Several adhesins and possible antigenic variants in surface exposed proteins of *M. hominis* have been chararacterized.[371–377] Attachment to eukaryotic cells, demonstrated with a variety of cell lines including HeLa cells, is believed to be due to surface-exposed proteins because treatment of *M. hominis* with trypsin and pronase reduces adherence.[378] Two proteins, the P100 and the Vaa antigen (variable adherence-associated antigen, aka P50), have been identified as adhesins based on inhibition experiments with monoclonal antibodies and purified proteins. The Vaa antigen is perhaps the best studied and contains one to four copies of tandem homologous, but not identical, cassettes of 121 amino acids. The number of copies of this cassette varies within a single strain, resulting in size-variant proteins.[374,376] In addition, the C-terminus of this protein is highly divergent between strains, possibly contributing to evasion of antibody-mediated immunity and differential adherence. Finally, this protein undergoes phase variation mediated by an insertion or deletion within a short tract of homopolymeric sequences in the 5′ region of the coding sequence that causes a translational frameshift, the loss of detectable protein, and inability to attach to cultured human cells.[372] Two other surface-exposed proteins, P120 and Lmp, are encoded by genes that are variable, contain tandem repeats within their coding sequences, and have homologs at other sites on the chromosome. Undoubtedly, all three surface-exposed proteins contribute to the antigenic variation within this species, differential ability to attach to host cells, and persistence in vivo.

The pathogenic effect of *M. hominis* has been studied in organs cultures and in animal models. Inoculation of *M. hominis* into fallopian tube organ cultures caused a subtle change, namely ciliary clubbing, in one study,[128] but not others.[127,181] The effect of hormonal changes in women, occurring during the menstrual cycle and pregnancy, on the natural history of *M. hominis* infection has not been examined, although there is evidence that hormones probably do have an effect based on observations made in animals. Thus, colonization of the genital tract of female mice was shown to be dependent on prior administration of estradiol, which induced the estrous phase of the cycle.[379] Progesterone, which induced diestrus, did not render the mice susceptible.[380] Indeed, progesterone given to estradiol-treated mice colonized by *M. hominis* converted the cycle to the diestrous phase and eliminated the organisms at least as effectively as tetracycline treatment.[380] *M. hominis* in some mice persisted for more than 6 months, with spread to the uterine horns and ovaries in a few.[379]

In summary, much needs to be learned about the pathogenesis of the genital mycoplasmas. Gene variation, presumably resulting in antigenic variation, phase variation, and possibly differences in adherence, are common themes in these organisms that are limited to animal hosts, including humans, for survival.[381] Interestingly, this variation is achieved by different mechanisms and by divergent surface proteins in the different species. The effect of hormone changes on colonization and pathogenesis of infection in humans is unknown. Identification and characterization of potential toxins and their effect on host cells, as well as the extent and effect of immune cell activation on the pathogenesis of infection remain challenges for studies elucidating the pathogenesis of these organisms.

ANTIMICROBIAL SUSCEPTIBILITY AND TREATMENT

SUSCEPTIBILITY PROFILES AND TREATMENT OF MYCOPLASMAL INFECTIONS

Mycoplasmas are resistant to all β-lactams and cephalosporins due to the lack of a cell wall. Rifampicin is also inactive.[382] Resistance to macrolides and tetracycline is variable among strains of the *Mycoplasma* and *Ureaplasma* spp. Notwithstanding, there are few outcome data documented in a controlled setting with microbiological information to assess the efficacy of antimicrobial treatment for *M. genitalium* infections. Clearly, such trials are needed.

As indicated earlier in this chapter, current data indicate that *M. genitalium* is a cause of NGU and possibly cervicitis, endometritis, and PID, so that antimicrobial therapy targeting this organism seems warranted. The usual treatment of NGU with macrolides or tetracyclines, appropriate for *C. trachomatis,* is also recommended for the treatment of *M. genitalium* by the U.S. Centers for Disease Control and Prevention.[383] However, microbiologic and/or clinical treatment failures with these two antibiotics have been reported,[42–44,46,48,384] a finding consistent with the association of this organism with chronic and recurrent urethritis[44–47,385] as well the detection of strains with decreased susceptibility to the tetracyclines in vitro.[386,387] Clearly, randomized treatment trials and susceptibility testing of contemporary *M. genitalium* strains are necessary to determine the optimal treatment regimens for this emerging pathogen.

Treatment of ureaplasmas in men with urethritis is controversial, given the variability in the association of this organism with reproductive tract disease between different studies. However, tetracycline-resistant *Ureaplasma* spp. have been detected[382,388,389] and resistance is mediated by the *tet*M determinant which encodes a protein that binds to the ribosomes, protecting them from the actions of these drugs.[70,390–392] The extent to which this resistance occurs undoubtedly varies geographically. Tetracycline resistance in *Ureaplasma* spp. has been associated with treatment failure in NGU,[68] although these studies were performed before the contribution of *M. genitalium* in NGU was appreciated.

Thus, patients with NGU who show no response to treatment with a tetracycline should be treated with an alternative antibiotic active against these organisms, for example, a macrolide (azithromycin or clarithromycin).[382]

Extragenital infections, often in immunocompromised hosts, are sometimes caused by multidrug-resistant mycoplasmas and ureaplasmas,[393] making guidance of chemotherapy by in vitro susceptibility tests particularly important. In this situation, eradication of infection may be extremely difficult, requiring prolonged therapy, preferably with at least two antibiotics with different modes of action, even when the organisms show susceptibility. This difficulty highlights the fact that a functioning immune system plays an integral part in mycoplasmal eradication and, as mentioned before, inhibition but not killing occurs with most commonly used antimicrobial agents in concentrations achievable in vivo. Antimicrobial profiles of the genital mycoplasmas are available in several publications.[71,386,394–397]

METHODS OF SUSCEPTIBILITY TESTING

Agar dilution, microbroth dilution, and the Etest have been used for testing the minimal inhibitory concentrations (MICs) for easily cultivable mycoplasmas. Agar dilution has been used extensively as a reference method because it is less sensitive to inoculum size, pH, and incubation time than the microbroth dilution method.[398,399] In the agar plate method, multiple strains can be tested on each of several plates containing different dilutions of antimicrobials. In contrast, the microbroth dilution is more practical if testing fewer or occasional strains against a wide variety of antimicrobials, because one strain can be tested for susceptibility to several antimicrobials in the same microtiter plate. However, using carefully controlled techniques and standard procedures, the agar dilution and microbroth dilution provide similar results for various antimicrobials tested against *Ureaplasma* spp. and *M. hominis*.[400] In addition, mycoplasmacidal, as opposed to static, activity can be tested directly by removing the mixture of organisms and antibiotic from the well of a microbroth dilution MIC assay, diluting it to a subinhibitory concentration in fresh medium, and looking for a color change as evidence of growth.[401] Detailed procedures for determining the minimal inhibitory and mycoplasmacidal concentrations for the mycoplasmas are available.[402] A modification of the microbroth dilution method is provided by commercially produced kits (bioMérieux), available in Europe for several years. These consist of microwells containing dried antimicrobials, generally in two concentrations, to classify a strain as susceptible, intermediate, or resistant.

The Etest (AB BIODISK, Solna, Sweden) agar gradient diffusion technique has produced results comparable to microbroth dilution for testing the susceptibility of the ureaplasmas and *M. hominis* to various antimicrobials.[403–405] The Etest is simple, provides endpoints which do not move over time, and is most cost-effective if only a small number of antimicrobials or a few isolates are to be tested. Irrespective of methodology, lack of universally accepted standards and guidelines for susceptibility testing has led to diverse and often inconsistent susceptibility profiles for mollicutes, especially for the genital mycoplasmas. Furthermore, the correlation between in vitro MICs and in vivo microbiological cure is not completely established. Tetracycline-resistant *M. hominis* and *Ureaplasma* spp. can usually be distinguished by broth or agar-based methods since the resistant strains generally have MIC values of >2 μg/mL. Because tetracycline resistance is often encoded by the *tet*M gene in these organisms, direct detection of *tet*M by PCR provides an alternative method of identifying resistant organisms.[406] Methods are currently under evaluation by the National Committee for Clinical Laboratory Standards (NCCLS) Subcommittee on Antimicrobial Susceptibility Testing of Human Mycoplasmas (Ken Waites, personal communication) to identify optimal methods for MIC testing of the ureaplasmas and *M. hominis.*

Due to the difficulty of culturing clinical strains of *M. genitalium*, antimicrobial susceptibility testing for this mycoplasma has been performed using the traditional broth dilution method on less than 10 strains.[382,387,394,396,397] However, the development of improved methods for isolation[300] and antimicrobial testing[386] of *M. genitalium* should foster a better understanding of the antimicrobial profile of this species.

42 Bacterial Vaginosis

Sharon Hillier, Jeanne Marrazzo, and King K. Holmes

Our knowledge of leukorrhea is unsatisfactory and incomplete. The majority of physicians neither appreciate the gross aspects of the condition nor discover the locality from which discharges arise, practically none of us possesses an adequate knowledge of the bacteria involved, and most clinicians admit that their curative efforts yield poor results.

Arthur H. Curtis, M.D. (1913)[1]

DEFINITION

Bacterial vaginosis (BV) is the most prevalent cause of vaginal symptoms among women of childbearing age. Many primary care providers perceive BV as a trivial and ill-defined syndrome of uncertain etiology. These perceptions may explain why clinicians still commonly prescribe ineffective treatments for BV.

When it is symptomatic, BV produces slightly increased quantities of malodorous vaginal discharge. Although past conventional practice allowed the diagnosis of BV only after excluding other causes of vaginal discharge, such as trichomoniasis, vulvovaginal candidiasis, or cervicitis, these conditions can undoubtedly coexist with BV. Physical examination and analysis of vaginal fluid among women with BV reveal the following: a thin homogeneous, white, uniformly adherent vaginal discharge; elevation of the pH of vaginal fluid above 4.5; development of a fishy odor after mixing vaginal fluid with 10% (wt/vol) KOH; and "clue cells" on microscopic examination of vaginal fluid. Whereas Gram stain of normal vaginal fluid shows a predominance of lactobacilli, the Gram stain of vaginal fluid from a woman with BV shows a decrease or absence of lactobacilli and a predominance of Gram-variable coccobacilli consistent with *Gardnerella vaginalis* or anaerobic Gram-negative rods species. Culture of vaginal fluid reveals mixed flora that typically includes genital mycoplasmas, *G. vaginalis*, and anaerobic bacteria such as peptostreptococci, *Prevotella* spp., and *Mobiluncus* spp., and cultivation-independent methodologies reveal an even wider array of anaerobic bacteria, as discussed below. Biochemical analysis of vaginal fluid from women with BV usually shows characteristic changes that are likely due to bacterial metabolism. The vaginal fluid contains an altered pattern of organic acids (e.g., increased succinate and decreased lactate) and abnormal amounts of putrescine, cadaverine, and trimethylamine that probably contribute to malodor. Mucin-degrading enzymes produced by Gram-negative anaerobic bacteria associated with BV are also abundant and are probably responsible for the increase in quantity of vaginal discharge. The pathogenesis of BV remains far from clear. Inflammation of the vaginal epithelium in the form of evident white blood cells is often, but not always, limited, and cytokine profiles characteristically deviate from those seen in the normal vaginal environment. The vaginal microbial ecosystem is clearly disturbed in BV, but whether this represents a true tissue or epithelial infection is unclear. Women with BV are at increased risk of prematurity and chorioamnionitis during pregnancy, pelvic inflammatory disease (PID), and pelvic infection following obstetrical or gynecological surgery, and, possibly, acquisition of genital herpes[2] and human papillomavirus.[3]

HISTORY

Nearly a century ago, Doderlein described a nonmotile bacillus, which he considered to be the normal flora of the vagina of pregnant women.[4] The Doderlein bacillus later became known as *Lactobacillus*. In 1899, Menge and Kronig reported isolation of both facultative and strictly anaerobic microorganisms, as well as the Doderlein bacillus, from the vagina of most women.[5] These early studies established that normal vaginal flora includes a mixture of microorganisms, with *Lactobacillus* spp. as the predominant species.

"Leukorrhea," or white discharge from the vagina, became the focus of much research in the first quarter of the century. Some thought that vaginal discharge resulted from infection of the uterus and treated the condition by curettage of the endometrium. In 1913, Curtis demonstrated that the endometria of women with leukorrhea lacked a white discharge, thus suggesting a vaginal, not endometrial, origin. He

confirmed that the vaginal flora of clinically normal, married women consisted of Doderlein's bacilli and that the greater the deviation of vaginal flora from the normal state, the greater the likelihood of vaginal discharge. Curtis linked vaginal discharge with high concentrations of black-pigmented anaerobes, curved anaerobic motile rods, and anaerobic cocci, and with Gram-variable diphtheroidal rods, which probably represented *Gardnerella*. Curtis' 1913 paper established three central themes: (1) the discharge arose from the vagina and not from the uterus, (2) women having white discharge did not have large numbers of Doderlein bacilli, and (3) the presence of anaerobic bacteria in the vagina, especially anaerobic rods, correlated with vaginal discharge.

Research on vaginal flora continued in the early 1920s when Schroder reported three different types of vaginal flora, which corresponded to the "rheinheitgrad" (grade of cleanliness) of the vagina.[6] He considered the flora of the first group, dominated by acid-producing rods (Doderlein's bacillus), the least pathogenic. A second group had a mixed flora with Doderlein's bacillus in the minority. The third group, designated as the most pathogenic type of flora, had mixed vaginal flora without lactobacilli.

Despite observations by Curtis and Schroder linking vaginal discharge with a shift in the community of vaginal flora (from predominance of lactobacilli to predominance of anaerobes), other workers attempted to attribute the symptoms of nonspecific vaginitis to a single microorganism. In 1950, Weaver again reported a link between lack of lactobacilli, presence of anaerobes spp., and nonspecific vaginitis.[7] However, the lack of association of other aerobic and facultative bacteria with abnormal vaginal discharge led him to conclude that no particular organisms caused this syndrome. The recognition of the association of *G. vaginalis* with nonspecific vaginitis by Gardner and Dukes in 1955[8] (discussed below) provided the first clear evidence that *G. vaginalis* caused nonspecific vaginitis. However, because these investigators failed (erroneously) to find an association between other anaerobic bacteria and BV, workers over the next 25 years tended to ignore the potential role of microorganisms other than *G. vaginalis.*

Confusion surrounding the etiology of this syndrome has prompted the use of various names to describe BV. Prior to 1955, leukorrhea or nonspecific vaginitis was the term most frequently used. Gardner and Dukes first applied the name *Haemophilus vaginalis* vaginitis to this syndrome in 1955, and today some clinicians still use the term *Gardnerella* vaginitis or vaginosis; others have used the term anaerobic vaginosis.[9] The term bacterial vaginosis is now relatively widely accepted, as BV is associated with vaginal overgrowth not only by anaerobic bacteria, but also by certain facultative bacteria, genital mycoplasmas,[10,11] and a broad range of other microrganisms.[12] Since vaginal inflammation, as defined by neutrophil predominance in vaginal fluid, is not always seen as a feature of this infection, the term "vaginosis" replaced the more familiar term "vaginitis."

EPIDEMIOLOGY

PREVALENCE OF BV AND ASSOCIATED MICROORGANISMS

Data on prevalence vary widely, because of differing diagnostic criteria and differences in clinical populations sampled as well as actual differences between populations. Relatively few nationally representative surveys have been performed. Recently, BV prevalence measured by the Nugent Gram's stain criteria was reported for women in the National Health and Nutrition Survey (NHANES),[13] which uses a complex, stratified, multistage probability sample design with unequal probabilities of selection to obtain a nationally representative sample of the U.S. civilian noninstitutionalized population.[14] Of over 12,000 women in the 2001–2004 NHANES who supplied a self-collected swab of vaginal secretions for Gram stain analysis by Nugent score, BV prevalence was 29.2% (95% CI 27.2–31.3, $p = 0.003$); only 15.7% with BV reported symptoms. Prevalence was 51.4% among non-Hispanic blacks, 31.9% among Mexican Americans, and 23.2% among non-Hispanic whites ($p < 0.01$ for each comparison). Detection of BV was also associated with increasing number of lifetime sex partners (chi square p for trend $p < 0.001$), a previous female sex partner ($p = 0.003$), douching frequency (chi square p for trend <0.001), low educational attainment, poverty, smoking, high body mass index, and having been pregnant. Current use of oral contraceptive pills was inversely associated with BV prevalence. Significant differences by race/ethnicity remained after accounting for other risk factors. Among young women entering the U.S. military, BV prevalence in a large cross-sectional study was 27%.[15] In a population-based sample of nearly 3000 women in Goa, India, BV prevalence was 17.8%.[16]

The prevalence of BV among pregnant women varies widely, as might be expected from the NHANES data, above. In one large study in the United States, 13,747 pregnant women at 23–26 weeks' gestation underwent evaluation for BV by standardized vaginal Gram stain criteria.[17] While 16.3% of the women had BV, the prevalence varied widely by ethnicity, from a low of 6.1% of Asians, to 8.8% of white women, 15.9% of Hispanics, and 22.7% of black women. Other studies have found antenatal BV prevalence of 5% among asymptomatic Italian women,[18] 12% in Helsinki,[19] 14% in Denmark,[20] 21% in London,[21] 14% in Japan, 16% in Thailand,[22] and 17% in Indonesia.[23]

In family planning clinics, BV prevalence was 14% among young Swedish women.[24] In Morocco, a three-city study of women with vulvovaginal or lower abdominal complaints showed BV based on clinical criteria in 19% of those attending

family planning clinics, and 24% of those attending primary health-care clinics.[25] In Lima, Peru, BV was detected in 25% of asymptomatic women seen in family planning clinics, and in 23% of asymptomatic women and 37% of women with symptoms of vaginal discharge seen in a gynecology clinic.[26] In women of 18 rural villages in Peru, BV prevalence was 44%.[26a]

Women attending sexually transmitted disease clinics have had relatively high BV prevalence—for example 24–37% of women attending STD clinics in Uppsala, Sweden[27]; Seattle, Washington[28]; and Halifax, Nova Scotia[29]; and Madagascar.[30] In Thailand, 33% of female sex workers had BV,[31] compared to the 16% prevalence found among pregnant Thai women. The highest prevalence of BV reported in a large population-based sample of women was 51% among 4718 rural Ugandan women.[32] On the other hand, BV was diagnosed in only 18% of women in the United States hospitalized with complications of AIDS.[33] In one longitudinal study, BV was detected among 43% of HIV-infected and 47% of HIV-uninfected high-risk women.[34] Over time, BV decreased among both groups of women, suggesting that HIV infection is not a risk factor for BV. Interestingly, treatment of HIV-infected women with HAART was associated with lower rates of BV.[34] These and other data, in aggregate, suggest that BV is common in most populations, is more common in STD clinics than in family planning or antenatal clinics, is more common among women with symptoms of vaginal discharge than among those without symptoms, has been related to ethnicity for unknown reasons, and is common in rural sub-Saharan Africans.

Is BV transmitted sexually? Sexually active women have vaginal carriage *G. vaginalis* more often than sexually inexperienced women,[35] but nonetheless 10–31% of sexually inexperienced adolescent girls have had positive vaginal cultures for *G. vaginalis*.[36,37] In one small study, of 20 virginal women, *G. vaginalis* and *Atopobium vaginae* were detected in 45% and 7%, respectively, and *G. vaginalis* detection was associated with history of receptive oral sex and hand–genital contact without penetrative vaginal intercourse.[38] While these studies demonstrated that *G. vaginalis* and—in the case of *A. vaginae*—other bacteria more specific for BV—can be detected in sexually inexperienced females, overall, the weight of evidence supports sexual transmission of this organism. Gardner and Dukes[8] and Pheifer et al.[39] detected *G. vaginalis* in the urethras of 79% and 86% of the male sex partners of women with BV, but not in male controls. As discussed below, more recent data on a potentially protective effect afforded by male partner condom use might support a role for unprotected sex in initiating or maintaining BV. Piot et al. developed a biotyping scheme for *G. vaginalis* and observed that isolates of *G. vaginalis* from the vaginas of women with BV and from the urethras of their male sex partners belonged to identical biotypes when the strains were isolated within the same 24-hour period from both partners.[39a]

Among postpubertal females, those reporting no sexual experience have had significantly lower prevalence of BV than those with sexual experience.[35] Some studies[40] but not others[35] found BV associated with younger sexual debut. Among college women, Amsel et al. found BV in zero of 18 virgins versus 69 (24%) of 293 sexually experienced women ($p < 0.03$).[35] Data on the relationship between BV and numbers of lifetime or recent sex partners are somewhat inconsistent but generally weigh in favor of a positive association. In heterosexual women, BV generally occurs more frequently among those who report new or higher numbers of male sex partners or more frequent intercourse, consistent with sexual acquisition.[20,41–45] Other risks consistent across studies include douching[44,46–48] (which promotes loss of H_2O_2 + lactobacilli), IUD use,[49,50] and black race[51] (independent of douching).[52] Hormonal contraception,[53,54] smoking,[20,53] menses,[55] and chronic stress[56] have also emerged as risks in different studies. One cohort study[44] of 182 women demonstrated acquisition of BV was associated not only with having a new sex partner, and (as discussed below) with lack of H_2O_2-producing lactobacilli (hazard ratio 4.0, $p < 0.001$), but also with douching for hygiene (HR 2.1, $p = 0.05$). Both Amsel et al.[35] and Holst et al.[57] found use of an intrauterine device more common among women with BV than among other women (18.8% vs. 5.4%, $p < 0.001$, and 35% vs. 16%, $p < 0.03$, respectively). In a prospective study, Avonts et al. reported a twofold increased incidence of BV among IUD users compared to oral contraceptive users.[42] A prospective study of female sex workers in Peru also found IUD use associated with more than a twofold increased risk of acquiring BV (J Sanchez, KK Holmes, unpublished). However, history of abnormal Pap smears, days of menstrual flow, days since last menstrual period, form of menstrual protection, age at menarche, and years since menarche have not been associated with BV.[35,58]

For reasons that are not understood, BV prevalence is highest among black women, even after controlling for amount and type of sexual activity of the women themselves, and douching habits.[51,52] Some investigators have examined the hypothesis that chronic stress associated with residing in urban environments may contribute to the link between African American race and BV. In a cross-sectional study of the prevalence of BV among 2304 women at first prenatal visit, stress was measured at the individual and community levels with the use of interviews and administrative records.[56] Black women had a significantly higher BV prevalence (64%) compared with white women (35%). Almost one-third of black women reported threats to personal safety compared with 13% of white women, and 63% of black women lived in neighborhoods with aggravated assault rates that were above the citywide mean compared with 25% of the white women. After adjustment for sociodemographic, behavioral risk, and perceived stress, the odds of BV associated with the community-level stressor of "homelessness" was significant

(odds ratio [OR], 6.7; 95% CI, 1.6–27.8). Inclusion of both individual and community-level stressors reduced the black/white BV OR by 27%. The authors concluded that measurement of stressors at multiple levels explained a significant proportion of the racial disparity in the rates of occurrence of BV. Stress is known to modulate key cytokines involved in local immune responses, so this hypothesis is of interest.

Condom use may prevent BV and its recurrence.[50,53,54,59] Women in a large prospective study that evaluated response to treatment had a fivefold reduction in BV persistence and recurrence if their partners consistently used condoms.[60] In another prospective study, women who reported less frequent use of condoms were less likely to have normal vaginal flora sustained over time.[45] A relationship between receptive oral sex and BV has been reported,[61,62] but not confirmed in other studies.[58,63] Although *G. vaginalis*, *Mobiluncus* species, and *M. hominis* have been isolated from the male genital tract,[64,65] short-course systemic antibiotic treatment of male partners of women with BV does not reduce BV recurrence.[64–71] One study of 38 women showed that male partners of 17 women with abnormal vaginal flora were more likely to be colonized with *M. hominis* than partners of women with normal flora, but this was not a significant difference.[72] Among heterosexual couples in Kenya,[73] multivariate analysis of factors specific to male partners of women with or without BV showed that crowded living and fewer bathing facilities were associated with higher odds of BV, while poor genital hygiene was associated with fourfold increase in their female partners' BV risk.[73] In later analysis, the male partner's HIV status was also highly associated with his poor genital hygiene.[74] Because 97% of men in this study were circumcised, an independent contribution of circumcision status to BV could not be assessed. The subprepuceal area may be a suitable environment for some bacteria associated with BV; also of interest, subprepuceal "wetness" (a surrogate for poor hygiene) has been associated with increased risk of HIV infection.[59]

BV is considerably more common among women who report sex with other women than among those who do not.[53,63,75–83] An important limitation of these studies is that women were self-referred and, thus, may not have been representative. In the NHANES study noted above,[13] BV prevalence was 45.2% (95% CI 35.5–57.4) among women who reported having had a female sex partner, compared to overall prevalence of 29.2% (95% CI 27.2–31.3, $p = 0.003$). Among STD clinic populations, report of sex with another woman has emerged as a risk for BV in larger, well-controlled studies.[53,83,84] Moreover, report of sex with another woman was associated with increased risk of BV recurrence in one prospective study.[84] The reasons that lesbians have a high prevalence of BV are unclear, but sexual practices that transmit vaginal fluid increase BV risk, and a high degree of concordance for the presence or absence of BV among lesbian couples has been reported.[63,76] Among 329 women who were sexually active with women,[63] risks for BV included higher number of female lifetime partners, shared vaginal use of sex toys, and report of oral–anal sex. Among 73 couples in this study, 95% were concordant for presence or absence of BV. Both partners had BV in 21 couples, and one woman had BV in only six couples; this degree of concordance differed dramatically from the expected distribution ($p < 0.001$). These data confirmed an earlier study that reported that, among 101 lesbians seeking gynecologic care, 29% had BV and pairs of monogamous lesbians had high concordance in having BV.[76] The likelihood of a female partner having BV was nearly 20 times greater if her partner had BV.[63] The authors concluded that this concordance probably reflected sexual transmission of BV. Lesbians' reportedly frequent practice of receptive oral sex[85] has been suggested as a risk for BV,[61] but few studies have detected this association.[44,63] Those that have found this association did not control for some important variables[61] or showed association between receptive oral sex and "unstable" vaginal flora,[58] not BV.

The relatively consistent association between report of anal sexual behaviors and BV in the few studies that have assessed this practice deserves comment.[63,73] Perineal transfer of rectal bacteria to the vagina is a well-recognized consequence of vaginal intercourse for common bacteria such as *E. coli* and Group B *Streptococcus*,[86] and it is possible that BV may be precipitated or promoted if unprotected vaginal intercourse encourages the translocation of key bacteria from the rectum to the vagina. Many of the bacteria that have been described using molecular approaches in the setting of BV (discussed below) appear to be strict anaerobes and hypothetically may prefer the rectal environment; whether and how they may play a pathogenic role in initiating BV is under study. Another possibility is that different species of *Lactobacillus* that colonize the rectum may be introduced into the vagina during vaginal intercourse and may somehow disrupt the normal vaginal environment,[87] although beneficial species of lactobacilli are also harbored in the rectum.

MICROBIOLOGY

CULTIVATION-BASED DEFINITION OF VAGINAL FLORA ASSOCIATED WITH BV

Gardnerella vaginalis

Leopold first reported the isolation of a small, nonmotile, nonencapsulated, pleomorphic Gram-negative rod from the genitourinary tract of women with cervicitis in 1953.[88] Two years later, Gardner and Dukes isolated this organism, which they named *Haemophilus vaginalis*, from 92% of 141 women with "bacterial vaginitis," 20% of women with

Trichomonas vaginalis infection, and 4% of women with clinical "moniliasis," and from none of 78 controls.[8] In an attempt to fulfill Koch's postulates, Gardner inoculated 15 women not infected by *H. vaginalis* with material from the vaginas of infected patients and reproduced the manifestations of this condition in 11 of 15 women. However, inoculation of pure *H. vaginalis* resulted in these manifestations in only one of 13 women, despite isolation of *H. vaginalis* from the vagina of all of these women 1 or more weeks after inoculation. Both Brewer et al.[89] and Heitai and Taleghany[90] confirmed the association between nonspecific vaginitis and *H. vaginalis*, but, unlike Gardner and Dukes,[8] they also isolated other organisms and concluded that *H. vaginalis* was not the sole etiology of nonspecific vaginitis.

The body of literature over the past 30 years has substantiated the association of *G. vaginalis* with VB. However, with use of more sensitive culture media *G. vaginalis* can be isolated, often in high concentrations, from women with no signs of vaginal infection and is estimated to colonize approximately 40% of women whose vaginal fluid is characterized by normal Nugent scores.[91] Many investigators now believe that *G. vaginalis* somehow interacts with anaerobic bacteria to cause VB. When assessed by a specific fluorescent probe, *G. vaginalis*, unlike several other recognized vaginal species, has been detected in large quantities within adherent biofilms among women with BV.[92]

ANAEROBIC BACTERIA

Anaerobic rods and cocci were first isolated from the vagina in 1897[5] and were found to be associated with vaginal discharge by Curtis in the early part of this century.[1] In 1980, Spiegel analyzed the vaginal fluid from 53 women with BV using quantitative anaerobic cultures and gas–liquid chromatography, to detect the short-chain organic acid metabolites of the vaginal flora.[10] She isolated *Bacteroides* spp. (now *Prevotella* and *Prophyromonas*) from 76% and *Peptococcus* (now called *Peptostreptococcus* [not further speciated]) from 36% of the women with BV and recovered both types of anaerobes significantly less often from normal women. The recovery of anaerobic species correlated directly with a decrease in lactate and an increase in succinate and acetate in the vaginal fluid. Paavonen et al. later confirmed the presence of succinate and other short-chain fatty acids in vaginal fluid from women with BV.[93] After metronidazole therapy, the anaerobic Gram-negative rods and cocci decreased, and lactate again became the predominant organic acid in the vaginal fluid. Spiegel concluded that anaerobes interacted with *G. vaginalis* to cause VB.

In our experience with cultivation of bacteria from vaginal fluid of women with BV, the most common anaerobic Gram-negative rods include *Prevotella bivia*, the black-pigmented species belonging to the genera *Prevotella* and *Porphyromonas*, *Bacteroides ureolyticus*, and *Fusobacterium nucleatum*.[11] Members of the *Bacteroides fragilis* group (*B. fragilis*, *B. ovatus*, *B. vulgatus*, and *B. thetaiotaomicron*), although common in the intestinal tract, are less common in the vagina and not associated with BV.[11] The vaginal flora of most normal women also includes anaerobic Gram-positive cocci.

Although researchers "discovered" *Mobiluncus* during the early 1980s, Kronig first observed a curved anaerobic rod by Gram stain of uterine discharge in 1895,[94] and Curtis first isolated such an organism from the uterine discharge of women with postpartum fever[95] in 1913. Prevot suggested the name "*Vibrio mulieris*" in 1940.[96] Most early microbiologic studies failed to detect this nutritionally fastidious and strictly anaerobic microorganism, but in 1980, Durieux and Dublanchet isolated and characterized 18 strains of succinate-producing anaerobic curved rods from women with vaginal discharge.[97] Spiegel detected this organism by direct Gram stain of the vaginal fluid from 31 (51%) of 62 women with BV and from none of 42 normal controls.[98] In 1984, Spiegel and Roberts proposed the genus name *Mobiluncus* for this motile rod. Two species were described: *M. curtisii* and *M. mulieris*.[99] One study employed DNA probe, culture, and/or Gram stain to demonstrate *Mobiluncus* spp. in 68% of women with BV.[100] In the vagina, *Mobiluncus* always occurs together with other organisms associated with BV and has also been associated with gonorrhea. *Mobiluncus* spp. have most frequently been recovered from black women but are not associated with young age at first intercourse, lifetime number of sexual partners, or having a new partner in the past month.[101]

Schwebke and colleagues[102] have reported phenotypic variants of *M. mulieris* and *M. curtisii.* The phenotypically and antigenically distinct *M. curtissii* strains are more frequently recovered from women with normal vaginal flora than from those with BV.[102] Recent studies have demonstrated serum antibody to *M. curtisii* very commonly in sexually experienced women (75%) (including many who denied a history of BV) and rarely in pediatric patients (6%) or virgins (0%).[103] The authors concluded that humoral antibody to *M. curtisii* may provide a useful serological marker for BV and that BV may commonly go unrecognized in sexually experienced women. The genus *Mobiluncus* and the genus *Falcivibrio* are closely related, and it has been proposed that *F. vaginalis* and *F. grandis* be transferred to the genus *Mobiluncus*.[103a]

GENITAL MYCOPLASMAS

In 1970, Mendel reported isolation of mycoplasmas from nearly half of patients with trichomoniasis or *G. vaginalis*, but without any specific disease.[104] Taylor-Robinson and McCormack first suggested in 1980 that *Mycoplasma hominis*

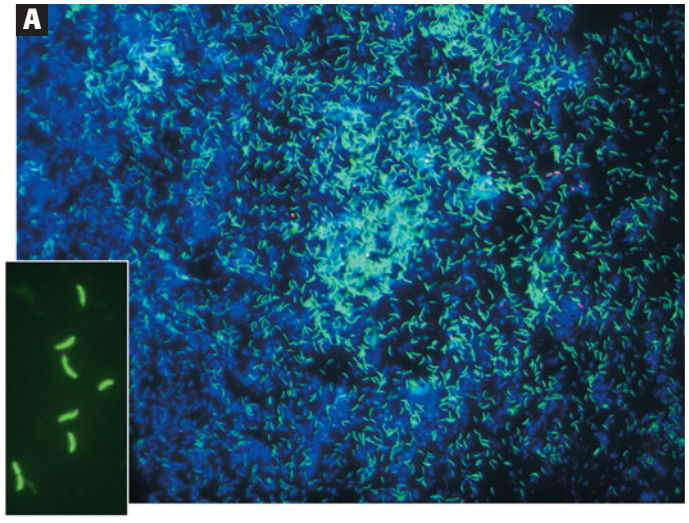
could have a role in nonspecific vaginitis, either in symbiosis with *G. vaginalis* and other organisms or as a sole pathogen.[105] Pheifer et al. supported this hypothesis, by recovering *M. hominis* from 63% of women with BV and 10% of normal controls.[39] In 1982, Paavonen et al. also reported the association of BV with *M. hominis* and *G. vaginalis* in vaginal fluid.[93]

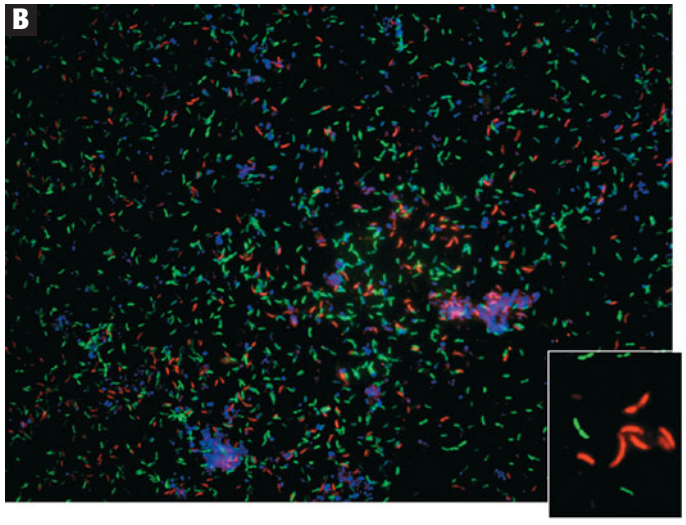
APPLICATION OF MOLECULAR ANALYSIS TO BV-ASSOCIATED FLORA

More recently, cultivation-independent techniques have been employed to define bacteria associated with BV.[12,106] These include various approaches to analyzing products of broad-range 16S rDNA PCR, including denaturing gradient gel electrophoresis (DGGE) and sequence analysis of all products or products screened for sequence diversity by amplified ribosomal DNA restriction analysis (ARDRA) and restriction fragment length polymorphism analysis (RFLP). On the whole, these studies have confirmed that women without BV typically have *Lactobacillus* species as the overwhelmingly predominant bacteria.[12,107,108] Women with BV, however, have even greater bacterial diversity than previously appreciated. In addition to confirming the presence of previously described cultivatable BV-associated bacteria, these studies have detected *A. vaginae*, *Lactobacillus iners*, *Eggerthella*, *Megasphaera*, *Leptotrichia*, *Dialister*, *Bifidobacterium*, *Slackia*, and bacteria related to *Arthrobacter*, *Caulobacter*, and *Butyrivibrio.*[109–114] One of the first studies, reported by Burton and Reid, used both bacterium-specific and broad-range 16S rDNA PCR with DGGE to follow vaginal flora over time in 20 asymptomatic, postmenopausal women.[109] Of seven women with BV, sequencing was consistent with the presence of *Gardnerella*, *Prevotella*, *Peptostreptococcus*, and *Bacteroides* species and of a 16S rDNA sequence that was 89% similar to an uncultivated bacterium found in soil. A small group of premenopausal women studied by this group generally had similar vaginal flora with the addition of unusual bacteria related to *Arthrobacter*, *Caulobacter*, and *Butyrvibrio* and frequent detection of *L. iners*.[109] Of note, the use of DGGE analysis allows for a relatively limited and occasionally less than specific assessment of bacterial diversity, as PCR products present in relatively low quantity may not appear as visible bands on the gel or, if they have similar mobility, may appear as overlapping bands. Using the DGGE approach, Ferris et al. identified *A. vaginae* in 12 of 22 women with BV and in only two of 24 normal women;[110] subsequently, this group applied a PCR assay specific for detection of *A. vaginae* to 19 women without BV, who had no *A. vaginae* detected, and to 11 women with BV, four of whom had *A. vaginae* detected. This was the first study to show that *A. vaginae*, while not always present in BV, is relatively specific for BV when it is present. Subsequently, a similar approach used by Burton et al. showed that approximately half of women with BV were positive for *A. vaginae*.[111] Of interest, *Atopobium* species have been detected in upper female reproductive tract disease and are resistant to metronidazole[115–118] and when present in vaginal fluid in higher quantity were associated with recurrent BV in one study.[119]

Another approach, which allows for detection of greater bacterial diversity than DGGE, has been to use the more labor-intensive technique of sequence analysis of cloned PCR products generated by broad-range 16S rDNA PCR. This was combined with cultivation techniques, for example, in a study by Verhelst et al. in which colonies were characterized using either fingerprint patterns by PCR of spacers between transfer RNA or actual sequencing of 16S rRNA genes.[113] Again, the predominance of *Lactobacillus* species was noted among women with normal flora, *A. vaginae* was present among many women with abnormal flora by Gram stain, and 47% of the species detected were identified only by cloning. Among 20 asymptomatic premenopausal women (not described by standard Amsel or Nugent criteria) studied by Hyman et al., seven women had clone libraries that consisted of more than 50 bacterial 16S rDNA sequence types, again supporting the observation that the diversity of bacterial species associated with BV is profound.[114]

Fredricks et al. used broad-range PCR to amplify a ~1000 base pair segment of the bacterial 16S rRNA gene from vaginal fluid samples from nine women with BV and eight without BV, defined by Amsel criteria and confirmed by Gram stain; four women were followed serially to assess changes with incident, cured, recurrent, and persistent BV.[12] The PCR products were cloned into *Escherichia coli*, 100 clones were selected, and plasmid inserts were screened for sequence diversity using RFLP analysis with two restriction enzymes (ARDRA). Inserts with unique ARDRA patterns were sequenced to identify bacteria or infer phylogenies. As noted consistently in all of these studies, women without BV had clone libraries dominated by a few *Lactobacillus* species, while those with BV had diverse flora that included several novel species in the *Clostridiales* order, as well as bacteria related to *Megasphaera*, *Leptotrichia*, *Dialister*, *Atopobium*, and *Eggerthella* species. Individual subjects studied longitudinally had parallel changes in vaginal flora with incident, cured, and relapsing BV that mirrored the cross-sectional study. These investigators also developed bacterium-specific PCR assays for the more sensitive detection of vaginal bacteria and applied these assays to a group of 27 subjects with BV and 46 subjects without BV. The uncultivated *Clostridium* species, termed BVAB1, BVAB2, and BVAB3, were highly specific indicators of BV (>95% specificity). The *Atopobium* and *Megasphaera* assays were very sensitive tests for BV (>96%), but detection of *Megasphaera* was more specific for BV (91%) than *Atopobium* (80%). They used fluorescent in situ hybridization with bacterium-specific probes to





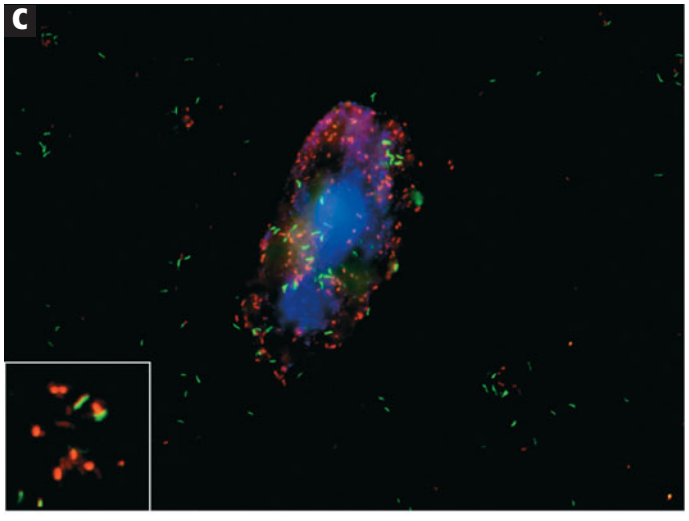


FIGURE 42-1. Vaginal fluid from a woman with bacterial vaginosis shows a field of bacteria hybridizing with probes for BVAB1 (green), BVAB2 (red), and other bacteria (stained with 4′, 6-daimidine-2-phenylindole, dihydrochloride [DAPI], blue). The inset in panel **A** shows that BVAB1 is a thin curved rod. A sample from the same subject shows bacteria attached to a vaginal epithelial cell (panel B). These bacteria include organisms hybridizing with probes for BVAB1 (green) and BVAB2 (red). The cell nucleus is stained with DAPI (blue). The insert in panel **B** shows that BVAB2 is a short, wide rod (red). In panel **C**, bacteria hybridize with a probe for BVAB1 (green) and mobiluncus (red). The inset in panel C shows that mobiluncus (red) is larger than BVAB1 (green), but both have a similar morphology (curved rod). (With permission from Fredricks DN, Fiedler TL, Marrazzo JM. Molecular identification of bacteria associated with bacterial vaginosis. *N Engl J Med* 2005; 353: 1899–1911.)

visualize these bacteria and showed that they are morphologically distinct from other vaginal bacteria, including *Mobiluncus* species, and that they apparently adhere to the surface of vaginal epithelial cells (Fig. 42-1).

Two major findings from these studies merit emphasis. First, several newly defined BV-associated bacteria are previously undescribed species that have to date not yet been cultivated, including BVAB1, BVAB2, BVAB3, and members of an entirely uncultivated phylum called TM7. Second, in contrast to *G. vaginalis*, several of these newly described bacteria appear highly specific for BV, including BVAB1, BVAB2, BVAB3, and *A. vaginae*. In one study, none of these bacteria were detected in women with normal flora as defined by Nugent criteria.[12] Because *Atopobium* species have been detected in upper female reproductive tract disease and are resistant to metronidazole and were associated with recurrent BV in one study, these findings have implications for understanding the pathogenesis and optimizing the treatment of BV and upper genital tract infection that involves previously undefined bacteria associated with BV.

OTHER MICROORGANISMS

Women with BV do not have increased rates of vaginal colonization by *E. coli* or other Gram-negative facultative bacteria, group B streptococci, coagulase-negative staphylococci, diphtheroids, or most species of viridans streptococci. However, vaginal colonization by *Enterococcus* occurs more frequently among women with *Lactobacillus*-predominant vaginal flora than among women with BV.[11]

It is apparent that no single organism causes VB. It is likely that BV is due to a consortium of bacteria, which may be interdependent from a metabolic perspective.

PATHOGENESIS

BV results from the replacement of the normal vaginal flora (*Lactobacillus*) with a mixed flora consisting of *G. vaginalis*, anaerobes, and *M. hominis*. Thus, most studies of the pathogenesis of BV have focused on how the microbial ecosystem of the vagina becomes altered. The epidemiologic data described above are consistent with the notion that introduction of a particular set of organisms via sexual intercourse may initiate the change in vaginal flora characteristic of BV.

Lactobacillus spp. may help normal women to resist vaginal and cervical infection. Vaginal lactobacilli inhibit *G. vaginalis*, *Mobiluncus*, and anaerobic Gram-negative rods in vitro.[120]

Some strains of *Lactobacillus* produce H_2O_2,[87,121,122] and studies have demonstrated that H_2O_2-producing strains of lactobacilli more frequently colonize the vagina of normal women, compared to women with BV.[11,22,44,87,122] Further, during a prospective study, women colonized with H_2O_2-positive lactobacilli less often developed VB than did those colonized with H_2O_2-negative lactobacilli.[44] The H_2O_2 produced by the vaginal lactobacilli may inhibit the growth of anaerobic rods, *Gardnerella*, *Mobiluncus*, and *Mycoplasma* in the vagina either directly via the toxic activity of H_2O_2 or by reacting with a halide ion in the presence of cervical peroxidase as part of the H_2O_2–halide–peroxidase antibacterial system.[122] Chapter 18 presents more information on the role of lactobacilli in modulating vaginal flora.

So far, no host factor has been identified that increases susceptibility to BV. A possible exception is IUD use, but the mechanisms by which IUD use may increase the risk of BV are not understood and newer types of progestin-releasing IUDs have not been evaluated for their association with BV. The redox potential (Eh) of the vaginal epithelial surface is lower in women with BV than in normal women.[123] After the women with BV were treated with metronidazole, the redox potential of the vaginal epithelium returned to the normal range, a result suggesting that the low vaginal Eh was not a persistent underlying host factor.[124]

It is thought that amines produced by the microbial flora, perhaps via the action of microbial decarboxylases, account for the characteristic abnormal fishy odor that is produced when vaginal fluid is mixed with 10% KOH. This so-called "whiff test" is thought to be due to volatilization of aromatic amines including putrescine, cadaverine,[124,125] and trimethylamine[125] at alkaline pH. *Mobiluncus* is known to produce trimethylamine,[125] but the other microbial sources of the amines are still unknown. However, it is still unknown which, if any, organisms produce these amines. Trimethylamine can be detected at relatively high concentrations in the vaginal fluid of VB, with a median concentration of 5 mM.[126] The presence of trimethylamine in the vaginal fluid is thought to be largely responsible for symptoms of malodor experienced by women with BV.

The vaginal fluid of women with BV has increased levels of endotoxin,[127] sialidase,[128,129] and glycosidases, which degrade mucin and decrease its viscosity.[130] An increased host response to BV has been documented in the form of increased levels of several cytokines and chemokines in the cervical mucus of both pregnant and nonpregnant women[131,132] with BV (see Chapter 18). In addition, secretory leukocyte protease inhibitor is decreased in the vaginal fluid of women with BV.[133] The effects of BV on the vaginal epithelium and on epithelial cell turnover have not yet been well studied. Nonetheless, the increased vaginal concentrations of anaerobic pathogens in BV may increase the risk of ascending upper genital tract infections, including cervicitis and endometritis, as discussed below.

CLINICAL MANIFESTATIONS

In a cross-sectional study of clinic patients, BV by Gram stain criteria was significantly associated with symptoms of vaginal malodor (49% of patients with BV vs. 20% without BV) and vaginal discharge (50% of patients with BV vs. 37% without BV), and with signs of a nonviscous homogeneous, white, uniformly adherent vaginal discharge (69% women with BV vs. 3% without BV) (Table 42-1[28]). As noted above, the malodor is attributed to the abnormal presence of amines, particularly trimethylamine. The discharge adheres uniformly to the vaginal walls, often visibly on the labia and fourchette before insertion of a vaginal speculum. Although a third of women with BV describe their vaginal discharge as yellow, most studies have found no significant increase in the mean number of polymorphonuclear leukocytes in vaginal discharge in this syndrome. The observation by Rein et al. of an association of BV with a positive test for lactoferrin (a marker for PMN leukocytes) stands apart from other studies in this regard;[134] in attempting to reconcile this finding with the generally accepted absence of pleocytosis, it was shown that BV-associated fluid was toxic for PMNs. The finding of PMNs in the wet mount should not exclude a diagnosis of BV. This is especially true if cervicitis is detected in the setting of BV. One study showed that leukorrhea (>5–10 white blood cells per high-power field on microscopic examination of vaginal fluid) may be a sensitive indicator of cervical inflammation with a high negative predictive value,[135] particularly among women with BV.[136,137]

Nearly all women with BV have a vaginal pH of ≥4.5 when measured with pH paper having an appropriate pH range, although this finding is by no means specific for BV. A fishy odor was noted when vaginal fluid was mixed with 10% KOH (the "whiff test") in 43% of those with BV versus 1% of those without BV. Microscopic evaluation of vaginal fluid at high power (400×) revealed clue cells representing ≥20% of vaginal epithelial cells in 81% of those with BV versus 6% of those without BV.[28] Clue cells are epithelial cells heavily coated with bacteria sufficient to obscure the cell borders. (Fig. 42-2) The bacteria covering the clue cells include *G. vaginalis* as well as anaerobes such as *Mobiluncus*. Newer approaches to visualizing uncultivatable bacteria associated with BV indicate that these bacteria may also contribute to the characteristic appearance of clue cells, as depicted in Fig. 42-1.

DIAGNOSIS

Self-diagnosis of vaginitis is frequently incorrect. In a study of 552 women aged 16 years or older, only 3–4% of women could accurately identify the symptoms associated with BV.[138] Many women believe that vaginal malodor is due to poor hygiene or are embarrassed about the symptoms and do not report this as

Table 42-1. Symptoms and Signs Among 661 Randomly Selected Women Attending a Sexually Transmitted Disease Clinic

	Bacterial Vaginosis (n = 311) (%)	No Bacterial Vaginosis (n = 350) (%)	Univariate Odds Ratio	*P*	Multivariate[a] Odds Ratio	*P*

[a]Each finding was adjusted for age, race, parity, education, occupation, current smoking, age at first intercourse, lifetime sexual partners, *C. trachomatis, N. gonorrhoeae*, yeast, and herpes simplex virus in the analysis. Women with *T. vaginalis* were excluded from the analysis.

[b]Adnexal tenderness scored as moderate to severe.

a symptom to their health-care provider. Thus, symptoms alone are not reliable for the diagnosis of VB. Amsel et al. recommended basing the clinical diagnosis of VB on the presence of at least three of the following four signs:[35] (1) characteristic homogeneous white adherent discharge, (2) vaginal fluid pH > 4.5, (3) release of a fishy amine odor from vaginal fluid when mixed with 10% KOH, and (4) presence of clue cells (usually representing at least 20% of vaginal epithelial cells). These simple clinical tests are inexpensive and available in most office settings. Evaluation of wet mounts of vaginal fluid is technically difficult and highly subject to interobserver variation. Therefore, determination of pH and amine odor can significantly enhance the accuracy of diagnosis of BV.

DISCHARGE

Douching, recent intercourse, menstruation, and concurrent infection all can alter the appearance of the discharge associated with BV. The white, nonfloccular discharge of BV adheres to the walls of the vagina and is only slightly or moderately increased in amount over that normally seen. Absence of a discernable white homogeneous discharge should not rule out BV, if the other manifestations are present.

VAGINAL FLUID pH

The vaginal fluid pH determination requires pH paper having appropriate range (pH 4.0–6.0). Commercially available pH paper suitable for this purpose includes a pH range of 3.0–6.5. Vaginal pH is best determined by swabbing the lateral or posterior fornices of the vagina, and then placing the swab sample directly on the pH paper. Alternatively, the pH paper can be placed on vaginal fluid pooling in the speculum after removal from the vagina. The cervical mucus must be avoided since it has a higher pH (pH 7.0) than the vaginal fluid. Eschenbach et al.[28] reported that none of 178 women with pH ≤4.4 had clue cells, while all of 257 women having ≥20% clue cells had vaginal pH ≥4.7. Of these 257 women, 89% had a homogeneous discharge, an amine odor, or both. Vaginal fluid pH has the greatest sensitivity of the four clinical signs, but the lowest specificity.

ODOR

Vaginal malodor is the most common symptom of women with BV, and release of the "fishy" amine odor from vaginal fluid after addition of 10% KOH greatly increases the detection of the malodor by the clinician. A drop of vaginal fluid should be placed on a glass slide and a drop of 10% KOH added, immediately releasing an amine odor as the pH of the mixture approaches the pKa of the amines (e.g., putrescine, cadaverine, histamine, and trimethylamine), and amines that are no longer protonated become volatile. The odor then dissipates quickly. A coverslip placed over this preparation permits microscopic exam for the pseudohyphal forms associated with candidiasis. Although the KOH odor test was reportedly the most powerful single predictor for diagnosis of BV,[139] others have reported this test to be the least sensitive of the four clinical tests for diagnosis of BV. Eschenbach et al.[28] reported a positive predictive value of only 76% for this test

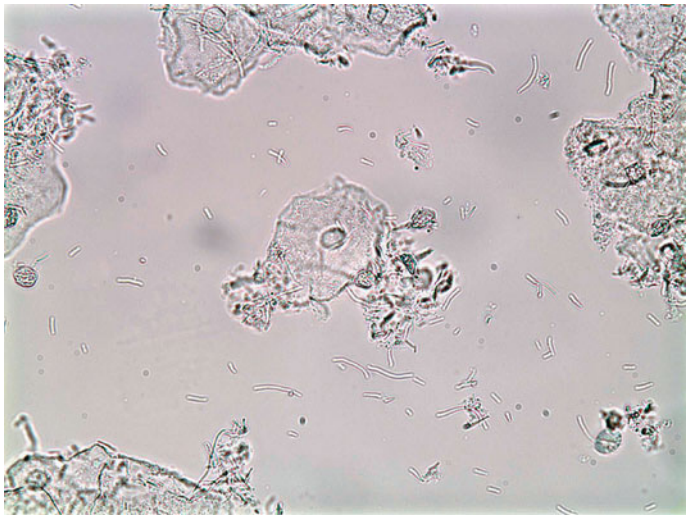

FIGURE 42-3. Wet mount of vaginal fluid showing absence of clue cells and presence of long lactobacilli morphotypes (×400 magnification). (*Photograph provided by Lorna K. Rabe.*)

compared with Gram stain diagnosis of BV. However, when an objective diamine test was used as a screening test for BV in 229 women, the detection of diamines was found to be 92% sensitive and 83% specific with respect to identification of clue cells.[140] In another study of 164 women attending a genitourinary medicine clinic, the same colorimetric diamine test had an 87% sensitivity and 98% specificity compared to Gram stain criteria.[141]

WET MOUNT EXAM FOR CLUE CELLS

Clue cells are squamous vaginal epithelial cells covered with many vaginal bacteria, giving them a stippled or granular appearance. The borders are obscured or stipled owing to adherence of small rods or cocci (Fig. 42-1), including *Gardnerella*, *Mobiluncus*, and other bacteria. Lactobacilli may also bind to exfoliated vaginal epithelial cells, although seldom in high enough concentrations to mimic clue cells. At least 20% of vaginal epithelial cells resembling clue cells should be present to establish a diagnostic criterion for BV. However, when an experienced microscopist identifies only 1–20% of vaginal epithelial cells as clue cells, this is highly correlated with Gram stain features of BV.[142] A sample of vaginal fluid obtained with a swab and mixed on a glass slide with a drop of normal saline is covered by a coverslip, and 10 fields examined under high power (×400) for clue cells. An example of a wet mount showing predominant vaginal lactobacilli is shown in Fig. 42-3, and a wet mount with numerous neutrophils is shown in Fig. 42-4.

VAGINAL CULTURE

Cultures for *G. vaginalis* or other individual microbes have little utility for the diagnosis of BV. *G. vaginalis* can be recovered from nearly all women with BV, but also from up

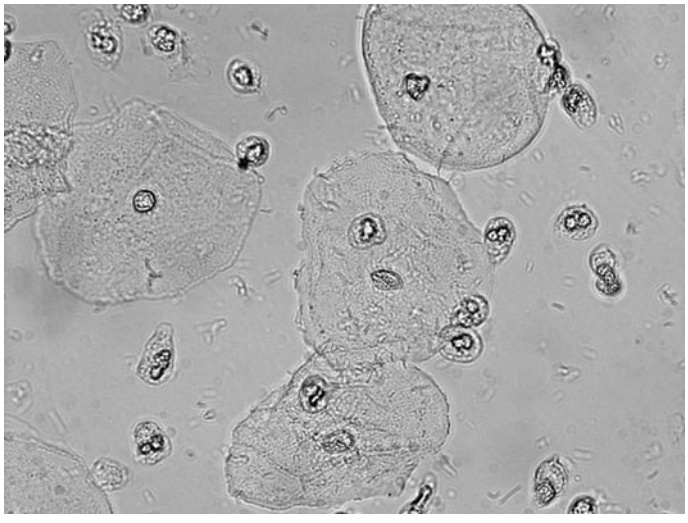

FIGURE 42-4. Wet mount of vaginal fluid showing absence of clue cells and presence of numerous PMNs (×400 magnification). (*Photograph provided by Lorna K. Rabe.*)

to 58% of those without BV.[28] A positive vaginal culture for *G. vaginalis* in the absence of the clinical signs of BV does not warrant therapy. Likewise, *G. vaginalis* culture does not constitute "test of cure," since many women without clinical signs of BV have positive cultures for this organism following effective treatment.

GRAM-STAINED SMEARS OF VAGINAL FLUID

Dunkelberg first proposed the evaluation of vaginal Gram-stained smears for diagnosis of BV,[143] and Spiegel et al. later published specific guidelines.[144] A standardized 0–10-point scoring system for evaluation of Gram-stained vaginal smears (Table 42-2) was later developed, based on three morphotypes: large Gram-positive rods (lactobacilli), small

Table 42-2. Standardized Method for Scoring Gram-Stained Smears for Diagnosis of Bacterial Vaginosis (1+, <1/1000× Microscopic Field; 2+, 1-5/1000×; 3+, 6-30/1000×; 4+ >30/1000×)

	Points[a] Scored per Morphotype				
Bacterial morphotype	None	1+	2+	3+	4+
Large Gram-positive rod	4	3	2	1	0
Small Gram-negative/variable rod	0	1	2	3	4
Curved negative/variable rod	0	1	1	2	2

[a]Score or 0–3 points, normal; 4–6, intermediate; 7–10, bacterial vaginosis.

Gram-negative or variable rods (*Gardnerella* and anaerobic rods), and *Mobiluncus*.[145] This method, based on the shift in bacterial morphotypes from predominance of lactobacilli (Fig. 42-5) to a mixed flora (Fig. 42-6) to predominance of *Gardnerella* and anaerobic bacterial morphotypes, including *Mobiluncus* (Fig. 42-7), has had 89% sensitivity and 83% specificity for diagnosis of BV, in comparison with clinical criteria,[146] and has had excellent intercenter reproducibility.[145,147] Two studies evaluating the Nugent Gram stain criteria for diagnosis of VB have reported sensitivities of 86–89% and specificities of 94–96%, compared to the Amsel criteria.[142,148] In one of the studies, the Nugent and Spiegel methods were directly compared.[149] Evaluation of vaginal smears by the Nugent criteria yielded similar sensitivity (86% vs. 83%) and greater specificity (96% vs. 89%), compared to the Spiegel method. The vaginal smear for Gram stain evaluation can be prepared at the same time that the wet mount is prepared by rolling (not streaking) the swab across the surface of a glass slide. After air drying, the slide can be stored for months or years prior to staining with no appreciable loss in quality. Self-obtained swabs have also been proven to be acceptable for preparation of Gram-stained vaginal smears.[149,150] The slide should be heat fixed and stained as usual in the clinical lab. The advantages of Gram stain for diagnosis include interpretation by standardized objective criteria by a microbiologist, suitability for quick screening, and storage for batch reading or later confirmation if desired.

OLIGONUCLEOTIDE PROBES

A specific oligonucleotide probe test adjusted to detect only high concentrations (>10^7/mL vaginal fluid) of *G. vaginalis* was 95% sensitive and 79% specific for the diagnosis of BV in 113 women (Affirm VP III, Becton-Dickinson,

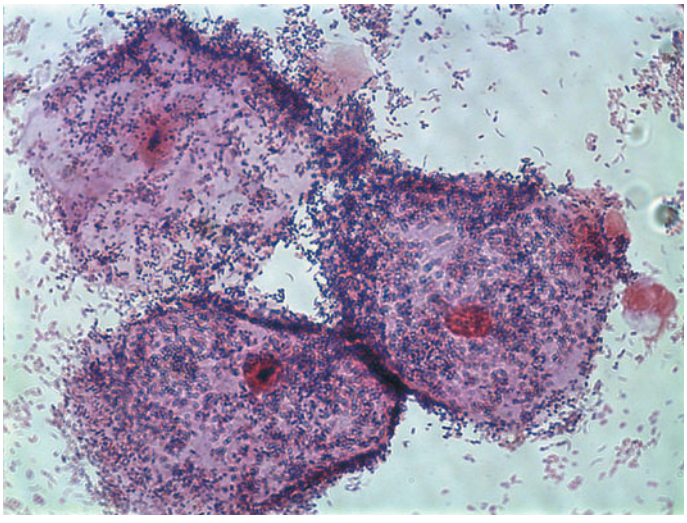

FIGURE 42-7. Gram stain of vaginal fluid from a woman with bacterial vaginosis showing absence of lactobacilli and large numbers of gram-negative or gram-variable coccobacilli. Curveed gram-variable rods are consistent with *Mobiluncus* (×1000 magnification). (*Photograph provided by Lorna K. Rabe.*)

Cockeysville, MD).[151] A commercially available 40-minute version of this test was 94% sensitive and 81% specific for the diagnosis of BV in an STD clinic population.[152] This test simultaneously detects *Candida* species as well as *T. vaginalis* and provides a laboratory-based option for detection of all three vaginal pathogens. The advantage of this system is that it is objective, detects mixed vaginal infections, and can be used in any setting approved for moderately complex laboratory tests. Other researchers have continued to work toward development of a broader array of DNA probes for detection of *p. bivia*, *B. ureolyticus*, and *Mobiluncus curtisii*, in addition to *G. vaginalis*.[153] In a study of 134 pregnant women, having multiple pathogens present by DNA probe was highly correlated with a Gram stain diagnosis of BV.

■ DETECTION OF METABOLIC PRODUCTS

Several published methods for BV diagnosis involve detection of metabolic products of the microorganisms in the vaginal fluid of women with BV. Some of these tests have been modified for ambulatory clinic use, with commercial availability of tests for detection of sialidase and proline aminopeptidase.

TREATMENT

Gardner first described triple sulfa cream as a treatment for "*H. vaginalis* vaginitis" in 1955.[8] Subsequently, sulfa creams have been shown to have low efficacy and are inappropriate for treatment of BV. Over the past 25 years, numerous studies of various therapies for BV have repeatedly shown that only those antimicrobial compounds with broad activity against most anaerobic bacteria are highly effective for the treatment of this syndrome.

■ METRONIDAZOLE

Pheifer et al.[39] first observed in 1978 that metronidazole used for vaginal trichomoniasis also cleared concurrent nonspecific vaginitis and went on to demonstrate the efficacy of a 7-day metronidazole regimen for this condition.

Most of the carefully conducted clinical trials used the Amsel criteria for diagnosis of BV, and cure or improvement was usually defined as resolution of two or more of Amsel's criteria[35] for diagnosis. Outcome was generally assessed 1 week and/or 1 month after therapy. Several studies found that 10–15% of women who initially respond to therapy relapse by 1 month after treatment. A 1998 draft guidance from the U.S. Food and Drug Administration recommends that clinical cure be defined as the resolution of all four clinical signs of BV and return to a Nugent's Gram stain score of 0–3. If this definition of "cure" is used, cure rates for metronidazole or clindamycin therapy are usually substantially lower, so an understanding of the criteria used to define cure is needed to interpret clinical trial data.[154]

In a meta-analysis of metronidazole therapy treatment of BV, Lugo-Miro et al.[155] reported initial cure in 87% of 280 women receiving oral metronidazole (400–500 mg) two to three times daily for 7 days, and an 86% response in 317 women receiving 5 days of oral therapy. From this analysis of over 1200 women, there was a consistent finding that over 85% of women responded initially to metronidazole therapy. However, these authors reported that the 2 g stat dose was equivalent to 7 days of oral therapy.

Our own analysis of six studies, which compared the single 2-gm dose of metronidazole versus 800–1200 mg per day for 7 days and followed patients for at least 1 month after treatment, shows that five of these six studies showed lower cure rates with the single dose.[156] When results from the six studies are combined, BV persisted at follow-up >4 weeks after completing therapy in 27% of those given a 2-gm single dose of metronidazole and in 18% of those given a 7-day treatment regimen ($p = 0.03$).

