** Columnar epithelium lining the human endocervix.

normally occurs at the cervical os and in men at the inner boundary of the fossa navicularis. Thus, the epithelium lining the endocervical canal (women) and the penile urethra (men) is columnar; furthermore, these regions contain numerous mucin-secreting glands. The urinary tract is lined with a transitional epithelium, so called because it has features that are intermediate (transitional) between stratified cuboidal and stratified squamous epithelium. This epithelium is highly specialized to accommodate the high degree of stretching that occurs in the urinary tract. The uterine endometrium is a highly specialized glandular epithelium that undergoes dramatic structural changes during the menstrual cycle and pregnancy.

Physical and chemical trauma and ulcerating infections can cause epithelial disruptions that provide pathogens access to unprotected cells in the germinal layer and lamina propria. Epithelial disruptions and cervical ectopy (extension of endocervical columnar epithelium into the vagina through the cervical os) are major risk factors for the sexual transmission of HIV-1 and other STIs.

Mucosal epithelial layers are by no means inert structures. They shed surface cells at a high rate; the rate of epithelial cell turnover is unknown for the genital tract but is estimated to be $>10^{11}$ cells/day from the human small intestine. Furthermore, epithelial cells can propel the mucus layer in which they are bathed through peristaltic and ciliary action. Shed cells and mucus carry with them a burden of microorganisms and their excretion is thought to constitute a major pathogen clearance mechanism. Furthermore, as described in a later section, epithelial cells actively participate in innate and acquired immune defense functions by secreting cytokines, chemokines, defensins, and other antimicrobial peptides, and performing antigen presentation functions via MHC Class II and CD1d pathways.

Mucus

Mucosal epithelial surfaces are coated with a mucus layer that lubricates and reinforces the epithelial barrier. Mucus obtains its structural characteristics from mucins, a family of large hydrophilic glycoproteins that contain tandem repeats of serine- and threonine-rich domains that are sites of extensive O-glycan attachment. Up to 80% of the mass of mucin molecules are comprised of complex oligosaccharides (for reviews on the molecular biology of mucins see[1,2]). To date, at least 18 mucin genes have been cloned, and based on sequencing data, two classes of mucins have been identified: membrane-associated mucins (MUCs 1, 3A, 3B, 4, 11, 12, 13, 15, 16, 17, and 20), and secreted mucins, which include large gel-forming (MUCs 2, 5AC, 5B, 6, and 19) and small soluble mucins (MUC7 and 9).

Membrane-associated mucins are expressed at the apical surface of epithelial cells throughout the male and female genital tracts. These mucins have hydrophobic domains near the carboxy terminus of the protein that allow them to span the cell membrane. The extracellular domain of membrane-associated mucins may extend up to 500 nm from the epithelial cell surface and form a dense glycocalyx along the apical surface of the epithelia. Negatively charged carbohydrate residues on the mucin protein backbone confer disadhesive properties. The extracellular domain is shed from apical surfaces, and thus these mucins may contribute to protection/lubrication of the epithelia in both soluble and membrane-tethered forms. Several membrane-associated mucins (i.e., MUC 1, MUC 4) are multifunctional molecules, providing not only barrier and lubrication functions but also signal transduction through their juxtamembrane regions.

Secreted mucins are classified into two groups: large gel-forming mucins and smaller soluble mucins. The gel-forming mucins, formed by linking multiple mucin monomers, can be extremely long, with lengths up to several microns and molecular weights ranging from 0.5 to 200 Mda. Secreted mucins are produced in abundance by epithelial goblet cells and associated submucosal glands such as those found in the endocervix and penile urethra.

Numerous mucin genes are expressed in the reproductive tissues of men and women (Table 17-1). Mucins of the female reproductive tract have been extensively studied (for reviews, see[3–5]). Human endocervical cells express 5 mucin genes

Table 17-1. Mucin Gene Expression in Human Genital Tract Tissues[a]

	Mucins	
	Transmembrane	Secreted
Female		
Vagina/Ectocervix	1, 4	
Endocervix	1, 4	5AC, 5B, 6
Uterus (endometrium)	1, 4, 6	8
Fallopian tube	1	
Male		
Urethra	1, 4, 20	5AC
Prostate	1, 3, 4, 20	5AC
Seminal vesicle	1, 20	6
Epididymis	1	
Testis	1, 20	
Foreskin	1, 17	

[a]Data summarized from Gipson et al. 1997; D'Cruz et al., 1996; Brayman et al., 2004; Hey et al. 2003; Bartman et al. 1998; Russo et al. 2006.

(MUC1, 4, 5AC, 5B, and 6); ectocervical and vaginal cells primarily express the membrane-associated mucins MUC 1 and 4. Expression of the large gel-forming mucin, MUC 5B, by the endocervix is under hormonal control, and dramatic changes in the amount and viscosity of cervical mucus can be demonstrated during the menstrual cycle. Midcycle cervical mucus is primarily comprised of MUC 5B. The uterine endometrium expresses MUC 1, and evidence from animal studies indicates that this mucin may play a critical regulatory role in embryonic implantation.

Mucin gene expression has also been described in tissues of the human male urogenital tract.[6] Several membrane-associated mucins (i.e., MUC 1 and MUC 20) were found throughout the male reproductive tract, whereas secretory mucins were expressed primarily in seminal vesicles (MUC6), prostate and penile urethra (5AC). Semen was found to contain high concentrations of MUC1, MUC5B, and MUC6.

The composition of genital tract mucus is affected by a number of factors. As shown in Table 17-1, individual tissues in both the female and male genital tract express distinct combinations of mucin genes. Furthermore, mucin gene products are subject to tissue-specific posttranslational processing (i.e., glycosylation). Therefore, the composition and structure of mucins vary considerably along the length of the genital tract. In addition, each mucin gene is polymorphic: their expressed proteins are polymorphic, and several membrane-associated mucins exhibit splice variants. This implies that there is significant variation in the structure of mucins between individuals. Furthermore, the composition of mucus can vary at different times within the same tissue due to several factors. The production and posttranslational modification of certain mucins is under hormonal control; for example, the expression of MUC5B in the endocervix and its glycosylation are both upregulated by estrogen, accounting for the large volume of watery mucus in the endocervical canal at the time of ovulation.[7,8] In addition, the amount, molecular size, and morphology of mucin glycoproteins can be altered in disease states. Studies on mucin production in the lung and gastrointestinal tract have shown that proinflammatory cytokines (e.g., Il-4, Il-13, TNF-a), bacterial lipopolysaccharides (LPS), and certain host proteases can upregulate mucin gene expression, whereas other glycosidases, proteinases, and glycosulfatases produced by pathogenic organisms can degrade mucins (reviewed in[9,10]). Lactobacillus organisms which colonize the normal human vagina can stimulate the expression of MUC2 and MUC3,[11] whereas microorganisms associated with bacterial vaginosis (BV) are capable of degrading cervicovaginal mucus.[12,13] Therefore, mucin composition can vary considerably between anatomical sites within the genital tract and between individuals due to distinctive tissue-specific expression patterns, genetic polymorphism, and other variables such as endocrine status, infection, and inflammation.

The physical and biological properties of mucins are beginning to be elucidated (reviewed in[14]). It has long been known that certain bacteria bind to specific oligosaccharide ligands on mucins. In the case of commensal bacteria, attachment to mucins in the glycocalyx could slow the rate at which they are shed by the host.[15] On the other hand, by providing competing receptors for cell-surface glycoconjugates, mucins may trap pathogenic bacteria and impede their attempts to colonize the epithelium.[16] Thus, the array of oligosaccharides expressed on the mucins of an individual may play a key role in determining colonization by commensal bacteria and susceptibility to bacterial infection. In terms of viral infection, mucin fibers are densely packed in the glycocalyx and exclude 30 nm-sized particles (the size of the smallest viral particles). Mucin fibers are less dense in gel-forming secreted mucins. The space between midcycle cervical mucus fibers is large enough (20–200 nm) for proteins and small viruses to diffuse virtually unhindered. HPV (55 nm) and other capsid viruses diffuse freely through human cervical mucus; on the other hand, diffusion of HSV (180 nm) is impeded due to its large size and also through the formation of low-affinity bonds between the virus and mucin strands.[17] Antibodies, especially polyvalent IgA and IgM, can agglutinate pathogens into clusters that are too large to diffuse through mucus. Secreted

antibodies also bind to mucin fibers through low-affinity molecular bonds with the Fc and SC components of the molecules[17] and through interaction with a mucin-like IgG Fc binding protein that is found in most mucosal secretions.[18,19] The interaction between antibodies and mucin fibers could promote trapping of pathogens within the mucus gel. Leukocytes migrate freely through midcycle human cervical mucus,[20] providing evidence that they can carry out immunosurveillance functions within this mucin layer. Soluble antimicrobial factors produced by the cells within the epithelium accumulate in the mucosal layer (see below). Commensal organisms that populate genital tract mucosal secretions also play an important role in preventing infections by maintaining an acidic environment and producing an array of antimicrobial factors. This topic is reviewed in detail in Chapter 18.

SECOND LINE OF DEFENSE: INNATE IMMUNITY

The innate immune system consists of cells that constitutively express antimicrobial factors and/or rapidly mount antimicrobial responses following recognition of conserved molecular features of microbes or substances produced during infections. The principal effector cells of innate immunity at mucosal surfaces are macrophages, neutrophils, natural killer (NK), epithelial and dendritic cells (DCs). Antimicrobial substances, an important feature of innate immunity, are abundant in mucosal secretions. These include small inorganic molecules (i.e., zinc, hydrogen peroxide, nitric oxide), small antimicrobial proteins (i.e., defensins and cathelicidins), and large proteins (i.e., lysozyme, azurocidin, cathepsin G, phospholipase A2, and lactoferrin). These antimicrobial factors limit the expansion of invading pathogens and provide time for more effective host innate and adaptive immunity to be generated. Activation of the innate immune defense system can also entail the secretion of type 1 interferons, which exert potent antiviral effects, and other chemokines and cytokines that attract and activate effector cells at the site of microbial invasion.

Innate immunity is triggered immediately after microbial invasion following recognition of highly conserved structures present on microorganisms. These include nucleic acids that are unique to microbes, such as double-stranded RNA found in replicating viruses or unmethylated CpG DNA sequences found in bacteria; features of proteins that are found in microbes, such as initiation by N-formylmethionine, which is typical of bacterial proteins; and complex lipids and carbohydrates that are synthesized by microbes but not by mammalian cells, such as LPS produced by gram-negative bacteria, teichoic acids in gram-positive bacteria, and mannose-rich oligosaccharides found in bacterial but not mammalian glycoproteins.

PATHOGEN-ASSOCIATED MOLECULAR PATTERNS AND PATTERN RECOGNITION RECEPTORS

The ability to discriminate self from nonself is a central feature of both acquired and innate immune defense. Innate immune recognition is principally mediated by cellular receptors known as pattern-recognition receptors (PRRs). These molecules detect virulent microorganisms through recognition of invariant pathogen-associated molecular patterns (PAMPs). The receptors of the innate immune system are encoded in the germ line and, therefore, have a much more limited repertoire than receptors involved in acquired immunity, which undergo somatic hypermutation recombination to attain their diversity. It is estimated that the innate immune system PRRs recognize about 10^3 molecular patterns whereas the acquired immune system can recognize 10^7 or more distinct antigens.[21]

PRRs are distributed throughout extracellular, cell membrane and cytoplasmic compartments to formulate a complete line of defense against extracellular and intracellular pathogens of viral, bacterial, fungal, and protozoan origin. Complement system components provide a front line of immune defense in extracellular spaces by opsonizing microbes for clearance by phagocytes. Microbes coated with opsonic fragments derived from C3 and C4 bind to complement receptors on the surface of phagocytic cells triggering phagocytosis; alternatively these microbes may be lysed by engagement of the membrane attack complex.[22,23] Another class of cell-surface PRRs, the C-type lectins, enable phagocytes to bind and ingest microbes via recognition of pathogen-associated carbohydrate structures.[24] Many members of the C-type lectin family bind with high affinity to terminal mannose or fucose residues displayed as densely packed repetitive arrays on bacteria and fungi. Members of this receptor family include the type 1 transmembrane mannose receptor (MR), primarily found on macrophages, and type 2 receptors found on DCs, such as DC-SIGN and Langerin. The MR plays a major role in clearance of *Candida albicans*.[24] While data suggest that DC-SIGN also has a role in host immune defense, some pathogens can use DC-SIGN as part of an immune evasion strategy. For example, the capture of HIV-1 by DC through binding to DC-SIGN concentrates virions at the DC-T cell synapse from which they are efficiently transmitted to T cells.[25] On the other hand, Langerin, a C-type lectin expressed on epithelial Langerhans cells (LCs), prevents HIV-1 transmission by internalizing virions into Birbeck granules where they are degraded.[26]

The most prominent members of the PRR class of molecules are the Toll-like receptors (TLRs), a family of membrane proteins that recognize a variety of microbe-derived molecules and activate both innate and acquired immune responses. TLRs and other key molecules involved in the innate immune response pathways are depicted in Fig. 17-2. TLRs are an evolutionarily ancient receptor family. Toll was

originally identified in Drosophila as an essential embryonic patterning molecule that was also required for innate defense against fungal infection.[27] Since then, TLRs have been identified in various animal species ranging from sponges to mammals. To date 10 human TLRs have been identified and function as homodimers or heterodimers. Human TLRs fall into two broad categories: TLRs 1, 2, 4, 5, and 6 are expressed on the cell plasma membrane and recognize structures on a wide variety of microbes including bacteria, fungi, protozoa, and mycobacteria; TLRs 3, 7, 8, and 9 are found in endosomal membranes and detect viral and/or bacterial nucleic acids (see Table 17-2). A set of adaptor proteins, MyD88, TIRAP/Mal, Trif and Tram, are differentially recruited by TLRs and provide a degree of specificity to TLR-induced responses. Coreceptors are also involved in ligand recognition and intracellular signaling. For example, the primary LPS recognition pathway requires TLR 4 combined with MD-2, LPS binding protein (LBP), and CD14, a soluble protein present in serum and semen. MD-2 is directly involved in ligand binding, whereas LBP and CD14 control ligand presentation to the TLR4/MD-2 receptor complex.[28] The genes that are expressed in response to TLR signaling encode proteins important in many different components of innate immune responses. Broadly speaking, there are two major signaling pathways activated by TLRs. The first of these, mediated by MyD88, culminates in the activation of the transcription factor NF-kB which acts as a master switch for inflammation, regulating the transcription of many genes that encode proteins involved in immunity and inflammation. The second, mediated by TRIF, leads to the secretion of Type 1 interferons through the IRF signaling pathways.[29,30]

Intracellular PRRs include the nucleotide-binding oligomerization domain (NOD)-like receptor gene family. These genes are related to ancient disease resistance (R) genes in the plant kingdom that provide immune defense against a host of infectious organisms.[29,30] Cytoplasmic proteins expressed by NOD-like receptor genes, such as Nod1, Nod 2, and NALP3 detect intracellular bacterial invasion and regulate inflammatory and apoptotic responses. Both Nod1 and Nod2 sense bacterial peptidoglycans but each recognizes distinct molecular motifs.[31,32] Nod1 expression is ubiquitous in human adult tissues whereas Nod2 expression

Table 17-2. Pattern Recognition Receptors (PRRs) and Pathogen Associated Molecular Patterns (PAMPs) Potentially Involved in STI Immune Defense

PRR	PAMP	Pathogen (Type/*Specific*)
I. C-type lectins		
Mannose receptor (MR)	Mannose, Fucose, *N*-acetyl glucosamine	*C. albicans*
DC-SIGN	Mannose, Fucose, *N*-acetyl glucosamine	HIV-1
Langerin	Mannose, Fucose, *N*-acetyl glucosamine	HIV-1
Dectin-1	β-glucans, zymosan	Fungi *C. albicans*
II. Toll-like receptors		
TLR 1	Bacterial lipoproteins	
TLR 2	Bacterial wall components	Gram-positive bacteria
	(lipoteichoic acid (LTA), peptidoglycan, lipoproteins, zymosan)	*C. trachomatis* HSV-2, CMV, HCV
		C. albicans
TLR 3	Double-stranded RNA	HSV-2
		Cytomegalovirus
TLR 4	Lipopolysaccharide (LPS)	Gram-negative bacteria
	Viral envelop proteins	*N. gonorrhoeae*
		C. albicans
TLR 5	Flagellin	Flagellated bacteria
TLR 6	LTA, diacyl lipoproteins, zymosan	Gram-positive bacteria
TLR 7	ssRNA, imidazoquinolines	HIV-1
TLR 8	ssRNA, imidazoquinolines	HIV-1
TLR 9	Unmethylated CpG DNA	Bacterial DNA

is restricted mainly to leukocytes, DCs, and epithelial cells.[33,34] Nod2 expression is increased by various inflammatory stimuli such as LPS, TNF-α, and IFN-γ[34,35] and by infection.[36] Nod1 and 2 activation results in their interaction with a downstream signaling molecule, the Rip2 kinase, which leads to activation of the NF-κB inflammatory pathway.[37] Certain members of the NOD-like receptor family form inflammasomes to coordinate inflammatory responses upon ligand recognition.[38] Another newly discovered intracellular PRR family, the RNA helicases with members RIG-I and MDA-5, detect virus infection of DCs leading to cytokine induction.[39]

Various TLRs have been detected in human female and male genital tract tissues,[40–44] and are presumed to play a role in innate immune defense against sexually transmitted pathogens and other organisms that infect the genital tract. TLRs are expressed by DCs, macrophages, T cells, and other immune cells residing in genital tissues and can also be expressed by genital tract epithelial cells. Very few studies to date have explored the functional significance of TLR expression in the genital tract. It was recently shown that human LC, specialized DC that live within the stratified squamous epithelium of the vagina, ectocervix, and foreskin, have a selective impairment of cell surface expression of TLR2, TLR4, and TLR5, all involved in bacterial recognition.[45] The first report to document expression and function of TLRs on epithelial cells of the genital tract revealed that primary and immortalized epithelial cells derived from normal human vagina, ectocervix, and endocervix express mRNA for TLR1, 2, 3, 5, and 6 but interestingly expressed undetectable levels of TLR4 and MD2, two essential components of the receptor complex for LPS. The cells did not respond to LPS, but responsiveness was induced by the addition of soluble CD14, a high affinity receptor for LPS and other bacterial ligands present in high concentrations in semen and serum.[46] The lack of responsiveness of genital LCs and epithelial cells to LPS and other bacterial products may account for their tolerance to commensal bacterial flora. Another study detected protein and mRNA for the TLRs that play a role in antiviral immune defense, TLRs 3, 7, 8, and 9, in epithelial cells from the ectocervix and endocervix; these cells responded to TLR 3 and 9 ligands but were unresponsive to TLR7/8 ligands.[47] In a recent study, the Il-8 response to *Chlamydia trachomatis* infection was dependent upon TLR2 and MyD88 expression, and these molecules were detected in intracellular chlamydial inclusions, suggesting that TLR2 is actively engaged in signaling from this extracellular location.[48] A recent clinical study correlated the presence of single nucleotide polymorphisms (SNPs) in five PRRs with the prevalence of *C. trachomatis*-associated tubal pathology in subfertile women.[49] Although the study was underpowered to achieve statistical significance, subfertile women carrying two or more SNPs in *C. trachomatis* PRR genes were at increased risk of tubal pathology (73% vs. 33% risk). This area of research will no doubt provide vital information on the role of PRRs in immune defense against sexually transmitted human disease.

Research on the regulation of TLR expression at mucosal surfaces is in its infancy. TLR expression in the endometrium appears to be affected by hormonal changes that occur during the menstrual cycle,[50] and recent studies have begun to uncover molecular events underlying steroid hormone repression of TLR-activated intracellular signaling pathways (reviewed in[51,52]). Evidence is also mounting that infections per se alter TLR expression (reviewed in[53]).

TLR agonists are excellent candidates for vaccine adjuvants because of their immunoregulatory and proinflammatory effects.[54] They are also being considered for inclusion in topical microbicide formulations because they can trigger antimicrobial innate immune responses. Imiquimod, a small imidazoquinolinen ligand for TLR7 and 8 is already marketed as a topical antiviral to treat pathology associated with persistent HPV infection.[55] Vaginal application of CpG oligodeoxynucleotides (TLR-9 agonists) and poly:IC (TLR-3 agonist) in mice induced upregulated expression of Type 1 interferons and protected the mice from herpes infection.[56] However, CpG and imiquimod (TLR-7 agonist) failed to protect rhesus monkeys from vaginal infection with simian immunodeficiency virus (SIV).[57] Manipulating the immune system with TLR agonists is often accompanied by unwanted side effects. The imiquimod-treated monkeys in the SIV-challenge study developed a severe vaginitis reaction that may have promoted SIV transmission. Other studies suggest that TLR activation may in some cases be associated with autoimmune syndromes and atherosclerosis.[58] This research area is clearly in its early days and holds much promise but should be pursued with due diligence.

ANTIMICROBIAL PROTEINS

Over 80 years ago, Alexander Fleming observed that respiratory mucosal secretions have microbicidal and microbistatic properties and went on to describe the activity of lysozyme, one of the principal antimicrobial factors in mucosal secretions.[59] At present, more than 700 animal and plant antimicrobial proteins are documented in the Antimicrobial Peptide Database (http://aps.unmc.edu/AP/main.php). A number of these antimicrobial host defense peptides are produced by genital tract mucosal epithelial cells and associated immune cells. Collectively, mucosal antimicrobial proteins have a wide range of antiviral, antibacterial, antifungal, and antiparasitic activities and modes of action and play an important role in innate immune defense at mucosal surfaces. Some of the prominent classes of antimicrobial proteins in genital tract secretions are the defensins, cathelicidins, lactoferrin, and lysozyme (Fig. 17-3).

Defensins are small (29–42aa), cationic, antimicrobial peptides with a broad spectrum of activity that includes bacteria, fungi, and enveloped viruses.[60] These peptides have six cysteine residues that form three disulfide bonds and depending on the spacing of the cysteines are classified as α-defensins or β-defensins.[60] The human defensin family includes at least 6 α-defensins and over 30 β-defensins.[61] Among the α-defensins, the human neutrophil defensins (HNP) 1–4 are predominantly secreted by neutrophils, whereas HD-5 and HD-6 are expressed by mucosal epithelial cells and contribute

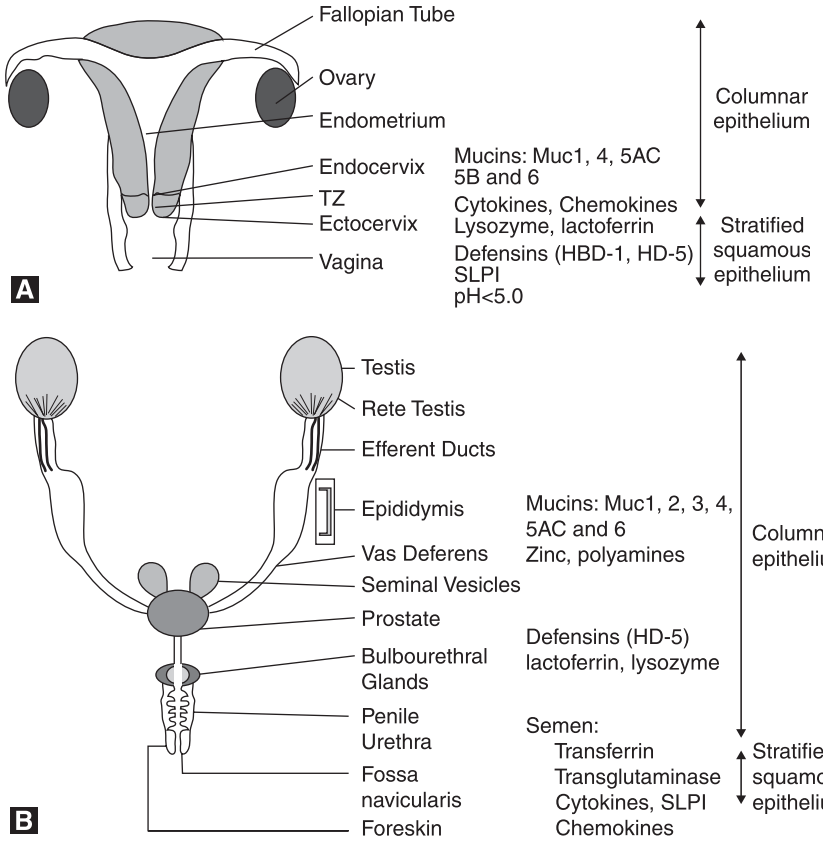

FIGURE 17-3. Soluble mediators of innate immunity in the human female, **A.**, and male, **B.**, genital tract. Abbreviations: TZ- transformation zone, HBD- human beta defensins 1–6, HD- human defensin, SLPI-serine leukocyte protease inhibitor.

to the innate defense of the mucosal surface. HD-5 is expressed by epithelial cells in the male and female genital tract. Constitutive expression of HD-5 was detected in human vaginal and ectocervical epithelial cells; expression was regulated by hormonal and proinflammatory factors in the endometrium and fallopian tube.[62] In the penile urethra, HD-5 was secreted as a propeptide and its expression was upregulated by *C. trachomatis* and *Neisseria gonorrhoeae* infections. HD5 was activated when levels of HNP 1–3 were elevated, suggesting that neutrophils contribute key proteases to convert proHD-5 to its bioactive form in the urethra during infection.[63] Six human β- defensins (HBD 1–6) are expressed in epithelial cells.[64] HBD-1 is the major antimicrobial factor in airway surface fluid[65] and has also been described in epithelial cells in the human vagina, cervix, and endometrium.[66] Defensins target the negatively charged phospholipids in bacterial membranes, forming channels in the membrane that allow defensins and other host defense molecules to penetrate into the bacterium and cell contents to leak out, leading to cell death.[67] Members of the α- and β-defensin families also have antiviral activity against number of sexually transmitted viruses including HIV-1, HSV-2, CMV, and HPV. This activity is mediated directly via interactions with the viral membrane, or indirectly through recruitment and activation of other immune cells (reviewed in[68]).

The cathelicidins comprise another important family of antimicrobial peptides. In humans, only one cathelicidin gene, CRAMP, is expressed. Most cathelicidins are found in the peroxidase negative granules of neutrophils, but the CRAMP gene product, human cationic antimicrobial peptide-18 (hCAP-18), is also expressed by mast cells, subpopulations of monocytes and lymphocytes, and epithelial cells in the human vagina, cervix, urinary tract, and epididymis.[69–73] hCAP-18 is synthesized as a propeptide and is proteolytically cleaved into two fragments, cathelin and the C-terminal peptide LL-37, both of which have a broad range of antimicrobial activity.[74] LL-37 has been attributed other important biological effects including neutralization of LPS, angiogenesis, and chemotaxis of neutrophils, monocytes, and T cells (reviewed in[75]). Human seminal plasma contains high concentrations of hCAP-18, which is cleaved by a prostatic enzyme in the vagina following intercourse to produce a unique 38-amino acid antimicrobial peptide, ALL-38.[76] Studies in CRAMP-deficient mice demonstrated that hCAP plays an important role in protecting the urinary tract against invasive bacterial infections.[73]

Both lysozyme and lactoferrin are produced in the genital tract (Fig.17-3) and are present in high concentrations in genital secretions (reviewed in[77]). Human lysozyme consists of a single polypeptide of 129 residues and is mainly produced by neutrophils. Lysozyme hydrolyzes the β(1–4) glycosidic bond between N-acetylmuramic acid and N-acetylglucosamine in gram-positive bacteria cell wall peptidoglycans[78] and also has other modes of action independent of its enzymatic activity including blocking of bacterial adherence through

steric hindrance, bacterial aggregation, and activation of bacterial autolysins.[77] In cell cultures lysozyme had no inhibitory effect on chlamydiae and at some concentrations it actually stimulated the formation of intracytoplasmic chlamydial inclusions.[79] Lysozyme may act most effectively in concert with other antimicrobial defenses.[78,79]

Lactoferrin is an iron-binding protein that may slow bacterial growth by competing for this essential element, or by direct microbicidal action.[80–82] Furthermore, lactoferrin is a highly basic protein with a pI of about 9, making it an extremely sticky protein that binds readily to other macromolecules.[83] Some of the antimicrobial actitivies of lactoferrin could be a result of this property. Lactoferrin has been reported to prevent infection by a variety of viruses including cytomegalovirus, HIV-1, herpesviruses, and hepatitis B and C.[84] The lactoferrin concentration in vaginal secretions ranges between 3.8 and 218 g/mg of protein, and the concentration can increase during inflammation as neutrophils release their lactoferrin. Lactoferrin concentration is greatest just after menses and falls off sharply during the latter (secretory) phase of the menstrual cycle. Women receiving estrogen/progesterone oral contraceptive pills were found to have persistently low levels of lactoferrin, providing further evidence of the hormonal regulation of this compound.[85–87]

Serine leukocyte protease inhibitor (SLPI) is also an important mediator of innate immunity in the genital tract. SLPI, a 10.7 Kda protein member of the trappin gene family, is produced and secreted primarily from epithelial cells, neutrophils, and activated macrophages. It is present in very high concentrations in mucosal secretions including breast milk, semen, and vaginal fluid.[88] SLPI participates in mucosal immune defense by reducing inflammation and inhibiting infection by bacteria, fungi, and viruses. Notably, SLPI protects human macrophages and $CD4^+$ T cells from HIV-1 infection[89] and also inhibits HSV-2 infection in vitro.[90]

CELLULAR MEDIATORS OF INNATE IMMUNITY

Epithelial cells

Epithelial cells express an array of PRRs including TLRs, NOD-like receptors, and complement and immunoglobulin receptors. When activated by pathogens or their products they release chemokines such as Il-8, RANTES, MIP-1α and β, and SDF1, which recruit other immune cells to the site of infection, proinflammatory cytokines including Il-1α and TNF-α, which activate leukocytes, and other cytokines such as Il-6, Il-15, TGF-β, and G-CSF that affect cell differentiation and regulate T and B lymphocyte responses. In addition, epithelial cells express adhesion molecules such as e-cadherin, ICAM-1, and LFA-3 that are important for leukocyte adherence and persistence within the epithelial layer. Mucosal epithelial cells are also capable of expressing MHC Class II and CD1d molecules, suggesting that they can present peptide and glycolipid antigens to resident immune cells. Thus, the epithelial cell initiates and coordinates mucosal immune responses by regulating the "professional" immune cells.[91,92]

The various types of epithelial cells in the male and female genital tracts express different sets of PRRs and produce distinctive arrays of chemokines and cytokines following activation. Epithelial cells are also rich sources of antimicrobial peptides including b-defensins, HD-5 and 6, hCAP-18, and SLPI. Therefore, genital tract epithelial cells can be considered the "gatekeepers" of both innate and acquired immunity in the genital tract.[93–95]

Dendritic cells

Dendritic cells are a class of antigen-presenting cells derived from hemopoietic bone marrow progenitor cells that initiate and modulate immune function through stimulation of naïve T cells. These cells develop branched projections, called dendrites, which give them their name and provide a large surface area for enhanced sampling of the environment for antigens. Their state of maturity and activation, defined by the display of molecules that induce an immune response (i.e., PRRs, major histocompatibility antigens, costimulatory molecules, cytokines, adhesion, and homing receptors) determines the nature of the immune response. Dendritic cell biology is a rapidly advancing field and readers are advised to check the current literature for updated information concerning this important cell type.

Langerhans' cells (LCs), originally described by Paul Langerhans in the late nineteenth century, are immature DCs that reside in skin and mucosal stratified squamous epithelia. They have high endocytic activity and low T-cell activation potential and are characterized by Birbeck granules and upregulated expression of langerin, CD1a, MHC Class II molecules, e-cadherin, and CD11c. Most of these phenotypic characteristics depend on TGF-β1 present in the epithelial microenvironment, as TGF-1β induces the expression of these molecules in vitro and TGF-1β knockout mice do not have LCs.[96] Recent evidence suggests that LCs do not express TLRs that convey the ability to recognize certain bacterial ligands (most notably LPS), and that gram-positive bacterial peptidoglycans trigger Il-10 but not Il-12 secretion in LCs, providing possible mechanisms for tolerance to endogenous microflora.[45,97] LCs are present in genital skin and the stratified squamous epithelial surfaces of the human vagina and ectocervix in women,[98] and foreskin and fossa navicularis in men[99–101] and may play an important role in antiviral immune defense in these locations.

Two other types of DCs have been characterized in mucosal tissues, the myeloid dendritic cell (mDC) and the plasmacytoid dendritic cell (pDC). MDCs reside in the lamina propria of most mucosal epithelia and express various TLRs and DC-SIGN, which enable them to interact with certain pathogenic bacteria and viruses. Once activated, these cells migrate to regional lymph nodes where they present antigen and activate naïve T cells. The capacity of mDCs to promote TH1 or TH2 $CD4^+$ T-cell responses depends on different patterns of cytokine production and TLR activation. Secretion of interferon gamma by $CD4^+$ TH1 cells triggers macrophage activation and a potent antimicrobial response whereas TH2 cells typically produce Il-4 and Il-5, which promote immunoglobulin production. PDCs express TLR 7 and 9 and specialize in microbial nucleic acid sensing. These cells produce large amounts of type 1 interferon and other proinflammatory cytokines in response to viral infection (for recent reviews on DCs.[102,103]).

Macrophages

Mucosal epithelia comprise the largest reservoir of macrophages in the body. Long-lived tissue macrophages are derived from blood monocytes and recruited to the mucosal lamina propria by endogenous chemoattractants in the noninflamed mucosa. These resident lamina propria macrophages in normal tissues have downregulated expression of PRRs such as TLR4 and Fc receptors, and low expression of proinflammatory cytokines, but their phagocytic and bactericidal capabilities remain intact. A different population of macrophages is recruited to epithelial mucosae by inflammatory chemokines and bacterial products during infection and inflammation. These inflammatory macrophages express an abundance of PRRs including Fc receptors, MRs, and TLRs and upon activation secrete cytokines such as Il-1, Il-6, Il-8, and TNF-α, which activate neighboring cells and amplify the immune response.[104]

Granulocytes

Granulocytes, short-lived, highly motile bone marrow derived white blood cells, rapidly migrate from the circulation to tissues upon activation. They migrate to sites of tissue damage and infection in response to selective chemokines (i.e., Il-8) and complement breakdown products (i.e., C5a). Human neutrophils express an array of PRRs that enable them to recognize pathogenic organisms including complement, Fc and lectin receptors, and TLRs 1–10 except for TLR3.[105] At sites of infection neutrophils (1) phagocytose pathogens, inactivating them in acidic endosomes, (2) release the contents of preformed granules which contain an array of antimicrobial substances such as defensins, lysozyme, lactoferrin, and reactive species of oxygen and nitrogen which inactivate extracellular pathogens, and (3) secrete cytokines and chemokines that activate and recruit additional immune cells.[106–108]

NATURAL KILLER (NK) CELLS

NK cells constitute a major component of the innate immune system and play an important role in the host-rejection of both tumors and virally infected cells. NK cells are large granular lymphocytes that do not express T-cell or B-cell antigen receptors but usually express the surface markers CD16 (FcγRIII) and CD56. NK cells kill target cells through the release of lytic proteins such as perforin and proteases known as granzymes. Perforin forms pores in the plasma membrane of the target cell through which granzymes can enter and induce apoptosis, leading to the destruction of the infected cell and the virus inside.

As NK cells have potent cytolytic potential, their activity is tightly regulated. Many NK cells express MHC Class I receptors which when activated inhibit their response and thereby protect healthy autologous cells from NK-targeted lysis. A subset of NK cells does not express such receptors, but are normally hyporesponsive unless activated.[109] Type 1 interferons play a crucial role in NK-cell activation; as these are released by pDC and other cells upon viral infection, they serve to signal to the NK cell the presence of viral pathogens. Il-2 and IFN-γ, produced by activated T cells, and IL-12, produced by macrophages and mDCs also can activate NK cells. NK cells express most of the TLRs and NOD proteins.[110] In addition, NK cells express Fc receptors which bind the Fc portion of antibodies and enable NK cells to target organisms against which a humoral response has been mobilized and lyse cells through antibody-dependent cellular cytotoxicity (ADCC).[111]

NKT cells are a subset of T cells that express a highly restricted T-cell receptor specific for nonpeptide lipids and glycolipid antigens presented by CD1d molecules on the surface of specialized antigen-presenting cells.[112] Their function appears to be similar to that of NK cells. MR1 restricted mucosal invariant T (MAIT) cells are found in gut lamina propria in mice and represent another specialized killer cell that appears to play an important role in innate immune defense at mucosal sites.[113] NK cells have been detected in the human cervix and penile urethra.[98,101] Specialized NK cells ($CD56^{bright}$, $CD16^-$) are numerous in the luteal-phase endometrium and decidua during the first trimester of pregnancy.[114]

Lymphocytes

Adaptive T-cell responses are generated when naive T-cells receive signals through their T cell receptors, costimulatory molecules, and cytokine receptors. However, T- and B-lymphocytes express TLRs and other PRRs and participate in innate as well as adaptive immune responses. Circulating human T cells strongly express TLRs 1, 2, 3, 5, and 9. Regulatory T (Treg) cells, a specialized T-cell population that maintains immune tolerance and limits effector responses to

prevent excessive immune-mediated tissue damage, express TLRs 4, 5, and 8.[115] Tregs are abundant in gut mucosae where they may downregulate immune responses to intestinal flora[116] and are also present in large numbers at the fetal maternal interface where they may promote immunological tolerance to fetal tissues during pregnancy.[117]

SYNERGY BETWEEN INNATE AND ADAPTIVE IMMUNITY

The innate and adaptive arms of the immune system work together. Innate immunity provides signals for the adaptive immune system to mount a protective host immune response. The molecules produced during innate immune reactions that function as second signals for lymphocyte activation include costimulators, cytokines, and complement breakdown products.

DCs serve as a major link between innate and adaptive immunity. DCs recognize a wide range of pathogenic organisms through the expression of an array of c-type lectin receptors and TLRs, and their location within and below the mucosal epithelium places them in the front lines of immune defense. When DCs encounter a pathogen, they undergo a differentiation process associated with the upregulation of MHC Class II and costimulatory molecules (i.e., CD80 and CD86) enabling them to present antigens to lymphocytes. They also release signaling cytokines such as Il-12 and Type 1 interferons, which activate and expand lymphocyte populations and promote TH(1) type immunity.[102]

Epithelial cells at sites of infection release chemokines such as Il-8, which recruits neutrophils, and RANTES and MIP-1beta, which recruit macrophages and T cells to the site. They also secrete cytokines such as Il-1, which activate lymphocyte mediators of adaptive immunity (reviewed in[94]).

The best-defined innate immunity signal for B-cell activation is a breakdown product of the complement component C3, called C3d. Microbes, including HIV-1, can activate complement through interaction with immunoglobulins, or directly through the alternate pathway, giving rise to complement breakdown products including C3d. When B-lymphocytes recognize a microbial antigen through binding to their antigen receptors, and simultaneously recognize bound C3d via surface complement receptors, they become activated to produce antibodies against the antigen. In addition, some of the mediators of innate immunity, such as B-defensins, are chemotactic for T lymphocytes.

Adaptive immune responses also serve to enhance innate immunity. For example, in cell mediated adaptive immune responses, antigen-specific T lymphocytes produce cytokines that activate phagocytes—important effectors of innate immunity. B-lymphocytes produce antibodies that use two effector mechanisms of innate immunity, phagocytes and the complement system, to eliminate microbes. This topic has recently been reviewed.[118,119]

THIRD LINE OF DEFENSE: ADAPTIVE IMMUNE MECHANISMS AT THE MUCOSAL SITES

OVERVIEW OF THE MUCOSAL IMMUNE SYSTEM

Interest in mucosal immunology has increased due to the realization that mucosal responses may be key to preventing mucosal STD transmission and adverse effects of STDs on mucosal tissues. However, to date none of the STD vaccines has been designed to specifically induce mucosal immunity. The mucosal immune system has discrete immune induction sites, primarily in the Peyer's patches in the intestine, which give rise to mucosal humoral and cellular responses that are distinct from peripheral responses. It is also recognized that mucosal immunity employs some components of systemic immunity: serum antibodies are detected in mucosal secretions, although at much reduced concentrations, and recent studies indicate that most T cells in mucosal tissue have characteristics, such as distinct VB gene sequences, that are similar to those found in T cells in the periphery, indicating a common derivation. Furthermore, recent studies indicate that the mucosal immune system is regionally compartmentalized. Recent research on cellular homing indicates that lymphocyte homing receptors differ between populations of cells that end up in peripheral mucosal sites such as the genital tract versus central mucosal sites such as the intestine, suggesting that the mucosal immune system is not "common" but in fact displays regional specialization. Some vaccine research groups are exploring ways to target STD vaccines to the genital tract mucosal immune system, but most of the large commercial efforts are still using systemic immunization protocols.

MUCOSAL HUMORAL IMMUNITY

Humoral immunity is mediated by antibodies produced by terminally differentiated antibody-secreting cells (ASCs) called plasma cells. Following stimulation with antigen, B cells residing in lymph nodes or spleen, undergo clonal expansion and differentiate into memory B cells or ASCs. IgA ASCs mainly arise in mucosal lymphoid tissue and preferentially traffic back to mucosal effector sites whereas IgG ASCs mainly traffic to the bone marrow or inflammatory sites. ASC trafficking patterns depend on the upregulated expression of specific chemokine receptors and adhesion molecules. Expression of CC-chemokine receptor 9 (CCR9) promotes the migration of ASCs to the intestinal mucosa which secretes the CCR9 ligand CCL25 (TECK), whereas expression of CXCR3 by IgG ASCs promotes trafficking to sites of inflammation, and expression of CCR10 on IgA ASCs enables them to traffick to various mucosal effector sites that

secrete CCL28(MEC) such as the salivary glands, bronchi, mammary glands, and intestine.[120] Little is known about specific homing mechanisms for genital tract ASCs. Genital tract ASCs could use CCR10, which appears to be a ubiquitous homing receptor for mucosal tissues. The genital tract epithelium secretes SDF-1,[121] which suggests that the CXCR4 chemokine receptor may also play a role in targeting ASCs to genital sites.

Antibodies produced in response to parenteral (systemic) immunization are detectable in mucosal secretions but usually in relatively low titer. Recent studies have shown that mucosal immunization generally achieves a superior antibody response in mucosal secretions. The mucosal immune response depends on inductive sites within mucosal tissues where antigens are sampled and host defenses committed. The best-studied inductive sites are the Peyer's patches in the small intestine (i.e., gut-associated lymphoreticular tissue), bronchus, and nasal tissue. It was once thought that such mucosal inductive sites activated cells that contributed to a common mucosal associated lymphoreticular tissue network,[122] but recent evidence indicates that homing receptors differ between various mucosal sites, and that humoral immune responses in the female genital tract are best induced by local immunization.[123]

IgA producing plasma cells are present in high numbers in the endocervix in women and the penile urethra in men.[101,124] In most mucosal secretions, the concentration of IgA exceeds that of IgG or IgM. This is true in regions of the genital tract with high concentrations of IgA plasma cells, such as the endocervix and penile urethra, but in commonly sampled genital tract secretions (i.e., semen, vaginal fluid) IgG isotype antibodies predominate.[122,124–128]

More than 40 mg/kg of mucosal IgA is generated each day.[122] The IgA found in mucosal secretions (sIgA) is different from serum IgA. It is composed of a 10-S dimer (300,000 daltons) and a J chain. The J chain is made by plasma cells and joins 7-sIgA monomers (the IgA normally found in serum) into 10-S dimers and IgM monomers into pentameric structures. A polymeric Ig receptor (p-IgR), primarily expressed in the genital tract by columnar epithelial cells in the endocervix and penile urethra, binds polymeric IgA and IgM and transports it through the cell to the luminal mucosal surface; after their release, s-IgA and s-IgM retain a portion of the pIgR, called secretory component, that provides resistance to proteolytic substances found in genital secretions. Interferon gamma and tumor necrosis factor upregulate the expression of p-IgR,[129] and increased concentrations of s-IgA have been detected in mucosal secretions at sites of infection/inflammation.[130]

Although sIgA antibodies are able to agglutinate bacteria, they do not have innate bactericidal activity.[131] However, sIgA antibody may activate the alternative pathway of complement and thereby transform into a lytic complex.[132] Lysozyme, sIgA, and complement may synergize to enhance antibacterial defense.[131,133] Complement is present in genital secretions but at reduced concentrations.[134,135] Several bacterial species (including gonococci) have evolved mechanisms to evade the bactericidal activity of serum.[136–138] The observation that many gonococci isolated from mucosal surfaces are sensitive to the complement-mediated action of serum raises serious doubt about the importance of the complement-mediated bactericidal mechanism as a mucosal defense.[139]

A variety of microorganisms elaborate a protease that cleaves IgA at the hinge, thereby rendering sIgA subclass I inactive.[140,141] Mulks and Plaut have reported that only pathogenic species of *Neisseria* produce IgA protease, implying that the protease is a major virulence factor in gonococcal infection.[142] The relative importance, however, of sIgA in defense against gonococci remains poorly understood; the presence of sIgA in urethral secretion does not seem to prevent recurrent infection.[143,144] On the other hand, sIgA may help to prevent symptomatic salpingitis in patients who develop local endocervical gonococcal infection.[145]

Secretory antibodies are of undoubted importance in defense against a variety of viruses, as demonstrated by the ablation of the mucosal carriage of poliovirus after oral (Sabin) vaccine and the protection offered against certain rhinoviruses by nasal immunization capable of eliciting sIgA.[146,147] The interaction between HIV and sIgA may be of particular importance in vaccine development. Serum IgA antibodies and sIgA induced by vaccination neutralize some strains of HIV in vitro[148] and block the transcytosis of HIV across epithelial layers.[149] In studies of women and men that have been highly exposed to HIV but remain uninfected, IgA antibodies directed against HIV were detected in cervicovaginal and seminal secretions.[150,151] HIV infection is associated with reduced levels of IgA in genital tract secretions.[152]

MUCOSAL CELLULAR IMMUNITY

Mucosal epithelia are covered by an epithelial cell layer sealed by tight junctions that exclude peptides and macromolecules. Some mucosal surfaces (e.g., bronchial and intestinal epithelia) have well-defined induction sites containing lymphoid follicles with an overlaying follicle-associated epithelium (FAE) including unique M cells which provide functional openings to the epithelium. The biology and function of the M cell have been extensively reviewed.[153] Antigens presented to naive T cells in intestinal induction sites lead to their activation and migration through the lymphatics and blood stream to eventually "home" back to mucosal effector sites.[154] Well-differentiated organized induction sites such as those in the intestine and upper airway have not been identified in the lower male or female genital tract. However, numerous antigen presenting and effector cells are present in the male and female genital mucosa.[155] Langerhans' cells reside within the

stratified squamous epithelial layers and their dendrites sample genital secretions and extracellular spaces for pathogens. DCs perform a similar function in the lamina propria. After activation, these cells migrate to regional lymph nodes and are very effective at presenting antigens to naïve T cells to generate a cellular immune response.[118] Macrophages are also numerous in the genital tract subepithelial lamina propria and can present antigens directly to CD8 and $CD4^+$ T cells that reside within or below the epithelium. Gamma interferon induces the expression of MHC class II and upregulates the expression of MHC Class I molecules in cervical epithelial cells, suggesting that these cells may be capable of presenting antigens to T cells at sites of infection.[156]

FEMALE GENITAL TRACT

The cellular components of the acquired immune defense of the female genital tract have been mapped and characterized (Fig. 17-4A).[98,157,158] Plasma cells are concentrated in the subepithelial layers of the human endocervix but substantial numbers are also found in the ectocervix, vagina, and fallopian tubes. Plasma cells are rarely detected in the human ovary, endometrium, or myometrium. The T-cell population of the human and primate female reproductive tract varies considerably from tissue to tissue. In the normal human endometrium, T cells are rarely seen in the proliferative phase of the menstrual cycle but increase in number in the secretory phase, often forming small aggregates.[159] The majority of these endometrial T cells express the CD8 antigen, particularly those found in the lymphoid aggregates and within the epithelium.[159,160] A population of phenotypically unusual ($CD2^+$, $CD3^-$, $CD4^-$, $CD8^-$, $CD56^+$) lymphocytes are seen in the endometrial stroma in the secretory phase of the menstrual cycle and early pregnancy.[159] CD8-positive T lymphocytes are numerous within the epithelium of the ectocervix, vagina, and transformation zone.[160–162] Substantial infiltrates of CD8 and CD4-positive cells are seen in the stroma of the transformation zone, but T cells are relatively sparse in the stroma of the ectocervix and vagina.[161] The particularly high numbers of T lymphocytes in the transformation zone of the cervix have led some researchers to speculate that this is a particularly immunologically dynamic region.[98,161] There are no apparent differences in the numbers of intraepithelial T cells in the lower genital tract at different stages of the menstrual cycle, although potential functional differences have not as yet been systematically addressed.

In the endometrium and endocervix, the predominant classical antigen presenting cells are macrophages and DCs; in the vagina and ectocervix, intraepithelial Langerhans' cells are also present.[161,163,164] These are potent antigen presenting cells that are found throughout the epidermis and nonkeratinized squamous epithelia. After activation, these cells migrate from the epithelium to draining lymph nodes, where they present antigens to T lymphocytes, thereby initiating an immune response. Langerhans' cells in the epithelium express a phenotype that is characteristically CD1a, MHC class II, Fcγ, CD3, and CD4 positive; following activation

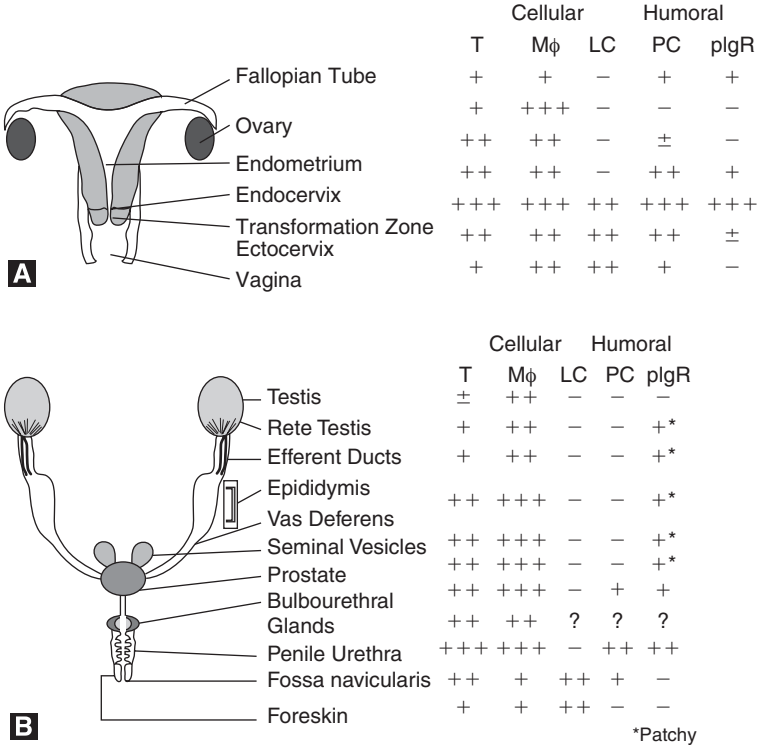

FIGURE 17-4. Mediators of adaptive immunity in the human female, **A.**, and male, **B.**, genital tract. Abbreviations: T-T lymphocyte, Mϕ-macrophage, LC- Langerhans' cell, PC- plasma cell, pIgR-polymeric immunoglobulin receptor.

they also express a variety of adhesion molecules, including ICAM-1 (CD54) and LFA-3 (CD58).[165] Langerhans' cells show marked variation in their distribution within the lower genital tract, with the highest numbers found in the vulva and transformation zone, and the lowest numbers in the vagina.[98,161] Macrophages and DCs express estrogen receptors, and antigen presentation capabilities within the female reproductive tract have been shown to vary with stages of the menstrual cycle.[166] This observation has implications for local vaccine delivery as well as for better understanding of the immunological events associated with reproductive processes.

Cervical and vaginal epithelial cells are a primary source of cytokines including IL-1α, IL-1β, growth factors including GM-CSF, M-CSF, TGF-β, and chemokines including Il-8, SDF-1, MIP1α, MIP1β, and RANTES.[134] Many of these cytokines can be detected in cervicovaginal secretions and provide important information on inflammatory and immune defense mechanisms in the lower female genital tract.[167] Cytokine concentrations differ between HIV+ and control subjects, and some cytokines may promote the replication of HIV.[134,167–170] Other infections known to affect vaginal cytokine levels include BV, HPV, and Chlamydia.[171–174]

Considerable effort is being spent on the development of improved methods to effect immune responses in the genital tract. There are essentially two schools of thought: The first contends that induction must occur in the gut or bronchus, with boosting and subsequent migration of sensitized cells to the genital tract mucosa; the second proposes that novel adjuvants or technologies can be developed to effectively stimulate and maintain local genital tract immunity.[175]

MALE GENITAL TRACT

Cellular and humoral immune mediators of the male human genital tract have been described and are summarized in Fig.17-4B. T lymphocytes are not usually detected in the healthy human testis but are seen in the rete testis, epididymis, vas deferens, and urethra, with $CD8^+$ cells predominating within the epithelial cell layer[101,176,177] A majority of the intraepithelial lymphocytes (IEL) in the urethra are positive for the integrin $\alpha^E\beta7$ (mucosal-associated antigen). T lymphocytes have been cloned out of human semen and urethral secretions and have been demonstrated to have cytolytic and helper cell functions.[178] Macrophages are abundant in the human and primate urogenital tract: in the testicular interstitium, the epididymis, the epithelium and connective tissue of the excurrent ducts and accessory glands, and in the penile urethra.[101,176,177,179,180] Testicular macrophages actively secrete a variety of cytokines that have been implicated in Leydig cell endocrine function as well as spermiogenesis. Unlike the female lower urogenital tract, Langerhans' cells are rarely detected in the penile urethra but are abundant in the epithelium of the foreskin and the fossa navicularis.[101,181]

CONCLUSIONS

Research over the past 20 years has garnered an astounding amount of information about the human immune system. Through the use of molecular tools, immunologists have identified and characterized the molecular signatures and functions of a wide array of immune cell types. Gene array technology has identified hundreds of molecules expressed by diverse immune cells undergoing various immunological functions. Improved tests of immune function, utilizing sophisticated techniques such as ELISPOT and flow cytometry, have enabled immunologists to monitor and understand immune responses at the level of the single cell. New molecular sequencing and synthesis methodologies have enabled scientists to construct precise antigenic epitope maps which have been used to study the fine specificity of immune responses; the most effective of the epitopes are being incorporated into molecularly-defined vaccines intended to elicit precise and maximally effective immune responses.

Yet the more we discover, the greater our appreciation and wonder for the complexities of biology and the immune response: the many ways infectious organisms subvert cellular mechanisms to infect and avoid detection in their host organisms; the intricate evolutionary dance between pathogens and the immune response; the fine line between protective immunity, immunopathology, and autoimmunity; the redundancy of molecular effectors of immune responses; the unexpected complexity provided by the genotypic, phenotypic, and functional polymorphism of many molecules involved in immune responses; and the elegance and importance of evolutionarily conserved genetic programs governing innate immune defenses.

Much has been learned about molecular immunology in a very short time. The STD vaccine effort, spearheaded by an intensive effort to develop an HIV-vaccine, is pushing forward through a combination of new-age molecular modeling technology and classical trial-and-error approaches. Consequently, a number of STD vaccine candidates are entering clinical trials. Knowledge about strategies used by STD pathogens to evade immune defense mechanisms may someday produce novel approaches to therapy and vaccination. Importantly, the immunological community is working together with unprecedented determination and urgency to address these problems. Microbes have experimented with the human immune system for millions of years; humans have only just begun.

18 Normal Genital Flora

Sharon L. Hillier

If we regard the vaginal microflora in its totality as a flexible population occupying a particular ecologic ride and acting as a barrier to the establishment of other organisms, then the degree of acute stress tolerated by this microflora must have defined limits. … If the acute stress is either too large or too long, the flexibility of the microflora may not accommodate this degree of change. The microflora may then collapse as a functional entity, providing a less protective environment against pathogenic microorganisms that are capable of rapid proliferation.

Andrew Onderdonk, 1992[1]

INTRODUCTION

Most women who become infected by sexually acquired microbes acquire them during heterosexual intercourse. For women, transmission of STDs occurs predominately within the vaginal ecosystem. However, our understanding of how the normal genital flora may confer resistance to STDs has been incompletely investigated. Several published studies provide support for a protective role for vaginal lactobacilli in decreasing a woman's susceptibility to heterosexually acquired HIV,[2–4] and recent data also suggest women lacking a predominant vaginal microflora composed of lactobacilli have an increased risk for acquisition of herpes simplex virus 2 (HSV-2),[5,6] human papilloma virus (HPV),[7] and may have enhanced susceptibility to bacterial STDs.[3] Disruption of the vaginal microflora is also associated with changes in the integrity of the mucin gel layer,[8] the numbers and types of immune cells, and immune products such as cytokines and chemokines.[9–14] This chapter on the human vaginal ecosystem is intended to summarize the microbial components of the vagina, the effects of contraceptive methods and sexual intercourse on this ecosystem, and how vaginal products can alter this flora. Further, the association between the vaginal flora and susceptibility to infections will be summarized.

HISTORICAL REVIEW OF THE STUDY OF VAGINAL MICROFLORA

The first definitive study of the vaginal flora was published by the German scientist Döderlein in 1894.[15] This groundbreaking study provided the first evidence that the normal vaginal flora of healthy women is dominated by the acid-producing gram-positive bacteria now referred to as *Lactobacillus* species. Döderlein was also the first researcher to report the use of probiotic approaches to the treatment of a sexually transmitted disease, with *Lactobacillus* recovered from healthy women being used as a treatment for gonorrhea among sex workers.[15]

The role of anaerobic bacteria in the vaginal microflora was first established in 1928 by Harris and Brown, who reported that 26 of 30 women sampled in the postpartum period had anaerobes present in the vaginal flora.[16] This work was extended by Weinstein a decade later when he reported that 93% of pregnant women and 90% of nonpregnant women had obligately anaerobic bacteria present as part of their vaginal flora.[17] The important role of estrogen in stimulating the disposition of glycogen in the vaginal epithelial tissue and its subsequent effect on the vaginal microflora was also described by investigators in the 1930s.[18,19]

In the 1970s, with the advent of newer methods for the culture and identification of anaerobes, several studies were published, which more carefully described the vaginal or cervical microflora.[20–23] Genital mycoplasmas were first recognized to be part of the vaginal ecosystem over 50 years ago, and their possible association with vaginitis syndromes was first suggested in 1958.[24] A study published in the early 1980s supported the role of *Mycoplasma hominis* in bacterial vaginosis (BV).[25]

Studies conducted over the past decade have relied on molecular techniques to identify previously noncultivable organisms in the vagina of women with "normal" and "abnormal" flora.[26–35] These studies have confirmed that the microflora of some women is predominated by species belonging to the genus *Lactobacillus*, while women having BV have a broad

range of aerobic and anaerobic microorganisms. It has become increasingly clear that even with these more advanced tools to characterize the microbial ecology of the vagina the full range of microorganisms present has yet to be fully described.

NORMAL VAGINAL ECOSYSTEM OF WOMEN OF REPRODUCTIVE AGE

As shown in Table 18-1, the frequency and concentration of many facultative organisms depends upon whether the woman has BV or *Lactobacillus*-predominant microflora.[36] However, even if "normal" vaginal microflora is restricted to those women having a *Lactobacillus*-dominant flora as defined by Gram stain, 46% of women are colonized by *G. vaginalis*, 78% are colonized by *Ureaplasma urealyticum*, and 31% are colonized by *Candida albicans*.[36]

The frequency and species of anaerobic members of the vaginal microflora based on culture techniques are summarized in (Table 18-2). Nearly all women are vaginally colonized by obligately anaerobic gram-negative rods and *cocci*,[36] and several species of anaerobic bacteria, which are not yet named, are also present. While some species of anaerobes are present at higher frequencies or concentrations among women with BV, it is clear that the microbial flora is complex and cannot be defined simply by the presence or absence of lactobacilli, *Gardnerella*, mycoplasmas, and anaerobes. This observation has been confirmed with molecular characterization of the microflora.[26–35]

VAGINAL MICROFLORA OF PREPUBERTAL GIRLS AND POSTMENOPAUSAL WOMEN

In premenarchal girls there is little glycogen or glucose present in the vaginal fluid and the vaginal epithelium is thin and fragile. At puberty, the vaginal epithelium undergoes profound changes under the influence of the female

Table 18-1. Frequency and Concentration of Facultative Microorganisms in the Vaginal Flora of 171 Pregnant Women, Stratified by Vaginal Flora Pattern (as Assessed by Gram Staining)[36]

Organism (s)	Frequency[a] Among Women with Indicated Pattern (cfu/mL[b]) Normal ($n = 85$)	Intermediate ($n = 47$)	BV ($n = 39$)	p[c]

[f]The 32 isolates from 23 women included *B. fragilis* (6), *B. vulgatus* (5), *B. ovatus* (7), *B. distasonis* (4), *B. uniformis* (2), *B. caccae* (3), and *B. multiacidus* (5).

sex hormone estrogen. The epithelium thickens and becomes rich in glycogen.[18] Glycogen is metabolized by vaginal epithelial cells to glucose and then to lactic acid, which serves to acidify the vaginal fluid from pH 7 in a prepubertal girl to pH 5 even when lactobacilli are absent (Table 18-3). In addition, serous fluid is transudated across the epithelium, the major source of glucose in the vaginal fluid. Both glycogen and glucose serve as substrates for *Lactobacillus* to produce to lactic acid, which can further reduce the pH of the vagina from 5 to 3.8–4.2. Any woman with sufficient estrogen to have glycogen deposition on the vaginal epithelium has enough glucose to furnish adequate nutrients for the growth of *Lactobacillus* in the vagina.

Aside from lactobacilli, other components of the vaginal microflora are also directly related to levels of estrogen and its resultant impact on the vaginal environment. The vaginal microflora of a newborn female is thought to be derived from the mother's microflora at the time of delivery. Therefore, the vaginal microflora of newborn females is similar to that of the mother, although the data to support this is scant. As the maternally derived estrogen is deplated over the first 2 months of life and until girls enter their premenarchal period, the vaginal flora is comprised predominately of anaerobic rods and cocci.[37] In a study of 19 prepubertal girls who had not been sexually abused, 89% were reported to have anaerobic gram-negative rods in the vagina, and 89% were colonized by anaerobic gram-positive cocci.[37]

Prepubertal girls[37] have low frequencies of lactobacilli, *G. vaginalis*, *Prevotella bivia*, genital mycoplasmas, and yeast (Table 18-4). In contrast, women of reproductive age without vaginal infections are usually colonized by lactobacilli (92%) and over half of women will be vaginally colonized by *G. vaginalis*.[36] In postmenopausal women who have not received estrogen replacement therapy, only about half remain colonized by lactobacilli and the frequencies of *G. vaginalis*, *P. bivia*, and the genital mycoplasmas are also decreased.[38] Other members of the vaginal microflora do not appear to be under estrogenic control. As shown in (Table 18-4), the frequency of *E. coli*, *Enterococcus*, viridans streptococci, and staphylococci are relatively constant among women regardless of estrogen status. *E. coli* may be somewhat less frequent among women having adequate levels of estrogen.

The complex interactions between vaginal pH and *Lactobacillus* is suggested by studies evaluating the effect of estrogen replacement therapy on the vaginal microflora of postmenopausal women. In two studies,[39,40] the frequency of vaginal lactobacilli increased among women receiving estrogen replacement therapy. In a study following a group of women before and after estrogen replacement therapy, it was found that the mean vaginal pH after estrogen therapy in lactobacilli-positive subjects was 4.4 ± 0.4 compared to 5.2 ± 0.3 in lactobacilli-negative subjects ($P = 0.02$).[40] Prior to estrogen therapy, there was no difference in vaginal pH for women with or without lactobacilli, suggesting that both the presence of estrogen and lactobacilli are needed to achieve an optimal vaginal pH. Heinemann and Reid[41] further supported the critical role played by reproductive hormones in maintenance of the vaginal flora in a study of 40 postmenopausal women using Premarin (conjugated equine estrogen in combination with progesterone) and 20 women not using hormone replacement therapy (HRT). They demonstrated that *Lactobacillus* species were dominant members of the microflora only among women receiving HRT based on denaturing gradient gel electrophoresis analysis of swabs taken at baseline and monthly for 3 months thereafter.

Table 18-3. Vaginal pH Over the Lifespan

Premenarchal girls	pH 7
Reproductive aged women with estrogen:	
Lactobacillus predominant	pH 4.0–4.5
Lactobacillus reduced or had intercourse in past 24 hours	pH 5–4.7
BV	pH 4.7–5.5
Menses	pH 6.0
Reproductive aged women breastfeeding	pH 6.5–7.0
Postmenopausal and no HRT	pH 6.5–7.0

ROLE AND SPECIES OF *LACTOBACILLUS* IN THE VAGINA

ROLE OF H_2O_2

In addition to producing acid, some species of lactobacilli produce hydrogen peroxide (H_2O_2).[42] H_2O_2 is toxic to a wide variety of microorganisms, and H_2O_2 of microbial origin interacts with peroxidases produced by the host along with halide (chloride) ion to generate a potent oxidant which is toxic to many bacteria. Over the past several years a number of studies have been published on the prevalence of H_2O_2-producing *Lactobacillus* in the vaginal flora of women. H_2O_2 production is detected by an agar plate method as shown in Fig. 18-1. H_2O_2-producing stains of lactobacilli reduce tetramethylbenzidine, causing colonies to turn blue. In studies of women between the ages of 16 and 45, the prevalence of H_2O_2-producing *Lactobacillus* has varied from 42% to 74%.[36,42–49] Comparatively, premenarchal girls are unlikely to be colonized with H_2O_2-producing lactobacilli,[37] while postmenopausal women have an intermediate prevalence of H_2O_2-producing lactobacilli.[38]

The capacity of H_2O_2-positive, but not H_2O_2-negative, strains of lactobacilli to kill HIV in vitro was first documented

in 1991.[50] The in vitro activity of H_2O_2-positive strains of lactobacilli against the BV-associated microorganism, *G. vaginalis*, and *P. bivia* was established by the same laboratory.[44] The specific importance of H_2O_2 as the toxic molecule produce by lactobacilli was shown by demonstrating that the microbicidal activity of lactobacilli was destroyed when catalase, an enzyme which degrades H_2O_2, was added. These data suggested that the H_2O_2 produced by lactobacilli may play an important role in acting as an endogenous microbicide within the vaginal ecosystem.

Several clinical studies conducted in populations of pregnant and nonpregnant women in the United States and Japan have shown that the prevalence of BV is low (4%) among women colonized with H_2O_2-producing strains of lactobacilli. By comparison, approximately one third of women who are vaginally colonized by *Lactobacillus* that do not produce H_2O_2 have BV.[45–47] As noted below, rectal colonization by H_2O_2-producing *Lactobacillus* is strongly linked to vaginal cocolonization and appears to confer a very low risk of BV.[49] Surprisingly, not all women lacking *Lactobacillus* have BV. These data suggest that the absence of *Lactobacillus* is not synonymous with the presence of BV. Further, the consistency of the findings among pregnant and nonpregnant women, and the similarity of the findings among women enrolled in the United States and Japan, suggests that the production of the H_2O_2 by lactobacilli may play a crucial role in protecting against the overgrowth of pathogens in the reproductive tract.

The identity of the species of *Lactobacillus* of importance in the vagina has been the subject of several studies.[42,43,48,49,51,52] Older studies using conventional identification methods such

as sugar fermentation and other biochemical assays have identified *Lactobacillus acidophilus* and *Lactobacillus fermentum* as the primary species of importance in the vagina. However, several investigators have since questioned the reliability and reproducibility of these methods for the species identification of *Lactobacillus*. One recent study demonstrated that commercially available methods which are used to identify *Lactobacillus* to the species level using phenotypic characteristics are usually incorrect.[53] In one study, investigators used phenotypic tests to identify 90 strains of lactobacilli recovered from the vagina of women as well as seven reference strains purchased from the American Type Culture Collection (ATCC). The commercial system correctly identified the species of lactobacilli, on the basis of DNA homology with ATCC type strains, for only 4 of 90 isolates. The inherent phenotypic variability of lactobacilli, combined with the limited database available in commercial identification systems for lactobacilli can lead to misidentification of *Lactobacillus* species derived from human studies of the microflora. The commercial system incorrectly identified *L. vaginalis* as *L. fermentum*, and *Lactobacillus crispatus* was always identified as *L. acidophilus*.[53] The lack of reliable plenotypic methods for identification of lactobacilli have led to a broad misunderstanding of the species of lactobacilli present in the vagina, and the common misperception that dairy and food derived lactobacilli are similar to those found in the vagina. The taxonomy of *Lactobacillus* has undergone extensive revision based on DNA homology.[54] When DNA homology methods were employed in evaluating the lactobacilli recovered from 27 healthy women, Giorgi et al. identified *crispatus* and *Lactobacillus jensenii* as the predominant vaginal *Lactobacillus* species which colonize asymptomatic women.[52] This has been confirmed in additional studies using based on nucleic acid methodologies.[40,49,55,56] Similar trends are seen among pregnant[56] and nonpregnant women.[49,55] Amplified ribosomal DNA restriction analysis, ribotyping, and PCR with specific oligonucleotide primers were used to identify lactobacilli recovered from 22 Bulgarian women. They reported that the species present included *L. crispatus*, *L. fermentum, L. gasseri, L. helveticus,* and *L. plantarum*.[57] Overall, hundreds of isolates obtained from women on different continents have been identified using molecular techniques, and *L. crispatus* has been identified as the most common species of vaginal lactobicilli, followed by *L. gasseri*, *L. jensenii, L. vaginalis,* and *L. iners*.

There are relatively few studies of lactic acid bacteria colonizing the vagina from women in Africa. One such study evaluated the lactobacilli recovered by culture methods from women in Uganda, and the isolates were then identified based on 16S rRNA and BLAST analysis.[58] The authors reported that *L. crispatus* was common in both African and Asian women, and that *L. reuteri, L. gasseri,* and *L. vaginalis* were the most frequent isolates recovered from Ugandan women. Because their initial detection of lactobacilli relied on culture detection using Rogoas agar, and *L. iners* do not grow well on this media, it is likely that *L. iners* was not recovered due to the failure to cultivate this organism during the primary culture.[58] By contrast, a study of 241 Nigerian women in which lactobacilli were identified using DNA sequencing and a BLAST algorithm[29] reported that *L. iners* was the predominant species (64%), followed by *L. gasseri* (7%) and other species. Additional studies will be needed to confirm whether the species distribution of lactobacilli actually differs from that observed among American women, or whether the reported differences reflect differences in methodology. *L. iners* do not produce H_2O_2,[49] so it is possible that the relative predominance of this species among African women could account for the high prevalence of BV observed in some studies of African women.[2] This may have implications for the future use of probiotic approaches for the restoration of normal flora among African women, which have been proposed as one approach to decrease the susceptibility of women to HIV.[59,60,61,62]

OTHER ANTIMICROBIAL PRODUCTS PRODUCED BY LACTOBACILLI

Lactic acid is the principle component responsible for vaginal acidity. Both vaginal and cervical epithelial cells have the capacity to convert glycogen to glucose, which is further metabolized to lactic acid through cellular glycolysis. The resident glucose can be converted to lactic acid by lactic acid bacteria which may be present in the vaginal microflora as well. Therefore, vaginal acidity is dependent on having adequate levels of estrogen as well as the presence of lactic acid producing bacteria such as lactobacilli.

Some authors have suggested that vaginal pH by itself is an important marker for bacterial pathogens and menopausal status. In 55 premenopausal patients who were evaluated and assessed for the presence of pathogens, Caillouette et al. described that women with normal flora or yeast colonization had statistically significantly lower vaginal pH levels as compared with women colonized by β-hemolytic streptococci, *G. vaginalis*, or mixed organisms.[63] Among postmenopausal women who had not received HRT, they reported that 55 of 64 women had vaginal pH levels above 4.5. By contrast, 80 of 88 postmenopausal women who had received HRT had a vaginal pH of $\leq$4.5. Further, these investigators noted that vaginal pH was a marker for the serum estradiol level. Although the study was small, the authors suggested that the use of vaginal pH assessment could be a powerful screening tool to assess estradiol levels and, in effect, to establish proper estrogen dosing.[63]

Some investigators have suggested that there is racial variation in vaginal pH among sexually active young women.[64]

In one study of 273 sexually active adolescents in Denver, CO, vaginal pH was measured through the use of pH paper. Women with lower genital tract infections including BV, were excluded. These authors reported that the mean vaginal pH among African American women was 5.3 ± 0.7, whereas women of other races had a mean pH of 4.7 ± 0.6. Some recent studies have also documented that African American women are less likely to be vaginally colonized by lactobacilli compared to Caucasian women.[65,66] This finding may explain the increased vaginal pH in African American women, but requires confirmation in additional studies.

Valore et al. characterized the antimicrobial components of vaginal fluid collected on preweighed tampons.[67] The extracted vaginal fluid was tested for total lactic acid and antimicrobial polypeptides. They performed individual assays for calprotection, lysozyme, lactoferrin, secretory leukocyte protease inhibitor, and human beta defensins for activity against target microorganisms. They reported that lactic acid, rather than host-derived defense molecules, is the major antimicrobial product in the vaginal fluid. They further documented that concentration of lactic acid in the vaginal fluid exceeded 5 mmole/L among women with a vaginal pH of 4.2 or less (Fig. 18-2). These data confirm the critical role of lactic acid as an antimicrobial agent in the vaginal fluid of women of reproductive age.

The antibacterial activities of human lactobacilli strains have been evaluated in a number of ways. Coconnier et al. evaluated the antibacterial properties of *acidophilus* using spent cultures supernatants.[68] They demonstrated that culture supernatants of human strains of *L. acidophilus* had in vitro activity against gram-negative and gram-positive pathogens as well as enteroinvasive pathogens. They also tested the activity of these supernatants in a *Salmonella typhimurium* mouse model and demonstrated the in vivo protective effect of this *Lactobacillus* metabolite. These authors speculated that the antimicrobial activity produced by *acidophilus* could be due to an unusual acidic amino acid present in a novel peptide agent.[68]

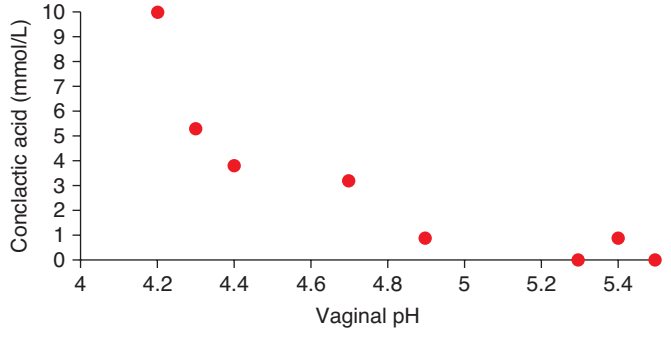

FIGURE 18-2. Lactic acid concentration vs. vaginal pH. (Data derived from Valore EV, Park CH, Igreti SL, et al. Antimicrobial components of vaginal fluid. *AmJ Obstet Gynecol* 2002; 187: 561–568.)

Other investigators have reported that *Lactobacillus* does not inhibit common genital pathogens such as *vaginalis* and anaerobic gram-negative rods.[69] However, the testing was performed at pH of 6.0–6.5, a vaginal pH not frequently found in estrogenized women. These investigators speculated that antagonistic properties between lactobacilli and other species in the ecosystem were probably due to bacteriocins. Lactacin B is a bacteriocin produced by *acidophilus*. Barefoot and Klaenhammer described bacteriocins produced by 52 vaginal strains of *acidophilus*.[70] There was no broad spectrum inhibitory activity of *acidophilus* against other organisms when the effects of H_2O_2 and other organic acids were eliminated. Lactacin B activity was limited to other lactobacilli. These investigators did not confirm earlier reports that a second bacteriocin called lactocidin was produced by lactobacilli.[71] Thus, Barefoot and Klaenhammer confirmed that production of bacteriocins occurs, but suggested that antagonism of lactobacilli against other pathogens may be due to other products.

Kaewsrichan et al. evaluated strains of lactobacilli recovered from Thai women, and identified a bacteriocin-like compound produced by *L. jensenii*, which has activity against *G. vaginalis, C. albicans*, and *E. coli* [72] They noted that the production of hydrogen peroxide by itself was insufficient to inhibit growth of *C. albicans*. Other investigators have continued to identify antagonistic activity of lactobacilli [73,74] But, the roles of these components in stabilizing the vaginal flora and preventing acquisition of infection is not known.

FLUCTUATIONS IN THE NORMAL VAGINAL FLORA

The normal vaginal flora is complex and dynamic. One method to assess daily fluctuations in vaginal microflora is through the use of Gram-stained vaginal smears.[75,76] In one such study, Schwebke et al. used self-obtained vaginal smears from 18 women to assess vaginal flora patterns over a 30-day period.[76] They reported that among women with a *Lactobacillus*-predominant vaginal flora, two patterns were observed. The first pattern was one in which *Lactobacillus* persisted at high levels throughout the 30-day period. A second pattern consisted of intermittent predominant lactobacilli interspersed with days in which *Gardnerella* and anaerobic gram-negative morphotypes appeared along with normal or reduced numbers of *Lactobacillus* morphotypes. Three of seven women who initially had *Lactobacillus*-predominant flora achieved vaginal scores as high as seven or eight, indicative of BV, but these alterations persisted for only 1–2 days. They noted that the increase in *Gardnerella* and anaerobic rod morphotypes was most concentrated around the time of menses, but that there were sporadic variations that also occurred throughout the cycle for some women. These authors suggested that alterations in vaginal microflora around the time of menses may represent a "critical period"

during which exogenous factors could tip the ecology balance in favor of BV.[76]

Fluctuations in normal vaginal flora was studied by Priestley et al.[77] Twenty-six subjects were followed over an 8-week period. Sampling was conducted two to seven times weekly and women completed diary cards reporting sexual and other behaviors. In addition, vaginal swabs were obtained for culture of *Candida, vaginalis*, anaerobes, *hominis*, and *U. urealyticum*. Only 4 of the 26 subjects had normal vaginal microbiology throughout the study period. One woman who was not sexually active had BV throughout the 8-week period of follow-up and 9 (35%) developed intermittent BV. While some women developed symptoms during the study period, symptoms correlated very poorly with microbiologic findings. These authors concluded that BV and candidiasis can occur intermittently at high frequencies and that acquisition of BV occurred more commonly among women having unprotected sex.[77] A third study using vaginal smears to assess vaginal microflora over menstrual cycle was conducted in 22 volunteers.[78] These authors reported that one half of the women had normal flora throughout the cycle and an additional third had basically normal flora which transitioned to intermediate flora or BV. Like the other studies, most of the changes in the microflora occurred during menses.

A fourth study of 101 women enrolled and followed at 4-month intervals for 8 months, reported that both a higher frequency of sexual intercourse and use of antibiotics was associated with loss of vaginal lactobacilli.[79] This study also showed that 23 (40%) of 57 women initially colonized by *L. crispatus* or *L. jensenii* remained colonized by these species over 8 months, while 1 (5%) of 21 women colonized by other species remained colonized by lactobacilli during follow-up. All these studies suggest that alterations in the vaginal microflora most frequently occur with menses, intercourse, and/or antibiotic usage, but that the species of *Lactobacillus* present may also influence the stability of the vaginal flora.

Two longitudinal cohort studies have been published assessing the vaginal microflora in pregnant women. One study was conducted in 163 women with paired cultures 4 months apart, in the second and third trimester of pregnancy.[45] Lactobacillus cultures and assessment of H_2O_2 production was assessed at each of the two visits. Seventy-nine percent of 107 women initially colonized by H_2O_2-producing *Lactobacillus* were persistently colonized by H_2O_2-producing strains 4 months later. By contrast, fewer than one half of women initially colonized by H_2O_2-negative strains of lactobacilli remained persistently colonized by those strains 4 months later. Finally, 40% of 20 women initially lacking lactobacilli remained negative for lactobacilli, whereas only 25% of women spontaneously acquired vaginal colonization by an H_2O_2-producing strain. These data are supportive of observation derived from studies of nonpregnant women, suggesting that H_2O_2-producing lactobacilli are more persistent over time than lactobacilli that do not produce H_2O_2.[46,79]

ROLE OF THE RECTAL RESERVOIR IN MAINTENANCE OF THE VAGINAL MICROFLORA

The gut has a complex microflora which is known to play a role in health. However, it is increasingly recognized that the rectum is an important reservoir for organisms that colonize the vagina. This also appears to be true for lactobacilli. In a study of 531 women, 80% were found to be colonized either vaginally and/or rectally by lactobacilli,[49] and 67% harbored H_2O_2-producing strains. While colonization of both the vagina and rectum with lactobacilli was common, lactobacilli were more commonly isolated from the vagina than the rectum (61% vs. 43%, $P < 0.001$). Among these 531 women, vaginal and rectal patterns of colonization were correlated with rates of BV. As shown in (Table 18-5) cocolonization of the rectum and vagina with H_2O_2-producing lactobacilli was associated with the lowest prevalence of BV, suggesting that

Table 18-5. Prevalence of Bacterial Vaginosis Among Women with Vaginal vs. Rectal Colonization by Facultative H_2O_2-Producing Lactobacilli

H_2O_2-Producing Lactobacilli Present		Total Women (n = 531)	BV (%)	RR (95% CI)
Vagina	Rectum			
+	+	198 (37%)	9 (5)	Referent
+	−	126 (24%)	25 (20)	4.4 (2.1–9.0)
−	+	32 (6%)	15 (47)	10.3 (4.9–21.6)
−	−	175 (33%)	123 (70)	15.5 (8.1–29.5)

colonization of both the vaginal and rectum may be protective against BV.

Song and colleagues[48] reported that *L. gasseri, L. fermentum*, and *L. paracasei* were the most common species of *Lactobacillus* isolated from the stool samples of Japanese women, while Antonio reported that *L. crispatus, L. jensenni*, and *L gasseri* were the most frequent rectal species.[49] The difference in species identified by these investigators may reflect the different specimen types evaluated (stool vs. rectal swab) or true differences in the two populations related to diet or behavior. Many commercially available preparations containing lactobacilli are sold as dietary supplements which are recommended for ingestion. One theory is that strains of lactobacilli delivered to the gut will migrate to the vagina and may thereby stabilize the vaginal microflora. None of the published studies has identified the species of lactobacilli, which are frequently used as probiotics such as *L. acidophilus* or *Lactobacillus delbrueckii bulgaricus* in the vagina, suggesting that these organisms rarely migrate to colonize the vagina.

EFFECT OF MENSES AND INTERCOURSE ON THE VAGINAL MICROFLORA

Longitudinal studies in which vaginal flora has been assessed using Gram-stained vaginal smears, suggest that *Lactobacillus* may decrease during menses and after intercourse, two times when vaginal pH is elevated due to the presence of menstrual fluid or semen. A study of 74 women characterized the flora of women who used no hormonal contraception or condoms over the menstrual cycle. Women were evaluated during menses (days 1–5 of the cycle), during the preovulatory phase (days 7–12 of the cycle), and in the postovulatory phase (days 19–24). The data from 50 women without BV were analyzed separately from that of the 25 women having BV. Among the women without BV, the changes in the *Lactobacillus* populations was modest, with a decreased in prevalence to 82% during menses and increasing to 98% after menses.[80] Other non-*Lactobacillus* components of the vaginal microflora decreased from a prevalence of 72% during menses to 40% following menses. Among women with BV, the only statistically significant change in the microflora was an increase in lactobacilli from 33% during menses to 54% following menses. These data suggest that there is a slight decrease in numbers of lactobacilli, with a concomitant increase among other organisms during menstrual bleeding.

Morison et al.[81] evaluated the impact of menses and sexual activity on the microflora of 30 women in Ghana.Women with BV collected a total of 1724 swabs from themselves on alternate days over a 4-month period, and the swabs were used to prepare vaginal smears that were evaluated by the Nugent criteria.[75] Days of menstruation and sexual intercourse were recorded by the women. Four groups of flora patterns were identified (Table 18-6). Eleven of the 30 women had stable normal flora, five had unstable normal flora, six were categorized as having unstable abnormal flora, and eight women had persistently abnormal flora. Women in each of the four groups were more likely to have BV flora patterns during menses (Table 18-6). In this same study, sexual intercourse had no significant input on acquisition of BV (data not shown).