Side effects of oral metronidazole include nausea, metallic taste, headaches, and gastrointestinal distress. Oral metronidazole may also lead to a disulfiram-like reaction after alcohol consumption, which may decrease patient compliance.

To reduce systemic absorption of metronidazole and decrease side effects, intravaginal metronidazole therapies have been developed (Table 42-3) summarizes a series of studies of topical metronidazole or clindamycin). In the initial study of intravaginal 0.75% metronidazole gel used twice daily for 5 days, 26 (87%) of 30 women were free of BV 4–16 days after therapy; four (15%) of the women relapsed at the 1-month follow-up,[158] giving a 73% cure rate at 1 month. Livengood and his colleagues evaluated this same formulation of metronidazole gel in 49 women and reported cure rates of 78% and 71% at the first and second follow-up visits, respectively.[159] A study

Table 42-3. Efficacy of Intravaginal Metronidazole or Clindamycin, for the Treatment of BV

Agent	Dosage	Frequency	Duration (d)	No. of Patients	Clinical Efficacy (%)[a]	Reference

[a]Efficacy determined 1 month after therapy, usually defined as absence of BV.

comparing intravaginal metronidazole versus triple sulfa cream showed higher efficacy of vaginal metronidazole.[160] Use of intravaginal metronidazole has resulted in fewer side effects than have been observed after use of oral metronidazole. None of 53 subjects who used the metronidazole gel experienced nausea or headache, or complained of having a metallic taste during this placebo-controlled trial. A direct randomized comparison of metronidazole vaginal gel twice daily for 5 days versus oral metronidazole 500 mg twice daily for 7 days showed that 5 weeks after therapy BV was eliminated in 71% (29/41) of the intravaginal metronidazole group, and in 71% (32/45) of the oral metronidazole group.[172] A once-daily dosage of the 0.75% metronidazole gel, given over 5 days, has been approved for use in the United States. In a randomized trial of 7 days of oral versus 5 daily doses of a topical metronidazole for treatment of BV during pregnancy, efficacy was similar for both groups.[131] Finally, limited data suggest that increasing the dose of vaginal metronidazole may effect higher cure rates for BV. Sanchez et al. compared metronidazole vaginal gel (Metrogel™) to Flagystatin™ (ovules containing 500-mg metronidazole and 100,000-U nystatin) given nightly for 5 nights.[60] Of 138 women evaluable for follow-up at a mean of 42 days, BV persisted in 38% in the Metrogel and 17% in the ovule group ($p = 0.01$). While the higher dose of metronidazole was presumed to be the reason for the superior efficacy of the combination product, a potential contribution of the antifungal component could not be ruled out in this study design. Moreover, the study was limited by relatively low rates of follow-up and assessment of cure at variable intervals. Nonetheless, the data are intriguing and support a potential route of investigation toward more effective regimens for BV treatment.

In summary, metronidazole therapy used orally or intravaginally has been evaluated in hundreds of women with BV. These studies have consistently reported resolution of BV in 71–89% or more of women 1 month after therapy. In smaller studies, intravaginal therapies have had efficacy similar to that of oral metronidazole regimens with fewer side effects.

CLINDAMYCIN

The effectiveness of oral clindamycin for treatment of BV was first reported by Greaves et al., who randomized 143 women

to receive metronidazole, 500 mg bid for 7 days or clindamycin 300 mg bid for 7 days.[173] The clinical efficacy at 1 week was 94% for the oral clindamycin group, compared to 96% for the oral metronidazole group. Overall 16% of the clindamycin group and 22% of the metronidazole group reported adverse effects, none of which necessitated discontinuation of therapy. Oral clindamycin appeared as effective as metronidazole for treatment of BV and was of particular interest for the treatment of pregnant women.

Intravaginal clindamycin for the treatment of BV in nonpregnant women has been evaluated in numerous studies.[163–170,174] Livengood et al.[164] and Hillier et al.[163] reported two dose-ranging studies of intravaginal clindamycin for BV. In a placebo-controlled, double-blind, randomized trial, women received 5 gm of clindamycin cream at concentrations of 0.1%, 1.0%, or 2.0% to be used each night for 7 nights. The authors concluded that 2.0% topical clindamycin was both clinically and microbiologically effective therapy for treatment of BV, whereas lower concentrations of clindamycin had lower clinical efficacy.

In a placebo-controlled trial of 2% intravaginal clindamycin, 50 (77%) of 66 women with BV given clindamycin and 17 (25%) of 69 women given placebo were free of BV at the first follow-up visit.[165] In a smaller, placebo-controlled trial of 3 days of intravaginal clindamycin therapy for BV, only one had persistent BV at first follow-up, and three additional patients developed recurrent BV at the second follow-up visit.[167]

Several double-blinded, placebo-controlled trials have compared 7 days of intravaginal clindamycin cream (and twice-daily oral placebo) to 7 days of oral metronidazole administered twice daily (and once-daily placebo vaginal cream) for treatment of BV.[166,168,169,171] In all of these trials, intravaginal clindamycin vaginal cream was as efficacious as 7 days of oral metronidazole therapy for the treatment of BV after both 1 week and 1 month of follow-up. Another study compared topical clindamycin, in the form of intravaginal ovules for these days with intravaginal metronidazole gel, applied daily for 5 days. Cure rates were not statistically significantly different for the two groups, although clindamycin-resistant microorganisms were detected more frequently among women in the clindamycin treatment group.[170]

In two of these placebo-controlled, double-blind trials directly comparing intravaginal clindamycin to oral metronidazole, side effects were also compared. Only 3% and 5% of women assigned to intravaginal clindamycin and oral metronidazole, respectively, discontinued treatment because of side effects. Metronidazole was associated with a slightly higher incidence of gastrointestinal upset and nausea and metallic taste. Vaginal irritation and yeast vaginitis occurred in similar proportions of the two treatments. In summary, intravaginal therapies with metronidazole gel or clindamycin cream, as described above, have been considered effective treatments for BV. Intravaginal therapies have been well tolerated. However, the costs of such therapies currently far exceed the cost of one dose or 7 days of oral metronidazole.

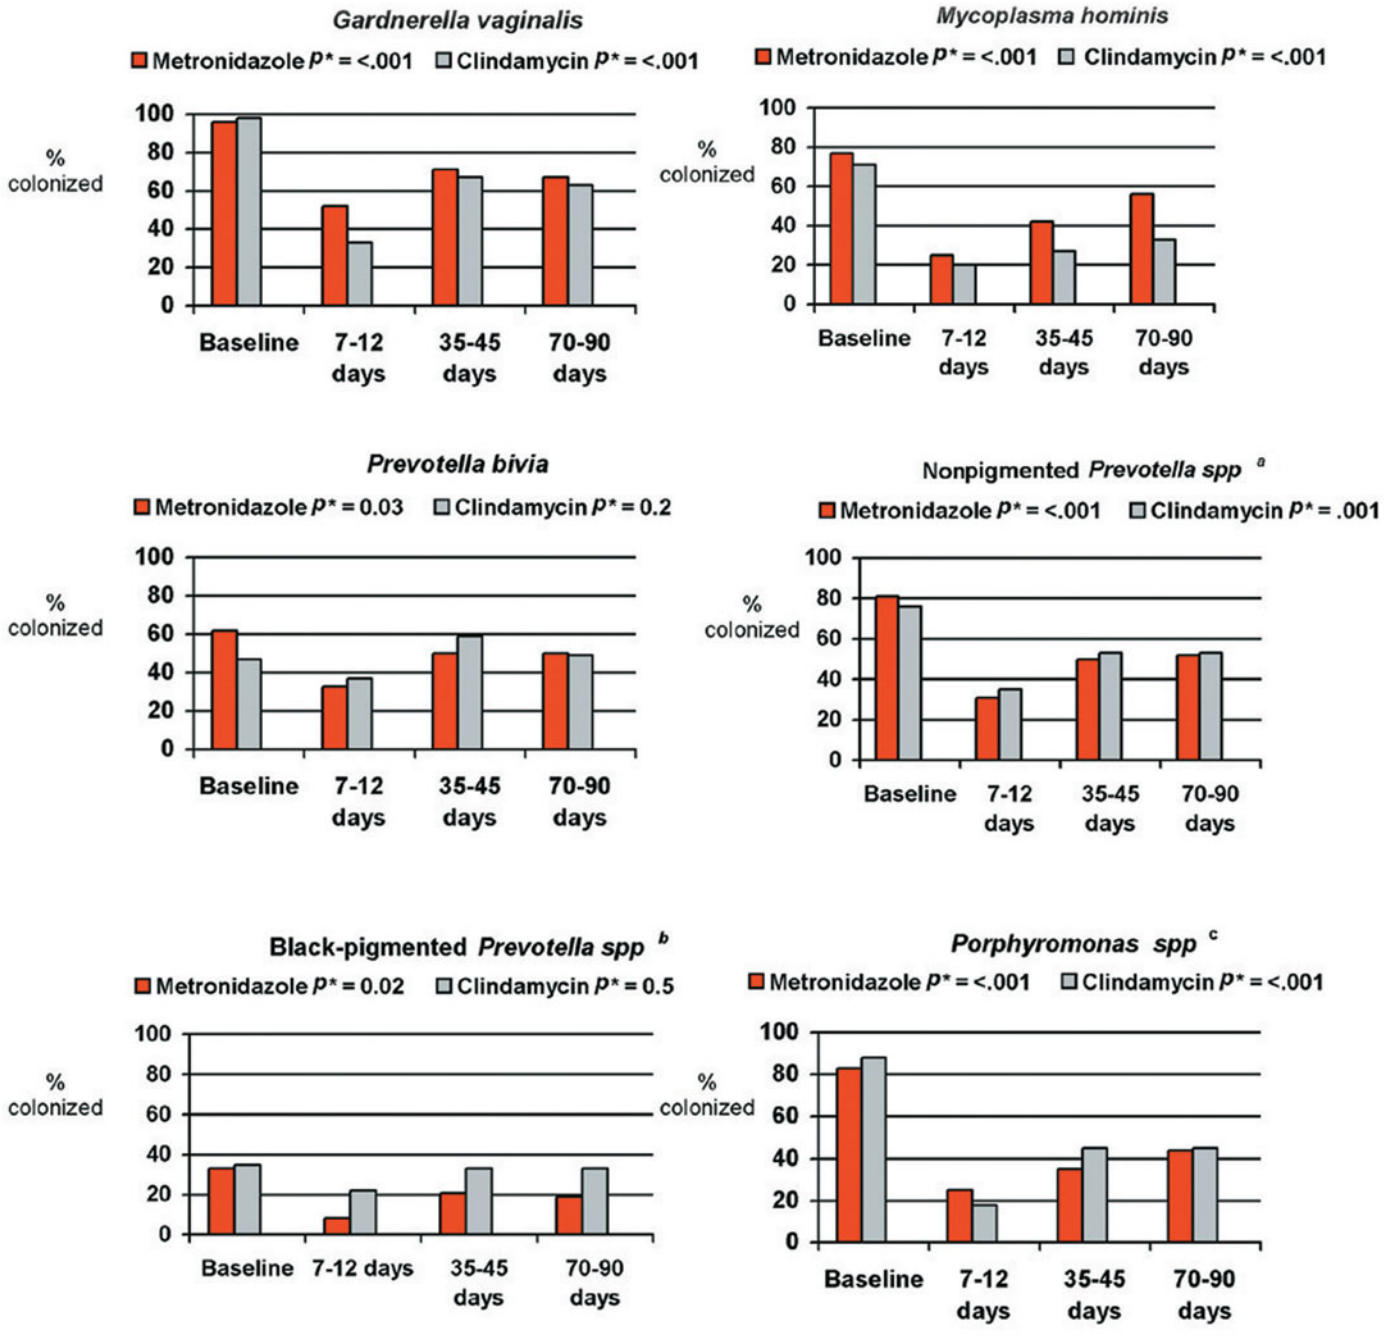
More recently, a sustained-release cream containing 2% clindamycin (Clindesse™) has been approved for the treatment of BV. The single published study on the efficacy of this product found that efficacy for BV was equivalent to that achieved with 7 days of vaginal clindamycin 2% cream (Cleocin™).[174] Overall 112 of 128 women (87.5%) given single-dose sustained release clindamycin cream versus104 of 125 women given the 7-day intravaginal regimen (83.2%) experienced resolution of at least three of four Amsel criteria.

In many developing country settings,[175] especially in Latin America, topical intravaginal therapies with various mixtures of metronidazole, antifungal, antibacterial, antiseptic, and anti-inflammatory drugs are very commonly used for vaginal discharge and are often dispensed by pharmacies without prescriptions. Apart from the study noted above,[60] we are not aware of any published data documenting the effectiveness of such peculiar preparations.

MICROBIOLOGICAL RESPONSE TO THERAPY WITH METRONIDAZOLE OR CLINDAMYCIN

Although metronidazole is active against Gram-negative anaerobes and *Mobiluncus mulieris*, it is less active against *G. vaginalis*, anaerobic Gram-positive cocci, and *Mobiluncus curtisii*,[177] and inactive against *M. hominis* and *A. vaginae*. *G. vaginalis* is more susceptible to the hydroxymetabolite of metronidazole than to the parent drug, but, nonetheless, about 50% of women clinically cured after treatment with metronidazole remain colonized by *G. vaginalis*. *M. curtisii* is not susceptible to metronidazole in vitro but is usually eradicated following metronidazole therapy. It is possible that inhibition or elimination of metronidazole-susceptible members of the vaginal flora in BV results in a decline in certain nonsusceptible members as well.

A graphical analysis comparing the changes observed among the vaginal microorganisms associated with BV isolated at baseline and 7–12, 35–45, and 70–90 days following therapy with metronidazole or clindamycin is presented in Fig. 42-8.[177] The presence of H_2O_2-producing lactobacilli are considered to be indicators of optimal vaginal ecology, and a significant increase in colonization by H_2O_2-producing *Lactobacillus* species was observed among women following therapy with either metronidazole or clindamycin over 90 days of follow-up ($p < 0.002$). However, the proportion of women colonized by H_2O_2-producing lactobacilli differed at baseline for the two treatment groups. Clindamycin treatment resulted in a larger increase in colonization by *E. coli*, compared with metronidazole-treated women, although these differences did not



*Cochran's Q test performed to determine P value for frequency of microbes between visits.
[a] Nonpigmented *Prevotella spp* includes: *P. oralis, P. buccalis, P. veroralis, P. oulorum, P. oris, P. buccae, P. capillosus and P. disiens.*
[b] Black-pigmented *Prevotella spp* includes: *P. intermedia, P. corporis, P. denticola, P. loeschii, P. melaninogenica* and *B. levii.*
[c] *Porphyromonas spp* includes *P. assachrolytica, P. endodontalis and P. gingivalis.*

FIGURE 42-8. Changes in vaginal microbiology from baseline among women with BV after therapy with topical metronidazole or clindamycin.

reach statistical significance (data not shown). A significant decrease in colonization by *G. vaginalis* and *M. hominis* ($p < 0.001$) was observed among women following therapy with either clindamycin or metronidazole.[177] Women treated with metronidazole had a significant decrease in colonization by *U. urealyticum* (from 94% to 79%, $p < 0.001$), whereas clindamycin-treated women did not (from 73% to 65%, $p = 0.3$). Following therapy with metronidazole, there was a significant decrease in colonization by *P. bivia* ($p = 0.03$) and black-pigmented *Prevotella* spp. ($p = 0.02$), two of the anaerobic Gram-negative rods associated with BV, but a significant decrease in these organisms was not observed among women who were treated with clindamycin (Fig. 42-7). Both *Porphyromonas* spp. and nonpigmented

Prevotella spp. decreased significantly following treatment with either regimen.

Antimicrobial susceptibility testing of anaerobic Gram-negative rods recovered from the women before and after treatment revealed a marked and sustained increase in the proportion of clindamycin-resistant anaerobic Gram-negative rods from women following therapy with clindamycin, but not from those treated with metronidazole. The proportion of *P. bivia*, nonpigmented *Prevotella*, black-pigmented *Prevotella*, and *Porphyromonas* isolates resistant to clindamycin before treatment with clindamycin was 8%, 14%, 11%, and 3%, respectively. However, at 7–12 days following therapy with clindamycin the percentage of clindamycin-resistant isolates was 51%, 43%, 68%, and 14%, respectively.[177]

In summary, treatment with clindamycin versus metronidazole for BV results in a different microbiological pattern following therapy. While both topical metronidazole and clindamycin yielded similar clinical responses to treatment, metronidazole may be superior to clindamycin, based on the lower level of resistance and its capacity to eradicate anaerobic Gram-negative rods from the vagina.

TINIDAZOLE

Tinidazole, like metronidazole, is a nitroimidazole with antiprotozoal and antibacterial activity and is approved in the United States for the treatment of trichomoniasis when given as a single 2.0-g dose orally. Outside of the United States, tinidazole has been used widely for the treatment of BV in various oral dosing regimens, including 2 g as a single dose or daily for 2 days, 500 mg twice daily for 5 days, and 150 mg twice daily for 5 days, and as an intravaginal regimen (given as a tablet) at 500 mg daily for 14 days. Because different standards and timing for assessing cure rates were used in several studies, comparing treatment efficacy is difficult, but in general, efficacy of the single 2-g oral dose ranged from 46% to 71% in placebo-controlled trials and from 75% to 94% when compared to comparable regimens of metronidazole or clindamycin. Efficacy for the 2-g dose given daily for 2 days ranged from 50% to 80%.

A multicenter, placebo-controlled randomized trial of oral tinidazole given as either 2 g daily for 2 days or 1 g for 5 days has recently been completed. Resolution of BV as defined by absence of at least three Amsel criteria was seen in 46% of subjects who received the 2-day regimen and in 64% of those who received the 5-day regimen.[178] In vitro, tinidazole has activity against anaerobes comparable to metronidazole, and somewhat greater activity against *G. vaginalis*.[176] In a study comparing a single dose of tinidazole followed by vaginal acidifier to 7 days of clindamycin cream treatment, the single dose of tinidazole was found to be as effective as 7 days of clindamycin.[179]

TREATMENT OF SEXUAL PARTNERS

Several placebo-controlled trials have demonstrated that treatment of the male partner(s) does not improve the clinical outcome of treatment of BV or reduce recurrence.[68,180–183] For example, Moi and his colleagues[180] reported no differences in initial response of BV to therapy or in recurrence at 4–12 weeks after therapy for women whose partners were or were not treated with oral metronidazole. In a double-blind, randomized trial, Vejtorp et al.[68] observed no effect of treatment of the male partner on symptoms, clinical signs of BV, or isolation of *G. vaginalis* from the vagina 1 and 5 weeks after treatment of BV. Similarly, Vutyavanich et al.[182] reported that tinidazole treatment of male partners in Thailand had no effect on clinical response in the female but was associated with a significant increase in side effects in the male partners who received tinidazole compared to placebo-treated men (22% vs. 7%, $p = 0.006$). In a study in which women were treated for BV with clindamycin vaginal cream, and their male partners were randomly treated with oral clindamycin or placebo, recurrences of BV were unrelated to treatment of partners.[183]

Because all carefully controlled trials of male partners show no benefit of treatment of male partners, the U.S. Centers for Disease Control Guidelines for STD Treatment do not recommend routine treatment of male partners. The discrepancy between data suggesting sexual acquisition of BV and the lack of benefit of treating the male partner remains puzzling. Part of the issue may be that the selection or dosing of the antibiotics used in the trials done to date was not appropriate or adequate for eradicating a potential reservoir for BV-associated bacteria in men. An explanation may await better understanding of the role of sexual exposure and of the male partner in transmission.

TREATMENT OF BV WITH OTHER ANTIMICROBIAL AGENTS

The relative efficacies of other antimicrobial therapies for treatment of BV are summarized in (Table 42-4). Although sulfonamide creams have been used to treat BV for over 40 years, numerous studies document an unacceptably low efficacy for this product.[160,184] Cephalosporins are generally less effective than metronidazole or clindamycin against BV, presumably because of their limited activity against anaerobic bacteria.[185] Although ampicillin has been used as an alternative therapy for BV, especially in pregnancy, and has in vitro activity against *G. vaginalis*, ampicillin has given cure rates as low as 43% in studies with sufficiently long follow-ups.[186,187] Lack of efficacy may be due to production of beta lactamase by the anaerobic Gram-negative rods in the vagina of women with BV. Like clindamycin, ampicillin is also active against lactobacilli and delays vaginal recolonization by lactobacilli.[187] The poor efficacy of ampicillin does not support its use for BV even during pregnancy.

Table 42-4. Comparative Efficacy of Various Agents and Regimens Other than Metronidazole, Tinidazole, or Clindamycin for the Treatment of BV Omit or Update

		Regimen				
Agent	Route[a]	Dosage	Frequency	Duration (d)	Clinical Efficacy (%)	Reference
Tinidazole	o	500 mg	bid	5	95	184
	o	2 g	Once daily	2	76	178
	o	2 g	Once daily	5	63	178
Cephadroxil	o	500 mg	bid	7	64	185
Ampicillin	o	500 mg	qid	7	43–48	186,187
Tetracycline	o	500 mg	bid	7	50	188
Erythromycin	o	500 mg	qid	7	23	189
Triple sulfonamide	v	500 mg	bid	7	44–77	184,186
Ofloxacin	o	300 mg	bid	7	28	190

[a]o, oral; v, intravaginal.

Antimicrobial agents used for the treatment of chlamydial or gonococcal cervicitis, including tetracycline, erythromycin, and ofloxacin, have very limited activity against anaerobic bacteria. Furthermore, erythromycin has limited antibacterial potency at the acid pH of the vagina, even at the slightly less acid intravaginal pH characteristic of BV. These antimicrobial agents cure BV in only one-fourth to one-half of women and are considered poor treatment choices.[188–190] A recent study showed that addition of azithromycin to metronidazole for treatment of BV did not improve response to therapy.[191]

SYNDROMIC MANAGEMENT OF VAGINAL DISCHARGE IN DEVELOPING COUNTRIES (SYNDROMIC MANAGEMENT OF VAGINAL DISCHARE IS DISCUSSED IN CHAPTER 55)

A recent study in West Africa involved syndromic management of vaginal discharge in women seen at primary care clinics in Ghana, Guinea, Mali, and Togo. Women were randomized to single-dose treatment with a single dose of tinidazole 2 g po plus a single dose of fluconazole (150 mg po) versus 7 days of metronidazole (500 mg bid for 7 days) plus clotrimazole vaginal cream for 3 days. The two treatment regimens were considered effective with complete resolution in 66% and 64% of participants, respectively, with similar results for women with BV, trichomoniasis, or vulvovaginal candidiasis, and for women with and without HIV infection.[191a]

ALTERNATIVE TREATMENTS FOR BV, INCLUDING RESTORATION OF NORMAL VAGINAL ECOLOGY

Because BV results from an ecological shift in the vaginal microflora, a number of researchers have evaluated therapies that either act as vaginal disinfectants or are aimed at restoring the vaginal ecosystem (Table 42-5).[192–198] Chlorhexidine pessaries reportedly had 79% efficacy in 34 women with BV, but 48% had recurrence at 1 month post-treatment. Povidone-iodine inserted vaginally twice daily for 2 weeks was completely ineffective in two studies. Studies reporting high success rates with povidone-iodine have usually had a very high incidence of spontaneous resolution of BV in the placebo group, suggesting potential problems with diagnosis, or in applying the data to populations in which the spontaneous resolution is low.

The efficacy of vaginal acidifiers in the form of gels, suppositories, and acid-soaked tampons has varied widely from 18% to 80% in several small studies. However, intermittent use over weeks is usually required. Vaginal acidifiers will suppress, but not kill, vaginal anaerobes, so may suppress without effecting a cure. Hydrogen peroxide douches have been advocated for BV treatment as an alternative to antimicrobial therapy. In one study of 23 women with recurrent BV, a 3-minute vaginal treatment with 3% hydrogen peroxide was reportedly effective in most women. However, the authors noted no recolonization of the vagina with lactobacilli. Concerns with this approach include that it involves

Table 42-5. Lack of Efficacy of Alternative Treatments for BV

Class	Type	Form and Use	No. of Women	Efficacy (%)	Follow-Up (d)	Reference
Disinfectant	Chlorhexidine, 150 mg	Pessary	34	79	7	192
	Povidone-iodine	Pessary bid ×14 d	28	20	7	193
Acidifier	Lactic acid	Suppository	125	20	30	194
	Lactate pH 3.5, 5 g	Gel, daily × 7 d	31	77	7	195
	Lactate pH 3.8, 5 g	Gel, intermittent use × 6 wk				
	Acetate	Gel	17	18	30	196
	5% acetic acid	Tampon, bid × 7 d	32	38	30	197
Yogurt	Commercial	Douche 10–15 mL	32	88	30	197
	pH < 4.5	bid × 14 d				
	Commercial	Daily	14	7	30	196
Lactobacillus	Vivag; Pharmac-	Suppository	28	43	1–4	198
	Vinci A/S, Denmark	bid × 6 d				

douching, a procedure most experts feel should be generally discouraged; that simple application of H_2O_2 may produce short-term disinfection but will not sustain resolution of abnormal flora over time; and that even H_2O_2-producing lactobacilli may be killed by high concentrations of H_2O_2.

Lactobacilli appear to be the primary microbiological deterrent to vaginal infection. Therapies employing yogurt probably have little utility. While Fredricsson et al.[196] found that yogurt had only 7% efficacy for treatment of BV, another report claimed 88% efficacy for twice-daily douching with yogurt for 2 weeks.[197]

In a placebo-controlled trial of purified *Lactobacillus* spp. in suppositories, about half of the women receiving *Lactobacillus* improved during therapy, but only four of 29 women remained free of BV at the second follow-up visit.[198] Even though certain lactobacilli may play an important role in maintaining the normal vaginal flora, it remains to be determined whether the application of such lactobacilli is sufficient to restore the vaginal microflora. Another study evaluated the effectiveness of Gynoflor®, Medinova Ltd, Zurich, Switzerland, a tablet containing hydrogen peroxide-producing *Lactobacillus acidophilus* in combination with 0.03 mg of estriol.[199] At least one human-derived strain of *Lactobacillus crispatus* is currently under study as treatment for BV but is not yet commercially available.[200,201] However, a recent study of orally administered lactobacilli reported a high level of effectiveness among African women.[202] Advocates of alternative or nature-based treatments for BV have not proven the efficacy of these therapies in large, well-controlled, randomized, double-blind trials.

PREVENTION OF RECURRENT BV

Only one study to date has reported on attempts to suppress BV using ongoing antibiotic therapy.[203] Sobel and colleagues performed a prospective multicenter study in which women with current BV and at least two prior episodes of BV in the previous year were initially treated with 10 days of vaginal metronidazole gel (Metrogel) and then, if cured, randomly assigned to receive twice-weekly metronidazole vaginal gel or placebo for 16 weeks.[203] They were subsequently followed off therapy for 12 weeks. Of 157 eligible women, 112 of 127 returning evaluable women (88.2%) responded clinically and were randomly assigned. During suppressive therapy, recurrent BV occurred in 13 women (25.5%) receiving metronidazole and 26 (59.1%) receiving placebo (modified intent to treat analysis, relative risk [RR] 0.43, CI = 0.25–0.73, $p = 0.001$). During the entire 28-week follow-up, recurrence occurred in 26 (51.0%) on treatment compared with 33 (75%) on placebo (RR 0.68, CI = 0.49–0.93, $p = 0.02$). Probability for remaining cured was 70% for metronidazole compared with 39% on placebo, which declined to 34% and 18%, respectively, by 28 weeks'

follow-up. Adverse effects were uncommon; however, secondary vaginal candidiasis occurred significantly more often in metronidazole-treated women ($p = 0.02$). The authors concluded that suppressive therapy with twice-weekly metronidazole gel achieves a significant reduction in the recurrence rate of BV. No other regimens, including clindamycin-based or oral metronidazole, have been studied for suppression of recurrent BV.

BV IN PREGNANCY

BV during pregnancy has been linked to a significantly increased risk of preterm/low-birth-weight deliveries, intra-amnionic infection, histological chorioamnionitis, and postpartum endometritis. Is treatment necessary among women with symptoms, or does BV resolve spontaneously during pregnancy? Two published studies have reported on the persistence of BV during pregnancy. The first study evaluated 762 pregnant women at 23–26 weeks' gestation and again at 31–36 weeks' gestation.[146] Women who used antibiotics during this interval were specifically excluded. In this study, 69% of women who had BV in the second trimester still had this syndrome in the third trimester. In a second study, VB persisted in almost half of the women who had the condition initially and who went to term, that is in 15 (47%) of 32, while the flora reverted to the intermediate stage in two women (6%) and to normal in 15 women (47%).[204] There was, however, a significant association between VB status at visits 1 and 3. Women who had the infection initially were more likely to have it at visit 3 than women who did not (15/32 vs. 4/144, McNemar's test $x^2 = 0.05$). These data suggest that spontaneous clearance of BV does not occur in most pregnant women and support the 2006 recommendation from the CDC that all pregnant women who have symptomatic BV require treatment.[205]

PRETERM LABOR, LOW BIRTH WEIGHT AND PROM

In 1984, Minkoff et al. published a prospective study of perinatal morbidity in 233 women enrolled for prenatal care at 14 weeks' gestation and followed through delivery; women underwent vaginal cultures for *Bacteroides* spp. and *M. hominis*, evaluation for BV (then called nonspecific vaginitis) based on clinical manifestations (vaginal pH > 4.5, clue cells, amine odor), and cultures for *T. vaginalis*, yeast, herpes simplex virus, *C. trachomatis*, and facultative bacteria.[206] BV was diagnosed in 30% of 218 women. Subsequently, 16% developed preterm labor and received tocolysis; 50% of those who failed tocolysis had BV, compared to 29% of those whose labor stopped with tocolytic agents. In a stepwise logistic regression analysis of risk factors for perinatal morbidity, adjusting for maternal age, parity, previous premature delivery, abortion, and vaginal bacteria, isolation of *Bacteroides* spp. from the vagina was associated with preterm delivery (RR = 1.4, $p < 0.03$), preterm premature rupture of membranes (PROM) (RR = 1.8, $p < 0.03$) and birth weight less than 2500 g (RR = 1.8, $p < 0.04$). This study was the first to describe the association of vaginal anaerobic bacteria and of BV with perinatal complications. Several subsequent studies supported and extended these findings, although randomized trials have not supported a role for routine treatment of BV for prevention of adverse pregnancy complications.[207]

From 1984 onward, a larger series of studies linking BV to preterm delivery or low birth weight have been published. Observational studies conducted in the United States, Scandinavia, and Australia, which included women from different ethnic and socioeconomic groups, have consistently reported an increased risk for preterm delivery and/or low birth weight among women colonized by BV-associated pathogens (anaerobic Gram-negative rods and *M. hominis*) and among those with clinical or Gram stain evidence of BV, and some have noted a decrease in prematurity among those vaginally colonized by *Lactobacillus* spp.[208–212]

CHORIOAMNIONITIS AND AMNIOTIC FLUID INFECTION

Several studies link BV with infection of the fetal placental membranes (chorioamnion) and amniotic fluid, suggesting that ascension of vaginal microorganisms into the decidua, chorioamnion, or amniotic fluid, resulting in infection and inflammation at these sites, represents a probable mechanism by which BV can initiate labor and result in preterm delivery. In two studies, BV diagnosed by Gram-stained vaginal smear was related to histological chorioamnionitis and to recovery of microorganisms from the chorioamnion (OR = 3.2, $p < 0.05$).[213,214]

Amniotic fluid infection results most commonly from invasion of lower genital tract bacteria through the placental membranes. Frequently, most isolates recovered from the amniotic fluid of women with intact membranes are the microorganisms associated with BV,[215] and women with BV are twice as likely to have invasion of the amniotic fluid as women with *Lactobacillus*-predominant vaginal flora. An increased risk of intra-amniotic infection among women with BV at less than 34 weeks of gestation has been reported by Hitti.[216] Watts et al. reported a relationship of BV diagnosed at the time of C-section to clinically diagnosed amniotic fluid infection: Amniotic fluid infection occurred among 22% of women with a Gram stain diagnosis of BV compared to 4% of those with a *Lactobacillus*-predominant vaginal smear.[217] Hitti evaluated 197 afebrile women in preterm labor with intact fetal membranes and found that women having a Gram stain consistent with BV were more likely to have amniotic fluid infection.[216] High concentration of IL-8 in the vagina and anaerobic flora were both associated with amniotic fluid infection.[216]

In summary, BV during pregnancy has consistently been related to chorioamnion infection, histological chorioamnionitis,

and amniotic fluid infection. These three entities are strongly interrelated and are associated with preterm delivery.

TREATMENT OF BV DURING PREGNANCY FOR PREVENTION OF PRETERM BIRTH

Multiple published studies have evaluated whether treatment of BV in pregnancy prevents preterm birth.[207] Because of the efficacy of clindamycin applied intravaginally for the treatment of BV, and early concerns with the potential teratogenicity of metronidazole in pregnancy,[218] initial efforts to reduce preterm birth among women with BV focused on the use of intravaginal clindamycin.[219,220] However, these and subsequent studies failed to demonstrate that clindamycin-treated women had the same incidence of preterm birth as placebo-treated women and at least some studies showed a trend toward a higher incidence of birth before 32 weeks' gestation and of low birth weight among the clindamycin-treated women.[220] One study did demonstrate a reduced incidence in preterm birth among women treated with topical clindamycin;[221] however, most studies did not support use of clindamycin vaginal cream for prevention of preterm birth among women with BV. Because of the increased incidence in adverse birth outcomes in these studies,[219,220,222] the CDC does not recommend use of topical clindamycin for treatment of BV in the first half of pregnancy.[205]

Several published trials have evaluated oral metronidazole for treatment of BV during pregnancy. Two studies were conducted among women who were considered at high risk of preterm birth because of a previous preterm delivery or low pregnancy weight.[223,224] In a study of 80 high-risk women with BV, 18% of those randomized to metronidazole versus 39% of those randomized to placebo delivered preterm, $p < 0.05$.[216] Hauth et al. evaluated oral metronidazole, 250 mg, tid for 7 days plus erythromycin 333 mg, tid for 14 days versus placebo in a population at high risk for preterm birth due to previous preterm birth or having a prepregnancy weight of <50 kg.[227] Among women with BV and a history of previous preterm delivery, the percent delivering preterm was 39% for those assigned to metronidazole plus erythromycin, versus 59% for those assigned to placebo (RR = 1.6, 95% CI 1.1, 2.1).[227] However, a randomized trial of oral metronidazole in a low-risk population of pregnant women failed to document a reduced incidence of preterm among metronidazole-treated women,[225] although the study lacked sufficient size to allow for statistical power to detect small decreases in incident preterm births. A large NIH-sponsored randomized trial used an unusual dosage regimen of metronidazole, consisting of two single 2-g doses to women with BV who were at 16 to less than 24 weeks of pregnancy. This large trial found no decrease in preterm birth or other adverse perinatal outcomes among women randomized to receive metronidazole.[226] Since the publication of that study, numerous agencies have evaluated the available data on treatment of BV in pregnancy and concluded that routine treatment of asymptomatic women with BV cannot be justified.[205,207] A Cochrane review published in 2007 concluded that (1) there was good evidence that antibiotic therapy was effective at eradicating BV, (2) treatment did not reduce the risk of preterm birth before 37 weeks or the risk of preterm PROM, (3) treatment before 20 weeks' gestation may reduce the risk of preterm birth at less than 37 weeks, and (4) treatment of women with a previous preterm birth did not affect the risk of subsequent preterm birth. This analysis is summarized in Table 42-6. Although some authors have asserted that BV may be more of a stimulant for preterm delivery at earlier gestational ages, an analysis of 12,937 deliveries failed to demonstrate that the risk of preterm birth was increased when BV was identified at earlier gestational ages.[227]

The mechanisms by which BV may cause prematurity and low birth weight are not completely understood, and some experts argue that BV may be a biomarker for other factors that lead to preterm birth. As discussed above, BV-associated microorganisms ascend to cause infections of the decidua, placenta, and/or amniotic fluid. Although some experts have postulated that BV could lead to initiation of preterm birth through local production of proinflammatory cytokines such as IL-8,[206] treatment of BV has been shown to normalize levels of proinflammatory cytokines and chemokines in the cervical fluid of women with BV.[131] It has become clear that the association of infection with preterm birth is complex and likely attributable to numerous interrelated factors. A greater understanding of these complex interrelations between infection, the immune response in pregnancy, and genetic differences in response to infection will be needed in order to develop the insights needed for more effective approaches to prevention of preterm birth.

OTHER COMPLICATIONS OF BV

POSTPARTUM ENDOMETRITIS

In a prospective study of risk factors for post-Cesarean endometritis in 462 women,[228] those with BV diagnosed by Gram strain had an increased risk of postpartum endometritis following Cesarean section compared to women with a *Lactobacillus*-dominant flora (OR 5.8, 95% CI 3.0, 10.9) after adjusting for possible confounding factors, including maternal age, length of labor, and duration of membrane rupture. Women with BV also had increased rates of abdominal wound infection, and all of the documented wound infections were related to anaerobic bacteria. The

Table 42-6. Cochrane Review of Impact of Antibiotic Treatment on BV in Pregnancy[207]; Conclusions

Outcome	OR (95% CI)	Number of Trials	Number of Women
Treatment eradicates BV in pregnancy	0.17 (0.15–0.20)	10	4357
Treatment did NOT reduce preterm birth <37 wk of gestation	0.91 (0.78–1.06)	15	5888
Treatment did NOT reduce preterm premature ruptures of membranes	0.88 (0.61–1.28)	4	2579
Treatment before 20 weeks' may reduce risk of preterm birth <37 wk	0.63 (0.48–0.84)	5	2387
Treatment did not affect risk of subsequent preterm birth among women with previous preterm birth	0.83 (0.59–1.17)	5	622
Treatment may decrease risk of PPROM and LBW	0.31 (0.13–0.75)	2	114
Clindamycin did not reduce risk of preterm birth before <37 wk	0.80 (0.60–1.05)	6	2406

endometrial aspirates from patients with BV who developed postpartum endometritis contained the microorganisms associated with BV.[228]

The risk of postpartum endometritis remains high in patients with BV despite routine use of antibiotic prophylaxis. Cephalosporin prophylaxis is presumably inadequate early because of the large number and variety of bacteria contaminating the amniotic fluid of patients with BV and because some of the bacteria present are not highly susceptible to the cephalosporin used. The impact of antibiotic prophylaxis on patients with BV undergoing cesarean section needs further study. While women undergoing cesarean section experience the highest risk for postpartum endometritis, and BV is a strong risk factor among patients who deliver by cesarean section, BV also appears to increase the risk for postpartum endometritis among patients who deliver vaginally, specifically when amniotic fluid becomes contaminated with bacteria associated with BV during labor.[228] Invasion of anaerobes (most commonly *P. bivia*), *G. vaginalis* and *M. hominis* in the amniotic fluid resulted in a twofold increased risk of postpartum endometritis among patients delivered vaginally or by cesarean section.

VAGINAL CUFF CELLULITIS

Vaginal cuff cellulitis occurs when vaginal bacteria contaminate the operative field during a hysterectomy. Women with more virulent bacteria in the vaginal flora, present in the increased concentrations characteristic of BV, would be expected to have increased risk of vaginal cuff cellulitis following hysterectomy. In two separate studies, postabdominal hysterectomy cuff cellulitis occurred four times more commonly among patients with BV than patients with a normal *Lactobacillus*-dominant flora. In one of the studies, presence of *T. vaginalis* also was associated with a threefold increase in cuff cellulitis; however, after adjusting for the BV, the relative risk of cuff cellulitis in those with *T. vaginalis* alone was not significantly increased.[229] A second study evaluated the association between clue cells and cuff cellulitis after abdominal hysterectomy and found a similar increased risk of infection among these with BV.[230]

POSTABORTION PID

PID is frequently caused by *Neisseria gonorrhoeae* and *C. trachomatis*. Many investigators have found PID following induced abortion related to *C. trachomatis*. Postabortal endometritis following induced first trimester abortion has also been related to BV. Postabortion PID occurred more commonly among patients with BV than among those with a *Lactobacillus*-dominant flora (OR = 2.4, 95% CI 1.1, 5.3).[231] *C. trachomatis* was also associated with postabortal PID ($p = 0.06$), but BV was more than twice as common as *C. trachomatis* infection, so that postabortion PID occurred in eight patients who had preoperative BV, two patients with preoperative *C. trachomatis* infection, and 18 patients with neither. In another study, 174 patients with BV underwent double-blind randomization to placebo or metronidazole prior to undergoing induced abortion.[232] Placebo-treated patients had higher rates of postabortal PID (OR = 30, 95% CI, 1, 11.8, suggesting

that prior treatment of BV could significantly decrease infectious morbidity following termination of pregnancy. However, a subsequent randomized trial in the United States of 393 women failed to document any benefit of metronidazole treatment for women having a termination of pregnancy.[233]

PELVIC INFLAMMATORY DISEASE

The role of BV in spontaneous PID not associated with abortion or instrumentation of the uterus is less clear, even though anaerobes have long been linked with salpingitis.[23] Among randomly selected STD clinic patients, those with BV had adnexal tenderness significantly more often than patients with a *Lactobacillus*-dominant flora, suggesting that spontaneous PID occurring without instrumentation may also be related to BV.[28] In this study, the relationship between BV and adnexal tenderness persisted after adjusting by multifactorial analysis for infection with *N. gonorrhoeae* or *C. trachomatis*. Many of the bacteria recovered from the endometrium and fallopian tubes of patients with PID are those present in the vagina in high numbers among women with BV.[234] However, the proportion of women with BV who develop overt symptoms and signs of PID without instrumentation may be relatively low compared to the proportion of those infected with *N. gonorrhoeae* and *C. trachomatis*. Further, the interactions between *C. trachomatis*, *N. gonorrhoeae*, and facultative bacteria in producing PID is not known, and the relationship between BV or intermediate flora and acquisition of *C. trachomatis* and *N. gonorrhoeae* is probably complex and may depend in part on the microbiologic composition of BV itself. In one study, that prospectively followed more than 1000 women for 3 years, BV at baseline was associated with concurrent chlamydial or gonococcal infection (adjusted OR 2.8, 95% CI 1.81–4.42) but not significantly with subsequent detection of either of these pathogens at follow-up visits (RR 1.52, 95% CI 0.74–3.13). However, among women whose BV at baseline was characterized by dense growth of pigmented, anaerobic Gram-negative rods, risk of subsequent detection of chlamydia or gonorrhea was increased (RR 1.93, 95% CI 0.97–3.83).[47] Therefore, until recently it has seemed that treatment of asymptomatic nonpregnant women with BV to reduce PID could be viewed as optional and of no proven benefit until further information is available. However, the risk of more subtle manifestations of endometritis attributable to BV may be greater than the risk of overt PID. A small amount of intermenstrual bleeding or increased bleeding with menses is a frequent occurrence in patients with endometritis and salpingitis. A randomized, double-blind trial was conducted among patients with BV who had these symptoms of abnormal bleeding. Abnormal bleeding resolved in all 11 patients treated with metronidazole and considered cured of BV versus only one (5%) of 11 placebo-treated patients not cured ($p = 0.04$).[235]

The foundation for our understanding of the connection between BV and upper-tract infections was laid in 1987, when Paavonen and colleagues published research showing that 29% of 31 patients who had histologic evidence of endometritis also had BV, while none of 14 controls without endometritis had BV.[236] In 1995, Korn and colleagues published the findings of a case–control study in which they performed endometrial biopsies on 41 women who presented to an STD clinic complaining of vaginal discharge or pelvic pain.[237] All of the biopsies were examined for histopathologic evidence of plasma cell endometritis and cultured for *N. gonorrhoeae*, *C. trachomatis*, *U. urealyticum*, *M. hominis*, and facultative and anaerobic bacteria. None of the patients had culture or serologic evidence of *N. gonorrhoeae* or *C. trachomatis* infection. Ten (45%) of the 22 women with BV had plasma cell endometritis, compared with only one of the 19 women who served as controls. Microorganisms associated with BV were cultured from the endometria of nine of the 11 patients who had plasma cell endometritis, as well as from eight of the 30 patients who did not have that histologic diagnosis.[229]

In a study of symptomatic women presenting for care, endometrial biopsies were obtained on 178 consecutive women with suspected PID.[238] Endometrial specimens as well as cervical swabs were tested for *N. gonorrhoeae* and *C. trachomatis*. Eighty-five of the patients also underwent laparoscopy to confirm a clinical diagnosis of salpingitis. Sixty-five percent, or 117, of the 178 patients had endometritis as confirmed by the presence of plasma cells and PMNs in the endometrial biopsy specimen. Among the patients with endometritis, 27% had *N. gonorrhoeae* present in the endometrium, while 13% had endometrial samples positive for *C. trachomatis*. Approximately 50% of the patients with endometritis had anaerobic Gram-negative rods in their endometrial samples. A logistic regression analysis on the data showed that endometrial *N. gonorrhoeae* was associated with a fivefold increase in endometritis, which was similar for endometrial *C. trachomatis* (OR = 4.8) and anaerobic Gram-negative rods (OR = 2.6), respectively. BV was not an independent risk factor for endometritis in the absence of endometrial anaerobes. However, it was concluded that when the anaerobic Gram-negative rods ascend and infect the endometrium, they are a cause of endometritis independent of STDs.

In a case–control study in which plasma cell endometritis was evaluated, 111 women with gonorrhea, chlamydia, or BV were compared to 24 women without any of these infections for plasma cell endometritis.[238] For the 5% of women with BV alone (those with coinfection by gonorrhea or chlamydia were excluded), plasma cell endometritis was detected in 42%, while endometritis was detected in only 13% of the controls (OR 6.4, 95% CI 1.7–35.0).[239] These studies suggest that women with BV may have clinically inapparent or "silent" endometritis. However, whether BV-associated endometritis leads to salpingitis and infertility is the focus of ongoing studies.

More recently, Wiesenfield and colleagues performed endometrial biopsies on women with BV (and other lower genital tract infections, including chlamydia and gonorrhea)[240] but without symptoms or signs of acute PID. Among 377 women with BV, 58 (15%) had evidence of subclinical PID (defined as the presence of five neutrophils per 400× field and one plasma cell per 120× field of endometrial tissue), while plasma cell endometritis (defined as the presence of at least one plasma cell per 120 of endometrial tissue) was present in 90 (24%). Subclinical PID, but not plasma cell endometritis, was more common in women with BV than in women without BV. Women with intermediate vaginal flora on Gram stain were at intermediate risk of subclinical PID ($p < 0.05$, test for trend), but not plasma cell endometritis. In a multivariate model that included proliferative phase of the menstrual cycle, previous pregnancy, black race, and current infection with *N. gonorrhoeae*, *C. trachomatis*, VB, or *T. vaginalis*, subclinical PID remained significantly associated with BV (adjusted OR 2.7, 95% CI 1.02–7.2).

CERVICITIS

A possible association between BV and cervicitis, independent of concomitant chlamydial and gonococcal infection, has emerged in several studies.[241–244] Moreover, intravaginal antibiotic therapy for BV in the treatment regimen for women with cervicitis was associated with enhanced resolution rates of cervicitis in two studies.[245,246] Marrazzo et al. reported that among 424 women with BV, cervicitis was relatively common, occurring in 15%, and the overwhelming majority (87%) was not associated with NAAT-based detection of cervical chlamydia or gonorrhea.[241] In this study, increasing age, fewer years of formal education, report of a new male sex partner or of a current female sex partner, more recent receptive oral sex, and absence of H_2O_2-producing *Lactobacillus* species were independently associated with an increased likelihood of cervicitis among women with BV. Intriguingly, vaginal colonization with H_2O_2-producing *Lactobacillus* species was associated with a 60% reduction in the likelihood of cervicitis.

The mechanism by which BV might cause cervicitis is not clear, and it could be multifactorial. Cervical shedding of HIV is increased in the setting of BV, suggesting that BV itself may have direct effects at the endocervical mucosa.[247,248] Factors that help regulate the normal function of mucosal defense systems include SLPI, which helps to maintain healthy vaginal mucosa and is decreased in the presence of several STD;[131] IL-10;[249] IL-1β; and TNF,[132] which may increase susceptibility to HIV-1 infection. IL-1β has been associated with a higher number of vaginal neutrophils among women with BV.[250] Even when vaginal flora is normal, the balance of pro- versus anti-inflammatory cervical cytokines may play a key role in modulating visible signs of cervical inflammation and in permitting ascension of STI pathogens or other potential pathogens to the upper genital tract. Decreased cervical proinflammatory cytokines—IL-1β, IL-6, and IL-8—have been associated with an increased likelihood of clinical manifestations of chorioamnionitis.[251] The possible role of proinflammatory vaginal cytokines, such as IL-1β, IL-6, and IL-8, in BV-associated cervicitis is also supported by the observation that these cytokines decline after successful treatment of BV.[131] Cervical inflammation may be linked to the degradation of mucins, which protect the cervix as well.[130]

BV AND HIV

As discussed in Chapter 18, there is growing body of evidence which suggests that the presence of BV, or absence of vaginal lactobacilli, may increase a women's risk of acquiring HIV via heterosexual intercourse. A direct association between HIV infection and BV has been seen in numerous cross-sectional studies[32,252–254] and supported by prospective studies.[62,255–257] Taha et al. followed 1196 pregnant women in Malawi for a median of 3.4 months in the antenatal and 2.5 years in the postnatal periods, with monthly assessment of vaginal flora and HIV serostatus.[255] They observed that the risk of HIV acquisition as measured by seroconversion increased proportionally to increasingly abnormal vaginal flora, as measured by clinical criteria ($p = 0.04$), and that, overall, BV conferred more than a twofold increase in risk of HIV acquisition ($p = 0.04$). They estimated that the population-attributable risk of BV was 0.33 for HIV acquisition. Among Kenyan sex workers seen monthly, absence of any vaginal *Lactobacillus* and absence of H_2O_2 + *Lactobacillus* and abnormal vaginal flora were independently associated with increased risk of HIV acquisition in multivariate models.[256] Absence of hydrogen peroxide-producing *Lactobacillus* strains conferred the highest risk of HIV acquisition (adjusted hazard ratio 2.8, 95% CI 1.1, 4.7). In a large, prospective, nested case–control study of women participating in a cervical cancer screening trial in Capetown, South Africa, HIV acquisition was significantly associated with interim BV (adjusted OR 2.01, 95% CI 1.12–3.62) after adjustment for sexual behavior and acquisition of other STD.[62] BV was suggested as a reason for low efficacy of STD control in reducing HIV acquisition in a community-based intervention trial in Rakai, Uganda,[258] because it frequently persisted after women received single-dose metronidazole.[257] In vitro data support the plausibility of a potentiating effect of BV on HIV. Some anaerobes associated with BV augment HIV expression in T cells in vitro, which could enhance frequency or quantity of HIV genital shedding or activate these T cells to further promote HIV transmission.[259–263] Among HIV-infected women, the quantity of HIV shed in vaginal secretions from those with

BV is increased nearly sixfold relative to those without BV;[248] high vaginal pH (>5.5) is associated with nearly twice the quantity of HIV shed.[247]

The specific reasons for the association of BV and HIV are not clear. In addition to the known viricidal properties of H_2O_2, and of the H_2O_2–halide–peroxidase system, some anaerobes associated with BV augment expression of HIV in T cells in vitro, which might enhance the likelihood or amount of shedding, or activate these T cells in a way that further supports viral transmission.[259–261] The relationship between BV and HIV acquisition may be most synergistic—and most alarming—in areas of the world where both are highly prevalent. The prevalence of BV among many women in sub-Saharan Africa has been 50% or greater in many studies; with HIV-1 seroprevalence up to 38% in some of these countries, even if BV confers only a small increase in the relative risk for HIV acquisition, the population-attributable risk could be considerable.[32]

UNRESOLVED ISSUES IN PATIENT MANAGEMENT

HOW COMMON IS LATE RECURRENCE AND WHY DOES IT HAPPEN?

In 1955, Gardner noted that "before the advent of antibiotics and sulfonamides, the treatment of bacterial vaginitis was discouraging because eradication of the causative organism was difficult and recurrences were common."[8] Unfortunately, 50 years after Gardner made his initial observation, the treatment of BV can still be discouraging because of the high rate of recurrent infection. Long-term BV recurrence rates exceed 70%.[84,264] Of 127 women in a prospective study of metronidazole-suppressive therapy, BV recurred in 84% by 4 months in the placebo group and was associated with black race, older age, and higher Nugent score at enrollment.[203] In a study of 139 women with symptomatic BV followed for a year, 58% had recurrence, which was directly associated with report of prior BV, having a regular sex partner throughout the study, or a female sex partner, and was inversely associated with hormonal contraception.[84] Possible reasons for high recurrence rates include failure to continually suppress growth of some pathogens due either to complete or partial antibiotic resistance,[177,265] reinoculation with pathogens from an exogenous source (possibly through sex), persistent host factors such as douching or IUD, failure to recolonize the vagina with H_2O_2 + lactobacilli, or infection with a phage that destroys lactobacilli.[156,266] None of these has been conclusively shown to explain recurrence or identify women at increased risk of BV. However, as noted above, twice-weekly suppressive vaginal metronidazole (Metrogel 0.75%, 37.5 mg) significantly reduced recurrence rates relative to placebo over 4 months.[203] Microbiologic studies have established that about half of women lack vaginal lactobacilli, which produce H_2O_2 following therapy with clindamycin or metronidazole.[177] Some investigators have promoted the use of H_2O_2 douches for women with BV recurrences,[267] but the utility of this approach is unproven.

SHOULD MALE PARTNERS BE TREATED?

While many women believe they have contracted BV from a male partner, no study to date has convincingly shown that treatment of the male partner decreases risk of recurrence. For this reason, the CDC does not recommend routine treatment of the male partner at present but does believe that better data on this approach are needed. Randomized, placebo-controlled trials of new approaches to partner treatment, with long-term follow-up in monogamous couples, would be of interest, with better understanding of how men carry and transmit the organisms responsible for BV necessary to guide such trials. No data are available to guide clinicians in empiric treatment of female partners of women with BV.

ARE OVER-THE-COUNTER PREPARATIONS OF LACTOBACILLI USEFUL?

A number of women have used over-the-counter lactobacilli products to attempt to reconstitute the vaginal flora. These include acidophilus milk, yogurt or various *Lactobacillus*-containing capsules, and powders available from health food stores. Some of the earliest treatments for VB involved attempts to restore the vaginal flora by application of *Lactobacillus* preparations.[268,269] Butler reported cure of 18 of 19 patients given from one to eight applications of pure culture of a human-derived strain of Doderlein bacillus at weekly intervals.[268] However, only one of 14 women were cured after applying yogurt intravaginally twice daily for 7 days.[196]

Bacteria found in an ecologic niche have uniquely adapted to that particular environment. However, the commercial strains of lactobacilli found in dairy products have adapted to the dairy food industry. Strains of lactobacilli that do not adhere well to vaginal epithelial cells may not successfully colonize the vagina. It is unlikely that currently available vaginal probiotic products are of therapeutic value for the treatment or prevention of BV. Treatment of BV using H_2O_2-producing lactobacilli has been an unsuccessful therapeutic option,[198] suggesting that recolonization of the vagina with exogenous lactobacilli will probably be of benefit as an adjunct to, rather than as a replacement of, antimicrobial therapy. However, even this approach has not been proven to be beneficial with currently available products.[270]

SHOULD WOMEN WITH SIGNS OF BV BE TREATED IF ASYMPTOMATIC?

In our experience, some women with BV are aware of a discharge or odor but discount it because it has been present for months or even years. Thus, many women who do not complain of symptoms will acknowledge symptoms of odor and/or discharge on questioning. Women with BV should be informed of their diagnosis, and treatment should be offered if requested. However, definitive recommendations for routine treatment of asymptomatic, nonpregnant women with BV await further studies defining risks of upper tract infection among women with BV and also await more information on the benefits of treating BV to prevent HIV acquisition, as well as improved strategies to prevent late recurrence.

PREVENTION

Since the microbiologic and host risk factors for acquisition of BV are poorly understood, it is difficult to define useful approaches for the prevention of this condition. Since BV is associated with sexual activity, abstinence may represent the most effective (if least popular) means of prevention. Information on condom use and risk of BV is limited, but more recent data indicate that condoms do protect against BV.[45,50,53,54,58,60] Since the role of sexual transmission in BV is not well defined, and concurrent treatment of male partners has not yet been shown to prevent recurrent BV, treatment of male sex partners cannot be recommended. Recolonization of the vagina with H_2O_2 lactobacilli may protect against infection by BV-associated organisms, but this has not yet been adequately evaluated. Similarly, treatment of BV has not yet been adequately evaluated as a method for preventing pregnancy and puerperal morbidity or postgynecological surgery morbidity. The role of IUD usage as a risk factor for BV requires further study, to confirm or refute the association, and assess the importance of IUD type to any relationships found. The role of genital hygienic practices in the male in protecting the female partner from BV warrants further study, as does the role of douching in increasing the risk among women.

SUMMARY AND FUTURE ISSUES

Several exciting areas in the field of BV offer the potential to significantly advance our understanding of vaginal microbiology and of ways to prevent BV and other STD, including HIV. First, the spectrum of organisms associated with BV will continue to expand as investigators apply culture-independent molecular methods to detect previously obscure organisms. Some of these organisms may help to provide clues to the epidemiology and natural history of BV. For example, are they associated with the oral or anorectal environments, and does that explain the intriguing relationship of certain sexual behaviors with BV acquisition? Can they be detected as part of the male genital flora and will there consequently be a role for targeted management of male sex partners in women with recurrent BV? Second, the field of probiotic therapy is in its infancy. Investigators have already engineered vaginal strains of *Lactobacillus jensenii* to express functional two-domain CD4 proteins that recognize a conformation-dependent anti-CD4 antibody and bind HIV-1.[271] This preparation inhibited HIV-1 entry into target cells in vitro in a dose-dependent manner. If this line of investigation continues to prove fruitful, the development of engineered commensal vaginal lactobacilli might be useful not only to inhibit heterosexual transmission and/or acquisition of HIV, but possibly other STDs. Third, research into vaginal microbicides that support or do not inhibit normal vaginal lactobacilli is likely to intensify as the need for female-controlled methods to protect against STI/HIV continues to intensify. Fourth, suppressive therapy for women with recurrent BV—now in the form of metronidazole, and possibly in future with other agents—may become more widely used, where it is affordable and feasible. Finally, there is a critical need to continue to clarify the complex immune dysregulation apparent in BV, particularly in relation to its role in mucopurulent cervicitis, upper genital tract involvement, and adverse outcomes of pregnancy.

PART 7

Sexually Transmitted Protozoa, Fungi, and Ectoparasites

This page intentionally left blank

43 *Trichomonas vaginalis* and Trichomoniasis

Marcia M. Hobbs, Arlene C. Seña, Heidi Swygard, and Jane R. Schwebke

INTRODUCTION

Trichomonas vaginalis is a pathogenic protozoan parasite of the human urogenital tract. Transmitted primarily by sexual intercourse, this organism causes vaginitis in women and urethritis in men, though a considerable proportion of infections are asymptomatic. *T. vaginalis* is also implicated in various other genitourinary syndromes. An association between maternal trichomoniasis and premature rupture of the membranes with concomitant preterm delivery has been reported,[1–3] and there is mounting evidence of an association with cervical cancer.[4–9]

The World Health Organization (WHO) estimates that trichomoniasis accounts for more than half of all curable sexually transmitted infections (STI) worldwide.[10] *T. vaginalis* caused an estimated 113 million new infections in Africa and Southeast Asia, and nearly 19 million in Western Europe and North America in 1999.[10] Although accurate surveillance data are not available, there were an estimated 5 million new cases of trichomoniasis per year in the United States in the late 1990s, exceeding similar figures for gonorrhea and chlamydial infections combined.[11]

Infection with *T. vaginalis* can be a marker for high-risk sexual behavior, and high prevalence rates in many populations indicate the need for counseling and behavioral change to reduce patients' risks for acquiring other STIs, including human immunodeficiency virus (HIV). As with other STIs, genital inflammation associated with trichomoniasis increases sexual transmission of HIV.[12–15] Epidemiological studies suggest that trichomoniasis is associated with increased HIV transmission. Coinfection with *T. vaginalis* and HIV may result in "epidemiological synergy" with prolonged or augmented infectiousness of both infections.[12,16] Because the prevalence of trichomoniasis is so high, a large proportion of HIV infections could be attributable to *T. vaginalis* infection in populations where both infections are common.[17]

HISTORY

T. vaginalis was first described in 1836 by French physician Alfred Donné who observed the organisms in a preparation of fresh vaginal discharge.[18] The protozoan was long regarded as a harmless inhabitant of the vagina. This opinion was unchanged by subsequent descriptions of *T. vaginalis* in the female and male urinary tracts.[19,20] During the next 50 years, many case reports were published, and in the 1940s, Koch's postulates were fulfilled establishing *T. vaginalis* as an etiologic agent of vaginitis.[21,22] *T. vaginalis* began to receive increased attention as a cause of urogenital morbidity in men as well.[23] Numerous reports of high prevalence rates for trichomoniasis in different populations have appeared in the literature in the intervening years. More than 150 years after the initial discovery of *T. vaginalis*, it is clear that trichomoniasis can no longer be considered a minor STI.[17,24–28] Diagnosis and treatment of trichomoniasis in women and men are assuming a higher priority in STI management.[29,30] However, active control programs for *T. vaginalis* infection are still lacking, and recognition of the importance of *T. vaginalis* infections, by clinicians, is slow in coming.

EPIDEMIOLOGY AND TRANSMISSION

Compared to other STIs, the epidemiology of *T. vaginalis* infection is not as well recognized due to limited diagnostic techniques, absence of screening programs, and lack of disease reporting, even in the most developed national surveillance programs. Prevalence reports for trichomoniasis vary widely, depending on the techniques employed in diagnosis and the population studied. Until the mid-1990s, studies reporting *T. vaginalis* prevalence relied on wet-mount microscopy and culture. Since then, more sensitive nucleic acid amplification techniques, primarily polymerase chain reaction (PCR), have also been used. Recent studies among female sex workers report *T. vaginalis* prevalence rates ranging

from 14.4% in India,[31] identified by wet-mount or culture, to 43.2% in China, detected by PCR.[10] In general, prevalence estimates range from 5% to 74% in women and 5–29% in men, with the highest rates in both genders reported among STD clinic attendees and other high-risk populations.[32,33] A community-based study in sub-Saharan Africa found a significantly higher prevalence of trichomoniasis (29–34%) among women in cities with high HIV prevalence compared to women in cities with low HIV prevalence.[15]

TRICHOMONIASIS AND HIV

T. vaginalis is epidemiologically associated with HIV, and can facilitate the transmission and acquisition of the virus due to inflammatory responses in the vaginal epithelium and ectocervix in women and the urethra in men. Cross-sectional studies demonstrating an association between trichomoniasis and HIV in women suggested two- to threefold increases in HIV transmission.[34,35] These findings were supported by a prospective study conducted among HIV-negative female sex workers that also showed a twofold increased rate of HIV seroconversion among women with prior *T. vaginalis* infection.[13] In men, urethritis associated with *T. vaginalis* has been reported to increase HIV shedding in semen eightfold.[36] Assuming that *T. vaginalis* increases the risk of HIV transmission by 90% (less than twofold) in a population with a 25% prevalence of trichomoniasis, one estimate indicates that approximately 20% of prevalent HIV cases could be attributable to *T. vaginalis*.[37] Another suggests that 6.2% of incident HIV infections among women in the United States may be attributable to trichomoniasis.[38]

Concomitant infection with other STIs occurs commonly in persons with trichomoniasis.[3,39] Mixed infections with *T. vaginalis* and *Neisseria gonorrhoeae* and/or *Chlamydia trachomatis* occurred in 1.4% of 504 East African transport workers, while 61.5% of 91 men with trichomoniasis in West Africa also had a gonococcal infection.[40]

PREVALENCE IN WOMEN

In general, *T. vaginalis* is highly prevalent among sexually active women. Community-based studies conducted in various parts of the world indicate prevalence figures for trichomoniasis in women range from 2% to 46%.[41–47] Clinic-based studies in women have found *T. vaginalis* prevalences of 3–18% in adolescent clinics,[48–50] 10–14% in gynecology or family planning clinics,[51,52] and 2–18% in STD clinics.[5,26,53,54] Commercial sex workers and incarcerated women have been identified with prevalences as high as 22–25% and 37–47%, respectively.[55–58]

In antenatal or prenatal clinics using culture for *T. vaginalis* detection, reported prevalences range from 10% to 18%.[59,60] Higher prevalences of 20–28% were reported among pregnant women in studies using PCR for *T. vaginalis* detection.[61,62]

Trichomoniasis has been identified as the most commonly diagnosed STI among HIV-infected women receiving care. Prevalence rates from 9% to 30% have been reported,[17,63–66] and trichomoniasis accounted for 89% of incident STIs in HIV-positive women in one U.S. study.[67] High rates of recurrent *T. vaginalis* infection have also been seen in HIV-infected women; one-third of a population of women attending a public HIV outpatient clinic were noted to be reinfected during the follow-up period.[68] These findings suggest that unprotected sex among HIV-positive women is not uncommon and raise serious concerns about the potential for increased spread of HIV among coinfected persons.