The shifts in vaginal flora observed during menses have been widely attributed to the increased pH of the vagina in the presence of menstrual fluid. However, there is no evidence that adherence of lactobacilli to vaginal epithelial cells is altered at increased pH. There was no significant difference in the adherence of *Lactobacillus* species, *vaginalis*, or *E. coli* to exfoliated vaginal epithelial cells over the menstrual cycle.[82] This suggests the alterations in the vaginal microflora observed over the menstrual cycle probably do not relate to hormonally related changes in binding of organisms to epithelial cells. Lactobacilli can bind to erythrocytes[83] and

Table 18-6. Variation in BV by Stage of Menstrual Cycle and Shifts in Vaginal Flora Associated with Sexual Intercourse[81]

Group	Women	Smears	Percentage of BV by Menstrual Cycle Day		
			< 7 Days	7–13 Days	14^+ Days
Stable normal flora	11	638	9.1[a]	4.1[a]	0.3
Unstable normal flora	5	278	37.7[a]	24.1[a]	10.5
Unstable abnormal flora	6	327	60.6[a]	72.9[a]	57.1
Stable abnormal flora	8	453	80.6[a]	93.3[a]	84.1

competitive binding of lactobacilli to erythrocytes could account for some of the observed decrease in lactobacilli during menses.

A large number of studies have evaluated the effects of various catamenial products on the vaginal microflora during menses. In one such study, the effect of tampon usage on the vaginal microflora of 35 healthy women was determined following the random assignments of these women to either tampon or sanitary napkins usage for three consecutive menstrual cycles.[84] Colonization by coagulase negative staphylococci increase significantly among tampon users compared to napkin users, but the shifts in microflora occurred only during menstruation and no difference in the microflora was noted at other sampling times, suggesting the changes observed during menses were transient.

A large study evaluated 101 women over two menstrual cycles using two different tampon types.[85] There were modest changes noted in the vaginal flora when comparing the premenstrual samples from those obtained from women during tampon use. Although anaerobic gram-negative rods and *vaginalis* were more prevalent during menses, the decrease in vaginal lactobacilli was subtle. It is unknown whether the use of tampons, which might absorb red blood cells during menses, may minimize the impact of menses on colonization by lactobacilli. However, some observational data suggests that women who routinely use tampons for catamenial protection are more likely to maintain colonization by lactobacilli compared to women who use pads for catamenial protection (Hillier, unpublished data).

Vaginal intercourse appears to have little effect on the presence of vaginal lactobacilli. However, in one study there was a significant increase in vaginal colonization by both *Enterococcus* and *E. coli*, and a trend toward increased colonization by group B *Streptococcus* following intercourse.[86] These three groups of organisms are all carried in the rectum and colonize the perineum. A second study evaluated 22 women randomly assigned to use no condoms or lubricated antispermicidal condoms. As with the larger study, vaginal intercourse was associated with increased colonization by *E. coli*, among both condom users and noncondom users.[87] It is likely that the act of heterosexual intercourse introduces fecal bacteria into the ecosystem, and that the increased vaginal pH occurring during intercourse may increase survival of these organisms.

EFFECT OF VAGINAL PRODUCTS AND BARRIER DEVICES BIRTH ON THE VAGINAL FLORA

Many young women use vaginal products including lubricants, contraceptives, antifungals, and douches. Each of these products can alter the vaginal ecosystem by changing vaginal pH, altering the vaginal fluid by direct dilution, or by altering the capacity of organisms to bind to the vaginal epithelium. Nonoxynol-9 (N-9) is the most commonly used over-the-counter contraceptive, and it is available in the form of gels, foams, suppositories, or creams for use with or without barriers. Some studies have demonstrated a significant decrease in lactobacilli among spermicide and diaphragm users[86,88] or with N-9 alone[89,90] while other studies have found no association between N-9 use and decreased populations of lactobacilli.[91] In vitro, N-9 was reported to have inhibitory activity against lactobacilli[92,93] but other more recent studies suggest that N-9 is not cidal to most strains of *Lactobacillus* recovered from the vagina.[94]

Clinical studies of N-9 have yielded conflicting results. Gupta published a prospective evaluation of 331 university students who were initiating use of a new birth control method. Women were evaluated at baseline and weekly thereafter.[88] Multivariate modeling of the data showed that use of an N-9 contraceptive in the previous week was associated with having an abnormal Nugent Gram stain score, and with increased colonization by *E. coli*, anaerobic gram-negative rods, and *Entercoccus*.[88]

However, in another study conducted among commercial sex workers, use of N-9 containing gel was actually associated with increased colonization by H_2O_2-producing lactobacilli compared to women using placebo gel.[91] In a study of 48 women evaluating the impact of N-9 on vaginal microflora, there was only a transient impart on vaginal lactobacilli but *E. coli* colonization was increased in women using these different formulations of N-9.[94] The lack of consistency among various studies evaluating different formulations of N-9 for different durations in different population has led to confusion regarding the impact of N-9 on the microflora.

A subsequent large prospective study of 235 women followed for 6 months randomly assigned to use of five different commercially available formulations of N-9, found no significant alterations in the vaginal microflora of most women. Only women having exposure to more than 280 mg of N-9 per week developed sustained changes in the vaginal microflora.[95] Different formulations of microbicide did not have differential effects on the flora. However, this study demonstrated that N-9 did have a dose-dependent impact on the prevalence of anaerobic gram-negative rods, and was associated with a twofoldincrease in BV (OR 2.3, 95% CI 1.1–4.7). It is likely that the inconsistencies observed in previous studies were attributable to small sample size, short study duration, and failure to account for total weekly exposure to N-9.

On the basis of the above data, it was not surprising that prophylactic use of a 3% nonoxynol gel during vaginal intercourse during a 6-month study did not reduce the incidence of BV, trichomoniasis or yeast vaginitis.[96]

Like the effects on the microflora, the effects of N-9 contraceptives on the vaginal epithelium probably relate to exposure frequency and dosage. Use of sponges containing 1000 mg of N-9 was associated with an increased frequency of genital

ulcers,[97] but daily application of a gel containing 52.5 mg of N-9 did not result in epithelial disruption among commercial sex workers.[98] However, in another study evaluating suppositories containing 150 mg of N-9, disruption of the vaginal and/or cervical epithelium occurred two to four times as frequently when women used N-9 one to four times daily as compared to women who used N-9 suppositories every other day.[99]

Several studies evaluated the effects of oral contraceptives (OCs) use on the vaginal ecosystem. In one study, 30 women (mean age 21.9 years; 87% nulliparous) were evaluated before and 2 months after the start of OC use. At both visits, genital symptoms were assessed by a questionnaire; vaginal signs were assessed by speculum examination and colposcopy; vaginal microflora was evaluated by quantitative culture; and a vaginal biopsy was obtained for histopathologic evaluation. The results showed that no change was observed in discharge amount, consistency, viscosity, cervical ectopy, or amount of cervical mucus. There also was no change in the prevalence of hydrogen peroxide-producing lactobacilli, yeast colonization, vaginal pH, or in thickness of the vaginal epithelium. Other studies reported that OC users are less likely to have BV, with one study noting the risk of BV is 50% less among OC users overall.[100,101] Depot medroxyprogesterone acetate (DMPA) produces a systemic hypoestrogenic state associated with decreased hydrogen peroxide-positive *Lactobacillus* colonization and a slight thinning of the glycogen vaginal epithelial layer. Such changes possibly comprise the vaginal barrier to infection.

Women who desired DMPA for contraception were evaluated before and at 3 and 6 months after initiation of 150-mg DMPA injections every 3 months.[102] At each visit, genital symptoms, vaginal microflora, and histopathology were assessed via vaginal biopsies. The most notable changes were in the epithelium in which the number of cell layers, thickness of glycogen, and mean number of microorganism-inducing polymorphonuclear neutrophilic leukocytes (PMNs) decreased over time. There was also a statistically significant reduction in hydrogen peroxide-positive lactobacilli from baseline to 6 months (53% vs. 32%; $P = 0.005$). Such changes possibly compromise the vaginal barrier to infection and BV.

Theoretically, intrauterine devices (IUDs) should be neutral to the vaginal ecosystem, since they are placed in the upper genital tract. None of the existing studies has evaluated the impact of progestin-releasing IUDs on the vaginal microflora. Cross-sectional longitudinal studies link nonhormonal IUD use with BV. In a 24-month study that compared IUD users to women who used OCs, BV occurred 2.8 times more frequently in IUD users than in OC users.[103] During the 2-year follow-up period, 50% of women using an IUD had at least one episode of BV, compared with 20% of the OC users ($P = 0.001$). Bacterial infections associated with IUD use may depend on the type of IUD used. A chronic inflammatory response in the upper genital tract might disrupt the vaginal flora. Since condom usage decreases following initiation of IUD use,[102] the decline in condom use by IUD users also may contribute to the increased BV.

Data are lacking with respect to the degree by which transdermal contraception affects BV, but since it delivers the same hormones as OCs, users of the patch may not be at increased risk for BV.

The connection between condom use and the incidence of BV has not been widely studied. During 7908 person-months of observation of 917 Peruvian female sex workers, the prevalence of BV, gonorrhea, chlamydial infection, and trichomoniasis declined significantly, and condom use increased significantly.[104] BV also was positively associated with the use of an IUD and negatively with douching. Because condoms are a barrier method of contraception, they are likely protective of the vaginal flora and have no known effects on the vaginal epithelium or immune cells.

The vaginal ring releases hormonal contraceptives, typically over a 3-week period. In a crossover study of 64 women of child-bearing age, patients were randomized to receive either a daily OC or the vaginal ring for three consecutive 28-day cycles, directly followed by three cycles of the other study drug[105] The results showed vaginal white blood cell count and pH were not significantly affected by either method. However, women who wore the vaginal ring had two- to threefold higher levels of hydrogen peroxide-producing *Lactobacillus*, suggested a possible benefit.

In summary, contraceptive methods have varied effects on the vaginal ecosystem. N-9 usage promotes *E. coli* colonization. DMPA may cause a decline in the density of hydrogen peroxide-possible lactobacilli, a thinning of the epithelium, and a loss of glycogen. IUDs have been linked with increased rates of BV, although newer progestin-releasing IUDs have not been evaluated for their effects on the vaginal microflora. Hormonal contraceptives appear to enhance a *Lactobacillus*-dominated flora. The impact of contraceptives on the vaginal ecosystem, including their impact on susceptibility to infection, has not been adequately investigated to date.

EFFECT OF DOUCHE PRODUCTS AND "DRY-SEX" ON THE VAGINAL ECOSYSTEM

Douching is a common practice in women throughout the world. Douching may alter a woman's susceptibility to infection by altering the vaginal microflora, removing protective components from the vagina or cervix or by promoting ascension of microorganisms from the lower to the upper reproductive tract. Douching is more frequent among low-income women and ethnic minorities in the United States.[106] Routine douching for hygiene has been shown to double the risk of acquiring BV.[46] A cross-sectional observational study

of African women showed an increased prevalence of vaginal yeast among women who used douche products containing antiseptics.[107] Women who douched using noncommercial preparations were 70% more likely to have HIV, while women douched with commercial antiseptics had a 40% decreased frequency of HIV.[107]

Onderdonk evaluated the effects of a single use of a douche product on the vaginal microflora. Nonmedicated douches had a more transient effect on the vaginal microflora compared to those containing antimicrobial agents such as iodine.[1] However, even nonantiseptic douches had an effect on the vaginal microbial ecosystem and persistent use apparently altered the microflora. A better understanding of how different douche products affect young women's susceptibility to infection are urgently needed so that women can be counseled appropriately regarding douching.

The thick, glycogen rich vaginal epithelium is one of the primary structural defenses mechanisms of the female reproductive tract. In premenarchal girls and postmenopausal women, the lack of estrogen results in a thinning of the vaginal epithelium. There is a decreased cell division on the basal and parabasal levels of the vaginal epithelium.[108] In postmenopausal women elastic fibers of the lamina propria are replaced with nonelastic collagen. The decreased thickness of the epithelium, combined with loss of elastic structure renders the vagina more susceptible to damage during sexual activity. In some cultures, the use of drying or astringent agents is common in order to heighten a sense of "tightness" during sex.[109] The practice of "dry sex" acts to remove the lubricating vaginal fluid and may increase the susceptibility of the genital tract to infection. Dryness during sex has been associated with pain during intercourse, which is linked to postcoital bleeding.[110] Postcoital bleeding increases the risk of male-to-female transmission of HIV three- to five-fold.[111,112] Whether the use of traditional vaginal agents for "dry sex" is linked to postcoital bleeding has not been studied extensively, but the use of these agents has been linked to the HIV in some populations.[113]

EFFECT OF ANTIBIOTICS USED TO TREAT GENITAL INFECTIONS ON THE VAGINAL MICROFLORA

Antimicrobial agents used to treat nongenital and genital infections can adversely affect the vaginal microbial ecosystem. Lactobacilli are susceptible to beta-lactam antibiotics such as amoxicillin as well as cephalosporins, which are frequently used to treat genital tract infections.[114,115] The impact of beta-lactam antibiotics on the normal vaginal microflora was evaluated by Sullivan et al.[116] who followed women at baseline, on the day of ovulation, and at 3 and 7 days after ovulation. During the second ovulatory cycle, women were treated with pivmecillinam (a penicillin which binds to penicillin binding protein 2) administered orally 200 mg three times daily for 7 days. They documented that antibiotic was detectable in the vaginal fluid at a concentration of approximately 2 μL per mL. Surprisingly, they found that antibiotic usage had only a modest impact on the vaginal microflora, with little impact on lactobacilli, anaerobic bacteria, staphylococci, or *Gardnerella*.[116]

The activity of systemic or local antibiotics on the vaginal ecosystem is hard to predict because they have effects on many organisms present within the ecosystem. For example, ampicillin has activity against lactobacilli and its use initially leads to a decrease in vaginal colonization by lactobacilli among women with BV. However, because ampicillin presumably has activity against some of the other organisms present in the vagina which compete in that same ecosystem, ampicillin usage was found to have a net beneficial impact on vaginal colonization by lactobacilli 1 month after therapy.[117] Metronidazole, applied either topically or orally was associated with a net increase in vaginal colonization by lactobaccilli.[117] Clindamycin cream used for the treatment of BV and applied locally lead to an initial decrease in colonization by lactobacilli but, like ampicillin, lead to an increase in *Lactobacillus* colonization 1 month posttherapy. Two recent studies comparing *Lactobacillus* colonization rates following metronidazole or clindamycin therapy for BV showed no long-term negative impact of clindamycin treatment on colonization by lactobacilli.[117,118] By contrast, one study, which followed a group of women over time to assess factors associated with loss of lactobacilli from the vaginal ecosystem, found that exposure to antibiotics was associated with loss of lactobacilli.[79] Like other factors, antibiotic usage may likely have a transient impact on the microflora of most women, but may play a more persuasive role among women with unstable flora.

Topical microbicides (Chapter 94) differ substantially from traditional antimicrobics in that they optimally target specific pathogens and should not impact other beneficial components of the vaginal microflora such as lactobacilli. Although it may be desirable to have microbicides with activity against all common bacterial STDs including *Chlamydia trachomatis, Neisseria gonorrhoeae, Trichomonas vaginalis*, herpes, and HIV, it is unlikely that any single microbicide agent will be effective against the full range of sexually transmitted organisms.

Assessment of the impact of any vaginal product being developed is now a standard part of the initial safety evaluation for new barrier and microbicide products. BufferGel is a product being developed as both a topical microbicide and as a contraceptive. It was evaluated in a study in which women used the product once or twice daily for 14 days.[121] Assessment of the flora was conducted prior to use of the product and after 14 days of gel exposure. There was no impact of this product on the frequency of lactobacilli, but there was a marked reduction in the prevalence of several

acid-sensitive organisms including *G. vaginalis* and the anaerobic gram-positive cocci and gram-negative rods associated with BV. However, there was a statistically significant increase in colonization by *E. coli* and other facultative gram-negative rods, which was also observed among women using N-9.[94] Because this agent is an acidifier rather than a surfactant like N-9, it is likely that the perturbation of flora and increase in *E. coli* is related to the insertion of the gel or disruption of innate immunity.

ASSOCIATION BETWEEN THE VAGINAL MICROFLORA AND STDs

In addition to playing a role in determining whether microbial flora are conducive to the development of BV, H_2O_2-producing lactobacilli may also confer protection upon exposure to sexually transmitted disease. The concept that the vaginal microflora plays a role in resistance to gonorrhea was investigated widely in the 1970s.[122–124] Kraus and Ellison speculated that the urethral flora of the male might protect against acquisition of gonorrhea.[122]In vitro studies showed that *gonorrhoeae* could be inhibited by some components of the normal microflora including staphylococci and diphtheroids.[123] Studies of female sex contacts of infected males suggested protection might be afforded by vaginal colonization by lactobacilli.[124] Presence of H_2O_2-producing lactobacilli was associated with decreased prevalence of *trachomatis, vaginalis*, and symptomatic *Candida*.[45] A larger study from the Vaginal Infections and Prematurity cohort of pregnant women found that the prevalence of *gonorrhoeae, trachomatis*, and *vaginalis* was significantly lower in women with predominant vaginal lactobacilli compared to women with reduced or no lactobacilli.[125] In a large cross-sectional study of rural Ugandan women, similar trends were found.[2]

Little is understood about how lactobacilli prevent these infections. However, H_2O_2-producing lactobacilli directly inhibit the growth and catalase activity of *gonorrhoeae* by producing a combination of acid, peroxide, and protein inhibitor of catalase activity.[45] A longitudinal study of sex workers in Kenya demonstrated a twofold-decreased incidence of gonorrhea acquisition among women vaginally colonized by lactobacilli.

RELATIONSHIP BETWEEN THE VAGINAL ECOSYSTEM AND VIRAL STIs

The relationship between the vaginal microbial flora and susceptibility to viral STIs is summarized in Table 18-7. Alterations in vaginal flora have been linked to an increased risk of HSV-2 in two studies.[5,6] Cherpes et al. screened 1207 women aged 18–30 years for HSV-2 antibody, and after excluding HSV-2 seropositive women, followed the remaining women quarterly for a year. There were 32 acquisitions of HSV-2 over 628 women-years of follow-up, for an incidence rate of 5 per 100 women-years. Women with BV by Gram stain had a twofold-increased risk of HSV-2 (HR 2.1, 95% CI 1.0–4.5, $P = 0.05$) after adjustment for education and having a new sexual partner.[5] BV was confirmed as a risk factor for acquisition of HSV-2 in a study by Gottlieb et al. which included 946 women attending STD clinics. These investigators estimated that the population attributable risk of BV for HSV-2 acquisition was 21%.[5] Cherpes et al. also documented an increase in HSV-2 shedding among women lacking a *Lactobacillus*-predominant flora.[5]

Only a single study evaluated the impact of vaginal microflora on the acquisition and persistence of HPV.[7] A total of 1763 HIV+ and 493 HIV– women were evaluated for genital infections, including testing for 43 types of HPV in cervicovaginal lavage semiannually. Women with a Nugent intermediate (OR 1.2, 95% CI 1.1–1.4) or BV score (OR 1.4, 95% CI 1.3–1.6) were at increased risk of incident HPV infection. However, vaginal microflora was not associated with persistence of HPV.[7]

Table 18-7. Longitudinal Studies of Altered Vaginal Flora and Risk of Viral Sexually Transmitted Infections

Pathogen	Author, Year	Number of Women	Reference	OR or HR (95% CI)
HSV	Cherpes, 2003[5]	670	5	2.1 (1.0–4.5)
	Gottlieb, 2004[6]	946	6	1.9 (1.1–3.5)
HIV	Taha, 1998[2]	1196	2	3.0 (1.2–7.6)
	Martin, 1999[3]	657	3	2.0 (1.2–3.5)
	Myer, 2005[4]	5110	4	2.0 (1.1–3.6)
HPV	Watts, 2005[7]	2256	7	1.4 (1.3–1.6)

Longitudinal studies have linked vaginal ecology to HIV acquisition. Taha et al. followed a group of 1196 pregnant women in Blantrye, Malawi, through delivery.[2] Alterations in vaginal ecology were assessed by measurement of vaginal pH, discharge, and amine odor. There was a dose-related increase in HIV risk associated with alterations of the vaginal flora. Martin et al. followed a group of sex workers enrolled in Mombasa, Kenya, and conducted monthly evaluations for HIV and vaginal lactobacilli.[3] He demonstrated that the absence of vaginal lactobacilli was associated with a twofold-increased risk of HIV acquisition. A third study from Cape Town, South Africa, assessed risk factors for acquisition of HIV in 5110 women enrolled in a cervical cancer trial. Eighty-six women who acquired HIV infection were matched in a nested case-control design to 324 women who did not acquire HIV during follow-up.[4] Compared to women having a Nugent score of 0–3, women having intermediate flora had a modestly increased risk of HIV (OR 1.5, 95% CI 0.6–4.3), while women having a Nugent score of seven or greater had a twofold-increased risk of HIV (OR 2.0, 95% CI 1.1–3.6).[4]

These studies suggest that there is a strong interaction between the health of the vaginal ecosystem and susceptibility to viral STIs. Some possible biologic explanations for these associations include the impact of lower pH on viral transmission, the effect of vaginal microbes on the mucin gel, which coats and protects the epithelium, and the proinflammatory environment of the cervix when BV is present. Some probiotic approaches using lactobacilli that bind to HIV have been proposed as one approach to address the increased risk of HIV observed in women lacking lactobacilli.[59–62]

These longitudinal studies showed a consistent link between increased incidence of HIV, HSV-2 and HPV and altered vaginal microflora. Additional studies will be needed to confirm the relationship between an altered vaginal microflora and acquisition of viral STIs. In addition, studies are urgently needed to better identify the biologic basis explaining why women with an altered vaginal system are at increased risk of HIV. Because the vaginal microflora is also impacted by sexual behavior and contraceptive use, it is critical that vaginal microflora be evaluated in ongoing studies of HIV risk associated with microbicides use, contraceptives, and behavior.

NORMAL VAGINAL ECOLOGY OF PREGNANCY

The vaginal ecology of pregnant women does not differ substantially from that of nonpregnant women. Studies have established that some organisms considered to be part of the normal vaginal microflora are associated with an increased risk of preterm and/or low birth weight delivery when they are present at high-density concentrations in the vaginal fluid. Both group B *Streptococcus*[128] and *E. coli* [129,130] have been linked with preterm and/or low birth weight delivery, and are known to directly invade the chorioamnion and cause chorioamnionitis.[131] Other vaginal microorganisms which are part of the normal flora, including those associated with BV, have been linked to an increased risk of preterm birth, amniotic fluid infection, and chorioamnionitis, as discussed. In contrast, high-density vaginal colonization by *Lactobacillus* species has been linked with a decreased risk of most adverse outcomes of pregnancy.[132–136] Thus, the constituents of the normal vaginal ecosystem play a role in establishing the risks of preterm and/or low birth weight delivery, amnionitis, chorioamnionitis, and postpartum infections during pregnancy. Data derived from a cohort of pregnant women evaluated at three time points (23–26, 30–33, and 34–36 weeks' gestation) has shown that the frequency of lactobacilli remains relatively constant over the second and third trimesters of pregnancy.[125]

Ethnicity has been reported to have an impact on the vaginal microflora of pregnant women. In a large study of pregnant women, it was found that black women were more likely to be colonized by group B *Streptococcus*, anaerobic gram-negative rods, *hominis*, and *urealyticum* as compared with white or Hispanic women.[137] Black women were also significantly more likely to have BV, *vaginalis*, *trachomatis*, and *gonorrhoeae* compared to white women. In contrast, Hispanic women were more likely than white women to be colonized by group B *Streptococcus*, but were otherwise very similar to white women with respect to the frequency of genital microorganisms. Asian women had comparatively lower frequency of all genital pathogens, and had significantly less *urealyticum* compared to white women.[137]

In a smaller study from Great Britain, African and Caribbean women were found to have higher levels of abnormal vaginal flora and BV compared to white women, while Asian women were found to have lower frequencies of BV and abnormal vaginal flora than white women.[134] It has been noted that when black women and white women of similar incomes are compared, there is still a twofold or greater discrepancy in the rate of preterm delivery among black women.[137] Hispanic women, on the other hand, have one of the lowest rates of low birth weight in the United States, even though the Hispanic women included in studies have usually had modest income levels. Some authors have postulated that the disparity of preterm low birth weight among black women versus white women may relate to the substantial ethnic differences in the rates of genital tract infections, which may lead to preterm birth.[137]

As noted above, sexual activity is thought to have an impact on the vaginal ecosystem. Frequency of sexual intercourse during pregnancy was evaluated in the Vaginal Infections and Prematurity Study.[138] Women were interviewed at 23–26 weeks' gestation, at two time periods in the third trimester and again at delivery. Not surprisingly, 61% of the pregnant women reported having vaginal intercourse one or more times weekly

in the second trimester of pregnancy while only 28% of women reported this frequency of intercourse in the last month of pregnancy. Women positive for *vaginalis* or *hominis* who engaged in frequent sexual intercourse during pregnancy were at higher risk of preterm delivery, compared to women colonized by these organisms who did not have frequent intercourse. The authors speculated that frequent sexual intercourse may introduce organisms from the vagina into the cervix, which could begin the process of upper tract infection leading to preterm birth. What emerged from this study was that intercourse itself was not a risk factor for preterm birth, but rather frequent intercourse among women with certain lower genital tract infections.

While many constituents of the normal flora have been linked with adverse outcomes of pregnancy, this is a substantial body of data, which suggests that vaginal colonization by lactobacilli may protect against adverse outcomes of pregnancy.[136,139,140]

In one study conducted in Great Britain, it was reported that women having *Lactobacillus*-predominant vaginal flora had a rate of pregnancy loss between 16 and 24 weeks' gestation of only 1%, compared to a 5% incidence amongst those with reduced lactobacilli, and an incidence of pregnancy loss of 7% in those women lacking vaginal lactobacilli.[134] A follow-up cross-sectional study compared the history of second trimester pregnancy loss among women with *Lactobacillus*-predominant flora, women with reduced lactobacilli, and BV. Women with *Lactobacillus*-predominant vaginal flora were significantly less likely to have a history of a second trimester pregnancy loss compared to women with reduced or no lactobacilli detected by direct Gram stain.[141] In the Vaginal Infections and Prematurity Study, women with *Lactobacillus* detected by culture or by vaginal Gram stain were significantly less likely to deliver preterm and low birth weight.[132]

The mechanism by which lactobacilli could protect against adverse outcomes of pregnancy probably relate to their effect against other genital pathogens including those associated with BV. Many women treated for BV do not become recolonized with *Lactobacillus*, which produce hydrogen peroxide.[117–119] Thus, additional strategies for reconstituting the vaginal microflora of women following treatment of BV are needed in order to prevent these adverse outcomes of pregnancy.

MICROBIAL INTERACTIONS IN THE VAGINAL ECOSYSTEM

The complex nature of the microbial interactions in the vaginal ecosystem have often been studied but little understood. Perhaps the most frequently discussed example of this misunderstanding relates to the perception that vaginal lactobacilli decrease yeast vaginitis. While some suggest in vitro studies that *albicans* is inhibited by culture supernatants of *acidophilus*,[142] others have reported no inhibition of yeast by lactobacilli.[72] Further, H_2O_2-produced by lactobacilli in combination with myeloperoxidase also have antifungal effects.[143] *Acidophilus* in various forms have been used to treat yeast vaginitis.[144] Some investigators have gone so far as to suggest that ingestion of yogurt containing *acidophilus* prevents recurrent *Candida* vaginitis.[145] Nevertheless, clinical studies of women with acute recurrent vulvovaginitis have demonstrated that women who have recurrent yeast vaginitis have the same frequency and concentration of *Lactobacillus* as women without recurrent infections.[146] Hawes et al. in their longitudinal study of vaginal infections showed that women who were vaginally colonized by lactobacilli had a somewhat increased risk of acquisition of yeast vaginitis compared to women without lactobacilli.[46] Nevertheless, many women who seek medical care for chronic vaginal symptoms report using *Lactobacillus*-containing products orally or vaginally to restore the vaginal microflora in the mistaken belief that this will prevent recurrent vaginitis.[147] Well-controlled trials have failed to document any decrease in vaginal candidiasis whether orally or vaginally applied preparations of lactobacilli are used by women.[148]

Microbial interactions in the vagina probably are much more complex than have been appreciated in the past. For example, Pybus and Onderdonk recently published data establishing that there is a commensal, symbiotic relationship between *vaginalis* and *P. bivia* involving ammonia.[149] *Vaginalis* produces amino acids, which are in turn utilized by *bivia*. *Bivia* produces ammonia, which stimulates the growth of *vaginalis*. The symbiosis between *bivia* and *vaginalis* may explain the increased frequency of these organisms in BV and the fact that they appear to increase in concert among women with abnormal vaginal flora.

Another example of microbial interactions in the vagina comes from Sturm, who described the inhibition of the chemotactic response by granulocytes by obligate anaerobes.14[7] Coincubation of *G. vaginalis* with *Mobiluncus mulieris* or *Bacteroides ureolyticus* significantly reduced the chemotactic response of granulocytes compared to *G. vaginalis* alone. Culture filtrates of *Prophyromonas asaccharolytica* similarly decreased the chemotactic response of granulocytes to both *G. vaginalis* and *E. coli*.[150] These data were interpreted as showing that the presence of succinate-producing anaerobes in the vagina could inhibit chemotaxis of white blood cells, which may play a role in inhibiting the immune response to these pathogens.

Vaginalis produces a number of cysteine proteases, which are thought to play an important role in the virulence of this protozoan.[151] The cysteine proteases must be activated by disulphide-reducing reagents in order to be functional. Alderete evaluated the vaginal washes from 48 patients and found vaginal fluid has a reducing environment adequate for activation for trichomonad proteases. Importantly, H_2O_2 reversibly neutralizes these trichomonad proteases.

This suggests that *vaginalis* may be carried as a commensal among women with H_2O_2-producing *Lactobacillus* because of its inability to express its primary virulence determinant. This is possible only if sufficient amount of H_2O_2 is produced, but this observation does raise other questions. For example, could the increased prevalence of trichomoniasis in African American women be related to a greater reducing level (higher pH) in the vaginal fluid, perhaps due to lower levels of lactobacilli?

Another manner in which vaginal microorganisms may interact is through their adherence to vaginal epithelial cells or their competition with other organism for attachment sites. Vaginal strains of *Lactobacillus* from healthy premenopausal women were shown to self-aggregate and adhere to vaginal epithelial cells, displacing other vaginal pathogens such as *vaginalis*.[152] The surface components of lactobacilli involved in self-aggregation appear to be proteins for *gasseri* and lipoproteins for *acidophilus* and *L. jensenii*. The vaginal epithelial cell receptors for lactobacilli apparently are glycolipids, which act as the targets for the competition between lactobacilli and other pathogenic microbes.[152] It is possible that lactobacilli in the vagina may protect the vaginal epithelium by self-aggregating and adhering to vaginal epithelial cells, or by interfering with colonization through binding of common receptors to those of potential pathogens. Binding of *L. crispatus* to vaginal epithelial cells was increased in women with a history of urinary tract infection ($P = 0.04$) and a nonsecretor phenotype ($P < 0.001$).[153] These data suggest there may be a complex interaction between the normal vaginal flora, pathogen, and host genotype. Efforts are underway to develop probiotic products containing lactobacilli for use in colonization of the vagina for prevention of disease.[154, 155] As summarized in Chapter 42, use of probiotic products for treatment of BV has met with limited success. The development of a successful probiotic for use in "normalizing" the vaginal microflora will require careful strain selection and a better understanding of the factors, which permit colonization of the vaginal ecosystem by various lactobacilli.

19 Pathogenesis of Sexually Transmitted Viral and Bacterial Infections

Stanley M. Lemon and P. Frederick Sparling

INTRODUCTION

Viruses and bacteria represent fundamentally different life forms. Although, like viruses, many bacterial species are obligate intracellular parasites, bacterial cells generally contain most if not all of the elements of an energy-generating system required for life (chlamydia are an exception). Viruses, on the other hand, derive their energy sources exclusively from those available within the host cell. Thus, viruses are typically much smaller and biochemically much simpler pathogens. Unlike bacteria, viruses generally contain only a single species of nucleic acid, either RNA or DNA, and follow biochemical processes of transcription and translation that are based on eucaryotic biology. Thus, viruses and bacteria differ fundamentally in their strategies for multiplication. Viruses dissociate into their constituent biochemical components following entry into host cells, then reassemble after replication of their genomes and expression of their protein components. Bacteria maintain their integrity throughout the multiplication cycle, even if they are obligate intracellular parasites.

Despite these basic differences in their biology, pathogenic viruses and bacteria have evolved remarkably similar strategies for invasion of and persistence within their human hosts. These common strategies include general mechanisms by which pathogens attach to and enter specific host cell types, cause disease, and attempt to evade host immune responses.

The production of disease by invading bacteria or viruses results ultimately from the tendency of these infectious agents to evolve toward species with enhanced capacity for survival within human populations. However, whether disease occurs or not is irrelevant to the infectious agent as long as its capacity to spread and persist among humans is maximized. This overriding Darwinian principle applies to all infectious agents and has resulted in many different microbial survival strategies. Some infectious agents have evolved strategies that maximize their replication within the infected host, such that large quantities of virus or bacteria may be shed and result in new human infections. Good examples of such pathogens are influenza virus and HIV, as well as the bacterium *Neisseria gonorrhoea*, although in the case of HIV much of the released virus may remain cell-associated. However, many infectious agents have evolved strategies that result in long-term colonization or persistence of infection, usually with lesser quantities of virus or bacteria present within secretions or shed into the environment. Long-term persistence results in repetitive opportunities for transmission of the agent between individuals, ensuring its survival within human populations. Examples include HIV, herpes simplex virus (HSV) and human papilloma virus infections, and *Treponema pallidum*, the bacterial cause of syphilis. Such persistence is typically dependent upon the ability of the pathogen to evade innate and adaptive immune responses either by stealth, deception, or active disruption of host responses. Thus, the ability to establish persistent infection is a common and important determinant of the pathogenicity of many bacteria and viruses. This is particularly true for sexually transmitted pathogens.

CELLULAR ATTACHMENT AND ENTRY

Cellular attachment and penetration represent the first two steps in the replication cycle of any virus. Similarly, virtually all bacteria must attach to cells to cause infection. Attachment is generally achieved through a highly specific interaction between surface features of the infectious virion or bacterium and one or more molecules expressed on the cell surface that represent the cellular receptor or accessory coreceptor molecules. In the case of viruses, binding to the cellular receptor molecule brings the virion into close proximity with the cell surface, while secondary interactions with coreceptors are often required to facilitate penetration of the cell by the virus. In the absence of either receptor or coreceptor, there is no infection. These interactions are important determinants of the pathogenicity of individual viruses and bacteria, as they often play an important role in determining cellular tropisms and host range.

The human immunodeficiency virus type 1 (HIV-1) represents a good example of such specific interactions among

sexually transmitted viruses. HIV-1 usually initiates infection of certain lymphocyte subsets, monocytes, and macrophages via binding of its surface envelope glycoprotein (env) with the cellular CD4 molecule. Although this interaction is generally necessary for infection of a cell by HIV-1, it is not sufficient, as further interactions between the virus and additional surface molecules (coreceptors) are essential for viral entry.[1,2] T-cell adapted laboratory strains of HIV-1 require a seven-transmembrane, G protein-coupled receptor, fusin or CXCR4, to mediate penetration. Fusin enables the env protein of HIV-1 to mediate cell fusion, and in CD4-negative cells it can also serve as a primary receptor for these strains of HIV-1. In the case of nonsyncytium-inducing virus strains that have a predilection to infect monocyte/macrophages, the viral coreceptor is the cellular beta chemokine receptor, CCR5. These molecular interactions have important clinical consequences. Caucasian individuals who are homozygous for a 32-basepair deletion that abrogates expression of functional CCR5 appear to be resistant to infection with macrophage-tropic or dual-tropic strains of HIV-1.[3] This mutant allele is present with a high frequency in Caucasian populations but absent in the black populations of Western and Central Africa. Population-based studies have also shown that the frequency of heterozygotes is 35% lower among HIV-1 infected persons than in the general population, suggesting that persons with a single mutant allele have quantitatively lower expression of CCR5 leading to relative resistance against the infection. In recent years, knowledge of the specific intramolecular interactions involved in virus entry has been exploited in the development of effective small molecule inhibitors that have proven to be useful for antiviral therapy in HIV-infected persons.[4]

There are numerous other examples where specific interactions of viruses with their receptors and accessory coreceptor molecules play an important role in defining the host range and thus pathogenicity of viruses. For many viruses, however, the identity of cellular receptor is not known. In other cases, the cellular receptor may be expressed in a ubiquitous fashion, and therefore plays little or no role in determining the types of cells that can be infected with the virus. This may be the case with human cytomegalovirus, as its surface glycoprotein B is capable of interacting with surface heparin sulfate proteoglycans from a wide variety of cell types.[5] Similarly, HSV is able to infect a wide variety of different cell types. The envelope glycoprotein D of HSV (gD) binds to no less than three different receptor molecules: the herpes virus entry-mediator molecule (HVEM) which is a member of the tumor necrosis factor receptor family, nectin-1 which is a cell adhesion molecule in the immunoglobulin superfamily, and a modified heparan suphate.[6] The expression of HVEM-1 in Chinese hamster ovary cells (one of few cell types resistant to HSV penetration and infection) renders these cells permissive for infection.[7] The interaction of gD with these receptor molecules leads to conformational alterations of multiple viral envelope glycoproteins, activating the fusogenic properties of the virus and causing the fusion of viral and cellular membranes.[8]

In the case of sexually transmitted bacteria, tissue and species tropisms are also determined, at least in part, by the specificity of interactions between attachment ligands and host receptors, and use of multiple binding ligands and specific receptors also is a common strategy. For example, gonococcal pili initiate attachment but the appropriate receptor is found only on human cells.[9] The receptor for binding pili had been thought to be CD46,[10] but this is now unclear. Gonococci also use opacity (Opa) proteins and probably Lipooligosaccharide (LOS) to bind tightly to host cells (see Chapter 34). Indeed there are multiple forms of the Opa proteins and individual Opa bind to quite different receptors, either in the glycosaminoglycan family or CEACAM family.[11] Binding by other ligand-receptor systems may convert initial loose binding mediated by pili to tightly adherent binding, and promote cellular invasion. Other gonococcal adhesins include the porin protein, which binds the CR3 receptor on cells from the female genital tract,[12] and LOS, which binds the asialoglycoprotein receptor on epithelial cells.[13] High-frequency phase and antigenic variation of attachment ligands may prepare the bacterium for attachment to different cells (which may have different receptor specificities), both on different organs in the same person, and on the same tissues in different persons. At least, this is the inferred basis for the very rapid (1–2 days) in vivo selection of different pili and opacity proteins that has been noted during experimental gonococcal infection of male volunteers.[14,15] These variants emerge too quickly for de novo immune responses to select such variants.

Many bacteria also invade host epithelial cells. Such bacteria include supposedly extracellular pathogens such as the gonococcus.[16,17] Others apparently do not invade cells but slip between cells during systemic infection. *T. pallidum* is an example of the latter. Mechanisms are unclear in both pathogens, especially *T. pallidum*. There are several coordinated steps involved in invasion of epithelial cells by gonococci, including expression of a particular Opa variant; a switch from the piliated to a nonpiliated state and a switch from a sialylated LOS to nonsialylated LOS.[16,18] With the apparent assistance of porin protein, the epithelial cell membrane is functionally penetrated, and at least a measure of intracellular growth ensues before gonococci egress from the basal surface, gaining access to the subepithelial space and to the bloodstream.[17]

OTHER DETERMINANTS OF TISSUE TROPISM

In addition to specific receptor interactions, other features of cellular physiology may define the host range and tropisms of

viruses as well as bacteria. Although they are known to exist, in many cases, the specific nature of these cellular "host factors" remain poorly defined. In the case of DNA viruses, it is likely that in many cases such host factors are differentiation-specific cellular transcription factors. This is where the general dependence of viruses on eucaryotic regulatory mechanisms becomes very important, as viruses utilize tissue-specific promoter-enhancer elements and may also express proteins capable of modulating the activity of cellular transcription factors.[19,20] For example, human papillomaviruses (HPVs) replicate only within suprabasal cells of the epithelium. These viruses cannot be propagated in conventional cell cultures, reflecting the absence of differentiated cellular function(s) required for their replication. In vivo, the expression of RNA transcripts from the DNA genomes of HPV type 16 and 18 (HPV16 and HPV18) is generally restricted to differentiated suprabasal cells, and there is little evidence that these DNAs are transcriptionally active within undifferentiated basal cells. This distribution matches the tissue distribution of the differentiation-specific transcriptional activator Epoc-1/Skn–1a. This transactivator specifically stimulates the E6/E7 promoters of multiple HPVs.[19,21] This positive interplay between differentiation-dependent, epidermis-specific transactivators and viral enhancer elements is likely to play an important role in restricting the replication of HPVs to differentiated epithelial cells. In turn, through interactions of the HPV E6 and E7 proteins with p53 and retinoblastoma protein (pRb), respectively, papillomavirus infection disrupts normal cell cycle controls, driving cellular proliferation and promoting a cellular environment favorable for replication of the virus.[22]

Similarly, the liver-specific tropism of human hepatitis B virus (HBV) may be related at least in part to a requirement for liver-specific transcriptional transactivators. Candidate transcriptional factors include hepatic nuclear factor 3 (hnf-3) and the CCAAT/enhancer binding protein (C/EBP). These have been shown to bind to, and in the case of C/EBP transactivate, the HBV enhancer element.[23,24] In the case of HBV, however, it is likely that other factors, including possibly cellular receptor interactions, also play roles in restricting the replication of the virus, since the HBV enhancer element is very active in rat hepatoma cells that do not otherwise support replication of the virus.[25] Liver cells do not maintain their differentiated functions for long periods in tissue culture systems; this likely explains why HBV cannot be grown in any type of continuous cell culture in vitro. However, HBV proteins are also capable of modulating the intracellular environment by manipulating the activity of cellular transcriptional factors and transcriptional coactivators. Recent work suggests, for example, that the HBx protein functionally interacts with the coactivators CPB/300 to modulate the activity of the transcription factor CREB.[26] Hepatitis C virus (HCV) is also highly hepatotropic. Unlike HBV and HPV, however, HCV is a positive-strand RNA virus that does not replicate its genome via a DNA intermediate (see Chapter 29). Nonetheless, HCV infection stimulates the activity of cellular E2F promoters by downregulating the abundance of the retinoblastoma protein, using a strategy with numerous parallels to that adopted by HPVs to promote the proliferation of epithelial cells.[27] The upregulation of E2F transcription factors activity by HCV promotes hepatocellular proliferation, both favoring replication of the virus and possibly promoting hepatocellular carcinogenesis. A number of other interactions of HCV proteins with host cell factors have been shown to be required for HCV entry or RNA replication, but the specific factors restricting replication of the virus to the liver remain unknown.

Some bacterial cell tropisms may have similar underlying mechanisms. *Haemophilus ducreyi* were found to grow preferentially in the deepest cell layers of the subepithelial dermis. In addition, chlamydia are requisite intracellular pathogens because they cannot synthesize their own ATP. As a consequence, they have evolved to scavenge intracellular mitochondrial supplies of ATP. Although there is no evidence that chlamydial tissue tropisms are driven by cellular differences in availability of energy, it is possible that this may contribute to the apparent preference of chlamydia for mucosal epithelium.

MECHANISMS OF DISEASE PRODUCTION

DIRECT VERSUS IMMUNOPATHOLOGIC EFFECTS ON THE INTEGRITY OF TISSUES

At the simplest level, infection of a cell by a virus or bacterium may lead to cell death. In the case of viruses, specific disease syndromes may be caused by destruction of certain subsets of cells that express essential differentiated functions. A classic example of this is the development of the AIDS following HIV-1 mediated depletion of the CD4 lymphocyte population. Virus-induced cell death may result from one or more specific mechanisms. Many viruses express specific proteins that have as their major function the induction of a blockade in normal host cell metabolism (cellular translation and transcription) such that the metabolic machinery of the cell is subverted preferentially to viral replication. For obvious reasons, the expression of such proteins is usually highly toxic to the cell. Cellular destruction or "direct cytopathic effect" is considered responsible for the disease manifestations of many lytic viruses, including, for example, HSV and poliovirus. On the other hand, many cells may respond to the presence of an invading virus by the induction of apoptosis and the initiation of programmed cell death. Some viruses appear to have evolved mechanisms to prevent or delay apoptosis, thus potentially prolonging productive infection and maximizing replication. For example, HSV-1 infection

induces apoptosis at multiple metabolic checkpoints but has also evolved mechanisms to block apoptosis at each point.[28] Importantly, the inhibition of apoptosis by HSV-1 also prevents apoptosis induced by virus-specific cytotoxic T lymphocytes, thereby conferring on the infected cell a certain measure of resistance to the host's cell-mediated immune responses.[29]

However, many viruses are not intrinsically cytopathic. HBV is a prime example, as many infected HBsAg carriers are asymptomatic and without overt evidence of active liver disease. Despite this, such carriers may be very infectious, with a high titer of virus in their blood, semen, saliva, and genital secretions (see Chapter 29). The presence or absence of liver disease is largely determined by the T-cell response to the virus.[30] Thus, chronic hepatitis B results from a relatively vigorous but unsuccessful attempt on the part of the host to eliminate the infection. Human leukocyte antigen (HLA)-restricted, CD8-positive T lymphocyte responses play a critical role in this process, initiating an inflammatory cascade that involves the elaboration of soluble cytokines, including interferon-γ, and the recruitment of other types of inflammatory cells to the liver. In some instances, this immunologic response ultimately results in elimination of the infection, perhaps largely as the result of soluble factors secreted by immune cells rather than T cell-killing of infected cells.[31] However, in many HBsAg carriers, these responses result in the immune destruction of hepatocytes and the activation of stellate cells that produce an abnormal matrix, the hallmark of cirrhosis. Oxidative stress accompanies this process and may lead to mutations in cellular DNA resulting in the malignant transformation of hepatocytes.[32] Thus, chronic liver inflammation and the occurrence of hepatocellular carcinoma reflect the immune response to the virus, rather than specific virus effects. Similar indirect mechanisms may contribute to the progressive immune destruction of infected CD4-positive lymphocytes in patients with HIV-1 infection.

Some bacterial disease processes may also be caused largely to immunopathologic responses. For instance, there is substantial evidence that complications of genital chlamydia infections (salpingitis, Reiter's syndrome) are correlated with and may be owing to stimulation of antibodies against a heat-shock protein (hsp60).[33,34] In principle, such antibodies can cross-react with human homologs, which are antigenically similar to chlamydia hsp60. Further evidence for an immune mechanism underlying tissue damage in chlamydia infections is the association of salpingitis with particular HLA haplotypes in primates and women.[35,36] Pathology associated with *T. pallidum* infections may also be owing to immune mechanisms. The paucity of organisms in spinal cord samples from patients with tabes dorsalis suggests a possible immunopathogenic process. In experimental inoculations of humans, gummas occurred only in those subjects who had a history of earlier syphilis, strongly suggesting that hypersensitivity contributed to the development of the granulomatous lesions.[37]

In contrast, gonococcal tissue damage appears to be caused by the direct toxic effects of lipid A and peptidoglycan fragments, although each of these endotoxins triggers a complex cascade of inflammatory mediators, including cytokines, which are integral to normal host immune defenses such as interleukin-1, tumor necrosis factor (TNF), and others.[38,39] Recent evidence shows that gonococci activate the inflammasome complex in macrophages, inducing cell necrosis and death, which may contribute to tissue damage in complicated gonococcal infection (personal communication JA Duncan and J Ting, 2007). Cytokines and chemokines may also play important roles in viral infections. For example, the HSV-1 envelope glycoprotein gD inhibits the interaction of LIGHT, a member of the TNF family and an important regulator of dendritic cell function, with its receptor, HVEM.[7,40] While LIGHT may interfere with the ability of HVEM to act as a cellular receptor for HSV-1, thus inhibiting HSV replication, the binding of gD to HVEM may alter normal downstream signaling processes leading to dendritic cell maturation and possibly promote immune evasion.[41] The replication of HIV is also significantly influenced by a complex network of inhibitory and stimulatory cytokines and chemokines, at least in part by modulating the availability of the HIV coreceptors, CCR5 and CXCR4.[42] Macrophage-tropic strains of HIV-1 induce a signal when the HIV env glycoprotein binds to the CCR5 chemokine receptor.[43] This signal may promote the replication of the virus by activating the infected cell, increasing the number of infected cells by inducing chemotaxis of activated CD4-positive cells to the site of virus replication. At the same time, recent evidence suggests that NS5A protein expressed by GBV-C virus induces release of the chemokine SDF-1, downregulating surface expression of CXCR4, and potently inhibiting HIV-1 replication.[44]

PRODUCTION OF TOXINS BY BACTERIA AND VIRUSES

Despite similarities in mechanisms of disease production by viruses and bacteria, there are important differences. The elaboration of extracellular toxins plays an important role in the pathogenesis of many bacterial infections, both purulent and nonpurulent. *H. ducreyi* is a prime example, since it produces two cytotoxins, which probably are crucial to the tissue-destructive, ulcer-generating pathology that characterizes chancroid.[45,46] In contrast, virus infections generally have not been associated with production of specific toxins. Recently, however, the nonstructural glycoprotein 4 (NSP4) of rotavirus has been shown to induce diarrhea in mice in an age- and dose-dependent fashion.[47] Rotavirus NSP4 enhances chloride secretion through a calcium-dependent signal transduction pathway, and thus it acts as a true

enterotoxin. In addition, the envelope protein of Ebola virus, a filovirus, has been suggested to be a major determinant of the enhanced vascular permeability that characterizes Ebola fever.[48]

ALTERED CELLULAR GROWTH AND DIFFERENTIATION

Some viruses are capable of altering differentiated cellular functions, resulting in the production of disease by mechanisms that do not exist among bacteria. A prime example is the altered cellular growth that follows infections by molluscum contagiosum virus (MCV), leading to the distinctive cutaneous lesions of molluscum. A more extreme example is the proliferation of epithelial cells that is induced by infection with HPVs. HPV-related epithelial malignancies and cellular transformation are related to the expression of two specific HPV proteins, the E6 and E7 oncoproteins, by high-risk HPV subtypes.[22] These proteins interact with p53 and pRb, both promoting cellular proliferation and cell survival. Oncogenic transformation is usually associated with high-level expression of E7 from integrated HPV DNA. The Kaposi's sarcoma-associated herpes virus (KSHV) also expresses a number of proteins that mimic important host regulators of cellular proliferation and survival, including virally encoded bcl-2, interleukin 6, cyclin D, and G-protein-coupled receptor.[49,50] Expression of these proteins may result in deregulation of cell growth, with changes in the cellular morphology and/or acquisition of the ability of the cells to form colonies in soft agar, changes that are indicative of transformation.

On the other hand, hepatocellular cancers occurring in the context of chronic viral hepatitis are likely to have an alternative explanation. Although it is possible that integration of HBV DNA may be responsible for altered cellular growth control in some hepatitis B-associated cases, liver cancer in this setting may be primarily immunopathogenic.[30,32] Chronic inflammation accompanied by oxidative stress and cellular DNA damage are likely to plan important roles. This may also be the case with hepatitis C-associated liver cancer although, as mentioned above, HCV appears to have evolved mechanisms similar to those of the HPVs that downregulate pRb abundance and promote cellular proliferation.[27] Because it is an RNA virus without the capacity for reverse transcription of its genome to DNA, HCV is incapable of integrating any of its genomic sequences into host chromosomes. Nonetheless, infection with this virus is increasingly associated with the occurrence of hepatocellular carcinoma, which is typically fatal. Evidence suggests that HCV may modulate the activity of several tumor suppressor proteins, p53, DDX3, and DDX5, as well as pRb, in order to promote cellular proliferation and enhance its replication. Altered p53 and pRb activities in HPV-infected cells may cause malfunctioning of critically important cell cycle checkpoints.[51] It is possible that similar effects on p53 and pRb associated with HCV infection may allow hepatocytes with damaged chromosomal DNA to survive and even proliferate. Such a model readily explains the synergy noted clinically between HCV infection and alcohol ingestion in promoting hepatocellular carcinogenesis.

MECHANISMS OF IMMUNE EVASION

Persistence of an infecting agent almost always involves a mechanism to evade or otherwise foil both innate and adaptive host immune responses. In the case of viruses, this involves four general strategies: latency, stealth, active disruption of immune responses, and antigenic variation. Bacteria use fundamentally similar strategies, with the exception of latency that, strictly defined, is specific to viruses.

VIRAL LATENCY

The induction of latent infection by herpes viruses such as HSV represents a uniquely effective mechanism of evading the host immune response. During latent infection only a very small number of viral proteins are actively expressed, providing few targets for the immune system.[52] Major structural antigens of the virus are not synthesized, and there is no production of infectious virus. There is no cytopathic effect, and the viral genome is maintained through cell divisions largely by the cellular metabolic machinery. However, latency is periodically reversed, with reactivation of the infection leading to the production of infectious virions. Thus, latent infections clearly contribute to the overall survival of herpes viruses within human populations. This general strategy is not available to bacteria (and most other types of viruses) because of fundamental differences in replication strategies.

However, certain bacteria can persist for prolonged periods with little evident replication: mycobacteria are one example and *T. pallidum* may be another. *T. pallidum* can be reactivated by corticosteriod therapy after a long period of dormancy in rabbits, and a similar phenomenon may underlie the long periods in which there is no disease activity (clinical "latency") before the onset of late syphilis. While not meeting the strict definition of latency as applied to the herpes viruses, there is some evidence that chlamydia can persist in eukaryotic cells without overt replication and release of infectious particles. Unlike latent viral infection, however, there is little evidence that such latency of chlamydia is clinically important.

EVASION AND DISRUPTION OF INNATE IMMUNE RESPONSES

The earliest immune responses to an invading pathogen are triggered by recognition of the products of viral and bacterial replication which act as ligands for "pathogen-associated

molecular pattern" (PAMP) receptors such as Toll-like receptors (TLRs), caspase recruitment domain-containing RNA helicases such as retinoic acid-inducible gene I (RIG-I), and other groups of cytosolic proteins called the NOD and NALP proteins.[53,54] These are specialized receptors, each of which recognizes a ligand expressed during invasion by a specific class of pathogen. For example, TLR3 recognizes double-stranded RNA produced during the replication of RNA viruses, while peptidoglycans produced by bacteria are recognized by a NOD protein. The engagement of these receptors leads through complex signaling cascades to the activation of a variety of cellular transcription factors, including interferon regulatory factors and NF-κB. This leads to the subsequent induction of dozens or even hundreds of genes encoding pro-inflammatory cytokines, chemokines, interferons, other cellular proteins with direct antiviral activities, as well as regulators of programmed cell death. These responses serve to limit the replication of viruses and regulate inflammation occurring in response to infection. They may also modulate cellular innate immune responses and contribute to the effective priming of cytotoxic T cells, thus potentially shaping the development of antigen-specific adaptive immunity. Because these responses are encoded in the germ line of the host, they are immediate, and may play important roles in limiting the degree of initial replication and/or spread of a virus. They can be viewed as important stopgap responses, buying the host time while antigen-specific adaptive immunity develops.

The activation of interferon regulatory factor 3 (IRF-3) through these pathways is central to the induction of interferons in response to virus infection, and in recent years many RNA and DNA viruses have been recognized to possess mechanisms that actively disrupt its activation. For example, HCV expresses a serine protease, NS3/4A, that targets cellular adaptor proteins that play essential roles in signaling pathways leading from TLR3 and RIG-I to the induction of interferon synthesis.[55,56] The proteolytic destruction of these adaptor molecules, TRIF and MAVS, enables the virus to evade type 1 interferon responses and escape cellular control of the infection, possibly contributing to viral persistence in chronic hepatitis C. HSV targets the same cellular signaling pathways to block the expression of type 1 interferons, in part through expression of its immediate-early protein ICP0, which prevents the nuclear accumulation of activated IRF-3.[57] Similar strategies have been evolved by bacteria. For example, invasive enteropathogenic strains of Shigella inject a set of potent enzymes into epithelial cells through their type III secretory system that target cellular pathways controlling inflammation and cell death.[58] A unique approach to evading activation of innate immune responses appears to be taken by HBV, which replicates its genome within nascent core particles and maintains the cccDNA form of its genome cloaked within host cell histones. This stealth approach prevents the recognition of viral components by cellular PAMP receptors and leads to a paucity of innate cellular antiviral responses in hepatitis B.[59] In addition to the mechanisms that viruses and bacteria have evolved to prevent or blunt the induction of innate immune responses, there are many examples, too numerous to mention here, of these pathogens blocking or disrupting the effector actions of cellular proteins induced through these pathways.

DISRUPTION OF ADAPTIVE IMMUNITY

Similar to the mechanisms by which viruses and bacteria may evade innate immune responses are mechanisms that directly disrupt the subsequent development of antigen-specific, adaptive immunity. Herpes viruses such as HSV and cytomegalovirus (CMV) express proteins (ICP47 in the case of HSV and US6 in the case of cytomegalovirus) that block the normal peptide transporter (TAP) function required for presentation of viral peptide fragments to major histocompatibility complex (MHC) Class I restricted T cells.[60,61] ICP47 binds to TAP within the cytosol, preventing the transport of peptide fragments into the endoplasmic reticulum, whereas the CMV US6 is a secreted glycoprotein that interacts with TAP within the lumen of the endoplasmic reticulum. Disruption of transporter protein function by CMV and HSV may lessen the extent to which the infection is recognized by the host immune system.

Bacterial strategies for disruption of adaptive immunity are an active area of investigation. They include production of enzymes that cleave immunoglobulins such as the gonococcal IgA1 protease. This cleaves IgA1 at the hinge region, thereby largely inactivating it, which may help to evade specific immune responses on mucosal surfaces. The importance of IgA1 protease is uncertain, however, since human responses at genital surfaces appear to be made up of 50% sIgA1 and 50% sIgA2. The latter lacks the hinge structures required for cleavage by the gonococcal IgA1 protease, and thus is protease resistant. Moreover, there are considerable quantities of IgG at the site of mucosal infections that is also not susceptible to IgA1 protease.

Many bacteria have the ability to downregulate the adaptive immune response. Gonococci appear to be able to suppress the B and T cell responses by engaging lymphocytes with particular members of the Opa family.[62,63] Induction of the innate immune responses that activate the cell death response "as distinct from apoptosis" may contribute to downregulation of B and T cell responses after gonococcal infection, contributing to the weak adaptive immune responses that characterize gonococcal infection.[64]

Another mechanism to escape the adaptive immune response is to interfere with the ability of complement to carry out its biological functions, thus impeding the effectiveness of antibodies that depend on complement for

their effect. Gonococci have evolved strategies for binding serum inhibitors of complement to the major outer membrane protein porin, which prevent the bactericidal activity of antibodies directed to porin or neighboring molecules. Two different inhibitors may be involved, binding to different domains of porin: C4bp binds to one epitope, whereas factor H binds to another loop epitope.[65,66] The net effect is to protect the gonococcus from an otherwise effective bactericidal attack by immune serum antibodies.

ANTIGENIC VARIATION

Antigenic variation is a very common strategy by which infectious agents foster persistence. Mechanisms exist among all classes of infectious agents, viruses, prokaryotes, and eukaryotes, for altering the sequence of key epitopes of the pathogen that are recognized by both cellular and humoral arms of the host adaptive immune system.

The simplest mechanism for antigenic variation is that which is found among the RNA viruses and lentiviruses including HIV-1. The polymerases expressed by these viruses, whether RNA-dependent RNA polymerase or reverse transcriptase, lack the 3′–5′ exonuclease activity associated with the proof-reading function of DNA polymerases. This results in a high error rate during transcription of the viral genome, leading to impressive mutational rates among these viruses (Fig. 19-1). The extent to which antigenic variation actually occurs is dependent on the ability of the viral protein to sustain mutations without loss of critical function (which limits viral fitness) and the strength and type of selective forces applied by the host immune response.

Prime examples of this phenomenon include antigenic variation within hypervariable regions of the envelope glycoproteins of HIV-1 and HCV. Antigenic variation in the V3 loop of HIV reduces the ability of preexisting antibodies to bind to the newly mutated peptide sequences in the loop. Thus, these mutations cause a reduction in the ability of these antibodies to neutralize virus infectivity.[67] Variation in the envelope glycoproteins is likely to contribute to B cell escape and viral persistence. Similar mechanisms have been posited to play an important role in the long-term persistence of HCV in chronic hepatitis C. Cytotoxic T-cell escape may also follow a mutational event within short sequential peptide sequences that serve as T-cell epitopes. These mutational and selection mechanisms account for the extensive "quasispecies" variation seen with many persistent RNA viruses such as HCV, and also result in the rapid emergence of resistance of HIV-1 as well as HCV to small molecule inhibitors of viral replication. The best defense against the latter phenomenon is to severely limit viral replication with a cocktail of antiviral drugs, as replication of the virus and transcription of its genome are essential to the generation of new quasispecies variants.

Antigenic variation is also common in many pathogenic bacteria. Among the sexually transmitted bacteria, the gonococcus is most completely studied. The dominant theme that emerges from these studies is the complexity and elegance of the strategies for rapid alteration in expression of cell surface antigens (on-off), and for variation in the primary sequence (and thus antigenicity) of many of these antigens. Pili and opacity proteins each undergo phase variation (expression alternating with nonexpression) and antigenic variation (variations in antigenic structure of the expressed protein) at rates approximating 1×10^3–1×10^4 per cell per generation (Figs. 19-2 and 19-3). Interestingly, these rates closely approximate the frequency of base misincorporation by the RNA polymerases of RNA viruses. In the case of *pili*, the fundamental mechanism is crudely analogous to those used in antibody variations. Recombination between one of many variant incomplete *pil* loci (*pilS*, for silent) and a pilin expression locus, *pilE* results either in a different pilin protein (antigenic variation) or a faulty one that cannot be secreted and assembled into a pilus (phase variation).[68–70] *Opa*

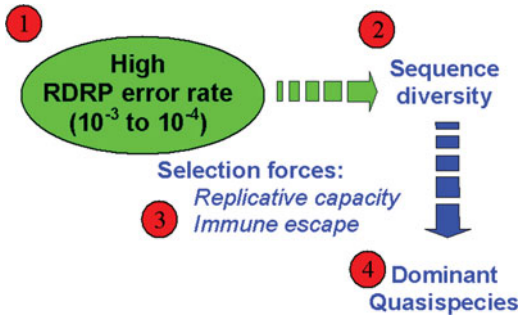

FIGURE 19-1. Mechanism accounting for antigenic variation among viruses such as hepatitis C virus and HIV-1 which replicate through an RNA intermediate. RDRP represents "RNA-dependent RNA polymerase" (or reverse transcriptase, in the case of HIV-1).

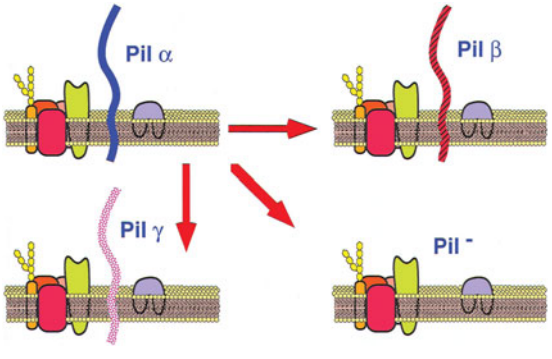

FIGURE 19-2. Phase and antigenic variation in gonococcal pilin. Recombination between variant incomplete *pilS* genes and *pilE* (the pilin expression locus) result in either antigenic variations (Pilα → Pilβ or Pilγ), or phase variation (Pilα → Pil$^-$). The Pil$^-$ phenotype sometimes reverts to Pil$^+$ when recombination with another for *pilS* gene restores the ability of *pilE* to produce functional pili.

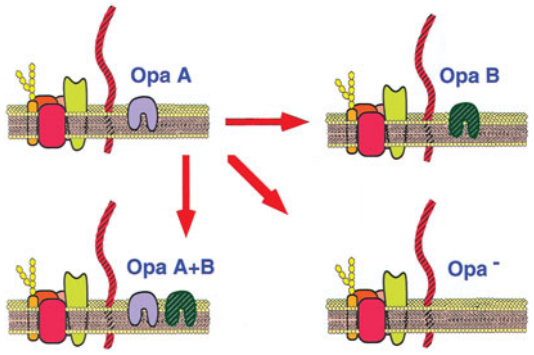

FIGURE 19-3. Phase and antigenic variation in the gonococcal opacity protein family. Gonococci possess multiple (up to 12) complete *opa* genes, each of which is transcribed but only some of which are translated. Successful translation depends on the number of [CTCTT] repeats in the *opa* genes; when N = 3, 6, 9, 12, 15 etc., Opa is expressed, but all other variations in the number [CTCTT] repeats throws the gene out of translational frame and no Opa is expressed. Slipped-strand errors during DNA replication frequently alters the number of the [CTCTT] repeats, resulting in spontaneous on-off switching in each *opa* gene. Since the product of each *opa* gene is somewhat different, this also results in antigenic variation.

proteins vary by a totally different mechanism involving slipped-strand mispairing of a pentameric CTCTT repeat element in the opa gene, leading to translational frame shifts. An *opa* gene is "off" when out of translational frame and "on" when in frame. Since there are about 12 complete *opa* genes, each of which is slightly different, the random high frequency shifting in each *opa* gene results in a constantly shifting mosaic of expressed Opa proteins.[71,72] Similar mechanisms underlie the high frequency variations in expressed length of the gonococcal core LOS polysaccharide chain (Fig. 19-3)[73,74] and also the on-off phase variation in expression of the *pilC1*, *pilC2* genes, and the *hpuAB* genes for utilization of hemoglobin and haptoglobin.[75] The result is that any population of $>10^6$ gonococci is quite heterogeneous, with multiple variants expressing a bewildering mixture of pili, Opa, and LOS antigens. This prepares the organism for specific immune evasion from antibodies aimed at epitopes on one of these antigens and for binding to different receptors on different cells on different tissues and/or people. Truly, gonococci always "have their bags packed ready to travel."

T. pallidum also apparently undergoes phase variation in expression of certain rare outer membrane proteins designated the *T. pallidum* repeat family, or *Tpr*. One of the TprD evolves in vivo and may contribute to immune escape from humoral immune responses to infection, perhaps helping to explain the remarkable persistence of *T. pallidum* in human infection.[76,77]

Other bacterial antigens undergo slower evolution by relatively rare missense mutations that slowly alter antigenic structure (e.g., gonococcal porin, chlamydia major outer membrane protein, or MOMP). Recently, however, it has been recognized that gonococci can exchange blocks of chromosomal DNA between different strains in nature, resulting in mosaic genes that have altered structure, function, and antigenicity.[78–81] Indeed, horizontal DNA exchange of this sort appears crucial to evolution of gonococcal IgA1 protease, altered penicillin binding protein 1, and probably porin protein (M. Hobbs et al., personal communication),[78,79] and plays a key role in the general problem of emergence of bacterial species.[82]

MASKING OF ANTIGENS

By "masking," we mean "covering up," as for instance one raises an umbrella to ward off rain. In a sense, all intracellular pathogens are "masked" because antibody and complement cannot follow them inside the cell. However, in this usage we refer particularly to production of specific structures that physically block access of host defenses to the cell surface of the pathogen. Bacterial capsules may play such a role but none is important for any of the bacterial STD pathogens. Although gonococci do not make a true capsule, they clearly display masking when they add neuraminic acid (sialic acid) to their LOS polysaccharide chain.[83,84] (This is done by the use of a gonococcal sialyltransferase and host-derived CMP-N-acetyl neuraminic acid.) Sialylation creates a sort of molecular umbrella, effectively covering up both LOS and neighboring porin protein from attack by complement fixing antibodies, rendering the organism resistant to bactericidal antibodies.[85,86] The extensive glycosylation of the HIV env protein and the HCV E1 and E2 envelope proteins (which results in an approximate doubling of molecular mass of each of the proteins) may also serve to mask the exterior surface of the viral envelope from antibody recognition.

EXPRESSION OF BLOCKING ANTIGENS

Production of so-called "blocking antigens" is yet another mechanism that bacteria have evolved to evade otherwise effective antibody defenses. In the case of the gonococcus, a constant (invariant) antigen designated reduction modifiable protein (Rmp) strongly elicits host production of noncomplement fixing IgG antibodies. On binding to Rmp, these antibodies prevent the proper conformational deposition of complement-fixing antiporin antibodies onto the closely juxtaposed porin molecule, thus blocking the antiporin bactericidal attack.[87,88] The presence of blocking antibodies helps to render gonococci resistant to killing by normal human serum and promotes infection between sexual partners.[89] Thus, gonococci have evolved two separate mechanisms for evading complement dependent attack; blocking antigen, and binding by porin of serum factors that inhibit complement, as described above. A somewhat similar masking strategy may also exist among viruses. Crystallographic studies suggest that the V3 loop of the HIV-1 envelope protein may act to mask the cellular receptor interaction site on the assembled HIV

envelope from antibody attack. This would be a clever trick, because the CD4 interaction site must be relatively conserved in structure if it is to function effectively. The CD4 receptor-binding site is unmasked by a conformational rearrangement of the env protein that flips the V3 away and precedes docking of the envelope protein to the CD4 molecule.

OTHER MECHANISMS OF IMMUNE EVASION

Although no term has been coined yet to aptly describe the phenomenon, *T. pallidum* is thought to evade host defenses in part by presenting very few antigenic proteins on its phospholipid rich outer envelope.[90] This strategy is not dissimilar to the mechanism adopted by HBV to evade detection by PAMP receptors, and by analogy to the relative radar invisibility of airplanes with certain shapes and compositions, this microbial strategy might also be termed "stealth."[91]

MOLECULAR MIMICRY

Another mechanism of pathogenesis involves the expression of proteins that are able to mimic specific host cell molecules in either structure or function. This strategy is particularly evident among viruses with larger genomes that are capable of expressing a wider variety of proteins. KSHV is an excellent example, as its genome encodes a number of proteins with sequences or motifs similar to those encoded by the human genome as mentioned above receptor.[49,92] Bacterial mimicry also occurs, as for example, the identity between host glycolipids and the terminal epitope on gonococcal LOS, and meningococcal group B sialic acid capsule and brain sialic acids of identical structure.[93]

CONCLUSION

Clearly, many STD pathogens are masters of immune evasion. This explains, at least in part, why herpes viruses, papillomaviruses, HIV, and *T. pallidum* persist so long in human hosts, and why gonococci are so adept at causing repeat infections. These concepts also help to understand how gonococci, chlamydia, HCV, and others persist in the host in the face of an apparently vigorous immune response. Details of the strategies are discussed further in the respective chapters that follow. We can readily appreciate how difficult is the task of designing vaccines for these infectious agents. Most have evolved over a very long time in humans, and it is no surprise that these pathogens are survivors.

20 The Biology of HIV, SIV, and Other Lentiviruses

Patrick R. Harrington and Ronald Swanstrom

INTRODUCTION TO RETROVIRUSES

TAXONOMY AND CLASSIFICATION

The human immunodeficiency viruses (HIV-1 and HIV-2) and the simian immunodeficiency viruses (SIV) (with a subscript indicating the species of origin) are members of the lentivirus genus of the *Retroviridae* family, commonly called retroviruses. Retro (Latin for backward) refers to an unusual step in the virus life cycle. Typically, the flow of genetic information in a cell is from DNA to mRNA to protein. However, retroviruses have a single-stranded RNA genome that serves as the template for the synthesis of viral DNA, reversing the normal flow of genetic information and giving retroviruses their name. This reverse flow of genetic information is not unique to retroviruses but rather identifies a widely dispersed set of viruses and endogenous genetic elements. Most share the feature of encoding the enzyme responsible for DNA synthesis utilizing an RNA template—reverse transcriptase (RT), first discovered in retrovirus particles in 1970[1,2] and now a key therapeutic target.

Many organisms carry mobile DNA elements that duplicate themselves at new positions in the host genome by reverse transcribing an RNA copy of the element into DNA and inserting the DNA copy at a new location in the host chromosome. With the availability of the human genome DNA sequence, it has become apparent that upward of 45% of our own is composed of various types of mobile genetic elements, although most of the copies are defective. A major component is the L1 family, representing 17% of our DNA. L1, and a parasitic element of L1 called Alu, are present in thousands of copies throughout our genomes. Both of these elements duplicate themselves using an RT activity encoded within L1. These elements are still active, giving rise to new human mutations.[3,4] There are three distinct families of viruses that utilize a reverse transcription strategy: the plant virus family of caulimoviruses (with cauliflower mosaic virus as the best known example), the hepadnavirus family (found in birds and mammals, with human hepatitis B virus as the best known example), and retroviruses.

Retroviruses are divided into two subfamilies: *Orthoretrovirinae* and *Spumaretrovirinae* (International Committee on Taxonomy of Viruses, http:// www.ncbi.nlm.nih.gov/ICTVdb/ICTVdB/index.htm). The spumaretroviruses have distinctive features of their replication cycle that require this more distant classification. They have been isolated from primates, but not humans, and are not associated with any known disease. The orthoretroviruses are divided into six genera and represent viruses that infect snakes, fish, birds, and mammals. The phylogenetic relationships among the orthoretrovirus genera, with selected examples of viruses within each genus, are shown in Fig. 20-1A.

Human infections occur with viruses from two of these genera. The Deltaretrovirus genus includes human T-cell leukemia virus type I (HTLV-I), the causative agent of adult T-cell leukemia,[5–7] and human T-cell leukemia virus type II (HTLV-II), which is not known to be associated with any disease syndrome. HTLV-I is also associated with another syndrome called HTLV-associated myelopathy (HAM). HTLV-I and HTLV-II are related to viruses found in primates and more distantly related to bovine leukemia virus. The lentivirus genus includes HIV-1[8] and HIV-2[9] as well as viruses found in a variety of mammals ranging from primates to sheep. Viruses within these different genera vary widely in the diseases they cause and the mechanisms of disease induction, in contrast to the many common features of their replication cycle.

In its DNA form the viral genome is inserted into the host genome (integration, see below). This step in the virus life cycle has important implications for several features of virus-host interactions. For example, viral DNA that integrates into the genome of a cell but is not expressed becomes silently carried in the descendents of that cell. When this happens in a germline cell, or in the cell of an early embryo that becomes a germline cell, this copy of viral DNA becomes a linked physical part of the host genome, is present in every cell in the body, and is passed on to subsequent generations. Such a genetic element is called an endogenous retrovirus. Most of the elements that become fixed are defective, as there is probably a strong selective pressure against elements that can activate to produce

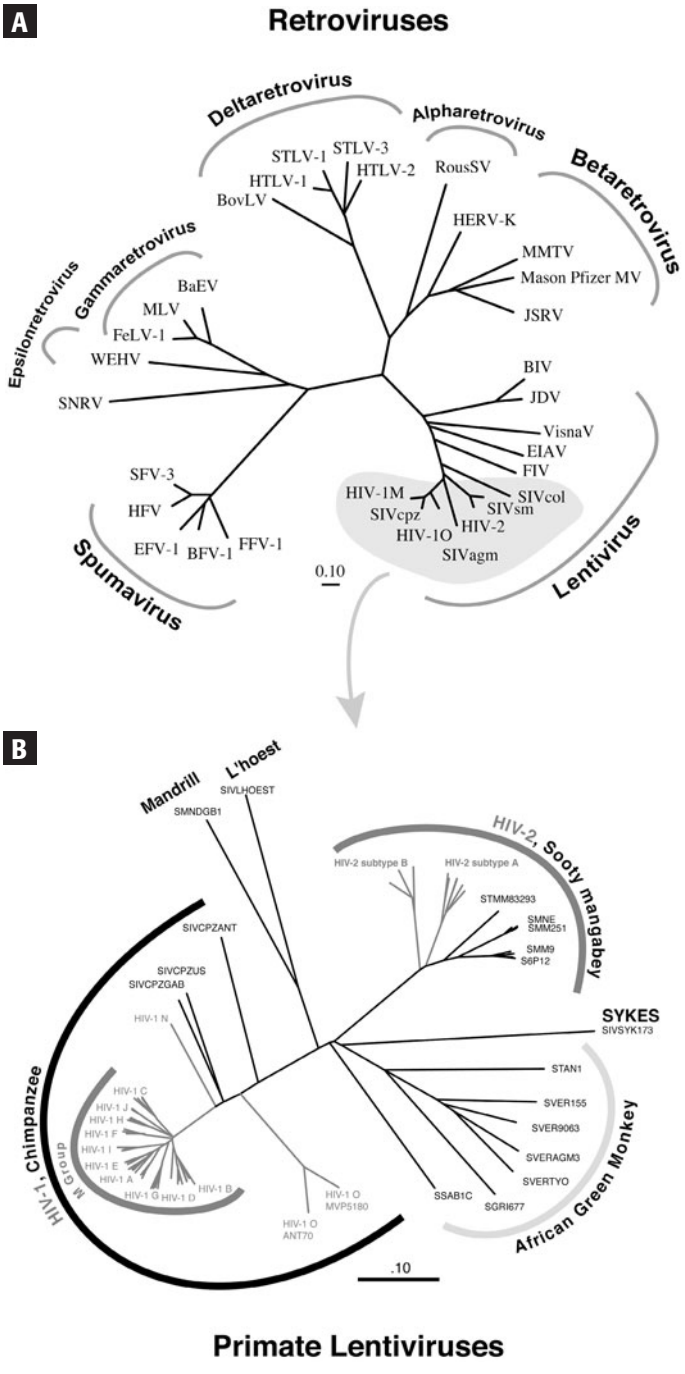

FIGURE 20-1. Phylogenetic relationships between, **A,** representative vertebrate retroviruses and, **B,** primate lentiviruses based on Pol protein sequences. Figure courtesy of Brian Foley, Los Alamos National Laboratory.

infectious virus. Thus, they represent an archive within the host genome of previous waves of retroviral infections. In fact, the human genome carries a record of retroviral infections over the last 40 million years of primate evolution. These are viruses that we do not recognize as active in the human population at present but are represented by 110,000 genomic inserts of gammaretroviruses, 10,000 inserts of betaretroviruses, and 80,000 inserts of a genus that may be distantly related to spumaretroviruses or may represent an uncharacterized lineage.[10] Most of these elements contain large deletions; however, if these deletions had been retained, our genomes would be 40% endogenous retroviruses by mass and outnumber our normal genes 7 to 1. A recent sequence analysis of one of these endogenous virus families has suggested that at least one of the elements may still be active within the human population, capable of infection and the creation of new endogenous virus loci in our genome.[11]

DISCOVERY OF RETROVIRUSES AS CANCER-CAUSING AGENTS

Most histories of retroviruses start with the dramatic discovery by Peyton Rous in 1911 that a virus, Rous sarcoma virus (RSV), could cause cancer.[12] Rous showed that a cell-free extract of a chicken sarcoma could be passed through a filter and the filtrate used to induce sarcomas in new chickens. The work of Rous was preceded by that of Ellermann and Bang, who described the transmission of chicken leukemia using cell-free extracts (avian leukosis virus, ALV).[13] However, the neoplastic nature of leukemia was not appreciated at the time and their observations received much less attention.

The isolation of other tumor-causing retroviruses followed and in time it became apparent that there were two broad classes of agents: one class of viruses caused cancer after a long latency period (e.g., ALV, mouse mammary tumor virus [MMTV], and murine leukemia virus [MLV]), while the other class caused tumors that appeared rapidly (e.g., RSV). We now know that the acutely transforming retroviruses carry a cell-derived oncogene that is responsible for the transforming activity,[14] while the slowly transforming retroviruses act by the chance integration of viral DNA near these cellular oncogenes in the host genome to induce their expression and promote tumor formation.[15,16] Importantly, many of these same genes can be mutated or overexpressed in human cancers, and the proteins they encode are now the targets of new generations of specific antitumor therapies (for example see review by Pegram et al.[17]). One can confidently surmise that the remnants of the beta- and gammaretroviruses littered in our genomes had such oncogenic effects when they were active. Ironically, for the active human retroviruses, HTLV-I causes tumors by a different but still poorly understood mechanism, and HIV is involved in tumor formation only indirectly through immune suppression.

DISCOVERY AND PHYLOGENETIC RELATIONSHIPS OF LENTIVIRUSES

The first description of a retrovirus was in retrospect that of an animal lentivirus (equine infectious anemia virus, EIAV), through the demonstration of transmission of anemia by a cell-free extract of blood from an infected horse.[18] However, the conceptual framework that has led to our understanding

of the lentivirus family came from later work with a lentivirus of sheep.

There are two fundamental differences between lentiviruses and most other retroviruses: Lentiviruses do not cause cancer and they establish chronic infections that result in a long incubation period followed by a chronic symptomatic disease. The "slow" (lenti is Latin for slow), chronic nature of these viral infections was first appreciated for a disease of sheep called maedi-visna (maedi = labored breathing, visna = paralysis and wasting). The recognition of this disease in Icelandic sheep flocks was likely the result of their previous prolonged isolation and the subsequent introduction of visna virus with the importation of European sheep.[19] Other animal lentiviruses were identified in goats (caprine arthritis and encephalitis virus, CAEV) and cows (bovine immunodeficiency virus, BIV) prior to the appearance of HIV-1, with feline immunodeficiency virus (FIV) identified later.

DISCOVERY OF HIV-1 AND OTHER PRIMATE LENTIVIRUSES

An infectious agent that would come to be recognized as HIV-1 was first suspected based on the appearance of opportunistic infections due to an acquired immunodeficiency syndrome (AIDS) among otherwise healthy, sexually active gay men in the United States in 1981.[20–22] A virus was isolated from one such case,[8] and a serological test based on this isolate and further isolations showed linkage between the presence of this virus and AIDS.[23–26] With the availability of a serological test it became clear that HIV-1 was spreading around the world and that the high infection rates in central Africa made this area the likely source of the virus. A second, related virus, HIV-2, was also identified among AIDS patients in western Africa.[9] Finally, it also became clear that there was a long clinical latency between infection and disease during which virus spread among the population was inapparent, a major public health challenge that persists.

At the time HIV-1 was discovered it seemed as if it had come out of nowhere. However, in 25 years since its discovery, we have learned of a complex history between this virus and the human host. Three observations initially suggested a longer history of this virus with humans. First, a clinical sample obtained in 1959 from a man with an AIDS-like illness and who had been in central Africa was shown to contain HIV-1 sequences.[27] This indicated that the virus had been in the human population prior to its inferred existence in 1981. Second, the level of genetic diversity of HIV-1 in central Africa was more consistent with established infections in isolated populations,[28–30] not an introduction of the virus into the population around 1980. Finally, the detection of related viruses among diverse primate species indicated that viruses like HIV-1 had been in the larger biological environment for a long time, as discussed below.

The larger history of primate lentiviruses (SIV) can be seen in the phylogenetic relationships shown in Fig. 20-1B. These viruses have not been detected in new world monkeys, suggesting that they entered the old world monkey population some time after the split of the continents ~40 million years ago. However, they are widely dispersed among old world monkeys, present in over half of the 70 primate species present in sub-Saharan Africa.[31] For some species it appears that the virus has been stably associated and coevolving with the host for an extended period of time, while other species may have been infected by a cross-species transmission event more recently. Finally, some of the viral genomes appear to be recombinants between different SIVs suggesting past dual infections.[32]

The relationship of the two human viruses, HIV-1 and HIV-2, is apparent from these phylogenetic relationships. HIV-2 is closely related to the SIV from sooty mangabeys,[33] and the interspersion of multiple HIV-2 isolates among different SIVsm isolates is most easily explained by multiple introductions of HIV-2 into humans from sooty mangabeys.[34] The geographical concentration of HIV-2 infections in western Africa overlaps the range of sooty mangabeys.

The relationship between HIV-1 and SIV has been more complex to unravel. A likely linkage to the SIV of chimpanzees was inferred from SIVcpz sequences, although the interpretation was complicated by surprising diversity among the SIVcpz sequences and the low prevalence of seropositive animals.[35,36] It is now clear that HIV-1 is derived specifically from SIVcpz of the chimpanzee subspecies *P. t. troglodytes*.[37] In a way that is analogous with HIV-2 and SIVsm, different isolates of SIVcpz from *P. t. troglodytes* are phylogenetically interspersed with HIV-1 group M, N, and O isolates, and this is most easily explained as three distinct introductions of HIV-1 into the human population. Chimpanzees appear to be recently infected as not all subspecies carry SIVcpz, a split in the chimpanzee population that occurred about 1.5 million years ago. Furthermore, SIVcpz itself appears to be a recombinant of several other SIV lineages.[32]

Although there have been three recognized transmissions of SIVcpz into the human population, giving rise to the M, N, and O groups of HIV-1, it is the M or "main" group of HIV-1 that has given rise to the global epidemic. Extant isolates of HIV-1 carry a phylogenetic fingerprint of what was likely an early isolation of distinct epidemics of the M group virus within central Africa. These lineages are called clades or subtypes and they continue to tell the story of the spread of HIV-1 among populations: subtype B in the United States and western Europe, subtype C in southern Africa and spread to India and then China, etc. It is not clear if the subtypes have any biological meaning as recombinants between subtypes are increasingly found, especially

in areas where two subtypes are cocirculating. Using the current sequence diversity in the HIV-1 population, the 1959 sequence, and estimates of the rate of sequence change per year, it has been possible to suggest that the cross-species transmission event that gave rise to the M group of HIV-1 occurred early in the twentieth century.[38] If we accept that SIVcpz has entered the human population three times in the last century (the three groups N, O, and M), then it follows that this virus likely has been transmitted to humans any number of times over the last 10,000 years. Only in the last century the human institutions of large cities and efficient transportation corridors have given these transmission events access to a human environment that could support an epidemic.