Among women presenting with vaginal complaints, the reported prevalence of trichomoniasis is as high as 75%.[33] The high prevalence of disease among women with vaginitis has prompted empiric treatment for *T. vaginalis* in syndromic management algorithms when vaginal symptoms are present.[69] However, approximately 50% of infections with *T. vaginalis* may be subclinical in presentation,[70] underscoring the need for identification of other risk factors associated with infection especially when universal screening for this pathogen is not feasible.

Factors associated with trichomoniasis in women

Because of the nonspecific clinical presentation of trichomoniasis in women, and the limited performance of available diagnostic methods for *T. vaginalis* in most clinical settings, studies have focused on identifying predictors of infection in women. In multivariate analyses, factors that have been independently associated with trichomoniasis in women include demographic, behavioral, and clinical characteristics (Table 43-1). In the United States, African American race has been strongly associated with trichomoniasis in women, with adjusted odds ratios (OR) between 5.6 and 13.5.[37,71,72] The association between African American race and trichomoniasis is likely to be multifactorial, and may reflect differences in sexual behaviors, access to care, and socioeconomic factors rather than variations in genetic or racial-based susceptibility to *T. vaginalis* infection.[17]

Behavioral factors associated with an increased risk for trichomoniasis include reported sex with nonsteady partners or older partners, and marijuana use among adolescent females.[73] In multivariate analyses, other health behaviors such as smoking, alcohol use, injecting drug use, and crack cocaine use have been associated with *T. vaginalis* infection.[56,66,74,78]

Clinical predictors of *T. vaginalis* infection include the vaginal pH > 5.0, color of vaginal discharge, cervical erythema, and friability (Table 43-1).[3,75] Cervical atrophy has been reported to be inversely associated with trichomoniasis, suggesting that reduced estrogen, which may affect cervical atrophy, is protective for *T. vaginalis* infection.[78] The presence of HIV infection and other genital infections such as bacterial

Table 43-1. Risk Factors Associated with Trichomoniasis in Women, from Multivariate Analyses

Reference	Population	*T. vaginalis* Prevalence	Factor	OR_{adj}[a]	95% CI[b]
15	Random population sample (Kenya and Cameroon)	18–29%	HIV infection	1.7	1.1, 2.7
			HSV-2 infection	2.2	1.3, 3.7
			Gonorrhea	3.0	1.0, 8.6
73	Adolescent females in primary care clinics (US)	13%	Typical sex partner ≥5 yrs older	2.6	1.3, 5.2
			Sex with nonsteady partners	1.9	1.2, 3.3
			Marijuana use	6.2	2.3, 16.6
			Delinquency	1.3	1.0, 1.6
66	HIV+ and HIV- women recruited from general population (US)	23–29%	Injecting drug use	6.7	4.8, 8.5
			Crack cocaine use	2.1	1.5, 2.6
			Alcohol use	4.4	3.1, 5.7
			BV	5.2	3.8, 6.7
			Vaginal candidiasis	1.4	1.0, 1.8
76	Women attending family planning clinics (Kenya)	5%	Unmarried	2.3	1.5, 3.4
			Current IUD use	1.5	1.0, 2.3
			HIV infection	2.4	1.5, 3.8
77	Incarcerated women (Portugal)	31%	Syphilis	9.3	1.8, 48.5
65	HIV-infected women attending clinic (US)	13%	Age < 22 years	1.3	1.0, 1.8
			African American race	2.4	1.6, 3.7
			Substance use	2.7	2.0, 3.5
			Presence of other STDs	1.8	1.4, 2.2
71	Women attending primary care clinics (US)	24%	African American race	13.5	NR[c]
			Douching >1/month	3.5	NR
3	Women attending prenatal clinics (US)	13%	Yellow/green/bloody vaginal discharge	1.6	1.3, 1.9
			Copious discharge	1.2	1.0, 1.5
			Abnormal consistency	1.2	1.1, 1.4
			Cervical friability	1.3	1.1, 1.5
			Cloudy/opaque cervical mucus	1.1	1.0, 1.3
75	Women attending family planning clinics (South Africa)	18%	No travel outside district	2.8	1.0, 7.7
			Cervical erythema	3.5	1.7, 7.5
			Nonclear, nonwhite vaginal discharge on examination	3.2	1.3, 8.1
56	Pregnant women attending jail clinic (US)	47%	Crack cocaine use	2.3	1.2, 4.5
			Serological evidence of syphilis, past or present infection	2.3	1.0, 5.3
37	HIV-infected women attending HIV outpatient clinic (US)	17%	African American race[d]	5.6	2.3, 13.3

vaginosis (BV), vulvovaginal candidiasis, gonorrhea, genital herpes, and syphilis have also been independently associated with trichomoniasis.[15,66,76] However, one retrospective study of female patients presenting to an emergency department with STI symptoms reported a strong negative association between *T. vaginalis* detected by wet-mount microscopy and coinfection with *N. gonorrhoeae* and/or *C. trachomatis*.[79]

Among HIV-positive women, young age, African American race, substance abuse, and presence of other STIs have been associated with *T. vaginalis* infection.[65] Trading sex for drugs or money has been reported to be a strong risk factor (adjusted RR = 25.2) for trichomoniasis in non-African American women coinfected with HIV.[37] Neither immune status defined by CD4 counts nor use of protease inhibitors among HIV-positive women was associated with initial or subsequent trichomoniasis, suggesting that *T. vaginalis* is not an opportunistic pathogen.[65]

PREVALENCE IN MEN

The prevalence of trichomoniasis in men is not well described, because most infected men are asymptomatic and may not seek evaluation. Furthermore, *T. vaginalis* diagnostic tests are seldom available or used for evaluation of male patients presenting for care. In a community-based study of men in Tanzania, *T. vaginalis* was found in 11% by microscopic examination and culture of urine sediment, and was the most common sexually transmitted pathogen identified in this population.[80] In clinic-based studies using *T. vaginalis* culture of specimens from male patients in the United States and Africa, prevalences of trichomoniasis ranged from 3% to 13%.[81,82,84] In one study in Malawi, a higher prevalence of 15.7% was noted among men with symptomatic urethritis, compared to 8.7% among asymptomatic men.[82]

Using more sensitive PCR detection methods with or without culture, other studies conducted in men suggest higher prevalences of *T. vaginalis* infection in STD clinics ranging from 13% to 20%.[16,28,74] In a U.S. study using PCR detection, the prevalence was significantly higher (51.4%) in asymptomatic men compared to men with urethral symptoms (23.0%).[28]

Factors associated with trichomoniasis in men

Only a few studies have identified independent risk factors associated with trichomoniasis in men (Table 43-2). Demographic factors associated with *T. vaginalis* infection in men from community- and clinic-based studies include older age and being married.[16,80] Not surprisingly, never having

used a condom was found to be associated with trichomoniasis.[16] A history of exposure to a woman with trichomoniasis and a history of prior trichomonal infection are clinical factors that have been significantly associated with *T. vaginalis* in men. In a U.S. study of men attending an STD clinic, the combination of symptoms of discharge, diagnosis of NGU, and age ≥ 30 years was highly predictive of *T. vaginalis* infection.[81] Among men with trichomoniasis, the strongest clinical association is with NGU.[25] In a study conducted in Malawi, where genital ulcer disease (GUD) is a common presenting complaint in STD clinics, men with GUD were also more likely to have *T. vaginalis* infection.[16]

TRANSMISSION

T. vaginalis is transmitted almost exclusively by sexual intercourse. In the past, however, there was active debate on the route of transmission for this pathogen.[85,86] Studies showing that trichomonads can survive for up to 45 minutes on toilet seats, washcloths, clothing, and in bath water fueled speculation that nonsexual transmission was common.[85] Although nonsexual transmission by contaminated fomites may explain reports of trichomoniasis in a few patients, such as sexually mature virgins, the data suggest that nonsexual transmission of *T. vaginalis* is rare.[87,88] Therefore, *T. vaginalis* detection in a prepubertal child should raise the suspicion for sexual abuse, despite the tendency to believe that the mode of transmission may be asexual. In a study of girls under 16 years of age who were referred for evaluation of sexual abuse, trichomoniasis, gonorrhea, and chlamydia were detected in similar proportions.[89] *T. vaginalis* infection has also been reported in both partners of a lesbian couple who denied use of penetrative sex toys or recent male partners, suggesting transmission may occur through mutual masturbation.[90]

Perinatal transmission can occur in about 5% of female children of infected mothers. Although neonatal genital infections

are usually self-limited, with progressive metabolism of maternal hormones,[91,92] respiratory *T. vaginalis* infection can occur in newborns of infected mothers and may be accompanied by suppurative nasal discharge and respiratory distress.[93–96] The detection of *T. vaginalis* by PCR from adult pharyngeal specimens has been recently noted among HIV-positive men with a history of orogenital sexual activity.[97] The significance of this finding is unclear, and further investigations are required to understand the potential role of orogenital transmission in the current epidemiology of trichomoniasis.

The consensus view that *T. vaginalis* is acquired predominantly by direct genital contact is strongly supported by evidence from (1) human inoculation studies, (2) isolation of the organism from urogenital sites, and (3) epidemiological data. Human challenge studies, conducted in the 1940s–1950s, before the availability of effective therapy, fulfilled Koch's postulates documenting that clinical trichomoniasis can be produced by inoculation of the human vagina or male urethra with pure cultures of *T. vaginalis.* [21,22,98] Intravaginal inoculation in women led to infection in up to 75%, regardless of the bacterial flora that was initially present (as definable at that time).[22] Findings characteristic of vaginal trichomoniasis occurred in experimentally infected women after a 5–28-day incubation period. In a study involving men, all five subjects inoculated intraurethrally with *T. vaginalis* developed urethritis within 24 hours of inoculation.[98] Two of the men also developed prostatitis, based on microscopic examination of expressed prostatic secretions.

The prevalence of *T. vaginalis* among sexual contacts of infected patients clearly supports the view that trichomoniasis is transmitted primarily by sexual contact. In various studies, *T. vaginalis* was isolated from 14% to 60% of male partners of infected women.[99–101] In addition, *T. vaginalis* was isolated from 67% to 100% of female partners of infected men.[86,102]

Factors affecting transmission or concordance of *T. vaginalis* infection between sexual partners are largely unknown. One large study of male sexual partners of women with trichomoniasis investigated demographic, clinical, and behavioral risk factors for concordant infection in couples.[103] Results from this study suggested that an abnormal vaginal pH > 4.5 in infected women and male partner age < 40 years are independently associated with concordant infection.[103] Further determination of factors associated with concordant *T. vaginalis* infection will improve our understanding of the dynamics of its sexual transmission.

PARASITE TAXONOMY AND MORPHOLOGY

Trichomonads are flagellated eukaryotic microbes belonging to the protozoan order trichomonadida. There are over 100 species; most are commensal organisms of the intestinal tract of mammals and birds. Three species are found in humans; *T. vaginalis* is a parasite of the genitourinary tract, while *T. tenax* and *Pentatrichomonas hominis* are nonpathogenic trichomonads found in the oral cavity and large intestine, respectively.

Trichomonads represent one of the most ancient eukaryotic lineages.[104,105] *T. vaginalis* has been considered a primitive eukaryote since it lacks many features of higher eukaryotes including mitochondria, peroxisomes, and 28S ribosomes. However, *T. vaginalis* ribosomes do have typical, conserved eukaryotic features; their smaller size is due to reduced or absent variable regions.[106] Furthermore, the identification of splicing machinery and intron-containing genes, previously thought to be absent in *T. vaginalis*,[107] suggests that many of the features that distinguish this amitochondriate protist from higher eukaryotes are the result of secondary loss of more typical eukaryotic structures and functions and do not necessarily represent primitive or intermediate development during early eukaryotic evolution.

The size and shape of *T. vaginalis* vary, depending on the vaginal microenvironment or on culture conditions. Typically, the organism has a pyriform shape approximately 7–32 μm long and 5–12 μm wide,[108] roughly the size of a leukocyte (Fig. 43-1A). Upon interaction with epithelial cells, *T. vaginalis* assumes an amoeboid form[109] (Fig. 43-1B), and recent clinical isolates readily attach to plastic. Free-swimming trichomonads demonstrate a characteristic erratic, twitching motility as they are propelled by four anterior flagella that originate in a structure known as the kinetosomal complex. A fifth flagellum originates from the kinetosomal complex and extends halfway down the organism, attached to the undulating membrane supported by a complex array of filaments known as the costa. The parasites contain an anterior nucleus, a parabasal apparatus, a Golgi complex, and an axostyle that runs centrally through the cell and protrudes to form a posterior tail, or projection. Parallel to the axostyle and costa are three rows of large chromatic granules including hydrogenosomes. Hydrogenosomes, characteristic organelles found in *T. vaginalis* and other protists that lack mitochondria, are double membrane-bound structures that generate hydrogen and ATP from metabolism of pyruvate.[110] The recent discovery of *T. vaginalis* hydrogenosomal proteins with notable homology to mitochondrial components suggests that these organelles may share a common ancestry with mitochondria.[111–113]

Trichomonads are generally thought to exist only in the motile, vegetative trophozoite form, and true cysts or resistant stages have not been described. However, *T. vaginalis* pseudocysts, which appear in vitro under unfavorable environmental conditions, have been observed.[114,115] Pseudocysts have altered structural features, including internalized flagellae and a compact form lacking a true cell wall.[116] Whether the pseudocyst form plays a role in trichomoniasis is not yet clear.

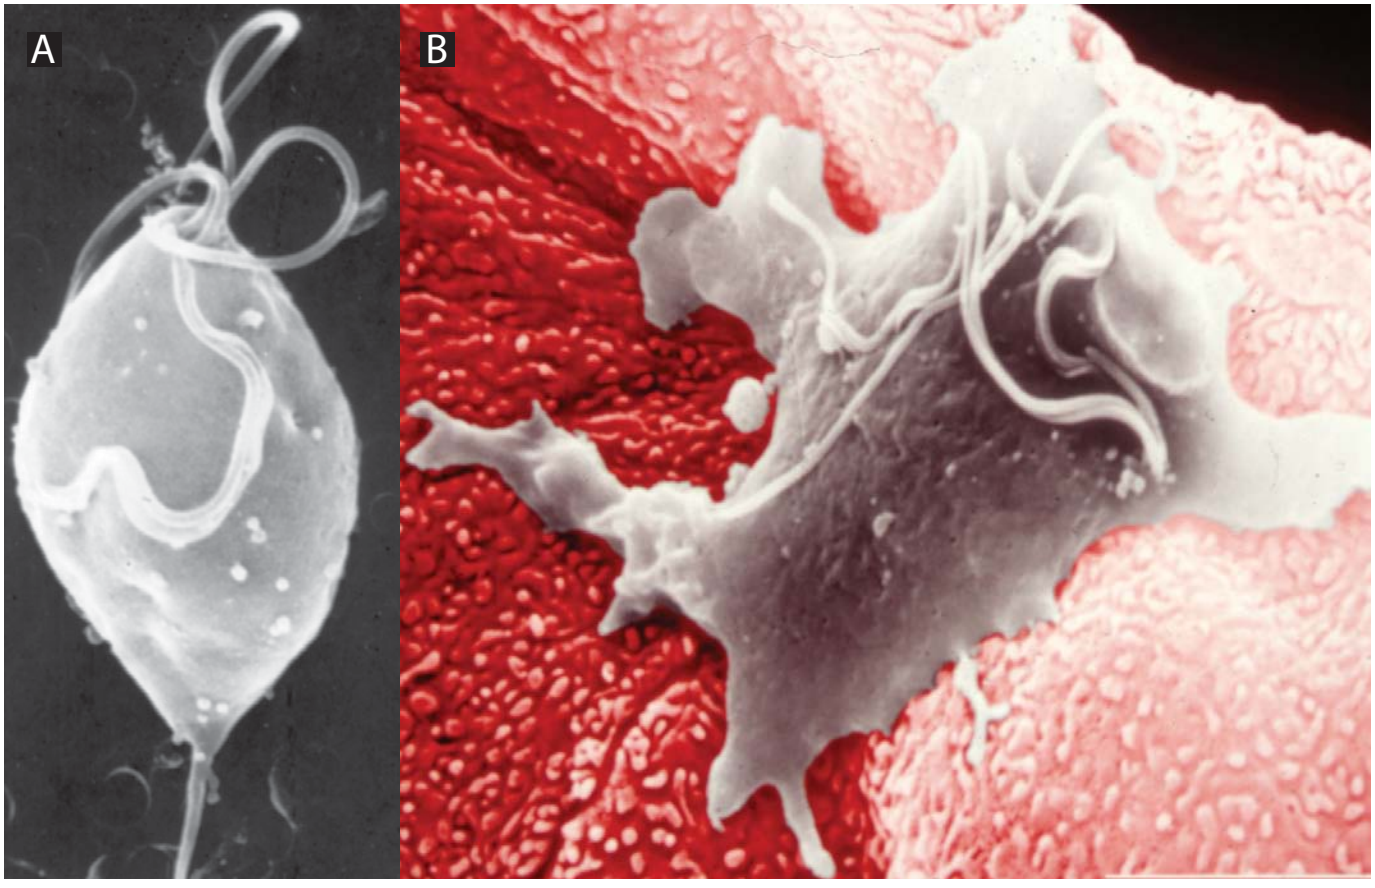

FIGURE 43-1. Scanning electron micrographs of *T. vaginalis*. T. VAGINALIS GENETICS AND BIOLOGY

NUCLEIC ACID CONTENT AND STRUCTURE

Trichomonads reproduce asexually by mitosis followed by longitudinal cell division. In an unusual process known as closed mitosis, the parasite nuclear envelope remains intact, and the mitotic spindle is external to the nucleus. Results of electrophoretic and cytologic analyses suggest that the *T. vaginalis* nucleus contains six haploid chromosomes.[117–119] However, preliminary data generated by the *T. vaginalis* Genome Sequencing Project (http://www.tigr.org/tdb/e2k1/tvg/) suggest a highly repetitive genome of approximately 180 megabases, much larger than anticipated based on earlier studies.[120] While the exact genome size and chromosome number are uncertain, the haploid nature of *T. vaginalis* is confirmed by the ability to disrupt genes by homologous recombination.[121]

Protein-coding genes in *T. vaginalis* are preceded by promoters that have structures similar to those of higher eukaryotes with a conserved core promoter region and upstream gene-specific regulatory elements.[122] Although trichomonad promoters lack a typical TATA-box sequence, there is a highly conserved sequence element surrounding the transcription start site of *T. vaginalis* genes.[122–124] Promoter features identified upstream of *T. vaginalis* genes include positive and negative regulatory sequences, and iron-responsive elements.[123,125,126]

A potentially functional transposable element in the *mariner* family has been documented in the *T. vaginalis* genome.[127] Sequence analyses identified several hundred copies of the transposon in strain G3, and Southern blot hybridization of several other strains suggested that the transposable element, named *Tvmar1*, may be widely distributed within the species. Transformation vectors based on transposons like *Tvmar1* are valuable tools for insertional mutagenesis studies in a variety of organisms, and this discovery suggests that similar studies in *T. vaginalis* may be possible.

Some *T. vaginalis* strains contain double-stranded RNA viruses known as *T. vaginalis* virus (TVVs). First described in the mid-1980s,[128] TVVs are a group of divergent viruses

classified in the *Totiviridae* family.[129,130] TVV RNAs encode a capsid protein and an RNA-dependent RNA polymerase, and some viral genomes appear to encode two additional proteins in alternate reading frames.[129] Whether these putative additional proteins are expressed in infected parasites and what their functions might be remain to be determined. Observations of purified virus particles from infected parasites indicate that *T. vaginalis* organisms can harbor different TVVs simultaneously.[131,132]

In studies of recent clinical *T. vaginalis* isolates, 50–80% contain TVV.[74,133–135] TVV-harboring *T. vaginalis* undergo phenotypic variation with respect to surface and cytoplasmic expression of the P270 protein.[136–138] Virus-negative trichomonads also exhibit decreased expression of P270 mRNA; thus, TVV influences trichomonal gene and protein expression. However, a role for TVV in the pathogenesis of trichomoniasis has not been established.

GROWTH AND METABOLISM

The growth and multiplication of *T. vaginalis* are optimal in microaerophilic or anaerobic conditions with temperatures between 35°C and 37°C and pH levels between 4.9 and 7.5. The organisms can be cultivated axenically in nutrient media designed to provide optimum redox potential, pH, and antimicrobials to suppress other microorganisms.[139] More robust, smaller organisms are observed at pH 5.5–5.8, whereas less motile, larger organisms are encountered at pH levels lower or higher than optimum. In batch cultures, parasites typically have generation times of 4–6 hours.[140]

T. vaginalis is an aerotolerant anaerobic protist. Growth is inhibited at high oxygen tensions due to deficiency of catalase,[141] but some multiplication can be observed in media equilibrated with air. This aerotolerance is attributed to the presence of active superoxide dismutase. Whether oxygen is absent or present, trichomonal metabolism is fermentative. Pyruvate produced by glycolysis in the cytosol is reduced to lactate in the hydrogenosomes. *T. vaginalis* hydrogenosomes can also metabolize malate via decaboxylation to pyruvate. These organelles contain pyruvate-oxidizing enzymes (pyruvate-ferredoxin oxidoreductase) and hydrogenase that are linked by an electron transport protein of low redox potential.

In addition to its role as the metabolic powerhouse, the trichomonad hydrogenosome is important in drug activation. Metronidazole and other nitroimidazoles, used in the treatment of trichomoniasis, enter the cell and subsequently the hydrogenosomes by passive diffusion in an inactive form.[142] Electrons required for drug activation are thought to be provided by 2Fe-2S ferredoxin. Ferredoxin-linked electrons are generated during oxidative decarboxylation of pyruvate catalyzed by pyruvate:ferredoxin oxidoreuctase. Additional electrons are released during oxidative decarboxylation of malate catalyzed by activity of NAD-dependent malic enzyme. Under anaerobic conditions, reduced ferredoxin transfers electrons to hydrogenase.[143] In the presence of 5-nitroimidazoles, ferredoxin preferentially transfers electrons for the reductive activation of the drug.[144] This process is highly efficient under anaerobiosis; however, under aerobic conditions, oxygen can compete with metronidazole for ferredoxin-transported electrons, thus inhibiting the drug activation. Consequently, the efficiency of the redox system of a particular *T. vaginalis* strain appears to be critical for susceptibility of trichomonads to the drug.[145]

Trichomonads, like most other parasitic protozoa, are unable to synthesize purine ring structures or to interconvert purine nucleotides. However, *T. vaginalis* can salvage the purine bases adenine and guanine and their nucleosides. Trichomonad nucleoside phosphorylase and nucleoside kinase activities appear to be responsible for conversion of the purine bases and nucleosides to nucleoside monophosphates. In vitro, *T. vaginalis* disrupts monolayers of human female- and male-derived genital epithelial cells.[146–150] The parasite can bind to nuclei released from lysed host cells, hydrolyze extracellular nucleotides, and incorporate ^{3}H-thymidine from labeled epithelial cells into its own DNA, suggesting that host cell nuclei may serve as a source of nucleotides for *T. vaginalis* growth in vivo.[150–152]

T. vaginalis also possesses hemolytic activity.[153–157] Specific association with erythrocytes (hemagglutination) and subsequent hemolysis are thought to be important for destruction of erythrocytes in menstrual blood, with release of iron, lipids, and fatty acids for parasite membrane biosynthesis.[158,159]

T. VAGINALIS STRAIN CLASSIFICATION

As early as the 1960s, mouse models of *T. vaginalis* infection using subcutaneous chambers or intraperitoneal inoculation were used to classify strains as virulent or avirulent.[160–162] However, correlation of strain characteristics in mice and clinical disease in patients was inconsistent.[163,164]

Early characterization of *T. vaginalis* isolates using traditional serotyping methods indicated some heterogeneity among strains.[141] Results of studies using polyclonal antisera in assays relying on hemagglutination, gel immunodiffusion, and complement-fixation estimated that there were from two to eight different serotypes in Europe. Isoenzyme patterns (zymodemes) of *T. vaginalis* were also evaluated in early attempts to characterize differences among isolates. Using this technique, isolates could be classified into groups. However, zymodemes were not useful for distinguishing virulence potential or antimicrobial drug sensitivity.[165,166]

T. vaginalis strain variation has been observed with respect to expression of the phenotypically varying P270 immunogen.[136,137,167] All *T. vaginalis* isolates can express a P270 protein under certain conditions, and size polymorphisms

have been attributed to different numbers of tandem repeats composing the central portion of the protein.[167] However, P270 expression and surface localization are influenced by iron and parasite infection with the TVV.[136,137] Microbial strain typing based on protein expression phenotypes is affected by differences in protein expression at the time of analysis that do not necessarily reflect intrinsic strain differences.

In more recent studies employing genetic typing methods, investigators have classified *T. vaginalis* strains using random amplified polymorphic DNA (RAPD) analysis[135,168,169] and restriction fragment length polymorphisms of specific genomic loci including ribosomal intergenic sequences.[170,171] While these studies indicate that there is substantial genetic variability among *T. vaginalis* strains, no reproducible, widely accepted strain typing system has yet been established. The availability of *T. vaginalis* genome sequence data should facilitate development and improvement of parasite genotyping tools for use in molecular epidemiological studies of trichomoniasis and its impact on transmission of other STIs including HIV.

PATHOGENESIS

To establish infection in the human urogenital tract, *T. vaginalis* penetrates the mucous layer to gain access to the underlying epithelial cells where parasites can attach, resulting in tissue damage and inflammation. Intensive research efforts have been aimed at elucidating the molecules and mechanisms involved in these processes. Although it is far from complete, an interesting and complex picture of trichomonas pathogenesis is emerging.

T. VAGINALIS ENZYMES AND ADHESINS

T. vaginalis produces numerous proteolytic enzymes, many of which have been shown to be involved in cytotoxicity, hemolysis, evasion of immune responses, or adherence. The genes encoding many of these proteinases are iron regulated, and examples exist for both increased[126,172,173] and decreased[174] proteinase expression under high iron conditions. Several cysteine proteinases have been identified both on the surface of the parasite and secreted during growth in vitro.[175–177] Trichomonal enzymes are found in vaginal secretions of infected women along with antibodies that recognize these enzymes.[178–180] Trichomonads bind mucin in vitro, and several secreted proteinases can degrade mucin. Mucinases are active over a pH range of 4.5–7.0,[174] consistent with a role in the vaginal, urethral, or prostatic milieu to facilitate parasite penetration of the mucous barrier.

Once *T. vaginalis* traverses the mucous layer, adherence to epithelial cells is mediated by parasite surface adhesin proteins known collectively as APs. Several APs have significant homology with known metabolic enzymes.[181–184] The localization of metabolic enzymes on the surfaces of microbial pathogens is a recently recognized example of functional diversity and molecular mimicry.[182]

T. vaginalis adherence to epithelial cells in vitro is required for parasite-induced cytopathic effects (CPE) with likely contributions to pathogenesis. Both contact-dependent[149,155,157,185] and -independent mechanisms[157,186] have been proposed to mediate CPE. *T. vaginalis* contains soluble and membrane-associated enzymes with phospholipase A (PLA) activity.[153,154,187] *T. vaginalis* PLAs lyse nucleated mammalian cells and red blood cells in vitro and may contribute to tissue damage and inflammation in trichomoniasis. In studies using male- and female-derived urogenital cells, *T. vaginalis* disruption of polarized epithelial monolayers facilitated penetration of HIV to underlying layers.[146]

Trichomonads adhere not only to host epithelial cells but also to extracellular matrix components including fibronectin and laminin.[188–190] *T. vaginalis* encodes a putative surface protein that contains a leucine-rich repeat domain also found in fibronectin-binding proteins from other organisms that colonize mammalian mucosal surfaces.[191] *T. vaginalis* binding to the host extracellular matrix may be important for persistence once the vaginal epithelium has been exfoliated, either by parasite-induced CPE or shedding during the menstrual cycle.

HOST COMPONENTS ASSOCIATED WITH *T. VAGINALIS*

Numerous host macromolecules are known to coat the *T. vaginalis* cell surface. These host-derived molecules are important to the survival of the parasite in vivo and contribute to *T. vaginalis* metabolism and pathogenicity, either through biological mimicky or through accumulation of nutrients from the host. These molecules include α_1-antitrypsin, α_2-macroglobulin, fibronectin, lactoferrin and other iron-binding and iron-containing proteins, lipoproteins, and lipids.[140] Specific receptor-mediated acquisition of iron-binding proteins is important in the pathogenesis of trichomoniasis. In vitro, *T. vaginalis* can obtain iron from lactoferrin, ferritin, hemoglobin, heme, and cytochrome c, but not transferrin.[172,192] Iron uptake and increased intracellular enzyme activity follow host lactoferrin binding to parasite surface receptors, and growth in high iron results in increased expression of many virulence genes involved in adherence.[125,172,173,181,190,193–195]

T. VAGINALIS PHAGOCYTOSIS

The capacity of *T. vaginalis* for phagocytosis has long been recognized.[196–199] Vacuoles, particles, bacteria, viruses, and rarely leukocytes, erythrocytes, and epithelial cell membranes can be found within the parasite cytoplasm.[155,200–205] Particle recognition and phagocytosis appear to be mediated by both nonimmunological means[206] and by specific immunological

cell surface receptors similar to the Fc and complement receptors of polymorphonuclear leukocytes.[207]

T. vaginalis infection is often clinically associated with detection of bacteria in the urogenital tract including *N. gonorrhoeae, C. trachomatis*, and *Mycoplasma hominis*,[41,78,80,83,208–210] and in vitro studies demonstrated that trichomonads readily take up these bacteria.[171,196,211–213] Early suggestions that gonococcal or chlamydial transmission or persistence could result from protection of engulfed bacteria inside *T. vaginalis* were contradicted by in vitro studies showing that phagocytized bacteria were efficiently killed by the parasite.[196] However, documentation of survival and replication of *M. hominis* within *T. vaginalis* suggests that the protozoan may play a role in transmission of mycoplasma.[211,213–215] Whether there are consequences of such a relationship for the pathogenesis of trichomoniasis remains to be determined.

HOST IMMUNE RESPONSES

Infection with *T. vaginalis* elicits cellular, humoral, and secretory immune responses. However, these responses do not protect patients against reinfection. Repeated infections in women are commonly encountered in clinical settings, and a history of prior treatment for trichomoniasis is a risk factor for infection in men.[83]

Inflammatory responses

Vaginal or urethral inflammation, characterized by an influx of polymorphonuclear leukocytes, represents the most obvious host response to infection with *T. vaginalis*. In some cases, inflammation is greater in patients with higher parasite loads.[163] Recent reports suggest that *T. vaginalis* can stimulate human neutrophil production of IL-8[216] and TNF-alpha production by murine splenocytes through activation of toll-like receptor 4(TLR4).[217] IL-8 is a potent chemoattractant produced by neutrophils and epithelial cells in response to microbial infection, and its stimulation likely induces further neutrophil recruitment to the site of infection. TLR-4 engagement on host cells, whether through binding of a parasite product or an endogenous ligand produced in response to *T. vaginalis* infection, would also result in stimulation of proinflammatory host responses. Increased proinflammatory cytokine production in trichomoniasis is consistent with increased HIV transmission, providing a plausible mechanism for the observed epidemiological synergy. *T. vaginalis* has been shown to activate HIV-infected leukocytes resulting in TNF-alpha production and increased viral replication.[146]

Antibody and complement

Antibody and complement components, present in serum and genital fluids of some individuals with trichomoniasis, can bind the surface of *T. vaginalis*, lyse trichomonads, and stimulate the neutrophil respiratory burst facilitating parasite killing via classical and alternative complement pathways.[140,218,219] *T. vaginalis* antigens recognized by antitrichomonal antibodies include surface and secreted cysteine proteases,[178,220] heat-shock proteins,[221] alpha actinin,[222] and the P270 protein.[223] However, there is little evidence that development of such antibodies contributes to parasite clearance. Furthermore, persistent trichomonal infections, a hallmark of trichomoniasis, suggest that humoral immune responses are not broadly protective. *T. vaginalis* resistance to humoral immune responses may be due to parasite production of proteinases that can cleave human immunoglobulins and complement components.[140,224,225] Expression of these proteolytic enzymes is upregulated under conditions likely to be encountered during infection such as high iron levels present during menstruation.

Despite the lack of protection afforded by immune responses to naturally acquired *T. vaginalis* infection, there is evidence to suggest that antibodies that block attachment of the parasite to mucosal surfaces could be protective. Reduced adhesin expression mediated by antisense RNA silencing results in reduced attachment,[226] and antibodies that bind surface adhesins block *T. vaginalis* adherence to host cells in vitro.[172,176,181,227] Moreover, administration of high doses of monoclonal antibodies against a trichomonad surface proteinase/adhesin protected mice from intraperitoneal challenge with *T. vaginalis*.[227] Whether these observations can be translated into an effective *T. vaginalis* vaccination strategy remains to be seen.

CLINICAL PRESENTATION

SITES OF INFECTION

In women, *T. vaginalis* has been isolated from all genitourinary sites. Vaginal infection is most common, followed by infection of the urethra, Bartholin's and Skene's glands, and endocervix. While concomitant infection of the urethra occurs in a majority of women with vaginal trichomoniasis, concordance of infection is not absolute. Among women infected with *T. vaginalis*, almost 10% demonstrated positive cultures only from the urethra.[228]

In men, *T. vaginalis* has been isolated from the urethra, urine, semen, external genitalia, epididymis, and prostate.[29,101,140,229] Marked rates of anatomically discordant sites of infection for men have also been documented. Figure 43-2 shows recovery of trichomonads from different urogenital specimens from men. Nearly one-third of infections in men will be missed when a single specimen is evaluated.[229]

INFECTIONS IN WOMEN

The spectrum of clinical presentations with *T. vaginalis* infections ranges from asymptomatic disease, to severe vaginitis.

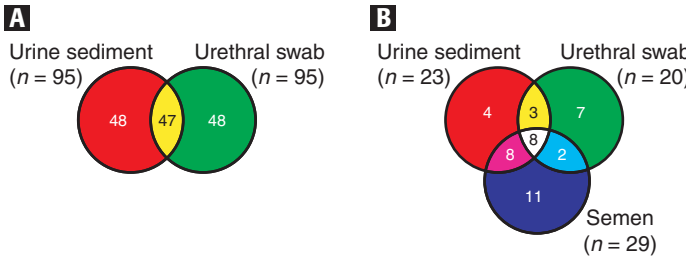

FIGURE 43-2. Detection of *T. vaginalis* in different urogenital specimens from men. **A.** Cases detected by use of urine specimen culture and urethral swab culture. A total of 143 infections were identified from a total of 1701 complete sets of specimens. **B.** Cases detected by use of urine specimen urethral swab and semen specimen culture. A total of 43 infections were identified from a total of 288 complete sets of specimens. (From Kaydos-Daniels SC, Miller WC, Hoffman I, et al. The use of specimens from various genitourinary sites in men, to detect *Trichomonas vaginalis* infection. *J Infect Dis* 2004; 189: 1926. With permission of the University of Chicago Press.)

FIGURE 43-3. Profuse purulent vaginal discharge due to trichomoniasis. Color is greenish yellow when viewed on a white swab. Appearance is occasionally frothy, as seen here.

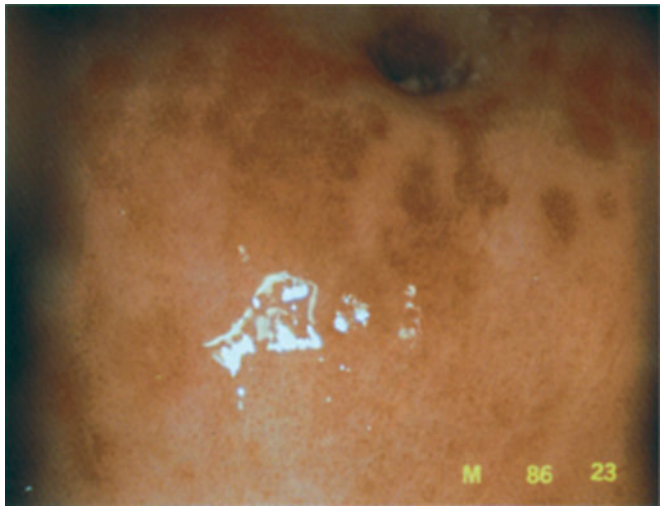

FIGURE 43-4. Colpophotograph of "strawberry cervix" showing petechiae on the ectocervix in a patient with trichomonal vaginitis and ectocervicitis.

The degree to which this variability in presentation is influenced by differences in host susceptibility or parasite-specific virulence factors is not known. Furthermore, studies describing clinical manifestations often rely on insensitive diagnostic methods for *T. vaginalis*, and frequent coinfection with other STIs confounds analysis of clinical presentation.[54]

Although many women are asymptomatic, the most common presenting complaint among symptomatic women diagnosed with *T. vaginalis* is vaginal discharge. Vaginal discharge is seen in more than 50% of cases. Other symptoms include pruritus, dysuria, and abdominal pain.[87,230] Some women remain asymptomatic until after menses, suggesting a role for iron in the pathophysiology of trichomoniasis.[194] Symptomatic patients may also complain of malodorous discharge. Dysuria is a common complaint and has been observed in up to one-third of women diagnosed with *T. vaginalis*.[75]

On genital examination, vulvar erythema and edema may be noted. Upon speculum examination, the vaginal discharge can have any color or characteristic, although a frothy yellow or greenish discharge has classically been associated with trichomoniasis (Fig. 43-3). An inflammatory vaginal discharge as defined by presence of polymorphonuclear cells may be present even in the absence of symptoms.[231] The vaginal walls may also be erythematous.

Cervical pathology may be seen with *T. vaginalis* infections. Colpitis macularis, or "strawberry cervix" (Fig. 43-4), is a result of microscopic, punctate hemorrhages on the cervix. Colpitis macularis may be observed in fewer than 5% of women with trichomoniasis; however, a proportion of trichomoniasis cases with colpitis macularis can be identified using colposcopy.[162,232,233] Although uncommon, this finding is highly specific for trichomoniasis; rarely, there are other etiologies.[234] The resulting cervicitis may lead to postcoital bleeding and cervical friability. Cervical mucopurulence and/or cervical erythema have also been observed in women diagnosed with trichomoniasis, but these findings are neither sensitive nor specific. Although women with trichomoniasis may present with mucopurulent cervicitis, other STIs such as gonorrhea and chlamydial infection should also be considered.

Women with trichomoniasis are more likely to present with an elevated vaginal pH, amine odor, milky discharge, or colonization by *Gardnerella vaginalis, Bacteroides* spp., or genital mycoplasmas than women with normal flora characterized by predominant lactobacilli. Specifically, *T. vaginalis* has been associated with intermediate vaginal flora characterized by reduced lactobacilli detected by Gram stain.[235] Because the vaginal environments for trichomoniasis and BV are similar, BV is found concomitantly in 25–60% of women with trichomoniasis.[74,235–238] One multicenter

study of 7918 pregnant women found that trichomoniasis was associated with reduced concentrations of vaginal lactobacilli.[235] Moreover, *T. vaginalis* growth in vitro is optimal at pH between 4.9 and 7.5; therefore, more trichomonads may be visualized in women with concomitant BV who have a resultant alkaline pH than in women with a normal vaginal pH. However, the debate continues as to whether trichomoniasis induces changes in the vaginal flora consistent with BV, or BV is a risk factor for acquisition of *T. vaginalis*.

Potential complications of trichomoniasis include vaginal cuff cellulitis following hysterectomy and atypical PID.[239,240] Abdominal pain, described in over 10% of women with trichomoniasis, may be secondary to adenopathy from the infection or concomitant infection with other sexually transmitted pathogens. Other complications associated with trichomoniasis include increased risk of low birth weight infants, premature rupture of membranes, and preterm delivery in pregnant women with trichomoniasis.[2,59,241]

INFECTIONS IN MEN

T. vaginalis infections are recognized as a cause of nongonococcal nonchlamydial urethritis in men, but are less well characterized than infections in women. This paucity of information is largely due to the fact that men are neither routinely screened for this infection nor commonly treated. The incubation period is thought to range from 3 to 9 days, though it could be much longer. In a study of untreated male partners of women with trichomoniasis, one untreated patient, who denied any ensuing sexual contact, continued to harbor the organism for months. However, more than two-thirds of men had cleared the infection after 2 weeks.[101]

Asymptomatic infection is common in men diagnosed with trichomoniasis.[39,80,242] When symptoms of trichomoniasis manifest in men, they include a urethral discharge that may be less profuse and purulent than discharge associated with gonorrhea.[39,243] Among symptomatic men diagnosed with trichomoniasis, dysuria is a common complaint.[242] In one study conducted in an urban STD clinic, men with trichomoniasis alone were more likely to complain of urethral discharge, have urethral discharge on examination or demonstrate inflammation on microscopic examination ($\geq$ 5PMNs/hpf on Gram stain) than men without *T. vaginalis*, gonorrhea, or chlamydia.[25]

T. vaginalis prostatitis and epididymitis have also been described. However, it is difficult to rule out contamination via passage through an infected urethra as an explanation for trichomonads in semen and prostatic fluid, and few studies have included histopathological confirmation.[244–247] *T. vaginalis* was documented by PCR from prostate biopsies from men with chronic prostatitis, despite negative urine and urethral cultures.[248] Persistent trichomoniasis has been associated with anterior urethral strictures, although a causal effect has not been clearly established.[140]

RECURRENT AND PERSISTENT TRICHOMONIASIS

The most common source of recurrent trichomoniasis is an untreated partner. Trichomoniasis may also recur following treatment if the organisms are resistant to antimicrobial therapy. Resistant trichomoniasis is an increasingly common clinical problem. No clinical signs or symptoms can differentiate between susceptible or resistant infections. A history of potential reexposure or sexual activity with an untreated sexual partner should allow differentiation between reinfection versus persistent infection.

Persistent trichomoniasis is a phenomenon that has been described anecdotally in female nursing home patients who have, reportedly, not been sexually active for years. Whether the organism is harbored silently in immunologically or physiologically "protected" sites is unclear. Given the problems with currently available diagnostic methods, it seems possible that these patients may have escaped detection by virtue of a low organism or symptom burden. The association between trichomoniasis and older age in women has lead some to speculate on the role of estrogen in *T. vaginalis* infection.[249–251]

TRICHOMONIASIS AND INFERTILITY

Trichomoniasis in women would appear to be an uncommon cause of infertility, since many studies have documented highly prevalent *T. vaginalis* infection in populations of pregnant women. However, in a recent study of Cuban couples attending an infertility clinic, *T. vaginalis* was cultured from one or both members of 10% of couples.[252] Early experiments showed that *T. vaginalis* parasites and proteins, secreted during growth in culture, inhibited sperm motility in vitro.[253,254] In one study, men with trichomoniasis were more likely than uninfected men to have abnormalities of sperm morphology and motility, along with increased seminal fluid viscosity and particulate debris.[255] These abnormalities improved after treatment. In a recent case report of *T. vaginalis* orchitis, severely low sperm count and lack of motility improved following antitrichomonal therapy.[256] Thus, *T. vaginalis* infection may contribute to male infertility.

DIAGNOSIS

Diagnosis of trichomoniasis based solely on clinical signs and symptoms is unreliable because the spectrum of infection is broad, and other sexually transmitted pathogens cause similar signs and symptoms.[140] Diagnosis may prove particularly difficult in men, where infections are characterized by fewer organisms than infections in women.[101,257] High concentrations of

zinc and other substances with antitrichomonal activity in prostatic secretions may help explain the lower concentrations of organisms in infected men.[207,243]

DIRECT MICROSCOPIC EXAMINATION

In clinical practice, diagnosis of trichomoniasis is most often based on examination of a wet-mount preparation of vaginal discharge or of male urinary sediment. In expert hands, wet-mount microscopy can be 50–70% sensitive in women, but the technique is much less reliable in men.[140] Diagnosis by wet-mount requires visualization of viable, motile protozoa; therefore, specimens must be examined immediately. The sensitivity of wet-mount is further reduced as a result of even short delays between specimen collection and microscopic examination.[258]

Various staining methods for visualization of *T. vaginalis* include Gram, Giemsa, Papanicolaou, periodic acid-Schiff, acridine orange, fluorescein, neutral red, and immunoperoxidase. Papanicolaou-stained smears can detect *T. vaginalis* in asymptomatic women during routine cytologic examinations.[259–263] However, detection using the Papanicolaou test results in a high percentage of false-negative results with a sensitivity of 60% and a specificity of 95–97%.[263,264] Confirmation of the finding of trichomonads using another method is recommended; however, most clinicians will only have access to wet-mount evaluation, which lacks adequate sensitivity.

CULTURE

Culture, using a variety of liquid and semisolid media, remains the "gold standard" for diagnosis of trichomoniasis in women.[139,140,265,266] Culture pouches containing modified Diamond's medium are commercially available and convenient. Once inoculated, cultures are incubated and examined daily using microscopy for 3–5 days. Cultures from women with trichomoniasis are usually positive in the first 3 days. However, cultures inoculated with specimens from men should be incubated and examined daily for the full 5 days, since they often do not become positive before 3–5 days of incubation.[267] Vaginal swab specimens transported in Amies gel transport tubes maintain *T. vaginalis* viability for up to 24 hours prior to inoculation into culture media.[268] Trichomonads from vaginal swab specimens have been shown to remain viable in a small amount of saline for up to 20 minutes prior to culture inoculation.[269] Self-collected vaginal swabs are as sensitive as clinician-obtained specimens for *T. vaginalis* culture.[270] A combined approach of microscopy followed by culture if the wet-mount is negative can be useful.[72]

In research settings, obtaining multiple cultures or evaluating multiple sites increases the rate of laboratory diagnosis. One study of 600 randomly selected women at high risk for trichomoniasis found that duplicate vaginal cultures using Feinberg-Whittington or modified Diamond culture medium resulted in a diagnosis of 82 and 78 cases, respectively, while the combination of the two cultures identified 88 infected women. In comparison, wet-mount examination detected only 60% of the cases.[271]

Although culture of *T. vaginalis* in men is preferred over wet-mount microscopy for diagnosis, the optimal site or specimen for culture is not clear. Studies indicate that evaluating multiple sites substantially increases the detection of *T. vaginalis*.[101,83,229] Semen cultures have been shown to be valuable for documentation of infection in men; infections may be diagnosed by positive semen cultures in the face of concomitant negative cultures from urine, urethral swabs, or external genitalia.[101,229] However, routine collection of semen may be problematic, and in busy clinic settings, thorough microscopic examination of more than one specimen per subject may be prohibitively time consuming. A practical approach is to combine a urethral swab specimen with a first-voided urine sediment in a single culture.[101]

RAPID DIAGNOSTIC TESTS

Other methods for diagnosis of trichomoniasis in women are now commercially available. The Affirm™ VPIII Microbial Identification Test is an office-based oligonucleotide probe test that has a sensitivity of 80–90% and a specificity of 95% compared to wet-mount and culture.[272,273] The OSOM® Trichomonas Rapid Test[274] and XenoStrip™-TV[275] are immunochromatographic assays that detect *T. vaginalis* antigens in vaginal swabs and have sensitivities of 78–83% and specificities of 98–99%, which is superior to wet-mount. These tests may be of value in settings where culture and microscopy are not possible. The current rapid Trichomonas tests are only as good as, or somewhat better than, wet-mount microscopy, which is widely recognized as inadequately sensitive, particularly in the diagnosis of infection in men. The tests are certainly better than nothing, and their simplicity and similar performance compared to wet-mount microscopy make them an important addition to the STI testing toolbox. But they are not good enough. The need remains for *T. vaginalis* diagnostic tests that can combine the sensitivity and specificity of nucleic acid amplification tests with the ease-of-use and rapid results of point-of-care tests. To achieve the maximum benefit, such tests should be applicable to noninvasive specimens including urine and self-obtained vaginal swabs or tampons, and validation of test performance in women and men is essential.

NUCLEIC ACID AMPLIFICATION TESTS

Several groups of investigators have reported on the development of PCR assays for the diagnosis of trichomoniasis in women. The performance of the various primers in clinical studies differ, with reported sensitivities of 85–100%.[276–284] Unlike PCR for STIs such as gonorrhea and chlamydia, for which amplification results in greater sensitivity than culture

methods, the currently published amplification techniques for trichomoniasis in women do not appear to offer a similar diagnostic advantage. PCR of vaginal swabs may be advantageous in settings where incubation of cultures is not possible and shipping specimens to a reference laboratory is required.

PCR is superior to culture for the diagnosis of *T. vaginalis* in men. Amplification assays that have been validated in specimens from men have reported sensitivities ranging from 80% to 100%.[82,257,285] In studies of men attending U.S. STD clinics, culture detected *T. vaginalis* infection in 3–5% of men versus 12–17% detected by PCR.[285,286] In a study of men attending STD or dermatology clinics in Malawi, the addition of urethral swab PCR to wet-mount microscopy and urethral culture increased *T. vaginalis* detection from 16% to 21% in symptomatic men and from 9% to 12% in asymptomatic men, compared to wet-mount and culture alone.[82] For diagnosis in men, PCR from urine appears to be more sensitive than from urethral swabs.[285] However, for PCR detection of *T. vaginalis* in men, just as for culture, testing multiple specimens will substantially increase the number of cases identified.

Perhaps the biggest obstacles to diagnosis of trichomoniasis are the lack of attention given to *T. vaginalis* infection in patients, particularly men, receiving care in general practice and the lack of access to sensitive nucleic acid amplification tests. In many medical centers and commercial laboratories, no diagnostic test beyond wet-mount microscopy is available. Development and widespread use of sensitive diagnostic tests in conjunction with increased awareness of *T. vaginalis* as an important pathgoen in men and women are essential for control of trichomoniasis.

ANTIMICROBIAL SUSCEPTIBILITY AND THERAPY

SUSCEPTIBILITY AND RESISTANCE

Metronidazole was the first effective treatment for trichomoniasis and remains the mainstay for therapy.[140] However, the U.S. FDA recently approved tinidazole for treatment of trichomoniasis in women and men. Metronidazole, tinidazole, and other drugs used in treatment of trichomoniasis are derivatives of 5-nitroimidazole. The specific antimicrobial effects of these drugs depend on their activation within *T. vaginalis* hydrogenosomes, resulting in the generation of cytotoxic nitro-radicals. The precise targets of these toxic radicals in *T. vaginalis* are not known, but damage to DNA, proteins, and interference with protein trafficking are likely.[287]

In most cases, trichomoniasis is easily treated with a single dose of metronidazole. Resistant strains do occur and may be increasing in prevalence.[135,288–290] The resistance is relative and can often, but not always, be overcome by treatment with higher doses.[290] However, side effects from metronidazole, such as nausea, are common and may limit the dose. The 5-nitroimidazoles share a common mode of action; not surprisingly, cross-resistance between drugs in this class has been reported.[142,291] However, differences in the pharmacokinetics between the drugs might affect their in vivo efficiencies.[292] The plasma elimination half-life of tinidazole is approximately twice that of metronidazole,[59,293] and in vitro studies suggest that tinidazole minimal lethal concentrations (MLCs) are commonly lower than those of metronidazole.[293]

In principle, there are two types of metronidazole resistance (aerobic and anaerobic).[287] Aerobic resistance is manifested only if some oxygen is present.[294,295] The MLCs of metronidazole determined in vitro under aerobic conditions for resistant clinical isolates range between 25 and 1000 μg/mL.[142,294,295] Although the exact mechanisms are not known, it has been suggested that impaired oxygen scavenging system is responsible for aerobic resistance.[142,296]

All strains responsible for clinical metronidazole resistance that have been examined so far display anaerobic resistance. Anaerobic metronidazole resistance depends on inactivation of the key components of drug-activating (electron-generating) pathways.[297] However, inactivation of a known *T. vaginalis* ferredoxin gene by genetic manipulation does not lead to aerobic or anaerobic resistance in vitro,[121] suggesting there may be additional mechanisms of drug activation. Anaerobically resistant strains developed in vitro display high MLC values in anaerobic assays (metronidazole up to 1425 μg/mL).[296]

CURRENT TREATMENTS

Treatment recommendations

Because *T. vaginalis* often infects the urethra and periurethral glands, systemic chemotherapy is superior to topical treatment.[140] Therapy that treats only vaginal organisms may leave organisms at other sites, resulting in subsequent endogenous reinfection. Metronidazole or tinidazole is the treatment of choice for trichomoniasis in both women and men, with various doses depending on the type of infection and treatment guidelines, summarized in Table 43-3.[298] Patients who are coinfected with HIV can receive the same treatment regimens as HIV-negative persons.

The recommended dose of metronidazole or tinidazole is 2 g orally in a single dose with reported cure rates of up to 97%.[301] Sexual partners should also be treated; simultaneous therapy for sexual partners increases the cure rates with single-dose treatment.[140] Alternative regimens include metronidazole 500 mg twice daily for 7 days.[30] For patients who fail therapy and have not been reinfected, higher doses of metronidazole (2 g oral dose once daily for 3–5 days) or a multiday dosing regimen of tinidazole are options.[292] Metronidazole intravaginal gel has limited efficacy against *T. vaginalis* and should not be used to treat trichomoniasis.

Table 43-3. Treatment Recommendations for *Trichomonas vaginalis* Infections

Treatment Regimen	Reference
Vaginal infections	
Recommended regimens	
Metronidazole 2 g orally in a single dose	30, 69
Tinidazole 2 g orally in a single dose	69
Metronidazole 400–500 mg orally twice a day for 5–7 days	297
Alternative regimens	
Metronidazole 500 mg orally twice a day for 7 days	30
Metronidazole 400–500 mg orally twice a day for 7 days	69
Tinidazole 500 mg orally twice daily for 5 days	297
Pregnancy	
Metronidazole 2 g orally in a single dose	30, 69
Urethral infections	
Recommended regimens	
Metronidazole 2 g orally in a single dose	30
Tinidazole 500 mg orally twice daily for 5 days	69
Metronidazole 400–500 mg orally twice a day for 7 days	69
Treatment failures	
Recommended regimens	
Metronidazole 500 mg orally twice daily for 7 days	30
Metronidazole 2 g orally once daily for 3–5 days[a]	30
Alternative regimens[b]	
Tinidazole 2 g twice daily for 14 days	298
Tinidazole 500 mg three times daily for 7–10 days	299
Tinidazole 1.5 g three times daily for 14 days	291
Tinidazole 1 g twice daily for 14 days	291
Neonatal infections	
Recommended regimen	
Metronidazole 5 mg/kg orally three times daily for 5 days	297

[a] Recommended regimen if treatment failure occurs again after metronidazole 500 mg twice daily for 7 days.[30]

[b] Alternative regimens can include oral and vaginal doses.

Current recommendations focus on epidemiological treatment of sexual partners of infected women, without specific diagnosis.[30] In situations where appropriate diagnostic facilities are unavailable, epidemiologic therapy is reasonable to reduce subsequent transmission and limit the potential for reinfection following successful treatment. However, epidemiological therapy is limited by compliance with partner notification and tends to miss partners of asymptomatic women, since such women are less likely to be diagnosed.[208] A specific diagnosis of trichomoniasis in men could prompt identification of more infected males and enhance detection of additional infected women through partner notification.[83]

Estimates suggest that approximately 2.5–5% of all cases of trichomoniasis display some level of resistance to treatment with metronidazole.[302] This resistance is relative and can usually be overcome with higher doses of oral metronidazole. For example, treatment of marginal resistance, defined as an aerobic MLC of metronidazole 50 μg /mL requires a total dose of 10 g administered over several days for cure, whereas treatment of high-level resistance (MLC of ≥ 400 μg/mL) requires 40 g. Intravenous formulations offer no advantage over oral medications for trichomoniasis. Some authorities have recommended higher doses of oral regimens in combination with pharmacy-prepared intravaginal preparations. There are limited anecdotal reports of success with paromomycin cream; however, there may also be a high incidence of local side effects associated with this therapy.[290]

Tinidazole, which was recently licensed in the United States, but has been used in other countries for years, may be particularly useful for treatment of metronidazole-resistant infections. The U.S. Centers for Disease Control and Prevention (CDC) tested 195 metronidazole-resistant *T. vaginalis* clinical isolates with both metronidazole and tinidazole. The mean aerobic MLCs were metronidazole 400 μg /mL, compared to tinidazole 100 μg /mL.[303] Several studies have evaluated different doses of tinidazole for treatment of metronidazole-resistant trichomoniasis.[292,299,300,304] In the largest study, 20 patients with clinically refractory trichomoniasis (failure to respond to therapy with oral metronidazole, at least 500 mg BID for 7 days) were treated with high doses of oral and vaginal tinidazole (2–3 g orally plus 1–1.5 g intravaginally for 14 days). The cure rate was 92%, and no patient discontinued therapy due to side effects.[292]

Relatively few studies have addressed treatment of trichomoniasis in men. In one study, a 7-day multidose metronidazole regimen proved highly effective in curing men.[140] The single-dose regimen has not been evaluated extensively, and existing reports are contradictory. One study indicated a 43% failure rate with single-dose therapy.[305] Other investigators found that metronidazole, 2 g as a single oral dose, was highly effective in curing men.[101,306]

Adverse reactions and toxicity of metronidazole and other 5-nitroimidazoles

Occasionally, patients present with an allergy to metronidazole, and we lack data on cross-reactivity with tinidazole. Since there is no effective alternative, desensitization followed by later treatment is recommended for metronidazole-allergic patients with trichomoniasis.[30]

Animal data suggest that metronidazole may be both carcinogenic and mutagenic.[140] However, human data suggest that metronidazole has limited carcinogenic or mutagenic

potential. A cohort of 771 women followed for 15–25 years after treatment with metronidazole showed no significant increase of cancer morbidity and mortality over the expected rate.[307] Taken together, the data suggest that the risk of short-term, low-dose metronidazole is extremely small. There are no documented cases of fetal malformation attributed to its use in pregnancy, even in the first trimester.[308] Based on these considerations, the Centers for Disease Control (CDC) recommends treatment of symptomatic pregnant women with trichomoniasis with a single 2-g oral dose of metronidazole.[30] This dose of metronidazole can also be used in breastfeeding women.

Recent controversy has arisen concerning the treatment of trichomoniasis in pregnancy and its relationship to preterm birth. Two studies suggest that treatment of trichomoniasis in pregnancy may actually increase the risk of preterm birth rather than decrease the risk as predicted.[309,310] However, there are limitations to both of these studies. One of the studies used much higher doses of metronidazole than recommended. In addition, the study was stopped prematurely because of the observed trend toward preterm birth in women who received metronidazole, and thus was not allowed to continue subject enrollment for a definitive analysis.[309] The second study was a subanalysis of a larger study investigating STD and HIV risk. The subanalysis was not primarily designed to assess risks of preterm birth associated with treatment of trichomoniasis in pregnancy.[310] Despite the publication of these reports, the CDC has not revised recommendations for treatment during pregnancy.

PREVENTION AND CONTROL

Primary prevention programs for trichomoniasis are unfortunately lacking, and rely mainly on individual management, counseling, and partner notification. In areas of high prevalence or among high-risk groups, syndromic management or screening for *T. vaginalis* has been applied depending on resources and available laboratory techniques. However, based on a mathematical model of disease transmission dynamics, success in controlling trichomoniasis through these interventions is likely to be transitory without a sustained investment in resources.[311] Given an estimated 50% of asymptomatic disease, high levels of syndromic management are projected to lead only to modest reductions in the endemic prevalence of trichomoniasis. In comparison, modest levels of constant screening (vs serial screening) for *T. vaginalis* can result in significant reductions in its prevalence as predicted by the model.[311]

Partner notification, whereby the index patients or the health-care providers notify the sexual partners of the potential exposure and encourage them to seek treatment, is essential for *T. vaginalis* control in light of the high rate of infection noted among partners.[208] Several studies have shown that treatment of male sexual partners of infected women improves cure rates and avoids recurrent infection.[24,312,313] Partners of patients with trichomoniasis who have had sexual contact with the index patient in the past 60 days should be notified for evaluation and treatment to decrease the reservoir of potentially infectious persons. Sexual abstinence for 7 days should be recommended following treatment of both the index case and the partner(s) for trichomoniasis. Patient-delivered partner medication shows promise as an approach for other STIs, but may not be a widely available option.[314–317]

The promotion of condom use and other barrier methods is important to decrease the transmission of *T. vaginalis*. A study evaluating condom effectiveness reported a significant reduction in female sex workers' risk of acquiring trichomoniasis.[318] Repeated behavioral interventions focused on preventive education and provision of testing and treatment for female sex workers has also been shown to successfully reduce the incidence of trichomoniasis and other STIs.[319]

Vaginal microbicides have received renewed interest because they are alternative agents to female condoms that do not require male cooperation. In vitro tests had suggested that spermicides containing nonoxynol-9 (N-9) can kill sexually transmitted pathogens including *T. vaginalis*.[320] However, a meta-analysis of randomized clinical trials to evaluate the effectiveness of N-9 for the prevention of trichomoniasis did not find a statistically significant difference between the microbicide and the no treatment groups.[321] A novel peptide antibiotic, D2A21, has been investigated as an intravaginal application and is reported to be efficacious in preventing vaginal *T. vaginalis* infections in mice.[322]

In light of the cost of treating frequent and recurrent trichomoniasis, there has been some research into vaccine development for *T. vaginalis*. A recent review of earlier studies details mechanisms by which protection from infection could potentially be achieved.[289] Two *T. vaginalis* vaccine candidates have been tested. In the 1960s, intravaginal inoculation with a heat-killed *T. vaginalis* preparation in a single study was reported to improve clinical symptoms,[323] but the work was not repeated and has not been pursued. In the late 1970s, a vaccine marketed in Europe under the name SolcoTrichovac was developed from heat-inactivated "abnormal strains of lactobacilli" isolated from the vaginal sections of women with trichomoniasis.[324] Despite initial reports claiming cure of existing *T. vaginalis* infection and protection from reinfection, the vaccine has not been evaluated in well-controlled, double-blind prospective studies, and is not recommended. Murine and bovine models have been developed for the related pathogen, *T. foetus*, and may provide insights for future *T. vaginalis* vaccine efforts.[325,326]

T. vaginalis warrants greater attention and concern as a highly prevalent sexually transmitted pathogen that has been associated with various adverse health sequelae and increased HIV transmission among sexually active men and women. Moreover, there appears to be an increasing incidence of

resistant infections with *T. vaginalis*,[290] and there currently is no safe and effective alternative to nitroimidazoles for treatment. Therefore, consideration of disease prevention and control strategies for *T. vaginalis* along with other STI control efforts is imperative. Future control strategies for *T. vaginalis* should include development of screening programs in populations with high prevalence, improvement and utilization of sensitive, noninvasive diagnostic methods in both men and women, and better surveillance to monitor disease trends which can assist in the development of potential interventions for trichomoniasis.

44 Intestinal Protozoa: *Giardia lamblia*, *Entamoeba histolytica*, *Cryptosporidium*, and New and Emerging Protozoal Infections

Cirle Alcantara Warren and Richard L. Guerrant

Enteric protozoan pathogens are increasingly recognized causes of diarrhea. This chapter reviews the biology of the major protozoan causes of diarrhea: *Giardia lamblia*, *Entamoeba histolytica*, and *Cryptosporidium*. Predominantly considered as low infectious dose pathogens, these protozoa may sometimes be transmitted directly by sexual practices that enable fecal–oral spread. *E. histolytica* and *G. lamblia* are the two most common protozoa isolated in men who have sex with men (MSM). *Cryptosporidium* infections present particularly severe problems in patients with the acquired immunodeficiency syndrome (AIDS). Other intestinal protozoa that may also cause severe diarrhea in HIV-infected patients include *Cyclospora* and microsporidia, which are discussed at the end of this chapter.

GIARDIA LAMBLIA

HISTORY, EPIDEMIOLOGY, AND CLINICAL MANIFESTATIONS

History

G. lamblia was probably first discovered by the inventor of the microscope, Anton van Leeuwenhoek, when he examined his own diarrheal stool. In a letter to the Royal Society on November 4, 1681, he described "a number of animalcules approximately the size of a blood cell, with flattish bodies and several legs, moving much like a wood louse running up against a wall."[1] In 1859, Vilem D. F. Lambl described the parasite and called it *Cercomonas intestinalis*. However, since this organism was found in a number of asymptomatic individuals,[2] it was not considered to be a pathogen until it was repeatedly observed to be associated with diarrhea,[3–5] malabsorption,[6] and occasional tissue invasion.[7] Even the demonstration of experimental human infection in 36% of volunteers ingesting 10–25 *Giardia* cysts in water, and the presence of moderate to marked diarrheal symptoms in 60% of 15 infected individuals, left some question about the pathogenicity of this flagellated protozoan parasite.[8] Since then have been numerous studies of the different strains of *Giardia*, its animal host-species specificities, its morphological and functional characteristics, its in vitro cultivation, and the possible mechanisms by which it may cause enteric disease. As with *E. histolytica*, the in vitro cultivation of *G. lamblia* has enabled the study of different strains at the molecular level.

EPIDEMIOLOGY

Several epidemiologic surveys have revealed that 2–9% of the population in many parts of the world excrete *G. lamblia cysts.*[9,10] Prevalence rates are higher in tropical areas and among travelers; exposed infants and children have the highest rates.[11,12] This skewed distribution of giardiasis toward children is in distinct contrast to amebiasis, where gain and loss of infections (with a median duration of 2 years) appears to be independent of age.[13] The geographic and age distribution, as well as increased frequencies of giardiasis in institutions where hygienic standards are difficult to maintain, indicate that spread occurs by the fecal–oral route.[3,14] The human volunteer studies by Rendtorff[8] suggest that ingestion of relatively small numbers of cysts in food or water or as a result of person-to-person contact results in infection. A food-borne outbreak was reported in which contamination of canned salmon apparently occurred after careful diaper changing of an infected infant.[15]

Venereal transmission of *Giardia* is also known to occur, predominantly, in MSM. Depending on the year and location of the study and the microbiologic techniques employed, the prevalence of giardiasis in MSM, ranged from 3% to 15.7%.[16–21] In patients with AIDS, the prevalence may be higher (up to 55% in an inner city AIDS clinic).[22,23] In one of the earlier studies looking at the association of enteric protozoan and helminthic infection and gender, and sexual practices, homosexuality and oral–anal sex were identified as the most important risk factors for infection.[24] In this study, 29 of 163 men and none of 17 women had an enteric infection. The prevalence of enteric infections *(E. histolytica, Giardia, or both)* was 21.5% in homosexual men, 6.2% in bisexual men, and

0 in heterosexual men. In a similar investigation, *Giardia* was isolated in 13% of MSM versus only 3% of the heterosexual men in the study population.[16] Although homosexual orientation has persistently been associated with giardiasis, specific sexual practices, e.g., oral–anal, orogenital, or penile–anal, and number of sexual partners were less consistently reported as risk factors, probably because of the nature of data extraction employed in the studies.[16,19,20,22,24–27] High degree of spatial clustering of giardiasis in AIDS patients has also been noted.[23]

Waterborne giardiasis has been widely recognized in the last 15 years and is now the commonest reported parasitic infection in England and the United States.[28] Although first suggested by an outbreak of amebiasis and giardiasis in 1946 in a Tokyo apartment building where sewage-contaminated water was implicated (*Giardia* cysts were demonstrated in 80% of symptomatic individuals who did not have amebiasis),[4] attention was drawn to waterborne giardiasis by an outbreak in Aspen, Colorado, in 1965, when 11% of skiers and 5% of residents were infected, and *Giardia* cysts were demonstrated in sewage that had contaminated the drinking water. A total of 23 additional outbreaks of giardiasis involving over 7000 individuals in the United States subsequently implicated water which was inadequately sedimented and filtered, often despite bacteriologically adequate chemical disinfection.[28–30]

More recently, *G. lamblia* has been reported as one of the most frequently identified agents in outbreaks associated with recreational water in the United States, accounting to 6% of the pathogens. Like cryptosporidiosis, giardiasis was associated with treated water swimming and wading pools.[31] In an analysis of voluntarily reported cases at the Centers for Disease Control National Electronic Telecommunications System, it was noted that a greater number of reports were received for children aged 1–9 years and adults aged 30–39 years. It was also noted that the seasonal peak in age-specific case reports coincided with the summer recreational water season.[32] Similarly, in a case control study in Southwestern England, swallowing water while swimming (odds ratio [OR] 6.2, 95% confidence interval [CI] 2.3–16.6) and recreational fresh water contact (OR 5.5, CI 1.9–15.9) had been identified among risk factors for sporadic infection with *G. lamblia*.[33]

Studies of travelers from the United States and other countries to Leningrad and Moscow, summarized in a 1974 journal article,[34] noted impressive attack rates of giardiasis, ranging from 22% to 41%. In one of these studies, the mean incubation period was 14 days, and 69% of those infected were symptomatic.

Besides humans, potential reservoirs include small animals such as beavers, which may be found contaminating even the remotest streams. As shown by Rendtorff in 1954,[35] *G. lamblia* cysts remain infectious for humans after holding in water for over 2 weeks. Furthermore, chemical disinfection of contaminated surface water is inadequate, especially when the water is cold, and appropriate flocculation, sedimentation, and filtration are necessary to remove infectious cysts. Cysts may also be killed by 2–5% phenol or Lysol. Transmission may also occur with contaminated, uncooked foods[15] or by person-to-person contact in families, nurseries, institutions, and day-care centers.[3,9,14] Fecal–oral and rectal–genital spread of *Giardia* have been implicated in homosexual men.[36–38]

Modern molecular techniques have recently been employed to elucidate further the epidemiology, risk factors, zoonotic potential, and environmental contamination of *Giardia*. Polymerase chain reaction of DNA extracted from fecal specimens from different geographic locations have identified *G. lamblia* assemblages A and B to be associated with human infections. Although helpful in investigating the role of zoonoses in giardiasis, the relationship of the different genotypes to the severity of clinical disease remains unclear.[39]

Clinical manifestations

In endemic areas, the majority of *G. lamblia* infections are asymptomatic; however, a significant portion of residents and most previously uninfected travelers are symptomatic. The most characteristic symptoms include diarrhea of more than 10 days' duration, cramping upper abdominal pain, bloating, flatulence, and weight loss.[29,34] Less commonly, nausea, vomiting, and fever may be seen.

Although the incubation period ranges from 1 to 8 weeks, symptoms often precede the first detectable fecal shedding of the parasites; the median prepatency period in one study (14 days) was 6 days longer than the median incubation period (8 days).[40] Thus, it may be necessary to examine upper small bowel aspirates or repeated fecal specimens to document a diagnosis of giardiasis. While the infection is usually self-limited,[8] symptoms may intermittently recur or persist for prolonged periods of up to months or even years.[24] The illness may last up to 6 or 7 weeks.[34]

Signs and symptoms of malabsorption, ranging from mild noninflammatory diarrhea, steatorrhea, or weight loss to a more severe celiac syndrome, especially in children,[6] are well documented, with malabsorption of D-xylose, fat, carotene, vitamin A, folate, and vitamin B_{12}.[5,41,42] Giardiasis has been associated with childhood malnutrition[43,44] and may have detrimental effect on cognitive development in late childhood.[45] Malabsorption may be especially severe in patients with achlorhydria,[41] immunodeficiency,[41,46] protein–calorie malnutrition,[47] or bacterial overgrowth[48] complicating their illnesses. In patients with hypogammaglobulinemia, giardiasis can be associated with mucosal inflammation, with villus flattening, and with lactase, maltase, or sucrase deficiency.[42,49,50] Likewise, giardiasis may mimic or accentuate the malabsorption seen in chronic pancreatitis.[51]

For poorly understood reasons, patients with giardiasis may rarely develop eosinophilia, urticaria, or other symptoms, such

as arthritis,[52] that are suggestive of an immune response to an antigen exposed during acute diarrhea. These symptoms respond to specific antigiardial therapy.[53]

While giardia-induced diarrhea is usually noninflammatory, with only rare tissue invasion,[7] inflammatory proctitis and vaginitis have been reported.[54] In MSM, coinfection with other pathogens, including other enteric (such as *E. histolytica*) and sexually transmitted organisms may occur. Sigmoidoscopy in symptomatic MSM to distinguish proctitis (secondary to herpesvirus, gonococcal, chlamydial, or syphilitic infection), colitis (*Campylobacter, Shigella, Clostridium difficile, or Chlamydia*), or noninflammatory diarrhea (due to *Giardia*) is recommended.[55]

STRUCTURE AND BIOLOGY OF THE ORGANISM

Named "*Giardia*" by Kunstier, who observed it in tadpole intestinal tracts in 1882, the genus was considered by Alexeieff and Dobell to be the same as the human flagellated protozoan. The genus and the disease are called "*Lamblia*" and lambliasis in eastern Europe; however, most authorities agree on the genus name *Giardia*. At least three species are recognized on the basis of morphology and host-species specificity.[56] Although species specificity is debated and size can be changed with host diet,[57] *G. lamblia* trophozoites usually measure 12–15 μm long by 5–15 μm wide and 1–4 μm thick. Cysts are usually 8–12 μm long by 7–10 μm wide. Shaped like a horseshoe crab, with a rounded dorsal surface and concave ventral surface, the *G. lamblia* trophozoite has four pairs of flagella directed posteriorly from the lateral and ventral surfaces.

The trophozoite (Fig. 44-1) has a unique anterior ventral adhesive disk, to which are attached a clockwise spiral of microtubules and contractile elements. The disk has a posterior vent where beating ventral flagella appear to expel fluid that may help establish a mechanical suction for adherence of the parasite to mucosal or other surfaces.[58,59] Alternate suggestions for the disk's functions include contractile or grasping actions. The adhesive disk is divided into two lobes, the medial surfaces of which are the median groove. Two nuclei lie dorsal to the adhesive disk lobes, and the eight flagella appear to arise from basal bodies located anterior to the nuclei.

Endocytic or exocytic vacuoles that have been shown to concentrate ferritin or even bacteria are found adjacent to the disk and elsewhere.[60] There is evidence that *G. lamblia* have surface receptors for lectins such as wheat germ agglutinin and that these receptors can be blocked by specific carbohydrates.[61] In addition, a 56-kDa protease-activated *Giardia* lectin has been isolated by SDS-PAGE from a lipopolysaccharide (LPS)-sepharose column.[62]

The median body appears to be a tight packet of microtubules that lies between the posterior poles of the nuclei; it appears to be unique to *Giardia* spp.[59] The median bodies of

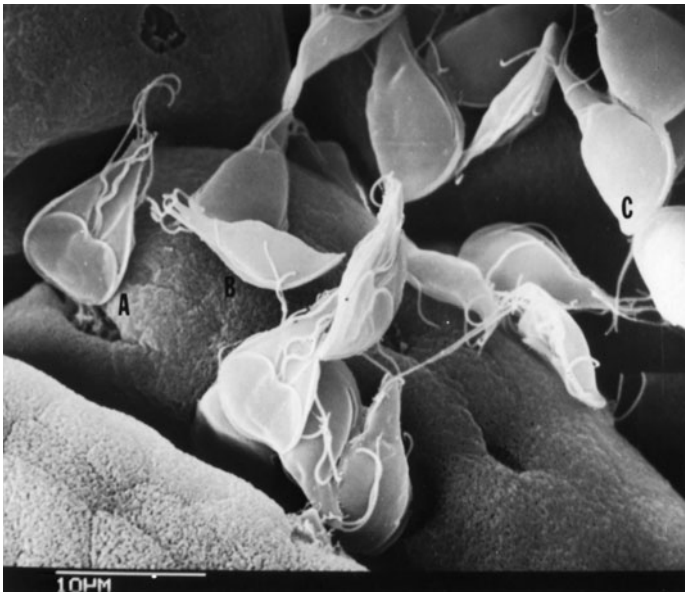

FIGURE 44-1. Scanning electron micrograph of *Giardia lamblia* trophozoites from a jejunal biopsy of a patient with symptomatic giardiasis. **A.** In the ventral view, flagella lead from the adhesive disk to the tapered posterior end. **B.** In the lateral view, anterior flagella can be seen. **C.** The dorsal view. (*Courtesy of R. L. Owen.*)

G. lamblia that infect humans, dogs, rabbits, and other mammals are characteristically claw shaped and lie transversely across the trophozoite. *G. muris* trophozoites from rodents or birds have small, round central median bodies, and the long, narrow *G. agilia* trophozoites from amphibians have long, tear-shaped median bodies.[56,57,62]

As with *E. histolytica*, differences among *G. lamblia* strains as to isoenzyme patterns,[63] antigens, and surface proteins,[64,65] and restriction endonuclease patterns[66] have been described. A double-stranded RNA virus has been described in the Portland I strain of *G. lamblia* that could infect another *G. lamblia* strain (WB).[67] Recent evidence on the antigenic variation of a cysteine-rich 170-kDa protein expressed on the surface of certain *G. lamblia* suggest frequent rearrangements at the gene locus as well as long tandem repeats in the DNA.[68,69]

Trophozoites may encyst in response to a reduced pH, detachment, immunologic attack, or other hostile environments in vivo;[59] encystment has been accomplished in vitro using primary bile salts.[70] Apparently, after a single division in the cyst and a period of maturation, two daughter trophozoites can be induced to excyst in vitro by special conditions and reduced pH.[71]

GROWTH, PHYSIOLOGY, AND CULTURE

Although culture has not been successful with other *Giardia* strains, the human strain *G. duodenalis* (*G. lamblia*) has been grown in vitro, first symbiotically with *Candida guillermondii* and then axenically (without other bacteria

or parasites) by Meyer.[72] In 1978, Bingham and Meyer successfully cultured trophozoites that were obtained in vitro from cysts shed by humans and monkeys.[71] As shown by Visvesvara, the conditions for culture of *G. lamblia* in vitro are similar to those for culture of *E. histolytica*. *G. lamblia* may be more oxygen tolerant, but both parasites require serum and cysteine.[73,74] Bile salts have been shown to support growth of *G. lamblia*.[74,75] Giardia trophozoites can be preserved at low temperatures in glycerol or dimethyl sulfoxide.

The in vitro cultivation of giardia trophozoites has enabled definition of their growth curves, with doubling times of 7–40 hours noted by different investigators.[73,74] *G. lamblia* appear to facultatively metabolize glucose to ethanol acetate and carbon dioxide via a flavin-mediated electron-transport system rather than a cytochrome-mediated electron-transport system or a Krebs cycle.[76]

IMMUNOLOGY AND PATHOGENESIS

Immunology and host response

A substantial number of studies of humoral and cellular immune responses to *Giardia* infection reveal a complexity ranging from partial protection to possible roles in pathogenesis. Evidence for acquired resistance includes the skewed age distribution toward children (in contrast to amebiasis),[13] the observation that long-term residents of endemic areas appear to have a lower infection rate than short-term residents,[77] and the tendency for individuals in endemic areas to be infected asymptomatically. In addition, prior infection appears to result in acquired resistance to *G. muris* infection in the mouse model.[78]

The nature of acquired resistance appears to be related in part to local antibody production. Although initial humoral responses to *G. lamblia* infection are predominantly IgM, there follows an IgA and IgG response[79] that correlates with the severity of the histologic jejunal lesion.[80] Although debated by others,[81] the findings of Zinneman suggested that patients with giardiasis had lower secretory IgA levels.[46] Of seven patients described by Hermans et al., who had type 2 IgA and IgM deficiency and nodular small bowel lymphoid hyperplasia, six had giardiasis that improved with therapy.[82] Ament et al. have shown that hypogammaglobulinemic patients who acquire giardiasis develop enteric symptoms and malabsorption.[83] However, the frequent occurrence of selective IgA deficiency without recognized problems with giardiasis suggests that other Ig classes or possibly still other factors are also involved in protection against symptomatic giardia infections.

Human serum kills *G. lamblia* trophozoites via activation of the classical complement pathway.[84] IgM-supported complement-dependent lysis of *G. lamblia* has been demonstrated. Anti-IgM treated mice develop heavy, prolonged infections (without any serum or local antibody responses) with *G. muris*.[85] Peyer's patch B cells show an early increase in surface IgM-bearing cells, followed by a switch to surface IgA-bearing cells with *G. muris* infection in mice.[86] The absence of severe disease with *G. lamblia* infections in AIDS patients (in contrast to cryptosporidial and mycobacterial infections, for example) militates against a major primary role for cellular immunity in preventing symptomatic giardiasis.

In the mouse model, transient protective immunity can be transferred by milk to suckling offspring, possibly at the cost of the nursing mother's effective intestinal immunity.[87] Whether this transient immunity is related to passive transfer of cellular or documented humoral immunity[88] or both remains to be determined. Anti-*Giardia* IgA in human breast milk has been reported to protect children against giardiasis early in life.[89]

Murine and human biopsy studies have suggested roles for several types of cells in the pathogenesis and resistance in *G. lamblia* infection: microfolded epithelial (M) cells overlying Peyer's patches that have to do with processing giardia antigens, small lymphocytes that undergo intralumenal migration and directly attack the parasite, and intraepithelial large T lymphocytes or macrophages which are also involved.[59,62,90] Paneth cells secrete defensins which has been shown to possess antigiardial activity in vivo.[91] Another recent mouse study implicated the role of bacterial endosymbionts in the trophozoites in the parasitocidal activity of Paneth cells.[92]

Evidence for a role for cell-mediated immunity in protection against *G. lamblia* infection again comes from the *G. muris* mouse model[93] in which athymic mice develop a prolonged *G. muris* infection.[94] Subsequent study has shown that the helper/inducer T lymphocytes (L3T4+), rather than the cytotoxic/suppressor (Ly-2+) subset, are responsible for clearance of murine *G. muris* infections.[95] Resistance to giardiasis may also be provided by toxic free fatty acids produced from breast milk by a bile-salt-stimulated lipase.[96,97]

The resistance to *G. lamblia* infection, however, is far from absolute. Normal human adults are usually susceptible to this widespread parasite; Rendtorff infected all 13 adults challenged with more than 100 cysts.[8] Despite the evidence for increased susceptibility when specific humoral or cellular responses are impaired or absent, the relative infrequency of giardiasis in most patients with IgA deficiency and the acquisition of incomplete resistance by athymic nude mice[93] show that resistance to *G. lamblia* infection is complex and may involve both local humoral and cellular immune responses.

The apparent increased frequency of giardiasis in patients with blood group A[98] may reflect less recognition of a parasite antigen similar to blood group A antigen,[99] or it may be related to other traits associated with blood group A, such as achlorhydria or differences in cell surface or mucus glycoproteins.

Pathogenesis

The initial stages in the pathogenesis of *G. lamblia* infection follow ingestion of a relatively small number of cysts (usually in water or by contact). Excystation and release of the short-lived "excyzoite" occur in the upper small bowel.[100] Each excyzoite generates four trophozoites which divide by binary fission. Larger inocula probably cause more severe infection.[8] Although gastric acidity may contribute to excystation,[71] several investigators have noted increased symptoms with giardiasis in hypochlorhydric or postgastrectomy patients.

There are several tantalizing hypotheses regarding the mechanism by which *G. lamblia* alters small bowel function or histology to cause disease. Some have suggested that the close adherence of many trophozoites mechanically impedes normal absorptive processes.[101] Holberton has shown evidence for a physical suction and some microvillus brush border damage under the ventral disk of giardia trophozoites that resulted in deformation of the gut cell cortex.[58] Imprints of the ventral disks have also been demonstrated in the microvillus brush border in the mouse model with *G. muris* infection.[102] Jejunal histology of infected mice showed reduction in the height of brush border microvilli.[103] However, this has not been shown in humans, nor do symptoms correlate with density or intensity of infection.[104] Instead, symptoms have been correlated with lymphocytic infiltration in the jejunal epithelium,[104] suggesting possible immunologic damage. Increased crypt cell production with lymphocytic infiltration has been noted in mice infected with *G. muris*.[105] Furthermore, Roberts-Thomson and Mitchell showed villus injury when T-lymphocytes were added to nude, athymic mice before infection with giardia protozoa.[94] Inflammatory responses with plasma cell infiltrates are also seen in segmentally damaged mucosa, especially in immunoglobulin deficiency states.[106]

Other researchers have described direct invasion of the mucosa by trophozoites in vivo.[107] Whether this tissue damage relates to cytotoxic or enterotoxic products of *G. lamblia* is unclear at present. Malabsorption and specific brush border enzyme deficiencies are well recognized in giardiasis.[42] These findings might be explained in part by increased epithelial cell turnover with increased villus-tip cell extrusion.[42,94] Others suggest that the parasite may compete with the host for nutrients.[101] Possible strain differences in pathogenicity based on differences in surface antigens, patterns of infection, and homologous immune responses have been suggested by studies in a gerbil model.

Finally, the interaction of *G. lamblia* with other microorganisms appears to be important in certain instances. Whether by host-tissue damage or by actual carriage of other microorganisms by giardia organisms,[60] severe malabsorption and steatorrhea with giardiasis has been associated with small bowel bacterial overgrowth.[35,47] Concentrations of 10^3–10^7 bacteria (mostly enteric coliforms) have been described with giardiasis and malabsorption or steatorrhea; in some instances the bacteria had to be eradicated before the symptoms resolved. Symptomatic responses to tetracycline without eradication of *G. lamblia* have also been noted.[108]

Bile salt deconjugation by bacterial overgrowth or by *Giardia* themselves has been postulated but not proved.[48] Smith and coworkers failed to confirm direct bile-salt deconjugation by *G. lamblia*;[109] however, direct uptake of bile salts by the parasite may be significant and clearly enhances its growth.[110] Development of the in vitro culture techniques and the animal models of *G. muris* in mice offer considerable promise of improved understanding of the pathogenesis of giardiasis, as do recent studies in gerbils, rats, and mice. The recent sequencing of the *G. lamblia* genome and development of gene array technology hold promise in elucidating the yet unclear mechanisms of disease in giardiasis.[111]

DIAGNOSIS

Examination of fresh and concentrated stool specimens

The diagnosis of *G. lamblia* infection can often be made by examining fresh or concentrated fecal specimens in cases of diarrhea that persist beyond the prepatency period of 5–7 days. As summarized in Table 44-1, the prompt examination of a fresh diarrheal stool specimen may reveal the striking motile trophozoites of *G. lamblia* on an unstained direct wet-slide preparation or a specimen that has been trichrome stained for cysts or trophozoites before or after concentration (Fig. 44-2).

The diagnosis of giardiasis is usually made by examining one to three stool specimens after concentration, using such methods as flotation in 33% zinc sulfate (after clarification by centrifugation in water) or formalin–ether sedimentation in approximately 10 mL of 10% formalin suspension with 3 mL

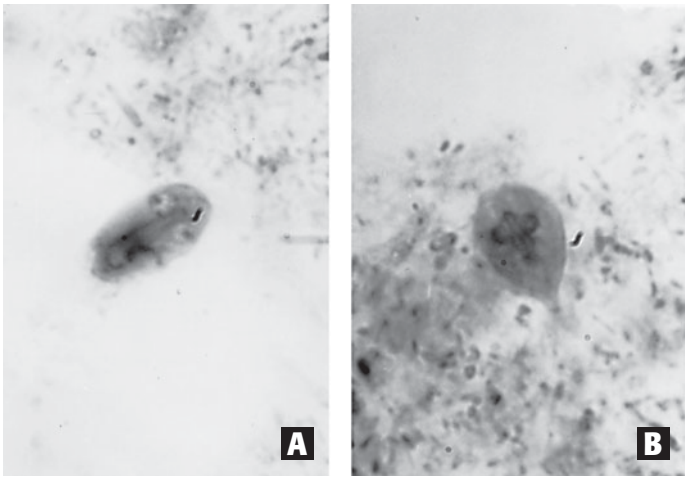

FIGURE 44-2. *Giardia lamblia,* **A.,** cyst and trophozoite, **B.,** from fecal specimens of a patient with active giardiasis. Gomori-Wheatley trichrome stain, oil immersion ×640 magnification. (*Courtesy of G. R. Healy.*)

Table 44-1. Diagnosis of *Giardia lamblia* Infection

Test	Sensitivity	Specificity
Microscopy		
Fresh fecal exam for motile trophozoites	Better with active diarrhea	Specific in experienced hands, but finding trophozoites does not prove disease causation
Stained, concentrated fecal exam		
Duodenal aspirate or string test	Approximately 34–98%	May be more sensitive than stool exam early in illness and in children (83–86%)
Jejunal biopsy/imprint Approaches 100%		
Serologic tests:		
IFA using patient's cysts or trophozoites	89% of symptomatic patients	71–100%
Immunodiffusion (with sonicated cysts)	91%	Approaches 100%
IFA (with cultured trophozoites)	97% $\geq$ 1:16	85–100%
ELISA (with cultured trophozoites)	81%	88%

ether. The concentrate is then stained with 1% potassium iodide saturated with iodine. While some report that three concentrated fecal specimens are adequate to diagnose the vast majority of cases, others have shown that as few as 34% of stool specimens from patients with the parasite in the upper small bowel were positive. Barium, kaolin products, oily laxatives, antibiotics, antacids, paregoric, enemas, and cotton swabs will greatly reduce the value of the microscopic examination.

A monoclonal antibody combination reagent for direct fluorescence detection of *Giardia* cysts and *Cryptosporidium* oocysts has proved useful in fecal microscopy.[112] In addition, fecal antigen ELISAs (enzyme-linked immunosorbent assays) using polyclonal or monoclonal antibodies range in sensitivity and specificity from 87% to 100%.[113] Finally, DNA-based probes for *G. lamblia* are in development, but they are not yet widely useful.[114]

EXAMINATION OF SMALL BOWEL CONTENTS OR TISSUE

From studies in adult volunteers, several observers have reported an improved yield (although this is debated by some researchers) with examining duodenal aspirates or even small bowel biopsies in patients whose fecal examinations are negative for *G. lamblia*.[115] When jejunal biopsy is performed, one should examine a Giemsa-stained sample of the "imprint" of the tissue, as well as the tissue itself, for the purple-stained trophozoites. Effective sampling of small bowel contents can also be accomplished, without intubation or biopsy, using the string test (Entero-Test, Hedeco, Palo Alto, CA). This involves swallowing a gelatin capsule with one end of the 140-cm (or 90-cm for children) nylon line taped to the side of the mouth. Removing the string after 4 to 6 hours and examining the bile-stained mucus has been helpful in demonstrating *G. lamblia* trophozoites, particularly in young children and in adults early in their illness. When jejunal biopsy is performed, one should examine a Giemsa-stained sample of the "imprint" of the tissue as well as the tissue itself for the purple-stained trophozoites.

ANTIBODY AND ANTIGEN ASSAYS

Primarily because of limitations on antigen supply prior to in vitro cultivation of *Giardia*, little was known until recently about serologic responses to *G. lamblia* infections. In 1976, Ridley and Ridley, using an indirect fluorescent antibody (IFA) test and patient isolates of cysts and trophozoites as antigen, found that 32–36 cases (89%) of giardiasis with malabsorption gave positive results, whereas neither of two cases of giardiasis without malabsorption and none of 17 controls was positive. There was a crude correlation of severity of jejunal histopathology with antibody titer.[80] FA titers fell in 11 of 19 cases (58%) 1 month or longer after therapy. Of 34 patients with malabsorption (mostly after travel to tropical areas) but negative stool and biopsy studies for giardia trophozoites, 10 (29%) had significant IFA anti-*G. lamblia* titers, which suggests that available diagnostic tests by direct examination may miss clinically significant giardiasis. These investigators also noted that use of mature cysts gave less reproducible results.

Vinayak et al. used washed, concentrated, sonicated *Giardia* cysts from fecal specimens to develop an immunodiffusion test for giardiasis that was said to be 91% sensitive as

well as negative in all 31 healthy or other-parasite-infected controls.[116] Visvesvara and colleagues have developed an IFA test using axenically cultured G. lamblia trophozoites as antigen.[117] They found antibody titers of 1:16 to 1:1024 among 29 of 30 patients with symptomatic giardiasis and 1:2 to 1:4 in 19 healthy controls. These positive titers could be absorbed with *G. lamblia* trophozoites in vitro. Fifteen patients with other parasitic infections for bacterial overgrowth syndromes had titers of ⩽ 1:16. Smith et al. reported the use of *G. lamblia* trophozoites cultivated in vitro in development of an ELISA that appeared to be specific and sensitive, with 81% of symptomatically infected patients developing antibody titer rises at 2 weeks to 15 months.[118] The sensitivity of an ELISA for detection of giardia antigen in feces has been 92–98% (probably more sensitive than fecal microscopy); the specificity is also high.[119–121] A rapid antigen detection method that distinguishes *G.lambia* from *Cryptosporidium parvum* using nonenzymatic solid-phase qualitative immunochromatographic assay has also recently been developed.[122] This test has a sensitivity and specificity of 93.5% and 95.5%, respectively. In a comparison of three assays—direct immunofluorescence antibody (DFA), enzyme immunoassay, and nonenzymatic immunochromatographic assay, DFA was found to be the most sensitive.[123]

GENETICS, ANTIMICROBIAL SUSCEPTIBILITY, AND THERAPY

Axenic cultivation of *G. lamblia* has enabled studies of the genetics of strain variation[66–68] as well as in vitro sensitivity testing to antiparasitic agents.[124] Because the natural history of giardiasis is usually self-limited but occasionally recurrent over long periods of time, studies of the clinical efficacy of antigiardial therapy are difficult at best. Table 44-2 summarizes the pertinent features of the drugs used to treat giardiasis. Quinacrine (Atabrine) 100 mg three times a day (t.i.d.)

Table 44-2. Agents Used in the Treatment of Giardiasis

Agent	Dosage	Cure Rate %	Side Effects
Acridine derivative			Occasional: toxic psychosis; insomnia;
Quinacrine (Atabrine)	100 mg t.i.d. for 5–7 days	63–100	headache; yellow sclerae, skin and urine; nausea; vomiting. Rare: exfoliative dermatitis. Contraindicated in patients with psoriasis.
	Pediadric: 6–8 mg/kg per day (or 2 mg/kg t.i.d.) for 5–7 days	84–93	
Nitroimidazoles[a]			Nausea, headache, metallic taste; occasional
Metronidazole (Flagyl)	250 mg t.i.d. for 5–10 days	56–70	insomnia, diarrhea, vertigo, paresthesia, rash; rare mild disulfiramlike reaction with alcohol, ataxia, urethral burning, reversible neutropenia. (Single daily dose metronidazole causes more gastrointestinal side effects.)
	750 mg t.i.d. for 3–10 days	95	
	1.6–2.0 g q.d. for 1–5 days	91	
	Pediatric: 15–25 mg/kg per day (or 5 mg/kg t.i.d.) for 5–7 days	61–90	
Thiazolides			Mild and transient abdominal discomfort, diarrhea,
Nitazoxanide	Pediatric, 12–47 months: 100 mg b.i.d. for 3 days	71–94	nausea; very rarely anorexia, enlarged salivary glands, fever, infection, malaise, mild jaundice, azotemia, elevated alanine transferase, pruritus, swearing, rhinitis, dizziness, discolored urine.
	Pediatric, 4–11 years: 200 mg b.i.d. for 3 days		
	Adults: 500 mg b.i.d. for 3 days		
Tinidazole and others (nimorazole, ornidazole)	2 g po for 1 dose	93–97	
	125 mg b.i.d. for 7 days		
Nitrofurantoin			Occasional nausea, vomiting. Headache; rare
Furazolidone (Furoxone)	100 mg t.i.d. for 7 days	72–92	disulfiramlike reaction with alcohol, arthralgia, rash, urticaria, hemolysis, other blood dyscrasias.
	Pediatric: 1.5 mg/kg suspension q.i.d. for 7 days		

[a]Not approved in the United States for giardiasis.

for 7 days, formerly the drug of choice in the United States, results in 80–100% cure rates,[9,41,125] but is no longer readily available. Whether the mechanism of action of quinacrine is related to its relative distribution and then intercalation into DNA or to other membrane effects is currently unclear.

Metronidazole (Flagyl) 250–750 mg t.i.d. for 10 days effects 70–95% cure rates, the cure rate varying with the dose.[41] Single daily doses of metronidazole of 1.6–2.0 g for 2 to 3 days also appear to be effective, but may cause more gastrointestinal side effects. Other nitroimidazole derivatives, including tinidazole, nimorazole, and ornidazole (Ro 7-0207), have also been effective, with possibly fewer side effects when given for 1 to 7 days.[126] The ability of nitroimidazoles to kill giardia protozoa may relate to inhibition of DNA synthesis, competition for reducing equivalents with electron-transport proteins, or other mechanisms that are not understood at present. As metronidazole is not officially approved in the United States for giardiasis and because of concern about its mutagenicity and carcinogenicity in some experimental animals, the potential risks should be weighed before this agent is used.

Nitazoxanide is a new thiazolide antiparasitic that shows in vitro activity against a wide variety of protozoa and helminthes. This has been approved for treatment of giardiasis for children ⩾1 year of age.[127] The recommended dosage for children aged 12–47 months is 100 mg b.i.d. for 3 days, and for children aged 4–11 years, the recommended dosage is 200 mg b.i.d. for 3 days. For adults, the dosage is 500 mg b.i.d. for 3 days. In vitro studies have shown that nitazoxanide inhibits pyruvate-ferredoxin oxidoreductase (PFOR), an enzyme essential to anaerobic energy metabolism.[128] Clinical studies have demonstrated the efficacy of nitazoxanide to be comparable to metronidazole.[129,130]

Furazolidone, which is available in liquid form for pediatric use, has also been suggested for treatment of giardiasis.[125] Tartrazine, which is in certain Latin American preparations of furazolidone, may be related to the serum sickness seen with this drug. Paromomycin has been used in pregnant patients with symptomatic giardiasis.[131]

Recent in vitro cultivation of *G. lamblia* has enabled studies of antigiardial activity of these agents.[124] Although the appropriate methods and standardized criteria remain to be determined, "4-day end point" killing of *Giardia* has been noted with 0.05–0.1 μg/mL quinacrine and with 0.05–6.4 μg/mL metronidazole.[56,72] Immobilization of the parasites by antigiardial agents in vitro has also been suggested.[132] Further definition of the in vitro inhibitory concentrations of these and other agents with axenically grown *Giardia* and amebas has recently become feasible and is under further study.

Epidemiologic control measures are needed, including improved hygienic and sanitary conditions as well as water treatment by means of flocculation, sedimentation, and filtration. In addition, recent developments in in vitro culture technique and animal models are now opening the potential for developing means to control giardiasis. The roles of external and in vivo environments, pH, mucus, specific parasite and intestinal surface receptors, gut motility, and interaction with bacterial or other flora in causing or controlling disease are among the current frontiers in giardiasis research. Despite tantalizing suggestions of a protective role for cellular or humoral immunity, it remains unclear at present whether a vaccine might actually worsen the disease process in giardiasis. The *Giardia* genome project, as well recent advances in molecular techniques are key to understanding the epidemiology and pathogenesis of giardiasis and holds promise in the development of preventive, as well as therapeutic interventions to this disease.

ENTAMOEBA HISTOLYTICA

HISTORY, EPIDEMIOLOGY, AND CLINICAL MANIFESTATIONS

History

For over a century, amebiasis has been recognized as an invasive enteric illness in humans. The clinical syndrome of amebiasis and effective therapy are well known. In recent years, there has been a renewed interest in the pathogenesis of *E. histolytica* infections.

The early history of amebiasis has been reviewed extensively.[133] Although a British surgeon, Timothy Richard Lewis, first described amebas in human stool in 1869, Lõesch is credited with the first description of amebic dysentery, in a patient from St. Petersburg, Russia, in 1875. Lõesch also reproduced colitis in dogs by introducing the patient's stool orally or rectally. Koch first noted amebas in tissue specimens in 1887, and in 1893 Quincke and Roos first described amebic cysts. In 1903, Fritz Schaudinn named the parasite *E. histolytica* from its apparent capacity to destroy tissue. In 1912, Bernard Rogers found that emetine extracts from the ipecac root effectively cured amebic dysentery and liver abscesses. *E. histolytica* was definitively shown to be a human pathogen (as distinguished from the commensal *Entamoeba coli*) in human volunteer studies by Walker and Sellards in the Philippines in 1913.[134]

More than a century after the first description of infection with *E. histolytica*, we now have the complete genomic sequence of the protist parasite, providing new insights into the evolution, virulence, metabolic pathways, and potential targets for chemotherapeutic or preventive interventions.[135]

Epidemiology

Entamoeba spp. infect 10% of the world's population; although the vast majority of those infected are asymptomatic, invasive

amebiasis is the third leading parasitic cause of death worldwide.[136] A distinct nonpathogenic species, *Entamoeba dispar*, has been identified by studies of isoenzyme patterns, genomic DNA, and ribosomal DNA.[137–139] *E. dispar*, morphologically indistinguishable from E. *histolytica*, does not invade the host or elicit a systemic immune response during transient intestinal infection. *E. dispar* infection is usually up to tenfold more prevalent than *E. histolytica* infection,[140] although foci of transmission of *E. histolytica* are often observed. Therefore, all invasive amebiasis syndromes result from *E. histolytica* infection. Although approximately 90% of *E. histolytica* intestinal infections are also asymptomatic, they typically induce a systemic antiamebic immune response.[141,142]

Epidemic outbreaks of amebiasis have been reported with food or water contamination from many areas.[4] However, endemic amebiasis as currently seen in the United States is acquired by the fecal–oral route, usually by person-to-person spread.[143] High-risk groups include mentally challenged institutionalized patients (with stool cyst excretion rates of up to 70%),[144] lower socioeconomic groups, recently immigrated Mexican Americans in the southern United States,[144] travelers to highly endemic areas such as Mexico, Southeast Asia, China, India, the Middle East, Africa, and South America,[17,145] and homosexual men (with cyst excretion rates in San Francisco and New York as high as 20% in the past).[145-148] In Japan, where only a minority of the cases are imported, the most common group affected by amebiasis are male homosexuals or bisexuals and the mentally handicapped in institutions.[149]

Overall, the combined prevalence of *E. histolytica* and *E. dispar* in the United States is approximately 4%,[136] but reported rates in MSM from the 1970s to early 1990s were higher and ranged from 20% to 37%.[16–20,26] Keystone et al. has reported the prevalence rate of infection with *E. histolytica* to be 27% in MSM versus only 1% in heterosexual men.[16] Prior history of STD, multiple sexual partners, and oral–anal sex were shown to be risk factors for amebiasis in some earlier studies.[19,20,24,25] However, the prevalence of *E. histolytica* infection in MSM has declined in the last decade; the decline has accompanied the alteration in sexual practices within this group.[148] A recent study in Taiwan reported a prevalence rate of only 6% in MSM visiting gay bathhouses.[150] Higher rates may be seen in the immunocompromised population as noted in another study in Mexico City where infection was observed to be higher in HIV/AIDS positive patients (5.9% by microscopy and 25.3% by PCR) than in HIV negative patients (2.9% by microscopy and 18.5% by PCR).[151]

Clinical manifestations

Clinical syndromes with *E. histolytica* infection range from asymptomatic cyst excretion to acute rectocolitis, chronic nondysenteric intestinal disease (which can be confused with inflammatory bowel disease), typhloappendicitis, ameboma, or toxic megacolon. Extraintestinal amebiasis usually results from hepatic abscesses and may extend to pleuropulmonary disease, pericarditis, or peritonitis. Unusual extraintestinal manifestations include venereal genital lesions, cutaneous lesions, and brain abscess.

Sexual transmission of *E. histolytica* results in enteric infection with possible dissemination or in venereal infection in males and females. Although many infections are asymptomatic or do not correlate with clinical symptoms,[16–19] sexually transmitted amebic colitis may occur primarily in MSM between 20 and 40 years of age, with anilingus being a significant risk factor for acquisition of *G. lamblia and E. histolytica* infections. Some infections may present with anorectal exudates or proctitis.[152] Penile and cervical amebiasis in conjugal partners is rare but reported.[153] In a review of literature performed by Antony and Lopez-Po, 148 cases of genital amebiasis confirmed by direct smear, cervical cytology, or tissue biopsy were identified between 1924 and 1997.[154] Vaginal discharge, usually bloody and foul smelling, was seen in all of the women ($n = 126$). In addition, infected women also presented with abdominal pain (37%), genital ulcers (8.1%), weight loss (2.8%), cervical squamous cell cancer (5.5%), and labial squamous cell cancer (0.79%). Most men (86%) presented with penile ulcers (86%) and urethritis (14%). Risk factors identified in the review included homosexual and heterosexual contact with infected partners and concomitant intestinal (also rectosigmoid) infection, poor genital hygiene, and vulvovaginitis. Very rare cases of uterine,[155] tubal,[156] testicular,[157] seminal vesicle,[157] and prostatic[158] involvements were also reported elsewhere.

STRUCTURE OF THE ORGANISM

E. histolytica and *E. dispar* trophozoites range in size from 10 to 60 μm, with an average size of 25 μm. Trophozoites contain a single 3–5-μm nucleus with fine peripheral chromatin and a central nucleolus (Fig. 44-3). The cytoplasm consists of a clear ectoplasm and a granular endoplasm that contains numerous vacuoles (Fig. 44-4). Cysts of *E. histolytica* average 12 μm in diameter (range 5–20 μm), and depending on their maturity contain one to four nuclei that have the same morphology as trophozoite nuclei. Like other members of the order Amoebida, young *E. histolytica* cysts contain chromatoid bodies with smooth, rounded edges. Immature cysts may contain clumps of glycogen which stain with iodine.

Other members of the Entamoebidae family found in humans include *Entamoeba polecki, E. coli, E. gingivalis, Endolimax nana, Iodamoeba butschlii*, and *Dientamoeba fragilis. E. hartmanni* is recognized as a distinct species,[159] differing from *E. histolytica* in being smaller, having distinct antigenic differences, and being noninvasive.[159] Most experts agree that another nonpathogenic species of *Entamoeba* is the Laredo-like strain, which grows in culture at lower temperatures (25°–30°C) and does not cause clinical disease.[160]

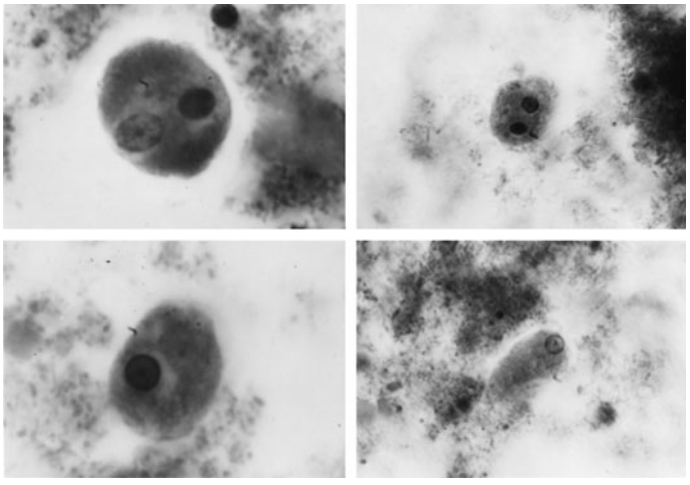

FIGURE 44-3. *Entamoeba histolytica* trophozoites from fecal specimens of a patient with amebic colitis. Gomori-Wheatley trichrome stain, oil immersion. (Right panel) ×320 magnification. (Left panel) ×640 magnification. Note single nuclei with central, punctate karyosome, with delicate peripheral nuclear chromatin. The top two trophozoites also have an ingested red blood cell. (*Courtesy of G. R. Healy*.)

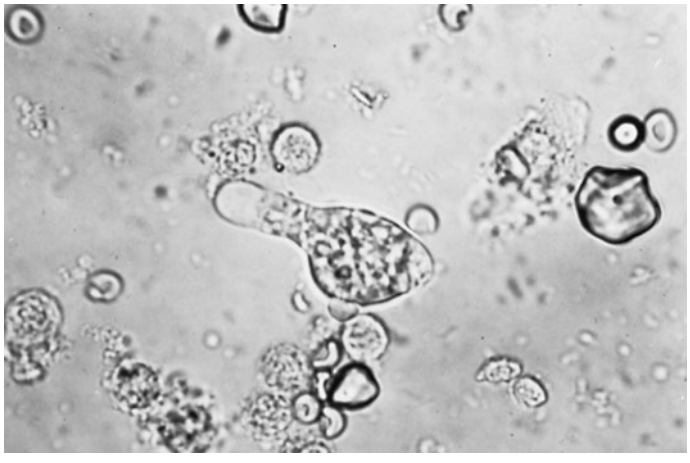

FIGURE 44-4. *Entamoeba histolytica* trophozoites from a saline suspension of a vaginal specimen from a patient whose partner also had amebic colitis. A single typically motile trophozoite is seen.

Extensive electron-microscopic studies of *E. histolytica* reveal no mitochondria; ribonucleoprotein exists in helical arrays in the cytoplasm.[1612–163] Endoplasmic and ectoplasmic vesicles are bound by a 120-Å double-layered membrane, much like the outer limiting membrane.[162]

Amebas also contain a uroid area where vesicles are noted external to the cell membrane.[164] An external fuzzy glycocalyx measures 20–30 nm on bacteria-associated trophozoites from tissue and 5 nm on axenic amebas.[165] Actin and structures resembling microfilaments have been identified in amebic trophozoites,[166,167] and the actin gene has been cloned.[168] Microtubules have not been demonstrated. Apparent functions for microfilaments, but not for microtubules, have been described in studies of the cytopathogenic capacity of *E. histolytica*.[169–171]

The surface membrane of *E. histolytica* has been well characterized biochemically. Amebas are agglutinated by the lectin concanavalin A,[172] which may be a marker for degree of pathogenicity of different strains.[172,173] Using concanavalin A binding to stiffen the external surface membrane, Aley et al. isolated relatively pure membrane preparations of *E. histolytica*.[174] Petri et al. have isolated the galactose-inhibitable adherence lectin of *E. histolytica*.[175] Microfilament-dependent capping, or aggregation of receptors, for concanavalin A or fluorescent-tagged antiameba antibody has been shown on *E. histolytica*, and the capped membrane material has been characterized biochemically, but the capping capacity does not appear to correlate with virulence.[176,177] However, capping may help amebas avoid attack by host defenses.

GROWTH, PHYSIOLOGY, AND CULTURE

Life cycle

The life cycle of *E. histolytica* has been well characterized.[178,179] Cysts are the infective form of *E. histolytica* because they can survive outside the host for weeks to months in a moist environment. Infected individuals excrete up to 45 million cysts per day.[178] Ingestion of cysts from fecally contaminated sources is followed by excystation in either the small or the large bowel. The nuclei then divide to form eight nuclei (transient metacystic stage), cytoplasmic division occurs, and eight amebic trophozoites emerge.[134] The trophozoite population then resides in the large bowel, where tissue invasion may occur. *E. histolytica* cyst walls contain chitin, an oligosaccharide of *N*-acetyl-D-glucosamine, sialic acid, and other cyst-specific antigens.[180,181] Encystation is an active process: anaerobic glycolytic respiration and DNA synthesis occur.[172] The conditions that induce encystation, excystation, and tissue invasion by amebas remain unclear and are the subject of current investigation.

Culture

Axenic cultivation of *E. histolytica* in medium without other organisms was first reported in 1961 by Diamond.[182] This was accomplished by microisolation of amebic cysts, which were then introduced into a monophasic medium seeded with crithidial trypanosomes. A liquid medium was reported in 1968, and the current medium in use (TYI-S-33: trypticase, yeast extract, iron, serum) was developed in 1978.[183] These culture techniques have made it possible to grow amebas in large numbers and to maintain cultures for prolonged periods. Clonal growth of *E. histolytica* in semisolid medium allows quantitative cultures for drug susceptibility testing and other laboratory studies.[184] Studies of axenic culture in vitro have clarified nutritional and other requirements for amebic growth. These include requirements for cysteine, riboflavin (B_2), vitamin B_{12}, iron, serum, optimal

pH, and low oxygen tension.[183] Recently, Clark has succeeded in establishing *E. dispar* in axenic culture.[185]

IMMUNOLOGY AND PATHOGENESIS

Immunology and host response

There is no evidence that intestinal colonization by *E. histolytica* elicits a protective host-immune response.[186] However, extensive but anecdotal evidence indicates that cure of amebic colitis or liver abscess is followed by resistance to subsequent invasive amebiasis.[187,188] The mechanisms of immune defense against *E. histolytica* infection have not been fully characterized. Serum from both healthy controls and infected patients (with high antibody titers to *E. histolytica*) are amebicidal to trophozoites through activation of the alternate complement pathway.[189,190] However, trophozoites that cause invasive disease are resistant to complement-mediated lysis. Complement-resistant amebas can be selected in vitro by culture in normal human serum.[191,192] Serum antibodies and coproantibodies have been demonstrated to increase during invasive disease.[191,192]

A protective role for humoral immunity is suggested by the presence of antibody to the parasite's galactose-inhibitable adherence lectin.[193] Human immune sera can prevent amebic in vitro adherence,[193,194] despite the parasite's ability to aggregate and shed attached antibodies. The other *E. histolytica* antigens most frequently recognized by human immune sera have also been characterized,[195] which may be useful for development of diagnostic tests and vaccines. Lectin recombinant antigens (such as a 52-kDa fusion protein including the cysteine-rich LC3 section of the 170-kDa subunit),[196] as well as the entire 29-kDa surface antigen,[197] have recently been shown to conserve antigenicity.

Mucosal IgA immune responses have been studied in subjects cured of amebic liver abscess and colitis or with asymptomatic *E. histolytica* intestinal infections. Salivary sIgA to purified native galactose-inhibitable lectin has been found in subjects with amebic liver abscess[198] and colitis.[199] Fecal and salivary anti-LC3 sIgA responses occur in amebic colitis[200] and liver abscess; such patterns are absent or diminished in subjects with *E. dispar* infection.[200] In a study of Bangladeshi children, fecal antilectin IgA has been associated with protection from intestinal reinfection.[201] Oral immunization of mice with the recombinant LC3 fusion protein and cholera holotoxin induced intestinal anti-LC3 IgA antibodies that inhibited amebic adherence in vitro.[202] Combined intranasal and intraperitoneal application of purified native Gal/GalNac lectin in the C3H mouse model of amebic colitis elicited fecal antilectin IgA response and protected against invasive intestinal disease.[203]

Cell-mediated immune (CMI) defense mechanisms appear to have a role in limiting invasive disease and possibly in resistance to recurrent invasion following pharmacologic cure.[186] Following invasive amebiasis, the CMI response consists of antigen-specific lymphocyte blastogenesis, with production of lymphokines (including gamma interferon) that activate monocyte-derived macrophages to kill *E. histolytica* trophozoites in vitro.[204–206] In addition, cured patients develop effective antigen-specific cytotoxic T-lymphocyte activity for *E. histolytica* trophozoites.[205] Purified native 260-kDa galactose-inhibitable lectin induced lymphocyte proliferation, gamma interferon production, and amebicidal activity in cultivated peripheral-blood mononuclear cells from subjects with serum antilectin IgG antibodies (indicating prior *E. histolytica* infection).[207] In addition, immunization of gerbils with native 260-kDa lectin induces a protective amebicidal cellular immune response.[208] However, in acute disease, CMI to *E. histolytica* is specifically depressed by a serum factor.[209] The high prevalence of *E. histolytica* intestinal infection in homosexual men with AIDS or certain other clinical manifestations of HIV infection without an increased incidence of invasive amebiasis[148] suggests that host resistance to the initial amebic invasion of the colonic mucosa does not involve CMI mechanisms.

Nonimmune host defenses may be most important in prevention of parasite attachment to and disruption of the colonic mucosa. In animal models, mucus trapping of *E. histolytica* trophozoites occurs,[210] and depletion of the colonic mucus blanket is always seen before parasite invasion.[211] *E. histolytica* elaborates a potent mucin secretagogue[212] that may contribute to depletion of the mucus layer. A family of thiol (cycteine) proteinases (EhCPs) apparently disrupt the polymerization of MUC2, the major component of human colonic mucus.[213] Chadee and coworkers demonstrated that purified rat and human colonic mucins, which are rich in galactose residues, are high-affinity receptors for the ameba's lectin, while mucin inhibits amebic adherence to and lysis of colonic epithelial cells in vitro.[214] Therefore, colonic mucin glycoproteins act as an important host defense by binding to the *E. histolytica* adherence lectin; however, this interaction may facilitate intestinal colonization by amebas and thus promote parasitism by *E. histolytica*.

PATHOLOGY

The pathology of human amebiasis provides clues to its pathogenesis. *E. histolytica* appears to exert a tissue lytic effect, for which the organism is named, whether in colon, liver, lung, or brain; this lytic effect leaves an amorphous, granular, eosinophilic material surrounding trophozoites in tissue[215] and can be studied in vitro. Consistent with the trophozoites' capacity to destroy leukocytes, inflammatory cells are found only at the periphery of amebic lesions and not adjacent to the trophozoites.[171,173,215,216]

The typical flask-shaped colonic ulcers are usually superficial, reaching only the muscularis mucosa level and separated by normal mucosa. Amebic trophozoites are seen in clusters in the periphery of necrotic areas. Light- and electron-microscopic studies have been alternatively interpreted as showing contact lysis of mucosal cells or diffuse mucosal damage prior to amebic invasion.[164,217] Current in vitro studies favor direct invasion and contact-dependent cytolysis by amebic trophozoites.

Liver pathology consists of the necrotic abscess and periportal fibrosis; however, the so-called abscess contains acellular, proteinaceous debris rather than white cells and is surrounded by a rim of amebic trophozoites.[215] Triangular areas of hepatic necrosis have been observed, possibly due to ischemia from amebic obstruction of portal vessels.[215] Periportal fibrosis alone, without trophozoites present, has been reported in patients with amebic colitis.[218] Whether this reflects past trophozoite invasion or host reaction to amebic antigens or toxins is currently unclear. "Amebic hepatitis" is a debated entity; liver function abnormalities commonly present with amebiasis are associated with periportal inflammation without demonstrable trophozoites.

PATHOGENESIS

The pathogenesis of invasive amebiasis can be divided into four steps: (1) colonization of the intestine with a virulent *E. histolytica* trophozoite, (2) disruption of mucosal barriers with adherence to colonic epithelial cells, (3) lysis of adherent epithelial cells and host inflammatory cells, and (4) resistance to host humoral and cellular defense mechanisms with deep tissue invasion. Recent in vitro studies have markedly increased our understanding of the biochemical and molecular mechanisms of the pathogenesis of invasive amebiasis.

VIRULENCE

Current evidence indicates that there exist distinct pathogenic and nonpathogenic strains of *Entamoeba*. Sargeaunt and coworkers (reviewed in Ref. 200) demonstrated that starch gel electrophoresis of *E. histolytica* clinical isolates reveals patterns for the enzymes hexokinase, phosphoglucomutase, and glucosephosphate isomerase, which are characteristic for invasive or noninvasive amebic infection at the time the sample was collected. The isoenzyme patterns are referred to as zymodemes. Sargeaunt[219] and others[220] proposed in 1986 that zymodeme studies reflect stable strain differences and that there was no need to treat individuals infected with *E. histolytica* expressing a "nonpathogenic" zymodeme.

Many *Entamoeba* strains producing nonpathogenic zymodemes are now thought to be *E. dispar*. Epidemiologic studies of thousands of subjects confirm that *E. dispar* is not invasive, nor does it elicit a serum antibody response.[141,142] Tannich and coworkers were the first to demonstrate differences in genomic DNA between *E. histolytica* and *E. dispar*.[221] Recent studies by Clark and Diamond further characterized *E. dispar*.[139] Earlier studies indicating conversion of *E. dispar* to *E. histolytic*a appear to be due to incomplete cloning of cultivated isolates.

In vivo experiments have drawn attention to the association of *E. histolytica* with bacteria (reviewed in Ref. 222). Associated bacteria facilitated early culture of *E. histolytica* in vitro, and Phillips et al. showed that bacteria were required for the establishment of invasive disease in germ-free guinea pigs infected with amebas grown with *Trypanosome cruzii*.[223] They interpreted the role of bacteria to be one of providing an environment which enables amebas to grow in the colon.[224] Wittner and Rosenbaum subsequently demonstrated that amebas required direct association with viable bacteria for virulence and that a soluble virulence factor could not be demonstrated.[225]

Recent axenic culture methods have allowed strains of amebas to retain virulence after prolonged periods (up to 9 years) of in vitro culture.[226] However, in vitro destruction of tissue-culture cells by axenic trophozoites is stimulated by parasite ingestion of viable bacteria.[227] Apparently these associated bacteria either accelerate the ameba's electron-transport system or increase its reducing capacity.[227] Viral particles have also been demonstrated in axenic amebas and can result in lysis of the amebas.[228] However, viral passage from amebic strains of higher virulence to less virulent strains does not consistently alter amebic virulence.[229]

Host nutritional factors appear to relate to the invasiveness of amebic infections. Weanling rats given protein-deficient diets are more susceptible to amebic infection; those already infected can eliminate the parasite when subsequently given high-protein diets.[229] High-carbohydrate, low-protein diets resulted in higher colonization but reduced tissue invasion compared with rats on a normal diet.[230] Faust and Read have noted an association of a poor nutritional state with more invasive amebic disease in humans.[231] Wanke and Butler reported a very high mortality for amebic colitis in malnourished patients in Bangladesh.[232] Although feeding of iron to experimental animals appears to increase the severity of experimental amebiasis, studies in humans do not reveal any correlation of invasive amebiasis with either serum iron or saturation of iron-binding proteins.[233] Finally, several investigators have noted an interesting association of ameba virulence with exposure of the parasite to cholesterol or with liver passage.[234,235] The increased virulence apparently persists for weeks after cholesterol exposure and is therefore not a temporary membrane or nutritional effect; it remains to be further elucidated.

ADHERENCE MECHANISMS

E. histolytica trophozoites maintained in axenic culture must establish adherence in order to lyse target cells.[169,170] Ravdin and coworkers have demonstrated that in vitro adherence of

E. histolytica trophozoites to Chinese hamster ovary (CHO) cells and human colonic mucins is exclusively mediated by the parasite's inhibitable surface lectin.[170,214,236] The galactose lectin also participates in amebic in vitro adherence to human leukocytes,[189,236] rat and human colonic mucosa and submucosa,[194] human erythrocytes,[170,237] Chang liver cells,[238] opsonized bacteria or bacteria with galactose-containing LPS,[239] and rat colonic epithelial cells.[214]

Ravdin and coworkers[240] produced monoclonal antibodies which inhibited amebic adherence to CHO cells. Using the lectin's carbohydrate-binding activity and lectin-specific monoclonal antibodies, Petri and coworkers isolated the *E. histolytica* adherence lectin.[241] Using ^{35}S-methionine, they metabolically labeled amebic proteins from a culture filtrate or detergent-solubilized amebas, which were then applied to an ASO affinity column. After washing, a peak of ^{35}S-methionine activity was eluted with galactose; with autoradiography, SDS-PAGE under reducing conditions demonstrated a 170-kDa metabolically labeled amebic protein (Fig. 44-5).

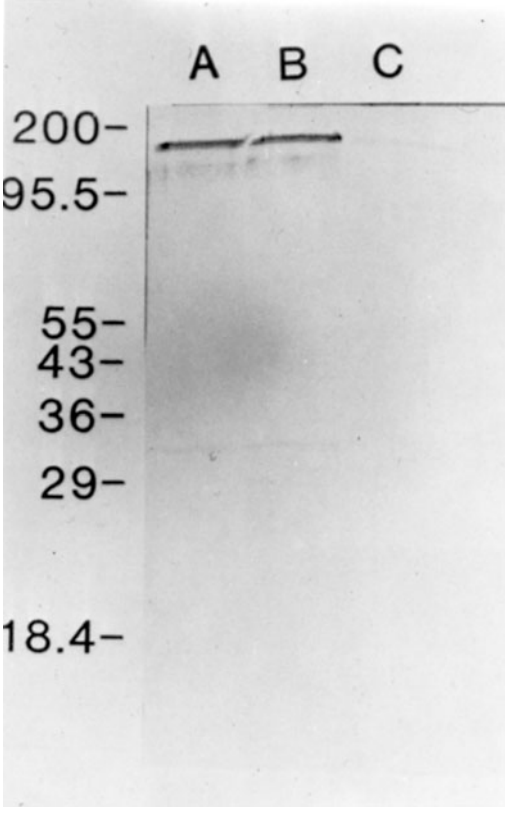

FIGURE 44-5. Galactose inhibition of binding of the amebic adherence lectin to the asialoorosomucoid (ASOR) affinity column. Autoradiograph of SDS-PAGE of [^{35}S]methionine-labeled proteins eluted with galactose from an ASOR column to which conditioned medium, **A.;** conditioned medium plus 0.5 M dextrose, **B.;** or conditioned medium plus 0.5 M galactose, **C.;** has been applied. The columns were extensively washed in 50 mM Tris, 200 mM NaCl, 10 mM $CaCl_2$, pH 7.35, and then eluted with 0.5 M galactose in the above buffer. Galactose-eluted fractions were electrophoresed on 10% polyacrylamide gels and analyzed by autoradiography. (Adapted from Petri WA, et al. Isolation of the galactose-binding lectin which mediates the in vitro adherence of *Entamoeba histolytica.* J Clin Invest 1987; 80: 1238.)

Petri et al. confirmed that the purified amebic protein is the galactose-inhibitable lectin in three ways: (1) application of [^{35}S]-methionine metabolically labeled amebic proteins to an adherence-inhibitory H8-5 antibody Affigel-10 column resulted in elution of the same protein; (2) on immunoblotting, the most adherence-inhibitory monoclonal antibody, F-14,[211] exclusively recognized the 170-kDa protein purified by ASO affinity chromatography; and (3) the lectin purified by H8-5 immunoaffinity chromatography bound to CHO cells in a galactose-specific manner and competitively inhibited adherence of viable amebas.