RETROVIRUS STRUCTURE AND GENOME ORGANIZATION

MORPHOLOGY OF THE RETROVIRUS PARTICLE

Retroviruses are enveloped viruses with two identical copies of viral genomic RNA condensed in a nucleocapsid core (Fig. 20-2). The viral envelope is derived from a cellular membrane of the host cell during virus budding. Inserted in the envelope are the Env glycoprotein spikes encoded by the viral *env* gene. The Env proteins are associated as trimeric complexes of gp120-gp41 heterodimers. Underlying the envelope is the viral matrix protein (MA), which is derived from the Gag (group-specific antigen) polyprotein precursor, the product of the *gag* gene. The nucleocapsid core consists of two other proteins derived from the Gag precursor, the capsid protein (CA) and the nucleocapsid protein (NC). The NC protein binds viral RNA in the core, which is surrounded by CA. The core can have a variety of forms depending on the retrovirus, ranging from essentially spherical to cylindrical. In the case of HIV-1 and other lentiviruses, the core is cone-shaped. The viral enzymes protease, encoded by the *pro* gene, as well as reverse transcriptase (RT) and integrase (IN), both encoded by the *pol* gene, are also associated with a retrovirus particle. In the case of HIV-1, the accessory protein Vpr and small amounts of two other accessory proteins, Vif and Nef, are also incorporated into virions.

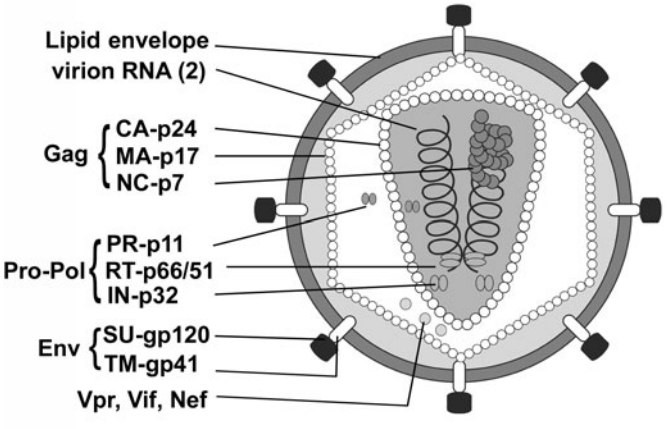

FIGURE 20-2. Virion structure. This diagram shows a model of the major components of the HIV-1 particle. Viral proteins are identified by size (e.g., p24 is a 24-kDa protein), by a two-letter identifier (e.g., CA for capsid), and as part of the gene product from which they are derived (e.g., CA from the Gag precursor).

RETROVIRUS GENOME ORGANIZATION

The viral genome as found in virus particles consists of two identical single-stranded RNA molecules noncovalently associated in a dimer structure. Each RNA molecule has features of a eukaryotic mRNA in that it has a 5′ cap, a 3′ poly-A tail, and is of the coding or positive sense. The length of the monomeric RNA for retroviruses ranges from approximately 7000 nucleotides for simple retroviruses to 10,000 nucleotides for complex retroviruses like HIV-1.

All retrovirus genomes encode four primary replicative genes: *gag, pro, pol,* and *env* (Fig. 20-3). The *gag* gene encodes the structural proteins of the capsid, *pro* encodes the viral protease responsible for cleaving precursor proteins, *pol* encodes RT and IN, and *env* encodes the Env glycoprotein. These genes always appear in this order in the retroviral genome starting near the 5′ end. More complex retroviruses, like lentiviruses, encode genes in addition to the four primary replicative genes, referred to as accessory genes. Contrary to their name, lentivirus accessory genes serve several indispensable functions in the viral replication cycle. The HIV-1 genome encodes six accessory genes, all within its 3′ half: *vif, vpr, vpu, tat, rev,* and *nef.*

Cis-acting replication sequences are those that function as part of the genome either to identify it as the viral genome or to participate directly in its expression or replication. The retrovirus genome exists in an RNA and a DNA state at different times during the virus life cycle, and as a result several *cis*-acting sequences are present in the genome that function within the context of either RNA or DNA (Fig. 20-3). A cis-acting sequence near the 5′ end of the viral RNA, termed the dimerization initiation signal (DIS), plays an important role in the dimerization of the RNA genome. The DIS is a stem-loop RNA structure that contains a 6-nucleotide palindromic sequence at the crown of the loop, such that the DIS loops of two monomeric RNAs can form Watson-Crick base pairs to initiate their dimerization (known as the "kissing loop" model). It is believed that this complex subsequently forms a more stable dimer, or "extended complex," by expanding the base pairing between sequences that represent the DIS stem structures, a process that is facilitated by the NC protein.[39,40] Also at the 5′ end, a packaging signal (ψ) tags the viral genomic RNA for encapsidation into the virus particle. The RNA has short direct repeats (R) at the 5′ end and at the

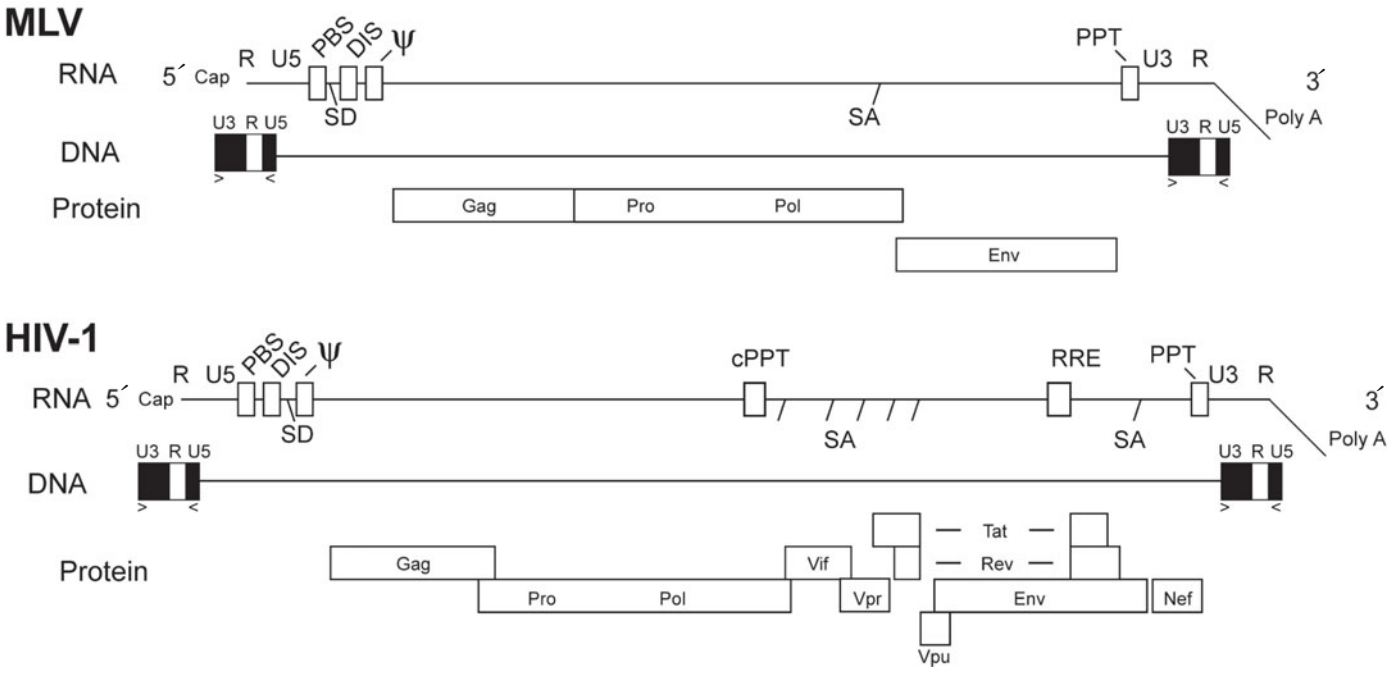

FIGURE 20-3. Retrovirus genome organization. The structure of viral genomic RNA, linear viral DNA, and the encoded protein reading frames are shown for both MLV (a simple retrovirus) and HIV-1 (a complex retrovirus). The RNAs are capped at the 5′ end and have a poly-A tail at the 3′ end. *Cis*-acting elements in the viral RNA and DNA include: the PBS, major splice donor (SD), splice acceptor (SA), dimerization initiation signal (DIS), the RNA packaging sequence (ψ), polypurine tract (PPT), long terminal repeats (LTRs), short inverted repeats ('>' and '<'), and for HIV-1 the Rev response element (RRE). For MLV, *gag* and *pro-pol* are in the same reading frame and their encoded proteins are joined at a low frequency by readthrough suppression during protein synthesis in which the termination codon is read as a coding triplet and translation proceeds from *gag* into *pro-pol*, forming the Gag-Pro-Pol precursor. For HIV-1, Gag and Pro-Pol are expressed from different reading frames and are joined at a low frequency by translational frame-shifting.

3′ end just inside the poly-A tail, which function during viral DNA synthesis.

Located near the 5′ and 3′ ends are positions for primers of the first and second strand of viral DNA synthesis. Near the 5′ end is the primer-binding site (PBS), a sequence that is complementary to the 3′-terminal 20 nucleotides of a cellular tRNA. A tRNA bound to the PBS primes the first, or minus, strand of viral DNA synthesis. A stretch of purines near the 3′ end, called the poly-purine tract (PPT), serves as a primer for the plus strand of viral DNA synthesis. An additional PPT present in the middle of the lentivirus genome allows the second strand of DNA to be synthesized in two segments, presumably to increase the rate of synthesis. The RNA also encodes signals for splicing and polyadenylation, functions that are carried out by the host machinery. Finally, two additional regions of HIV-1 RNA interact with two viral gene products: the TAR region interacts with Tat to upregulate the synthesis of full-length viral RNA during transcription, and the Rev response element (RRE) interacts with Rev to enhance nuclear export of singly spliced and unspliced viral RNAs.

A different set of *cis*-acting sequences functions at the DNA level. During viral DNA synthesis, the U5 and U3 sequences of the viral RNA are duplicated to make a DNA product that is longer than its RNA template. This generates direct repeats at both ends of the DNA that were not present in the RNA, known as the long terminal repeats (LTRs). Within the LTRs are sequences that function as promoters and enhancers for the expression of viral RNA, but these sequences are selectively active only in the 5′ LTR. Also, the LTRs are themselves flanked by short inverted repeats that function at the ends of the DNA during the integration reaction.

RETROVIRUS LIFE CYCLE

Some of the basic biological properties of retroviruses were characterized prior to the identification of HIV-1 in the 1980s, including the size and components of a retrovirus particle, its genome organization, the reverse transcription process that converts viral RNA to DNA, and even the realization that certain aspects of the retrovirus life cycle are inhibited by heritable host factors. However, the identification of HIV-1 as the infectious cause of AIDS and the subsequent recognition of its enormous impact throughout the world has resulted in a large amount of research focused particularly on HIV-1. Although most of the precise molecular details about the life cycle that are described below are specific for HIV-1, the general replication steps and their order of succession are applicable to all retroviruses: attachment, entry, reverse transcription, nuclear import and integration of viral DNA, transcription of proviral DNA, RNA nuclear export and processing, expression of viral proteins, assembly, budding, release, proteolytic processing, and virion maturation.[41]

ATTACHMENT AND ENTRY

The process of infection initiates when a retrovirus binds to its receptor molecule on the surface of a target host cell, a process mediated by the Env protein spikes. Each spike on an HIV particle consists of a complex of three Env gp120-gp41 heterodimers. The receptor for HIV-1, HIV-2, and SIV is the CD4 molecule,[42] a surface protein that marks the T-helper subset of T lymphocytes, and is also expressed on macrophages and certain other cells of the monocyte lineage. Binding to CD4 is not sufficient for infection, as entry requires Env attachment to a second molecule, or coreceptor, which for HIV-1 is usually either CCR5 or CXCR4.[43] In general, viruses able to utilize CCR5 (R5-tropic HIV-1) can infect both macrophages and $CD4^+$ T cells, while viruses that can only utilize CXCR4 (X4-tropic HIV-1) usually only infect $CD4^+$ T cells. Coreceptor use by HIV-1 is often associated with disease stage, as R5-tropic HIV-1 is most often transmitted and predominates throughout infection, while X4-tropic HIV-1 can emerge later in infection and is associated with more rapid disease progression.

Attachment, fusion, and entry of HIV-1 and other lentiviruses is a complex, multistep process that requires multiple conformational changes in the viral Env protein before the viral core can enter the cytoplasm of the target cell (Fig. 20-4).[44,45] The gp120 subunit of Env in the virus spike first binds to CD4 on the target cell. Once bound, a conformational change occurs in gp120, exposing a binding site for subsequent attachment to a coreceptor. After binding to the coreceptor, a second conformational change occurs in the Env complex, this time in gp41 that exposes an amino terminal fusion peptide that inserts into the plasma membrane of the target cell. At this point the Env complex is in a "prehairpin intermediate" form, resulting in the exposure of an N-terminal heptad repeat domain of gp41 (HR1). Next, gp41 folds to bring together HR1 with a C-terminal heptad repeat (HR2), resulting in the formation of three sets of antiparallel HR1-HR2 helical complexes in the trimeric Env complex, termed the "six-helix bundle." The formation of the six-helix bundle brings the virus in close proximity with the target cell, driving fusion of the viral envelope with the plasma membrane. Finally, the viral core is released through a fusion pore and into the cytoplasm of the target cell. The first clinically available HIV-1 entry inhibitor, T20, is a peptide mimetic of HR2 and, therefore, binds to HR1 in the prehairpin intermediate, blocking the association of HR1 and HR2 that is required for fusion to progress.[45]

In some instances HIV-1 can utilize other mechanisms for attachment to target cells. In rare cases, especially in vivo, HIV-1 may infect cells in a CD4-independent manner or may utilize alternative coreceptors.[43] The HIV-1 gp120 subunit of Env can also attach to dendritic cells (DCs). Although DCs themselves are probably not infected, the attachment of HIV-1 to DCs can augment infection of target cells. The HIV-bound DCs can efficiently pass the virus directly to target $CD4^+$ T cells, known as trans-infection.[46,47] Alternatively, HIV-1 virions can be internalized into DCs, trafficked through cellular endosomes, and released via the exosome pathway at sites of contact with susceptible target cells. Some studies have suggested that viral interactions with DCs may play an important role in HIV-1 transmission, especially at mucosal sites of infection.[48,49]

Multiple host genetic factors that likely affect viral attachment in vivo have been shown to influence one's susceptibility to HIV-1 infection. Individuals that are homozygous for a deletion in their CCR5 gene, known as the CCR5-Δ32 allele, are highly resistant to infection by CCR5-tropic HIV-1, while having few recognizable adverse effects due to the lack of functional CCR5 expression on cellular surfaces.[50] It was also recently demonstrated in a large population-based study that humans have a wide copy number range of the CCL3L1 gene, which encodes a ligand for CCR5 that acts as a potent inhibitor of

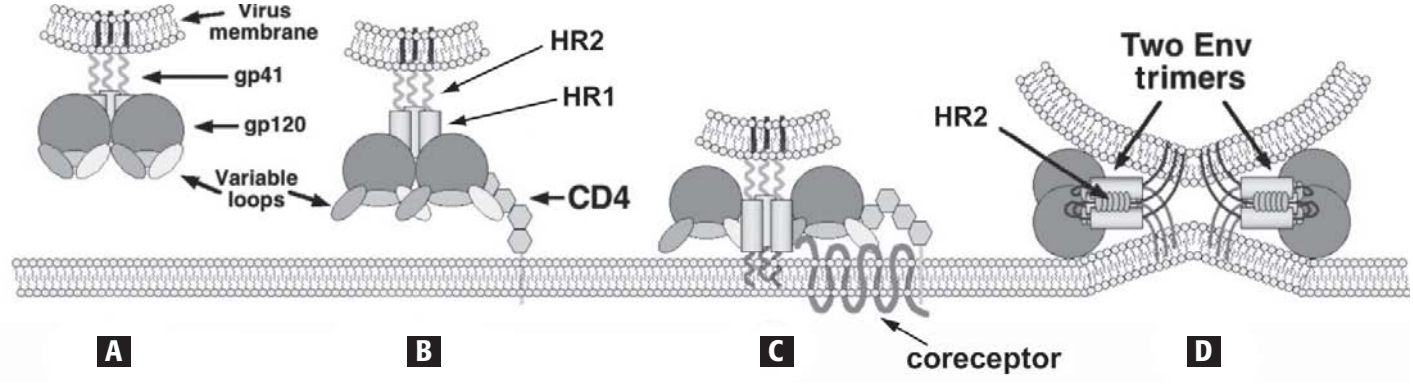

FIGURE 20-4. Steps of HIV-1 attachment and entry. **A.** Attachment and entry of HIV-1 is a multistep process mediated by the Env protein, which is present in the virion as a trimeric complex of gp120-gp41 heterodimers. **B.** Attachment to target cells is initiated by the binding of one gp120 subunit of Env to CD4. **C.** Following a conformational change in gp120, the virus attaches to a coreceptor (either CCR5 or CXCR4), and gp41 undergoes structural changes to insert a hydrophobic fusion peptide into the target cell plasma membrane. **D.** The association of the HR1 and HR2 helices of gp41 into a six-helix bundle structure brings the viral and cellular membranes in close proximity. Contact between the viral and cellular membranes results in membrane fusion and the formation of a fusion pore through which the viral core passes into the target cell cytoplasm. (Figure modified from a version kindly provided by Robert W. Doms, University of Pennsylvania, and John P. Moore, Weill Medical College of Cornell University, with permission.[45])

HIV-1 infection in vitro, the MIP-1α chemokine.[51] A higher copy number the CCL3L1 gene results in greater expression levels of the CCR5-interacting chemokine, which can reduce one's susceptibility to HIV-1 infection presumably by the competitive inhibition of HIV-1 attachment to CCR5. These and other observations suggest that drugs targeting the coreceptor binding step may be effective in treating HIV-1 infection. In fact, multiple steps of the HIV-1 attachment and entry processes are targets for several novel antiretroviral therapies that are currently in clinical development.[44,52]

VIRAL DNA SYNTHESIS

The synthesis of viral DNA follows an elegant and complex pathway.[53] There are two aspects of this process that make it especially distinctive. First, during the course of DNA synthesis three breaks in the template must be negotiated. The second distinctive feature of DNA synthesis is that the DNA product is longer than the RNA template.[54,55] RT that was packaged during virion formation mediates the synthesis of viral DNA in the cytoplasm of a newly infected cell. The template for DNA synthesis is the single-stranded viral RNA genome. The essential elements of viral DNA synthesis are (1) RT, (2) its associated RNase H activity that degrades the RNA template after it is converted into an RNA-DNA hybrid, (3) a cell-derived tRNA annealed to the PBS at the 5′ end of the viral RNA, which serves as the primer for the minus strand of DNA synthesis, and (4) one or more PPTs in the RNA template that are left by RNase H to prime synthesis of the plus strand of DNA.

Viral DNA synthesis initiates from the tRNA primer annealed to the PBS near the 5′ end of the viral RNA. The growing minus strand DNA chain quickly reaches the 5′ end of the template (first template break in DNA synthesis), generating a DNA complement to the U5 and short direct repeat (R) RNA sequences. The 5′ end of the RNA template is then degraded by the RT-associated RNase H activity. Reverse transcription continues when the newly synthesized DNA subsequently base pairs with the R sequence at the 3′ end of the viral RNA, priming minus strand DNA synthesis to continue along the length of the remaining template until it terminates at the PBS at the 5′ end of the RNA (second break). During minus strand DNA synthesis the RNase H activity of RT continues to digest the RNA template that has been reverse transcribed, but the RNA is incompletely digested, leaving one or more PPT RNAs of approximately 11 bases annealed to the newly synthesized minus strand DNA. The PPT RNA(s) primes plus strand DNA synthesis, which continues copying the minus strand DNA until the RT complex reaches a modified base in the tRNA primer, which is still attached to the 5′ end of the minus strand DNA template. Plus strand DNA synthesis stops at this point because RT cannot copy the modified base (third break). The RNase activity of RT then removes the tRNA primer, leaving a plus strand DNA overhang sequence at the 3′ end. At this point the 3′ end of the plus strand DNA represents the PBS sequence, while the 3′ end of the minus strand DNA is its complement, allowing the sequences at the 3′ end of each DNA strand to base pair to generate a circularized molecule. DNA synthesis continues as each strand uses the other as a template and concludes with a strand displacement event to decircularize the molecule, creating a complete, linear, double-stranded DNA product. A more detailed description of this process is reviewed elsewhere.[41]

Although there are no new sequences in the newly synthesized DNA, some of the sequences in the RNA are duplicated and rearranged during DNA synthesis so that the DNA product is longer and has several features that were not present in the RNA template. Where the RNA template had a short terminal repeat R, the newly synthesized DNA has an LTR. The LTR sequences flanking the linear DNA are generated by synthesis through the template breaks, bringing together U3, R, and U5 sequences (Fig. 20-3). This complex process of viral DNA synthesis is necessary for the critical translocation of transcription and integration signals in the viral DNA and also ensures the authentic viral RNA genome is reproduced during transcription.

NUCLEAR IMPORT AND INTEGRATION OF VIRAL DNA

Prior to integration into the host genome, newly synthesized lentiviral DNA remains associated with multiple cellular and viral proteins, collectively termed the preintegration complex (PIC). Unlike other retroviruses, lentiviruses do not require cells to undergo mitosis and breakdown their nuclear envelope for the viral DNA to access the host genome for integration. Instead, the PIC can be actively transported into the nucleus, a process that involves multiple host and viral factors.[56] This property of lentiviruses enables them to infect nondividing cells, such as macrophages, and, therefore, plays a key role in pathogenic processes of lentivirus infection. The role of monocytes and macrophages in lentivirus infection in vivo is discussed later in this chapter.

The integration of viral DNA is mediated by the viral IN protein, which like RT is also brought into the cell as part of the infecting nucleoprotein complex. At least one host factor, lens epithelium-derived growth factor (LEDGF/p75),[57] is required for efficient integration of viral DNA into the host cell DNA. The integration reaction actually starts in the cytoplasm as each 3′ end of the linear, double-stranded viral DNA is shortened by the removal of the two terminal nucleotides that are adjacent to a conserved CA dinucleotide.[58] A short inverted repeat that is a feature of the LTR boundaries plays an important role in the efficiency and specificity of IN-mediated processing of the viral DNA 3′ ends. The CA-3′-hydroxyl DNA ends serve as the intermediate for the second step of integration mediated by IN, known as strand transfer, which occurs once the PIC is imported into the nucleus.[59] Here, IN makes a

cleavage in the host DNA that is staggered by five nucleotides and joins the 3′ ends of the shortened strands of linear viral DNA to the cleaved host DNA. At this intermediate stage, the 5′-phosphate ends of viral DNA are not yet linked to the host DNA. Finally, cellular repair enzymes fill in the five-base, single-stranded gap at each integration junction, generating a short direct repeat of the host DNA flanking the integrated viral DNA, and also trim the two-base flap at each of the 5′ ends of the viral DNA to complete the integration reaction. In the integrated state, the viral DNA is referred to as the provirus or proviral DNA. The IN enzyme is unique to retroviruses and required for their replication, and, therefore, represents a promising therapeutic target. Consequently, HIV-1 IN-inhibitors are currently in clinical development.[59]

TRANSCRIPTION OF INTEGRATED DNA AND PROCESSING OF VIRAL RNA

Integrated DNA is transcribed into RNA by the host RNA polymerase II, and the RNA transcript has the features of a cellular mRNA, including a 5′ cap and a 3′ poly-A tail. Transcription starts within the 5′ LTR and ends just downstream of the corresponding position in the 3′ LTR, creating the "R" repeat in the RNA. Viral DNA sequences upstream of the RNA start site, referred to as the U3 region, function both as promoter and enhancer for transcription, utilizing primarily host machinery for these functions. Many retroviruses also encode *trans*-acting transcription activators that enhance viral RNA synthesis. In the case of HIV-1, short, prematurely terminated RNAs are often generated in the absence of any supplementary host or viral transcription factors. To enhance transcription of HIV-1 DNA, newly synthesized Tat protein interacts with a host protein, termed cyclin T, to bind the trans-activation response element (TAR) RNA stem-loop, which forms near the 5′ end of newly synthesized viral RNA. The Tat-TAR-cyclin T complex recruits a cyclin-dependent kinase, CDK9, that hyperphosphorylates the C-terminus of RNA Pol II, resulting in enhanced transcription elongation and increased synthesis of full-length viral RNA.[60,61]

Newly synthesized HIV-1 RNA has one of four fates, all of which are essential for completing the viral replication cycle. (1) It can be multiply spliced, which removes several introns to generate small transcripts that encode *tat, rev,* or *nef*. (2) It can be singly spliced, which removes a single intron spanning *gag, pro* and *pol* to express *env* and *vpu, vpr,* or *vif*. (3) It can remain unspliced and used as mRNA for *gag, pro,* and *pol*. (4) Finally, it can remain unspliced and serve as genomic RNA in the assembly of new virions. In general, cellular pre-mRNAs remain in the nucleus until splicing is complete, which poses a problem for export of singly spliced and unspliced viral RNAs since they retain *cis*-acting splicing signals. To overcome this nuclear export problem, the singly spliced and unspliced RNAs of HIV-1 and other lentiviruses interact with the Rev accessory protein.[62–64] After being translated in the cytoplasm from a multiply spliced viral RNA, Rev is imported back into the nucleus with the assistance of cellular nuclear import machinery. Once in the nucleus, Rev binds to a region of secondary structure in the viral RNA called the RRE, which is located within the *env* gene and in the *tat/rev* intron. The Rev-RNA complex interacts with a nucleocytoplasmic transport factor, Crm1, to exit the nucleus using a pathway that is normally not used by cellular mRNAs.[65,66] Finally, uncoupling of Rev-RNA complexes occurs in the cytoplasm prior to translation or packaging of the viral RNA.

SYNTHESIS OF VIRAL PROTEINS

Most of the viral proteins are synthesized in the cytoplasm of the host cell. The exceptions are the integral membrane proteins Env and Vpu, which are synthesized by endoplasmic reticulum (ER)-bound ribosomes and transported into the lumen of the ER. Most of the RNAs encode a single protein. Viral mRNAs for *vif, vpr, tat, rev,* and *nef* are expressed from separate spliced RNAs. However, HIV-1 uses two different strategies to translate two different multicistronic mRNAs. First, the full-length RNA transcript is translated using the 5′ most open reading frame to synthesize the Gag protein. Approximately 5% of the time a frame-shifting event occurs near the 3′ end of the *gag* reading frame that leaves the translation machinery in the –1 reading frame, which encodes the *pro* and *pol* genes. Translation continues, generating a Gag-Pro-Pol fusion protein that is present at 5% the concentration of the Gag precursor. In contrast, a small open reading frame for *Vpu* is present upstream of the *env* reading frame. Both the vpu and Env proteins are synthesized from a single bicistronic mRNA.[67]

ASSEMBLY AND BUDDING

The Gag p55 precursor plays a primary role in the assembly process and can even assemble and bud from infected cells in the absence of any other viral proteins.[68,69] During the virus life cycle, Gag is involved in (1) recruiting viral proteins essential for the next round of infection to sites of assembly, (2) binding to cellular factors involved in the budding process, and (3) binding and encapsidation of the viral genomic RNA. Distinct functional domains in Gag drive the assembly and release processes. The N-terminal MA domain of Gag is myristylated, which targets the protein to cellular membranes, and also contains several basic residues that interact with negatively charged lipid head groups to further stabilize Gag-membrane associations. The preferential targeting of Gag to lipid raft microdomains enhances the association of assembly complexes with the plasma membrane.[70] The CA domain is involved in multimeric Gag-Gag interactions during particle assembly. The NC domain binds and packages the viral RNA and also promotes Gag-Gag interactions. The late (L)

domains, which are near the C terminus of HIV-1 Gag, interact with cellular proteins during budding and release.

The Gag and Gag-Pro-Pol precursors multimerize at sites of assembly, incorporate other viral and cellular proteins, and encapsidate the viral RNA genome to complete the assembly process. Like other membrane glycoproteins, newly synthesized retroviral Env proteins use the cellular secretory machinery to traffic to cellular membranes. The Env precursor, gp160, is translocated into the ER as a transmembrane protein during its synthesis where it is glycosylated and forms a homotrimer. The Env protein is then transported into the Golgi where it is cleaved by a cellular furin-like protease to generate the gp120 and gp41 mature products that stay noncovalently associated. The mature Env proteins, now in a trimeric complex of gp120-gp41 heterodimers, are then transported to the cell surface membrane. A specific interaction between the cytoplasmic tail of gp41 and the MA domain of Gag brings oligomeric gp41/gp120 complexes into the virus particle as it buds through a cellular membrane. During the assembly process the viral accessory protein Vpr is packaged into virions through an interaction with Gag,[71,72] as are small amounts of Vif and Nef.

Recent advances in cell biology and virology have revealed that retroviruses, and probably many other enveloped viruses, utilize the protein sorting machinery of their host cells to bud at sites of viral assembly. This general mechanism of retrovirus budding first became evident when it was observed that an interaction between the C-terminal p6 region of Gag and a key component of the cellular endosomal sorting complex, Tsg101, is essential for HIV-1 release.[73,74] The L domains of retrovirus Gag p6 proteins associate with cellular proteins involved in the formation of vesicles that bud into multivesicular bodies (MVBs), which are late endosomal compartments that normally sort and transport cellular proteins to the lysosome. Ubiquitin tags direct many cellular proteins to the MVB machinery, and the Gag proteins of multiple retroviruses, including HIV-1, are also ubiquitylated, although the precise role of ubiquitin transfer in retrovirus budding remains to be determined. Remarkably, it appears that retroviruses have preferentially exploited the cellular MVB machinery to assist in the budding process due to the unusual ability of MVB vesicles to bud away from the cytoplasm, much like an enveloped virus buds from an infected cell.[68]

Retroviruses redirect this host cell MVB machinery to sites of assembly at the plasma membrane to bud from infected cells (Fig. 20-5). Retroviruses can also bud intracellularly, presumably into MVBs, followed by release into the extracellular space via the cellular exosome pathway. This has been suggested to be a preferred exit strategy for HIV-1 in macrophages.[75,76] Similarly, HIV-1 virions that have been captured and internalized by (DCs) are subsequently released through exosomes.[77] Regardless of the site of budding, retroviruses are often released at sites of cell-to-cell contact, termed "virological synapses," which may have important implications for virus spread in vivo.[78,79] The ability to release at virological synapses may increase the chance that a newly produced virus reaches a target cell for its next round of infection, and may also protect viruses from immune recognition.

PROTEOLYTIC PROCESSING

An integral part of the assembly and maturation process is the proteolytic processing of the Gag and Gag-Pro-Pol precursors by the *pro*-encoded viral protease (PR). The protease is activated during the assembly process and mediates the cleavage of these precursors to their mature components (for HIV-1 Gag: MA, CA, NC, and p6; for Pro: PR; and for Pol: RT and IN). The enzymes gain full activity only after being released from the precursor, and with the processing of the Gag precursor the virion undergoes a dramatic morphological change from an open immature state to a condensed nucleocapsid core. The proteolytic processing of Gag is a required step for virion maturation and subsequent infectivity, and for this reason the viral protease is an important therapeutic target.

ROLE OF ACCESSORY PROTEINS

Some retrovirus genomes encode only Gag, Pro, Pol, and Env and their entire replication scheme can be understood with only the function of these proteins. However, primate lentiviruses encode additional gene products, termed accessory proteins, which perform a number of functions that are essential in the virus life cycle. The HIV-1 genome encodes six accessory proteins: Tat, Rev, Vpr, Vpu, Vif, and Nef. As described above in more detail, Tat functions primarily as a transactivator of transcription, and the primary role of Rev is to direct nuclear export of singly spliced and unspliced viral RNAs. The Vpr protein is packaged into virions and serves multiple functions, including participating in nuclear translocation of the PIC, enhancing Tat-induced transcription, and facilitating virus production by arresting infected cells in G2 of the cell cycle.[80,81] The Vpu protein assists Env translocation to cellular membranes by degrading intracellular CD4 and may enhance virus particle release by disrupting an uncharacterized host cell restriction.[82–85] Vif is packaged into virions and has been known for many years to play an important role in the reverse transcription process during the next round of replication, with its activity being dependent on the virus-producing cell. It was recently revealed that Vif functions to ensure the fidelity of HIV-1 replication by blocking a robust intracellular antiviral defense (described in detail below).[86]

The Nef protein is produced by all primate lentiviruses and has several known and postulated functions.[87,88] The most extensively characterized activity of Nef is its ability to downmodulate CD4 from the cell surface and target it for

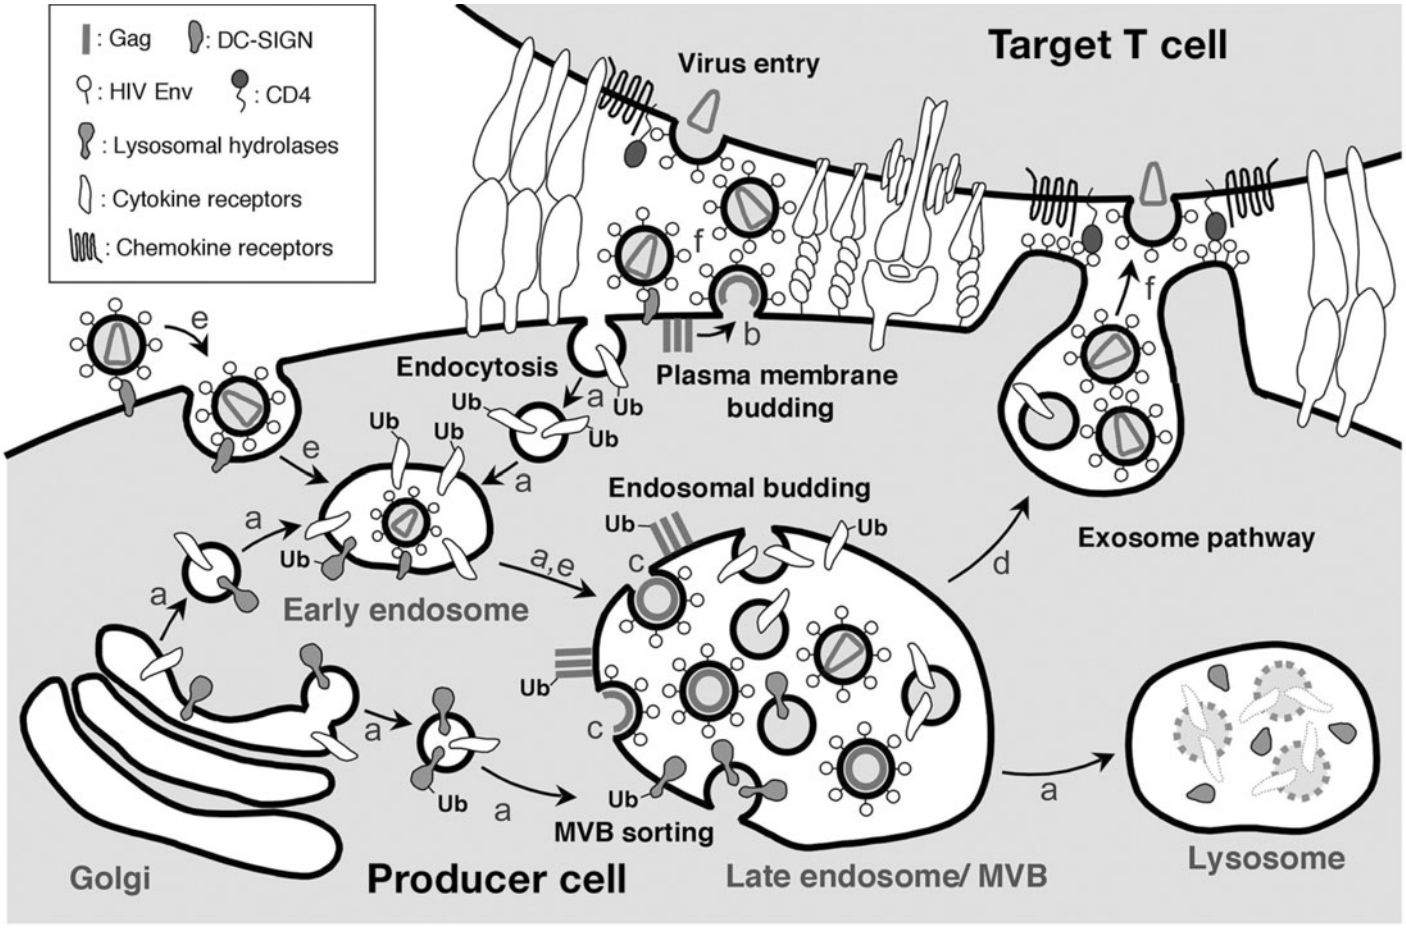

FIGURE 20-5. Mechanisms of HIV-1 Release. This model illustrates, (a) the normal cellular trafficking of molecules from the Golgi and plasma membrane to the lysosome; (b) HIV-1 budding at the plasma membrane; (c) HIV-1 budding at the multivesicular body; (d) release of cellular molecules and HIV-1 via the exosome pathway; (e) Internalization and endosomal trafficking of infectious HIV-1 particles in dendritic cells; and (f) release of HIV-1 at sites of close contact with target T cells. Figure modified from a version kindly provided by Eiji Morita and Wesley Sundquist, University of Utah.[68] (Reprinted with permission from the Annual Review of Cell and Developmental Biology, Volume 20 ©2004 by Annual Reviews www.annualreviews.org.)

lysosomal degradation.[89,90] By reducing levels of cell surface CD4, the processes of assembly, budding, and release are less inhibited by the localized presence of receptor molecules on the virus-producing cell. In addition, Nef disrupts the immune response to virus-infected cells by modulating cell surface expression of major histocompatibility class I and II (MHC I/II), T-cell receptor, and other immune effector molecules,[91–95] and also interacts with host p21-activated kinases (PAKs) to enhance viral replication.[96,97] One or more of the functions of Nef greatly enhance the infectivity and pathogenesis of SIV and HIV infections in vivo, as evidenced by a much slower disease course in macaques and humans infected with *nef*-defective viruses.[98–101]

■ INTRACELLULAR RESTRICTIONS ON RETROVIRUS REPLICATION

Based on studies of MLV infection of mice, it has been apparent for decades that certain heritable host traits can govern susceptibility to retrovirus infection.[102–104] However, several recent studies of virus-host interactions have dramatically enhanced our understanding of some of the mechanisms of innate intracellular restriction on virus replication, and it also appears that retroviruses have evolved efficient mechanisms to evade such restrictions. A major class of intracellular antiviral defenses was first uncovered by the observation that the HIV-1 accessory protein Vif interacts with a host protein termed APOBEC3G (apolipoprotein B mRNA-editing enzyme, catalytic polypeptide-like 3G).[105] The APOBEC3 host-cell proteins are cytidine deaminases, which mutate single-stranded DNA by converting cytosine residues to uracil. Cellular APOBEC3G (or APOBEC3F[106]) packaged into virions during the assembly process targets viral minus strand DNA that is synthesized during reverse transcription in the next round of infection.[86] The cytidine deaminase activity of APOBEC3G/F can be detrimental to retrovirus replication in two ways: First, the presence of uracil residues in newly synthesized DNA tags it for degradation by a host enzyme termed uracil-DNA glycosylase (UDG). If any viral DNA survives UDG-mediated degradation, the conversion of

a C nucleotide to U in the DNA minus-strand will result in a G-to-A mutation when the positive-strand is synthesized. The presence of G-to-A hypermutation in the proviral DNA would likely alter coding sequences or even introduce premature stop codons throughout the genome, thus rendering any number of essential viral genes nonfunctional. To counter this antiviral defense, Vif prevents incorporation of APOBEC3G/F into virions by binding to the host protein and targeting it for degradation.[103] Subsequent studies have revealed that an active, low-molecular-weight form of APOBEC3G is present in resting $CD4^+$ T cells and targets incoming virions to restrict HIV-1 infection in a manner that is independent of cytidine deamination,[107] which may partly explain the relative resistance of these cells to HIV-1 infection.

A second major class of intracellular restriction that targets incoming lentivirus capsids has also recently been elucidated. Previously referred to as Ref1 and Lv1 (for "restriction factor 1" and "lentivirus susceptibility factor 1"), the TRIM5α (tripartite interaction motif 5 alpha variant) proteins of humans and nonhuman primates strongly inhibit retroviral infection in a somewhat species-specific manner.[108–112] For example, rhesus macaque TRIM5α potently restricts infection by HIV-1, but not SIV, whereas human TRIM5α normally has little effect on HIV-1 replication. Replacing the SIV capsid gene with that of HIV-1 in a chimeric SIV-HIV virus construct (SHIV) renders the virus susceptible to rhesus macaque TRIM5α, indicating that the HIV-1 capsid is the target for restriction. Interestingly, different human and nonhuman primate TRIM5α variants exhibit different potencies and ranges of retrovirus restriction. The mechanisms by which different TRIM5α proteins interact with incoming retroviral capsids, and how these interactions restrict retrovirus infection are active areas of research.

In the case of HIV-1, another host protein termed cyclophilin A (CypA) participates in viral restriction processes,[113] although its precise role is unclear. A specific site on the HIV-1 capsid binds CypA, and inhibition of capsid-CypA binding impairs HIV-1 replication during the next round of infection in human cells. Conversely, inhibition of capsid-CypA binding enhances HIV-1 replication in owl monkey cells, which are otherwise poorly infected by HIV-1. The observation that owl monkey cells express an unusual TRIM5α-CypA fusion protein has provided additional clues regarding the relationship of TRIM5α and CypA and their role in HIV-1 restriction.[112] Remarkably, of all retroviruses, only the HIV-1 capsid is known to bind CypA, and the owl monkey TRIM5α-CypA has been shown thus far to specifically restrict only HIV-1. Taken together, these findings suggest a preliminary, though not fully resolved,[114] model in which CypA bound to the HIV-1 capsid protects the virus from human TRIM5α-mediated restriction, while binding of the HIV-1 capsid to the CypA component of the TRIM5α-CypA fusion protein brings it in close association with the TRIM5α component, resulting in potent TRIM5α-mediated restriction in owl monkey cells.[103,104]

The study of innate intracellular restriction of retrovirus infection is still in an early stage, and the precise molecular interplay between the virus and host that results in either retrovirus restriction or escape has only begun to take shape. It is also likely that additional restriction factors exist and target various other stages of the viral replication cycle. As mechanisms of innate antiviral restriction are resolved, and aspects of retrovirus replication that are indispensable for countering such host defenses are revealed, research in this emerging field of retrovirus biology will almost certainly result in novel strategies to treat HIV-1 infection.

MECHANISMS OF VIRAL GENETIC DIVERSITY

VIRAL REPLICATION RATES

HIV-1 grows efficiently only in cells expressing CD4 and CCR5 (for R5 viruses) or CXCR4 (for X4 viruses). Robust replication occurs in cell culture in activated CD4 positive T cells. Resting T cells can also be infected but viral DNA synthesis is much less efficient and slower, requiring 2–3 days.[115–118] Reduced levels of nucleotide precursors[119] and an active form of APOBEC3G[107] restrict the efficiency of viral DNA synthesis in resting T cells. Viral replication is similarly slow in macrophages. While viral DNA is synthesized within a 4–6 hour period in activated T cells, this process takes 36–48 hours in differentiated macrophages.[120] Viral replication (HIV or SIV) in vivo can be detected in activated T cells but also in resting memory T cells.[121] Replication in these cells has been proposed as a major mechanism of pathogenesis leading to the early depletion of the large fraction of resting $CD4^+$ T cells found in the gut lamina propria and other lymphoid tissues.[122–124]

SOURCES OF POINT MUTATIONS

Viral DNA synthesis is usually characterized as an error-prone process. The appearance of sequence diversity in the viral genome is the result of several factors: an error prone DNA polymerase (RT), a large replicating population, many generations, and ultimately selective pressures that lead to the fixation of mutations. The most accurate measurements of the error rate during replication show that about one nucleotide substitution occurs per every three HIV-1 genomes synthesized.[125,126] Deletions and insertions can also occur but in general these will be deleterious and only occasionally give rise to a beneficial change.[127] RT does not have a proof-reading function for misincorporated nucleotides, so it is assumed that the viral enzyme is the source of the high error rate; the inability to remove misincorporated

nucleotides makes viral DNA especially sensitive to the chain terminating nucleoside analogs that are an important part of current therapies. It is unlikely that the host cell DNA replication machinery contributes to the error rate, but the contribution of RNA polymerase II during the synthesis of viral RNA is plausible.[128] Another source of sequence diversity is cytosine deamination of minus strand DNA associated with APOBEC3G.[105,129–131] Although the virus uses the Vif protein to block APOBEC3G activity, any leakiness will lead to G to A changes in the coding strand. When this happens as hypermutations it is likely always deleterious. However, the potential for low-level activity leading to additional sequence diversity has not been ruled out and may be contributing to the A-rich nature of the HIV-1 genome.

RECOMBINATION

Whereas the effects of point mutations are evident in HIV-1 sequence diversity and in the appearance of drug resistance mutations, a major factor in the utilization of sequence diversity in the virus population is recombination. The virus particle contains two copies of the RNA genome. During viral DNA synthesis, RT moves back and forth between the two templates to make a DNA product that is a mosaic of the two RNA strands. If the sequence of the two strands is identical then this process is inapparent. However, if the virus particle is produced from a cell that has two genetically different proviruses, the particles can contain one copy of each RNA (forming a heterodimer). The resulting DNA copy can link the sequence markers that differed between the two RNAs. HIV-1 recombination rates are very high, even among retroviruses, resulting in up to 10 strand switches per round of viral DNA synthesis.[132,133] However, a prerequisite for recombination to be biologically relevant is the need for dually infected cells that would allow genetically different viruses to be brought together for heterodimer formation. The detection of an average of 3–4 proviruses per cell in infected cells found in the spleen[134] reveals the potential of recombination in vivo to be a major determinant of HIV-1 sequence evolution. It has recently been argued that successful therapy is in part the result of the reduction in the number of dually infected cells, closing off this pathway of sequence evolution and making the virus a more static target for therapy and the immune system.[135]

EVOLUTION OF HIV-1 INFECTION

CORECEPTOR SWITCH

HIV-1 requires two cell surface proteins to enter the cell: CD4 and a chemokine receptor that serves as a viral coreceptor. Most variants of HIV-1 use CCR5 (the receptor for the chemokines MIP1α, MIP1β, and RANTES) as the coreceptor, and this is the specificity of most transmitted viruses (called R5 variants). However, in a subset of infected people, HIV-1 will evolve to use CXCR4 as the coreceptor as the CD4 cell count decreases (reviewed by Moore et al.[136]). The appearance of these X4 variants is associated with an immunodeficient state and a more rapid decrease in CD4 cell counts, although it is still not known which is cause and which is effect. R5 variants replicate predominately in memory T cells, while X4 variants, when they appear, are found in naïve T cells, perhaps suggesting some of the selective pressures at work in the evolution of X4 variants.[137,138] In one model of Env protein function the V3 loop interacts with the extracellular domains of the coreceptor.[139] In support of this model, the major changes in *env* sequence in X4 variants are in the V3 loop, typically involving the addition of basic amino acid residues at specific positions in V3.[140]

IMMUNE EVASION

There are three arms of the immune system and HIV presents examples of evasion of all three. APOBEC3G/F represent a novel feature of innate immunity with the ability to be packaged into virions and modify the newly synthesized viral DNA during the subsequent round of infection; the viral Vif protein blocks uptake into the virion thus protecting the next round of viral DNA synthesis (as described above). The evasion of innate immunity typically involves specific strategies, such as the evolution of a protein that can modulate or inactivate a cell-based protective activity. However, viral evasion from the two arms of host adaptive immunity requires a more dynamic strategy.

Cell-mediated immunity is based on the presentation of peptide epitopes by MHC class I molecules, with the specificity of the epitopes presented determined by the alleles at the MHC locus. Evasion of cell-mediated immunity occurs by two mechanisms. As noted above, the viral Nef protein is able to reduce the level of MHC class I molecules on the surface of the cell by directing the newly synthesized molecules to a lysosomal compartment.[91–93] This results in a reduced capacity of the cell to present viral peptide epitopes to cytolytic $CD8^+$ T cells (CTLs).[141] The second mechanism of immune evasion is through viral sequence evolution within the epitope. Sequence changes within CTL epitopes are clearly associated with the initial viral escape to establish the viral set point[142–144] and also with delayed immune escape.[145–147]

The virus particle displays copies of a single viral protein on the surface of the membrane envelope, the viral Env protein. Although the host makes antibodies to all of the viral proteins, only the Env protein on the surface of the particle is the target of virus-neutralizing antibodies. The Env protein is also a target of CTL selection, but being the target of neutralizing antibodies likely dominates the biology of this

protein. The *env* gene is the most variable gene in the viral genome. Much of the variability is concentrated in linear sequences that represent surface loops on the protein structure.[148] The variability in these loops likely represents decoy targets for antibody binding that can tolerate rapid sequence evolution. Another mechanism for avoidance of antibodies is the placement on nonimmunogenic carbohydrate side chains on much of the surface of the Env protein. The HIV-1 Env protein typically encodes signals for 25 carbohydrate addition sites capable of occluding much of the Env protein surface. Furthermore, small adjustments of the placement of the carbohydrate side chains can further impact the binding of neutralizing antibodies.[149] One of the features of the viral Env protein is that it undergoes at least a limited number of sequential rounds of evolution giving rise to neutralization escape variants.[150,151] An important question is how long the host can maintain this response during the course of infection, and whether immunogens can be designed to induce responses that have potent and broad neutralizing activity.

KINETICS OF VIRAL REPLICATION IN VIVO

Infection with HIV-1 typically involves a very small inoculum, as indicated by the low transmission rates. The presence of one or a few genotypic variants after transmission supports the notion that infection is started by a single virus particle or at most a small number of particles.[152–154] There is an initial period of logarithmic expansion of the virus with the virus doubling every 10–20 hours, and each infected cell results in the infection of approximately 20 new cells.[155] Peak viremia is reached in approximately 3 weeks, concurrent with a large depletion of memory $CD4^+$ T cells in mucosal tissues and peripheral lymphoid organs.[156] A decrease in the amount of virus in the blood is correlated with the appearance of a $CD8^+$ T cells response.[144,157,158] By 4–6 weeks the level of virus has reached a steady state, or set point, that is predictive of the rate of disease progression.[159] During this steady state the half-life of an infected $CD4^+$ T cell is only 1–2 days.[160–162]

ROLE OF MONOCYTES IN VIRAL PERSISTENCE

One of the paradoxical features of a long term HIV-1 infection is the inverse relationship between the levels of virus found in the blood and the number of target $CD4^+$ T cells. Not only is the amount of virus present in the blood plasma predictive of the rate of $CD4^+$ T cell loss,[159] but the level of virus in the blood increases with the decline of $CD4^+$ T cells. There are two models to account for the increase in virus as the target cells are decreasing. First, reduced immune surveillance could result in increased virus production per infected cell. Evidence in support of this explanation comes from studies in which SIV-infected macaques were given an anti-CD8 antibody, which transiently reduced the number of cytotoxic $CD8^+$ T cells. In these animals there was a transient increase in the amount of virus detected in the blood.[163,164] Second, tissue macrophages are known to be infected and may produce substantial amounts of virus even with the decline of $CD4^+$ T cells.[165,166] Macrophages are an attractive target cell to be the source of persistent viral infection as they have a longer half-life than a productively infected $CD4^+$ T cell, at least in vitro. *env* gene markers for viruses that are able to infect macrophages have been identified in the context of virus isolated from the CNS.[167,168] It will be important to identify the extent to which, and under what circumstances, viruses with these properties can be found in the peripheral blood as an indication of the source of the virus and as a function of disease progression.

VIRAL RESERVOIRS DURING HAART

Perhaps the most confounding aspect of HIV-1 infection has been the inability of an infected patient to clear the virus, even with the use of multidrug therapy. Regardless of the length of time on suppressive therapy virus invariably reappears with therapy discontinuation. There are two models to explain the persistence of virus on therapy.

In one model, viral replication persists at a low level despite the presence of active antiretroviral drugs. The stable persistence of low levels of detectable virus while on therapy supports the idea that residual virus replication is occurring.[169–171] However, the absence of sequence evolution in some patients on suppressive therapy and the inability to suppress viremia below a stable set point with intensified therapy argue against active replication, but leave unexplained the source of residual virus or the virus that rebounds when therapy is discontinued.[172–174] The alternative model is that although virus replication is halted by antiretroviral therapy, there is sufficient integrated viral DNA in resting $CD4^+$ T cells to be the source of virus to rekindle active replication when the drugs are removed. Virus can be cultured from such cells taken from people on suppressive therapy,[175–177] and the activation of these cells may well induce expression of a quiescent provirus to produce infectious virus. The viral DNA reservoir that persists during suppressive therapy includes not only DNA encoding infectious virus but also various forms of defective DNA that may not be useful for producing virus but is able to maintain the genetic complexity of much of the history of the infection in that host. More recently a novel model of HIV-1 persistence during therapy was proposed, where in infected stem cells of the monocyte-macrophage lineage undergo clonal expansion and produce low levels of virus, which may explain the detection of residual, clonal HIV-1 populations in some patients on antiretroviral therapy when such viruses cannot be detected in resting $CD4^+$ T cells.[178] It remains debatable whether a single reservoir is

responsible for HIV-1 persistence during suppressive antiretroviral therapy,[179–181] but it is widely assumed that it will be necessary to clear all possible HIV-1 reservoirs to permit the long-term cessation of treatment. Strategies are being explored,[182] although this remains a very challenging problem.

LESSONS FROM OTHER LENTIVIRUSES

The lentivirus genus is distinctive among the genera of retroviruses. The entire lineage of lentiviruses fails to induce tumors (except indirectly through immunodeficiency). Also, lentiviruses are characterized by a persistent infection that frequently involves neurologic involvement. A unifying hypothesis is that the ability of lentiviruses to establish a persistent infection is linked to their ability to infect macrophages. This is a common feature of a number of lentiviruses where it has been examined. The ability of these viruses to persist would then be linked to the long-lived nature of macrophages. Similarly, the ability of macrophages to migrate into the CNS, and/or the ability to infect microglia as cells of the monocyte/macrophage lineage, would account for the frequently observed neuropathogenesis. Finally, infection of other cell types that shares the receptors used to infect macrophages could account for differences in pathogenesis associated with different lentiviruses. Ultimately it is difficult to study macrophages in vivo given their dispersion in the body. However, the study of pathogenic mechanisms of other lentiviruses will continue to inform the study of HIV-1 and to define common features of this entire group of distinctive viruses.

21 Immunology and Pathogenesis of Human Immunodeficiency Virus Infection

Susan Moir, Tae-Wook Chun, and Anthony S. Fauci

INTRODUCTION

HIV/AIDS is best described as an infectious disease of the immune system. First described in 1981 by puzzling accounts of opportunistic infections and lymphadenopathy in otherwise healthy gay men, HIV/AIDS has evolved over the years to become one of the most devastating diseases to afflict humankind in history. The effect of HIV on the host is one of profound immunodeficiency in the setting of aberrant immune activation.[1] Whereas immune activation is desirable in most infections, helping the body rid itself of the pathogen, the relentless hyperactivity observed in HIV infection leads not only to an increase in the number of cell targets available to the virus for productive replication but also to aberrancies in lymphocyte turnover, differentiation, and function that ultimately lead to exhaustion of the immune system.

In the early years of the pandemic, when effective antiretroviral therapy (ART) and sensitive means of measuring HIV were not available, immunopathogenic mechanisms associated with the virus were difficult to delineate in infected individuals, and the majority of in vitro models developed were later found to be poor surrogates of in vivo events.[2] Since the availability of triple drug regimens in the mid-1990s, the benefits of effective ART have extended beyond the obvious declines in morbidity and mortality to include new opportunities toward understanding the immunopathogenic mechanisms associated with HIV infection. Through cross-sectional and longitudinal studies, it is now possible to establish clear correlates of disease progression and to distinguish in some cases between those effects related predominantly to declining $CD4^+$ T cell counts and those effects induced directly or indirectly by ongoing HIV replication. The advent of effective ART, combined with improved techniques for detecting and measuring HIV,[3] has also led to a better understanding of HIV reservoirs. These include actively turning over cell populations such as activated $CD4^+$ T cells and macrophages, extracellular reservoirs consisting primarily of follicular dendritic cells (FDC) in lymphoid tissues where over 90% of the viral burden resides,[4] and persistent intracellular reservoirs such as the resting subset of $CD4^+$ T cells. The presence of reservoirs for HIV is thought to be one of the major impediments to the eradication of HIV.[5]

Over the past decade, more thorough analyses of the distinct stages of HIV infection have led to a better understanding of the virologic and immunologic parameters associated with disease progression (Fig. 21-1). Such advances have also given rise to debates on when to initiate ART and when/whether to interrupt ART.[6] There is growing evidence that the acute phase of HIV infection, defined as the first several months following primary infection, differs markedly from the chronic phase of infection in terms of immune competency and dynamics of HIV replication.[7] The initial burst of HIV viremia is followed by a reduction in the viral burden that some would argue is mediated by an immune response against HIV and others would argue is driven by exhaustion of the existing pool of target cells for HIV.[8] The ensuing chronic and usually clinically asymptomatic phase of the disease is thought to be modulated by set-point parameters of infection, including levels of plasma HIV RNA and $CD4^+$ T cell count.[9] There are also indications that the integrity of the immune system, especially $CD4^+$ T cell function, can be preserved if ART is initiated during the acute phase of infection.[10,11] Recent findings suggesting the rapid and possibly irreversible decimation of the $CD4^+$ memory T cell pool during the early phase of HIV infection[12,13] may explain why early intervention with ART preserves immune function.

At the molecular level, impressive advances have been made in a number of areas, ranging from identifying components of the innate immune system involved in transmission of HIV, to delineating why only certain variants of HIV are transmitted, to the discovery of certain host factors thought to be involved in restricting HIV replication and disease progression. The identification of host factors involved in restricting HIV has relied heavily on a select group of HIV-infected patients who remain healthy for many years after infection without having received ART. These individuals called long-term nonprogressors have provided a wealth of

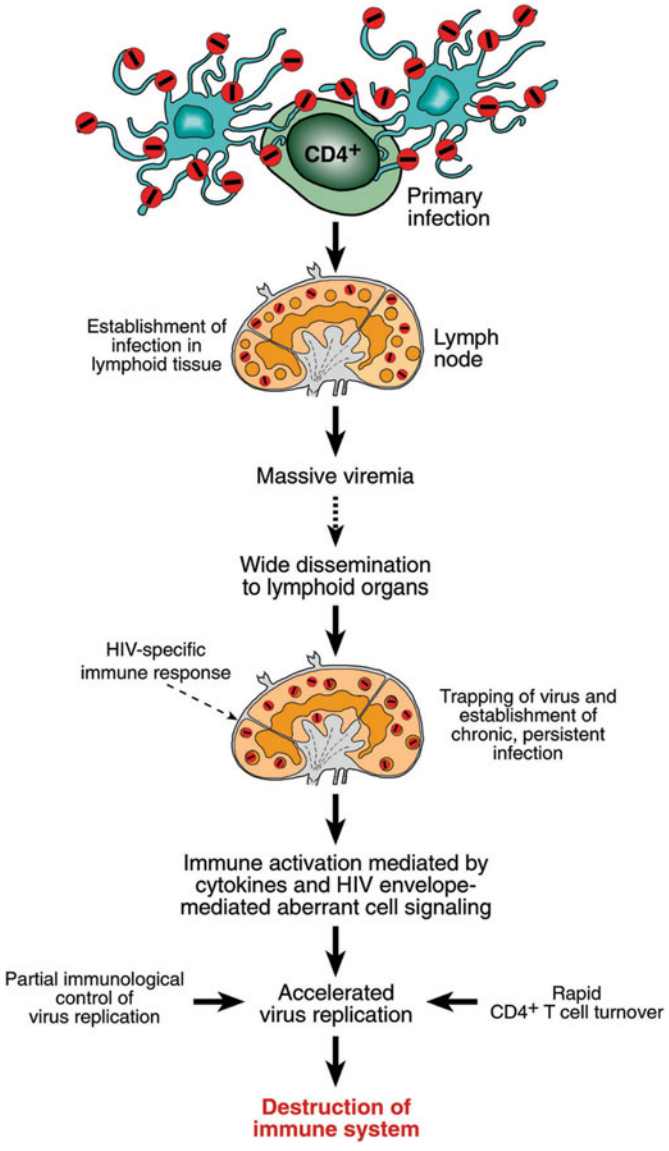

FIGURE 21-1. Events associated with HIV immunopathogenesis, beginning with the initial burst of viremia during primary infection, followed by the induction of an HIV-specific immune response that ultimately fails, leading to exacerbation of HIV-induced immune activation and finally, destruction of the immune system. (From Fauci AS. HIV and AIDS: 20 years of science. *Nat Med* 2003; 9: 839.)

information on the correlates of disease progression and how genetic factors may dictate some of these traits.

The objective of this chapter is to provide an overview of the immunopathogenic mechanisms of HIV disease, to highlight the complex process of immune cell depletion and dysfunction that leads to the collapse of the immune system, and to discuss the host immune response to HIV.

TROPISM AND TRANSMISSION

Several studies carried out in 1983[14] and 1984[15–17] definitively established HIV as the causative agent of AIDS. In 1984, CD4-expressing helper T lymphocytes were identified as selective targets for HIV replication,[18] another seminal finding that would begin to explain why $CD4^+$ T cells are depleted in HIV-infected patients. However, it would take almost another decade before the full scope of the insult exacted by HIV on the immune system would be appreciated. In 1993, with the use of in situ hybridization, studies on clinically asymptomatic patients revealed that HIV replication was unabated in the germinal centers of lymphoid tissues.[19,20] It is now well accepted that from a very early stage of infection, HIV establishes itself in lymphoid tissues, where it replicates in $CD4^+$ T cells and macrophages, and becomes trapped on the surface of FDC. Whereas lymph nodes and spleen have been extensively studied as sites of active HIV replication, more recent studies indicate that other lymphoid tissues, namely, gut-associated lymphoid tissue (GALT), are also sites of intense viral replication.[12,13]

Despite the fact that it was well established in 1984 that CD4 was the primary receptor for HIV, mounting evidence over the years indicated that CD4 alone was essential but not sufficient for entry of HIV into its target cell. It became clear that entry of HIV into susceptible cells required a second receptor. The discoveries of chemokine receptors CXCR4[21] and CCR5[22–25] as coreceptors for HIV heralded a new era of research on pathogenesis, transmission, epidemiology, and treatment (Fig. 21-2). Prior to these discoveries, variants of HIV were characterized as either T-tropic or M-tropic for their capacity to replicate in vitro in $CD4^+$ T cell lines and macrophages, respectively. Pursuant to the discoveries of the chemokine coreceptors, T-tropic variants became known as X4 variants for their ability to infect CXCR4-expressing cells such as $CD4^+$ T cell lines which express CXCR4 but not CCR5. Conversely, M-tropic variants became known as R5 virus for their ability to infect CCR5-expressing cells including macrophages.

The discoveries of CXCR4 and CCR5 as coreceptors for HIV have also led to a better understanding of the events that take place during the establishment of infection. Irrespective of the route of transmission and the tropism of transmitted virus, it is increasingly clear that there is strong selection in favor of R5 variants of HIV during transmission and into the early phases of infection.[26] Compelling evidence that X4 variants of HIV do not transmit efficiently comes from two sources: (1) individuals who are homozygous for a 32-base-pair deletion in the *CCR5* gene that prevents cell surface expression of the receptor are extremely resistant to HIV infection,[27] and (2) rapid reversion to R5 variants has been observed in individuals who have been accidentally infected with pure X4 laboratory variants.[28] It has been intensely debated whether the selective forces favoring R5 variants are related to available target cells at the site of transmission as discussed below, or replication fitness, or host-mediated responses. However, the fact that all routes of primary infection lead to R5 variants would argue for selection against X4 variants. A related debate that has yet to be resolved

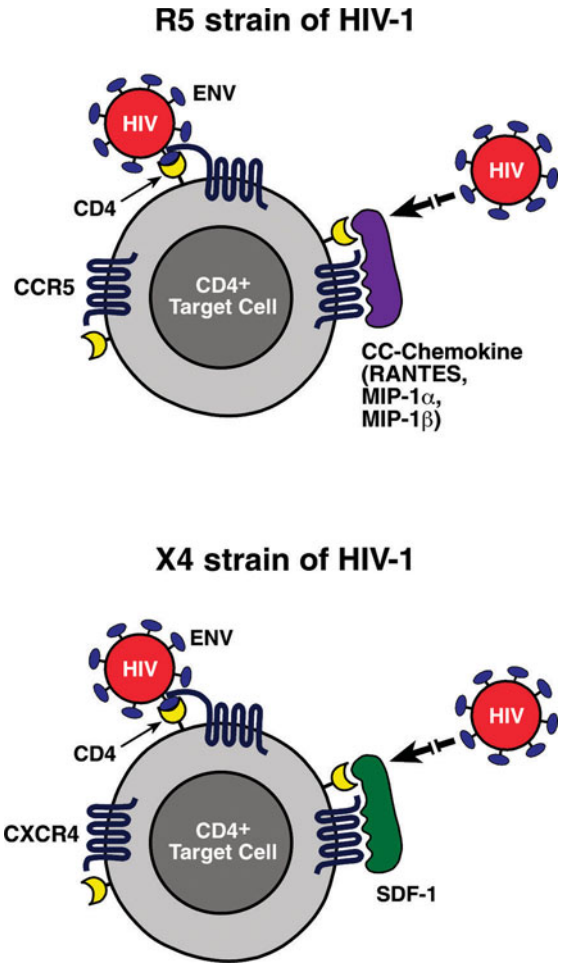

FIGURE 21-2. Elements associated with the tropism and restriction of HIV. Early events of transmission restrict HIV replication to R5 strains of HIV that use CCR5 for entry into CD4-expressing target cells. These strains can be blocked by CC-chemokines. Later during disease progression, X4 strains of HIV may arise. These strains use CXCR4 as coreceptor and can be blocked with SDF-1, the sole natural ligand for CXCR4.

involves the observation that disease progression is associated with the appearance of X4 variants in some but not all patients. Whether the switch relates to the exhaustion of targets for R5 variants or a decline in host responses that keep X4 variants in check remains an open question that has implications not only for pathogenesis but also for the development of antiretroviral therapies aimed at blocking the availability of the CCR5 or CXCR4 receptors to the virus.

Several new areas of HIV research have begun to provide answers to some of the controversies surrounding the earliest events of transmission. Dendritic cells (DC) have long been proposed to play a key role in the transmission of HIV across mucosal barriers and in the migration of HIV to draining lymph nodes where high levels of viral replication take place.[4] Although DCs are not considered major sources of productive HIV replication, they have the ability to capture virus and form stable conjugates with $CD4^+$ T cells, creating favorable conditions for efficient passage of HIV through cell-to-cell contact.[29,30] More recently, with advances in imaging technology, the passage of replication-competent HIV from DCs to $CD4^+$ T cells has been demonstrated at the cellular membrane level, establishing the term of "infectious synapse" to describe the formation of pores where transfer of HIV from a cell that binds HIV but does not allow replication to a virus-replicating cell is shown to occur.[31] The binding or "capture" of virus and transfer of HIV virions is thought to be facilitated by C-type lectin receptors (CLR) such as DC-SIGN which was first described in 2000 for its capacity to capture HIV particles and transfer them to target cells for productive viral replication.[32] CLR, enriched on DCs,[33] recognize complex carbohydrate structures expressed on pathogens such as the envelope of HIV. These receptors are participants in the innate immune response where pattern recognition, such as recognition of complex carbohydrates by DC-SIGN and the growing number of related CLRs, is being proposed as an important early step in the process of mounting an immune response against an invading pathogen.[34] The harnessing of CLRs by HIV is yet another example of how well HIV hijacks various elements of the immune system to facilitate its transmission and propagation.

Finally, there are some indications that macrophages and various DC subsets present in the epithelium and submucosa selectively express CCR5, and as such, may contribute to the selection of R5 viruses during transmission.[33,35] The selective forces favoring R5 variants of HIV during early infection may also relate to recent evidence indicating that CCR5-expressing memory $CD4^+$ T cells, enriched in the GALT, are the primary targets of HIV. Several well-controlled studies in the SIV model have shown that the GALT is decimated during the early phase of infection, with the majority of the depletion being observed in the memory $CD4^+$ T cell compartment.[36–38] Recent findings on intestinal tissues obtained from HIV-infected patients at various stages of disease also suggest that massive depletion of CCR5-expressing memory $CD4^+$ T cells occurs during early infections.[12,13]

IMMUNE ACTIVATION

Immunodeficiency in the face of aberrant immune activation remains one of the most paradoxical hallmarks of HIV disease.[1] In the vast majority of HIV-infected patients who do not receive ART, progression to AIDS is an inevitable outcome that results from a gradual and relentless destruction of the immune system (Fig. 21-3). As will be discussed in greater detail below, the assaults on the immune system are not only restricted to direct and indirect effects on $CD4^+$ T cells but also include detrimental effects on B cell, NK cells, and $CD8^+$ T cells. Of note, the increased expression of activation markers on $CD8^+$ T cells resulting from HIV-induced chronic activation has been shown to be a better indicator of disease progression than either plasma HIV viremia or declining $CD4^+$ T cell counts.[39]

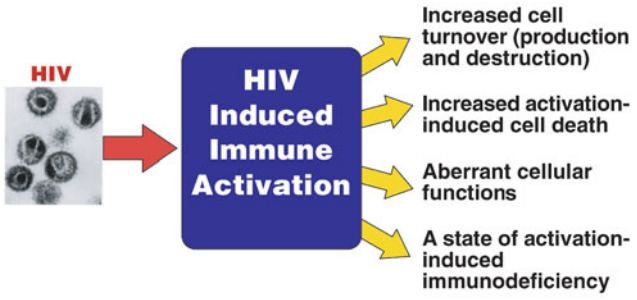

FIGURE 21-3. HIV replication is associated with immune activation that has profound and extensive effects on all cellular compartments of the immune system.

Recent studies on the course of SIV infection in natural and experimental settings in nonhuman primates are providing potentially important insights into HIV-mediated immunopathogenesis in humans. Whereas naturally occurring SIV infection in sooty mangabeys and African green monkeys proceeds without disease progression, the artificial infection of rhesus macaques with the same strain of SIV leads to rapid disease progression in association with heightened immune activation.[40] A detailed analysis of the differences between these dichotomous outcomes has revealed that sooty mangabeys infected with SIV remain healthy with relatively constant $CD4^+$ T cell counts and little evidence of immune activation, despite high levels of viral replication.[41] The current thinking suggests that similar to artificially SIV-infected rhesus macaques, disease progression in HIV-infected humans occurs as a result of aberrant immune activation; however, this association of disease progression with aberrant immune activation needs further delineation.

Why hyperactivation of the immune system would be induced in a pathogenic but not in a nonpathogenic host-virus relationship is a matter of intense research, and has regenerated interest in dissecting virus-host factors involved in the direct and indirect effects of ongoing viral replication on disease progression.[1] As will be elaborated in the following sections on defects of various cell populations of the immune system, there is considerable evidence for indirect effects of ongoing viral replication on cells that are not themselves direct targets of HIV replication. There is also considerable evidence that even cells that can be direct targets of HIV replication, such as $CD4^+$ T cells, die through indirect effects of ongoing viral replication, including bystander apoptosis and increased turnover, both proposed to be consequences of persistent immune activation.[42]

The dysregulation of cells of the immune system that occurs during the course of HIV disease has in part been attributed to HIV proteins released from infected cells and imbalances in cytokine production (Fig. 21-1). The literature is replete with evidence from in vitro models demonstrating that HIV-mediated dysregulation occurs through a variety of direct virus or indirect host factors. However, very few of these observations have been validated in vivo where a myriad of interdependent factors contribute to pathogenesis. The studies that have addressed dysregulation patterns in vivo have provided conflicting views, some indicating a skewing of the immune system toward a cytokine pattern that would impede cellular immune responses while others have been unable to confirm such shifting patterns.[43] Whether cytokine dysregulation plays a role in HIV disease progression remains an open question. Nonetheless, with recent advances in genomic and proteomic technologies, there is good reason to believe that in future the multifactorial nature of HIV immunopathogenesis will be more clearly delineated and correlates of diseases progression and immunologic control will be better understood.

ABNORMALITIES IN CELLS OF THE IMMUNE SYSTEM

■ $CD4^+$ T CELLS

Mechanisms of $CD4^+$ T cell depletion

The depletion of $CD4^+$ T cells constitutes one of the major hallmarks of HIV infection and is a primary indicator of disease progression. The underlying mechanisms that lead to progressive $CD4^+$ T cell depletion remain a topic of intense debate. This area of research can be broken down into three broad categories: (1) the direct effects of HIV replication on $CD4^+$ T cell depletion, (2) the indirect effects of HIV replication on $CD4^+$ T cell depletion, and (3) the more elusive systemic effects of the virus on the dynamics of cell turnover, trafficking, and replenishment. Each of these categories will be addressed in this section.

HIV infects and replicates in host cells that not only express CD4 but also express genes that will enable the virus to complete its life cycle.[44,45] Activated $CD4^+$ T cells fulfill both these requirements and as such, represent the main target for HIV. Once a cell is infected, it is likely to die through HIV-induced cytopathic effects or cytotoxic T cell (CTL) activity, thus contributing to $CD4^+$ T cell depletion as a result of direct HIV infection. In recent years, investigation of the mechanisms of $CD4^+$ T cell depletion by HIV has focused on the subsets of $CD4^+$ T cells that were depleted and on their anatomical location. Because HIV also requires a chemokine receptor to enter a cell and because the chemokine receptor CCR5 is the main coreceptor used by HIV, especially in the early stage of infection, it was not surprising to find that memory $CD4^+$ T cells, enriched for CCR5 expression, harbored more virus than their naïve counterparts in infected individuals.[46] More recently, it was also demonstrated that HIV preferentially infects HIV-specific $CD4^+$ T cells, suggesting that the virus not only kills $CD4^+$ T cells in general, but it has a

preference for those cells whose function is to recognize HIV and mobilize an immune response against it.[47] These HIV-specific CD4+ T cells are preferred targets in large part because they are activated. The concept of activated memory CCR5-expressing CD4+ T cells being the preferred targets for HIV has been at the forefront of provocative recent findings suggesting that a preponderance of these cells in mucosal tissues, which are in close proximity to the major routes of HIV transmission, leads to a massive depletion of such cells shortly after infection with either HIV or SIV.[12,13,37,38] It remains to be determined how these findings impact the slow progressive depletion of CD4+ T cells over the subsequent course of HIV infection, and whether such a massive loss of memory CD4+ T cells accounts for some of the defects in immune response against HIV. It should also be noted that while mucosal tissues may represent an underappreciated site of HIV replication, peripheral lymphoid tissues throughout the body sustain the bulk of the viral burden, both by virtue of the close proximity of target CD4+ T cells and the high density of virions trapped on FDC, and the high levels of activation as evidenced by extensive HIV-induced cellular hyperplasia.[19,20]

Early in the course of the HIV pandemic it quickly became apparent that the relatively low frequency of infected CD4+ T cells during the chronic stages of infection could not account for the progressive depletion of CD4+ T cells. Even with the development of sensitive tools to measure HIV and with the ability to probe various tissues, this discrepancy remained true.[48] Part of the explanation is likely to come from indirect effects of HIV replication on CD4+ T cell depletion, often referred to as bystander effects. These effects can be further divided into those bystander effects that are directly induced by HIV proteins and those that are related to a more systemic consequence of viral replication. Apoptosis appears to be the main mechanism by which CD4+ T cells die as a result of bystander effects of HIV replication.[49,50] The aberrant levels of activation induced by HIV lead to the upregulation of ligands and receptors associated with apoptosis, of which Fas (CD95) and FasL (CD195) are participants of the main proapoptotic program that is activated in HIV infection.[51] For example, activated Fas-expressing bystander CD4+ T cells undergo apoptosis after interaction with infected CD4+ T cells that express FasL as a result of induction by the HIV protein Nef.[52] Other viral proteins such as Vpr,[53] Tat,[54] and Env[55] have also been associated with the induction of bystander apoptosis. Taken together, there is a large body of evidence to suggest that bystander killing of uninfected CD4+ T cells represents an important mechanism of CD4+ T cell depletion.

Finally, CD4+ T cell depletion must also be considered in the context of cell turnover, cell trafficking, and the very challenging concept of lymphocyte homeostasis, which reflects how the body strives to maintain a constant number of cells. All three of these elements are controversial and have been actively debated.[42,56] With regard to T cell turnover, there is an abundance of evidence to suggest that HIV infection results in increased T cell turnover that reflects an increase in both cell proliferation and cell death. In the 1990s, a series of seminal studies were conducted in HIV-infected individuals before and shortly after receiving effective ART, providing new insight into viral dynamics and lymphocyte turnover.[57,58] The findings indicated that HIV itself undergoes a high rate of turnover and that HIV-infected CD4+ T cells have a very short lifespan, and that the result is a faster rate of CD4+ T cell destruction compared to proliferation. In more recent years, notions of increased T cell proliferation and death resulting from HIV-induced immune activation have been added to the paradigm,[42,56] based primarily on studies that applied DNA labeling techniques to investigate cell turnover in HIV-infected and uninfected individuals.[59,60] It is now more widely accepted that progressive immune cell depletion occurs over time because cell death occurs at a faster pace than cellular proliferation. However, other factors including cell trafficking, cellular regenerative capacity, and homeostatic compensation, while beyond the scope of this review likely contribute to a greater or lesser degree to the phenomenon of immune cell depletion. HIV infection leads to changes in the expression of receptors involved in migration of cells between tissues, collectively known as homing receptors. Changes in the expression of homing receptors are especially seen in HIV-infected individuals who manifest poorly controlled viral replication.[61] It has been argued that when these individuals begin ART, part of the changes observed in CD4+ T cell numbers has to do with tissue redistribution and not simply replenishment.[62] Furthermore, one of the markers (TREC) used to study the replenishment of CD4+ T cells in ART-treated individuals,[63–65] which measures thymic emigrants such as naïve CD4+ T cells, is also modulated by other factors such as immune activation and rate of cell division.[66] Finally, it is also clear that HIV disease progression is associated with poorly-understood homeostatic compensations, including a tendency to replace loss of CD4+ T cells with CD8+ T cells as well as CD4+ T cells, and increased levels of cytokines such as IL-7.[67]

Functional abnormalities of CD4+ T cells

In addition to causing the depletion of CD4+ T cells, HIV leads to perturbations in the function of CD4+ T cells, limiting their capacity to provide help to the adaptive arms of the immune system. One of the earliest abnormalities to arise in HIV-infected patients is the loss of responsiveness to recall antigens such as tetanus and influenza,[68] a function that is dependent on the memory response of CD4+ T cells. In most patients who do not initiate ART, the degree and spectrum of CD4+ T cell defects increase over time to include loss of responsiveness to soluble antigens, mitogens, and finally alloantigens.[69] Many of these dysfunctions have more recently been attributed to phenotypic changes of CD4+ T cell subsets

that occur over the course of HIV infection.[70] Loss of expression of CD28, a costimulatory molecule for CD4+ T cell effector function, occurs during HIV disease progression,[71] possibly as a result of loss of central memory CD4+ T cells.[72] Production of IL-2 by antigen-specific CD4+ T cells also declines over the course of HIV infection.[68] This decline is more pronounced against HIV than other antigens,[73,74] and recently it has been linked to alterations in CD4 T cell subsets.[75,76] Finally, CD4+ T cells demonstrate poor proliferative response against specific antigens,[77] a defect that has also recently been linked to the central memory compartment.[72]

Studies have shown that ART can reverse many of the CD4+ T cell defects described in untreated HIV-infected individuals,[77,78] although recoveries are often incomplete.[77,79,80] There are indications that individuals who initiate ART during the acute phase of infection, reconstitute their CD4+ T cell functions more completely than do those who initiate treatment later during the chronic phase of infection.[81] This reconstitution appears to be more dramatic for HIV-specific CD4+ T cell responses.[10,11] The myriad of functional defects that arise early after infection may be related to the selective and extensive depletion of memory CD4+ T cells that has been described in the mucosal tissues.[37,38] It remains to be thoroughly investigated whether these changes explain the differences in functional reconstitution between rapid and delayed initiation of ART.

B CELLS

Very early into the pandemic, even before HIV was identified, numerous abnormalities in B cell of HIV-infected individuals were reported. The initial observations indicated that HIV-infected individuals manifested increased levels of polyclonal B cell activation as evidenced by hypergammaglobulinemia, spontaneous immunoglobulin secretion of cultured cells, and decreased B cell proliferation in response to B cell mitogens resulting from excessive hyperactivity in vivo.[82] Other signs of aberrant cellular activation include the presence of circulating immune complexes and autoantibodies,[83–85] increased numbers of circulating B cell expressing markers of activation,[86–88] and increased risk of developing B cell malignancies.[89] Although the precise mechanisms associated with increased B cell activation have not been fully delineated, ongoing viral replication is a major contributing factor to the B cell aberrancies observed in the setting of HIV infection. Both cross-sectional and longitudinal studies have demonstrated that B cell abnormalities observed in HIV-viremic patients are absent or greatly diminished in HIV-aviremic patients.[90–93] Furthermore, although some of the effects of HIV on B cell function may in part be related to direct interactions between virions and B cell,[94] it is widely accepted that most of the detrimental effects of HIV on B cell are due to indirect mechanisms associated with systemic manifestations, such as imbalances in cytokine and chemokine profiles,[87,95] and the effects of HIV proteins such as the viral envelope on B cells that are altered by HIV infection.[96] More recent evidence suggests that interferon-induced genes play an important role in HIV-mediated immune activation through the induction of genes associated with B cell apoptosis and modulators of B cell terminal differentiation.[91] As described below for other cellular immune defects, interferon-induced genes affect all cells of the immune system and may represent a major determinant in dictating disease progression in SIV-infected nonhuman primates.

One of the most paradoxical observations regarding HIV pathogenesis is the notion of profound immune deficiencies in the face of massive cellular immune activation. A very telling example is the notion that B cell demonstrate numerous signs of activation in vivo, yet patients respond very poorly to immunization. Antibody responses to both T-dependent and T-independent antigens have been shown to be defective in HIV-infected patients, especially late stage patients.[97–100] There are indications that ART can partially restore certain responses, especially those to T-independent antigens.[101] Antibody responses to HIV itself will be dealt with in a later section.

There is little evidence that HIV productively infects B cell in vivo. However, as alluded to above, direct interactions between HIV virions and B cell have been demonstrated both in vivo and in vitro.[94,102] The major mode of interaction described in vivo involves interaction between components of complement protein C3 breakdown products, which along with anti-HIV antibodies shroud HIV particles circulating in vivo, and the receptor for C3, the complement receptor CD21, expressed on B cell and FDC. This interaction enables B cell and FDC to serve as extracelullar reservoirs for HIV, with B cell having the unique capacity to migrate in and out of the circulation and into lymphoid tissues where they contribute to the dissemination of HIV infection throughout the body through direct interactions with CD4+ T cells.[103] There has also been some evidence to suggest that the HIV gp120 envelope binds to B cell through a superantigenic type of interaction with members of the VH3 gene family of immunoglobulins.[104] There has also been evidence that this interaction leads to preferential deletion of B cell that express surface immunoglobulins of the VH3 family,[105] although these observations remain controversial.

The role of CD21 in HIV pathogenesis is not only restricted to participation in the dissemination of virus; CD21 also serves as a powerful marker for identifying a subset of B cell that appear to account for a large portion of the functional defects ascribed to B cell in viremic HIV-infected patients.[90] The expression of CD21 is tightly regulated during B cell differentiation, first appearing when immature B cell start to form functional B cell receptors, modulated to various

degrees in the secondary lymphoid tissues, and downregulated in the final stages of differentiation when B cell become antibody-secreting cells, otherwise known as plasma cells.[106] In HIV-infected viremic patients, a substantial proportion of B cell no longer express CD21, an observation that is consistent with changes that occur during terminal differentiation, including increased immunoglobulin secretion, decreased proliferation in response to mitogenic stimulation, and distinctive morphologic changes.[90] This subset of B cell, which gradually disappears in aviremic HIV-infected patients, may thus account for several of the B cell abnormalities first described over 20 years ago,[82] and recent findings demonstrate that it accounts for several of the abnormalities described by DNA microarray technology.[91]

In addition to loss of CD21 expression, HIV-infected patients manifest deficiencies in frequencies of memory B cell, as measured by phenotypic and functional markers.[107,108] In contrast to the loss of CD21, decreased levels of CD27, the major marker used to identify memory B cells, are observed in all chronically HIV-infected patients, irrespective of viral burden.[108] Whether this defect can be modulated depending on the stage of HIV infection at which patients initiate ART, in essence asking whether there is an immunologic benefit to be gained from starting ART during acute infection, remains to be determined. Finally, if the relative percentage of total B cell represented by memory B cells is depleted in HIV-infected patients then the question arises as to what subpopulaton replaces these memory B cell. Increases in the frequency of B cell expressing activation markers have been described in both the naïve[109] and more differentiated[88,91] B cell compartments, in addition to increases in more immature B cell,[86] and B cell expressing CD5, a marker often associated with autoimmunity.[85] A few of these findings are conflicting, likely a reflection of the wide variability in the expression levels of certain markers such as CD27, and differences in disease status of patients. A clarification of these observations will require analysis of large number of patients representing a wide spectrum of HIV disease.