Subsequent studies determined that the galactose-inhibitable lectin consists of two subunits with masses of 170 and 35 kDa.[242] The lectin has a mass of 260 kDa under nonreducing conditions. The 170-kDa subunit is highly antigenic and immunogenic. It contains the galactose-binding activity, as determined by recognition with adherence-inhibitory monoclonal antibodies and by the in vitro galactose-specific binding of an in vitro expressed PCR product based on 170-kDa subunit DNA.[243] The amebic genes encoding the 170-kDa subunit have been identified and sequenced,[244,245] as has the gene encoding the 35-kDa subunit.[246] The 35-kDa subunit is not antigenic and apparently exhibits fibronectin-binding activity.[246] The 170-kDa subunit of the *E. histolytica* adherence lectin is the most prominent antigen immunoprecipitated by a pool of human immune sera (Fig. 44-6); immune sera from such diverse geographic regions as Mexico, India, the United States, South Africa, and Zaire all recognize this adherence protein on immunoblotting.[175,247,248]

A chitotriose-inhibitable lectin in *E. histolytica* homogenate which agglutinated erythrocytes was described by Kobiler and Mirelman.[249] In a high-ionic-strength buffer, amebic adherence to Henle cells was inhibitable by 40% with chitin.[250] The chitotriose-inhibitable lectin may have a role in encystation.[181] Arroyo and Orozco[251] produced monoclonal antibodies which inhibit parasite adherence and ingestion of fixed human erythrocytes by up to 60% and on immunoblotting recognized a 112-kDa *E. histolytica* surface protein. Carbohydrate specificity of this putative amebic adhesin is not described; apparently more than one amebic adhesin mediates adherence to erythrocytes.[177]

Cytolytic mechanisms

The pathology of invasive human amebiasis has a characteristic appearance: amebas are surrounded by amorphous granular debris, presumably due to tissue lysis.[215] Axenic *E. histolytica* trophozoites kill target cells only upon direct contact rather than via secreted cytotoxins.[169,170] Lectin-mediated adherence is required for lysis of target CHO cells, Chang liver cells, rat colonic epithelial cells, and human PMN or mononuclear cells.[170,233,236–238] Purified lectin is a cytotoxin which induces rapid reversible increases in target-cell $[Ca^{++}]_i$.[252] Amebic cytolytic activity is dependent on parasite

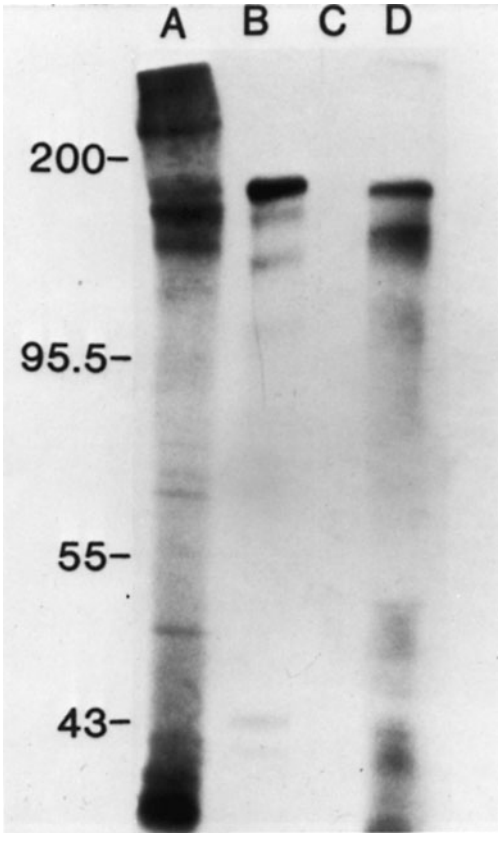

FIGURE 44-6. Immunoprecipitation of [^{35}S]methionine metabolically labeled amebic protein with H8-5 and pooled human immune sera (PHIS). Autoradiograph of SDS-PAGE (10% acrylamide separating gel) of [^{35}S]methionine-labeled amebic proteins, **A.;** immunoprecipitated with monoclonal antibody H8-5, **B.;** normal human serum, **C.;** or PHIS, **D.;** A 170-kDa metabolically labeled amebic protein was immunoprecipitated by lectin-specific H8-5 and PHIS and is the most intensively labeled antigen recognized by PHIS. (Adapted from Petri WA, et al. Recognition of the galactose- or *N*-acetylgalactosamine-binding lectin of *Entamoeba histolytica* by human immune sera. *Infect Immun* 1987; 55: 2327.)

microfilament function,[169,170] $[Ca^{++}]_i$,[252,253] Ca^{++}-dependent parasite phospholipase A (PLA) activity,[253,254] and maintenance of an acid pH in amebic endocytic vesicles.[255] Establishment of adherence by *E. histolytica* trophozoites is followed by a marked sustained elevation of target-cell $[Ca^{++}]_i$, , which contributes to but may not be totally sufficient for target-cell death.[252] Phorbol esters specifically augment amebic cytolytic activity.[256]

An ionophorelike *E. histolytica* protein induces lipid bilayers or vesicles of target cells to leak Na^+, K^+, and to a lesser extent Ca^{++}.[257–261] This protein, packaged in dense intracellular aggregates, can depolarize erythrocyte membranes.[259,260] The amebic ionophore apparently acts as a defense mechanism against ingested bacteria. It has homology to the pore-forming proteins granulysin and NK-lysin produced by cytotoxic T cells and natural killer cells.[262] The gene encoding the ionophore has been sequenced.[261] The *E. histolytica* genome reveals 3 genes encoding for amebapores and additional 16 genes encoding for structurally similar proteins, all belonging to the family of saposin-like proteins.[263]

E. histolytica contains numerous proteolytic enzymes, including a cathepsin B protease,[264] an acidic protease,[265] a collagenase,[266] and a major neutral protease.[267] Proteases appear to be involved in dissolution of the extracellular matrix-anchoring cells and tissue structure.[267] Twenty genes for cysteine proteinases have been identified and expression of these genes had been correlated with pathogenicity.[268,269] Recent data involve cycteine proteases also in proteolysis of enterocyte villin causing effacement of microvilli.[270] Furthermore, they have also been shown to cleave and activate preinterleukin-1B possibly contributing to inflammation during the early colonic invasion.[271] *E. histolytica* enterotoxigenic activity[272,273] may induce a secretory diarrheal component.

In vivo models of amebic liver abscess[274,275] and in vitro studies[238] demonstrate that parasite adherence to and lysis of host polymorphonuclear leukocytes enhances tissue destruction by release of toxic neutrophil oxidative products. A further understanding of the biochemical and molecular basis for the pathogenicity of *E. histolytica* should aid in the development of a vaccine or pharmacologic strategies to combat this disease.

DIAGNOSIS

Stool and proctoscopic examination

The key to laboratory diagnosis of colonic amebiasis is the stool examination. Three stool specimens or one purged specimen should be examined for maximum yield prior to use of barium, antacids, enemas, or antimicrobial or antiparasitic agents, which will interfere with the microscopic examination.[276,277] If fecal specimens cannot be examined immediately, they should be refrigerated or fixed. Trophozoites in stool will rapidly lyse at room temperature or at 37°C. A saline wet-mount should first be examined to establish the presence of amebic trophozoites or cysts. Differentiation of *Entamoeba* spp. requires permanent stains (trichrome or iron-hematoxylin) following fixation in 10% formalin or polyvinyl alcohol to reveal characteristic nuclear morphology, as described above (see Figs. 44-3 and 44-4). The most common error in diagnosis is mistaking fecal leukocytes or macrophages for amebic trophozoites.[137] Of note, fecal leukocytes are usually pyknotic or absent in patients with amebic colitis, in contrast to patients with bacterial dysentery, possibly because of the direct toxic effect of amebas on leukocytes.[171,173,215]

The stool examination is positive in approximately 90% of patients with invasive amebic colitis;[278] however, if the stool examination is negative in a suspected case of amebic colitis, proctoscopy or colonoscopy is indicated.[279,280] The margin of a colonic ulcer should be scraped (not swabbed, as amebic trophozoites may adhere to cotton swabs) and appropriate stains made of the scraping material, which often shows the

parasite. If tissue is obtained, a careful search for invading trophozoites should be made on routine hematoxylin and eosin (H&E)- and periodic acid–Schiff (PAS)-stained material.

Genital specimens

Genital amebiasis may be diagnosed by direct smear (or Papaniculaaou smear) of vaginal, cervical, or urethral discharge.[154] Ulcerative lesions require biopsy to demonstrate invading trophozoite, in addition to inflammatory infiltrate and necrotic debris.[281]

In vitro cultivation

E. histolytica can be cultured from clinical specimens. Numerous culture media have been used, including liver extract (Cleveland and Collier), egg-infusion medium (Balamuth), and alcohol-egg extract of Nelson.[282] However, none is selective for *E. histolytica*. Both cysts and trophozoites can be cultured, a technique which can help differentiate *E. histolytica* from *E. coli, E. hartmanni*, and the Laredo strain of *E. histolytica*. Cleveland and Collier's medium can be made more selective by adding rice powder and antibiotics (penicillin and streptomycin).[160] Failure of the culture to grow at low temperatures excludes the Laredo-like strain, which grows well at 23°C.[160] These methods can be used to document amebiasis in patients. Zymodeme determination using starch gel electrophoresis of in vitro cultivates can be used to differentiate *E. dispar* from *E. histolytica*. However, this is a laborious technique that is available only in research laboratories.

Antibody and antigen assays

Numerous techniques have been developed for study of the serologic response to *E. histolytica* infection (Table 44-3). All methods are highly specific; patients without exposure to *E. histolytica* are rarely positive. These tests are usually quite sensitive for detection of patients with amebic liver abscess or invasive colitis; *E. dispar* infection does not elicit a serum antiamebic antibody response, whereas asymptomatic *E. histolytica* infections do. Therefore, a negative serology is quite helpful in ruling out *E. histolytica* infection in an endemic area.[141,142] The indirect hemagglutination test (IHA) is the most widely used method at present in the United States.[191,283,284] The IHA uses antigen prepared from axenic cultures of *E. histolytica* (usually strain HK9). Serum is heat inactivated and added in serial dilutions to sheep or human red blood cells sensitized with amebic antigens; hemagglutination is evaluated in comparison with known positive and negative controls.[285] IHA titers are usually elevated at the time of initial presentation with invasive amebiasis, often to titers of ≥1:1024,[283] and then fall to lower levels 2–11 years after therapy.[191,283,284]

When repeated exposure or persistent infection renders the IHA less useful,[284] the gel diffusion precipitin test, which remains positive for shorter periods following acute illness (6 months), may be helpful.[284] Serologic testing for amebiasis should be considered and may be quite helpful in differentiating inflammatory bowel disease from amebic colitis. Fewer than 2% of patients with inflammatory bowel disease and negative stool examinations for amebas have positive IHA titers.[283–285] Because of the widespread occurrence of amebiasis, patients in whom the diagnosis of inflammatory bowel disease is considered should have sera tested and stools examined for amebic infection, especially before steroid therapy is considered.

Other techniques used for detection of serum antibodies to *E. histolytica* include counterimmunoelectrophoresis, amoebic gel diffusion test, complement fixation, indirect fluorescence assay, latex agglutination, and ELISA.[286]

Antigen-based ELISA are now commercially available for detection of infection in fecal specimens. These kits use monoclonal antibodies against the Gal/GalNAc-specific lectin of *E. histolytica* (*E. histolytica* test II; Techlab,

Table 44-3. Systems in Use to Evaluate Serologic Response to Infection with *E. histolytica*

Serologic test	Percent positive in Controls	Cyst Passes	Rectocolitis	Liver Abscess
Indirect hemagglutination	0–7	8–15	81–98	83–100
Indirect immunofluorescence			57	57
Countercurrent immunoelectrophoresis		0–1.7	87	95–100
Agar gel diffusion	0–18	1–52	55–95	80–100
Enzyme-linked immunosorbent assay (ELISA)			50	100
Complement fixation	0–16	28	85–90	83–100
Cellulose acetate membrane precipitation		0	100	
Immunoelectrophoresis		87	93	
Latex agglutination	0	75	100	
Thin layer immunoassay				79

Blacksburg, VA) or monoclonal antibodies against the serine-rich antigen of *E. histolytica* (Optimum S kit; Merlin Diagnostika, Bornheim-Hersel, Germany). These antigen assays may have good correlation with PCR from stool specimens for detecting infection.[287]

Nucleic acid amplification techniques are currently for research purposes only, but may become the technique of choice in the future.

TREATMENT

At present, drug susceptibility of *E. histolytica* is based on clinical activity and nonquantitative observations. Quantitative, clonal growth of *E. histolytica* provides a method for drug evaluation that can be standardized for static and amebicidal activities.[288,289] Appropriate drug therapy of amebiasis must take into account drug distribution (absorption, penetration, excretion in the intestinal tract) and sites of amebicidal activity. For example, antibiotics are usually active only in colonic and not in hepatic disease. Drugs that are active in all tissues include metronidazole, tinidazole, dehydroemetine, and emetine hydrochloride.[278,290–292] Agents which may help eradicate gut luminal infection include diloxanide furoate, paromomycin, bismuth iodide, and diiodohydroxyquin.[279,292,293] Tetracycline and erythromycin have some activity in colonic disease and chloroquine may be active in hepatic disease.[278] Recommended drug regimens, including dosages and possible adverse reactions, are outlined in Table 44-4. Nitazoxanide is a new thiazolide agent with in vitro activity against a wide variety of protozoal and helminthic pathogens including *E. histolytica*. Its clinical efficacy for amebiasis, though, is yet to be proven.

Standard medical regimen should be sufficient for genital amebiasis. However, surgical intervention may be necessary in neglected and progressive lesions.[294,295]

PREVENTION AND BIOLOGICAL CONTROL

At present, prevention of amebiasis rests on interference with fecal–oral transmission by improved hygiene, sanitation, and water treatment; by abstaining from oral–anal–genital contact; and by proper isolation of index cases.[296] Numerous tantalizing but unexplored possibilities for biological control also exist. One approach would be to prevent commensal carriage in the human host; another, disregarding carriage, would be aimed at altering the parasite or host to avoid tissue invasion. Systemic and especially local intestinal immunity for alterations in microbial flora might well alter the parasite's carriage and shedding or its invasiveness. A number of ameba proteins had been identified to be potential vaccine candidates. The most promising among these proteins are the 25-kDa serine-rich *E. histolytica* protein called SREHP and the 260-kDa galactose and *N*-acetylgalactosamine-inhibitable ameba lectin,[297] showing encouraging results in animal models of intestinal amebiasis.

Certainly giardiasis and amebiasis rank among the widespread, often devastating human diseases for which the current renaissance of immunobiologic research holds great promise of many exciting developments. The groundwork that has been laid has already resulted in improved understanding of the biology of the giardia protozoa and amebas through in vitro culture and animal models. We now stand at the threshold of greatly improved understanding of the pathogenesis and, hopefully, eventual control of these two protozoan enteric parasitic infections.

CRYPTOSPORIDIUM

INTRODUCTION AND HISTORY

Organisms of the genus of *Cryptosporidium* are small (2–6 μm) coccidian protozoans that may inhabit the gastrointestinal, respiratory, and biliary tracts of a variety of animals including humans. In 1907, Tyzzer first described this parasite as a cause of asymptomatic infection in the gastric glands of the common laboratory mouse.[298] In 1955, Slavin reported the first case of symptomatic diarrheal disease in poultry due to *Cryptosporidium*.[299] The parasite was subsequently demonstrated to be a pathogen of many animals and to cause epidemics of diarrheal disease. However, the first instance of symptomatic human disease was recorded in 1976 in a young immunocompetent child.[300]

Human infection with *Cryptosporidium* was considered rare prior to 1982, the result of opportunistic infection with a pathogen outside its normal host range. With the recognition of AIDS in the early 1980s, an increasing number of cases of severe cryptosporidiosis were reported.[301] *Cryptosporidium* has been identified to be the most common pathogen associated with chronic diarrhea and AIDS among MSM, accounting to 16% of 49 cases in one U.S. study.[302] In another European study of AIDS patients with chronic diarrhea, the overall prevalence of intestinal cryptosporidiosis was 15.6% (43 of 275); the prevalence was noted to be significantly higher in MSM (33.3%) than in intravenous drug users (10.6%).[303] In 1983, an outbreak of symptomatic cryptosporidiosis among animal handlers stimulated clinical interest leading to the recognition of this parasite as an important diarrheal pathogen in the immunocompetent host.[304] Numerous waterborne and swimming pool outbreaks have since occurred, culminating in 1993 in the largest waterborne outbreak in US history, involving over 400,000 people in Milwaukee. These outbreaks, along with studies in developing areas, have placed cryptosporidiosis among the leading causes of diarrhea worldwide.[305–309]

PATHOGENESIS

Historically, *Cryptosporidium* was assumed to be host specific, similar to another coccidian parasite, *Eimeria*. Although the exact number of distinct species of *Cryptosporidium* is

Table 44-4. Treatment of *E. histolytic* Infections

Condition and Drug	Dose and Duration	Cure Rate	Adverse Reactions
Cyst passage			
Diloxanide furoate (obtain from CDC)	500 mg tid for 10 days	87–96%	Mild gastrointestinal upset (uncommon).
Diiodohydroxyquin (followed by tetracycline)	650 mg tid for 20 days	95%	Subacute optic neuropathy, dermatitis, diarrhea, headache. Avoid if hepatic disease or iodine intolerance present.
Paromomycin	300 mg/kg per day for 5–10 days	80–90%	Gastrointestinal upset.
Invasive colitis			
Metronidazole[a]	750 mg tid for 10 days 750 mg tid for 5 days[b] 2.4 g qd for 2–3 days[b] 50 mg/kg for 1 dose[b]	>90% >90% >90%	10–20% Gastrointestinal upset (less with divided dosage), disulfiram effect, bitter taste, seizures, possible carcinogenesis.
Tetracycline	250 mg qd for 14 days[b]	>90%	Gastrointestinal upset, hepatotoxicity, fungal suprainfection, teeth discoloration.
Dehydroemetine	1–1.5 mg/kg per day IM for 5 days†	80–90%	25–50% Cardiotoxicity (tachycardia, hypotension, angina, electrocardiograph changes), neuromuscular (tremor, muscle tenderness, and weakness), gastrointestinal.
Liver abscess[c]			
Metronidazole	750 mg tid for 5–10 days[b] or 2.4 g qd for 1–2 days[b]	99%	See above.
Dehydroemetine (followed by chloroquine)	1–1.5 mg/kg per day for 5 days† (600 mg qd for 2 days)	90% (60% Alone)	See above. Gastrointestinal upset, headache, pruritus.

[a]Alternate therapies to metronidazole with possibly less toxicity, but which are unavailable in the United States, include the following drugs: tinidazole, 50 mg/kg per day for 3 days (plus lumenal agent from the therapy for cyst passage), and tiberal, 15–30 mg/kg per day for 5 days (plus lumenal agent from the therapy for cyst passage).

[b]Plus lumenal agent from the therapy for cyst passage.

[c]Aspiration of abscess not necessary for cure, but in experienced hands it may decrease symptoms and recovery time. The only absolute indication is a lack of response or worsening while the patient is on medical therapy for 3–5 days.

debated, recent studies indicate a limited number of valid species that can be distinguished by size, life-cycle characteristics, ability to transmit infection between animals (e.g., mammal to mammal vs. mammal to poultry), and chromosome pattern.[310–315] Recent advances in molecular tools for species differentiation, genotyping, and subtyping have led to identification of 13 accepted species of *Cryptosporidium* and over 30 genotypes. Eight *Cryptosporidium* spp./genotypes have been identified in humans, including *C. hominis, C. parvum, C. meleagridis, C. felis, C. canis, C. muris, C. suis, and Cryptosporidium* corvine genotype.[316,317] The two most common causes of human infections are *C. hominis* and *C. parvum*. The genome sequences of these two species had recently been completed, revealing new insights on the host interactions, pathogenesis, and possible targets for therapeutic and preventive interventions.[318,319]

Disease among animal hosts includes diarrhea in large mammals such as calves, piglets, lambs, foals, and goats; intestinal and respiratory disease in poultry; and asymptomatic carriage in most rodents. Persistent infection associated with diarrhea has been reported in nude (nu/nu) BALB/c mice infected at 6 days of age; when the mice were inoculated at 42 days of age, only asymptomatic infection developed.[320] These observations and the fact that AIDS patients manifest severe symptomatic disease suggest that T lymphocytes, particularly the T-helper subset, are important in recovery from infection and the development of protective immunity.[321] In general, young animals are more susceptible to infection, possibly because innate resistance develops or specific protective immunity is acquired as the animal matures. Experimentally, diarrheal disease develops in gnotobiotic animals monoinfected

with *Cryptosporidium*, indicating that this parasite is a primary enteric pathogen.[322,323]

The life-cycle of *Cryptosporidium* is similar to that of other coccidia (Fig. 44-7).[323,324] Infection is initiated when the host accidentally ingests oocysts. Although the infectious dose for many animal species is not clear, inoculation of 100–500 oocysts causes infection in 50% of Swiss-Webster mice.[325] A report of a researcher who acquired infection after a rabbit inoculated with *Cryptosporidium* coughed on him suggests that the infectious dose is also low in humans.[326] Indeed, studies in human volunteers demonstrate that an estimated ID_{50} is 132 oocysts,[327] and some have estimated from mathematical modeling in the Milwaukee outbreak that the infectious dose may be as low as one oocyst for some individuals.[305,328]

The asexual cycle of *Cryptosporidium* is initiated when gastric acid and proteolytic enzymes in the upper small bowel cause the oocyst wall to dissolve at its single suture, resulting in a slitlike opening from which the four sporozoites can exit the oocyst.[329] The sporozoites are able to penetrate and parasitize the intestinal epithelial cells and potentially other epithelial surfaces contiguous to the gastrointestinal tract, such as respiratory or biliary tract epithelium. Within the host cells, sporozoites develop into trophozoites and subsequently into type I meronts. The type I meront releases six to eight merozoites capable of reinfecting the host epithelial cell. Some of these merozoites develop into type II meronts containing four merozoites. The merozoites released by type II meronts initiate the sexual cycle with the development of macrogamonts and microgamonts. Microgamonts are aflagellar but motile and fertilize macrogamonts, resulting in immature oocysts that develop within the intestinal epithelial cell. Oocysts released from the host epithelial cell are either thin- or thick-walled and immediately able to initiate infection (i.e., fully sporulated). Thin-walled oocysts may excyst within the bowel, releasing sporozoites which reinfect the host epithelial cells. Thick-walled oocysts are excreted by the host and are known to be extremely hardy.

Thus, autoinfection of the host can occur due to either type I meronts or thin-walled oocysts. This may account for the ability of *Cryptosporidium* to cause sustained symptomatic infections in the immunocompromised host, potentially lasting for the life of the individual.[324]

In general, the pathogenesis of *Cryptosporidium* infections is poorly understood. In humans, detailed studies of intestinal histopathology and function are provided only by case reports of immunocompromised patients, primarily with the AIDS. Ultrastructural studies generally show that the intestinal mucosa are intact and the enterocytes well preserved.[330,331] Microvilli are displaced at the sites of parasite attachment to the enterocyte surface, and they may be elongated next to the parasite. In addition, "peaking" of the host-cell cytoplasm may occur at the point of attachment of the cryptosporidia.[330,332]

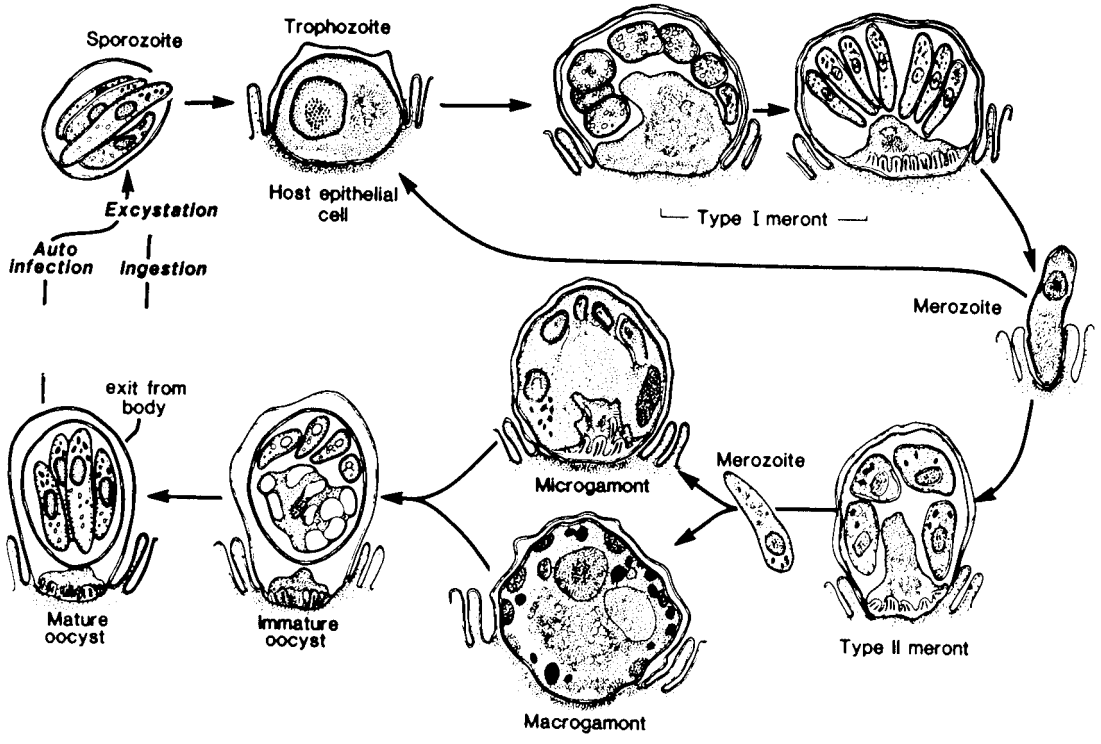

FIGURE 44-7. Diagrammatic representation of the life cycle of *Cryptosporidium*. Sporozoites excyst from an oocyst and enter the microvillus of an epithelial cell, where they differentiate into trophozoites. Trophozoites undergo nuclear proliferation to form type I meronts. A merozoite leaves the type I meront to form either a type I or II meront. A merozoite leaves the type II meront to form microgamonts or a macrogamont. The microgamont fertilizes the macrogamont, which then develops into an oocyst. Oocysts sporulate in situ and either release sporozoites for autoinfection or pass from the body in the feces. (Adapted from Fayer R, Ungar BLP. *Cryptosporidium* spp and cryptosporidiosis. *Microbiol Rev* 1986; 50: 458.)

In some infections, villous architecture by light microscopy is moderately to severely abnormal, revealing crypt elongation and villous atrophy.[333,334] However, significant diarrhea (⩾1 L/day) may occur with minimal histopathologic change in the gut.[331] The degree and cell content of the inflammatory infiltrate in the lamina propria of gut infected with *Cryptosporidium* in clinically affected patients has ranged from minimal[335] to substantial[331,333,334] and may include plasma cells, lymphocytes, macrophages, and/or polymorphonuclear leukocytes. One limitation of these human case reports is that it is often not clear how extensively the patients were evaluated for additional enteropathogens.

In animal studies, the degree of pathologic abnormality has tended to correlate with the extent of infection and in some animals, including calves, lambs, and piglets, with the severity of clinical illness.[321,323,336,337] In rodents such as mice, rats, and guinea pigs, no obvious clinical illness occurs, and pathologic findings range from inapparent to moderate.[337,338] In studies of spontaneously infested guinea pigs, cryptosporidial organisms have been observed deep in the cytoplasm of M-cells overlying Peyer's patches and associated with macrophages subjacent to the M-cells. These observations suggest antigenic sampling by the intestinal immune system.[339]

The mechanisms by which *Cryptosporidium* causes diarrhea in either the immunocompetent or the immunocompromised host have not yet been elucidated. Both secretory (unaffected by fasting) and malabsorptive diarrhea have been reported in AIDS patients infected with *Cryptosporidium*.[331,340,341] D-xylose and vitamin B_{12} malabsorption, steatorrhea, and increased fecal α_1-antitrypsin clearance have been reported.[331,334,340,341] Radiographic studies have also showed results consistent with malabsorption, such as flocculation of the barium, mucosal thickening, and dilation in the small bowel.[342] Animal studies have confirmed lactase deficiency and xylose malabsorption in calves infected with *Cryptosporidium*.[321,336]

Detailed electron micrograph studies indicate that *Cryptosporidium* develops intracellularly in the host epithelial cell but is extracytoplasmic.[312,332] A striking electron-dense zone described as a "feeder organelle" forms at the interface between the parasite and the host cell.[312,332] It may be through this zone that the parasite receives nutrition and delivers products capable of stimulating intestinal secretion. The observation that voluminous, watery diarrhea may occur in the immunocompromised host might suggest production of an enterotoxin or neurohumoral products by the parasite. Experimental results to date are mixed.[343–345] Reports of enterotoxic effects do not distinguish the source of potential secretory products.[346,347] Indeed, Argenzio et al. suggest that the cytokines [such as tumor necrosis factor (TNF)] and macrophages seen in cryptosporidiosis may elicit prostaglandin-dependent secretion, possibly via secondary cells such as fibroblasts.[348,349] Studies in humans with cryptosporidiosis show villus tip damage and malabsorption.[350] Analysis of gene expression profiles of a *C. parvum*-infected human epithelial cell line revealed upregulation of genes of actin, tubulin, heat shock proteins, and proinflammatory chemokines IL-8, RANTES, and SCYB5.[351] Host genes associated with cell proliferation and apoptosis were differentially regulated. This study suggested that infection with *C. parvum* alters the host biochemical pathways by affecting gene expression.

CLINICAL MANIFESTATIONS

Infection with *Cryptosporidium* has been documented in both immunocompetent and immunocompromised patient populations.[304,314,335,336,344,352,353] In immunocompetent hosts, the majority of cases are sporadic and may involve either children or adults, in both the developed and developing world.[352] Infection has also been reported in animal handlers,[304,314] homosexual men,[334] travelers,[354,355] and contacts of infected individuals (e.g., household contacts or hospital personnel).[314,353,356,357]

The clinical manifestations of cryptosporidiosis depend on the immune status of the host. In the immunocompetent host, infection results in a flulike, noninflammatory gastrointestinal illness characterized by malaise, anorexia, vomiting, abdominal pain and cramps, and sometimes fever. Blood and pus are not present in the stool and the fecal leukocyte examination is negative. Diarrhea lasts on average 6–14 days, although some patients will have a more prolonged illness, with diarrhea lasting a month or even, rarely, as long as 4 months.[335,353,358–360]

Diarrhea may occasionally be much more severe (e.g., 17 L of daily stool output) in immunocompromised hosts with defects in either humoral or cell-mediated immunity.[301,314,361] In these hosts, infection is frequently persistent and the resulting morbidity—for instance, in AIDS patients—may contribute to earlier mortality.[362] AIDS patients have been reported to develop extraintestinal infection involving the respiratory or biliary epithelium.[335,363–368] Although the contribution of respiratory cryptosporidiosis to clinical disease is unclear, individuals with biliary infection may present with the clinical picture of cholecystitis and may also be coinfected with cytomegalovirus.[335,368]

The incubation period of the infection is usually between 3 and 14 days.[314] Experimental data show that the parasite can complete its developmental cycle in 3 days.[324] Until recently, asymptomatic carriage of the oocysts in clinically unaffected populations has been thought to be infrequent. For instance, in three studies examining predominantly asymptomatic homosexual men attending sexually transmitted diseases clinics during the early 1980s, none of 375 individuals were found to have *Cryptosporidium* oocysts in their stools. In contrast, *G. lamblia* was found in 3.3–6.5% and *E. disbar* in 5.5–23.5% of the men.[369–371] In studies examining the prevalence of infection with *Cryptosporidium* in developed countries such as the United States, Australia, or Europe, rates of infection in

situations other than outbreaks average 2.1% in symptomatic individuals (range = 0.26–22%).[308] Among controls, only 0.2% of stools were positive.[308,309] In contrast, infection rates have been highest in developing countries, with rates of 6.1% in individuals with symptoms (range = 1.4–40.9%) and 1.5% in controls.[308,309,372–374] Persistent asymptomatic oocyst excretion may extend beyond clinical illness.[358,359,375–377] Oocyst excretion lasts an average of 7 days beyond illness but may, on occasion, extend for several weeks.[358,359]

Several potential modes of transmission for *Cryptosporidium* have been identified. Earlier studies documented the potential for animal-to-human spread, and *Cryptosporidium* is clearly a zoonotic infection.[304,314,335,352,361] Both domestic animals such as calves and companion animals such as puppies and kittens serve as potential sources of human infection. Increasing evidence indicates that person-to-person spread of this infection is important and is probably a major mode of transmission.[314,335,352,353,357] Since large numbers of *Cryptosporidium* oocysts can be present in feces and the infectious dose is quite small, it is very likely that fecal–oral contamination through sexual contact could play an important role in transmission.

Human-to-human transmission is particularly well illustrated by the reports of outbreaks of diarrhea associated with *Cryptosporidium* infection in day-care centers,[359,378,379] and by reports of intrafamilial spread of infection in households showing that they are among the highest for any enteric pathogen.[306] In addition, waterborne outbreaks traced to surface water[380] or to sewage contamination of both chlorinated well water and fully treated municipal water have been reported.[305,381,382] *Cryptosporidium* oocysts have been identified in treated sewage effluents and surface waters, and several outbreaks have occurred with public swimming or wading pool exposure.[383,384] Unpasteurized apple cider has also been a source of *Cryptosporidium* infection.

Because the clinical syndrome associated with cryptosporidiosis is not unique, the differential diagnosis includes the extensive list of enteric pathogens which cause noninflammatory diarrhea. Rotaviruses and enterotoxigenic *Escherichia coli* are the leading causes of acute noninflammatory diarrhea worldwide, especially among young children; Norwalk-like viruses must also be considered. In immunocompromised individuals such as AIDS and bone marrow transplant patients, adenoviruses and coxsackieviruses may cause diarrhea.[385] The diagnosis of *Cryptosporidium* infection is especially important in patients with AIDS, as is the diagnosis of even more treatable causes of diarrhea in this setting. These causes include microsporidiosis and *Cyclospora* infection (see section "New and Emerging Protozoal Infections"), as well as *G. lamblia, Strongyloides stercoralis*, and *Isospora belli*, all potential parasitic causes of noninflammatory diarrhea. Epidemiologic data such as travel history, food ingestion (e.g., raw seafood), and recent antibiotic use may be helpful in prioritizing the diagnostic possibilities.[386] Cryptosporidiosis causes a substantial mortality (>30%) in HIV-infected patients with low CD4 counts, especially when the biliary tract is involved.[382,387]

DIAGNOSIS

The diagnosis of cryptosporidiosis is established by staining the stool with a modified acid-fast or immunofluorescence technique specific for the oocyst stage of *Cryptosporidium* and observing the characteristic oocyst morphology (Fig. 44-8). Examination of at least two fecal smears may be necessary for diagnosis,[358,388] and concentrating the stool may improve detection of the parasite, particularly in nonacute illness or in evaluation of contacts of infected individuals. Oocyst excretion may be intermittent; positive and negative smears from the same patient on the same day have been reported. In addition, a minority of the oocysts may not readily take up the acid-fast stain and may appear as empty holes in a fecal smear.[389] This variability in the staining characteristics of the oocysts does not hinder diagnosis in experienced hands.

A direct immunofluorescent antibody stain is sensitive and specific and may require less technician time.[388,390,391] Several ELISA methods are available for detection of fecal cryptosporidial antigen; these are 83–95% sensitive in diarrheal specimens but may miss lighter infections or asymptomatic carriage.[388,392] ELISAs for detection of serum IgM and IgG antibodies to *Cryptosporidium* have been developed;[393] when both these tests were used, over 90% of the patients with cryptosporidiosis, including patients with AIDS, had detectable antibodies at the time of medical presentation. These ELISAs for detection of immunoglobulins should prove to be particularly helpful in epidemiologic studies of cryptosporidiosis.

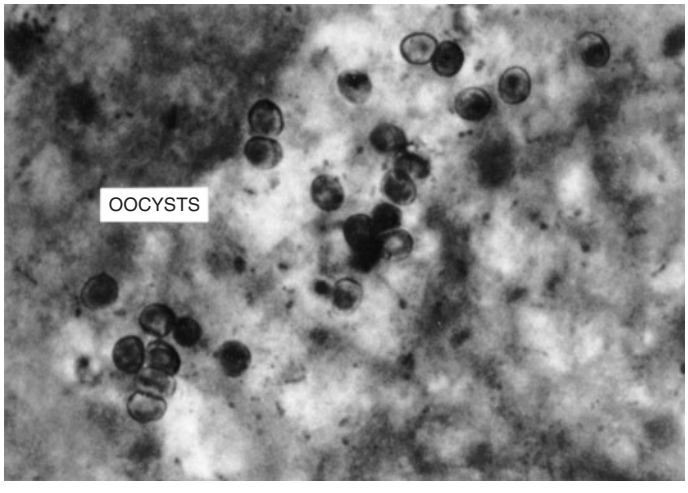

FIGURE 44-8. *Cryptosporidium* oocysts stained with a modified acid-fast stain. Oocysts are approximately 4–6 μm in diameter.

There is growing interest in the use of PCR assays for diagnosis of cryptosporidiosis; however, cost remains an issue for clinical laboratories.[394] The development of multiplex rt-PCR assay, which allows for diagnosis of multiple pathogens such as *E. histolytica, Giardia*, and *Cryptosporidium* spp. and genotypes, is on the horizon. Solid evidence for the clinical significance of PCR positive fecal samples is still lacking.

PREVENTION OF INFECTION AND THERAPY

The primary therapy for all forms of diarrheal illness, including cryptosporidiosis, is fluid and electrolyte replacement. Rehydration may be oral or intravenous, depending on the clinical status and age of the patient. In studies to date, from 0% to 30% of immunocompetent patients have required hospital admission for intravenous rehydration during *Cryptosporidium* infections.[314,353,395–397] Although many drugs have been evaluated in animals or humans, no clearly effective pharmacologic therapy for cryptosporidiosis has emerged.[314,335,361,398–401] Paromomycin has shown modest benefit in a controlled study, but it fails to eradicate the parasite in immunocompromised patients.[402] Development of an effective specific therapy for cryptosporidiosis has been hindered by the lack of a simple model for testing of drug sensitivity. Although nonspecific antidiarrheal therapies such as kaolin plus pectin (Kaopectate), antimotility agents (loperamide, paregoric), or bismuth subsalicylate (Pepto-Bismol) may be helpful in controlling symptoms, their efficacy and safety in cryptosporidiosis have not been evaluated.

Nitazoxanide has also been shown to have activity against *Cryptosporidium*.[127] However, it has only been proven to be effective in resolving symptoms and eradicating parasites in HIV-negative children so far.[403,404] The results of clinical trials in adults and HIV-positive patients had been varied, and thus nitazoxanide is only FDA-approved for use in otherwise healthy children. The recommended dosage for children aged 12–47 months is 100 mg b.i.d. for 3 days, and for children aged 4–11 years, the recommended dosage is 200 mg b.i.d. for 3 days. Higher dose and prolonged treatment may be required for clinical and parasitological response in the immunocompromised host.[405]

The thick-walled oocysts of *Cryptosporidium* are known to be very hardy and resistant to chlorine and numerous tested disinfectants. Only heat (boiling for 1 minute, at sea level), freezing, and prolonged treatment (18 hours) with 10% formalin or 5% ammonia, have been shown experimentally to reduce the infectivity of the oocysts.[336,406,407] Therefore, careful hand washing and enteric precautions in the hospital setting are important to interrupt person-to-person spread of infection. Current USPHS/IDSA guidelines for prevention of opportunistic infections in HIV infected persons include avoidance of fecal exposure during sexual contact; careful hygiene, including hand washing in handling pets and avoidance of new pets under 6 months of age; precaution concerning exposure during travel; and possible boiling or filtering of drinking water.[408] Future research to better understand the ecologic niches of this parasite will be important in the development of measures to control the spread of infection.

NEW AND EMERGING PROTOZOAL INFECTIONS

In addition to *G. lamblia, E. histolytica*, and *C. parvum*, additional intestinal protozoan infections are increasingly recognized. *Cyclospora cayetenensis* appears to be spread in contaminated water and is a potentially treatable cause of diarrhea in both normal hosts and in patients with AIDS.[409,410] Cyclospora infections are diagnosed with acid-fast stain of fecal specimens and are treated with sulfamethoxazole-trimethoprim.[411–415]

Microsporidial infections with *Enterocytozoon* bienusi or *Encephalitozoon* (formerly *Septata*) *intestinalis* are found predominantly in patients with AIDS and diarrhea, and can be diagnosed with a special trichrome stain of fecal specimens.[416,417] However, their epidemiology and routes of transmission remain largely unknown. Importantly, these infections, especially *Encephalitozoon* (*Septata*) *intestinalis*, appear to respond to albendazole therapy.[418–420]

ACKNOWLEDGMENT

We would like to acknowledge Drs. Cynthia L. Sears and Jonathan I. Ravdin who are coauthors in the previous editions of this chapter.

45 Vulvovaginal Candidiasis

Jack D. Sobel

Previously, symptomatic infections of the vagina due to *Candida* spp were termed *Candida* vaginitis; however, since symptoms and signs almost invariably involve the vulva, vulvovaginitis better reflects the disease process. The term vulvovaginal candidiasis (VVC) was introduced to be more inclusive and includes not only symptomatic *Candida* vulvovaginitis, but less frequent asymptomatic *Candida* vaginal infection with positive microscopy and culture. VVC does not refer to the very common carrier state, in which asymptomatic women without signs of disease and with negative routine microscopy are found to have positive vaginal yeast cultures.

The earliest reports of VVC appear in the writings of Hippocrates and Galen. Frank is purported to have written the first clinical description in 1792.[1] A report by Wilkinson in 1894 is the earliest clinical description that also linked clinical manifestation with fungal etiology.[2]

EPIDEMIOLOGY

Information on the incidence of VVC is incomplete, since VVC is not a reportable entity. Collecting data on VVC is hampered by inaccuracies of diagnosis and using nonrepresentative study populations. Most studies suggest a VVC prevalence of 5–15%, depending on the population studied.[1]

VVC affects most females at least once during their lives, most frequently in the childbearing age, at an estimated rate of 70–75%,[3–5] of whom 40–50% will experience a recurrence.[5,6] A small subpopulation of probably fewer than 5% of all adult women has recurrent episodes of VVC defined as ≥4 episodes per annum. Among women with symptoms of vulvovaginitis, 29.8% had yeast isolated, confirming the diagnosis of VVC.[7] Most studies indicate that VVC is a frequent diagnosis among young women, affecting as many as 15–30% of symptomatic women visiting a clinician. Regrettably, the recent availability of over-the-counter antimycotics will further limit the ability to measure asymptomatic *Candida* carriage and VVC in women populations. Diagnosis and therapy of VVC, together with lost productivity, result in an estimated cost of 1 billion dollars annually in the United States.[3] Statistical data in the UK derived from the patients whose conditions were diagnosed at genitourinary medicine centers show a sharp increase in the annual incidence of VVC from 118 per 100,000 to 200 per 100,000 women during the last decade.[8] In the United States, VVS is the second most common cause of vaginal infections following bacterial vaginosis (BV).[9,10] The number of prescriptions written to treat yeast infections between 1980 and 1990 indicates that the incidence of VVC almost doubled during that time; approximately 13 million prescriptions were written in 1990.

Point-prevalence studies indicate that *Candida* spp may be isolated from the lower genital tract of approximately 20% (range 10–80%) of asymptomatic healthy women without abnormal vaginal discharge.[11–13] Higher cumulative incidence of *Candida* colonization is reported.[14]

MICROBIOLOGY

Between 85% and 95% of yeast strains isolated from the vagina belong to the species *Candida albicans*.[15,16] The remainder are non-*albicans* species, the commonest of which is *Candida glabrata (Torulopsis glabrata)*. Non-*albicans* species can also induce vaginitis, which is clinically indistinguishable from that caused by *C. albicans*; moreover, they are often more resistant to therapy.[13,17,18] In many parts of the world, non-*albicans* isolates, notably *C. glabrata,* affect 10–20% of women.[19,20]

It has been claimed, but not proved, that VVC caused by non-*albicans* strains is rising dramatically.[21,22] The use of single-dose oral and topical regimens, together with low-dosage azole maintenance regimens and the availability of over-the-counter antimycotics, have been blamed for this increase. Two large multicenter studies failed to confirm any increase in the prevalence of VVC caused by non-*albicans* species.[23,24] Diabetes mellitus is a risk factor for *C. glabrata* vaginitis. Infrequent causes of fungal vaginitis include *C. parapsilosis*, *C. tropicalis*, and *C. krusei*, although virtually every species of *Candida* has been associated with vaginitis.[25,26]

Typing of vaginal *C. albicans* isolates has failed to demonstrate strains of tropism for the vagina. Similarly, no evidence emerged of vaginopathic strains demonstrating greater or lesser virulence to explain why some women remain entirely asymptomatic despite being heavily colonized with *Candida* spp, whereas other women develop severe symptomatic vaginitis. The concept of yeast vaginopathogenicity is not entirely without merit and may be the result of switching phenotypic and virulence properties, but upon gene activation.[27] Yeast adaptation would facilitate persistence and survival in the vagina.

In general, yeast blastospores (blastoconidia) represent the phenotypic form responsible for transmission and spread, including the bloodstream phase, as well as the form associated with asymptomatic colonization of the vagina. Germinated yeast with production of mycelia (hyphae) most commonly (but not exclusively) is found in symptomatic vaginitis.

CANDIDA VIRULENCE FACTORS

Colonization of the vagina requires yeast adherence to vaginal epithelial cells. *C. albicans* adheres in significantly higher numbers to such cells than do *C. tropicalis*, *C. krusei*, and *C. keyfer*.[28] All *C. albicans* strains appear to adhere equally well to both exfoliated vaginal and buccal epithelial cells. In contrast, there is considerable person-to-person variation in in vitro vaginal epithelial cell receptivity to *Candida* organisms in adherence assays.[29] However, no increased receptivity has been revealed in women with recurrent infections.[30] No epithelial cell receptor for *Candida* has yet been identified, and the yeast adhesin appears to reside with the surface mannoprotein.

Germination of *Candida* cells enhances colonization[31] and facilitates tissue invasion. Using a mutant strain of *C. albicans*, which failed to germinate at 37°C, Sobel and coworkers demonstrated in vivo that nongerminating mutants were incapable of inducing experimental VVC.[31] Accordingly, factors that enhance or facilitate germination might promote symptomatic vaginitis, whereas inhibit and germination may prevent vaginitis in asymptomatic carriers of yeast.[32]

Little is known regarding the role of candidal proteolytic enzymes, toxins, and phospholipase in determining the virulence of the organisms. Secreted aspartyl proteinases elaborated by pathogenic *Candida* spp has been identified in vaginal secretions and are detected in women with symptomatic vaginitis, but not in those with asymptomatic colonization.[33,34] These proteolytic enzymes, which have broad substrate specificity, destroy free and cell-bound proteins that impair fungal colonization and invasion.[35] Several genes governing proteinase production (SAP1, SAP2, and SAP3) have been cloned, and a strong correlation exists both in vitro and in experimental vaginitis between gene expression, aspartyl proteinase secretion, and ability to cause the disease.[36,37] Mycotoxin, including a vaginal identified gliotoxin, may act to inhibit phagocytic activity or suppress the local immune system. High-frequency heritable switching occurs in colony morphology of most *Candida* spp grown on amino acidrich agar in vitro at 24°C.[38] The variant phenotypes represent a varying capacity to form mycelia spontaneously and to express other virulence factors, including drug resistance, adherence, etc. There is insufficient evidence that phenotypic switching occurs in vivo at 37°C; however, this is an attractive hypothesis to explain spontaneous in vivo transformation from asymptomatic colonization to symptomatic vaginitis. Fresh clinical vaginal isolates obtained during acute vaginitis have been found to be in a high-frequency mode of switching. These multiple phenotypes are derived from the same or related genetic strains.[27,39,40]

In one patient with recurrent VVC (RVVC), who was sampled during three episodes of vaginitis, Soll observed colony phenotype switch with each recurrence of infection, even though DNA fingerprinting (genotype) remained identical.[27] Schroppel, using DNA analysis demonstrated that even though the same strain may persist long-term in the vagina, a certain degree of yeast genetic instability exists associated with repeated courses of antifungal therapy.[41]

Iron binding by *Candida* organisms facilitates yeast virulence.[42] Availability of erythrocytes and hemoglobin in the vagina creates an ideal niche for yeast possessing erythrocyte-binding surface receptors.

PATHOGENESIS

Candida organisms gain access to the vaginal lumen and secretions predominantly from the adjacent perianal area.[43,44] Two questions are critical in understanding the pathogenesis of VVC. First, the mechanism whereby asymptomatic colonization of the vagina transforms to symptomatic VVC. The second is the mechanism whereby some women suffer from repeated and chronic VVC. (Fig. 45-1)

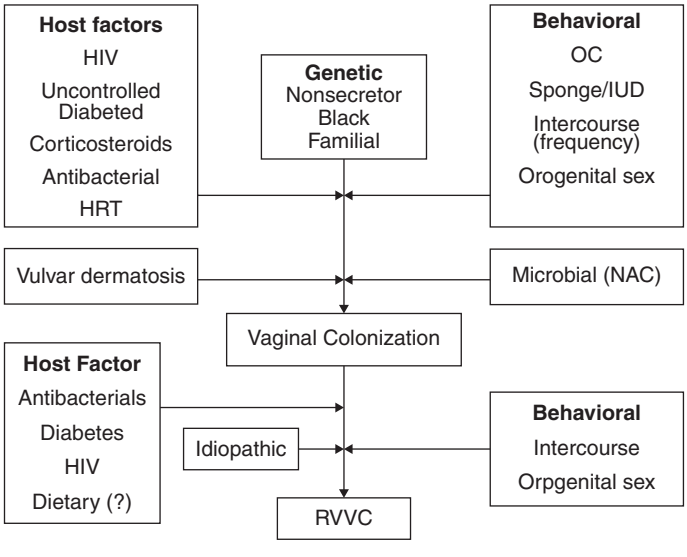

FIGURE 45-1. Pathogenesis of vulvovaginal candidiasis.

Hurley et al. fostered the view that *C. albicans* is never a commensal in the vagina, maintaining that clinicians can almost always detect vaginal pathology even in asymptomatic patients from whom such strains have been isolated.[5,6] Subsequent investigators have disagreed observing that many if not all women carry *C. albicans* in the vagina at sometime, yet without symptoms or signs of vaginitis, usually with low concentration of yeast organisms.[11,14] Accordingly, *Candida* may be either a commensal or a pathogen in the vagina and that changes in the host vaginal environment are usually necessary before the organism induces pathologic effects.

PREDISPOSING FACTORS

PREGNANCY

During pregnancy, a higher prevalence of vaginal colonization and symptomatic vaginitis occurs.[23,45] The latter is maximally increased in the third trimester, symptomatic recurrences are also more common, and therapeutic response is reduced.[18,45] High levels of reproductive hormones, by providing a higher glycogen content in the vaginal tissue, provide an excellent carbon source for *Candida* organisms.[46] A more complex mechanism seems likely in that estrogen enhances adherence of yeast cells to the vaginal mucosa. A cytosol receptor, or binding system, for female reproductive hormones has been documented in *C. albicans* resulting in enhanced mycelial formation.[47]

CONTRACEPTIVES

Many small, poorly controlled studies have produced conflicting data. Several studies have shown increased vaginal colonization with species of *Candida* following high estrogen-content oral contraceptive use.[1,48] Studies of women using low estrogen-content oral contraceptives have not found an increase in VVC.[49–52] Nevertheless, most investigators continue to incriminate oral contraceptives as predisposing to RVVC.[48] Increased carriage of such yeasts is reported in IUD users,[53,54] in diaphragm and condom users, with or without use of spermicide.[52,55,56] Other risk factors may include the contraceptive sponge. Foxman, in an extensive study of risk factors in college students, failed to identify increased risk in users of oral contraceptives, diaphragms, condoms, and spermicides.[51]

DIABETES MELLITUS

Vaginal colonization with *Candida* is more frequent in diabetic women. Women with NIDDM are more prone to colonization with *C. glabrata.*[57] Although uncontrolled diabetes undoubtedly predisposes to symptomatic vaginitis, well-controlled diabetics do not suffer from an increased prevalence of VVC.[1,58] It has become traditional to perform glucose tolerance tests (GTTs) in all women with RVVC. The yield of these expensive studies is extremely low; testing, therefore, is not justified in premenopausal women. Occasionally women with RVVC describe an association between "candy binges" and exacerbation of symptomatic vaginitis. Donders et al. performed GTTs in women with RVVC.[59] Although an increased frequency of abnormal GTTs compatible with diabetes or prediabetes was not found, plasma glucose levels were still significantly higher than in control subjects suggesting that a diet high in refined sugars may contribute to the risk of VVC.[59]

ANTIBIOTICS

Onset of symptomatic VVC is frequently following vaginal or systemic antibiotics.[60–63] All antimicrobials appear responsible. Estimates of postantibiotic VVC include a range of 28–33%.[64,65] Vaginal colonization rates increase from approximately 10% to 30%.[66,67] Antibiotics are thought to act by eliminating the protective vaginal bacterial flora allowing *Candida* overgrowth in gastrointestinal tract, vagina, or both.[67] Vaginal, particularly *Lactobacillus* spp, flora are thought to provide colonization resistance and prevent germination, maintaining low numbers of yeast, and preventing superficial mucosal invasion. Auger and Joly found low numbers of lactobacilli in vaginal cultures obtained from women with symptomatic VVC.[68] Studying adult mice, Pultz et al. reported that antibiotics that inhibit intestinal anaerobes promote *C. glabrata* gut colonization.[69] Lactobacillus–yeast cell interactions include competition for nutrients as well as stearic interference by lactobacilli with *Candida* adherence, elaboration of inhibitory bacteriocins by lactobacilli, as well as a direct antibiotic-induced stimulatory effect on growth of *Candida* spp.[68]

In contrast, Agnew and Hillier failed to demonstrate a reduction in vaginal lactobacilli following several antibiotic regimens.[70] In spite of the evidence indicating a role for antibiotics, most women who receive antibiotics do not develop symptomatic VVC.[71] Moreover, the majority of women with acute VVC have not been recent recipients of antibiotics. Hence, only a subpopulation of women, already colonized by potentially virulent species of *Candida*, are at risk of vaginitis following antimicrobial therapy.

BEHAVIORAL FACTORS

The incidence of VVC increases dramatically in the second decade, corresponding to the onset of sexual activity. It peaks in the third and fourth decade, declining in females older than 40 years, until the permissive effect of hormone replacement therapy becomes apparent. Several studies have shown that sexual transmission of *Candida* organisms occurs during vaginal intercourse, although the role of nonsexual practices

in introducing *Candida* organisms into the lower genital tract has not been appraised.[44,72–75] There exists conflicting evidence as to the role of sexual behavior in causing symptomatic VVC.[3,51,52] Some authors suggest that recent sexual intercourse frequency is correlated with acute vaginitis,[51,75,76] and others have identified receptive orogenital sex.[76–78] In spite of anecdotal evidence, Foxman found no epidemiologic evidence incriminating female hygiene habits as risk factors for VVC.[51]

The use of well-ventilated clothing and cotton underwear may be of value in preventing infection.[79] On the other hand, Foxman found no increased risk for VVC among wearers of tight clothing or noncotton underwear.[51] There is no evidence confirming that iron deficiency predisposes to infection.[80] Chemical contact, local allergy, or hypersensitivity reactions may alter the vaginal milieu and permit the transformation from asymptomatic colonization to symptomatic vaginitis.

SOURCE OF INFECTION

INTESTINAL RESERVOIR (REINFECTION)

Although the gastrointestinal tract may well be the initial source of colonization of the vagina by *Candida* organisms, controversy continues regarding the role of the intestinal tract as a source of reinfection in women with RVVC.[81]

Candida isolates were recovered on rectal culture from 100% of women with RVVC and found identical on typing,[82] supporting the concept of a persistent intestinal yeast reservoir. Reinoculation of the vagina might occur from the persistent rectal focus following apparent eradication of vaginal yeast by topical therapy. Several authors, however, have found much lower concordance between rectal and vaginal cultures in patients with RVVC.[44,45] The high rate of anorectal cultures in some studies likely reflects perineal and perianal contamination from the vaginal discharge. Moreover, VVC recurred frequently in women in the absence of simultaneously positive rectal cultures. Two controlled studies using oral nystatin treatment, which reduces intestinal yeast carriage, failed to prevent symptomatic recurrence of vaginal candidiasis.[83,84]

SEXUAL TRANSMISSION

Asymptomatic male genital colonization with species of *Candida* is four times more common in male sexual partners of infected women.[73] Penile *Candida* organisms are present in approximately 20% of partners of women with RVVC.[73,74] *Candida* organisms are most commonly found in uncircumcised, usually asymptomatic males. Infected partners usually carry identical strains[44]; however, the contribution of sexual transmission to the pathogenesis of infection remains unknown. From the prevalence of positive penile and urethral cultures, it appears that the role of sexual spread is limited. Limited evidence is available that anogenital and particularly orogenital contacts transmit infection.[78]

VAGINAL RELAPSE

After clinically effective antimycotic therapy of VVC, negative vaginal *Candida* cultures once more turn positive within 30 days in 20–25% of women, strongly supporting the concept of vaginal persistence of some strains of yeast and hence a vaginal as opposed to intestinal reservoir. Strains isolated before and after therapy are of the identical type in more than two-thirds of recurrences.[44] Small numbers of the microorganisms persist within the vaginal lumen, generally in numbers too small to be detected by conventional vaginal cultures. It is also conceivable that small numbers of *Candida* organisms might sojourn temporarily within superficial cervical or vaginal epithelial cells only to reemerge some weeks or months later.[85]

VAGINAL DEFENSE MECHANISMS

HUMORAL SYSTEM

Patients with profound immunoglobulin deficiencies are not susceptible to VVC. Following acute VVC, systemic (IgM and IgG) and local (S-IgA) responses are elicited.[86,87] The protective role of vaginal antibodies is unknown. Lower antibody titers have been described during active vaginal infections, which may reflect an adsorption effect. Polonelli and coworkers, using an experimental animal model of vaginitis, reported suggestive evidence for a protective role of specific antibodies induced by immunization.[88] Experimental studies in mice have provided some evidence for protection using *Candida*-specific antibodies.[89] Patients with recurrent vaginitis, however, do not lack antibody, in fact high serum immunoglobulin titers are typically found.[90] Elevated serum and vaginal IgE antibodies to *Candida* organisms were detected in some women with RVVC, even though the total IgE levels were normal.[91–93] In summary, the protective role of vaginal anti-*Candida* antibodies is controversial. Certainly, women with recurrent disease do not lack antibody. It is also feasible that antibody-based anti-*Candida* hypersensitivity reactions (IgE) may contribute to symptoms.

PHAGOCYTIC SYSTEM

Although both polymorphonuclear leukocytes (PMNs) and monocytes play an important role in limiting systemic candidal infection and deep-tissue invasion,[94] these phagocytic cells are characteristically absent from vaginal fluid during acute VVC.[95] Accordingly, phagocytic cells have not been thought to play a role in influencing mucosal colonization or

prevent superficial invasion by *Candida* organisms. In the rat model of experimental VVC, as in humans, histology of the vagina fails to demonstrate leukocytes in the vaginal fluid or stratified squamous epithelium. Polymorphonuclear cells can be seen concentrating within the underlying lamina propria, but appear not to be presented with a chemotactic signal to induce migration into more superficial layers or vaginal fluid. Recently, Fidel et al. have challenged this view and suggested that mucosal and luminal PMNs play a prominent early protective role against *Candida* organisms.[96] This view is based upon experimental mice VVC and human *Candida* vaginal challenge studies.[97–99]

CELL-MEDIATED IMMUNITY

Oral thrush, which correlates well with depressed cell-mediated immunity (CMI), is frequently seen in debilitated or immunosuppressed patients. This is particularly evident in patients with chronic mucocutaneous candidiasis or with AIDS. Accordingly, one might anticipate that lymphocytes similarly contribute to normal vaginal defense mechanisms, possibly preventing yeast mucosal invasion by the elaboration of cytokines such as gamma-interferon, which inhibits germ-tube formation.

Most healthy adult women have positive cutaneous delayed hypersensitivity reactions, as well as in vitro lymphoblast proliferation response to *Candida* antigens. Earlier studies reported cutaneous anergy and depressed lymphoblastic response to *Candida* antigens in women with RVVC.[94,100–103] The existence of a subpopulation of suppressor lymphocytes or serum factors inducing suppression of local vaginal CMI in women with RVVC.[104] In conflict with these observations, more recent studies using a variety of *Candida* antigens and measurement of cytokine elaboration demonstrated a normal systemic CMI response in women with idiopathic RVVC.[105] Observations showed that the previously reported cutaneous anergy was transient only—the consequence and not the cause of RVVC—and that impaired systemic CMI was not involved in the pathogenesis of RVVC. This conclusion was compatible with the observation that women prone to RVVC are not prone to oral, esophageal, or cutaneous candidiasis. Several additional studies by Fidel et al., using the mouse vaginitis model, determined that systemic CMI has a minor role only in providing a defense function at the level of the vaginal mucosa.[98,99,106,107] These studies also demonstrated that local and systemic immunity to infection by *Candida* organisms could be induced by vaginal sensitization and that the immunity provided is partially protective in the vagina.[107]

The studies by Fidel et al. did not exclude the possibility of an acquired local vaginal defect in CMI predisposing to RVVC.[98,99,105,107] In this regard, Witkin et al. reported in vitro studies supporting impaired CMI in women with RVVC.[102,108] They postulated that local elaboration of prostaglandin E2 by the patient's macrophages blocked local protective lymphocyte function (Th-1), possibly inhibiting interleukin-2 production.[109] According to this hypothesis, abnormal macrophage function could be the result either of local IgE antibodies to *C. albicans* in the vagina of women with RVVC or of inhibitory serum factors.[110] The protective mechanism of vaginal T lymphocytes was postulated to conform to a Th-1 profile and disease state, i.e., RVVC with Th-2 state.[99] Additional studies indicate unique subpopulations of vagina-specific lymphocytes.[97]

Accordingly, an aberrant Th-2 dominant profile is postulated to be operative in women with RVVC. Nitric oxide (NO), another component of the innate immune defense against *Candida*, is produced by macrophages.[111] The *anti-Candida* activity of NO is strongly inhibited by IL-4,[112] a cytokine product of the Th-2 subset of cytokines. IL-4 inhibits production of proinflammatory cytokines by Th-1 T cells and blocks macrophage activation. Babula et al. recently reported elevated vaginal concentrations of IL-4 in women with RVVC, providing a possible hypothesis and explanation for an impaired *Candida* control mechanism.[113] In the same study, increased IL-4 levels appear to correlate with reduced NO concentrations. Most importantly, a single nucleotide polymorphism consisting of a C →T transition at position –589 in the promoter region of the IL-4 gene has been reported. Possession of the T variant is associated with increased IL-4 production. In the study by Babula et al., the frequency of IL-4 was 76.2% in patients with RVVC and 23.3% in control subjects. In the same study, vaginal mannose-binding lectin (MBL) levels were similarly measured. MBL, a component of the innate immune systems, binds to mannan residues on *C. albicans* and promotes complement activation and killing. Women with RVVC had significantly reduced MBL levels.[113]

The T cell or CMI role in health or disease (VVC) is anything but clear. Based upon mice and human challenge studies, Fidel et al. found no evidence of Th-2 activity in vaginal secretions.[114] He concluded that natural protection to *Candida* organisms in the vagina is provided by PMNs and vaginal epithelial cells (innate immunity) only and that VVC supervened when yeast numbers increase and exceed natural defenses.

VAGINAL FLORA

Probably the most important defense against both candidal colonization and symptomatic inflammation is the normal vaginal bacterial flora. Any newly arrived *Candida* organisms, in order to survive and persist, must initially adhere to epithelial cells and then grow, proliferate, and germinate in order to colonize the vaginal mucosa successfully. Although microbial competition for nutrients has long been considered the most important source of competition, animal studies suggest that lactobacilli as the most prevalent bacteria and *Candida* organisms frequently survive side by side.[115] The

role of bacteriocins in inhibiting yeast growth and germination requires additional investigation.[68] Although antibiotic-induced VVC suggests a critical role of lactobacillus deficiency in causation of VVC, virtually all studies of vaginal flora in non-antibiotic-related situations have failed to confirm that lactobacillus deficiency both qualitatively and quantitatively predisposes to VVC or RVVC.

MISCELLANEOUS DEFENSE MECHANISMS

Although not studied in the vagina, various natural secretions have been shown to possess considerable antifungal activity. Pollock et al. reported fungistatic and fungicidal activity against *C. albicans* of human parotid salivary histidine-rich polypeptides.[116]

VAGINAL EPITHELIAL CELLS

Investigators reported that vaginal epithelial cells from mice and nonhuman primates as well as human oral epithelial cells inhibited the growth of *Candida* in vitro.[117,118] Epithelial cell-mediated anti-*Candida* actually involves cell contact between a carbohydrate moiety or the epithelial cell and *Candida* with no role for soluble factors, phagocytosis, or oxidative killing.[118] No differences in activity at various stages of the menstrual cycle was observed.[119] Women diagnosed with RVVC under similar study conditions had reduced epithelial cell anti-*Candida* activity. These results suggest a possible protective role for epithelial cells in providing an innate host-resistance mechanism against *Candida* and that reduced activity may contribute to RVVC.[120] MBL has been suggested as an innate defense against *Candida*, enhancing complement activation.[121] To date, no such lectin has been reported for vaginal epithelial cells.

TRANSFORMATION TO SYMPTOMATIC VAGINITIS

The mechanism whereby *Candida* organisms induce inflammation is not yet established. Yeast cells are capable of producing several extracellular proteases as well as phospholipase. The paucity of phagocytic cells in the inflammatory exudate possibly reflects the lack of chemotactic substances elaborated. Both blastoconidia and pseudohyphae are capable of destroying superficial cells by direct invasion.

During the symptomatic episode, there is a conspicuous appearance of the germinated or filamentous forms of *Candida* cells. Hyphal elements not only enhance colonization but also represent the dominant invasive phase capable of penetrating intact epithelial cells and invading the vaginal epithelium, although only very superficial layers are involved.[122] Although symptoms are not strictly related to the yeast load, VVC does tend to be associated with greater numbers of *Candida* organisms and with hyphal elements.[122] Approximately 10^3–10^4 *Candida* cells per milliliter of vaginal fluid may be recovered in both symptomatic and asymptomatic states.[1]

The clinical spectrum varies from an acute florid exudative form with thick white vaginal discharge and large numbers of germinated yeast cells, to the other extreme of absent or minimal discharge, fewer organisms, and yet severe pruritus. Based on this, it is suggested that more than one pathogenic mechanism may exist. In the presence of pruritus alone, host hypersensitivity or immune mechanisms are likely to be involved.[123–125] Although clinical signs and symptoms are indistinguishable in infections caused by different *Candida* spp, *C. glabrata* and *C. parapsilosis* tend to be associated with milder and often absent symptoms.[19,25] Not infrequently, male partners of asymptomatic female carriers of *Candida* develop postcoital penile erythema and pruritus, which usually last several hours only.

CLINICAL MANIFESTATIONS

Acute pruritus and vaginal discharge are the usual presenting complaints, but neither symptoms is specific to VVC. Vaginal discharge is not invariably present and is frequently minimal. Although described as typically cottage-cheese-like in character, the discharge may vary from watery to homogeneously thick. Vaginal soreness, irritation, vulvar burning, dyspareunia, and external dysuria are commonly present. Odor, if present, is minimal and inoffensive. Examination reveals erythema and swelling of the labia and vulva, often with discrete pustulopapular peripheral lesions (Fig. 45-2). The cervix is normal, and vaginal epithelial erythema is present together with adherent whitish discharge. Characteristically, symptoms are exacerbated in the week preceding the onset of menstrual flow.

Several surveys indicate the unreliability of patient diagnosis.

Although *Candida* spp occasionally cause extensive balanoposthitis in male partners of women with vaginal candidiasis, a more frequent event is a transient rash, erythema,

FIGURE 45-2. Clinical appearance of acute vulvovaginal candidiasis.

and pruritus or a burning sensation of the penis which develops minutes or hours after unprotected intercourse. The symptoms are self-limiting and frequently disappear after showering.

DIAGNOSIS

The lack of specificity of symptoms and signs precludes a diagnosis that is based on history and physical examination only.[126,127] A positive culture alone of *Candida* should be regarded as a satisfactory basis for diagnosis of VVC.[128] The most specific symptom in genital candidiasis is pruritus without discharge, and even this criterion correctly predicted VVC in only 38% of patients.[127]

Most patients with symptomatic vaginitis may be readily diagnosed on the basis of microscopic examination of vaginal secretions. Accordingly, a wet mount or saline preparation should routinely be done, not only to identify the presence of yeast cells and mycelia but also to exclude the presence of "clue cells" and motile trichomonads. A 10% potassium hydroxide (KOH) preparation is more sensitive in identifying germinated yeast (65–85%) sensitivity (Fig. 45-3). Large numbers of white cells are invariably absent in VVC and when present should suggest a mixed infection. Similarly, vaginal pH estimations reveal a normal pH (4.0–4.5) in VVC, and the finding of a vaginal pH in excess of 5.0 usually indicates BV, trichomoniasis, or a mixed infection.

Unfortunately, up to 50% of patients with culture-positive symptomatic VVC will have negative microscopy.[43] Thus, although routine cultures are unnecessary if the wet-mount of KOH preparations shows yeast and mycelia, vaginal culture should be performed in symptomatic women in the presence of negative microscopy, if VVC is suspected on the basis of symptoms or signs and a normal pH estimate (Fig. 45-4). The PAP smear is unreliable as a diagnostic modality, being positive in only about 25% of patients with culture-positive symptomatic VVC.[129]

Although vaginal culture is the most sensitive and specific method currently available for detecting *Candida* cells, a positive culture alone does not necessarily indicate that the yeast is responsible for the vaginal symptoms since 10–15% of normal asymptomatic women are colonized with *Candida* and hence culture positive.[130] Positive microscopy usually correlates with relatively high yeast concentrations in vaginal secretions as confirmed by quantitative vaginal cultures, and in most women the yeast cell numbers correlate with severity of clinical signs and symptoms,[127] and that commensal yeast vaginal carriage tends to be associated with lower numbers of vaginal yeast. Diagnosis of VVC requires a correlation of clinical findings, microscopic examination, and vaginal culture. Although some prefer to use a selective medium, there is no difference in using Sabouraud agar, Nickerson's or Microstix-*Candida* media, or in adding antibiotics such as chloramphenicol to the isolation medium. There is no reliable serologic or antigen detection technique available for the diagnosis of VVC.

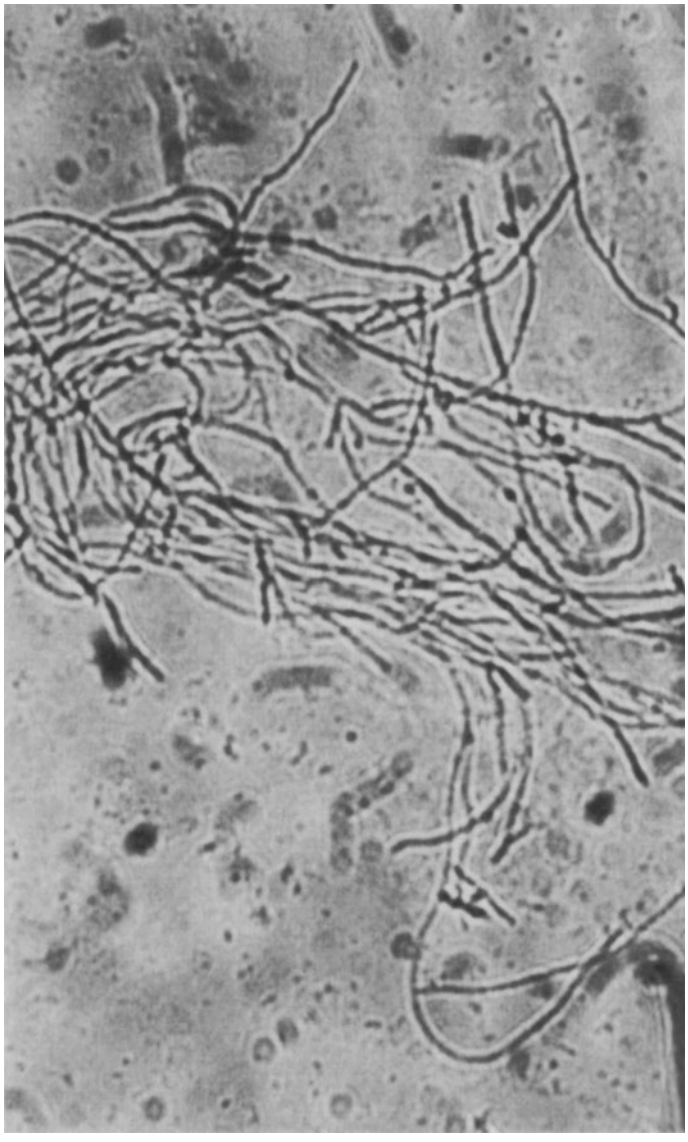

FIGURE 45-3. Wet-mount examination of vaginal discharge from a woman with vulvovaginal candidiasis, showing mycelia. 1000× magnification.

Since the majority are unable or unwilling to measure vaginal pH and perform microscopy, current diagnosis worldwide is empiric and extremely inaccurate. The majority of women with vulvovaginal symptoms remain incorrectly diagnosed.

PCR detection of *Candida* spp in vaginal samples is possible but not an available diagnostic test.[131]

DIFFERENTIAL DIAGNOSIS

Most clinicians consider only trichomoniasis and BV in the differential diagnosis of VVC. Given the profound differences in pH, PMN count, and wet-mount appearances, these three common clinical infectious entities are easy to differentiate. More consideration is needed in the symptomatic patient in whom these three conditions have been excluded. The differential

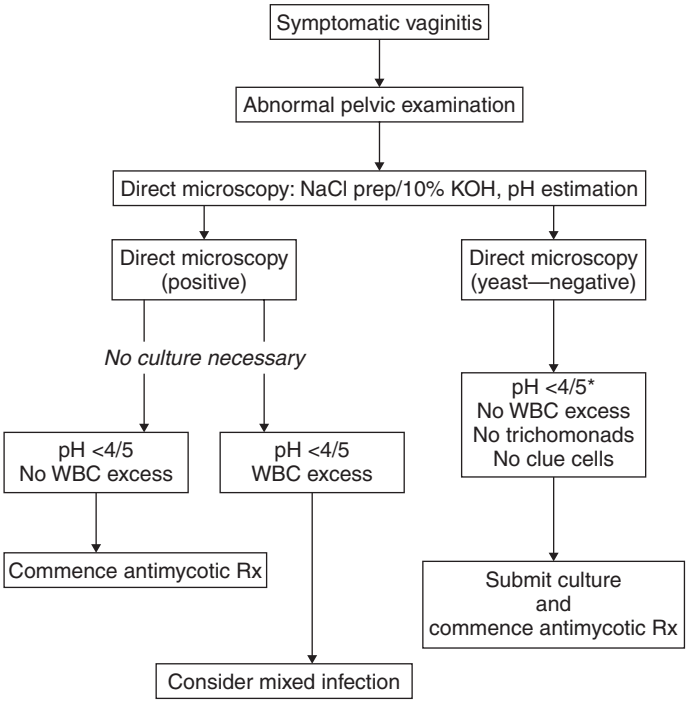

FIGURE 45-4. Algorithm for diagnosis and treatment of vulvovaginal candidiasis.

diagnosis of vulvovaginitis in the presence of normal pH, PMN count, and negative yeast cultures includes unrecognized genital herpes and numerous noninfectious causes, including hypersensitivity, irritant and allergic vulvovaginitis, idiopathic focal vulvovestibulitis, and physiologic leukorrhea.

TREATMENT

■ ACUTE SYMPTOMATIC VAGINITIS

A classification of VVC is available which determines the selection and duration of antifungal therapy. The majority of women with VVC suffer from uncomplicated vaginitis (Table 45-1) characterized by sporadic, infrequent attacks of mild-to-moderate severity due to *C. albicans* and these attacks occur in healthy adult women without unique host-predisposing factors. In contrast, 10–20% of women suffer from complicated VVC in which attacks are either more severe, occur on a recurrent basis, or are due to non *C. albicans* spp. Patients with complicated VVC more frequently have underlying host factors in the form of uncontrolled diabetes or immunosuppressed conditions.

According to this classification, women with severe vulvovaginal symptoms and signs do not respond well to the single dose and short-course antifungal therapy.[24] This approach was verified in a randomized study in which single and sequential doses of fluconazole were compared.[132] The study confirmed the premise that treatment of VVC requires individualization and more prolonged duration, i.e., 5–7 days, is essential.

A variety of highly effective topical azole agents are now available in a variety of formulations (Table 45-2).[133,134] No strong evidence exists that any one formulation results in superior cure rates, nor is there convincing evidence of the superiority of any specific azole over another azole in the treatment of VVC.[133,134] Overall cure rates for topical azole agents, defined as eradication of symptoms and mycologic-negative cultures, are of the order of 80–90%. Oral systemic azole agents achieve comparable or questionably marginally higher therapeutic cure rates, although most patients prefer the convenience of oral administration, which eliminates local side effects and messiness.[135] Oral azoles suffer the drawback of potential systemic toxicity, which has dramatically limited the use of ketoconazole, although not a consideration for itraconazole and fluconazole. In a meta-analysis, performed by Watson et al.,[136] of 17 trials published between 1989 and 1995 involving 2919 antifungal treatments for uncomplicated VVC, azoles were similarly effective when administered by either the oral or vaginal route.

Use of topical vaginal antimycotics has been remarkably safe and free of untoward side effects, although high-dose regimens of terconazole were associated with fever and flu-like

Table 45-1. Classification for Vulvovaginal Candidiasis

	Uncomplicated	Complicated
Severity	Mild to moderate and	Moderate to severe or
Frequency	<4 episodes per year and	≥ 4 episodes per year or
Microscopy	Pseudophypae/hyphae and	Budding yeast only or
Host	Healthy, nongravid	Adverse factors (pregnancy, diabetes, immunocompromise)
Treatment	Any short-course antimycotic therapy	Intensive regimens (avoid short-course)

Table 45-2. Azole Therapy of Vaginal Candidiasis

Drug	Formulation	Dosage
Fluconazole (Femstat)	2% cream	5 g × 3 days
Gynezole	2% cream	Single dose
Clotrimazole	1% cream	5 g × 7–14 days
(Gynelotromin, Mycelex)	10% cream	5 g single application
	100 mg vaginal tab	1 tab × 7 days
	100 mg vaginal tab	2 tab × 3 days
	500 mg vaginal tab	1 tab once
Miconazole (Monistat)	2% cream	5 gm × 7 days
	100 mg vaginal supp	1 supp × 7 days
	200 mg vaginal supp	1 supp × 3 days
	1200 mg vaginal supp	1 supp once
Econazole (Gyno-Pevaryl)	150 mg vaginal tab	1 tab × 3 days
	150 mg vaginal supp	Single dose
Fenticonazole	2% cream	5 g × 7 days
Sertaconazole (Monazol)	300 mg supp	Single dose
Ticonazole (Vagistat)	2% cream	5 g × 3 days
	6.5% cream	5 g single application
Teraconazole (Terazol)	0.4% cream	5 g × 7 days
	0.8% cream	5 g × 3 days
	80 mg vaginal supp	1 supp × 3 days
Fluconazole (Diflucan)	150 mg tab	Single dose
Ketoconazole (Nizoral)	200 mg tab	2 tab × 5 days
Itraconazole (Sporonox)	100 mg tab	2 tab × 3 days

symptoms, which resulted in the withdrawal of this topical agent in high concentrations.[137] Among the shortcomings of the azole class is their relatively poor efficacy in vaginitis caused by non-*albicans* species of *Candida*.

There has been a growing tendency to use shorter and shorter courses of both topical and oral agents.[133,138] Single-dose therapy by any route is effective in mild to moderate disease. Many of the single-dose drugs such as vaginal clotrimazole (500-mg suppository) and fluconazole (150-mg oral tablet) possess pharmacokinetic properties such that concentrations of the antimycotic persist in the vagina for up to 5 days following the single administration of these agents.[139,140] Hence, single-dose therapy may be more than "single-day" therapy. Asymptomatic vaginal colonization is not considered an indication for treatment.

At the same time, patient expectations should be reasonable with regard to resolution of symptoms. While pruritus usually resolves in a few days, soreness, tenderness, discomfort, and dyspareunia may take several more days to completely resolve following a severe attack.

ACUTE VAGINITIS IN PREGNANCY

Management of VVC during pregnancy is more difficult, since clinical response tends to be slower and recurrences more frequent.[141–144] In general, most topical antifungal agents are effective, especially when prescribed for longer periods (1–2 weeks).[145] Longer duration of therapy may be necessary to eradicate yeast infection. However, single-application, high-dose topical therapy with clotrimazole has been shown to be effective in pregnancy and may be considered for the initial therapeutic attempt.[145,146] In the past, nystatin was considered the drug of choice in the first trimester of pregnancy; however, all topical imidazole agents can be used throughout pregnancy. Oral azoles are contraindicated.[147]

MANAGEMENT OF RECURRENT VULVOVAGINAL CANDIDIASIS

Prior to initiation of treatment, diagnosis must be confirmed by culture. Thousands of women carry the label of "RVVC" when their symptoms are in fact due to noninfectious etiologies such as allergic and hypersensitivity vulvitis. Following confirmation of VVC, every effort should be made to eliminate factors predisposing to VVC. However, in the majority of women no reversible or correctable causal factors are present.

Initial antimycotic therapy requires an induction course of either oral or vaginal antimycotic therapy, which must be continued daily until the patient is completely asymptomatic and a culture-negative status has been achieved. In RVVC, failure to initiate a maintenance regimen will result in a clinical relapse of VVC in 50% of patients within 3 months.[148,149] Maintenance-suppressive regimens include ketoconazole 100 mg daily and once-weekly regimens of either 500 mg clotrimazole suppositories or 100 mg fluconazole orally. All three maintenance regimens are effective in preventing breakthrough vaginitis.[148,150,151] In a recent multicenter prospective randomized control trial, following induction therapy, patients with RVVC were assigned to receive fluconazole 150 mg or placebo weekly for 6 months and followed up for a further 6 months off therapy. The proportion of women who remained attack free at 6, 9, and 12 months were 90.8%, 73.2%, and 43.9% as compared with 35.9%, 27.8%, and 21.9%, respectively, in the placebo group.[149] The median time to clinical recurrence in the fluconazole group was 10.2 months, as compared with 4.0 months in the placebo group ($P<0.001$). No evidence of fluconazole resistance in isolates of *C. albicans* or of superinfection with *C. glabrata* emerged. The superior safety profiles of fluconazole and clotrimazole have resulted in the latter two agents replacing ketoconazole suppressive prophylaxis. Whatever the maintenance regimen, cessation of therapy is accompanied by symptomatic relapse in half the women within a short time of stopping therapy.[148–152] Relapse following cessation of fluconazole suppressive prophylaxis is invariably caused by the original strain of *Candida* responsible for preprophylaxis vaginitis, and the organism remains susceptible to fluconazole. Most experts recommend reinstitution of maintenance fluconazole prophylaxis.

The role of treatment of male sexual partners was reviewed by Sobel, and no benefit was demonstrated in several large studies.[133] Similarly, Fong evaluated systemic ketoconazole treatment of male partners and failed to reduce the recurrence rate in women with RVVC,[153] although Spinillo et al. did report decreased RVVC in women when attempts were made to eradicate *Candida* organisms in both partners.[75] Dennerstein reported a reduced rate of recurrence in RVVC in 15 patients during a 3-month period of depomedroxyprogesterone acetate therapy.[154] In a small study using patients as their own controls, Hilton et al. reported fewer episodes of VVC in women placed on oral yogurt.[155] Given the small numbers and lack of controls in this unblinded study, the role of yogurt in preventing *Candida* vaginitis remains unproved.

An alternative approach to long-term maintenance antifungal therapy is the use of hyposensitization with *Candida* antigen preparation. Two small studies achieved encouraging results, but this is rarely used.[125,156]

RESISTANT AND NON-*ALBICANS CANDIDA* VAGINITIS

In contrast to oral candidiasis, vaginitis caused by azole-resistant strains of *C. albicans* is extremely rare.[157,158] Only a single case in a HIV-negative woman is reported.[159] Although clinically resistant VVC due to in vitro resistant *C. albicans* is rare, the isolation of *C. albicans* strains with higher MICs to fluconazole is not infrequent.[160] In general, peak vaginal concentrations of fluconazole do not exceed 4–8 μg/mL; therefore, only isolates with a fluconazole MIC > 8 μg/mL should be clinically resistant to conventional doses of fluconazole. However, both clinical and research experience do not support this prediction, i.e., in vitro susceptibility testing is not validated or reliable in predicting clinical response. This is in sharp contrast to systemic candidiasis, as well as oral candidiasis, where a good correlation exists between in vitro susceptibility tests and clinical outcome. A partial explanation for this lack of correlation and to explain why isolates with higher MICs still respond may relate to proven in vitro synergy between fluconazole and organic acids, e.g., acetic acid normally found in the vagina.[161] Adding acetic to the yeast–fluconazole mixture converts fungistatic fluconazole to fungicidal and dramatically enhances its antiyeast activity potentially enhancing its in vivo effect. It should be emphasized that azole-resistant strains of *C. albicans* are similarly rarely the cause of RVVC.[149]

On the other hand, RVVC is not infrequently due to non-*albicans* species, the majority of which show reduced susceptibility to all azoles. *C. glabrata* is particularly common, and

approximately half the strains show reduced sensitivity to available azoles.[162,163] Boric acid 600 mg administered vaginally once daily in a gelatin capsule has been shown to be moderately effective in this clinically resistant infection.[163–165] Therapy should be continued until cultures are negative (usually 10–14 days), and when a history suggests RVVC, a maintenance regimen of alternate day and then twice-weekly boric acid should be prescribed. Unfortunately, there is still little experience published on the efficacy of this maintenance regimen, and the long-term safety of intravaginal boric acid has not been confirmed. *C. krusei* vaginitis is resistant to fluconazole therapy, but usually responds to boric acid or other azole therapy.[26]

Sobel et al. reported their experience with boric acid and 17% flucytosine topical therapy in women with azole-resistant vaginitis due to *C. glabrata*.[164] Boric acid was successful in approximately 70% of symptomatic patients, and if this failing, a success rate of >90% was achieved with a 2-week course of topical flucytosine. Flucytosine for vaginal use should be limited because of the potential for the acquisition of resistance. *C. krusei* isolates are resistant to flucytosine.

OVER-THE-COUNTER ANTIFUNGAL THERAPY OF PATIENT-DIAGNOSED VVC

In most industrialized countries, topical imidazoles and nystatins are available over the counter without the need for physician prescriptions.[166] The topical agents, in their own right, are undoubtedly effective and identical to other topical prescription antifungals. With rare exceptions, oral azoles are not available at present without prescriptions, although most are now generic and hence dramatically less expensive. The critical issue is the use of these readily available topical antifungal agents for self-diagnosed VVC. Multiple studies have consistently demonstrated the inability of many women to correctly self-diagnose VVC in the presence of vulvovaginal symptoms.[167] In the most recent study, Ferris et al. found that only 34% of women acquiring over-the-counter antifungals for presumed VVC actually had VVC. A history of previous clinically based diagnosis of VVC and reading the package label did not help women self-diagnose VVC properly. Unfortunately, ready access to these products is associated with wasted financial expenditures, unfulfilled expectations, and a delay in correct diagnosis for a substantial number of women. This entire problem could resolve overnight with future availability of a simple inexpensive *Candida* detection diagnostic tests.

VULVOVAGINAL CANDIDIASIS IN HIV-POSITIVE WOMEN

From the onset of the AIDS epidemic, both the prevalence and the significance of oral and esophageal candidiasis were recognized.[168] As the percentage and numbers of women with HIV grew in the 1980s, vaginal candidiasis was increasingly reported.[169,170] Without supporting data, RVVC was regrettably incorporated as an AIDS-defining illness.[171]

The increased prevalence of oral candidiasis occurred on the basis of the loss of oral mucosal CMI defense mechanisms, and the deficiency was thought also to apply to the vagina.[172] Furthermore, given the enormous quantities of broad-spectrum antibiotics administered for prophylactic and therapeutic purposes to women with HIV, together with the women's progressive debilitation, one might similarly predict the frequent occurrence of symptomatic *Candida* vaginitis, especially with severe immunodeficiency.

A 1987 report indicated that 24 HIV-infected women followed at the Walter Reed Army Medical Center had a history of unexplained chronic vaginal candidiasis for at least 1 year.[169] All the patients described had oral thrush and severe T-helper cell depletion and most were anergic. Within a 30-month follow-up, 80% of the patients developed other severe opportunistic infections. The authors emphasized that RVVC was the presenting complaint, predating the recognition of oral thrush, and was frequently the only clinical indication of severe underlying immunodeficiency. HIV-associated RVVC was considered unique in having only temporary symptomatic improvement following the use of intravaginal antifungal agents and in requiring constant therapy for control of symptoms. The authors concluded that HIV-positive women with RVVC were at serious risk for rapid progression to AIDS, as are males with recurrent oral thrush.[168] Rhoads et al. concluded that women with "chronic refractory" vaginal candidiasis should be tested for HIV, but did not define either word.[169]

A subsequent report described *Candida* vaginitis in 70% of an HIV-positive female cohort from Rhode Island.[170] In this study, VVC responded well to appropriate therapy, but had a tendency to recur. The authors also reported increased severity and duration of episodes of VVC.[173] More than half the women with new onset of increased frequency or severity of *Candida* vaginitis described their symptoms as originating 6 months to 3 years before the diagnosis of HIV infection had been considered. Over 90% of the women presenting with oral candidiasis had experienced new onset of increased frequency of vaginal candidiasis. The location and severity of *Candida* infections in these HIV-positive women were closely related to degree of immunosuppression at the time the infection developed as measured by CD4 counts. Thirty percent of HIV-positive women with only vaginal candidiasis and no oral disease had CD4 counts identical to those of HIV-positive women without evidence of mucosal candidiasis. The authors concluded that mucosal infections by *Candida* organisms occur in a hierarchical pattern (first VVC, then oral, and finally esophageal candidiasis) in women with HIV infection, and that recurrent, often severe, vaginal candidiasis was common with little or no suppression of CD4 cells.[173]

A major limitation of the above studies is the lack of information concerning diagnosis of *Candida* vaginitis. Any epidemiologic information based on the history only or on physical examination without KOH or culture confirmation is unreliable. In the absence of an HIV-negative control group, it is possible that RVVC in HIV-positive women with high CD4 counts, as described by Imam et al.,[173] reflects background VVC prevalence in a sexually active group of women still possessing a sense of well-being. Moreover, if progressive loss in mucosal immunity accompanies the decline in CD4 cells, one would anticipate a further increase in frequency of RVVC accompanying advanced AIDS, but none of the published reports have described this occurrence. Duerr et al. observed that the rate of vaginal carriage of *Candida* organisms did not increase until the CD4 count dropped below 200 cells/μL.[171]

Most of the data that accrued in the second decade of the HIV epidemic regarding VVC in HIV-infected women originated from cross-sectional studies, and even those based upon longitudinal cohort studies failed to measure the true attack rate of symptomatic VVC in both HIV-ART treated and untreated women.[174] Based upon epidemiologic definitions of asymptomatic VVC, but including women with both *Candida* microscopy positive and culture positive women, results indicate a small moderate increase in VVC in HIV-positive women not receiving ART.[175] Including positive microscopy in the epidemiologic definition of VVC was an attempt to differentiate VVC from vaginal colonization. Overall, the increased incidence of VVC in HIV-positive women was modest compared to the increased occurrence of oropharyngeal candidiasis.[176] Certainly, vaginal colonization is significantly more common in HIV-positive women, as is duration of colonization, both in contrast to *Candida* vaginitis. Higher HIV loads were significantly associated with increased odds of incident or persistent vaginal colonization and candidiasis.[176] CMI, as reflected by CD4 counts while significantly associated with increased odds of oral colonization and candidiasis, was not associated with vaginal colonization or candidiasis.[176] In contrast, Duerr et al., using a different definition for VVC, did find an association between lower CD4 count and VVC. Notably, regardless of the definitions used to characterize VVC, none of the studies have indicated that VVC is more severe or less likely to respond to therapy than in HIV-infected women.[175,177]

The microbiology of VVC in HIV-positive women appears identical to that of matched high risk HIV-negative women, although longitudinal studies indicate that with time and possible, but unmeasured, azole exposure, there is a gradual tendency to observe an increased frequency of isolation of non *albicans Candida* spp, notably *C. glabrata*.[178] Moreover, with time, a mild increase in isolation of fluconazole-reduced sensitivity *Candida* isolates of all species were found.[179] To date, these changes have not translated into altered treatment response.

As with other forms of lower genital ulceration and inflammation, *Candida* vaginitis has been associated with enhanced vaginal HIV shedding with increased genital-tract HIV RNA level.[180,181] Hence, VVC may facilitate HIC transmission, although its contributory role is unknown.

The issue of HIV testing in the presence of VVC was previously controversial.[182] Most women experiencing a single episode of VVC today are obviously not HIV infected and clearly do not require testing. Even in the case of women with RVVC, the issue is anything but clear, since the overwhelming majority of women with RVVC are HIV-negative. Only women with RVVC who have risk factors for HIV infection should be tested, but high-risk women should be tested anyway, regardless of the presence of *Candida* vaginitis.

Treatment of symptomatic *Candida* vaginitis in HIV-positive women is identical to that of HIV-negative women, i.e., uncomplicated VVC should be treated with short course of fluconazole (150 mg single dose) or topical azoles for short duration. In contrast, complicated vaginitis should be treated with longer duration oral systemic or topical regimens and maintenance weekly fluconazole should be used for RVVC.[177] Regardless of HIV serostatus, occasional failures occur due to fluconazole-resistant *C. glabrata* infection.

Treatment of asymptomatic VVC remains controversial. In HIV-negative women, antifungal therapy is generally not advised. In HIV-positive women with *Candida*-positive microscopy, because of associated enhanced HIV virus vaginal shedding,[181] an argument can be made for treating asymptomatic VVC so as to theoretically reduce the risk of HIV transmission, although little data of its utility are available.[183]

PREVENTION OF VULVOVAGINAL CANDIDIASIS

No measures are routinely required for all women undergoing or exposed to factors that may precipitate VVC, unless they reveal a history of RVVC. Even then, given the complex etiology of VVC, there are no universal steps that protect against all pathogenic mechanisms. Moreover, there are few studies evaluating widely used methods of prophylaxis.

The most obvious scenario is the receipt of antibiotics (systemic or local vaginal) in those women known to be susceptible to antibiotic-induced VVC. Postantibiotic VVC is certainly a common problem in general practice and women frequently resort to use of probiotic *Lactobacillus* spp to prevent and treat this. A recent study conducted in Australia by Pirotta et al.[184] used a four-arm study of oral lactobacillus, oral placebo, vaginal lactobacillus, and vaginal placebo in an attempt to prevent postantibiotic VVC. Unfortunately, both routes of lactobacillus administration failed to prevent postantibiotic prophylaxis. Many practitioners recommend prophylactic oral fluconazole 150 mg

not daily, but with the onset and combination of antibiotics, and possibly additional fluconazole dosing if duration of antibiotics is prolonged. No data has been published in support of this approach; moreover, given the expense involved, treatment should be highly selective, aimed at susceptible women only.

Fluconazole prophylaxis has already been discussed in relation to idiopathic RVVC.[149] However, other categories of secondary RVVC may benefit from fluconazole prophylaxis, often long term, for example, presence of underlying dermatosis lichen sclerosus or coexistent vaginitis, DIV, or BV. Frequently, multiple predisposing factors accumulate to result in secondary RVVC, e.g., underlying dermatosis in a postmenopausal women prescribed topical steroids as well as topical estrogen dramatically enhancing risk of opportunistic VVC (three risk factors) after a single supervening episode of VVC, it is reasonable to prescribe long-term suppressive fluconazole.

Preventable measures also depend upon the predisposing cause. Accordingly, poorly controlled diabetics can prevent exacerbations of symptomatic disease by controlling hyperglycemia. Likewise, when identified in individual women, avoidance of individual-specific dietary factors such as a candy binge, alcohol consumption, or diet high in refined sugars may be useful. As mentioned above, treatment of male partners with local or systemic antifungals is of no value. Finally, sexual behavioral factors have been suggested in some but not in the majority of women as contributing factors for RVVC. Occasionally, women report cessation of episodes of RVVC following major changes in sexual activity, e.g., cessation of receptive oral sex.

46 Pubic Lice and Scabies

Peter A. Leone

PUBIC LICE

The order Anaplura includes over 400 species of sucking lice, which are ectoparasites of mammals. Sucking lice are dorsoventrally compressed, wingless, and small, with retractable piercing–sucking mouthparts. One species is the cause of a common sexually transmitted disease (STD): pubic lice, or "crabs."

Three species of lice infest human beings: *Phthirus pubis,* the crab louse; *Pediculus humanus humanus,* the body louse; and *Pediculus humanus capitis,* the head louse. This chapter focuses principally on pubic lice, but head and body lice will be considered briefly for purposes of comparison.

HISTORY

Lice have been constant companions of human beings since antiquity. DNA analysis of lice suggests that lice specific to humans and lice specific to chimpanzees appeared 5.6 million years ago[1]. Israeli scientists confirmed that the warriors in Bar Kochba's Jewish revolt against Rome 18 centuries ago were afflicted with lice. These lice were morphologically identical to *P. capitis* (Anaplura: Pediculidae) that continue to afflict human populations today. The lice were discovered in the hair and clothes of archeological remains from caves in the Sudan desert.

LIFE CYCLE AND REPRODUCTION

Lice have five stages in their life cycle: egg (or nit), three nymphal stages, and the adult stage. All stages occur on the host. Sucking lice undergo a simple metamorphosis in which immature lice are morphologic miniatures of adults but have no reproductive ability.

The egg of the crab louse is smaller than the eggs of either the head or body louse, which measure approximately 0.8 mm long and 0.3 mm wide.[2] The nit is oval in shape and opalescent in color; it contains a cap (operculum) that comes off intact when the egg hatches (Fig. 46-1). An egg will hatch within 5–10 days after being incubated in the heat of the host's body. Interestingly, the young nymph emerges through the cap by sucking air into its body and expelling it from its anus until a cushion of compressed air is formed, which then pops the cap open and allows the nymph to escape.[3] Over a period of 8–9 days, the nymph produces three molts. The louse remains on the body and requires frequent blood meals after having hatched. When lice reach adulthood, mating occurs after approximately 10 hours and continues until the lice die. The female louse lays approximately four eggs per day.

In the case of the body louse, the egg case is attached to hair or clothing by a cement like material secreted by the female louse. After hatching, the empty shell may stick to hair or clothing for some time. It is often difficult to remove by washing or shampooing or by vinegar or organic solvents. If all else fails, the empty egg cases are eventually moved away either by growth of the hair, by the use of a fine-tooth comb, or by cutting the hair.

Little is known about the actual life span of the adult louse. Under artificial conditions, lice have survived for about 1 month. Ambient temperature, humidity, and availability of human blood are thought to influence the life span of all types of human lice. Off the host, all stages of the louse can be expected to die within 30 days, regardless of temperature. Unfed adult head and body lice can survive for up to 10 days, whereas adult pubic lice rarely survive more than 24 hours off the host.[4] Lice leave the host voluntarily only when the host has died or becomes febrile or when there is close personal contact with another host.

The life of the louse is dependent on human blood. When ready to feed, the louse anchors its mouth to the skin, stabs an opening through the skin, pours saliva into the wound to prevent clotting, and pumps blood from the wound into its digestive system. During feeding, dark-red feces may be deposited on the skin.

The pubic louse has greatly enlarged middle and hind legs and claws; the abdomen is wider than it is long, giving it the appearance of a crab (Fig. 46-2). Pubic lice are about 1 mm in length. Adult head and body lice have a longer body

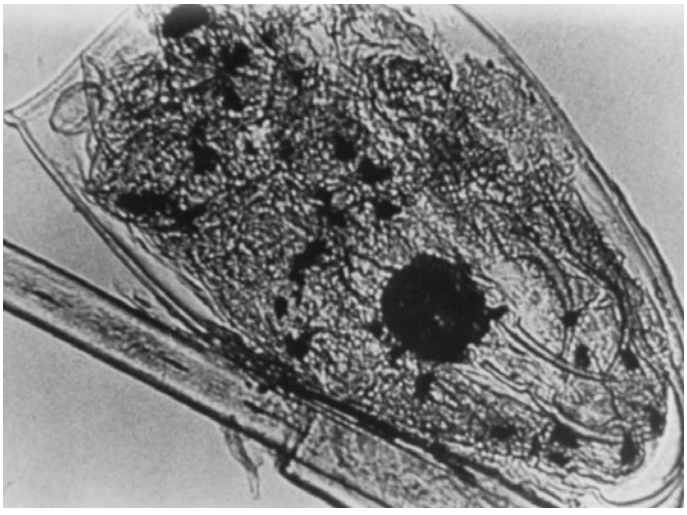

FIGURE 46-1. Close-up micrograph of a louse nit (egg).

FIGURE 46-2. Pubic louse after a recent blood meal. *(Courtesy of V. D. Newcomer.)*

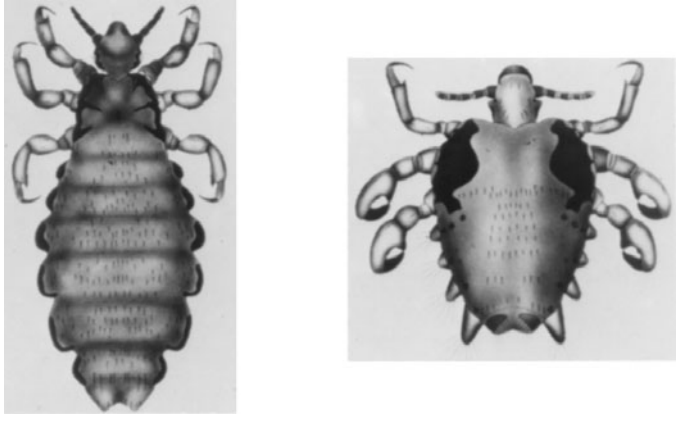

FIGURE 46-3. Comparison of gross structure of *(left)* the head louse and (*right*) the pubic louse.

(approximately 3 mm in females and 2 mm in males) and relatively shorter middle and hind legs (Fig. 46-3). The pubic louse has three parts: a head (with a pair of eyes), a thorax (with three pairs of legs), and a segregated abdomen. At the

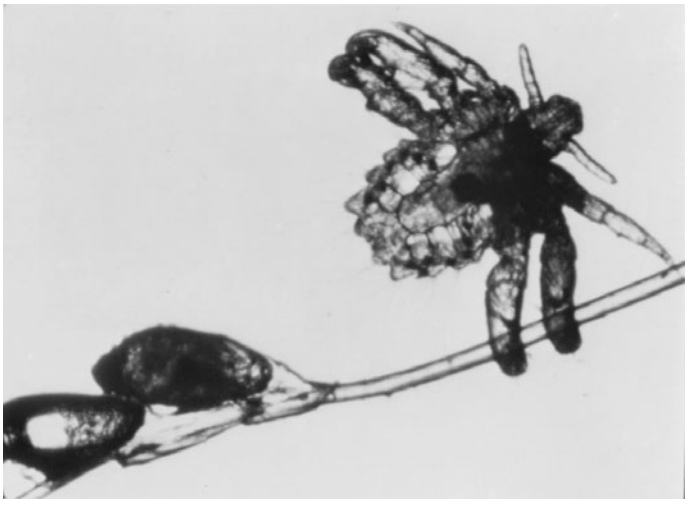

FIGURE 46-4. Pubic louse and nits on a hair shaft. *(Courtesy of V. D. Newcomer.)*

FIGURE 46-5. Adult pubic lice and nits.

end of each leg, there is a hook-like claw and opposing thumb, that enable the louse to maintain its hold on hair (Fig. 46-4).

A difference between body and head lice and the pubic louse involves their grasping ability. The grasp of the pubic louse's claw matches the diameter of pubic and auxiliary hairs; hence, pubic lice may be found not only in the pubic area (Fig. 46-5) but also have been recovered from the axillae, beard areas of the face, eyelashes (Fig. 46-6), and eyebrows.[5,6] It is rare in these other areas and is probably mechanically moved to these areas via the fingers. The diameter of the head louse's grasp seems to be uniquely adapted to the diameter of the scalp hair. Therefore, it is very difficult to transplant head lice to other areas of the body.

Another difference between the species is that of egg laying. Adult female pubic lice and head lice glue their eggs to hairs, while the female body louse usually oviposits on the fiber or in the seams of clothing.

FIGURE 46-6. Adult pubic lice and nits on eyelashes.

The third difference is the rate of movement. Pubic lice seem to be the most sedentary. Nuttal and Payot[7] recorded pubic lice moving at a maximum of 10 cm in a day. Body lice can wander as much as 35 mm in a 2-hour period. Temperature, ambient humidity, and availability of a blood meal also influence the rate of movement. Lice do not like light and will move frantically to escape light.

EPIDEMIOLOGY AND TRANSMISSION

It is estimated by sales figures on pediculicides that more than 3 million cases of pediculosis are treated each year in the United States.[8] Most cases are due to head and pubic lice infestations. Infestation by body lice seems to be less common in this country. Infestations with pubic lice are more common in people of low socioeconomic status.[9] Epidemics of louse-borne relapsing fever and epidemic typhus are now rare since the body louse is the only species implicated as their vector. Mass epidemics of these diseases have resulted when large populations have lived in unsanitary conditions as in times of famine, disaster, and war.

"Vagabond's disease" is a diagnosis made in persons who continually harbor these lice and whose skin becomes hardened and darkly pigmented as a result of frequent louse bites and patient response.

P. pubis infestation is frequently associated with the presence of other sexually transmitted infections, and patients presenting with pubic lice should be examined for such infections.[10]

Human lice are transmitted from one person to another primarily by intimate contact. Although all types of human lice are relatively host-specific, crab lice occasionally have been reported to infest dogs. Both head and body lice are transmitted by sharing personal articles such as hairbrushes, combs, towels, or clothing. Pubic lice do not seem to spread as rapidly as other human lice when off the host. They have a shorter life span (24 hours compared with several days for other lice) and their movements are more lethargic. Sexual transmission is considered the most important means of pubic lice transmission. However, there are documented cases of transmission from toilet seats, beds, and egg-infested loose hairs dropped by infested persons on shared objects.

The population with the highest incidence of pubic lice is similar to that of gonorrhea and syphilis: single persons, ages 15–25 years. Prevalence of pubic lice infestation declines gradually to age 35 and is rare in persons older than age 35. Head lice are most common in children up to 6 years of age.

CLINICAL MANIFESTATIONS

Sensitivity to the effect of louse bites varies with the individual. When previously unexposed persons are bitten, there may either be no signs or symptoms or a slight sting with little or no itching or redness. At least 5 days must pass before allergic sensitization can occur. At that point, the main symptom is itching, which leads to scratching, erythema, irritation, and inflammation. An individual who has been bitten by a large number of lice over a short period may have mild fever, malaise, and increased irritability.

Ectoparasites produce a variety of immunologic responses in the host.[11] Apparently, many persons eventually develop some degree of immunity to the bite of the louse. Persons infested for a long time may even become oblivious to the lice on their bodies. The opposite may also occur. Excessive scratching may lead to superinfection. Characteristic small "blue spots" may appear in the skin as a result of the crab louse bites; these persist for several days. A tubo-ovarian inflammatory mass attributed to *P. pubis* has been reported.

DIAGNOSIS

Diagnosis of lice infestation is made by (1) taking a careful history from the patient, (2) considering lice infestation as a possible or probable cause of the patient's signs and symptoms, and (3) careful examination of the patient. Both adult lice and their eggs (nits) are easily seen by the naked eye (see Figs. 46-5 and 46-6).

Head lice characteristically are found on the scalp surface with the nits attached to the hair. Since scalp hair grows at a rate of about 0.4 mm per day and nits of the head louse usually hatch within 9 days, most of the unhatched nits are within 5 mm of the scalp surface. Nits on scalp hair are usually cemented at an oblique angle, which helps to distinguish them from foreign material that slides up and down and frequently surrounds the hair.

Upon examination of the groin or pudendal area, pubic lice may be perceived as scabs over what first were thought to be "scratch papules." When taking a closer look, if nits appear

on the hairs, the proper diagnosis becomes obvious. When no adult lice are available, the demonstration of nits under the microscope will also confirm the diagnosis.

When one sees with the naked eye white flakes on the hair, other possible considerations are seborrheic dermatitis (dandruff flakes), hair casts, solidified globules of hair spray, and certain accretions on hair shafts.

MANAGEMENT

Treatment and disinfection regimens should be individualized. Ideally the regimen should employ a pediculicide that will effectively kill both the adults and the egg.[12] Patients should be instructed to avoid intimate contact with their sexual partner until they have been treated and both individuals have been seen in follow-up. Examination of other household contacts of the patient should also be made so that both source and spread cases can be treated.

Recommended treatment regimens are listed in Table 46-1. In addition, all bedding, towels, and clothing should be washed. Some patients may require a second application of topical therapy in 3–7 days after the initial treatment.[13] Infestation of eyelashes should be treated by application of an occlusive ointment such as petroleum jelly twice a day for 10 days. Other agents that may be effective in treatment of *Pthirus pubis* are 0.5% malathion, 0.5–1% carbaryl, and 0.2% phenothrin.[13]

Since 2000, to our knowledge, there have been no new treatment trials published concerning the treatment of *Pthirus pubis*. However, there were three randomized clinical treatment trials assessing the treatment of head lice. In one comparative trial conducted in Florida, 0.5% malathion compared to 1% permethrin demonstrated a clearance rate of 98% with malathion compared to 55% with permethrin.[14] Permethrin coupled with oral TMP/SMX enhanced the efficacy of therapy with permethrin.[15] Combing did not improve clearance in response to therapy with permethrin.[16] One study assessed both in vitro susceptibility of lice and in vivo response to topical lice treatment in children in Bath and Bristol, England. Both cohorts of children had lice that demonstrated a decreased mortality rate in response to permethrin and malathion.[17] Children in Bath were treated with malathion with a 36% cure at 48–72 hours. Children in Bristol were treated with permethrin and had a 13% cure at 48–72 hours. The sample size of this study was only 30 children, but it suggests the presence of dual resistance to permethrin and malathion in these cohorts.

Additional in vitro evaluations were performed by Pollack et al.[18] who sampled head lice from children in Massachusetts, Idaho, and Malaysian Borneo. They found that among lice in the United States, the mortality was ~50% in response to treatment with permethrin. The mortality rate was unaltered by increasing concentrations of drug. Conversely, the lice from Malaysia had a 37% mortality rate at the lowest concentrations of permethrin. Their fatality increased linearly with increasing permethrin concentrations to a maximum mortality rate of about 95%. This study used different evaluation times for the U.S. and Malaysian lice because of baseline differences in survival times. Regardless, this study suggests possible emergence of drug resistance in U.S. head lice. The concern raised by these results is amplified by another in vitro analysis demonstrating that lice with permethrin resistance also have resistance to sumithrin and a newer agent for treatment, deltamethrin.[19] The emergence of drug resistance in head lice throughout the world is concerning but the implications for the treatment of *Pthirus pubis* are unclear. A case of pubic lice resistant to pyrethrins in vitro was reported but the patient demonstrated clinical clearance with 5% permethrin.[20] The current recommendations for treatment of *Pthirus pubis* are listed in Table 46-1. Since 1996, there have not been any studies in the English language documenting significant treatment failure in the management of *Pthirus pubis*.

Table 46-1. Treatment Regimens from *Pediculosis pubis*

	Average Wholesale Price in U.S. $	Instructions for Use
Permethrin 1% crème rinse (2 oz)	7.67[a]	Apply to affected areas and wash off after 10 min
Lindane 1% shampoo	3.00–14.72[b]	No longer recommended as first- line therapy due to toxicity. Should only be used as alternative due to inability to tolerate other therapies.
		Apply to affected areas and wash off thoroughly after 4 min
Pyrethrins with piperonyl butoxide		Apply to affected area and wash off after 10 min
(2 oz) shampoo	1.67[c]	
(5.5 oz) mousse	9.20[c]

The use of 1% gamma benzene hexachloride (lindane) has several disadvantages and is no longer recommended as a first or second line of therapy. It can be absorbed percutaneously when applied to severely excoriated skin. Case reports have alluded to mild signs and symptoms of neurotoxicity when it has been ingested, applied too frequently, not washed off as directed, or used on massively excoriated skin. In one study, 9% of a single dose was found in the urine in a badly excoriated patient in 5 days following the treatment. No other studies, however, have shown blood, tissue, and urine levels.[21,22] Nonetheless, blood dyscrasias such as aplastic anemia and leukopenia have been described after use of lindane in agriculture and against ectoparasites in animals and humans, and lindane is reportedly cytotoxic in vitro for human hematopoietic progenitor cells.[23] In particular, lindane use should be avoided in small children, pregnant women, and individuals with massive excoriations or multiple lesions over the scrotum.

Itching is an important feature of all lice infestations. The initial treatment with a pediculicide may be effective for killing both the adult lice and the eggs, but the itching may continue because of an allergic reaction and/or irritation. The possibility of posttreatment pruritus should be discussed with the patient; a mild topical antipruritic/anti-inflammatory cream or ointment may need to be prescribed. The patient should be reevaluated 4–7 days after initial treatment. Attention to these considerations is crucial, since it often prevents excessive pediculicide use and may prevent parasitophobia and feelings of "being unclean."

CONTROL ASPECTS

In discussion of control of epidemic lice infestations with administrators of schools or institutions or control measures with and for an individual, the set of guidelines that can be recommended are as follows:

1. Document that lice are truly the cause of the problem.
2. Diagnose, which louse species is involved.
3. Establish an effective therapeutic regimen, including
   a. treatment of the individual with a pediculicide that kills adult lice and the nits;
   b. environmental disinfection;
   c. treatment of household and intimate contacts;
   d. reassurance to the infested persons that they are not "unclean" and that they will get better.

Ectoparasites continue to be a common cause of skin disease throughout the world. Topical agents are generally effective in management but are accompanied by sometimes-serious side effects and resistance has been documented to several agents. *Pthirus pubis* is usually effectively treated with topical agents, but rising rates of resistance in head lice warrant concern regarding future efficacy of current topical agents in the treatment of pediculosis pubis.

SCABIES

Scabies is one of the great epidemic diseases of humankind.[24,25] The risk of outbreaks or epidemics of scabies have been associated with wars or other events that lead to the disruption of social order. Scabies have been linked to the death of King Herod the Great (73–4 BC) and the "spider" who "sat down beside her and frightened Miss Muffet away."[26,27] It is caused by the scabies mite or "itch mite" *Sarcoptes scabiei* (Fig. 46-7). Transmission of the mite can occasionally occur by touching an infected subject, but most commonly infection requires prolonged physical contact, i.e., sharing a bed or sexual contacts. The mite was first discovered by Bonomo in 1687, but this knowledge was not generally accepted until the details were worked out by Von Hebra in the nineteenth century. The pathophysiology of infection was most clearly demonstrated by Mellanby[29] in his elegant studies using conscientious objectors during World War II. Mellanby watched asymptomatic burrowing of the mites for 3–6 weeks, followed by the development of local and systemic pruritus and increased inflammation around the burrow. He also demonstrated that experimental reinfestation would produce itching within hours. These experiments provided very strong evidence that the patients had made an immune response. The timing of the response following reinfection and the associated itching implied that the mites had induced immediate hypersensitivity. Mellanby suggested that this immune response could be important in controlling infestation and that scratching was an effective method of dislodging the mites from the skin.

Adult scabies mites have a body structure and short legs that facilitate entry into the skin. Like all acarids, they have four pairs of legs and lay eggs. They are a member of the class that includes spiders, ticks, and chiggers, but they are most closely related to dust mites of the genus *Dermatophagoides*. The adult female is approximately 400 μm in length and is best seen with a hand lens. Mites can move at a rate of ~2.5 cm/min on warm skin when choosing a site to burrow. They penetrate down to the stratum granulosum and then extend their burrows by half inch or less over the next month. Mite burrows concentrate on the hands and wrists but they can also be found on axillary folds, breasts, the periumbilical area, and the penis. Arlian and Vyszenski-Moher[29] have demonstrated that scabies mites, especially the adult females, are selectively attracted to several lipids that are found in human skin. The lipids include odd-chain-length saturated (e.g., pentanoic and lauric) and unsaturated (e.g., oleic and linoleic) fatty acids as well as cholesterol and tripalmitin. The results suggest that lipids present on the skin of humans and other mammals may influence both the incidence of infection

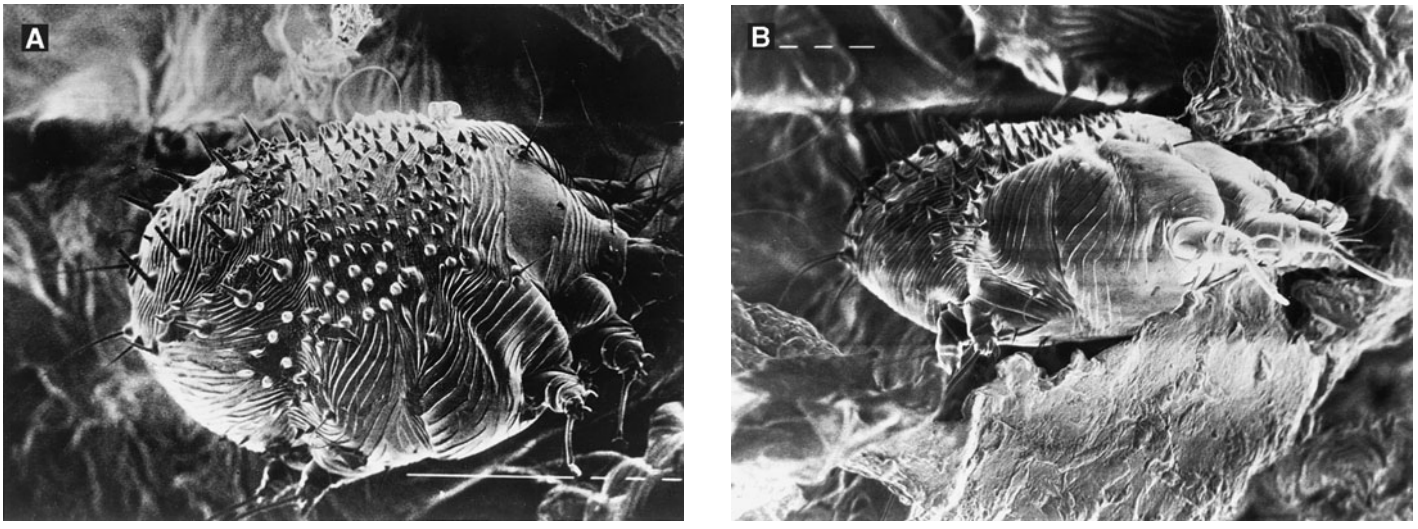

FIGURE 46-7. (A. & B.) Scanning electron micrographs of *Sarcoptes scabiei*. *(Courtesy of L. Arlian, Wayne State University.)*

and also the distribution of mite burrows on the body. Once established in a burrow, the mites can lay eggs daily. The eggs are approximately 100 μm in length and can progress to the adult stage in about 10 days. The adult male is short-lived but the females can live up to 6 weeks. Although the potential for multiplication is enormous, the average number of adult females on an infected normal host is less than 20. Adult mites deposit both eggs and fecal pellets in the burrows, and by analogy with dust mites, it is likely that digestive enzymes in the fecal pellets are important antigens for the immune response to scabies mites.[30,31]

IMMUNOLOGY AND PATHOGENESIS

Investigation of the immunopathology before 1980 demonstrated a cellular infiltrate and immunoglobulin deposits around lesions as well as circulating immune complexes. It had also been reported that the lesions contained IgE deposits. In 1980, Falk and Bolle[32] reported that patients with scabies had elevated total serum IgE and IgE antibodies to *D. pteronyssinus.* This result could have meant that scabies was common in atopic individuals or that infestation with *S. scabiei* produced an immune response including IgE antibodies that cross-react with dust mites. The latter view has been supported by studies showing extensive cross-reactivity between scabies mites and dust mites involving several different proteins.[33] Furthermore, in rabbits it has been demonstrated that immunization with *D. pteronyssinus* extract can protect the animals against infestation with scabies.[34]

Although it is now clearly established that the scabies mite induces IgE antibodies and immediate hypersensitivity, it is not certain that this response and the associated pruritus play a role in controlling infestation. The lesions around a mite burrow are infiltrated with inflammatory cells.[35,36] From experimental work with ticks, it is likely that the cellular immune response to scabies is comparable with cutaneous basophil hypersensitivity in experimental animals and that eosinophils and basophils could play a direct role in killing mites.[37] Although the immune response to scabies mites includes IgE antibodies, the relationship to atopy is not clear. Thus, there are no reports that atopic individuals are significantly more likely to become infected. Equally, there is no clear evidence that becoming allergic to dust mites is protective against scabies in humans, as would be predicted from the results in rabbits.[34] The lesions are often eczematous or urticarial; in addition to the intense pruritus, all of these are in keeping with a pathogenesis related to immediate hypersensitivity.[38]

Applying dust mite fecal antigens to the skin of patients with atopic dermatitis will induce a patch of eczema and a characteristic dermal infiltrate of eosinophils, basophils, and T cells.[39] A relation between atopic dermatitis and scabies has been reported. On the other hand, almost all adults with atopic dermatitis have high-titer IgE antibodies to dust mites that would be expected to cross-react with scabies mites and make serologic investigation difficult. In other cases of scabies, the lesions include urticaria or nodules as well as papular lesions. All of these could be related to a complex immune response including mast cells sensitized with IgE antibodies and a cellular response induced by cytokines released from Th2 cells and/or mast cells.

EPIDEMIOLOGY

Epidemics of scabies appear to cycle at approximately 10- to 30-year intervals.[24,25] The causes of epidemics are not clear but poverty, sexual promiscuity, waning immunity, travel, and other factors may all contribute. Scabies can occur in any population but is reported to be less common among African Americans. The infestation appears to require prolonged contact for transmission and is thus more likely when partners spend the night together. Among young

adults, sexual transmission is the most likely method of infection; however, tracing routes of infection is made difficult by the long, asymptomatic "incubation" periods. If multiple members of a family develop itching, the diagnosis is usually straightforward, and unlike most other venereal diseases, scabies can be transmitted by nonsexual contact within a family. Casual contact outside families is unlikely to transfer mites except from crusted scabies. For example, although scabies is frequent in school-age children, transmission in school is uncommon. Transmission to hospital staff is also rare but some cases have been reported. Crusted scabies can give rise to cases among hospital staff. When this happens, the infestation in these individuals is usually localized and not severe. However, occasional case reports have been made of severe scabies contacted from a patient with crusted scabies.[40] In another case where the scabies was lindane resistant, 12 people were infected before the patient was cured with permethrin.[41] Fertile adult female mites generally transmit infection, and the heavier the infestation, the more likely transmission is to occur.

Transmission can occur to humans from mange in animals. In the dog, mange is caused by *S. scabiei* var. *canis*. This mite is very similar to the human scabies mite morphologically, but infection of humans is generally short-lived, lasting some 3–6 weeks (compared with the "seven-year itch" attributed to *S. scabiei* var. *hominis)*. The fact that infestation with mites derived from an animal does not give rise to typical burrows and is relatively short-lived may reflect differences in the mites. Thus, they may be attracted by different fatty acids and may be more susceptible to killing by a basophilic or eosinophilic response in the skin. However, detailed studies of the killing of animal mites or the more severe variants of human scabies have not been carried out. Infection of several members of a family from a newly acquired animal can occur, but human-to-human transfer of the dog mite is thought to be rare. Thus, animal-acquired scabies will only produce a few cases and does not usually require treatment of other members of the family.

CLINICAL MANIFESTATIONS

The most common manifestation of scabies is pruritic, papular, eczematous lesions on the sides of the fingers and in the interdigital webs (Figs. 46-8 and 46-9). The burrows are often diagnostic and sufficient to recommend specific treatment. Burrows may also be clearly visible on the wrists and elbows. By contrast, lesions elsewhere on the body are papular, nodular, crusted, or lichenified (Fig. 46-10 and Fig. 46-11). In all situations, the lesions are inflamed and extremely pruritic; the pruritus may initially be restricted to the lesions but often becomes generalized. Diagnosis depends on thinking of scabies, demonstrating the mites by scraping or biopsy, and/or observing a response to specific therapy. Itching does not begin for 3–4 weeks after initial infestation, but reexposure may produce itching within hours.

SPECIAL FORMS OF SCABIES

Scabies can be difficult to diagnose both because of the wide range of skin lesions and because of atypical distribution. Some special forms are worth describing, but scabies needs to be in the differential diagnosis of all pruritic skin diseases.

Nodular scabies

Although unusual, nodular scabies is important to consider because the mildly pigmented, pruritic nodules can persist for months. Clinically, biopsy of the lesions may be necessary to exclude lymphomas of the skin. Diagnosis of scabies may become obvious from biopsy, but sometimes it will not. It is interesting that some cases of chronic atopic dermatitis develop similar nodules. In cases where the diagnosis is not clear from inspection, scrapes, or biopsy, it has to come from a history of scabies in a contact or a trial of specific treatment.

FIGURE 46-10. Grouped excolorations due to scabies on the lower buttocks. Simulating dermatitis herpetiformis.

FIGURE 46-11. Scabies of the penis. Pyoderma of the penis is highly suggestive of scabies.

Scabies incognito

Like all forms of inflammatory dermatitis, scabies responds to steroids either topically or systemically. In most cases, this response is so poor that the diagnosis becomes obvious. However, in some cases steroid treatment may obscure the diagnosis, leading to a more chronic and widespread form that is easily confused with other generalized forms of eczema. These patients remain infectious, so they may come to light because of infection in other members of the family.

Scabies in infants

In infants infection with scabies can give rise to failure to thrive or to generalized eczema. In young children widespread vesicles with an impetiginous appearance or secondary infection with *Staphylococcus aureus* is common.[42,43]

Crusted or Norwegian scabies

Crusted scabies is characterized by exuberant scaling lesions that are heavily infested with mites. The term *Norwegian scabies* refers to the country of original description of the syndrome and should be replaced by the more descriptive term *crusted scabies*.[44] The diagnosis is easily made once the possibility is considered. Unlike those with classic scabies, these patients can infect through casual contact. Whether this simply results from the large number of mites present or reflects a different strain of mites is not clear. However, most individuals who become infected because of contact with a case of crusted scabies develop typical scabies, suggesting that it is the host response that is abnormal. Detailed studies on the immunology of the response to crusted scabies have not been reported and would be interesting. The disease is seen commonly in patients who are physically or mentally disabled but also in patients with a defined immunologic defect or who are on immunosuppressive treatment. Therapy may require supportive treatment and antibiotics as well as repeated courses of specific treatment with acaricides.

■ SCABIES IN PATIENTS WITH HIV/AIDS

The immune response to *S. scabiei* is responsible for much of the symptomatology of the infestation as well as for its control. Thus, it is hardly surprising that the clinical spectrum of scabies is different in patients with AIDS than it is in those with normal immune systems. Although firm data are lacking, it is likely that a disproportionately large number of AIDS patients develop crusted scabies.[45–51] Although scabetic involvement of the face and scalp is relatively rare in normal adult hosts, AIDS patients often present with lesions in these areas. Likewise, the nails are involved with greater frequency than they are in normal hosts.[46,48] Unusual presentations of scabies in immunocompromised hosts may invite confusion with Darier–White disease (keratosis follicularis),[46,48] in which scaly papular lesions develop on the seborrheic areas of the body, including the trunk, face, scalp, and groin.[52] On the other end of the spectrum, patients may present with generalized pruritus and few lesions.[48] Scabies should also be considered in the differential diagnosis of AIDS patients with psoriasiform lesions, and some cases have been diagnosed initially as eczema.[49]

Pruritus is a hallmark of scabies in normal hosts, and even in patients with AIDS, pruritus may be quite marked. In other patients, however, perhaps as a consequence of a blunted immune response, pruritus may be markedly decreased, and this phenomenon seems to be associated with the conversion to crusted lesions.[46]

In AIDS patients as well as others, lesions of crusted scabies contain large numbers of mites, and the condition is highly contagious. Several cases of nosocomial transmission to other patients and to health-care workers have been reported.[46] Transmission has occurred even in settings

wherein the disease was quickly recognized and treated.[40] Crusted scabies results in a dramatic breakdown of integumentary defenses. When combined with the systemic immunodeficiencies of AIDS, it is hardly surprising that bacteremias have resulted. In addition to the usual bacterial pathogens associated with scabies, *S. aureus* and group A streptococci,[43] other streptococci, and gram-negative rods including *Enterobacter cloacae* and *Pseudomonas aeruginosa* have been recovered from the blood of septic AIDS patients with scabies. Although some authors have recommended prophylactic antibiotic treatment of scabetic AIDS patients,[49] it would seem that careful surveillance and a high level of suspicion are more appropriate in this group.

Treatment of crusted scabies in AIDS patients often requires prolonged application of scabecides. Weekly applications of lindane over 6 weeks have been successful in individual cases[48,49,51] as have two or three applications at intervals of 48–72 hours.[48,52] Permethrin has been used in a smaller number of cases.[55] Concomitant use of a keratinolytic agent such as 6% salicylic acid is recommended.[48]

Difficulty is often encountered in treating crusted scabies in AIDS patients because of the high mite load and because of the difficulty in obtaining adequate penetration of topical scabecides scabicides through the crusts. Thus, considerable interest has been generated in the oral treatment of scabies with ivermectin. Ivermectin is a derivative of one of the avermectins, a group of macrolide lactones with broad antiparasitic activity. It is widely used in the treatment of human onchocerciasis. In small series, the drug has been administered as a single oral dose of 200 μg/kg with excellent results, even in cases recalcitrant to topical therapy.[40,45,47] Multiple administrations of the same dose have been used in some patients as well.[55]

SCABIES AS A SEXUALLY TRANSMITTED DISEASE

That scabies is reliably transmitted during sexual intercourse is not questioned.[56] Although not all cases of adult scabies are so acquired, the disease is recognized as sexually transmitted.[56–58] As a consequence of this epidemiology, one can make certain clinical assumptions about the disease. First, because the sexually transmitted infections are diseases of lifestyle, individuals with one STD are at significantly higher risk of others to be infected. Thus, patients diagnosed with scabies should be evaluated for other STDs (e.g., chlamydial infection, HIV infection) that may be clinically silent but have greater eventual clinical significance.[56,57] Second, close household contacts and, particularly, sexual partners within the past month should be examined and treated if necessary.[57]

DIAGNOSIS

Typical scabies occurring within a family and presenting with burrows visible on the hands may be obvious by the time the patient has finished describing the symptoms. Furthermore, many atypical cases can be diagnosed because of an associated typical case that responds to specific treatment. In the isolated atypical case, the differential diagnosis includes many different pruritic dermatoses. Since the lesions of scabies can be eczematous, urticarial, or nodular, the list includes contact dermatitis, atopic dermatitis, infected atopic dermatitis, multiple insect bites, chiggers, dermatitis herpetiformis, papular urticaria, chronic urticaria, and mastocytosis.

TECHNIQUES FOR IDENTIFYING MITES IN LESIONS

Using a hand lens to examine burrows is a standard practice. Burrows can be made more easily visible by allowing them to take up ink. After rubbing ink from a fountain pen on the area, the ink should be wiped off with alcohol, and ink in the burrows becomes visible[59] (Fig. 46-12).