CD8$^+$ T CELLS

One of the most prominent features of HIV infection is the chronically elevated levels of CD8$^+$ T cell numbers that are contrasted with a gradual loss of viral suppression by CD8$^+$ T cells, especially observed in individuals experiencing high plasma viremia. Among the many immunologic surface markers expressed on CD8$^+$ T cells, the presence of CD38 has consistently been shown to be associated with HIV disease progression. CD38 expression is thought to be directly associated with HIV-mediated aberrant immune activation, a process that disables CD8$^+$ T cells from effectively controlling viral replication and preventing disease progression.[110,111]

Although control of viral replication by CTLs is thought to occur in the initial stage of HIV infection,[112,113] the emergence of HIV escape mutants that evade virus-specific CD8$^+$ T cells is almost inevitable and ultimately leads to loss of control of viral replication.[114–116] However, not all viral CTL epitopes bear signs of escape from immune selection,[117] suggesting that functional impairment of CD8$^+$ T cells may also contribute to the failure to control viral replication. In this regard, it has been suggested that the bulk of HIV-specific CD8$^+$ T cells resides within the CD38$^+$CD8$^+$ T cell compartment of infected individuals, and that these cells are prone to deletion by apoptosis.[118] These findings suggest that increased levels of CD38 expression and increased susceptibility to spontaneous and CD95/Fas-mediated apoptosis in CD8$^+$ T cells of infected individuals with active viral replication may seriously compromise the effectiveness of HIV-specific CD8$^+$ T cells in eliminating productively infected target cells.[118] It has also been suggested that the loss of help from HIV-specific CD4$^+$ T cells to HIV-specific CD8$^+$ T cells due to impaired proliferation and expansion of the former may contribute to poor CTL function.[10]

Several additional mechanisms of immunologic dysfunction of CD8$^+$ T cells have been described over the past few years as basic understanding of factors associated with an effective CTL response have been elucidated and new tools for analyzing them have been developed. The delineation of functionally distinct subsets of CD8$^+$ T cells, based on the expression of the homing chemokine receptor CCR7,[119] led to the observation that one of these subsets, namely preterminally differentiated CD8$^+$ T cells lacking expression of CCR7, was overrepresented in HIV-infected individuals and was likely to contribute to the skewing of the HIV-specific memory CD8$^+$ T cell response observed in these individuals.[120] It was speculated that high levels of antigenic stimulation due to ongoing HIV replication, combined with a lack of adequate CD4$^+$ T cell helper function, were responsible for the skewing of the HIV-specific memory CD8$^+$ T cell response. Chronic antigenic stimulation was also proposed as an explanation for the appearance of a dysfunctional subset of HIV-specific CD8$^+$ T cells, defined by the expression of CD57, that produced cytokines but failed to proliferate, and were more susceptible to activation-induced apoptosis than were their CD57- counterparts.[121] In a similar type of study, HIV-specific CD8$^+$ T cells from HIV-infected individuals who had not progressed after over 10 years of infection were found to be qualitatively superior to those of patients who progressed at a faster pace.[122] In this case, it was the effector phase of the CTL response, as measured by the release of perforins which are involved in lysing target cells, that was maintained in HIV-infected individuals who were not experiencing disease progression and lost in individuals who were. Finally, recent studies on both CD4$^+$ and CD8$^+$ T cell compartments have demonstrated that the pattern of cytokine expression is important for function. It is thought that the expression of

both IL-2 and IFN-γ is necessary for an effective cell-mediated response against HIV and that in the setting of HIV infection, the less effective IFN-secreting T cells often predominate over the more effective IL-2- and IFN-γ-secreting T cells.[73,123] While this concept needs to be more thoroughly investigated, the notion that the qualitative nature of a $CD8^+$ T cell response is more important than its quantitative nature may explain in part the immune cell dysfunction in HIV infection. In essence, these findings are beginning to explain how the paradoxically high levels of CTLs in HIV-infected can nonetheless be ineffective at controlling the virus.

NK CELLS

Natural killer (NK) cells are a subset of lymphoid cells that participate in immunosurveillance against tumors and virally infected cells.[124] They are characterized by the lack of expression of conventional receptors for antigen, but are able to distinguish between cells expressing normal levels of MHC class I molecules and cells that have lost expression of such molecules as a consequence of HIV infection.[125] A delicate balance between opposite signals delivered by the MHC-I-specific inhibitory NK receptors (iNKRs) and by the activating receptors, such as natural cytotoxicity receptors (NCRs) and NKG2D, regulates NK cell cytotoxicity.[126,127] NK cells are capable of eliminating HIV-infected target cells by direct lysis and by mediating antibody-dependent cellular cytotoxicity (ADCC) during the effector phase of immune responses.[128] It has been demonstrated that HIV downregulates MHC class I molecules on the surface of infected cells, most likely in order to escape from lysis by $CD8^+$ T cells;[129,130] however, there are a number of subgroups of HLA class I molecules that are relevant to the ability of NK cells to exert their cytotoxic effects on HIV-infected targets.[131,132] HIV appears to selectively downregulate HLA-A and -B molecules while preserving the expression of HLA-C and -E molecules on the cell surface.[133] The above findings suggest that the NK-mediated cytotoxicity is probably limited to infected cells that lack HLA-C and –E as certain NK cell inhibitory receptors can bind to those molecules to abrogate lysis.

Several phenotypic and functional abnormalities of NK cells have been described in HIV infection, although it is unclear how HIV induces such changes. Phenotypic analysis of NK cells has shown an expansion of the $CD56^{neg}/CD16^{high}$ subset in HIV viremic individuals.[134] This subset of NK cells expresses higher levels of iNKRs, significantly lower levels of NCRs, and is defective in lysing cell targets, suggesting that the expansion of a highly dysfunctional $CD56^{neg}/CD16^{high}$ NK population in HIV viremic individuals is likely to be at least in part responsible for the defective NK cell functions.[134]

It has been demonstrated that the suppression of HIV replication by NK cell-secreted soluble factors is almost entirely mediated by CC-chemokines.[135] The ability of NK cells to secrete CC-chemokines and thereby to inhibit entry of HIV into $CD4^+$ T cells is significantly depressed among infected individuals with active viral replication.[136] Finally, NK cells of chronically infected individuals have been shown to be impaired at mediating FCγRIII (CD16) receptor-dependent ADCC in vitro against target cells expressing HIV envelope proteins.[137]

IMMUNE RESPONSES TO HIV

$CD8^+$ T CELL RESPONSES

$CD8^+$ T cell-mediated immune responses play an important role in host defenses against viral infections. The importance of $CD8^+$ T cells in suppression of HIV infection was initially demonstrated in vitro.[138] Subsequently, it was shown that HIV-specific $CD8^+$ CTLs play a central role in controlling viral replication, as evidenced by the emergence of CTL activity coinciding with a decline in plasma viremia during primary infection[112,113] and a diminution of CTL responses preceding disease progression in infected individuals.[139,140] CTLs have been found in large quantities in various tissue compartments in infected individuals. They exert their antiviral activities against virally infected cells via several mechanisms. CTLs can directly lyse HIV-infected cells from infected individuals.[141] They can also produce CC-chemokines, such as MIP1-α, MIP1-β, and RANTES, which block entry of virus into susceptible target cells[142] and secrete granzymes and perforin after being triggered by antigen presenting cells.[143] Perhaps the most compelling evidence for the importance of CTLs came from several studies in which $CD8^+$ T cells were depleted using monoclonal antibodies to CD8 in SIV-infected monkeys, resulting in an increase in plasma viremia and rapid disease progression.[144,145]

The qualitative nature of the CTL response is also thought to predicate the ultimate clinical course of HIV infection. T cell subsets (both $CD4^+$ and $CD8^+$ T cells) can be divided into families based on the variable (V) region of the β chain of the T cell receptor. There are 24 Vβ families within the T cell receptor repertoire. In examining the diversity of the CTL response during primary infection, it was observed that some individuals had a marked expansion of an individual Vβ family, while others had more marginal expansions of multiple Vβ families.[146] Those individuals with restricted $CD8^+$ T cell expansions appeared to be at greater risk for disease progression.[147] The basis of such a clinical outcome is unclear but may involve the rapid deletion of the expanded, high-affinity, HIV-specific CTL clones as well as the selection of viral variants that escape killing by CTLs because of the restricted nature of the CTL response.[115,116] In contrast, patients who generate a broad CTL response, with respect to both epitope and protein targets and the diversity of the T cell repertoire, may be best able to handle the mixture of viral variants or quasi-species that evolve during the course of their infection. The

initial observation that CTL responses may be involved in immune selection of viral variants originated from the observation that particular viral epitopes underwent progressive changes in sequence over time in infected individuals, resulting in subsequent changes in the CTL response of that individual.[148] It was then observed that adoptive transfer of in vitro expanded autologous CTL clones that were directed against the HIV Nef protein resulted in the selection of viral variants possessing escape mutations within that viral protein.[149] Moreover, CTL-driven selection of new viral variants was observed in primary HIV infections[114] and later during the chronic phase of infection.[116] The MHC class I haplotypes of HIV-infected individuals also play a major role in predicting clinical outcome. Given that infected cells display fragments of HIV proteins in association of MHC class I molecules to initiate CTL-mediated immune responses, the magnitude of virus-specific CTL-responses is largely determined by the MHC class I molecules. Indeed, the expression of the MHC class I molecules HLA-B27 and HLA-B57 is associated with favorable clinical outcomes in HIV-infected individuals.[150] The inadequacy of the CTL response to eliminate viral persistence could be attributed to several mechanisms. The best documented evidence comes from the fact that HIV escapes immunologic control by generating mutations in targeted viral epitopes.[114] It has been demonstrated that when CTLs exert selection pressure against a particular viral epitope, the error-prone HIV reverse transcriptase and the generation of an enormous number of virions allow replacement of preexisting wild-type virus with ones carrying resistant mutations against CTLs. In addition, there is a marked shift in the composition of the $CD8^+$ T cell population following acute infection, with expansion of total $CD8^+$ T cells and $CD8^+CD28^-$ cells in particular.[151] Induction and expansion of CTLs in the latter subpopulation may be less efficient due to the absence of a vital CD28-CD80 costimulatory pathway.[152] The persistence of these activated CTLs, especially those coexpressing CD38, could be subject to signals that induce apoptosis.[118] In addition, there is some experimental evidence that viral variants can actually inhibit CTL effector function against wild-type viruses.[153] Infected cells may be less susceptible to lysis as a consequence of Nef-dependent downregulation of MHC class I expression, required for the presentation of processed antigen.[129,130] Finally, the expansion of certain $CD8^+CD57^+$ cells has been associated with the production of factors that inhibit cytotoxic function.[121,154]

$CD4^+$ T CELL RESPONSES

$CD4^+$ T cells play a pivotal role in adaptive immune responses by providing help to both B cell and $CD8^+$ T cells as they mount and maintain antibody and CTL responses, respectively. As described above, the depletion of $CD4^+$ T cells that occurs over the course of HIV infection is an important factor contributing to the inadequacy of the HIV-specific immune response to control viral replication. However, even from the earliest studies there was considerable evidence to suggest that in addition to the quantitative loss of $CD4^+$ T cells, there are also qualitative defects that arise in these cells during disease progression and that contribute to the lack of immunologic control of HIV.[68,155] Similar to the CTL response, most untreated HIV-infected individuals develop HIV-specific $CD4^+$ T cell responses,[156] yet these responses are thought to be ineffective due to imbalances in cytokine profiles,[73] skewing of $CD4^+$ T cell subsets,[74–76] apoptosis,[51] and inadequate proliferation.[157] It should be noted, however, that several of these observations remain controversial because there have been conflicting data regarding the association between $CD4^+$ T cell responses and HIV viral load. Nonetheless, there is a general consensus to suggest that functional abnormalities in HIV-specific $CD4^+$ T cells contribute to loss of immunologic control of HIV in infected individuals.

Evidence that HIV-specific $CD4^+$ T cells contribute to the control of HIV infection comes from two sources: HIV-infected individuals who are long-term nonprogressors and those treated early after infection. Strong HIV-specific $CD4^+$ T cell lymphoproliferative responses have been documented in individuals who are considered long-term nonprogressors.[11,158]. Similarly, high levels of HIV-specific $CD4^+$ T cell responses have been documented in HIV-infected individuals treated during primary infection.[10,11] It has been suggested that early intervention with ART is associated with a strong HIV-specific $CD4^+$ T cell response that leads to a better immunologic control of HIV, as evidenced by slow rebound of HIV viral load when such individuals interrupt therapy.[10] Although these observations are of considerable interest, the number of individuals who were carefully studied remains low and there are indications that the immunologic control is not sustained. In this regard, the effect and clinical relevance of early ART intervention on the HIV-specific immune responses warrant further investigation.

ANTIBODY RESPONSES

Antibody responses play a central role in clearing established viral infections and in providing protection from infection following vaccination. HIV infection is relatively unique in that antibodies appear to be ineffective at clearing the virus in infected individuals or at providing protection against infection. It is not that antibodies are not elicited; to the contrary, the high levels of HIV replication that often occur in the absence of antiretroviral drugs are accompanied by high serum titers of anti-HIV antibodies that decrease substantially as viral load is decreased with antiretroviral therapy.[92] The reason why HIV is so difficult to neutralize remains a matter of much debate and is the subject of intense research. The high genetic

diversity and high rates of mutations associated with HIV are well accepted as reasons for the lack of effectiveness of the anti-HIV antibody response; however, structural properties of the HIV envelope and its difficulty in eliciting a broadly reactive neutralizing antibody response, the mode of interaction with CD4 and chemokine receptors, as well as immunologic sanctuaries and the timing of the antibody response have also been added to the growing list of reasons why HIV is so difficult to control by antibody.

The initial HIV-specific antibody response that appears 2–4 weeks following infection is non-neutralizing and is thought to have little impact on the dynamics of early viral replication.[159,160] Recent studies indicate that the appearance of neutralizing antibodies places a strong selective pressure on HIV, and that from that point onward,[161,162] the presence of antibodies capable of neutralizing the replicating virus is always one step behind virus diversification, essentially enabling HIV to escape its antibody response. This is not to say that HIV-specific antibodies cannot alter the course of infection. There are indications from simian models that the infusion of larger quantities of isolate-specific neutralizing antibodies, a process known as passive immunization, can prevent the establishment of infection.[163,164]

HIV-1 has evolved a number of strategies to successfully evade control by antibody. At the top of the list is the structure of the HIV envelope, the primary target of HIV-specific antibodies. The external receptor-binding component of the HIV envelope, gp120, assembles as a trimer and associates with the membrane cell-fusion component of the HIV envelope, gp41, through noncovalent interactions. The trimeric nature of the HIV envelope, while regarded as an essential component for a successful vaccine strategy, is also considered a hindrance to antibody binding because of steric occlusion.[165] Another strategy that HIV uses to resist an effective antibody response is to shroud its envelope with carbohydrates, which are highly variable and far less immunogenic than protein. This masking of the HIV envelope, recently termed a glycan shield, is thought to represent an important mechanism of persistence for the virus.[162] Furthermore, the most exposed epitopes of the envelope, namely, the variable loops V1-V5, are as their name implies, highly variable and strain-specific, which make them poor candidates for vaccines and prime candidates for escape. The positioning of the five variable loops also provides a physical barrier to the neutralization-sensitive and more conserved regions of the envelope,[165] adding a further layer of protection for the virus. Recent studies also indicate that the face of the envelope involved in receptor binding is highly malleable and not very accommodating for antibody binding, a concept termed conformational masking.[166] Combined with previous observations indicating that the CD4 binding site is largely inaccessible to the immune system by its positioning at the bottom of a deep cleft,[167] these recent findings underscore the difficulties the host faces in mounting an effective antibody response against the HIV envelope. Thus, HIV uses a variety of mechanisms to shield its most vulnerable components, namely, the CD4 and chemokine receptor binding sites, from the immune system.

Over the past few years, a major emphasis has been placed on characterizing the few naturally occurring anti-HIV monoclonal antibodies that have been shown to possess broadly cross-reactive neutralizing activities against HIV. It is hoped that by understanding the nature of these unique antibodies it will be possible to find ways of eliciting similar ones either during the course of HIV infection or following vaccination. Four classes of antibodies specific for various constant regions of the HIV envelope have been considered as targets for vaccine development: (1) antibodies to the CD4 binding site of gp120, (2) antibodies to sites in gp120 induced by the binding of envelope to CD4, (3) antibodies to carbohydrate entities on the side chains of gp120, and (4) antibodies to epitopes in gp41. The CD4 binding site of gp120 is highly conserved, restricted in its conformational flexibility, and not very accessible in primary isolates. However, one human monoclonal antibody directed against the CD4 binding site of gp120, b12, has been extensively studied and found to have an unusual protrusion that enables it to fit into the pocket that forms the CD4 binding site and to neutralize a broad range of HIV isolates.[168] Efforts are underway to design an immunogen that would elicit similar antibodies. Similar approaches have been applied to better define and expand those antibodies that bind the HIV envelope more effectively once CD4 is bound. These antibodies, termed CD4-induced antibodies, are found in HIV-infected individuals[169] and have been shown to recognize epitopes of gp120 involved in binding chemokine receptors.[21] Two of these antibodies, 17b and 48D, have been shown to neutralize most HIV isolates,[170] and it is hoped that the extensive information gleaned from crystallographic studies of this class of antibodies will lead to new vaccine candidates. The conformationally unique and broadly neutralizing antibody 2G12, directed against a carbohydrate moiety in gp120,[171,172] has also received considerable attention in terms of vaccine potential. However, it remains to be determined whether a carbohydrate entity, which is not usually very immunogenic, could be used as a target for an effective HIV-specific antibody response. Finally, several regions of gp41, the fusogenic component of the HIV envelope, have been shown to be effective targets for neutralizing activity. The most widely discussed anti-gp41 antibody, 2F5, directed against a conserved epitope in the membrane-proximal region of gp41,[173] is broadly neutralizing[174] and thought to represent an attractive target for vaccine development.

One of the most immunogenic and structurally important regions of the HIV envelope is the V3 loop. Neutralizing antibodies against the V3 loop are the first to arise in HIV-infected individuals,[175] yet have poor immunogen potential for vaccine

development because they are strain-specific and easily mutate under selective pressure. The pressures of the immune system on the V3 loop and other variable regions of gp120 have recently been extensively documented as a means of understanding how the virus mutates in the presence and absence of neutralizing antibodies. Several years ago, when it became evident that most HIV envelope-specific antibodies with potent neutralizing activity against strains of HIV grown in the laboratory, known as laboratory adapted strains, were ineffective at neutralizing isolates obtained directly from infected individuals, the reasons for this conundrum remained unknown. It is now accepted that strains of HIV that are grown in vitro, in the absence of immune pressure, alter their variable regions to expose receptor binding sites and as such, increase their replicative fitness.[176] Conversely, it would be expected that as a neutralizing antibody response is mounted following infection, the virus would alter its variable regions in order to protect its vulnerable regions from exposure. Evidence now exists for immune pressure-driven changes in the HIV envelope;[177] early after infection, when neutralizing antibodies are absent, the HIV isolates present are highly susceptible to neutralization. As neutralizing antibodies begin to appear, modifications in the glycosylation and variable loops of the HIV envelope begin to arise so as to restrict the exposure of conserved vulnerable regions such as the CD4-binding site,[177] in essence, preventing the existing antibodies from accessing neutralization-sensitive regions of the envelope and preventing new antibodies from arising. This extraordinary flexibility thus enables HIV to stay one step ahead of an effective immune response.

HOST ANTI-HIV FACTORS

CC-Chemokines

In 1995, shortly before chemokine receptors were shown to be coreceptors for HIV entry into target cells, CC-chemokines MIP-1α, MIP-1β, and RANTES were identified as potent inhibitors of replication of certain strains of HIV.[142] This seminal discovery revealed the nature of a major class of soluble HIV-suppressive factors produced by activated $CD8^+$ T cells. The general phenomenon of $CD8^+$ T cell-derived factors that suppress HIV replication was first described in 1986.[138] Several months later, CCR5, a chemokine receptor that binds CC-chemokines, was discovered to be a major coreceptor for HIV, thus elucidating the mechanism by which this family of chemokines blocks HIV replication.[22,23] CC-chemokines are secreted by a variety of cells, including $CD8^+$ T cells, NK cells, monocytes, and dendritic cells.[178] They exert potent anti-HIV activity by binding CCR5 on CD4-expressing cells and blocking R5 strains of HIV from accessing their coreceptor (Fig. 21-2). The intrinsic capacity of CC-chemokines to modulate HIV infection and disease progression has been proposed based on genetic studies,[179,180] in vitro studies,[181,182] and association with lack of disease progression.[183,184] There are also indications that susceptibility to HIV infection is influenced by levels of CC-chemokines that vary according to patterns of gene duplication in the CC-chemokine family.[185] These latest findings suggest that intrinsically high levels of MIP-1α can outcompete HIV by blocking enough CCR5 receptors to prevent a host from becoming infected. Finally, there is also hope that natural host factors such as CC-chemokines can be developed as therapeutic and prophylactic anti-HIV agents.[186]

$CD8^+$ T cell-mediated noncytolytic, nonchemokine, anti-HIV factors

The main role of $CD8^+$ T cells is to destroy infected cells through MHC-restricted pathogen-specific CTL activity; however, activated $CD8^+$ T cells have also been shown to potently inhibit HIV replication through a mechanism that is not related to CC-chemokines.[187] When activated $CD8^+$ T cells are added to cultures of infected peripheral blood mononuclear cells (PBMCs) from HIV-infected patients they can profoundly inhibit HIV replication.[138,187] The soluble factors that mediate this CD8-derived inhibitory effect other than CC-chemokines have not been fully delineated. The CD8-mediated inhibition occurs independently of the haplotype of the donor used as source of the $CD8^+$ T cells, indicating that the effect is not MHC-restricted.[187–189] When HIV-infected $CD4^+$ T cells, obtained either directly from HIV-infected individuals or following HIV infection in vitro of $CD4^+$ T cells isolated from HIV-negative donors, are cocultured with activated $CD8^+$ T cells derived either from HIV-infected or uninfected individuals, potent suppression of HIV occurs although the magnitude of the effect can vary greatly.[138,183]

The inhibitory effect of $CD8^+$ T cells does not require direct contact with $CD4^+$ T cells, as activated $CD8^+$ T cells separated by a membrane filter still inhibit HIV replication; however, the magnitude of the effect is greater if the cells are in direct contact with each other.[183,186,187,189] The anti-HIV activity exhibited by $CD8^+$ T cells requires that they be activated with stimulating agents such as mitogens and antigens. With the latter, inhibition can be observed with either mixed populations or specific clones, including HIV-specific and non-HIV-specific CTLs.[190] Whereas $CD8^+$ T cells produce a number of well-characterized cytokines that inhibit HIV in vitro, addition of antibodies that neutralize these cytokines do not fully abrogate the anti-HIV activity exerted by activated $CD8^+$ T cells.[186] The fact that the inhibitory activity cannot be fully neutralized may be related to the nature of the cytokines being secreted by the $CD8^+$ T cells, where some may have HIV-inhibitory properties while others have HIV-stimulator properties. Finally, whereas CC-chemokines exert their antiviral activity at the entry of HIV into $CD4^+$ T cells and

macrophages, the unknown soluble factor(s) has been shown to suppress viral replication at a postentry step, as evidenced by decreased HIV transcription in infected cells.[187,191]

OTHER HOST-DERIVED ANTI-HIV FACTORS

Recently, a number of studies have described new cellular factors that inhibit HIV replication, some of which may eventually lead to new therapeutic opportunities.[192,193] One of the most interesting discoveries involves members of a family of enzymes with cytidine deamination activity, called APOBEC, that are involved in various facets of DNA and RNA editing.[194] The best known member of this family, called AID for activation-induced deaminase, is a key player in the immunoglobulin gene diversification process that takes place as B cell mature in their ability to mount an antibody response. With regard to HIV, another member of the APOBEC family, APOBEC3G, was discovered a few years ago to have potent anti-HIV activity but only when the accessory protein, Vif, was deleted from the viral genome.[192] Shortly thereafter, the mechanism of action was determined, revealing that under wild-type conditions, Vif inactivates the very potent retroviral cDNA-editing activity of APOBEC3G.[195,196] In the absence of Vif, APOBEC3G induces extensive and debilitating mutations in the HIV genome, essentially rendering newly formed virions incapable of undergoing subsequent rounds of infection. Whether the tightly regulated cellular enzymatic activity of APOBEC3G and its relatives can be harnessed to inactivate HIV without causing extensive damage to the host cell itself remains a daunting task, albeit one that could lead to one of the most potent natural suppressors of HIV.

■ VIRAL RESERVOIRS

CD4⁺ T cells

Any cell type that expresses the CD4 molecule, along with a chemokine coreceptor, can be infected with and harbor HIV in vivo. However, it has been firmly established that CD4⁺ T cells and CD4⁺ cells of the monocyte/macrophage lineage constitute the major reservoirs of HIV in infected individuals.[197–200] Cellular activation plays a key role in viral replication as well as in the pathogenesis of HIV disease.[201] In terms of HIV replication, the level of cellular activation in CD4⁺ T cells dictates the extent of the completion of the viral replication cycle in infected cells.[44] At any given time, only approximately 5–15% of CD4⁺ T cells in the peripheral blood are in an activated state, explaining the relatively low frequency of infected cells found in this compartment.[202,203] In contrast, a much higher level of cellular activation is observed in the lymphoid tissue compartment where the vast majority of HIV replication and productive infection of CD4⁺ T cells take place.[19,20] In addition, it has been recently demonstrated that nearly every memory CD4⁺ T cell in mucosal tissue of SIV-infected rhesus macaques becomes infected during the primary phase of infection.[37] During the chronic phase of infection, a relatively constant state of heightened cellular activation allows maintenance of stable levels of productively infected CD4⁺ T cells.[201,204]

The introduction of effective ART has enabled patients to achieve a substantial degree of viral suppression and consequently achieve a dramatic reduction of the frequency of HIV-infected CD4⁺ T cells.[205] These observations generated considerable optimism and hope that HIV could be eradicated in infected individuals receiving effective therapy.[206,207] However, over several years this optimism has largely subsided with the realization that certain HIV reservoirs persist and may be impossible to eliminate, even after several years of effective antiretroviral therapy.[208–210] One of the most sobering realities regarding efforts to completely eradicate HIV in infected individuals relates to the persistence of latently infected, resting CD4⁺ T cells carrying replication-competent HIV.[203,209,210] Latently infected, resting CD4⁺ T cells were first identified in chronically infected individuals by demonstrating the presence of integrated HIV DNA and replication-competent virus in these quiescent cells.[203,211] Numerous studies have since demonstrated that this pool of cells carrying infectious virus persists in essentially all infected individuals tested, who have received effective ART for considerable time, and in whom plasma viremia has been suppressed to below levels of detection, as measured by the most sensitive assays.[212–215] The mechanism by which latently infected, resting CD4⁺ T cells persist in vivo is unclear. The long lifespan (a half-life of up to 44 months) of infected resting CD4⁺ T cells has been proposed as a possible mechanism for the persistence of virus-infected cells, although low levels of ongoing viral replication may serve to continually replenish the latent viral reservoir in infected individuals receiving effective antiviral therapy.[212,213,215]

CD8⁺ T cells

Several anecdotal studies have shown that CD8⁺ T cells can sustain HIV replication when patients experience disease progression and their activated CD8⁺ T cells coexpress CD4.[216,217] However, recent data have indicated that the frequency of highly enriched CD8⁺ T cells carrying HIV is extremely low in infected individuals.[218] Therefore, it is unlikely that the various immunologic abnormalities observed in the CD8⁺ T cell compartment of HIV-infected individuals are the consequence of direct viral infection. It is also unlikely that CD8⁺ T cells contribute significantly to the viral burden of the infected individual. Finally, it is unlikely that CD8⁺ T cells serve as a significant reservoir for HIV.

Natural killer T cells

NK T cells are a subset of lymphocytes that have been shown to be susceptible to HIV infection.[219] These cells expressed

CD4 and coreceptors CXCR4 and CCR5. It is unlikely that infected NK T cells are of any clinical significance.

Dendritic cells

Dendritic cells play an important role in modulating the initiation of HIV infection. The primary role of dendritic cells is to capture antigen in peripheral tissues for transport to the lymphoid tissue compartments where proteins are processed and presented to T cells.[220] As discussed in a previous section, HIV can be captured by DC-SIGN expressed on dendritic cells, yet the question of whether these cells can be productively infected in vivo remains controversial.[31,221,222] However, a growing body of evidence suggests that dendritic cells fuel HIV replication by concentrating infectious viral particles on their surface and transmitting them to $CD4^+$ T cells.

Monocyte/macrophages

Monocyte/macrophages express low levels of CD4 and several chemokine coreceptors, therefore making them targets for productive HIV replication in vivo.[199,200] They also express high levels of heparan sulfate proteoglycans that facilitate adsorption of virus on to their surface by binding to gp120.[223] The degree of cytopathicity of virus for monocyte/macrophages is relatively low; hence, their longevity predicts that they may play an important role in the dissemination of HIV and serve as a viral reservoir that is relatively resistant to effective antiviral therapy.[224]

Follicular dendritic cells

FDC do not constitute a source for productive HIV replication; however, in the absence of ART, they represent a formidable extracellular reservoir for HIV by trapping an estimated 5–50 billion virions during the acute and subsequent stages of infection.[19,20,225] Virions bind to FDC in the form of immune complexes that include complement breakdown products and antibodies. Passage of FDC-bound virions to $CD4^+$ T cells is very effective and has been shown to occur even in the presence of neutralizing anti-HIV antibodies.[226] Furthermore, this extracellular reservoir is impervious to antiretroviral drugs and has been shown to persist for long periods of time, thus representing a long-lived reservoir that can contribute to the maintenance of low levels of viral replication even in the presence of effective ART.[227]

SUMMARY

This chapter has attempted to give an overview of HIV infection as it relates to the impairment and ultimate destruction of the immune system. While it is clear that the information that has been presented will be refined and even altered over the next several years, a few key elements of the disease deserve emphasis. First, among HIV-infected individuals who do not receive ART, the vast majority will progress to AIDS within an average of 10 years. Second, HIV infection, when left untreated, leads to a quantitative and qualitative destruction of $CD4^+$ T cells. Third, other cells of the immune system, including $CD8^+$ T cells, NK cells, B cell, and cells of the myeloid lineages, also become dysfunctional over the course of HIV disease. Fourth, a substantial proportion of the deleterious effects of HIV on the components of the immune system can be attributed to HIV-induced immune activation. Fifth, there is clearly a distinction to be made between the events that take place during the acute phase of the infection and the chronic, protracted phase of the infection. It remains to be determined whether therapeutic intervention during the acute phase of disease can reverse the level of immune dysfunction observed during the chronic phase of disease. Sixth, it is clear that the virus uses sanctuaries that enable it to persist, perhaps for the lifetime of the infected individual. Finally, effective correlates of immune protection have yet to be delineated, making the development of an effective vaccine problematic at this time.

22 Human T-cell Lymphotropic Viruses

William A. Blattner and Manhattan E. Charurat

The field of human retrovirology was inaugurated with the discovery of human T-cell lymphotropic-virus type 1 (HTLV-1), first isolated in 1979 from an African American patient with what is now recognized as adult T-cell leukemia lymphoma (ATL), but then classified as a variant form of cutaneous T-cell leukemia.[1] This discovery is the culmination of a long search for human retroviruses dating to the first decade of the twentieth century, and proof of such viruses in humans—along with the techniques developed—accelerated the discovery of the HIV family of viruses that cause acquired immune deficiency syndrome (AIDS). There are now a total of three known members of the HTLV family of viruses. HTLV-2 was discovered in 1982[2] and HTLV-3 discovered in 2005.[3,4] A single isolate, termed HTLV-4, has also been sequenced but has yet to be confirmed.[3] Beyond HTLV-1, the other members of this class of viruses do not have clear relationships with disease. All four HTLV viruses have related nonhuman primate homologues in old world primate species; the recent discovery of HTLV-3 and the putative HTLV-4 resulted from molecular epidemiologic field studies targeting persons from remote areas of Cameroon, where human–primate contact through hunting and processing of primate meat is common. The HTLV viruses entered man thousands of years ago and spread exogenously with HTLV-1 and -2 having a well-defined, worldwide distribution characterized by endemic foci and defined modes of transmission, while patterns for the newly discovered types beyond suspected enzootic spread are not yet determined. An estimated 15–25 million people worldwide harbor HTLV-1 infection with approximately 4% developing ATL and an equal number nonmalignant, HTLV-associated diseases.[5,6]

CLASSIFICATION AND MORPHOLOGY

CLASSIFICATION

Within the taxa of RNA reverse transcribing viruses, the HTLV viruses, along with bovine leukemia virus (BLV), are classified in the subfamily *Retroviridae* within the genus *Deltaretrovirus* (formerly termed oncovirus).[7] The oncogenic properties of these viruses and their molecular structure distinguish them from retroviruses HIV-1 and HIV-2, which are the member of the genus *Lentivirus*. Both *Deltaretroviruses* and *Lentiviruses* are capable of prolonged asymptomatic infection. In vitro, however, HIV-1 and HIV-2 have cytopathic effects on human T cells, whereas HTLV-1 and HTLV-2 are capable of transforming T cells, resulting in immortalized cell lines.

MORPHOLOGY

HTLV-1 and HTLV-2 are diploid single-stranded RNA viruses that replicate through cDNA, a proviral intermediate, via reverse transcriptase, a viral enzyme.[8] This strategy seems to be central to the ability of retroviruses to induce lifelong infection and diseases of long latency. Both viruses are approximately 100 nm in diameter, with a thin, electron-dense outer envelope and an electron-dense, roughly spherical core (Fig. 22-1).

REPLICATION CYCLE

The life cycle of the HTLV viruses involves attachment, membrane fusion, and reverse transcription from an RNA template to a circular DNA provirus that is transported to the cell nucleus and integrated into the host genome. There are, as detailed below, certain viral genes that process structural, genomic, and regulatory processes to create new virions. Both cell-free and cell-to-cell transmission of HTLV-1 are documented, but once infected, viral expansion is primarily through proliferation of proviral DNA-harboring cells rather than through repeated cycles of cell-to-cell infection.[9] Cell-free transmission engages a cell receptor that has eluded identification for almost 25 years; while cell-to-cell transmission engages additional structures. The discovery of the receptor for HTLV-1, Glut-1, the major vertebrate glucose transporter, derived from careful molecular analysis of the first 160 residues of the HTLV-1 and -2 envelopes. This envelope receptor binding

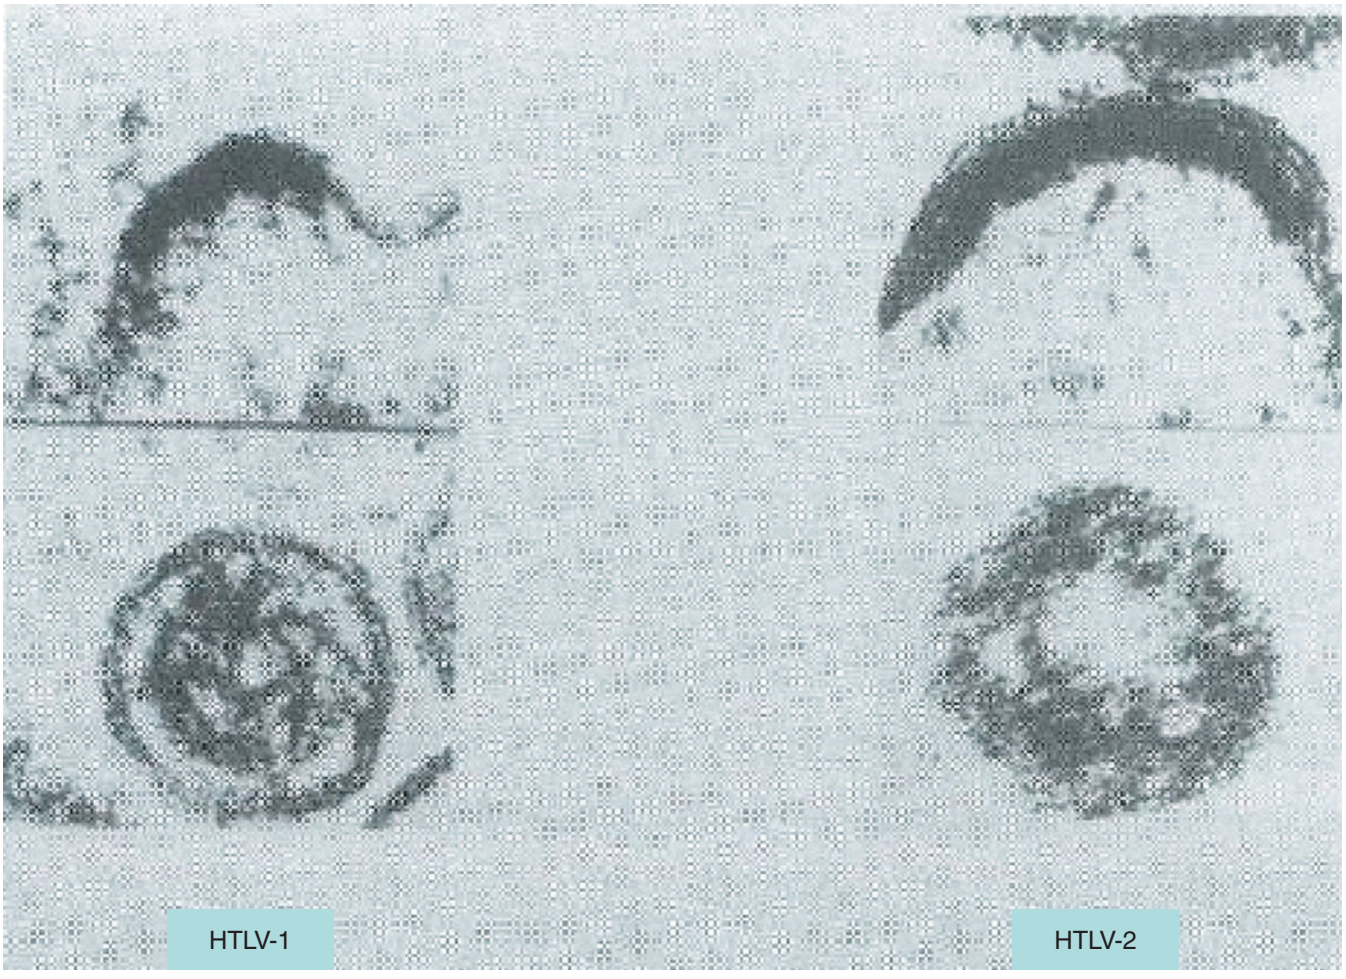

FIGURE 22-1. HTLV-I and HTLV-II have a diameter of approximately 100 nm. The budding particles are shown in the upper panel for each virus and the mature virion in the lower panel. The HTLV-I and HTLV-II viruses have a roughly spherical electron-dense core.

motif shares homology with similar structures of other *Gammaretrovirus* envelopes which also use multimembrane-spanning nutrient transporters as receptors.[10–12] Given the ubiquity of this receptor, the cellular trophism of HTLV-1 for CD4 cells and HTLV-2 for CD8 cells appears to involve postinfection transcriptional mechanisms, in contrast to HIV which targets CD4 cells through direct binding with a cell-specific receptor.[13] However, recent studies employing chimeric HTLV-1 and -2 viruses where envelope sequences were swapped demonstrate that cellular trophism is determined by type-specific envelope indicating that *env* is a major viral determinant for HTLV T-cell transformation trophism in vitro.[14] HTLV is preferentially transmitted via direct contact between infected and target cells, through a structure referred to as the virological synapse. The homologue of the *Drosophila* Dlg tumor suppressor (hDlg), a widely expressed scaffold protein implicated in the organization of multiprotein complexes, serves as a cellular binding partner of the envelope glycoprotein of HTLV-1 by stabilizing these glycoproteins at the virological synapse formed between infected and target cells, hence assisting the cell-to-cell transmission of the virus.[15] HTLV-1 employs a novel strategy to trigger synapse formation by employing the Tax protein in conjunction with ICAM-1 engagement to cause microtubule polarization. In this process, Tax provides an intracellular signal that synergizes with ICAM-1 engagement to cause the T-cell microtubule polarization observed at the virological synapse.[16]

MOLECULAR VIROLOGY AND PATHOGENESIS

GENOMIC STRUCTURE AND GENE EXPRESSION

The HTLV provirus genome consists of roughly 9000 nucleotides with two *long terminal repeats* (LTRs) at the 5′ and 3′ ends of the genome (Fig. 22-2A). LTRs mediate proviral integration and *cis*-acting regulatory elements important for viral transcription, viral mRNA processing, and reverse transcription. Retroviral genes generally code for large overlapping polyproteins that are processed by a virally encoded protease and cellular proteases into functional peptide products. The HTLV viruses share with other replication-competent

retroviruses the three main genomic regions of *gag* (group-specific antigen), *pol* (protease/polymerase/integrase), and *env* (envelope) (Table 22-1). However, unlike other vertebrate leukemia viruses, these *Deltaretroviruses* have an additional region called pX that contains four small open reading frames (ORFs): pX-I, pX-II, pX-III, and pX-IV, which employ alternative splicing for protein expression[17] (Fig. 22-2B). The pX ORFs III and IV encode two transcriptional regulatory proteins, the Tax and Rex proteins, which are involved in regulation of virus expression. As shown in Fig. 22-2A and B, two overlapping reading frames are involved in the expression of both of these gene products translated from a doubly spliced mRNA involving the initiation codon from *env* and the remaining sequences from the pX region. The pX ORFs I and II employ alternate splicing to code for other accessory and regulatory genes whose protein products involve cell cycle regulation.[18]

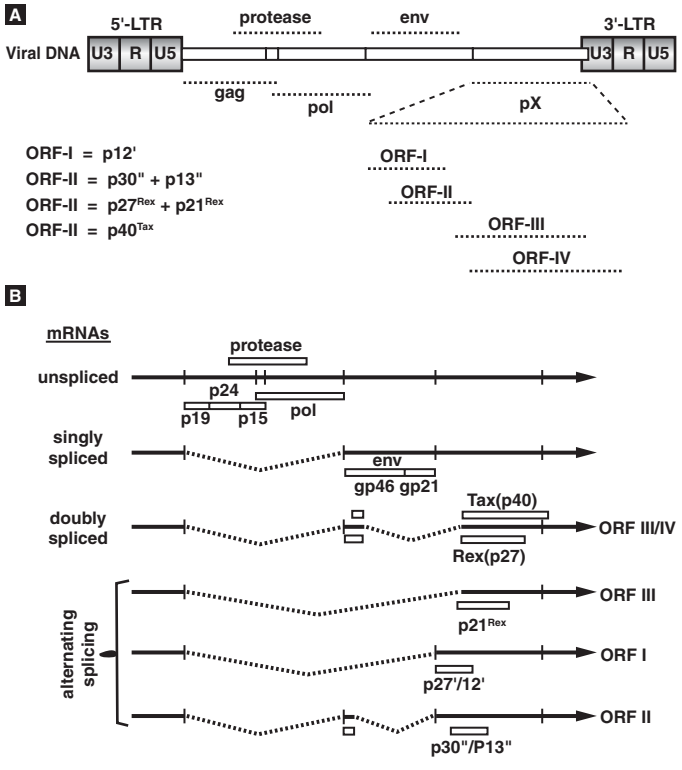

FIGURE 22-2. A. Genomic structure of HTLV-I. The long terminal repeat is organized into three regions: (1) US, R, and U3, which house the polyadenylation site; the (2) *rev* (response element); and (3) 21-bp enhancer transactivating response elements which are involved in controlling virus expression. *Gag*, group specific antigen, whose products form the skeleton of the virion (matrix, capsid, nucleocapsid, nucleic acid binding protein); *pol/pro*, gene for reverse transcriptase, integrase, and protease; *env*, envelope gene; *tax*, transactivator gene; *rex*, viral regulatory gene involved in promoting genomic RNA production. **B.** HTLV-1 employs several splicing strategies for producing various gene products including unspliced, singly spliced, doubly spliced, and alternatively spliced message. Table 22-1 summarizes the function of various gene products. (With permission from Azran I, Schavinsky-Khrapunsky Y, Aboud M. Role of Tax protein in human T-cell leukemia virus type-I leukemogenicity. *Retrovirology* 2004; 1: 20.)