Scraping of the skin with a no. 15 scalpel blade should be sufficiently vigorous to disrupt the top of burrows or papules.[60] The scrapings are transferred to a slide, covered with mineral or immersion oil and a coverslip, and examined for mites, eggs, and fecal pellets under a microscope (×20 or ×100) (Fig. 46-13). Samples can also be obtained from lesions using a needle or a curette.

Biopsy of atypical lesions may be helpful to identify mites or their eggs. However, it is important to remember that the typical adult case has only 12 live mites, so biopsies are only likely to be helpful if they are of the inflamed lesions. In general, punch biopsies are used, but an epidermal shave biopsy may be simpler and can often be carried out without local anesthetic on even a relatively uncooperative patient.[61]

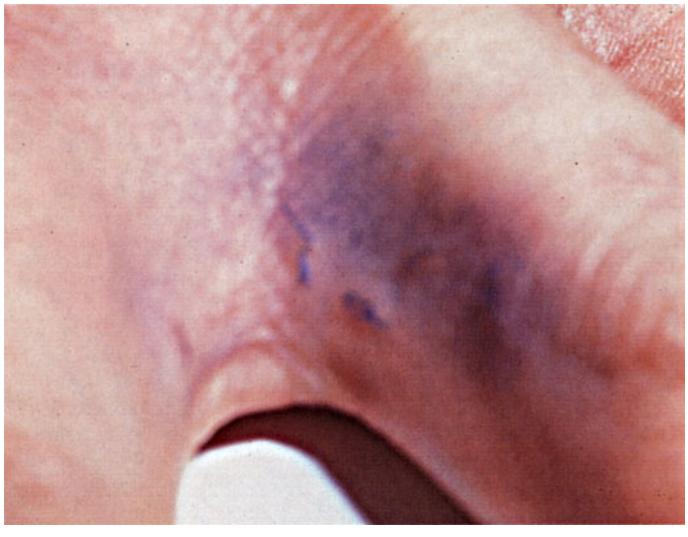

FIGURE 46-12. Intradermal burrow of scabies demonstrated by coating the skin with ink, then wiping away surface ink, leaving the intradermal burrow filled with ink.

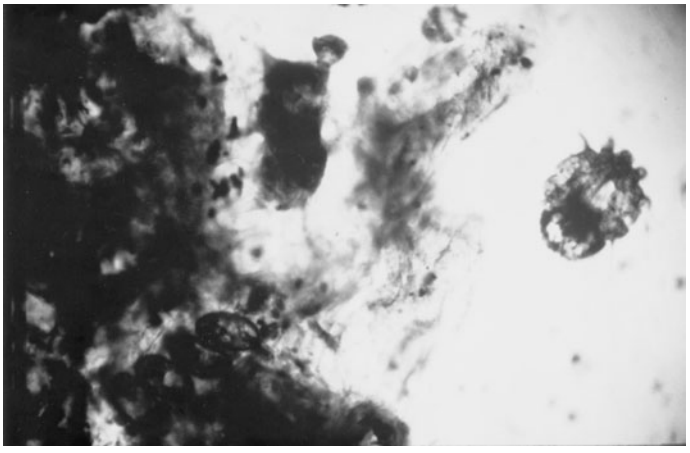

FIGURE 46-13. Skin scrapings of unexcoriated papules fortuitously disclose adults, larva, eggs, and fecal pellets, any of which would be diagnostic.

Table 46-2. Treatment of Scabies with 5% Permethrin Cream

- Massage cream in the skin from head to feet (30 gm is sufficient for an adult).
- Remove cream by washing after 12 hours.[a] Family and sexual partners should be treated simultaneously.
- Patients may experience burning of the skin and increased itching after application. In addition, patients should be warned that itching may persist for days or weeks after successful treatment.

THERAPY

Regimens for the treatment of scabies are presented in Table 46-2. Although not studied in randomized controlled trials, treatment of all close contacts and housemates of persons with scabies and washing bedding, towels, and clothing in warm to hot water are generally recommended. Items that cannot be washed should be isolated from use for 3 days. Since 1996, five randomized, controlled clinical trials of scabies treatment have been reported in the English-language literature.[62–65] Usha et al.[26] performed an important study addressing the relative efficacy of topical permethrin and oral ivermectin. They found that a single topical dose of permethrin produced a clinical cure rate for scabies (97.8%) that was superior to that produced by a single dose of ivermectin (70%). However, two doses of ivermectin administered at a 2-week interval were as effective as a single dose of topical permethrin.

In a comparison of topical lindane and oral ivermectin, 53 patients were enrolled in the study and were randomized to follow a blinded treatment regimen.[27] Only 43 patients completed the study, and final results were determined by as-treated analysis. This study suggested treatment equivalency between these medications after administration of two courses of therapy separated by 2 weeks. On clinical evaluation, the rate of cure of signs and symptoms of scabies was 95% for ivermectin and 96% for lindane. This study was limited by low statistical power. Madan et al.[62] compared ivermectin (200 mg/kg as a single dose) with 1% lindane lotion, with 180% of patients who were given ivermectin demonstrating a marked clinical improvement at 4 weeks of therapy, compared with 44% of patients given lindane lotion. Their study suggests that ivermectin may be a better treatment choice than lindane because of the good clinical response, lower toxicity, and improved adherence associated with ivermectin. A study conducted in Vanuatu compared benzyl benzoate with a single dose of oral ivermectin (200 mg/kg).[66] There was no statistically significant difference between the findings in the two arms in the study. The reported cure rate was low, with a cure rate slightly better than 50% noted 3 weeks after treatment initiation. The study was limited by a 27% rate of failure to return for follow-up by the single dose of ivermectin administered and by the short-term follow-up. Several other clinical studies have been conducted. One retrospective comparative study analyzed the outcomes of 39 HIV-infected inpatients with 60 episodes of scabies treated with benzyl benzoate, ivermectin, or a combination of benzyl benzoate and ivermectin.[67] Benzyl benzoate achieved a cure in 9 (47.4%) of 19 patients; ivermectin, in 10 (62.5%) of 16 patients; and combination treatment, in 4 (100%) of 4 patients.

Of interest, a cure was not achieved for any of the four patients with crusted scabies who received either treatment alone. All the patients who received combination treatment had been given a diagnosis of crusted scabies, and, for all these patients, a cure was achieved using a combination of topical benzyl benzoate and oral ivermectin. This study provides some preliminary evidence for the use of combination treatment for severe scabies in HIV-infected patients. Several open-label studies of ivermectin for the treatment of patients with uncomplicated scabies have been published since 1996.[68–71] The studies evaluated 1–2 doses of ivermectin (200 mg/kg separated by 7 days). In the largest study, which included 120 patients, the clinical response rate, as determined by as-treated analysis, was 88% after administration of 1 dose of ivermectin. After 4 weeks and administration of 2 doses of ivermectin, the cure rate increased to 100%.[68] There have been reports of several other open-label studies that involved smaller patient cohorts treated with ivermectin (200 mg/kg) given in 1–2 doses, with cure rates of 76–100% noted.[66,67,69] These studies included few cases of crusted scabies. In a cohort study, 20 patients with crusted scabies were treated with 1–3 doses of ivermectin (200 mg/kg) combined with a topical scabicide and a keratolytic agent. Eight of

20 patients had an initial complete response, and 8 of 10 patients had a response to three doses of ivermectin.[72]

Finally, in a study of 10 patients with uncomplicated scabies, a complete response was seen in all 10 patients after receipt of 3–4 treatments with topical 1.8% ivermectin cream.[73] In vitro testing of six different scabicides (neem, permethrin, benzyl benzoate, ivermectin, lindane, and tea tree oil) showed that all reduced mite survival, with the exception of neem.[74] However, of the five treatments that reduced mite survival, the duration of survival was found to be longest with permethrin exposure.

A clear challenge facing scabies treatment in the future is the optimal management of populations with high rates of endemic scabies. In one recent study, community-wide permethrin treatment was followed by treatment of patients with newly diagnosed scabies at all follow-up visits.[75] At 25 months of follow-up, the prevalence of scabies had decreased from ~28% to 7% ($P = 0.002$). In Papua New Guinea, inhabitants of two villages were evaluated for filariasis and scabies.[76] The inhabitants of one village were selected to receive ivermectin (400 mg/kg) as a single dose. The inhabitants of the treated village experienced a decrease in the prevalence of scabies (from 87% to 26%) at 5 months of follow-up. These studies suggest a role for community-wide treatment in controlling disease in communities where scabies is endemic; however, additional studies will be needed to clarify the long-term influence of these treatments and their economic feasibility.

Scabies epidemics in long-term care facilities were the focus of several additional cohort studies that demonstrated good control of the epidemic with the use of 1–2 doses of ivermectin.[77,78] One of these studies reported that ivermectin treatment was successful after treatment with several different topical scabicides failed.[76]

TREATMENT TOXICITY

Topical agents have been the most extensively used type of scabies treatment, and, therefore, their toxicity profiles are fairly well defined. Both permethrin and benzyl benzoate have been reported to cause rash and diarrhea.[79] More worrisome are the reports of convulsions and aplastic anemia occurring in association with benzyl benzoate and lindane.[80,81] According to the World Health Organization (WHO) 1998 Collaborating Centre for International Drug Monitoring, convulsions have been associated with the use of benzyl benzoate, crotamiton, lindane, malathion, and permethrin. Deaths were reported to occur in association with crotamiton, lindane, and permethrin treatment.[79] In 2003, the U.S. Food and Drug Administration issued a health advisory that lindane should be used only as an alternative therapy if other treatments are not tolerated or if other approved therapies have failed. It is thought that warm baths and extensive dermatitis may increase systemic absorption of lindane. Lindane is not recommended for pregnant or lactating women, for children 2 years of age, or for patients with extensive dermatitis. Given the warnings and concerns about toxicities, lindane is not recommended as a first-line or alternative therapy for scabies. The use of lindane would best be reserved for patients for whom the inability to tolerate other therapies leaves this as a last option.

In a randomized controlled trial of lindane versus ivermectin treatment, all reported adverse effects were mild and transient.[27] Patients treated with lindane more frequently complained of headache, but some patients treated with ivermectin noted abdominal pain and vomiting. One patient developed transient hypotension. Ivermectin has been well tolerated in all but one study. This study described an outbreak of scabies in a long-term care facility for elderly individuals; in the study, patients received multiple applications of topical scabicides before finally receiving treatment with a single dose of ivermectin.[82] Over the following 6 months, there was an increased incidence of death among these 47 patients, compared with age- and sexmatched control subjects. These patients experienced lethargy and anorexia before death. Other investigators argue with the outcomes of the study, pointing out that patients were not matched for comorbidities, such as severity of dementia.[83] No other studies have demonstrated increased mortality occurring in association with a history of ivermectin therapy. In another study, involving ~220 patients in a psychogeriatric nursing home who were treated with ivermectin for a scabies outbreak, the mortality rate in the 6 months after treatment was compared with that occurring in the 30 months before treatment; no significant difference was found.[76] Of note, a rash and a transient increase in pruritus have been reported in the first 3 days after scabietic patients receive ivermectin.[67]

PERSISTENT SYMPTOMS

All patients should be informed that the rash and pruritus associated with scabies may persist for up to 2 weeks after treatment.[65] When symptoms and signs persist for 12 weeks, there are several possible explanations, including treatment resistance, treatment failure, reinfection from family members or fomites, drug allergy, or worsening rash due to cross-reactivity with antigens from other household mites.[84,85]

Poor response and presumed resistance to lindane have been reported elsewhere.[78,86–90] Treatment failure not related to resistance can be due to faulty application of topical scabicides. Patients with crusted scabies may have poor penetration of scabicides into thick scaly skin and may harbor mites in these difficult-to-penetrate layers. Particular attention must be given to the hyperkeratotic fingernails of such infested patients. Certainly, to avoid reinfection, it is recommended that all close contacts of patients with scabies be empirically

treated. All linens, bedding, and clothing should be washed, if possible, during the time of application of the topical scabicide. Even when treatment is successful and reinfection is avoided, symptoms may worsen secondary to allergic dermatitis. This complication has been seen with several of the topical scabicides.

Finally, ordinary household mites may drive persistent symptoms resulting from cross-reactivity between antigens. In a study of 25 patients, scabietic patients had higher skin-prick test results and higher levels of IgE to house dust mite and storage mite antigen than did control subjects.[83]

Overview of STD Care Management

This page intentionally left blank

47 STI Care Management

Caroline A. Ryan, Mary Kamb, and King K. Holmes

Medicine is a science of uncertainty and an art of probability.
Sir William Osler

INTRODUCTION

Rapid advances in biomedical knowledge and technology provide clinicians with a continuously expanding armamentarium of potential diagnostic and therapeutic options. In addition, an increasing number of rigorous biomedical and behavioral research studies—particularly in the form of randomized controlled prevention trials—are providing efficacy data on preventive interventions in specific settings.[1–7] Unfortunately, randomized trials have not been set up to grapple with all the specific questions needed to pragmatically translate research findings into practice for local programs or individual practitioners. Outside of effective use of vaccines,[8–10] positive trial results have not always been replicable in other settings.[11] For example, enhanced syndromic STI care management appeared to be fairly effective in reducing HIV as well as curable STIs in paired rural communities with high prevalence of curable STIs and low and rising HIV incidence.[1] However, a subsequent trial of mass treatment for STIs in another rural community setting reduced the prevalence of vaginal trichomoniasis in the general population but did not prevent new HIV infections.[5] Furthermore, a second trial of syndromic STI care management plus enhanced education conducted in a nearby rural setting was effective in reducing new gonorrhea and syphilis infections but did not prevent HIV infection.[6] Reanalyses of data from these three studies using mathematical models suggested that lower prevalence of STIs and fewer sexual-risk behaviors during the latter two studies may have partly explained the failure of the STI interventions in these two studies to prevent HIV infection.[12] Additionally, the phase of the HIV epidemic and population dynamics affecting STI and HIV transmission may have been important (most HIV transmission in the negative trials occurred within established partnerships). Although the studies of STD syndromic management have helped foster consensus that STI care management can reduce curable STIs in a community, the varying results in terms of HIV prevention have led to considerable discussion about the best ways, and even the need to approach STI control for HIV prevention. Although a 2006 WHO consultation group[13] concluded that STI interventions remain important for HIV prevention—especially in concentrated HIV epidemics and among population subgroups with high STI prevalence and high rates of partner change—important questions are still unanswered. Will syndromic STI management programs prevent HIV infections in communities with longer-standing, higher-prevalence HIV epidemics? What about settings with lower population prevalence of curable genital ulcer disease or inflammatory STDs?

Ambiguity about benefit outside research settings also exists for other STI prevention interventions. For example, brief, client-centered counseling approaches have been found to reduce new STIs in primarily young, heterosexual STD clinic patients in the United States. However, these results have not been widely replicated, and insufficient information is available on whether these counseling approaches are effective for other populations (e.g., homosexual men with multiple risks, injection drug users, or heterosexual men and women in developing world settings).[14,15] Recently, results from three separate randomized trials found that adult male circumcision reduced new HIV infections substantially in heterosexual men in Africa.[7,16,17] Even with such consistency of results, experts worry that these trials cannot answer whether beneficial results will translate equally to other settings where circumcision rates are higher or where heterosexual transmission is less common, or address whether subsequent behavioral disinhibition (risk compensation) in newly circumcised men may lead to riskier behaviors and thus attenuate or reverse any benefits.[18,19] It is increasingly clear that although rigorously conducted experimental studies help answer some important questions, they often introduce new ones.

Despite this ambiguity about what may be effective for HIV prevention at the population level, or STI control in the community, the public is concerned about efficacy of STI care management at the individual level and expects diagnostic certainty and effective medical care. Clinicians in developed countries themselves grow increasingly dependent on advanced

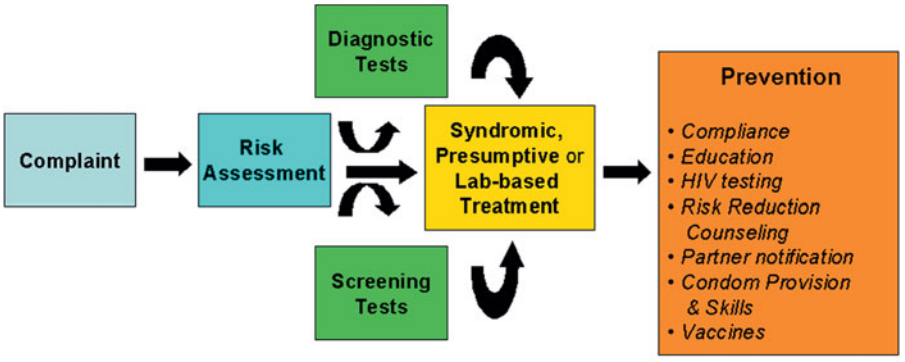

FIGURE 47-1. Essential components of STI care management.

technology in diagnostic and therapeutic decision making. As resources for clinical care management become more constrained even in the best of circumstances, and new epidemiologic models call for greater outreach to resource-poor settings to achieve STI control, clinicians need guidance.[20] Clinicians are increasingly asked to do more with fewer resources and forced to practice under conditions of great uncertainty. The desire to help and not harm prompts several questions: What is the true diagnosis? Which laboratory tests will help? What treatment will alleviate symptoms and cure infection? What evidence warrants treatment of sex partners? And increasingly, which preventive interventions work and should be promoted?

The most appropriate answers to these questions depend on a number of factors: the clinical setting, the probability of various infections, the resources available, the expectations of patients, cultural constraints, the overarching programmatic goals of the clinical service (e.g., primary patient care, public health STD clinic, family planning, or prenatal clinic), and the available evidence. Even in developed countries, continuing crises in health-care financing have made clinicians all too aware of the economic implications of their decision making. Diagnostic evaluation and disease treatment concern not only health benefits but also economic costs.[21–24] A society lacking infinite resources to spend on health care can no longer focus only on the percentage of infections a new screening or treatment program detects, cures, or prevents; we now must examine the balance between costs and proven benefits. But unfortunately, even health economic evaluations are unable to answer all our questions. Many of the proven-effective interventions have been shown to be highly cost effective and even cost savings in their research settings,[25–28] but whether cost–benefit data from rigorous research settings can be generalized to the "real world" is also unknown.[29] Further, relatively few "decision-tree" cost–benefit analyses have gone beyond the benefits received by the individual patient to examine in dynamic models the population-level benefits.[30,31]

In this section of the book, Chapters 48–54, as well as Chapter 69, deal with risk assessment and patient-centered counseling, the importance of a nonjudgmental, patient-friendly approach to providing care for STIs, including HIV infection in detail. This chapter provides an overview of STI clinical management, examining the various approaches that are commonly used in the diagnosis and treatment of STIs in a variety of clinical settings, and focusing on strategies clinicians can use to increase their effectiveness. We think (with due respect to William Osler) that medicine is a science of probability and an art of managing uncertainty.

DEFINITION AND GOALS OF STD CARE MANAGEMENT

STI care management requires managing asymptomatic as well as symptomatic individuals. The major steps in effective STI care management include risk assessment and clinical evaluation; identification of persons with STIs (whether symptomatic or asymptomatic) who are unlikely to seek diagnostic and treatment services; appropriate diagnosis and treatment of infected persons; prevention education, counseling, and other strategies around avoiding reinfection and new infections; and effective evaluation, treatment, and counseling of sex partners of STI-infected persons. Additionally, in most parts of the world, HIV infection is also linked to sexual behaviors, and an STI clinical encounter is an opportunity to encourage HIV testing and counseling. Furthermore, pre-exposure vaccination of persons at risk of vaccine-preventable STIs is likely to play an increasing role in STI clinical management[29] (Fig. 47-1).

Several factors external to the clinical setting affect STI management. For example, the most effective programs will be driven by prevalence of specific pathogens or STI sequelae and will be responsive to the factors driving infection in the community. Additionally, the presence of a clearly defined national plan, coupled with practical guidelines and supportive laws and policies, will ensure more effective programs. Another systems-level factor critical to STI management is availability of effective drugs, made increasingly important with emerging antimicrobial resistance. Factors affecting access, acceptability, and cost of the clinical services also affect how they are used by the clients to whom the STI services are targeted.[32,33]

There are several goals of STI care management; the most obvious are to cure or ameliorate the infection and prevent complications and sequelae of the infection (including complications related to pregnancy or family planning). Additional goals are to prevent transmission of the infection

to others, reduce risk for HIV transmission and acquisition, provide counseling on avoiding future infections and (if necessary) on coping with chronic STI, and provide outreach for care management to exposed sex partners or unborn children. In general, the earlier the diagnosis, treatment, and counseling, the greater the impact on preventing further transmission of STIs and their complications.[1,34]

POTENTIAL STEPS REQUIRED TO TREAT AND PREVENT STIs

Clinic-based STI care management has been, and remains, a cornerstone for STI control and prevention. However, the limitations to clinical care are graphically illustrated in Fig. 47-2 by the Piot–Fransen model for sexually transmitted management that was developed using data collected from rural women in several African nations. Improving clinical care does not address the issue of subclinical (i.e., asymptomatic) STIs, or problems of poor access to services or treatment-seeking behavior by individuals with STI symptoms. Fig. 47-3 shows (1) the potential effects of (1) well-conducted clinic-based STI care management, which requires symptomatic persons seek and obtain appropriate diagnosis, treatment, and preventive services; (2) the potential additional benefits of targeted and other community-based programs that are able to identify and effectively treat most symptomatic STIs in the community; and (3) the additional benefit of screening asymptomatic persons.[35–37] In the future, provision of preventive vaccinations may go even further, addressing individuals at risk of specific STIs before they are exposed to infection.

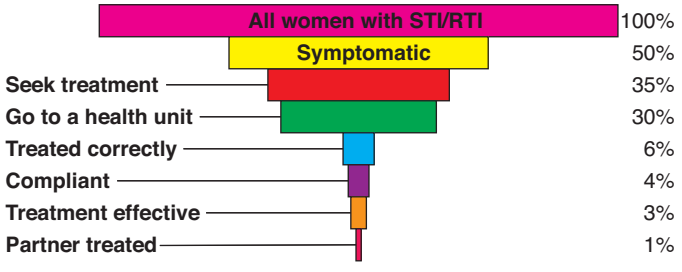

FIGURE 47-2. The Piot–Fransen model of STI prevalence and effects of STI care management.

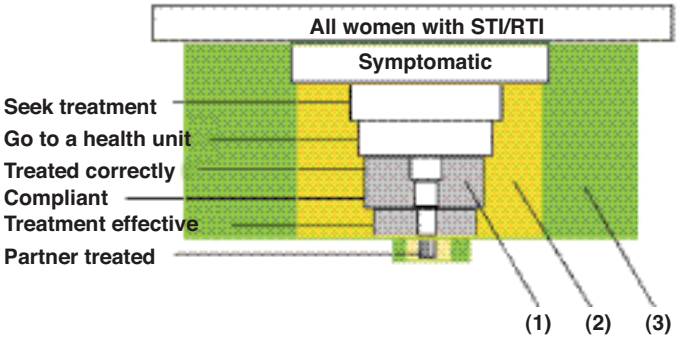

FIGURE 47-3. Piot–Fransen model: Potential effects of additional STI control/prevention strategies in concert with STI care management.

It is important that clinicians recognize that when STI care management is focused only on diagnosis and treatment of patients seeking care for STI symptoms, this may have only modest benefits for the population as a whole. The Piot–Fransen model illustrates the importance of additional STI control measures such as partner notification; education of patients and communities on STI symptom recognition, ensuring access to care for those who need it; and screening for subclinical infection[36]—all too often overlooked or beyond the control of busy clinicians.

A COMPREHESIVE APPROACH TO STI CARE MANAGEMENT

"From inability to let alone; from too much zeal for the new and contempt for what is old; from putting knowledge before wisdom, and science before art and cleverness before common sense; from treating patients as cases; and from making the cure of the disease more grievous than the endurance of the same, Good Lord, deliver us."

—Sir Robert Hutchinson

A comprehensive approach to STI care management combines essential services into a practical delivery package. Such an approach begins with a basic knowledge of community disease prevalence and includes an individualized risk assessment (of sexual behaviors, specific exposures, and sociodemographic and other markers of high risk), a history of reproductive health and past STIs, and a clinical assessment (elicitation of specific symptoms and detection of signs of STIs) (Fig. 47-1). Depending on available resources for testing, the results of these assessments may lead to confirmatory diagnostic tests (for symptomatic patients) or screening tests (for asymptomatic individuals judged to be at sufficiently high risk to warrant testing). In some situations, routine screening for specific STIs is recommended. For example, syphilis screening to prevent congenital syphilis is routinely recommended for pregnant women in most of the world, as is routine "opt-out" antenatal HIV screening (especially in communities with generalized HIV epidemics).[38,39] For other situations or syndromes, rapid tests may be used to narrow the spectrum of initial therapy (e.g., wet mount for women with vaginal discharge, Gram stain for men with urethral discharge and women with cervical mucopus, and darkfield examination and rapid serologic test for syphilis for genital ulcer disease).[40]

STI care management concludes with a series of prevention approaches to reduce the risk of reinfection and help the patient prevent new infections, sometimes referred to as "the six Cs." These include information about curative (or in the case of herpes, palliative) therapies along with assurance of compliance with medication instructions ("compliance");

sex partner ("contact") notification and (if appropriate) treatment; sufficient information and advice about STIs and how they are transmitted, in order to reduce new infections ("counseling"); and provision of condoms along with information on how to use them ("condoms"). A fifth "C" that is sometimes overlooked, but is an integral part of good STI management, is assurance of confidentiality.[33] A sixth "C" that is consistent with provision of integrated primary health-care services is contraception, if appropriate. Two additional prevention strategies that are important parts of comprehensive STI care management are routine provision of voluntary HIV counseling and testing and, if appropriate, prophylactic STI vaccinations.[32,33] Although this approach specifically applies to care management for STIs, essentially the same steps apply to care management of most if not all infectious diseases—with the preventive steps represented by these approaches differing for different diseases.

In most settings, in both developed and developing countries, treatment of patients with symptoms highly suggestive of an STI is often started on a syndromic presumptive basis (i.e., treatment is selected to cover the most likely causes of the symptoms and signs); in developed countries, treatment often begins while results of confirmatory laboratory tests are pending.

COMMUNITY DISEASE PREVALENCE

In some communities, STI prevalence in the general population is high while, in other communities STIs are largely confined to specific population groups.[32] Some wealthier countries have almost eliminated certain bacterial STIs such as chancroid, LGV, and syphilis, while these same STIs are still common in many developing world settings. However, as is the case with all infectious diseases, STI rates are dependent on a number of factors such as changing demographics, stage of the HIV epidemic, social and economic structure, population mobility, and existing STI control measures.[41] STI prevalence rates in a community can change rapidly.[41] In addition, an increasing number of communities are finding that certain STI pathogens such as *N. gonorrhoeae* are no longer susceptible to commonly used antibiotic therapies.[42] An understanding of community STI and HIV trends, including antimicrobial resistance patterns, is important to providing effective STI care management.[43]

RISK ASSESSMENT AND CLINICAL EVALUATION

Patients may consult a clinician with a set of symptoms (manifestations of the disease perceived by the patient and either volunteered or brought forth during the history taking) and signs (manifestations of the disease identified during the physical examination). Other individuals with STIs may lack symptoms or fail to perceive symptoms that occur, or may perceive symptoms of infection but feel that they are too trivial or too embarrassing to prompt them to seek care or to tell the clinician.[40,44,45] Routine risk assessment can serve as a guide to selective clinical evaluation and selective laboratory testing for STIs in patients who do not report typical symptoms and can also aid in the interpretation of any symptoms or signs that are presented.[46–51] Thus, clinical evaluation and risk assessment for STIs actually proceed concurrently: Positive risk assessment prompts and guides the clinical evaluation for STIs, and conversely, clinical findings compatible with STIs should prompt risk assessment, since a positive risk assessment increases the probability that suspicious findings actually represent an infection. Chapter 48 reviews risk assessment for STI/HIV, and Chapters 49 and 50 describe the approach to the physical examination of the male and female genitalia as part of the clinical evaluation for STIs.

As discussed earlier, clinicians will best understand which patients need specific clinical evaluation and testing for STIs, and education and prevention counseling services and so forth, when they understand the risk factors driving the spread of infection(s) in their community and ask about those factors. Adolescents in particular may be willing to discuss their sexual behaviors and concerns but will often not bring up the subject unless asked.[52,53] A U.S. national survey showed that primary care physicians assessed sexual behavior for less than one-half of their patients,[54] and another survey of U.S. adults who had a routine medical checkup during the previous year found that only 28% were asked about STIs during their evaluation.[55] Examples of risk assessment tools are available (see Chapter 48).[33,56] Communities will benefit from collaboration between clinical and health education staff of STI, HIV, and family planning programs, and other community-based organizations to promote sharing or adaptation of existing materials that support counseling of high-risk patients on recognizing and reducing risk. Clinical and public health systems should collaborate to provide clinicians with a comprehensive list of agencies available within the community to refer patients as needed for services that are identified during the risk assessment and examination.

LABORATORY TESTING

Chapters 52, 70, and 104 present different aspects of STI/HIV laboratory testing. Testing of symptomatic patients (diagnostic testing) to establish the microbial etiology of STI-related symptoms is distinguished from testing of asymptomatic individuals who are brought to care as contacts of an infected person or are seeking care for reasons other than symptoms or signs of STDs (case-finding tests), and from testing of individuals identified through outreach to populations outside the clinic (asymptomatic screening). In this chapter, the term "screening" encompasses both case-finding and asymptomatic screening, as defined in the preceding text. As

potential cost benefits of screening (or of any intervention) are directly related to disease prevalence, risk assessment guides selective, cost-effective allocation of resources for each of these types of laboratory testing.[22,44,48,49] Screening of asymptomatic individuals is most justifiable when disease sequelae are severe. For example, syphilis screening is routinely recommended for pregnant women because of the potential for fetal loss or neonatal morbidity and mortality associated with untreated maternal infections.[32] Similarly, cervical screening using Papanicolaou (Pap) smears or, where resources are limited, other techniques such as direct visual inspection of the cervix are a means of detecting precursor lesions of cervical cancer, which is the second leading cause of cancer mortality among women globally and the leading cancer cause among women in many developing nations.[32] Because of the association between chlamydial infection and infertility, annual screening for *C. trachomatis* is currently recommended in the United States for all sexually active women 24 years of age or younger.[33] Besides cost, screening asymptomatic individuals is more acceptable to patients and providers when screening tests are simple and noninvasive, which is increasingly the case with STI laboratory testing.

Laboratory testing for specific potentially causative infectious agents can provide the strongest evidence for infection and justification for treatment, and for preventive interventions such as partner treatment. For *N. gonorrhoeae* and *H. ducreyi*, and to some extent for viral pathogens, isolation of the pathogen also permits testing for sensitivity or resistance to antimicrobial agents. Increasingly, for some pathogens, HIV resistance to antiviral or other antimicrobial agents can be identified by detecting resistance mutations even without isolation of the pathogen. For syphilis, quantitative reagin antibody tests allow monitoring the response to therapy.[57] For cervicovaginal HPV infection, identification of oncogenic HPV types is a potential guide to prognosis and for further diagnostic and therapeutic interventions (see Chapters 28, 57, and 58). Similarly, typing of genital HSV helps predict the likelihood of recurrence.[58–60] In addition, positive laboratory tests provide the most specific evidence of infection for surveillance purposes.

However, many laboratory tests obviously are not available at all clinic sites, and even when tests are available, test results are often not available soon enough to guide therapy or partner management decisions during the initial patient visit. Further disadvantages of some laboratory tests include high cost and variable test performance. When intrinsic test characteristics or inadequate laboratory quality assurance lead to less than 100% sensitivity, or when patients do not reliably return for test results and treatment, then treatment of symptomatic patients, based only on positive test results rather than on syndromic diagnosis (see below), can lead to undertreatment. Similarly, mathematical modeling suggests that the required sensitivity of a point-of-care test, in terms of STI transmissions averted, can be quite low, relative to a gold standard test if there is substantial transmission during the delay in treatment while waiting for results of the gold standard test, or many persons do not return for treatment, or both.[61,62] Likewise, low specificity of a test can lead to overdiagnosis of STI and attendant unwarranted problems with partners (e.g., conflict, perhaps leading to violence), stigmatization for the patient, drug reactions, and drug resistance. The diagnostic tests with best performance characteristics currently available for the more important STIs oftencannot be used where the test is too expensive or limited in availability.[60,32] Specimen collection procedures, such as pelvic examination for cervical samples, urethral swabbing, or venopuncture for obtaining blood, may also discourage patients from seeking testing or providers from performing the test.[63] Increasingly, less invasive sampling techniques, such as self-collected vulvovaginal swabs or urine for DNA amplification tests or saliva collection for detection of antibody, help to overcome these problems. Nonetheless, clinical, epidemiologic, technical, and especially resource considerations dictate the extent to which laboratory tests are useful in STI care management.

Even when resources do permit rapid laboratory tests on specimens collected noninvasively, an additional practical concern is that rapid tests used to guide initial therapy of symptomatic patients often must be performed in an office or clinic without nearby laboratory support. This requires the clinician or office staff to perform the tests needed to guide treatment of acute disease syndromes. For example, an office- or clinic-based laboratory analysis of a vaginal specimen is often used to guide management of vaginal infections. A microscopic examination allows recognition of fungal hyphae indicative of vulvovaginal candidiasis, "clue cells" suggestive of bacterial vaginosis, and motile trichomonads indicative of trichomoniasis.[64] Since 1988, in the United States, these microscopic tests for vaginal infection have been classified as "physician-performed microscopy" tests under the U.S. Clinical Laboratory Improvement Amendment, placing a diagnostic burden on U.S. clinicians in small offices choosing to maintain a laboratory.[65] Primary care clinicians have demonstrated high specificity but low sensitivity when identifying vaginal trichomoniasis and vulvovaginal candidiasis by microscopic techniques.[66] Correct microscopic diagnosis of bacterial vaginosis was even more difficult for clinicians. Not surprisingly, clinicians were less accurate than DNA oligonucleotide probe tests in diagnosing vaginal infections.[66] Thus, in general, a need remains for more reliable, but inexpensive, and rapid clinic-based tests for the acute symptomatic STIs to guide prompt therapy.

Since the early 1990s, a number of new initiatives have promoted diagnostic test development for STI control, particularly for use in the developing world.[67,68] Perhaps the most notable of these is the STI Diagnostics Initiative (SDI) located in the UNICEF/United Nations Development Programme/World Bank/WHO Special Programme for

Research and Training in Tropical Diseases (TDR). Lack of a substantial array of appealing tests had been the most pressing issue in the past. A 2001 inventory carried out by the SDI identified more than 40 rapid tests for syphilis, *C. trachomatis* and *N. gonorrhoeae* on the market, but found that few had had performance evaluations adequate to meet the needs of clinicians or STI control programs in low-income settings.[68] Since that time, progress in science and technology and funding from major international donors have stimulated rapid test development. A joint consultation held in 2001 by the SDI and Wellcome Trust concluded that rapid point-of-care tests for *N. gonorrhoeae* and *C. trachomatis* remained the highest priority to reduce overtreatment among women presenting with vaginal discharge.[68] The consultation also noted an urgent need for a rapid point-of-care test for syphilis, to aid in screening antenatal women at risk of congenital syphilis. The SDI has focused on evaluating existing and new tests as they emerge, with researchers noting that their biggest current challenge is ensuring that adequate-quality, rapid tests are accessible to the developing country populations that need them most.[68]

APPROACHES TO STI DIAGNOSIS AND TREATMENT

Health-care providers have generally used either laboratory tests or clinical findings to establish or infer the likely etiology of symptoms and signs of STIs. Previously, treatment guidelines focused on treatment of specific, laboratory-defined STIs, albeit sometimes with guidelines for management of a few syndromes as well (e.g., NGU, pelvic inflammatory disease [PID], and epididymitis). However, in resource-poor settings, where laboratory tests are not available, the low validity of clinical impression alone for inferring a specific microbial etiology of specific STI syndromes has led to emphasis on guidelines for syndromic management of STIs using antimicrobial regimens likely to have activity against all of the major causes of particular syndromes.

LABORATORY-BASED ETIOLOGIC DIAGNOSIS

Sometimes referred to as "test-based management," this approach involves identifying the organism causing symptoms using microscopy or other laboratory tests, and using test results to support antimicrobial treatment choices. Even when testing is available, treatment is often initiated on the basis of syndromic diagnosis while test results are pending. In practice, rapid testing (if available) can guide initial choice of therapy. Laboratory test results can also strengthen the case for partner evaluation and/or treatment; however, testing is not essential to prompt partner services when certain STI syndromes (e.g., for urethral discharge or genital ulcer) are sufficiently specific. The potential for sequelae with most STI, together with problems of increasing antimicrobial resistance, risk of coinfections, and the limitations of test performance all generally warrant patient follow-up and the assessment of clinical response, regardless of initial testing and choice of antimicrobials.

PRESUMPTIVE ETIOLOGIC DIAGNOSIS BASED ON CLINICAL FINDINGS

This approach, also referred to as "therapeutic trial," involves making a best guess as to the microbial etiology of symptoms and signs, and providing antimicrobial treatment based on clinical experience without the aid of laboratory tests. This approach is often used in developing countries as an alternative to nonavailable, unreliable, or unaffordable diagnostic tests, in an effort to infer the etiology of symptoms and signs, and in developed countries while awaiting results of laboratory tests. Typically, initial therapy is chosen to cover the most likely diagnosis, or the condition most likely to progress rapidly to serious illness if not treated, or to use the least expensive antimicrobial—all in hopes of avoiding or deferring use of expensive tests or antimicrobials.

A drawback of presumptive etiologic diagnosis is that even experienced STI service providers are often unable to accurately infer the microbial etiology of STI syndromes, based on symptoms and signs. For example, studies from a number of settings, including Africa, the United States, and Jamaica, have consistently demonstrated the inaccuracy of clinical impressions as to the microbial etiology of genital ulceration.[69–76] In a South African study of 100 men and 100 women with genital ulcers, clinicians correctly identified only about one-third of the cases of chancroid or syphilis in the men, about one-half of the cases in the women, and less than 10% of mixed infections.[73] Reasons cited for this low accuracy of clinical diagnosis include (1) similarities in clinical appearance of various types of infection, (2) simultaneous infections with more than one organism, and (3) atypical appearance owing to long-standing disease, prior self-treatment with ineffective therapy, or concomitant HIV infection.[69–77] Not infrequently, a presumptive etiologic diagnosis approach to STI care management can lead to a series of therapeutic trials with different antimicrobial regimens until definitive testing is performed; this can be costly for patients. Therapeutic trials of less expensive but suboptimal antimicrobials should be discouraged, as this approach can lead to inadequate treatment, and thus chronic sequelae, as well as promote antimicrobial resistance.

SYNDROMIC DIAGNOSIS

In resource-poor settings, the most practical approach often is syndromic diagnosis and treatment, or "syndromic management," ideally with a risk assessment. For treatment of genital ulcers and urethral discharge, this approach has been demonstrated to be cost effective and feasible for health settings with limited resources and laboratory capacity, as it is less technically demanding than laboratory-based or presumptive diagnosis of microbial etiology based on clinical

findings.[78,79] The WHO has encouraged use of syndromic case management since 1990[78] and has developed a series of flow charts or clinical algorithms for the standardized management of STIs, recommending that national STD control programs in developing countries incorporate diagnostic and therapeutic flowcharts in their STI management guidelines and adapt them for local conditions.[78,79]

The basis of the syndromic approach is the identification of a syndrome, that is, a set of easily elicited symptoms and easily recognized signs associated with a limited number of well-defined microbial etiologies. The advantages of syndromic management include expedited care, with treatment at the first visit and thus less opportunity for patients to be lost to treatment if they do not return for test results or comply with referrals; cost savings by not using expensive laboratory tests; and increased patient compliance and satisfaction.[78,80] The use of flowcharts in STI management also standardizes diagnosis, treatment, referral, and reporting, thus allowing for improved surveillance and program management.

Significant limitations of the syndromic approach include lack of utility for asymptomatic people with STIs, particularly for asymptomatic women with cervical infections. In addition to low sensitivity, the relatively low specificity of the syndromic approach relative to laboratory testing for some infections (especially for cervical infections) leads to many false-positive diagnoses, and thus to unnecessary use of drugs and to potential social problems attending a false-positive diagnosis.[80] Further, the quandary remains about when to attempt treatment of sex partners of individuals treated on the basis of syndromic diagnosis alone. In clinical settings where acquisition of infection by the patient from a steady sex partner is probable—for example, among women in family planning clinic settings—reinfection of the patient would be very likely without treatment of the steady partner. However, in the absence of specific confirmatory laboratory diagnosis, sex partners may not be offered treatment. The thinking too often appears to be that the treatment should work, and, in the absence of a specific diagnosis, partner treatment may be too challenging to directly address.

In resource-poor nations, promotion of syndromic case management since 1990 has likely contributed to substantial declines in incidence and prevalence of certain bacterial STIs, particularly chancroid, syphilis, and gonorrhea[32,81] (see Chapter 5). Chancroid was considered the most common cause of genital ulcer syndrome seen by clinicians in 1993, but had become a rare disease in many countries by 2002; syphilis has also rapidly declined as a cause of genital ulcers in many developing world settings.[77] Unfortunately, genital ulcer syndrome is not disappearing, as genital herpes has emerged as the most common cause of genital ulcers worldwide, particularly in settings with high HIV prevalence.[13,32,43,82] For example, a study comparing 1993 and 2002 cross-sectional evaluations of genital ulcer etiology in Botswana suggested some reduction in overall prevalence of genital ulcer syndrome over the period but demonstrated that, as the proportion of ulcer cases due to chancroid declined from 25% to 1%, the proportion due to herpes simplex virus rose from 23% to at least 58%.[43]

Design of flowcharts for syndromic diagnosis

As described in Chapter 101 and in a compilation of articles on syndromic management of STDs, a clinical flowchart (also referred to as an "algorithm" or "decision tree") depicts a path of diagnostic reasoning.[80,83–94] The structure of a flowchart can be hierarchical or nonhierarchical.[83] In hierarchical algorithms, the presence of a single symptom is the limiting factor for entry, and one diagnosis excludes another. A nonhierarchical algorithm allows the consideration of several risk markers, signs, or symptoms at once and allows consideration of different diagnoses at the same time. To ensure efficient use for STI care management, WHO recommends that flowcharts be adapted to the level of development of the health-care system and the particular health-care facilities for which they are intended.[78] Culture-specific perceptions about STIs, patterns of health-seeking behavior, and expectations about health care, to a large extent, determine the usefulness of certain flowcharts.

Common STI syndromes

The major STI syndromes include genital ulcer disease, urethral discharge in men, intrascrotal pain and swelling, lower abdominal pain (LAP) in women, and abnormal vaginal discharge. A growing body of data provides information on how well the major syndromes and various adaptations of flowcharts or algorithms have performed in different clinical settings throughout the world.[80,83–94]

Genital ulcer syndrome in men and women is most commonly attributable to chancroid, syphilis, or genital herpes, and less commonly to LGV or granuloma inguinale (donovanosis). A 2000 review of studies evaluating syndromic management found five reporting on adapted versions of the WHO algorithm for genital ulcer syndrome, demonstrating 72–100% cure rates for syphilis and chanroid regardless of facility type, but poorer performance for herpes.[80]

Urethral discharge syndrome in men is often attributable to gonococcal or chlamydial infection, or to nongonococcal nonchlamydial urethritis. The latter has numerous other potential etiologies, including *Mycoplasma genitalium, Ureaplasma urealyticum, Trichomonas. vaginalis*, and HSV and probably some still undefined pathogens. The 2000 report reviewed five studies implementing algorithms for urethral discharge, four in primary care settings and one in an STD clinic. Sensitivity of syndromic diagnosis with respect to presence of gonorrhea or chlamydial infection (87–99%) or cure rate (92–99%) was high even without microscopy. but specificity of syndromic diagnosis with

respect to these two infections ranged widely (7–90%), indicating that treatment of patients without gonorrhea or chlamydia for urethritis was common.[80] Addition of a Gram stain improved specificity of syndromic diagnosis of urethritis with respect to these two infections in one study but not another, reflecting varying prevalence of gonorrhea and chlamydial infection. Note that the role of *M. genitalium, U. urealyticum, T. vaginalis*, and herpes simplex virus as other causes of urethritis means that a substantial proportion of cases of urethritis in men would not be expected to be attributed to gonorrhea or chlamydial infection (i.e., specificity of syndromic diagnosis with respect to these two infections would not be expected to be high). No doubt in the future, a more relevant use of the terms "positive predictive value" and "specificity" would not be in terms of gonorrhea and chlamydial infection alone, but rather in terms of the presence of any infection likely to respond to the antimicrobial regimen recommended for management of the syndrome.

The syndrome of *acute, unilateral intrascrotal pain and swelling* in heterosexually active men under the age of 35 years most commonly reflects acute epididymitis due to the sexually transmitted pathogens *N. gonorrhoeae* or *C. trachomatis*. In heterosexual men over 35 years of age, particularly those with underlying genitourinary disease, coliform bacteria or *Pseudomonas* are more likely etiologies. Similarly, coliforms are the likely cause of epididymitis in homosexual men who practice anal-insertive sex. WHO guidelines remain unchanged and recommend first exclusion of testicular torsion and trauma, and then treatment with antimicrobials that cover *N. gonorrhoeae* and *C. trachomatis*. In those who fail to respond to treatment, clinicians must consider alternative diagnoses, including testicular neoplasia or other chronic infections, such as tuberculosis and other chronic granulomatous diseases.

LAP syndrome in women has many potential causes, including PID caused by cervical pathogens (*N. gonorrhoeae, C. trachomatis*, perhaps *M. genitalium*) and by less pathogenic vaginal bacteria (including vaginal anaerobes) (see Chapters 42 and 56). In general, algorithms for LAP do not perform well in detecting cervical gonococcal or chlamydial infection in most clinical settings, in large part due to the insensitivity and the nonspecificity of the elicited symptom of LAP with respect to objective evidence of salpingitis or endometritis (unless coupled with signs of PID elicited by trained gynecologists).[84,85,87]

The term *lower genital tract infection* (LGTI) syndrome in women, as discussed in Chapter 55, has had a broader connotation, including mucopurulent cervicitis; ectocervicitis; vaginal discharge that is abnormal in amount, color, or odor; as well as vulvar and urethral inflammation. This definition encompasses disparate cervical, vulvovaginal, and urinary tract infections with overlapping clinical manifestations. The term LGTI is not sufficiently specific to guide treatment for cervical or vaginal infection but is still useful in calling attention to the need for further evaluation for such infections, and perhaps as an entry point to a flowchart that branches with different syndromes. Below, we consider two such syndromes.

Mucopurulent endocervicitis may be caused by gonorrhea or chlamydia infections, both are also associated with PID and infertility. It is also commonly associated with trichomoniasis and may be caused by other infections as well. Signs of yellow endocervical discharge, edema of the zone of cervical ectopy, and easily induced endocervical bleeding with or without symptoms of abnormally yellow vaginal discharge have been useful predictors of cervical infection in settings with high prevalence (prior probability) of gonococcal and chlamydial infection, particularly in women with positive risk assessment for these cervical infections.[80,83–94] In such settings or patients, this syndrome remains potentially useful in supporting the diagnosis of PID and as a guide to syndromic management of cervical infection and/or to selective screening for cervical infection. However, in settings with low prevalence of gonococcal or chlamydial infection, mucopurulent cervicitis has a lower predictive value for such infections, remaining useful as a criterion for selective diagnostic testing but not necessarily for treatment of these infections. Note that, as with urethritis in men, mucopurulent cervicitis has also been associated with *M. genitalium* infection in multiple studies and that HSV and *T. vaginalis* also cause distinctive types of inflammation of the cervix (see Chapter 55). The addition of risk assessment to identify women with risk factors *plus* signs of mucopurulent cervicitis or PID has relatively lower sensitivity, but relatively higher specificity and positive predictive value for cervical infection, with gonococcal, chlamydial, and *M. genitalium* infection.[83,84,95] Critical factors in development and use of such algorithms include development of locally defined, culturally acceptable risk assessment algorithms and the training, experience, and skill of the clinician in detecting manifestations of mucopurulent cervicitis or PID.[80,84,85]

Vaginal discharge syndrome is usually caused by bacterial vaginosis or trichomoniasis. The symptom of increased amount of vaginal discharge per se has not proven very useful for diagnosis of cervical infection either with *N. gonorrhoeae* or with *C. trachomatis*, or of vulvovaginal candidiasis. In general, symptoms and signs of abnormal vaginal discharge have shown strong correlation with detection of bacterial vaginosis and trichomoniasis, and symptoms of vulvar pruritis and signs of vulvar inflammation have shown strong correlation with vulvovaginal candidiasis.[80,83,85,87,96] The true utility of algorithms dealing with vulvovaginal symptoms in many clinical settings lies in the management of vaginal infections. This conclusion from several studies of syndromic management of vaginal discharge actually represents an important practical advance in women's health-care practice in developing countries, as

many women suffer substantial symptoms related to bacterial vaginosis, trichomoniasis, or vaginal yeast infection that can be relieved with simple treatment regimens.

Of the three major categories of abnormal vaginal discharge symptoms (abnormally increased amount, abnormal odor, or abnormally yellow color), only the last (abnormally yellow color) has been associated with cervical infection in most studies published to date, after adjusting for the presence or absence of trichomoniasis or bacterial vaginosis.[77,84,97] In developing countries, classical hierarchical algorithms and risk score-based algorithms for "vaginal discharge" have been tested and compared in a few countries and mainly in family planning or antenatal clinic attendees or in female sex workers.[80,84,87,88,90–94,98,99] Unfortunately, relatively few studies have been conducted in STD clinics or primary care or gynecology clinics that serve symptomatic women for whom the algorithms are intended.[83,85–89,97] The 2000 review found that the success of various vaginal discharge algorithms for detecting endocervical gonococcal or chlamydial infection in women ranged from 29% among low-risk women attending antenatal clinics to as high as 93% in symptomatic women attending primary care clinics, but generally demonstrating the futility of using the vaginal discharge algorithms as screening tools for cervical gonococcal or chlamydial infection in most settings.[80] The addition of speculum evaluation was useful in some studies but not in others; however, the use of risk scores (as noted above for mucopurulent cervicitis) tended to improve sensitivity and specificity.

In summary, in most developing countries, syndromic algorithms calling for treatment for gonococcal and chlamydial infection in men with urethral discharge and for treatment for syphilis and chancroid in men or women with genital ulcers have been found sensitive, specific, and preferable to presumptive etiologic diagnosis based on clinical findings. However, in settings where genital herpes is common, chancroid uncommon, and serologic testing for syphilis feasible, other modified algorithms can defer antibacterial therapy for chancroid and provide antiherpes treatment when herpetic vesicles are seen. Syphilis serologic testing is always indicated, and results can guide partner notification. In many settings, for patients who may not return or may expose others, initiating syphilis therapy at the first visit for genital ulcer is often best, even when a rapid syphilis serologic test is initially negative, since about one-third of patients with primary syphilis still have negative rapid plasma reagin or VDRL tests at the first clinic visit. Prompt treatment of primary syphilis deserves high priority.

TREATMENT FOR STIs

Principles of STI treatment are discussed in Chapter 51. The diagnosis of a curable STI, regardless of the means on which diagnosis has been arrived, should lead to curative treatment. Curative antimicrobial therapy is available for all bacterial STIs, as well as for those caused by protozoa and ectoparasites.[32,33] For viral STIs, available drugs are suppressive but not curative; nonetheless, they can alleviate symptoms and prevent or delay complications. For genital herpes, suppressive therapy can reduce transmission of HSV from the patient who adheres to therapy without abandoning other protective measures. For HIV infection, the effect of suppressive therapy in preventing HIV transmission to an uninfected partner is being examined in at least one randomized trial.

DIRECTLY OBSERVED THERAPY, SHORT COURSE

WHO guidelines recommend that the most appropriate drugs for STI treatment are those that are highly efficacious, have acceptably low toxicity, are unlikely to select for antimicrobial resistance, can be administered orally (preferably in a single dose), and are not contraindicated for pregnant or lactating women.[33] Although one significant barrier to curative treatment is the patient's failure to comply with a full course of medication, a less well-recognized but perhaps more important barrier is failure of clinicians to provide or prescribe effective therapies that are available and affordable and for which compliance is easy. Effective single-dose curative therapies have been developed for all the major curable STDs (including early syphilis, chancroid, gonorrhea, trichomoniasis, and chlamydia infections), and this should help address this problem.

AVAILABILITY OF EFFECTIVE DRUGS

Ongoing problems for many developing nations are that the most desirable drugs (described above) are often not included on a nation's essential drug formulary or drug logistics are underdeveloped. This can lead to a "two-tiered" system of drug availability, in which the most effective—and often most expensive—drugs are only available at referral levels, while only less effective drugs are available at more peripheral health-care levels.[100] This, in turn, can result in an unacceptable rate of treatment failures and unnecessary referrals and is also likely to erode confidence in health-care systems and promote development of antimicrobial resistance.[32]

Additionally, although antiviral agents against chronic, recurrent HSV-2 infections exist, they are often underutilized, especially in the very settings most likely to benefit. Underutilization may occur because antiviral agents against HSV-2 are not yet included on the national essential drug lists of many countries, or not included as part of the syndromic algorithm for genital ulcer syndrome. Since less costly and often off-patent (e.g., acyclovir) drug formulations effective against HSV-2 exist, many experts believe these should be made available to clinicians providing STI care management everywhere.[13]

A recent development in STI treatment involves monitoring therapy and providing assistance in self-management. Drugs are now available not only for treatment of HSV infection, HIV infection, and chronic hepatitis B or C. Over time, cumbersome treatment regimens for chronic viral STIs (including HIV and HSV) have been replaced with twice or even once per day drug dosing.

ANTIMICROBIAL RESISTANCE

Antimicrobial resistance has complicated STI treatment in many settings, because the most available or convenient (e.g., single dose) drugs may no longer be effective. This is particularly the case for *N. gonorrhoeae*, as globally many strains are now resistant to former first-line therapies such as the penicillins and tetracyclines, and increasingly more strains (particularly in Asia, but rapidly throughout the world) are no longer susceptible to fluoroquinolone antibiotics. This situation has limited the potential to use oral antibiotics against gonorrhea in many settings; affected communities must resort to more expensive and less available drugs (e.g., cefixime) or drugs that require an injection (e.g., ceftriaxone). In some developing settings, newer formulations against resistant organisms are not available on essential drug formularies or, if they are, are too expensive or require such specialized procurement processes that they are unavailable to most patients. The resulting situation is that even when gonorrhea is correctly diagnosed, it is not cured, leading to further selective spread of resistant strains.

NATIONAL STI TREATMENT GUIDELINES

Development and promotion of STI treatment guidelines at national and local levels can help greatly with effective STI management. In addition, adoption of locally validated, syndromic management approaches by many low-income nations has helped ensure that the drugs recommended or provided are effective against the STIs (or syndromes) for which they are being used and has increased the likelihood that they are available on national essential drug lists.

PREVENTION APPROACHES

As noted earlier, many of the goals of effective STI management involve prevention: prevention of complications and sequelae of the STI—including complications related to pregnancy or family planning—through effective treatment; prevention of transmission of the STI to others, thus breaking the "chain of transmission" in the community through partner notification or repeated STI screening; prevention of reinfections through partner notification and treatment[101]; preventing new HIV cases that may arise from the enhanced risk of HIV transmission and acquisition risk associated with certain STIs, through prompt cure (bacterial STI) or suppression of recurrent genital herpes; and prevention of future infections through sufficient education, risk-reduction counseling, and skills training provided along with condoms.

Partner notification is an important prevention area that can be overlooked or simply ignored if specific etiologic diagnoses cannot be made. However, as pointed out earlier, unless sex partners are treated, individual patients run the risk of reinfection. Several promising new strategies have been evaluated recently, mainly in the United States, but some of these may have application widely. These are discussed in more detail in Chapter 54.

Substantial efforts have been directed toward development and rigorous evaluation of practical behavior change interventions to reduce new STIs and HIV, especially among patients who have been diagnosed with an STI. Several brief interventions suitable for clinical settings have been developed (e.g., individual or group counseling focusing on personal risk reduction, waiting room demonstrations focusing on building skills around correct condom use, and skills building videos).[4,11,102–108] Many of these have had moderate effects, resulting in up to 40% reductions in new STIs and even larger reductions among adolescents, supporting the notion that an STI diagnosis provides a "teachable moment" in which behavior change interventions may be more successful. Primary interventions have been particularly beneficial for adolescents or other groups who may lack knowledge or skills around safe sex. Less success has been met with interventions geared toward certain populations (e.g., homosexual men), who may already be highly informed, have repeated higher risk exposures, or both.

It is hoped that STI vaccines will be an increasingly important part of STI prevention and care management in the future. Since 1988, safe and effective vaccines against hepatitis B have been available, and substantially less expensive recombinant vaccines have been widely marketed (see Chapter 29).[8,9] In many countries, the hepatitis B vaccine series is recommended as part of routine infant vaccination, but this has not yet occurred in some of the nations most affected by the sequelae of chronic hepatitis B, the most severe of which include cirrhosis, end-stage liver disease, and hepatocellular carcinoma. As nations are increasingly able to vaccinate infants, an STI clinical encounter offers an opportunity to protect susceptible adults or adolescents who are at most risk of acquiring hepatitis B sexually (and who may not otherwise be easily accessed). New recommendations of the U.S. Advisory Committee on Immunization Practices (ACIP) for adolescent and adult hepatitis B virus immunization now support a more comprehensive immunization strategy to eliminate HBV infection.[109,110] Recently, vaccines against the HPV subtypes associated with most cervical cancers—HPV 16 and 18—have been found highly effective in preventing acquisition of infection with these

oncogenic HPV types and the associated precursor lesions. The U.S. ACIP now recommends routine vaccination for females 11–12 years of age and catch up vaccination for young women age 13–26 years who have not been vaccinated previously. The HPV vaccine currently costs more than US $300 for the series; however, even this expense may be very cost effective in nations with high rates of cervical cancer. (See Chapter 57.)

In summary, the importance of viewing the STI clinical care encounter as a prevention opportunity, and STI care management as a package of treatment and prevention services, should not be overlooked by providers. The STI clinical encounter may be the easiest or only way to access highly stigmatized or vulnerable populations who have high prevalence (or risk) for HIV and other STIs. Prevention research suggests an STI diagnosis is a time of heightened perception of personal susceptibility, when patients may be most amenable to trying behavior changes. In addition to on-site prevention messages, the clinical visit provides an opportunity for referrals for more extensive prevention services in the community. Furthermore, at least some experts postulate that the beneficial effects of STI control identified in the Mwanza community trial could be at least partly attributable to providers' instructions to their symptomatic STI patients who had primary HIV infection (and may have had high HIV viremia) about taking medicines properly and avoiding sex until symptoms resolved.[37]

ENSURING QUALITY OF SERVICES

Routine, periodic quality assurance for established programs has long been recognized as an essential component of ensuring that medical and public health programs are conducted as they were intended. Six general aims for quality improvement highlighted in 2001 by the U.S. Institute of Medicine address safety, effectiveness, patient centeredness timelines, efficiency, and equity (see *Informing the Future. Critical Issues in Health*, 3rd edn. National Academy of Sciences, 2005, pp. 7–10). A variety of specific strategies have been employed to ensure that comprehensive STI clinical management is provided as expected, and in a manner acceptable to patients. Several of these are described in Table 47-1. Provider training is important for the appropriate use of any STI management approach but is particularly critical for provision of syndromic algorithms.[100] Training providers on the overall rationale and utility of the syndromic management approach is important,

Table 47-1. Strategies That Have Been Used to Ensure High Quality of STI Clinical Management

- Development of national STI management guidelines for availability at the clinical setting–as possible with provider aids (e.g., posters with algorithms and laminated cards).
- Training courses on national STI guidelines that cover a "package" of services (e.g., STI diagnosis and treatment, locally supported prevention strategies, maintaining confidentiality of services, and promotion of user-friendly services).
- Development of procedure manuals for STI care management consistent with local policies and availability of commodities (e.g., laboratory tests, condoms, and drugs).
  - Focus should be on critical issues (e.g., confidentiality/privacy of information, nonjudgmental and helpful providers, accurate assessments, appropriate drugs, provision of condoms, routine provision of condom demonstrations by provider or patient, routine recommendation of HIV testing and appropriate education/counseling).
- Timely evaluation of locally collected data with feedback down to local programs and up to policy makers.
- Routine active supervision that focuses on critical issues that involves direct observation and immediate, constructive (not punitive) feedback to providers.
- "Secret shoppers" (i.e., simulated patients) who evaluate service and provide feedback.
- Peer observation and constructive feedback.
- Refresher courses and continuing professional education.
- Case conferences and formal and informal in-service trainings.
- Consultations and communication between health centers and referral centers through visits and radio or telephone links.
- Periodic client satisfaction surveys asking clients about what happened during their visit.

as many health professionals (and particularly physicians) are trained in laboratory-based or presumptive etiologic diagnosis and are hesitant to adopt other approaches that may be viewed as "less scientific." Some experts have pointed out that the behavior change needed for providers to adopt syndromic management may be even more difficult than what is asked of patients to avoid future STIs.[100] Regardless of the STI care management approach used, training for health providers should include a comprehensive package of services (i.e., all of the elements of Fig. 47-1 ought to be addressed in the training). Specialized training courses offer an opportunity to reinforce elements that may be overlooked, such as the utility and means of providing routine partner treatment, providing condoms and demonstrating (or asking patients to demonstrate) their correct use, and reasons to specifically recommend HIV testing.

INTEGRATING STI CARE MANAGEMENT INTO HEALTH-CARE SYSTEMS

Although vertical STI programs were the norm until recently in much of the world, in most countries today the majority of clinical services, including STI management, occur at the primary health-care level. This approach appears to have led to better delivery of services for women, an important consideration, given the fact that women and infants bear most of the long-term burden of STI-related morbidity, including infertility, reproductive morbidity, adverse pregnancy outcomes, and cervical cancer.[32] On the other hand, municipal STI clinics were able to serve large numbers of symptomatic men, who may be important in driving STI prevalence in their communities. Men, especially in developing countries, seem disinclined to seek care in primary-care clinics, at least initially. For many men, the informal health sector and pharmacies often represent the point of first encounter for STI care management. In nations with high STI prevalence, one essential issue for STI control that must be addressed is how to effectively access, diagnose, and treat infected men. In developed countries, declining rates of STIs may warrant a stronger emphasis on STI care management in the public health sector, as STI control relies increasingly on targeted outreach to marginalized (often uninsured) populations with high STI prevalence who are not easily reached.

In light of increasingly integrated services, it is useful to recognize how the different approaches used for STI care management are related to the primary mission and goals pursued by different types of servisce. Rather than dwelling on the limitations of each service type, it seems more productive to recognize the different primary missions of each service and to consider what each can contribute to STI care management and to STI/HIV prevention within the framework of its mission. Table 47-2 summarizes the relationships between various services' primary goals and the resulting emphasis on STI care management.

INTEGRATING STI MANAGEMENT INTO REPRODUCTIVE HEALTH SERVICES

Throughout the world, sexually active women access medical care through antenatal and family planning clinics; these facilities offer important opportunities for delivering STI care and prevention services to a population at risk of long-term STI-associated sequelae.

FAMILY PLANNING CLINICS

The International Conference on Population and Development held in Cairo in 1994 stressed that broadening the scope of family planning services could enhance their acceptability and effectiveness.[111] However, family planning clinics have been less likely to reach adolescents, single, sexually active women, including sex workers, and women who have completed their childbearing. STI rates found in women attending family planning clinics tend to reflect the rates among the general population of low-risk women, with wide ranges in prevalence depending on the specific infection and geographic region.[80] Incidences and prevalences of STIs, including HIV, are generally higher in urban than in rural areas, related to a combination of factors such as population density, migration, sex ratio imbalances, availability of commercial or transactional sex, loosening of family ties and traditional norms, and economic opportunity.[32,100] Consequently, STI prevalence in rural family planning clinics is generally considerably lower than in urban clinics. Syndromic approaches for STIs in asymptomatic women in family planning clinics—especially rural clinics—have generally not provided effective STI care management, as most symptoms are related to causes other than STIs. However, syndromic approaches may be reasonable management strategies for other reproductive tract infections (RTIs) (described below).