LONG TERMINAL REPEAT

The LTR is organized into three regions: (1) U5, R, U3; (2) rev (response element); and (3) 21-bp response element (Fig. 22-2A). The U3 region contains sequences that control transcription of the provirus. The 21-bp repeats are necessary for *trans*-activating transcriptional activation involving Tax protein. The U3 region also contains sequences responsible for termination and polyadenylation of mRNAs.

GAG AND POL

The Gag proteins form the nucleocapsid, capsid, and matrix structures with a size of p15, p24, and p19, respectively. The *pol* gene encodes for several enzymes: protease that cleaves Gag and Gag-Pol polypeptides into proteins of the mature virion; reverse transcriptase that generates a double-stranded DNA from the RNA genome; and integrase that integrates viral DNA into the host-cell chromosomes. Production of the Gag proteins derives from the translation of the full-length mRNA, which yields a large precursor polypeptide that is subsequently cleaved by the virally coded protease. For the Pol proteins, production depends on translation made possible when the stop codon of the *gag* gene is bypassed, leading to a large polypeptide including *gag*- and *pol*-related proteins, which are subsequently cleaved into functional proteins by the viral protease.

ENV

The *env* gene encodes the major components of the viral coat: the surface glycoprotein of 46,000 MW (gp46) and the 21,000-MW transmembrane glycoprotein (gp2 l). The envelope is involved in defining cell trophism of HTLV-1 and -2.[14] Production of the Env surface and transmembrane proteins involves translation of a spliced message (Fig. 22-2A) that results in an envelope precursor, cleaved into the subunits.

TAX

From the point of view of viral pathogenesis of HTLV-associated diseases, particularly ATL, the gene products of the pX region—especially HTLV-1 Tax—are among the most intriguing viral proteins in human virology. HTLV-1 Tax is a 40-kilodalton (kDa) protein (p40), while HTLV-2 Tax is a 37-kDa protein (p37).[19,20] These proteins localize primarily to the nucleus of infected cells, although small amounts of Tax have been found in the cytoplasm and at the viral synapse at the cell surface. The Tax proteins are responsible for enhanced transcription of viral and cellular gene products and are essential for transformation of human T-lymphocytes.[21] The Tax viral regulatory protein for HTLV-1, like its counterpart, Tat of HIV-1, plays an important role in promoting viral growth and disease pathogenesis. Both promote transacting, transcriptional

Table 22-1. Major Structural and Regulatory Proteins of HTLV-1

Viral Gene	Gene Product (Protein Size in Kilodalton)	Function
LTR		Regulation of viral gene expression, integration of provirus into host genetic material, and regulation of virion production
gag	p15	Nucleocapsid is a small basic protein found in the virion in association with the genome RNA characterized with zinc finger motifs associated with nucleic acid binding
gag	p19	Matrix protein forms close linkage to internal surface of viral envelop via myristic acid
gag	p24	Capsid protein forms the major internal structural feature of the core shell of the virion
gag	p53	Precursor protein for other gag
pol	Integrase	Integrates viral DNA into the host-cell chromosomes
pol	Reverse transcriptase (95 kDa)	Reverse transcriptase generates a double-stranded DNA from the RNA genome
pro	Protease (p14)	Cleaves Gag and Gag-Pol polypeptides into proteins of the mature virion
env	gp46	Envelop surface glycoprotein attached to surface lipid bilayer involved in virion binding to target cell
env	p21e	Envelop transmembrane protein
pX	Tax (p40)	Transactivator for enhanced transcription of viral and cellular gene products
pX	Rex (p27/p21)	Regulator of expression of virion proteins for HTLV stabilizes viral mRNAs and modulates the splicing and transport from the nucleus of viral RNA
pX	ORF I ($p12^{I}$)	Activation of STAT5 and interference with MHC I trafficking; elevation of cytoplasmic calcium which is antecedent to T-cell activation
pX	ORF II ($p30^{II}$, $p13^{II}$)	Inhibition of acetyltranferase activity of P/CAF on histones and stabilization of p53. Functions as "latency" protein

activation of the LTR, but the effect of Tax appears to be mediated via expression of cellular growth factors that are abundantly activated by Tax through its transactivation properties. This transactivation of cellular genes by Tax not only facilitates viral replication but has also emerged as a cofactor in disease pathogenesis. The *tax* gene is responsible for the transactivation of virus transcription via *tax*-responsive elements of a number of regulatory enhancers such as the 21-bp enhancer, the nuclear factor-kB (NF-κβ) binding site, and serum-responsive element. Such promoter interactions lead to activation of a number of cellular genes such as those encoding interleukin-2 (IL-2) and the IL-2 receptor (IL-2R), which promote cell proliferation. Additionally, *tax* activates the proto-oncogenes c-*fos* and c-*erg*, as well as the gene for granulocyte-macrophage colony stimulating factor, an array of early response genes, the human lymphotoxin gene, and parathyroid hormone-related protein gene, while it transrepresses the β-polymerase gene. Overproduction of IFN-γ via this pathway has been implicated in promoting chronic inflammation that characterizes diseases such as HAM/TSP.[22] The mechanism by which Tax interacts with a variety of cell regulatory elements involves nuclear regulatory elements (the NF-κβ pathway); Tax also operates cytoplasmically through the induction of nuclear translocation of active transcriptional factors, but not via pathways typical of other oncoviral proteins that target tumor suppressor genes.[23] The potential role of Tax in leukemogenesis is detailed below.

REX

The *rex* gene of HTLV-1 and HTLV-2 encodes two protein species in each virus. In HTLV-1, a 27-kDa protein (p27) and

a 21-kDa protein (p21) appear to result from the use of alternative initiator methionine codons. In HTLV-2, however, a 26-kDa protein appears to be formed by phosphorylation of a serine residue in a 24-kDa protein.[24] Unlike the products of *tax* gene, Rex does not directly regulate RNA transcription but, instead, appears to act chiefly at a posttranscriptional level to regulate viral gene expression. The Rex (regulator of expression of virion proteins for HTLV) stabilizes viral mRNA and is essential for export of full-length *gag/pol* and single-spliced *env* mRNA from the nucleus to cytoplasm.[25] This function is analogous to that of Rev in HIV-1 and HIV-2.[26–28] Rex localizes to the nucleus and specifically to the nucleoli of infected cells.[29,30] Phosphorylated Rex binds with high affinity to *cis*-acting RNA sequences, called Rex-responsive elements, in the viral mRNA.[31–33] This interaction facilitates the export of mRNA. Rex binding also inhibits mRNA splicing by preventing early steps in spliceosome assembly.[34] As a consequence of the accumulation of Rex in the cell, there is an accumulation of unspliced and single-spliced mRNA, favoring the production of structural proteins (Gag and Env). This is accompanied by a decrease in the levels of double-spliced mRNA encoding Tax and Rex. Rex accumulation may also inhibit *tax*, thus slowing viral transcription.[35] A fine balance between *tax* and *rex* expression and function may dictate the rate of viral replication within infected cells.

OTHER PROTEINS ENCODED BY THE pX REGION

pX ORF I, produced by a similar double-splicing mechanism to the gene products of pX ORF III and IV, codes for a hydrophobic 12-kDa protein, $p12^{I}$, and pX ORF II result in the production of two nuclear proteins, $p13^{II}$ and $p\ 30^{II}$.[18] In addition to activating nuclear factor of activated T-cells[36] (NFAT), $p12^{I}$ localizes in the endoplasmic reticulum and *cis*-Golgi apparatus and elevates cytoplasmic calcium which is antecedent to T-cell activation and essential for establishing persistent infection.[37] Other major structural and regulatory proteins of HTLV-1 are summarized in Table 22-1. The gene products of pX ORF I and II also appear to impact cell proliferation and modulate host-immune responses to HTLV-1 infection.[38] Tax and the ORF I and II gene products may play an integral role in pathogenesis of HTLV-associated diseases through their effects on cyclins that regulate cell growth.

MOLECULAR COMPARISON OF HTLV-1 AND -2

There is 65% overall nucleotide homology between HTLV-1 and HTLV-2 isolates. For the regions of HTLV-3 that have been sequenced, the distances between HTLV-3 and HTLV-1 and -2 are comparable to the distances between HTLV-1 and HTLV-2. Homology is lowest within the LTRs (30%) and highest within the 3′ Tax and Rex regulatory genes (75–80%).[39–41] The polymerase region contains the largest ORF in the HTLV genome, potentially able to encode an 896-amino acid product for HTLV-1 and a 982-amino acid product for HTLV-2, which share only 56% homology between types.

DETECTION

Several commercially available enzyme-linked immunosorbent assays (ELISA) are the mainstay of HTLV diagnosis, but are not able to distinguish between HTLV-1 and HTLV-2 infection.[42] The Western immunoblot is the standard confirmatory test,[43] and current versions use recombinant synthetic peptides both to confirm positivity and distinguish virus type based on reactivity to both *gag* and *env* gene products. The interpretation of WB results such as reactivities to *gag*-encoded proteins (p19, p24, or p53) without reactivity to *env*-encoded glycoproteins (gp21, gp46) is still a question that needs to be solved in order to avoid overestimating the rate of HTLV-1/2 seroprevalence.[44–46] The polymerase chain reaction technique (PCR) has proven useful in epidemiologic studies for precisely confirming virus type and more recently for quantifying viral load.[9] PCR has also been useful for confirming that infection in the absence of antibody is extremely rare.[47]

WORLDWIDE EPIDEMIOLOGY OF HTLV-1

Geographically, HTLV-1 is widely disseminated and estimated to infect 15–25 million persons worldwide.[6] As shown in Fig. 22-3, distribution is not uniform, with endemic clustering of virus in selected populations in Japan, the Caribbean, central and west Africa, and pockets in Iran and south India. Molecular epidemiology suggests that the three major subtypes identified in man arose from separate interspecies transmissions from simians to humans.[48] The three major lineages are Melanesian (Papua New Guinea, Melanesia, and Australian aborigines), Central African, and Cosmopolitan groups. Within the Cosmopolitan group are four subtypes: (A) Transcontinental, (B) Japanese, (C) West African, and (D) North African. Within these subtypes, there is a high degree of sequence stability of the viral genome despite hundreds of thousands of years of evolution since human adaptations of these viruses of simian T-lymphotropic retrovirus origin entered man. The stability of HTLV-1 arises because HTLV-1, compared to HIV-1, favors viral expansion through proliferation of proviral DNA-harboring cells rather than infection of new cells by cell-free virions.[49] As such, the replicative machinery of the cell, rather than the error-prone viral reverse transcriptase, is responsible for maintaining viral genomic stability. HTLV-1 is distributed at low endemicity worldwide but has unique macro- and microepidemiologic features. Virus prevalence varies significantly by geographic region, racial and/or ethnic group, and risk-group subpopulation.[50] Geographic clustering is

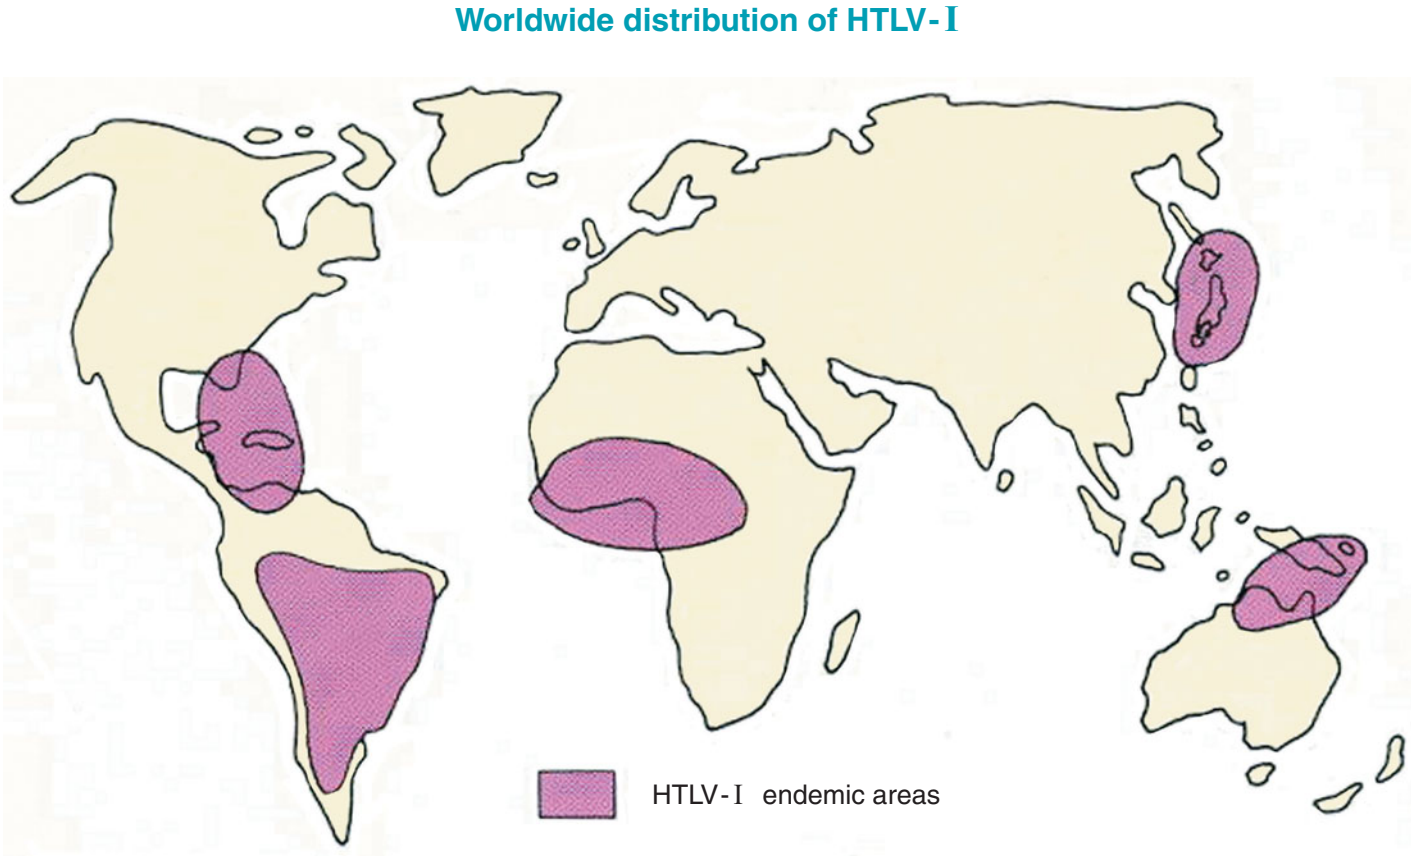

FIGURE 22-3. Geographic distribution of five molecular subtypes of HTLV-I. HTLV-I is endemic to some regions of the world, especially southwest Japan, the Caribbean islands, Southern India, Central Iran, the countries surrounding the Caribbean basin, parts of South America, and parts of Central Africa.

evident in that adjacent national populations are characterized by markedly different prevalence rates. Microgeographic clustering is also observed within endemic regions, with adjacent regions, villages, houses, and families having disparate prevalence rates.

■ ASIA

Geographic clustering of HTLV-1 was first documented in southern Japan (Kyushu, Shikoku, and Okinawa),[51] where population prevalence levels of up to 30% have been recorded, but infection was also seen in villages in Honshu and in Hokkaido in the north among the aboriginal Ainu[52,53] and among migrants from these endemic areas. Based on *gag* and *env* sequencing, the virus prototype from Japan is termed Cosmopolitan because it is found in other parts of the world, including Africa and the Caribbean, but very rarely in the rest of Asia. HTLV-1 seems to be largely absent in mainland China, Taiwan, Korea, and Vietnam.[50] Isolates from southern India map with subgroup A (Transcontinental subgroup) of the Cosmopolitan group with diversity representing examples of South African/Caribbean, Middle Eastern, and East Asian subtypes.[54,55] The Seychelles in the Indian Ocean also appear to be endemic for HTLV-1, probably again reflecting migration of peoples of African descent.[56] Melanesia has an unexpectedly high seroprevalence rate, particularly in Papua New Guinea,[57] where a rate of 14% has been recorded in certain population groups. High rates are also noted in Australian aborigines and in some areas of the Solomon Islands but not in Polynesia.[57] These Melanesian and Micronesian isolates display the greatest sequence diversity of all HTLV subtypes, implying that they entered when these populations were cut off from outside populations many thousands of years earlier.

■ CARIBBEAN BASIN

This is a well-studied endemic focus of HTLV-1 infection. Soon after the description of ATL in Japan, it was observed that cases of ATL occurred among Caribbean migrants to the United States[58] and the United Kingdom, and that the virus and disease were prevalent in the region.[59] Serosurveys have since documented significant rates of positivity in Jamaica, Trinidad and Tobago, the French Antilles, Barbados, St. Lucia, Haiti, and the Dominican Republic.[60–63] Adjacent areas of South America, including Venezuela, Guyana, and Surinam, and some areas of Central America, including Panama and Honduras, harbor significant foci of seropositivity.[64] Infection seems to correlate with African-derived New World

populations, fueling the speculation that HTLV-1 was brought to the New World via the slave trade. In Trinidad, where the population is equally divided between Afro-Caribbeans and persons of Indo-Asian descent, and despite these two groups sharing a common environment for over 100 years, HTLV-1 positivity is confined almost exclusively to persons of African descent.[61,65] These data support the concept of an African origin of the virus in the region. In Jamaica, a population survey provided no evidence of microgeographic clustering such as that reported in Japan.[66] Socioeconomic group appears to be a strong determinant of seropositivity, and may reflect host factors that serve to maintain low endemicity. Level of sexual exposure is also important, and men and women attending sexually transmitted disease (STD) clinics have markedly elevated rates of seropositivity in both Jamaica and Trinidad.[67,68] Among blood donors, usually healthy young adults, rates are generally lower than in other population groups.[69]

SOUTH AND CENTRAL AMERICA

Endemic foci of HTLV-1 have been observed in South and Central America, but the distribution of HTLV-1 infection is markedly varied and detection is confounded by the coincidence of HTLV-2 infection in many of the same regions. Along the Pacific Coast of Colombia, in an area with an unusually high rate of HTLV-1-associated neurologic disease, very high rates of HTLV-1 seropositivity have been reported among persons largely of African descent.[70] Altitude is also a significant correlate of HTLV-1 seropositivity in Colombia. Controlling for race, HTLV-1 rates are higher in persons residing at low altitude; controlling for altitude, rates are higher in persons of African compared with Mestizo background. Other areas in South America with documented foci of HTLV-1 include Brazil, Peru, and Chile.[71] The majority of seropositives are persons of African descent, except in Brazil, but some isolated Amerindian groups usually linked to endemic HTLV-2 infection have been found to harbor HTLV-1. One survey in Chile identified pockets of HTLV-I in persons of non-African descent, which raises the possibility of a transpacific viral passage.[72] Study of DNA from pre-Columbian mummies have confirmed that the molecular characteristics of this Chilean virus are closely related to the virus from Japan.[73]

NORTH AMERICA

HTLV-1 infection has been documented in African Americans, in certain Alaskan population groups, and in migrants from endemic areas. Blood donors in the United States have rates of HTLV-1/2 infection of 0.43 per 1000, with approximately half the positives carrying HTLV-2.[74] Among HTLV-1-positive cases, the demographic profile of the positive donor includes direct or indirect links to known viral endemic areas.[75] HTLV prevalence is higher among tissue donors than among blood donors, with a prevalence rate of 0.068% and incidence of 5.586 per 100,000 person-years (py).[76] Various population surveys including military populations show a similar pattern, with persons with ancestry in a viral endemic region having elevated rates of seropositivity.[77] Infection acquired early in life in a viral-endemic area can be carried to a nonendemic area and even transmitted to the next generation. Examples of such migrant groups include persons born in Okinawa who migrated to Hawaii and individuals from the Caribbean who came to the United States.[78] Another source of seropositivity of persons residing in the United States are persons who have experienced sexual exposure as part of travel in viral-endemic areas or through marriage to a seropositive person from a viral-endemic area.[79]

AFRICA

Numerous countries, including Ivory Coast, Cameroon, Ghana, Nigeria, Democratic Republic of Congo (DRC), Kenya, Tanzania, and South Africa, have elevated rates of HTLV-1 seropositivity, but significant artifacts resulting from false-positive results on screening and confirmatory assays have made it difficult to precisely quantify rates.[46,80–82] In some instances, this "false positivity" has been shown to be due to new variant viruses, HTLV-3 and -4.[3,4,83] Population-based surveys in Africa have not been specifically designed to fully characterize the patterns of HTLV-1 occurrence, and therefore detailed epidemiologic profiles have not been developed. In the DRC (formerly Zaire), an area of microgeographic clustering of HTLV-1 was detected in the northern equatorial region by surveying HTLV-1 among female prostitutes from different provinces residing in the capitol, Kinshasa.[84] Reports suggest that HTLV-1-associated neurologic disease is common in this area,[85] which is now also the epicenter for the DRC HIV-1 epidemic. A cluster of this neurologic disease has also been detected in Senegal.[86]

EUROPE AND THE MIDDLE EAST

In Europe, most infected individuals are migrants from viral-endemic areas.[50] In the Middle East, a focus of HTLV-1 has been detected among Iranian Jews from northeastern Iran but residing now in Israel and New York.[87] Studies in Iran demonstrate a focus of viral endemicity among persons residing in the Mashad region.[88] The high frequency of intermarriage among the Mashad people could have amplified and sustained HTLV-1 in this isolated population, and the proximity to ancient transcontinental trade routes could have contributed to viral introduction.

DEMOGRAPHIC FEATURES AND EPIDEMIC BEHAVIOR OF HTLV-1

There is a consistent age-dependent increase in HTLV-1 seroprevalence in practically all geographic areas studied. For example, the age-related HTLV-1 prevalence patterns in

Jamaica and Okinawa share similar features, although the overall prevalence of infection in Okinawa is higher than in Jamaica (Fig. 22-4). Characteristically, the rise in both male and female rates begins in adolescence, but prevalence levels off in males around age 40, while it continues to rise in females.[52,60] This may be explained by continued exposure throughout life, primarily via sexual exposure but with more efficient male-to-female transmission, and a cohort effect where declining rates of infection in younger birth cohorts give the appearance of rising rates in older birth cohorts.[89]

There is considerable evidence to document that new infections are taking place, in particular among sexually active populations such as attendees of STD clinics.[90] For example, the rates of seroconversion in STD clinics in Jamaica and Trinidad could potentially account for the age-dependent pattern and the female-to-male rate differential. Among discordant couples identified in the context of transfusion transmission of the index case, the male-to-female rate is estimated at 1.2 transmissions/100 py (95% CI, 0.1–4.3) and 0.4 transmissions/100 py (95% CI, 0.05–1.6), consistent with more efficient male-to-female rather than female-to-male transmission.[91] In Japan, there is evidence to support a cohort effect due to a decline in infection rates in younger birth cohorts contributing to the apparent age-dependent rise.[92] Possible explanations for this declining rate include changes in standard of living leading to improved nutrition, changes in breast-feeding patterns, elimination of environmental cofactors that facilitate transmission, and declines in other STDs that amplify transmission. Among migrants from Japan to Hawaii, HTLV-1 rates were highest in those born in Okinawa, lower in first-generation Hawaiian born, and lowest in the grandchildren of migrants.[93] The likely factors explaining this pattern of declining prevalence include changes in environmental cofactors for transmission and improvement in socioeconomic status. Nevertheless, there is evidence in Japan of both more common male-to-female and less common female-to-male transmission in older HTLV-1-discordant couples, which may explain the continued rise in female prevalence after that in males plateaus.[94]

EPIDEMIOLOGY OF HTLV-2

HTLV-2 shares some features with HTLV-1 in that endemic clusters have been identified in aboriginal people including selected native American populations and in some isolated populations of pigmys in central Africa.[95,96] Amerindians residing in North, Central, and South America have varying rates of positivity for HTLV-2. Pockets of relatively high prevalence are encountered among the Seminoles in south Florida and the Pueblo and Navajo in New Mexico but not among various tribal groups in Alaska, a pattern also observed in South America: some indigenous populations in Brazil in the Amazon River basin and Argentina and Paraguay have high rates of HTLV-2.[97] In Central America, the Guaymi Indians, residing in northeastern Panama near the Costa Rican border, have high seroprevalence rates, but this is not the case for the Guaymi living in southwest Panama. Worldwide spread of the virus has occurred via injection drug use, and very high rates are reported among

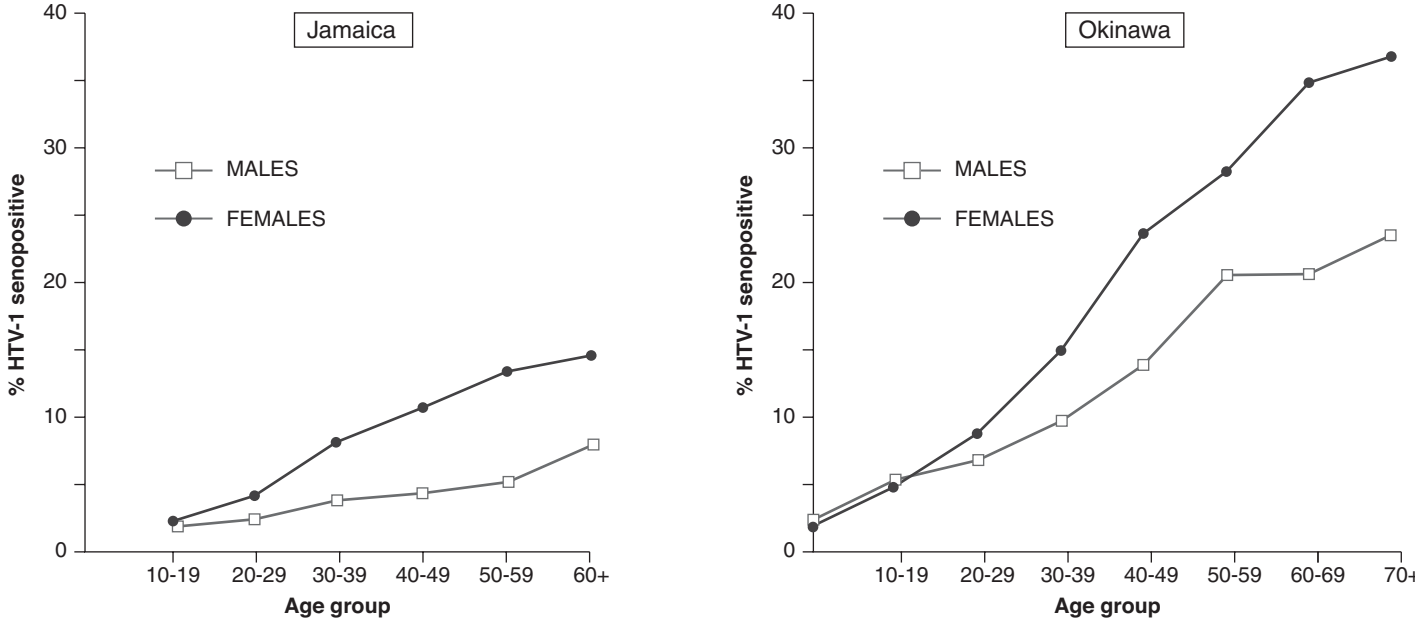

FIGURE 22-4. Age-specific seroprevalence of HTLV-I in Jamaica and Okinawa. There is a characteristic pattern of higher rates in females than in males, with an age-dependent increase in seroprevalence and a plateauing in males at age 50 but an increase in females. Seroepidemiologic study of antibody to adult T-cell leukemia virus in Okinawa, Japan. *Am J Epidemiol* 1986; 123: 41–47; Murphy EL, Figueroa JP, Gibbs WN, et al. Human T-lymphotropic virus type I (HTLV-I) seroprevalence in Jamaica: I. Demographic determinants. *Am J Epidemiol* 1991; 133: 1114–1124.)

injection drug users in the United States and Europe. Samples from injection drug users dating back to the 1960s document evidence of HTLV-2 infection with prevalence rates of 10–15% and higher. From a molecular epidemiology perspective, HTLV-2 includes four subtypes which appear to originate from a common human ancestor virus that emerged from only one simian-to-human transmission, and the evolutionary pattern in human and primates is separate without the repeated interspecies jumps that characterize HTLV-1.[49] However, the epidemic spread of HTLV-2 through intravenous drug users to many geographical regions is associated with a 150–350-fold higher mutation rate than observed in endemic strains among aboriginal peoples. The implications of this shift on viral virulence is unknown.[49] HTLV-2, like HTLV-1, has a characteristic age-dependent increase in the seroprevalence of HTLV-2 antibodies, but without gender differences at any age. Unusually high rates of seropositivity in older groups of injecting drug users in the United States have been linked to the sharing of injection equipment, increasing the possibility of a "cohort effect" resulting from the use of injection techniques that increase risk of blood exposure (e.g., using an eyedropper in place of a syringe).

MODES OF HTLV TRANSMISSION

Table 22-2 shows the list of the routes, modes, and cofactors associated with HTLV-1 and HTLV-2 transmission. The available evidence suggests that routes of transmission of HTLV-2 are similar to those of HTLV-1.

SEXUAL TRANSMISSION

Sexual transmission of HTLV-1 occurs among married couples and within sexually active population groups such as commercial sex workers and homosexual/bisexual men. Male-to-female, female-to-male, and male-to-male transmission has been documented. In a well-conducted study of secondary transmission to sexual partners following transfusion-acquired infection, the rate found was 0.6 transmissions/100 py (95% CI, 0.2–1.6).[91] Cross-sectional surveys of heterosexual couples show an excess of couples concordant for HTLV-1 infection; among discordant couples, the female partner is more likely than the male to be positive, except among younger couples, where the low prevalence in husbands approaches that in wives.[98] The difference in HTLV-1 prevalence between men and women probably reflects the low efficiency of female-to-male transmission as noted above,[91] which requires longstanding sexual exposure, except in the presence of cofactors that interrupt normal mucosal barriers.

Even in the absence of obvious cofactors, female-to-male transmission does occur, as seen in a group of Marine Corps veterans married to seropositive Okinawan women[99] and in a community-based cohort study conducted in the prefecture of Miyazaki, southwestern Japan, in which over 100 discordant married couples have been followed.[100] Seroconversions have been documented in both husbands and wives, with transmission taking place up to the seventh decade. Of 33 seronegative wives married to carrier husbands, 9 (27.3%) converted to antibody-positive status, whereas 4 (6.7%) of 60 initially seronegative husbands of carrier wives seroconverted. Based on these data, the incidence rate of male-to-female transmission (4.9 per 100 py) is 4.2 times higher than that of female-to-male transmission (1.2 per 100 py), with the 95% CI around this estimate of relative risk being 1.3–13.5. While this rate is higher, the relative efficiency (3 or 4:1) of male-to-female versus female-to-male is similar to that reported among sexual partners of seroconverting transfusion recipients

Table 22-2. Transmission of HTLV-1/2

	HTLV-1	HTLV-2
Mode of transmission		
Mother to infant		
Transplacental	Low efficiency	Not known
Breast milk	High efficiency	Probable but not quantified
Sexual		
Male to female	Most efficient	Yes but not quantified
Female to male	Efficient	Yes but not quantified
Male to male	Efficient	Not known
Parenteral		
Blood transfusion	Very efficient	Very efficient
Intravenous drug use	Efficient	More efficient
Cofactors of transmission		
Elevated virus load		
Mother to infant	Yes	Not known
Heterosexual	Yes	Not known
Ulcerative genital lesions	Yes	Not known
Cellular transfusion products	Yes	Yes
Sharing of needles and paraphernalia	Yes	Yes

(male-to-female 1.2 transmissions/100 py [95% CI, 0.1–4.3]) and compared to 0.4 transmissions/100 py (95% CI, 0.05–1.6) for female-to-male transmission.[91] In contrast, among 359 concordantly negative couples from the Japanese cohort, the seroincidence was 0.048 per 100 py for females and zero for males over the same period.[94] The late seroconversion of a discordant partner with a longstanding sexual relationship may be explained in part by increases in virus titer, a marker of virus load that may occur as the couple ages. This relationship has been more directly documented using quantitative PCR; the presence of anti-*tax* antibody is also associated with heightened transmission in this setting.[101]

Markers of enhanced sexual activity are linked to HTLV-1 transmission. A cross-sectional study conducted in 1989 in Fukuoka Prefecture, Japan, documented a significantly higher HTLV-1 prevalence of 5.1% in female prostitutes, 5.7% in female STD patients, and 2.8% in male STD patients when compared with age- and sex-matched blood donor controls.[90] Among those with STDs, female patients with syphilis and gonorrhea and male patients with nongonococcal urethritis had a significantly higher HTLV-1 prevalence than controls. Among attenders of an STD clinic in Jamaica, seropositivity in females but not males was associated with a large number of sexual partners.[67] In a group of homosexual men in Trinidad, a higher number of lifetime partners and longer duration of sexual activity were associated with HTLV-1 seropositivity.[102] The coincidence of other STDs involving an ulcerative genital lesion appears to amplify the risk of horizontal HTLV-1 transmission. In the Jamaican study, current diagnosis of syphilis, among other factors, was associated with HTLV-1 positivity in the STD clinic population.[103] A study of Haitian women infected with HTLV-1 (n = 45) and HIV-1 (n = 95) found a significantly higher coincidence of antibodies to herpes simplex virus type 2 (HSV-2) in both the groups, consistent with the notion that recurrent disruptions of the mucous membranes caused by HSV-2 infections facilitate transmission of both the viruses.[104]

Studies in Latin America have documented the role of sexual transmission of HTLV-1 in commercial sex workers. In Peru, 467 prostitutes from the capital, Lima, had an overall prevalence of 21.8% compared with 3.1% overall among 510 antenatal clinic patients.[105] The estimate of annual HTLV-1 incidence in this prostitute population over a 3-year period was 1.6%.[106] Further study of 400 sex workers in Lima showed that the prevalence of HTLV-1 increased almost linearly with the duration of prostitution, reaching 16% in those with over 6 years' experience. In a multivariate analysis, duration of prostitution, lack of consistent condom use, and past infection with *Chlamydia trachomatis* were independent risk factors for HTLV-1 infection.[107] In Paraguay, HTLV-1 prevalence was 2.2% in 178 city prostitutes and 3.4% among 117 gay/bisexual men.[108] However, in Chile, where the population prevalence appears to be much lower, serologic testing of 502 prostitutes from Santiago revealed a 0.8% prevalence, similar to other population-based groups. Additional evidence is available from other parts of the world to support enhanced HTLV-1 transmission in population groups with greater sexual exposure.[109,110]

PARENTERAL TRANSMISSION

Transfusion involving the cellular components of blood is associated with transmission of HTLV-1; approximately 50% of recipients of 1 unit of HTLV-1-positive blood seroconvert.[111] Transfusion of plasma or cryoprecipitate is not associated with transmission, and whole blood or packed cells are less likely to be infectious if stored for prolonged periods (greater than 1 week), presumably because of the loss of white blood cell viability.[112] Elevated antibody titer (a surrogate for virus load) is not associated with increased risk for transmission.[74] Recipients on immunosuppressive drugs such as corticosteroids are more susceptible to infection, possibly due to a blunting of the immune response to HTLV-1 in the recipient. Blood bank screening was implemented in the United States following reports of HTLV-associated myelopathy in transfusion recipients. U.S. donors with a positive Western blot have a 50% HTLV-1 and a 50% HTLV-2 distribution; risk factors for seropositivity include intravenous drug abuse, birthplace in a viral-endemic area, and sexual contact with a person with this profile.[75,113] Japanese studies clearly demonstrate that blood donor screening effectively prevents transfusion transmission.[114] Intravenous drug use is also a significant vector for the spread of HTLV-1, but most transmission associated with intravenous drug use involves HTLV-2.[115]

MOTHER–INFANT TRANSMISSION

Mother-to-child transmission may account for up to 15% of all cumulative infections,[116] and this early-life infection may disproportionately contribute to the subsequent risk for adult T-cell leukemia.[117] HTLV-1 has been detected in breast milk and transmitted via breast milk in nonhuman primate and rabbit animal models.[118] Intervention trials done in Japan, where bottle feeding is widespread, showed that breast-feeding accounts for most perinatal transmission.[119] Bottle-fed infants experienced a 1–2% seroconversion rate, whereas breast-fed infants experienced a 20% seroconversion rate. In a prospective study conducted in Jamaica,[120] among children born from HTLV-1 positive mothers in follow-up for more than 2 years, 32% of children breast-fed for 12 months or longer were HTLV-1 seropositive, compared with 9% of those breast-fed for less than 12 months. These data strongly suggest that limiting the duration of breast-feeding to less than 12 months might significantly reduce mother-to-child transmission of HTLV-1. Serial Western blots of seroconverting infants of HTLV-1-positive mothers show a pattern in which maternal antibodies are present in

the first few months, but all bands usually disappear at about 6 months of age and new bands subsequently appear in association with native infection. For some infants, breast-feeding had ceased several months prior to seroconversion, but latent HTLV-1 viral infection was not detected by PCR of peripheral blood. Viral load measured by maternal antibody titer and viral antigen level on short-term culture is a significant predictor of transmission; presence of antibody to the *tax* antigen is also associated with transmission. Directly measured provirus load in breast milk is the strongest predictor of risk of transmission to children, with the risk of transmission increasing from 4.7/1000 person-months when the provirus load in breast milk was <0.18% to 28.7/1000 person-months when it was >1.5%.[121] Elevated HTLV-1 transmission was reported in association with high-titer antibodies to certain envelope epitopes; this suggests that enhancing antibodies might contribute to transmission.[122] Additionally, while particular HLA types were not associated, high levels of concordance between maternal and child HLA types are strongly associated with mother-to-child transmission, suggesting a role for cell-mediated immune responses in preventing transmission.[123]

MODES OF HTLV-2 TRANSMISSION

Sexual transmission of HTLV-2 has been difficult to study in the United States because of the high frequency of injection drug use among the study populations. In virtually every study of female prostitutes, injection drug use was the major risk factor for seropositivity. Studies in aboriginal populations do document evidence for sexual transmission. For example, a case-control study conducted among the Guaymi Indians of Panama showed among females that early sexual intercourse and number of lifetime sex partners were associated with increased risk. Among males, intercourse with prostitutes was associated with HTLV-2 seropositivity.[124] Among blood donors in the United States, high viral load and duration of relationship in concordant couples support a role for sexual transmission as well.[125]

HTLV-1 AND HTLV-2 DISEASE ASSOCIATIONS

Since the first description of the link between ATL and HTLV-1, the list of possible associations has expanded greatly (Table 22-2). ATL is a clinicopathologic entity first described in 1977 in Japan[126] and subsequently shown to be caused by HTLV-1, representing the only disease where a virus is directly involved in leukemogenesis. Other HTLV-1-associated diseases include a chronic neurologic disease called *HTLV-1-associated myelopathy/tropical spastic paraparesis* HAM/TSP),[127] a chronic skin condition of children called *infective derm-atitis,*[128] and a variety of inflammatory/autoimmune syndromes thought to result from immune perturbation.

ADULT T-CELL LEUKEMIA/LYMPHOMA

ATL was first reported in Japan as a mature T-cell leukemia/lymphoma with a spectrum of clinical signs and symptoms including peripheral blood involvement, characteristic polylobated mononuclear cells called "flower" cells, hypercalcemia, lytic bone lesions, and cutaneous, nodal, and extranodal lymphoma exhibiting considerable pleomorphism.[129,130] HTLV-1 was originally isolated in the United States from an African American male patient presenting with features of classic ATL but originally diagnosed as having an aggressive variant of mycosis fungoides.[1]

HTLV-1 and ATL

Studies in Japan and the Caribbean and among migrants from these areas unequivocally linked HTLV-1 to ATL[59,58] and through molecular analysis documented monoclonal integration of HTLV-1 in the genome of the cell. ATL cases have been reported in Africa, North and South America, the Caribbean region, the Middle East, Taiwan, Japan, and in Australian aborigines.[131] ATL occurs with equal frequency in men and women, despite the disproportionate occurrence of HTLV-1 infection in women—a finding consistent with the hypothesis that most ATL is associated with early-life infection with HTLV-1 when the sex ratio is equal.[132–135] For unexplained reasons, the peak incidence of ATL is in the fifties in Japan and a decade younger in the West Indies.[58] In persons under the age of 50, HTLV-1 is the chief cause of lymphoma in viral-endemic areas.[136]

Risk of ATL among HTLV-1 carriers