The integration of STI/HIV services with family planning services, while justified for a number of reasons, requires integration of somewhat differing approaches and objectives.[112] Family planning clinics provide a commodity (contraceptives) to consumers and tend to promote the methods most effective in preventing pregnancy, including long-acting contraceptive methods such as the IUD, sterilization, and injectable or implantable hormones, rather than reversible methods such as condoms that are less effective in preventing pregnancy but effective in preventing STIs. STI services, on the other hand, follow the model common to the control of communicable disease. As noted, this model ideally involves case identification, treatment, follow-up of contacts, provision

Table 47-2. Interrelationships Between Type of Health-Care Delivery System, STI Prevalence and the Relative Utility of the Syndromic Diagnosis, Presumptive Diagnosis, and Laboratory-Based Etiologic Diagnosis

Comparison of STD Delivery Systems

Type of Health-care delivery system	STI Prevalence	Goal(s)	Utility of Syndromic Approach	Utility of Presumptive Diagnosis	Utility of Lab-Based Etiologic Diagnosis[a]	Utility of Asymptomatic Screening[b]
Family planning clinic	Low	Protect reproductive health of client, couple and ensure safe and effective contraceptive use	Poor	Poor	Fair/good, especially CT, GC, HIV[b]	Good for cervical cancer, If no cervicitis present. Poor for syphilis.
Antenatal care clinic	Low	Prevent adverse pregnancy outcomes, maternal morbidity, and neonatal infections	Poor	Poor	Good, syphilis, GC, CT, HIV	Good for syphilis, HIV, GC, CT, and possibly TV and BV.? HSV
Primary health-care clinic	Varies	Relief of symptoms	Good	Fair	Good, but costly	Targeted approaches best. If targeted, good for syphilis, HIV, BV, and TV. May be poor for cervical cancer (Pap) if cervicitis present. HPV screening may be helpful.
STD specialty clinic	High	Prevent STI transmission, relief of symptoms, and HIV transmission/acquisition	Very good	Fair/good	Good, but costly	Good for syphilis, HIV, GC, and CT. May be poor for cervical cancer (Pap) if cervicitis present. HPV screening may be helpful.
Female sex worker clinic	High	Prevent STI transmission and HIV transmission/Acquisition	Good	Fair	Good, but costly	Good for syphilis, HIV, BV, GC, CT, and TV. May be poor for cervical cancer (Pap) if cervicitis present.
Adolescent/teen clinic	High	Prevent STI/HIV acquisition via education and counseling, relief of symptoms	Good	Fair .	Good, but costly	Good for CT and HIV.
Men's health clinic	High	Provide safe circumcision, STI clinical management, HIV testing, and prevention services	Good	Fair/good	Good, but costly	Good for syphilis and HIV.

[a]Dependent on types of tests available and whether rapid tests are available.

[b]Dependent on STI prevalence in the community.

of condoms, and promotion of other STI prevention services. Reasons for integrating STI care management into family planning services include the opportunity for educating women about STIs and how they can be prevented, need for symptomatic women to know whether they have an STI or are at risk of STI/HIV, and, ideally, to tailor contraceptive options and safer sex counseling to their needs. Family planners are particularly interested in ensuring safety of IUD insertion and of abortion and, therefore, have particular interest in detecting and treating infections before performing these procedures. They are also concerned that women who begin contraception, especially those who then begin sexual activity, may acquire an STI that causes symptoms that could be erroneously attributed by the individual client, and eventually by all women, to the contraceptive method. This could lead to discontinuation of the contraceptive by the client and, eventually, to decreased uptake of the method.

Promotion of dual contraceptive methods (e.g., hormonal plus barrier) is increasingly justified not only because certain clients who are not in stable or mutually monogamous relationships are at risk of pregnancy as well as STIs including HIV, but also because of data suggesting that hormonal contraception may increase the risk of acquiring certain STIs.[113,114] Although data are less compelling that hormonal contraception increases HIV susceptibility for HIV-uninfected women, for HIV-infected women who are coinfected with HSV-2, hormonal contraceptives may increase cervical shedding of HIV, perhaps rendering them more infectious to partners.[115]

The term reproductive tract infections (RTI) is increasingly used by women's health-care workers to encompass cervical, uterine, and vaginal infections. Bacterial vaginosis in particular is referred to by some as an STI and by others as an RTI. In the family planning clinics—a setting where the diagnosis of STI is often unexpected—the term RTI has the advantage of not provoking marital discord for management of diseases that do not currently warrant partner notification, such as BV or HPV infection, but also the disadvantage of potentially not emphasizing the need for partner treatment when this is essential (e.g., gonococcal or chlamydial infection).

ANTENATAL CLINICS

The primary mission of antenatal clinics is to maintain the health of the mother throughout pregnancy, ensuring uncomplicated pregnancy and a healthy newborn. Chapters 78–88 outline the relationships of various STIs to reproductive health, pregnancy, the newborn, and pediatrics and the importance of STI care management in pregnancy in preventing congenital and peripartum infections of the newborn, preterm rupture of membranes, amniotic fluid infection, premature delivery, and puerperal infection of the mother. The footnote to Table 47-2 summarizes precautions about treatment of trichomoniasis during pregnancy. Among the most cost-effective preventive health measures is antepartum screening for syphilis and neonatal ophthalmia prophylaxis.[32] Despite this, WHO experts estimate that 1000–4000 neonates still become blind each year because of untreated maternal gonorrhea and chlamydia infections.[32] Furthermore, these experts note that untreated syphilis will result in a stillbirth rate of 25% and will account for an additional 14% of all neonatal deaths—resulting in an estimated overall perinatal mortality of 40% among mothers with syphilis.[32] Antenatal detection of several STIs, including *C. trachomatis, N. gonorrhoeae*, bacterial vaginosis, hepatitis B, and HIV, should lead to curative treatments, preventive treatments, vaccination, or avoidance of breastfeeding, in order to prevent the above-mentioned complications.

Antenatal clinics serve women seeking obstetric care, rather than women with symptoms of STIs, and thus syndromic approaches tend to perform poorly, and detection of STIs requires asymptomatic screening involving laboratory testing. Although most nations today have national policies recommending universal STI screening for pregnant women early in pregnancy, in practice this does not always occur.[32] Many women do not access antenatal care at all, or not until late in pregnancy when adverse outcomes have already occurred. For women who access antenatal care early, tests may be unavailable, or when available may be unreliable without the hands of trained staff in controlled settings (e.g., nontreponemal card tests). When tests are sent out, women may be lost to follow-up by the time test results return. On-site, rapid serologic testing for syphilis in antenatal clinic settings in developing countries would help ensure that infected women are detected and receive effective treatment, and these tests are increasingly available at low cost; however, they can lead to substantial overtreatment in the settings that need them most.[67,68] The expectation in the near future of an affordable, rapid, dual-antigen test for point-of-care detection of syphilis seroreactivity is expected to greatly improve the likelihood of early detection and treatment of maternal syphilis among pregnant women attending antenatal clinics. Similarly, reliable rapid tests for chlamydia and gonorrhea would greatly assist in identifying infections in women attending antenatal and family planning clinics and could prevent substantial unnecessary sequelae.[67,68]

INTEGRATING STI MANAGEMENT INTO PRIMARY HEALTH CARE

Increasingly, all over the world, primary care providers now diagnose the majority of STIs and will likely assume an even greater role in STI prevention and control because of the declining emphasis on vertical public health programs.[106] Integrating STI services into existing primary care systems has potential benefits; perhaps most important (as is the case for reproductive health services) is the expanded access of STI services for women, who are most affected by STI sequelae but also most affected by stigmatization around STIs.

PRIMARY HEALTH-CARE CLINICS

Health care in the primary care setting tends to emphasize relief of symptoms, and preventing complications in individual patients served, rather than protecting the public health. Consequently, services tend to be client centered, directed toward the patient's perceived needs, and treatment is frequently based on management of the patient's symptoms. Advantages of STI care in the primary care setting include the ongoing relationships between the clinician and the individual, which can increase the likelihood of early STI detection and effective preventive interventions, such as regular clinician counseling. In addition, incorporating STI-related services into primary care may improve access to services, since primary care providers are much more numerous than public STI clinics, especially as public funding for public health programs decreases.[111] Because STI-related services provided in primary care clinics are not provided in isolation, but rather in the context of other medical problems, primary care clinics do not carry the stigma associated with dedicated STD clinics. Primary care providers may have more opportunity and success in coordinating the variety of health and social services available in the community, which are especially needed by those persons at highest risk of STIs and other infectious diseases that often require multiple services. In addition, certain prevention interventions, such as provision of STI vaccines and referrals, may be easier to accomplish.

Although development of STI care management services at the primary care level has advantages, disadvantages for effective STI care management may also be numerous. At the primary health-care level, STI services tend to be less efficient and more rudimentary. Training in clinical evaluation and risk reduction counseling may be lacking in some primary care settings, especially in developing countries where the quality and effectiveness of services designed for STI care management (e.g., use of syndromic management flowcharts) have not been extensively documented. The interaction between health systems may be inefficient. A study of sexual and reproductive health services in Ghana found that, some years after decentralization of services, many systems-level challenges remained, particularly clarity on how different agencies related to each other and to regional and district health authorities.[116] Such challenges are not restricted to the developing world. A 2003 study of genitourinary medicine (GUM) clinic attendees in England found that 40% of those diagnosed with an STI had already visited a primary health-care clinic for their problem but had been referred to (or preferred) the GUM clinic for specialized services.[117] In the United States, private health insurance plans often cover STI services but may be inconsistent in their coverage, sometimes restricting or excluding some basic types of services related to reproductive and sexual health concerns.[118] Around the world, regardless of the health systems in place, public health agencies will be most effective if they can develop partnerships that support delivery of locally tailored, comprehensive STI care management and prevention services to the entire community.

COMMUNITY-BASED CLINICS

Community-based health providers at urban community health centers, school-based health clinics, and adolescent clinics, serving teens and young adults, represent a particular type of primary health care that has potential to ensure effective STI care management for younger, otherwise hard-to-reach patient populations with high prevalence of STIs. Although many community-based health programs provide STI-related clinical services, most have not made STI management a priority, even when STI prevalence in their patient population is high. This may occur if community-based practitioners lack knowledge about local STI prevalence (or prevalence among their patients), expertise about management, or the essential technical resources needed to provide such effective STI care management services. Enhanced training opportunities (e.g., when standardized national guidelines are developed) and collaboration with local public health agencies or health-care training institutions could improve the quality of services offered.

PRIVATE SECTOR

As is the case for primary health-care management, the goal of STI care management in the private sector is predominantly treatment and relief of symptoms presented by clients. In many settings, patients with STI symptoms who can afford to do so seek evaluation with private providers rather than at public clinics, even when they perceive public clinics to provide better care technically.[100] This seems to be related to concerns about privacy and confidentiality of information, judgmental attitudes of providers or prior experiences of "scolding" by public providers, or long waits or inconvenient or limited hours of operation at public clinics.[100] Symptomatic individuals may seek treatment with private practitioners who are part of the official private sector or may seek treatment directly from pharmacies or in the unofficial private sector (e.g., with traditional healers or alternative providers), and while this occurs all over the world, it is particularly common in certain developing country settings.[100,119] Given the public trust and use of the private sector, strategies aimed at improving STI care management in a community are likely to be more effective if private provider training and management can also be addressed.

Private practitioners

Throughout the world, private providers, often general practitioners, see most patients with STI symptoms who seek

health care from clinicians. Although private providers clearly have the potential to play important roles in disease management (and surveillance), they are often neglected in national STI control strategies. Nonetheless, a number of factors, including development of national guidelines, inclusion of STI care management in the training curricula at professional schools, and provision of incentives (e.g., accreditation, licensure, and continuing education credits) for completing STI training courses, all have been shown to aid in improving STI care management by private providers.[32,100] In settings where syndromic management approaches are the standard of care, inclusion of private practitioners as part of expanded training courses may improve overall STI management and will at least ensure that all providers understand the rationale behind the approach and thus limit negative perceptions that public STI care management is somehow inferior to that provided in the private sector.

Treatment by pharmacists

In much, if not most of the world, a large proportion of patients—particularly men, but also many women—receive initial care from pharmacies or the informal medical sector, rather than from trained clinicians.[120–126] As is the case for other private providers, the goal of STI care management in pharmacies is predominantly treatment and relief of symptoms presented by clients, together with sales of pharmaceutical products.[123] Pharmacy workers tend to recognize STI syndromes in men better than STI syndromes in women as being attributable to sexual transmission but without training may do a poor job with both.[120,122,123] For example, a study in Peru that used standardized simulated patients with scripted scenarios who presented to pharmacies found most of the simulated patients were offered medication.[122] However, effective, recommended medication was rarely, if ever, offered to patients presenting with PID, genital ulcer syndromes, or vaginal discharge syndrome and was offered to only 30% of men complaining of urethral discharge symptoms.[122] Similar results have been reported elsewhere.[120,123] Additional problems have been observed: In some settings, most people working in pharmacies are actually clerks, with trained pharmacists often not being available on the premises.[120] Conformance to published guidelines for STD treatment in pharmacies has been recognized as very poor, and pharmacists uncommonly recommend preventive practices such as partner management, condom use, or risk reduction.[122,123]

Nonetheless, the perceived accessibility, confidentiality, and lack of judgmental remarks of pharmacists make them very attractive to patients with STIs.[119,123] Adoption of validated, national syndromic algorithms has helped some countries justify standardized training courses for professionals providing STI care, including pharmacists and physicians and nurses in the private as well as public sectors.[32,100] Research suggests that pharmacists are willing to participate in expanded training on STI care management, and several communities have proposed or already experimented with training alternative providers, including pharmacists and traditional healers, on understanding and appropriate referral for STI syndromes.[100,119,120,122–126] Additionally, there is some evidence that prepackaged kits containing the appropriate antimicrobials for urethral discharge sold at pharmacies can lead to high cure rates and condom use (although these has not been found to improve partner notification).[125,126] The use of incentives and other measures discussed above for private providers may be helpful in encouraging and supporting pharmacists to provide effective STI care management.[100] Again, in Lima, Peru, a district-randomized trial was carried out in which 14 districts were paired and randomly assigned to receive training and support for management and prevention of STIs or a control intervention concerning management of diarrhea. The multicomponent and sustained STI intervention addressed recognition and management of four STI syndromes (urethral discharge, vaginal discharge, genital ulcers, and PID) and included STI/HIV prevention counseling; "prevention salespersons" subsequently distributed materials to pharmacies that included STI/HIV prevention packets containing information, condoms, and cards given to patients for referral of their sex partners. Standardized simulated patients visited pharmacies in intervention and control districts at 1, 3, and 6 months after training to assist outcomes. By "intention-to-train" analyses intervention district pharmacies performed significantly better in syndromic recognition and correct antimicrobial management for all four syndromes and more frequently recommended future condom use and treatment of partners ($p < 0.05$ for 47/48 outcome comparisons).[127]

INTEGRATION OF STI CARE MANAGEMENT INTO SPECIALTY CLINICS

Specialty clinics seek to provide STI/HIV interventions including STI care management to populations with high STI prevalence or risk or who are highly vulnerable to STIs (e.g., sex workers and migrant men). In addition to preventing important STI-related sequelae, the prevention interventions (including STI care management) provided at specialty clinics may reduce STI prevalence in a community if the populations targeted have high rates of sex partner change.

SEX WORKER CLINICS

Sex workers are obviously at high risk of contracting STIs, including HIV, and can also promote spread of STIs in the community. Most urban centers and port cities throughout the world have clinics providing STI care management, and several models from industrialized and developing countries

have demonstrated that rates of STIs can be lowered among sex workers in these communities.[84,128–131,135] Rather limited attention was given to the quality of care or efficacy of the STI care management provided in such clinics in the past. However, more recently, over the past several years, several studies have addressed the quality, client satisfaction, and cost effectiveness of services provided.[132–134] Additionally, some STI care management models for sex workers have been found effective in preventing new cases of gonorrhea, chlamydia, and trichomoniasis, although thus far not HIV infection.[128–131,135] Clinical services with regular STI screening, with provision of condoms, has led to increases in condom use and reductions in STI and HIV prevalence.[135–137] Another model, employing periodic presumptive therapy (routine provision of directly observed antimicrobial drugs, even without symptoms) has been found to rapidly reduce STI rates in some settings; however, once prevalence rates are brought down, other longer-term strategies may be required.[135,136] Additionally, STI rates have been observed to drop dramatically among sex workers enrolled in HIV prevention trials when they are provided access to free condoms, risk-reduction counseling, and STI therapy, suggesting that such trials may provide the needed commodities, information, or empowerment to support reductions in sexual risk taking.[137,138] Overall, evidence is strong that clinical services for sex workers offer an opportunity to access a high-risk, often hidden population (particularly true for non-brothel-based sex workers) and allow provision of important prevention services such as HIV testing, empowerment programs promoting consistent condom use and negotiation of condom use with partners, and even alternative physical barrier methods such as female condoms.[128–138] In some places, sex worker clinics are offered HIV clinical services (e.g., provision of highly active antiretroviral therapies) (Marie Laga, personal communication). However, where sex workers are required to register with municipal authorities and to attend clinics for regular periodic examinations, the threat of withholding health cards needed to work, if STI is detected, can provide a disincentive to attend clinics.

HIV CLINICS

HIV-infected persons may be at particular risk of STIs, both behaviorally through sexual risk taking and biologically through enhanced expression of certain STIs (e.g., HSV and HPV). Additionally, HIV-infected persons who are coinfected with HSV or with some curable STIs have genital inflammatory lesions and higher levels of HIV viremia, providing more opportunity to transmit HIV to partners, and treatment of certain curable STIs has been found to reduce HIV plasma viral load.[139] Current randomized trials are examining the impact of suppression of genital HSV recurrences on transmission or acquisition. The HIV clinical care system offers an opportunity to identify persons coinfected with STIs whose higher HIV viral load may lead to enhanced transmission to others. Strategies addressing prevention of HIV transmission for HIV-infected persons have addressed the potential utility of initial, and possibly periodic, STI testing among HIV-infected persons in clinical care, particularly in communities or subpopulations with high STI prevalence.[32,140,141] Routine testing for certain STIs among HIV-infected persons may also help access sex partners who require STI therapy and, importantly, HIV testing. This strategy can ensure more prompt identification of HIV infection in sex partners, and referral into HIV clinical care, as well as specialized prevention strategies for negative (i.e., HIV discordant) partners, such as specialized couples counseling to reduce HIV transmission. Discordant couples counseling has been shown to be associated with reduced HIV seroconversion rates in several settings but is a strategy which still requires rapid scale up in many places.[142,143]

ADOLESCENT CLINICS

Adolescents, particularly women are at high risk of STIs for a variety of biological, behavioral, social, and economic reasons discussed in more detail in Chapter 11. In fact, globally it has been estimated that one in every 20 adolescents will develop a new STI.[100] In most developing countries, more than half of the population is under 15 years of age; thus, adolescents represent a group that not only is susceptible to STIs, but may also drive STI (and HIV) transmission and prevalence in a community. Adolescents are often unwilling or unable to access typical health-care services for a variety of reasons, and many experts recommend development of specialized clinical and prevention services for them, perhaps incorporated into other programs of interest to adolescents.[32] While specialized services offer an opportunity to access this important population, specialized training on how to provide services in ways that are acceptable (and encourage participation by other adolescents who hear through word of mouth) will likely be important.[100]

MALE HEALTH-CARE CLINICS

As discussed, many high-risk men do not utilize public sector primary care systems, preferring to access STI care through the private sector or with alternative providers (e.g., traditional healers and pharmacists) who may be utilizing inadequate STI management strategies. In 2005 and 2006, results from a series of randomized controlled trials evaluating adult male circumcision in preventing HIV and other STIs consistently found circumcision to result in approximately 50–60% reductions in new HIV infections.[7,144,145] Several communities with high HIV prevalence have already begun considering the best ways to implement and scale up circumcision interventions for men, one of which may be to develop model clinics targeting men's

health. Such male health clinics would offer an opportunity to provide a variety of services, including comprehensive STI care management, HIV testing and counseling, risk reduction counseling around high-risk sexual behaviors and partners, and skills building around correct and consistent condom use. These are likely to be particularly used in developing world settings with high HIV prevalence where many men are not circumcised. The 2006 WHO Strategy for STI Prevention and Control includes "male involvement, male motivation and services for men" as one of five new technologies for strengthening a response to STI/HIV control.[32]

CONCLUSION

The dynamic advances in medical technology and public expectations drive clinicians to use more and more services that are increasingly sophisticated and costly. This trend must be balanced by streamlined systems of STI care management that use common sense to apply available resources most efficiently in a patient-oriented manner. In addition, comprehensive systems must address each of the potential levels for intervention shown in Fig. 47-1. Clinicians are increasingly called upon to discard old paradigms and consider new ways to package services or referrals within existing systems. Effective STI care management requires providers to consider which systems-wide actions will help solve the major sources of STI-related sequelae facing a population. For example, is active screening for young, sexually active women (e.g., in family planning settings) a more effective approach to prevent infertility than more passive screening approaches? For resource-poor settings, would training alternative providers (e.g., pharmacists) in effective syndromic approaches help reduce STI burden in some communities[127] or should such training be focused on aiding alternative providers to make prompt referrals to clinicians? Could better training on use of the algorithms and rationale behind various STI management approaches in professional school curricula help health providers in developing country settings better support and utilize syndromic approaches, and would this lead to reductions in the curable bacterial STIs most associated with HIV risk? Can practical partner notification approaches substantially prevent reinfections and further STI spread into the community? Could provision of comprehensive STI care management, together with condom promotion, STI risk reduction and contraception counseling, and provision of male circumcision in specialized men's health clinics, reduce the prevalence of curable STIs (and possibly HIV) in developing world settings hard-hit by HIV/AIDS? Clinicians must continue to focus on the care they provide to their clients. However, providing clinicians a better understanding of the epidemiology and transmission dynamics of HIV and other STIs, the magnitude of their social and economic complications, and the potential benefits of a comprehensive STI care management package may help them undertake new and effective actions for reproductive health and prevention of STIs, including HIV.

48 Individual-Level Risk Assessment for Sexually Transmitted Infections, Including HIV

Ann E. Kurth and Freya Spielberg

The taking of a thorough history is the foundation of excellent clinical care. This is especially the case for sexual health issues, which some patients may be hesitant to introduce without elicitation. Individual risk assessment conducted in the form of a sexual history focuses sexually transmitted infection (STI) testing, enhances individualized counseling and appropriate referrals, and provides patients the opportunity to address issues of concern.[1] Clinicians, counselors, public health professionals, and community health workers can play central roles in preventing STIs including HIV infection, and in limiting the morbidity and mortality of STIs by identifying and treating these infections as early as possible; by providing risk-reduction counseling to prevent further transmission; and by instituting prophylactic measures for at-risk individuals not yet infected.[2,3]

There is growing interest in methodologies for ecological or population-level risk assessment for STI/HIV (see Chapters 3 and 5).[4,5] This chapter concerns individual-level risk assessment for STI/HIV infection, primarily in clinical settings.

Primary care, urgent care, emergency department (ED) settings,[6] private physician offices,[7] chemical dependency treatment centers,[8] prison discharge facilities[9] and outreach sites,[10] prenatal and family planning clinics, and clinics serving adolescents[11] represent important settings for identifying individuals at moderate and high risk for HIV and STIs, and often provide the first opportunity for health-care professionals to identify those with mild and sometimes protean symptoms of early infection. In resource-constrained countries, pharmacists are often a first point of contact for individuals seeking care for infections manifesting as sexually transmitted disease (STD), and such providers can be trained to do syndromic management.[12,13]

Other important settings for risk assessment include STD or genitourinary medicine clinics[14,15] and HIV testing sites including mobile outreach units.[16] These settings generally conduct STI/HIV risk assessment as a part of their primary function. However, a national survey of sexual history forms in use at STD clinics in the United States found great variability in risk behavior items and periods that are routinely assessed. Few (19%) of the history forms in use incorporated questions for men who have sex with men (MSM), and condom use problems were rarely explored (6%). Most forms documented STI/HIV counseling, though few (23%) delineated specific risk reduction plans.[17]

In STI/HIV care management, individual-level risk assessment has been most extensively used as a guide to selective screening for gonococcal, chlamydial, and HIV infections.[18–22] STI/HIV risk assessment can also initiate and personalize counseling on behavioral risk reduction, as well as assess the need for prophylactic measures, such as hepatitis vaccines, and also (in conjunction with elicitation of symptoms and signs) for presumptive diagnosis of STDs and for management of certain STD syndromes (see Chapter 47).[23] Table 48-1 summarizes the overall goals of risk assessment as an initial component of STI/HIV management.

Although a number of guidelines address STI/HIV risk assessment, they often lack details on how to carry this out, and the literature still contains relatively few formal validations of the reliability and utility of STI/HIV risk assessment in various settings.[24] We will review the requirements and potential elements of STI/HIV risk assessment and close with recommendations for improving the consistency with which such assessments are conducted by health-care providers.

EFFECTIVE RISK ASSESSMENT AS A PUBLIC HEALTH STRATEGY

Risk-based screening followed by treatment can prevent secondary and tertiary complications for STI-positive individuals and primary disease transmission to others.[5] In general, risk assessment must have high sensitivity, specificity, and predictive value in discriminating between those at high and low risk. For a risk-based, selective intervention to be effective, those affected must have a risk profile different from those unaffected; and an intervention must exist that will alter favorably the natural history of the condition.[25] Referrals should be made for those

This chapter was based on Curtis JR, Holmes KK. Individual-level risk assessment for STD/HIV infections, Holmes et al., STD, 3rd edn, 1999, with permission.

Table 48-1. Sexually Transmitted Infection (STI)/HIV Risk Assessment Goals by Patient Status

Patient Status	Objectives of Risk Assessment
Symptomatic patient	Use risk assessment to determine the prior probability that an STI causes the symptoms; guide testing, syndromic management, and partner treatment
Asymptomatic patient, infection status unknown	Decision on whether to not to screen (cost-effective use of resources) or to use postexposure prophylaxis or preventive treatment
Known uninfected	Individualized counseling to decrease risky behavior to protect oneself from STI/HIV acquisition; assess need for prophylaxis (e.g., hepatitis B vaccine)
Known infected	Individualized counseling to decrease risky behaviors: To protect others To protect oneself against potential reinfection To protect oneself against other STIs or, if HIV-positive, other strains of HIV
All patients	Address sexual concerns

identified to be in need of services, and ethically, such services should be available in order to justify screening in the first place. The US Preventive Services Task Force (USPTF) has emphasized the desirability of delivering preventive services to people with limited access to medical care.[20] While it may often be the case that those at highest risk are the least likely to have access to health-care services, this concern must be countered by the public health perspective that for communicable STIs including HIV, intervention in those at highest risk, particularly those most likely to transmit infection, can benefit the entire population. STI transmission dynamics are increasingly understood to be a complex system involving individuals with a multiplicity of risks, often linked through sexual networks, resulting in population level patterns of transmission.[26]

MODEL OF STI/HIV RISK

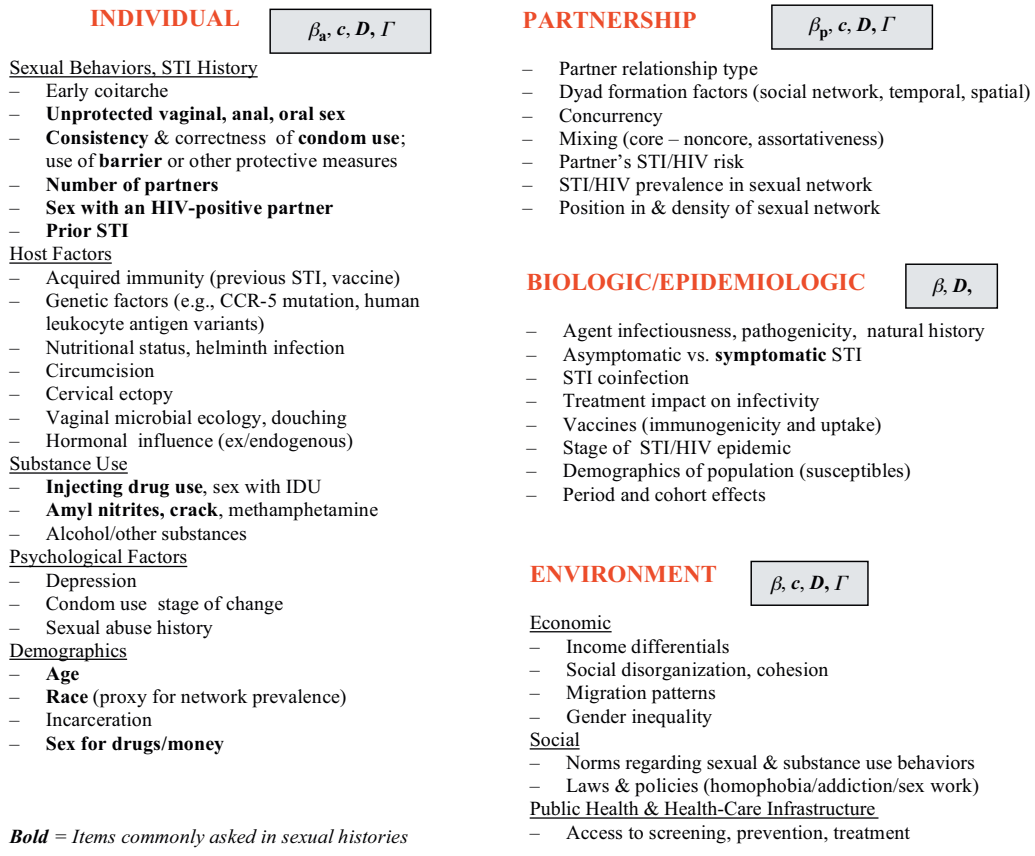
This leads to asking what should be measured for STI/HIV risk assessment. Disease transmission probabilities are affected by individual-level factors such as host immunity and biologic pathogenicity. Understanding specific sexual partnership patterns is also important. The risk of acquiring STI/HIV is related to infection status of the chosen partner(s), specific sex acts, and condom and possibly other barrier method use,[27] all of which have been shown to vary by sexual partner type (e.g., main vs. casual partners, or partners perceived to be risky vs. those perceived to be low-risk).[28] One large behavioral intervention trial found that STD clinic attendees tended to have safe (condom-protected) sex with partners thought to be risky and had risky (unprotected) sex with partner perceived to be safe from STIs/HIV.[29] While much epidemiologic focus has been on the individual characteristics that are associated with risk of STI acquisition, recent work points out the limitations of such an approach to explaining incident STIs.[30]

As outlined in other chapters of this book, it is increasingly clear that sexual behaviors and STI transmission dynamics can be predicated on factors beyond those controlled by the individual or the sexual dyad or couple.[31] These may include sexual and social[32] network characteristics, socioeconomic factors,[33] community social cohesion and trust measures,[34] and sex-ratio disruptions in minority communities due to higher rates of incarceration,[35] inter alia. The epidemiologist Meryvn Susser has declared that with these supraindividual "contexts unmeasured, neither patterns of mortality and morbidity, nor epidemic spread, nor sexual transmission may be explained."[36] The interdependence of STI risk behaviors necessitates an ecologic approach,[37,38] since infectious diseases and social behaviors are not statistically independent: the outcome in one person influences the outcome and alters risk factor effects in other people.[39]

While simulation modeling and some empiric evidence now demonstrate the importance of understanding sexual network-level factors, most STI risk assessment questions have focused on individual-level factors such as "number of sexual partners," since the individual patient tends to be the primary unit of focus in clinical settings. Sexual histories that focus only on individual level variables may be epidemiologically incomplete, but in practical terms, clinicians are not able to factor in sexual partner risks and other structural-level data in real time during an examination. Of necessity, clinicians will continue to rely on risk assessment questions that reliably target the individual. Some of these standard items are highlighted in bold in Figure 48-1, which also includes the variety of other supraindividual factors that may influence both individual and population-level STI acquisition and transmission.[40] The figure also classifies the ways in which these factors relate to the classic formula of the basic reproductive rate for STI transmission.[41,42]

INTERVIEW MODALITY AND THE RELIABILITY OF PATIENT SELF-REPORT

Along with the question of what should be measured for STI risk is the question of how to best capture accurate risk



From Kurth A. Audio computer-assisted self interviewing for sexually transmitted infection prediction. Doctoral dissertation, epidemiology. University of Washington, 2003.

FIGURE 48-1. A model of STI/HIV risk.

exposure information. Social desirability,[43] self-presentation, recall, and other biases such as item nonresponse can lead to serious measurement error in sexual behavior surveys.[44,45] The lack of a gold standard limits interview modality comparisons, since there are few biochemical measures to document actual sexual practice or STI exposure and thus, to validate behavioral self-reports.[46] Attempts have been made to measure semen,[47] prostate-specific antigen,[48] and Y-chromosome deposition in vaginal fluids[49] as a way to validate reports of unprotected penile-vaginal intercourse, but this cannot distinguish frequency, multiple partners, or nonvaginal intercourse sexual behaviors. Another difficulty is that there is not a linear relationship between a specific behavior (such as unprotected sex with an infected person) and STI acquisition.[29,50]

Sex partner concordance has also been assessed as a way to validate self-reported behaviors. Some studies have found reasonably high concordance in partners' reports of recent joint behaviors (83–96%),[51] but recall of all recent partners tends to be lower, with 15–72% of partners from the last 1–3 months forgotten.[52] However, a National Institutes of Health working group concluded that self-reports of sexual behavior can be useful even if subject to some inaccuracy.[42] Likewise, a National Academy of Sciences review of the research literature has pointed out that people can consistently report STI-risk-related information.[53]

Computer-assisted self-interviewing (CASI), sometimes with audio, video, or telephone enhancements, has been used to assess patient histories[54–56] in a variety of clinical settings including STD clinics.[57,58] STI/HIV risks have been surveyed using CASI among blood donors,[59] university students,[60] adolescents in resource-rich and -poor settings[61–64] and injecting drug users (IDUs).[65–68] Test-retest reliability of a complex audio CASI survey administered in English and Spanish to recently-diagnosed HIV patients was good ($\kappa = 0.77$, $r = 0.73$).[69] CASI formats have been found acceptable among low-income, minority, and low computer-literate populations[70–73] and among patients in clinical exam settings.[74] Older persons, those with hearing difficulties and those with low technology-exposure[75] may be less suitable for CASI interviews. Higher levels of sensitive behaviors such as drug use, same-sex behavior, and anal intercourse have been reported in CASI compared with face-to-face and self-administered paper interview modes in some settings.[76–78] A video-CASI study in a New Orleans STD clinic found that 30% of women with chlamydia reported discordant responses in a face-to-face interview versus a V-CASI instrument.[79] Another study comparing clinical sexual histories with audio CASI self-report by 609 STD clinic attendees found that men's behavioral reports were equivalent between interview modalities, while women's were not, with a tendency to report socially sensitive behaviors more often on the computer.[57] Patients seeking care for STIs may be more motivated than general population samples to report risk behaviors truthfully. Nonetheless, even in that setting, computer interviewing may still provide advantages of data quality and completeness[80] and may enhance the efficiency of the provider-patient interaction rather than resulting in differential risk reporting per se.[81]

THE ROLE OF RISK ASSESSMENT FOR DECISION ANALYSIS AND SYNDROMIC MANAGEMENT

By using data from the patient history, physical examination, or simple diagnostic tests to categorize heterogeneous populations into subgroups of risk, clinical prediction rules help clinicians identify which patients require further diagnostic tests.[82] In clinical decision analysis, identifying risk factors for STDs in patients with various sets of symptoms and signs increases the prior probability that a particular STI causes those signs and symptoms; this might lead to selective testing for that STI, to initiation of treatment while results of tests obtained are pending, or to initiation of empiric treatment without testing—especially if the prior probability of an STI becomes so high that confirmatory tests are not deemed cost-effective.

In the United States, selective screening criteria have been developed for chlamydia in particular.[83–86] In part because validation of screening rules is not always carried out among populations different from the ones on which they were developed, these rules may not always be reproducible and may leave out predictors found to be important in other populations.[87] No screening algorithm or rules can replace clinical judgment. But if soundly developed and validated, they can minimize reliance on subjective assumptions or untested heuristics[88] regarding the STI-risk likelihood of patients based on perceptions of social class, relationship status, and other nonsensitive markers of STI risk. The predictive value of clinical judgment may also be affected by disease probabilities.[89] When a particular STI is ubiquitous, e.g., human papillomavirus or herpes simplex virus type 2, it is harder to intuit which persons are at highest risk.

Like any other test, a clinical prediction rule's diagnostic value is affected by prevalence.[90] Likelihood ratios build on the clinician's judgment and estimated pretest probability of the underlying clinic prevalence and are more stable across different populations.[91] Clinics can use likelihood ratios to set thresholds for the point at which the test result would change clinical action.[92] An example of this can be seen in one STD clinic that used sexual history-derived risk assessment criteria to find that as chlamydia prevalence increased, the risk score necessary to justify chlamydia laboratory testing decreased.[93]

Figure 48-2 illustrates how risk assessment influences the potential for under- , over- , and correct diagnosis of an STI in a patient with a hypothetical STI-related syndrome, in a population where the prevalence of that STI is 10%, and the sensitivity and specificity of the symptoms and signs that make up the syndrome are 90% and 85%, respectively, for that STI. For a risk factor or combination of risk factors that carries an odds ratio for the STI of 10.0, the prevalence of STI among those with that risk factor would be 36%, and if treatment were offered, the probability of correct treatment of an STI, relative to the probability of overtreatment, is greatly increased among those who have both the syndrome and the risk factor.

Risk assessment is routinely used by clinicians as an adjunct to diagnosis and management of most diseases, including several STD syndromes, including unilateral intrascrotal pain and swelling (epididymitis); lower abdominal and pelvic pain in women (PID); vaginal discharge; proctitis; acute hepatitis; various STD-associated neurologic and rheumatologic syndromes; and HIV-related clinical syndromes, including the primary infection syndrome, the generalized lymphadenopathy syndrome, various neurologic and hematologic syndromes, and other syndromes related to acquired immunodeficiency. Risk assessment is also potentially useful in managing mucopurulent endocervical discharge, genital lesions, rashes, etc.

For some syndromes, simply age and sexual experience are sufficient to rule in or out the likelihood of an STI in the

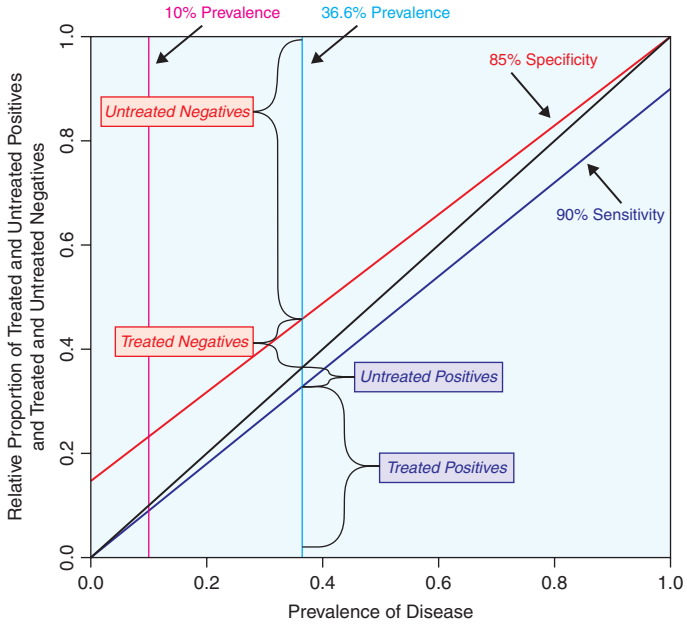


FIGURE 48-2. The plot shows the impact of screening only those who are risk assessment (RA) positive in a population with 10% infection prevalence. In this example, the odds ratio for infection of RA positives against RA negatives was taken to be 10; this means that RA positives have a posterior probability of infection (i.e., prevalence) of 36.6%. The sensitivity and specificity of the diagnostic test was taken to be 90% and 85%, respectively. In this plot, the top line represents the stated specificity of 85%, the middle line the performance of a perfect test, and the bottom line represents the stated sensitivity of 90%. The left-hand vertical line in the plot represents the prevalence of infection in the entire population; the right-hand vertical line in the plot represents the prevalence of infection in the risk assessment-positive subset of the population. The division of the vertical, prevalence lines into four segments represents the performance of the diagnostic test. From top to bottom, the segments represent the relative proportion of patients in the following groups: untreated-negatives, treated-negatives, untreated-positives, or treated-positives. The relative size of the four segments is determined by the prevalence of infection in the group tested and the sensitivity and specificity of the diagnostic test. This plot is one way to examine the performance of a test across different levels of disease prevalence. Note that at 10% prevalence, the ratio of treated negatives/treated positives is 3/2; whereas at 36.6% prevalence that ratio is 2/7. (*Figure courtesy of Barry N. Courtois.)*

differential diagnosis. For example, in evaluating testicular pain and swelling in an adolescent who has not been sexually active, the likely diagnoses are testicular torsion or trauma; in a sexually active young man the likely diagnoses are acute epididymitis owing to gonococcal or chlamydial infection; and in an older man in a mutually monogamous relationship the likely diagnoses are acute epididymitis caused by urinary pathogens. For other syndromes, more information on risky practices or partners is also useful.

Risk assessment has been most extensively studied recently as an adjunct to syndromic management of vaginal discharge, for which it appears to be less successful than for other syndromes such as genital ulcer disease or urethral discharge.[94–96]

It was hoped that risk assessment of women with symptoms or signs of vaginal discharge could help identify women with cervical gonococcal or chlamydial infection and that those with vaginal discharge and positive risk assessment could be treated for cervical infection. Unfortunately, because abnormal vaginal discharge (especially increased amount or abnormal odor of the discharge) does not predict cervical infection, and because risk factors for certain vaginal infections may be similar to those for cervical infection, this approach has been generally disappointing for identification of cervical infection or for differentiating cervical from vaginal infection. Although risk factors for cervical infection can usually be identified, in most clinical settings even those with positive risk assessment have a prevalence of cervical infection too low to warrant routine treatment solely on the basis of positive risk assessment. A review of the literature by Pettifor and colleagues found that sensitivities for vaginal discharge algorithms ranged from 73% to 93% among women presenting with vaginal discharge symptoms and from 29% to 86% among asymptomatic women. Vaginal discharge was not seen to be an independently effective screening tool to detect women with cervical infection, especially in low-risk or asymptomatic populations, though the authors stress that incorporating risk scores tailored to local community risks can improve the accuracy of algorithms to detect cervical infection.[97]

RISK ASSESSMENT AS A GUIDE TO SELECTIVE SCREENING FOR ASYMPTOMATIC INFECTION

Because many STIs are asymptomatic, particularly in women, risk screening based on presenting symptoms alone is insufficient. Even when symptoms occur, not all patients will recognize them as such. A national study involving five STD clinics whose populations have high STD knowledge and known access to care found that even with clinician questioning, 50% of new STIs were unrecognized by patients.[98] Behavior changes in response to STI symptoms (such as forgoing sex in the presence of vaginal or urethral discharge) may vary by gender and other patient characteristics and cannot in any case be presumed to occur universally.[99]

In industrialized countries, STI/HIV risk assessment is probably used most extensively to guide selective screening for chlamydial infections and HIV infection, and to a lesser extent, to guide selective screening for gonorrhea and syphilis. The Centers for Disease Control and Prevention (CDC), the USPSTF, the Canadian Task Force on the Periodic Health Examination, and national clinical organizations recommended risk-based routine screening for chlamydial infection, with risk criteria generally focused on age and sexual activity (asymptomatic women aged <26 years with sexual activity or risk, or women over

age 25 who have risk factors such as new or multiple sex partners).[100] The CDC has created software that clinics can use to determine resource allocations based on chlamydia test and treatment costs, protocols, and prevalence.[101] Since 2000, such screening has been included as a Health Plan Employer Data and Information Set (HEDIS) quality of care indicator in the United States.[102]

Screening for *Chlamydia trachomatis* evaluated in one health maintenance organization resulted in a 56% decline in PID rates among women 14–55 years of age, for a relative risk (RR) of 0.44, 95% confidence interval (CI) 0.20–0.90.[103] Despite this apparent benefit, screening levels nationally remain low: 26% of female enrollees aged 16–26 years in commercial plans and 38% of those in Medicaid plans, in 2001.[104] This occurred even though payment for such screening is provided, highlighting some of the challenges to integrating STI screening even when such screening is recommended as a quality assurance measure and is a reimbursed procedure.

As the prevalence of gonorrhea has declined in the United States, the indications for cost-effective risk-based screening for gonorrhea have become less clear. Because syphilis in the United States tends to be geographically clustered, routine syphilis screening of asymptomatic persons is not recommended, though the USPSTF recommends screening all pregnant women and all persons at increased risk based on local incidence, including MSM who engage in high-risk sex, sex workers, persons who exchange sex for drugs, and adults in correctional facilities.[105] Syphilis outbreaks among MSM—many of whom were also HIV-positive, and often related to internet sex-seeking[106]—in the early 2000s in some U.S. cities and western European countries did lead to an increased emphasis on bacterial STI screening in MSM.[107,108] Screening for gonorrhea and syphilis in other populations has focused less on individual risk assessment and more on population and venue characteristics by screening in juvenile detention centers, jails and prisons, or in particular census tracts with relatively high rates of these two infections.[109–112]

RISK ASSESSMENT IN HIV POSTEXPOSURE PROPHYLAXIS OR STD PREVENTIVE TREATMENT

Prophylactic or preventive treatment (to prevent occurrence of infection or disease manifestations, respectively) is commonly provided to patients with known or suspected exposure to an STI. Administration of antiretroviral therapy following occupational exposure to HIV via needle stick or mucosal contamination is an example of the importance of risk assessment in guiding therapy. Updated CDC guidelines regarding PEP in the occupational setting for HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV) exposure recommend using a combination of risk assessments related to exposure inoculum and source patient risk to guide HIV postexposure prophylaxis (PEP) therapy initiation and regimen selection.[113] In most cases, a 4-week two-drug regimen is advised, with a third drug added for deep percutaneous or visibly contaminated exposures associated with higher risk of transmission.[114] Consultation is available via the National Clinicians' Post-Exposure Prophylaxis Hotline ([PEPline] 1-888-448-4911).

Guidelines promulgated by the CDC first in 1998 and then in 2005 address the issue of using PEP in nonoccupational exposure situations (nPEP), i.e., involving sexual or IDU exposure. The earlier guideline factored in transmission risk related to the inoculum, the risk of the source, and also the likelihood of whether this nonoccupational exposure was likely to be sporadic or ongoing, to determine whether PEP administration was appropriate.[115] The 2005 guidelines stratified risk, recommending a 28-day course of highly active antiretroviral therapy (HAART) for persons seeking care within 72 hours after nonoccupational exposure to blood, genital secretions, or other potentially infectious body fluids of a person known to be HIV infected, when that exposure represents a substantial risk for transmission. For persons seeking care within 72 hours after nonoccupational exposure to body fluids of a person of unknown HIV status, no recommendations are made for the use of nPEP. Clinicians are encouraged to evaluate risks and benefits of nPEP on a case-by-case basis.[116]

A review of European countries found that 23 of 27 had national guidelines regarding occupational exposure PEP, whereas only 6 out of 27 had policies for nonoccupational PEP.[117] Emergency care clinicians are often on the front lines of determining both occupation and nonoccupational PEP utilization.[118,119]

Prophylactic or preventive treatment may be offered to individuals following known exposure to an STI, while test results from the exposed individual are pending (e.g., for *C. trachomatis* or *Neisseria gonorrhoeae*); or even if initial screening test results are negative (e.g., for syphilis); or in the case of sexual assault. In these cases, the risk assessment consists of defining whether the time of exposure of the individual to the person with a known STI fell within the period when that person was potentially infectious (e.g., within 2 weeks or less before recognition of symptoms of gonococcal urethritis); or was sufficiently recent that the exposed individual might still be in the incubation phase prior to seroconversion to a reactive serologic test for syphilis. In the case of sexual assault, the CDC recommends STI evaluation and prophylaxis, with consideration of HIV exposure likelihood for nPEP.[120,121] Despite these guidelines, analysis of the National Hospital Ambulatory Medical Care Survey has noted that a large proportion of patients are neither screened nor receive STD medications in EDs following forcible rape.[122]

BROADENING ACCESS TO STI SCREENING AND PREVENTION

Efforts to modify sexual and drug use risk behaviors to decrease the transmission of HIV infection and other STIs have been effective in selected populations. However, STI incidence is increasing in some populations such as MSM,[123] and HIV seroprevalence continues to increase among large groups such as minorities and women. In addition, moderate- or high-risk sexual behaviors remain common in many populations. The dynamic epidemiology of STI/HIV infection necessitates a broad approach to assessing risk behaviors. It is not adequate to concentrate HIV risk assessment solely on MSM or IDUs in high-prevalence regions. Risk assessment should become a part of routine clinical care throughout the United States and in most parts of the world. As heterosexual HIV transmission increases, it becomes important not simply to address an individual's personal sexual and drug use history but also the risk of the individual's sexual partners and social and sexual networks.

Although changing epidemiology makes risk assessment increasingly challenging, the changing patterns of health-care delivery in the United States and elsewhere may provide opportunities that will facilitate systematic risk assessment. The increase in managed care and large systems of health-care delivery offer the opportunity to define effective risk assessment practices in different communities and implement standardized and effective risk assessment strategies. The ability of managed care organizations to promulgate and monitor practice guidelines provides unique opportunities to enhance STI/HIV risk assessment and risk reduction counseling. This may be accomplished through relatively low-cost means, as in one study that used key providers as opinion leaders to reinforce STD screening practices. This intervention was associated with increased patient recall of providers asking about sexual risk factors (OR 1.7; 95% CI, 1.2–2.6) and discussing personal risk reduction (OR 2.6; 95% CI, 1.6–4.3). Overall, 52% of patients with self-reported high-risk behaviors recalled discussing these topics with their provider, an absolute improvement of 13% from preintervention levels, though short of the 75% counseling level recommended by the USPSTF.

A review of STD guidelines has emphasized elements that make guideline incorporation more likely in managed care organizations. These include focusing on primary prevention, addressing health systems practice integration issues, and promulgating the guidelines in the form of pocket handbooks or online versions,[124] which may be downloaded to personal digital assistants (PDAs) increasingly used by providers. Encouragingly, a seven-city review of STD guideline compliance among Medicaid managed care organizations found that most organizations and primary care providers interviewed provided recommended preventive counseling while taking a sexual history (though higher-cost services such as partner notification were less often provided).[125]

Partnerships between managed care organizations, which can provide primary and secondary STD/HIV prevention, and categorical public STD clinics, which will likely continue to see high-risk "core group" attendees, may be facilitated by collaborative agreements.[126]

STI/HIV RISK ASSESSMENT IN CLINICAL SETTINGS: CURRENT RECOMMENDATIONS AND CURRENT PRACTICE

Many agencies and professional organizations recommend that clinicians routinely perform STI/HIV risk assessment, and/or offer voluntary screening and counseling to individuals seen in clinical settings, including HIV clinics. Such organizations include the USPSTF, the CDC, the American Medical Association, the Infectious Disease Society of America, the American Academy of Pediatrics, the American College of Obstetricians and Gynecologists, the American Academy of Family Physicians, the Canadian Task Force on the Periodic Health Examination,[127] and the World Health Organization.[128–134]

Despite these recommendations, clinicians do not consistently or adequately screen for sexual and substance use-related STI/HIV risk among their patients. A national survey of 4,226 randomly-sampled U.S. physicians found that fewer than one in three routinely performed STI screening of men or women (pregnant or nonpregnant).[135] In a representative survey of 3390 adults aged 18–64 (the 1994 U.S. National Health Interview Survey), only about one-quarter of U.S. adults reported being asked about STDs during routine checkups; being under age 45, male, and with income below federal poverty level was associated with increased likelihood of discussion. An indicator of provider discomfort may be surmised by noting proportions of patient who said their provider asked about the patient's smoking (58.7%) and exercise (52.3%), versus about illegal substance use (31.3%) and sexual activity (27.9%)[136]

Adherence with STI screening recommendations is often low even in settings serving at-risk populations, such as in EDs[137] and among obstetrician-gynecologists.[138] The infrequent provision of preventive STI/HIV services to adolescents in a variety of health-care settings is especially troubling.[139] One study of a California health maintenance organization found that pediatricians, on average, screened 92% of their adolescent patients for immunization status but only 34% for sexual intercourse.[140] Physicians' self-reported practice of preventive health measures and counseling may overestimate actual practice patterns.[97,98] One study of

primary care physician screening found that even among standardized patients with classic presentations for HIV and STDs, risk assessment was highly variable.[141]

Fewer data are available on the performance in STI/HIV risk assessment and risk behavior counseling of clinicians other than physicians. A survey of 1265 randomly selected clinicians in Colorado found that obstetrician-gynecologists, nurse practitioners, and pediatricians were most likely to report regularly taking a sexual history (90.1%, 88.6%, and 76.0%, respectively), while internal medicine specialists were the least likely(43.9%).[142] Another study using unannounced standardized patients found that only 18% of physicians and 27% of nurse-practitioners asked about history of STDs, while 18% and 63%, respectively, inquired about condoms and IDU.[143] Some studies suggest that female and younger clinicians are most likely to assess and follow up on STI risk with their patients.[144]

PROVIDER–PATIENT COMMUNICATION

This dearth of routine STI/HIV risk assessment may occur because some clinicians lack the tools and training; experience discomfort and embarrassment;[145,146] or are constrained by time demands, financial disincentives,[147] or confidentiality concerns that prevent them from performing extensive risk screening and counseling. Regardless of the reasons, and despite widespread recommendations, clinician-initiated risk assessment is not being performed in most primary care settings. Thus, in clinical settings there are many missed opportunities both for STI/HIV control as well as for holistic care, given that many patients have sexual lives and concerns.

Patients want to discuss sexual health with their providers, even when they think their doctor may be dismissive of their concerns, according to one poll,[148] and are willing to disclose sensitive sex and drug use behaviors to their clinicians when asked.[149] It has been noted, however, that while adolescents want to talk about sexual issues,[150] few will initiate the conversation.[151,152] Stigma (i.e., a societal response seen to set someone apart) has been identified as a significant potential barrier both to disclosure of sexual behaviors to health providers and to STD care-seeking services among females in a Baltimore household sampled-study population.[153] If patients perceive that providers are uncomfortable with discussions of sexual and drug-use risk behaviors, they are less likely to disclose important information. A UK study of gay men, for example, found that fewer than one in three (30%) had discussed safer sex with their general practitioner, compared with 87–92% who had talked about it with lovers and friends, respectively ($p < 0.001$).[154] Creating a clinical practice climate where STI/HIV risk assessment and counseling are routine can be an effective way to ameliorate patient concerns and reduce STI/HIV-related stigma.

BENEFITS OF RISK ASSESSMENT IN PREVENTION AND MANAGEMENT OF STIs/HIV AND THE COSTS OF MISSED OPPORTUNITIES

The benefits of appropriate risk assessment for HIV and STIs can be divided into two categories. First, the benefits to those with unidentified infection include preventing complications, limiting progression, and, where possible, curing infection. Second, the benefits to those at risk for infection but still uninfected include preventing acquisition of infection through appropriate treating of any infection and stimulating risk reduction.

In addition, risk assessment in the context of family planning and prenatal care[155] can help reduce maternal and neonatal morbidity and mortality. This involves tailoring risk reduction counseling, STI/HIV tests or referrals, and contraceptives, including dual method use[156] and/or access to emergency contraception,[157] to the patient's needs. For example, those at increased risk for STDs would be poor candidates for IUDs but may be good candidates for barrier or dual methods.

Benefits to those with unidentified HIV infection

HIV risk assessment leading to voluntary HIV testing represents the first step in the provision of direct health benefits to individuals with undiagnosed HIV infection. Such health benefits include vaccinations, prophylactic therapies, and antiretroviral therapy that, together, can greatly improve both the quantity and quality of life for these individuals. HAART regimens have improved the survival and quality of life for persons with HIV infection, including in resource-poor settings[158] where they have become more available in recent years. Timely initiation of HAART optimizes survival and cost-effectiveness;[159] thus, risk assessment can identify individuals early enough to realize maximum benefit from these therapies. In addition, the myriad of prophylactic measures that can be instituted for primary prevention of opportunistic infections in persons with HIV infection make it critically important that individuals with early HIV infection be identified and offered the appropriate prophylactic measures.[160] Many of these interventions, such as pneumococcal and other types of vaccinations and skin testing for identification of tuberculosis infection, will be most effective if performed as early as possible in HIV infection.

In the United States, up to an estimated 30–40% of HIV infections have been diagnosed late in the course of disease. One study of a managed care organization's membership found that 26% of patients diagnosed with HIV had risks documented in their charts at least 1 year prior to diagnosis, and that this was an underestimate of actual risk. The authors concluded that in their population, effective risk assessment of demographics and behavioral factors would have been more effective than eight HIV-associated clinical indicators

(such as unexplained cachexia or lymphadenopathy) to identify HIV infection in individuals who could benefit from HIV treatment.[161] Given these HIV treatment advantages, and to reduce late diagnoses, as early as 2000, some called for expanded routine HIV screening in health-care settings.[162,163] Screening based on risk factors does identify persons at substantially higher risk but could miss a substantial proportion of those infected. Therefore, the CDC and others have concluded that routine offering of HIV testing to sexually active adults is warranted.

Another potential benefit of identifying individuals with HIV or STIs is the possibility of notifying previous sexual partners of their risk for these infections. Partner notification is an underutilized public health measure, particularly for HIV. One U.S. survey of jurisdictions with 500,000 or greater population or that reported 200 or more AIDS cases in 2001, found that health departments interviewed fewer than one in three people with newly reported HIV (32% of 20,353 persons).[164] Partner counseling and referral services can take the form of information sharing conducted by the index patient alone (patient referral), provider or health department alone (provider referral), or through a combination of these strategies (Chapter 54).[165]

Providers often express a preference for patient referral;[166] however, not all patients are able or willing to disclose STI/HIV exposure information to sex partners[167] and should be able to receive health system assistance to do so. Provider/health department notification can, on the whole, be more effective. One early randomized controlled trial of partner notification for HIV infection found that when individuals had full responsibility for notifying their partners, only 7% of the partners were notified. If, however, counselors were available to assist in partner notification, 50% of partners were successfully notified and, of the partners notified, 94% were unaware that they had been exposed to HIV; 23% of those notified and tested were HIV-positive.[168] Voluntary partner notification programs have been found to be acceptable to HIV-positive individuals and have been successful at notifying individuals of their risk for HIV infection.[169] Ongoing evaluation of the need for sex partner counseling and referral services is important, as not all individuals living with HIV will necessarily disclose their status to all new sex partners over time.[170] Despite the current inadequacy of recommending and producing partner notification, risk assessment and selected STI/HIV screening can lead to the identification of previous partners who would benefit from testing, early intervention, risk-reduction counseling, screening for STIs, and secondary HIV prevention, among persons living with HIV.

Many individuals do reduce sexual and other transmission risk behaviors once they learn that they are HIV-positive.[171,172] Several meta-analyses of studies from the United States, Europe, and Africa have shown that the majority of individuals found to be HIV-positive reduce their risk behaviors.[173–175] However, studies show that clinicians often fail to address the critically important issue of HIV transmission risk reduction with their HIV-positive patients.[176] Guidelines for doing so have been published.[131] In one study of 618 HIV-positive patients as they exited from their health providers' office, only 6% said that they had experienced a detailed risk assessment of specific behaviors such as partner gender, type of sex, and condom use, from their provider that day.[177] Infectious disease specialists, who often provide excellent HIV clinical care, were found in several studies to be significantly less likely to provide counseling around condom and substance use.[178,179]

Clinical HIV care providers have limited time that is often focused on medication management and lab monitoring.[180] The importance of long-term supportive relationships often established by HIV providers with their patients may accentuate providers' fears that bringing up sexual and substance use risk behaviors that can transmit HIV could undermine that relationship. Nonetheless, relatively high incident STI rates demonstrate the missed opportunities for STI detection among HIV-positive individuals.[181–183]

Encouragingly, brief, clinician-delivered counseling can reduce sexual risk behaviors among persons living with HIV. Two meta-analyses have shown that interventions, including those delivered in HIV care settings, can reduce unprotected sex and incident STIs among persons with HIV.[184,185]

Richardson and colleagues have shown that "loss" or consequence framing of prevention messages may be more effective than "gain framing" in promoting safer behaviors among HIV-positive persons engaged in risky sex. The loss-frame counseling approach emphasizes consequences—"Unsafe sex may expose you and others to other STDs and strains of HIV"—rather than advantages of safer sex. Individuals presented with these messages in a randomized trial had significantly less unprotected sex at follow-up compared with those presented with gain framing messages emphasizing the benefits of condom use (OR 0.42, 95% CI 0.19–0.91).[186]

Another promising intervention uses a scaling algorithm to have patients assess their self-confidence and importance of risk behavior change and provides "prevention prescriptions."[187] Similar prevention counseling risk reduction "contracts" have been found effective in reducing sexual risk behaviors among persons living with HIV in Uganda.[188]

Benefits to those with other unidentified STIs

The individual patient benefits of risk assessment and selective screening for chlamydial infection have been demonstrated by Scholes and colleagues, who showed more than a 50% reduction in the risk of PID among women randomly assigned to selective risk-based screening for *C. trachomatis* infection.[103] Similarly, risk assessment prior to IUD insertion to exclude those at risk of STIs is the standard of care to

prevent IUD-related PID.[189] For any of the curable STIs, risk-based screening followed by treatment can lead to secondary prevention of complications at the individual level and primary prevention of transmission at the population level.[5]

Benefits to those at risk but without STI or HIV infection

Risk assessment plays an important role in the prevention of further transmission of HIV and other STIs. For those with HIV infection, risk behavior screening and HIV testing can be the first step to behavioral interventions that can limit the transmission of HIV to those who are uninfected. Addiction treatment, needle exchange programs, and primary care for substance users also decreased reported high-risk behaviors among IDUs.[190,191] Similarly, HIV-related risk reduction efforts, when added to the improving early diagnosis and treatment of curable STD, have undoubtedly contributed to the declining incidence of these other STDs.

For individuals with STI/HIV risk behaviors who screen negative for infection, provision of risk reduction counseling is optimal since behavior change among those testing HIV negative may be more difficult. Several randomized clinical trials of behavioral interventions in individuals at increased risk of STI have achieved significant reduction in STI incidence and in reported risk behaviors.[192] HIV risk reduction interventions may also be successful among HIV-negative IDUs,[193] although such interventions may require more complex approaches than the standard individual counseling approach that is routinely offered with HIV and STI testing.[194]

THE COSTS OF MISSED OPPORTUNITIES FOR RISK ASSESSMENT

"Missed opportunity" has been defined as an encounter with a health-care provider, by a patient who is engaging in risk behavior, where testing[195] and risk reduction counseling was not performed. The overall population-level costs of missed opportunities for STI/HIV risk assessment could ultimately exceed several billion dollars in direct medical costs in the United States to the extent that risk assessment leads to selective early detection and treatment, to effective risk reduction counseling and education, and ultimately to the secondary prevention of complications and to primary prevention of transmission.[196] Widespread risk assessment for HIV (and STIs) and appropriate selected screening could potentially lead to the prevention of a substantial proportion of these illnesses.

METHODS FOR ASSESSING HIV AND STI RISK

Screening for HIV infection or STIs can be implemented in a variety of different ways: screening can be routine or selective, voluntary or mandatory, and confidential or anonymous. Screening is routine when HIV serology or STI screening cultures or serologies are offered to every individual regardless of risk profile. Selective screening involves testing following risk assessment; screening is recommended to those individuals for whom a certain level of risk is identified. Both routine and selected screening can be mandatory or voluntary and both can be anonymous or confidential. Routine voluntary HIV or STI screening is cost-effective and indicated when the prevalence of infection exceeds a certain level and when effective interventions are available. In this circumstance, the virtues of routine screening outweigh the potential harm of false-positive tests because of the large number of infected individuals identified. The cost-benefits of screening for STIs depend on the cost of the various tests available, the prevalence of infection, and the costs of the specific STI and its complications and sequelae.

In many health-care settings throughout the world routine testing for HIV infection or other STI is neither indicated nor feasible, since if the population is low-risk a substantial proportion of those with positive screening tests would represent false-positive tests, with potentially substantial financial and emotional costs. Consequently, in many health-care settings, selective voluntary screening based on risk assessment to identify individuals at increased risk for HIV or STI will remain the most effective method of targeting those individuals who should be offered HIV and STI screening, unless HIV seroprevelance is 1% or greater, where HIV testing should be routinely offered. In settings offering routine testing, risk assessment is still important in order to identify those uninfected with STIs/HIV but at high risk of acquiring infection.

STRATEGIES FOR CONDUCTING STI/HIV RISK ASSESSMENT

Ideally, STI/HIV risk assessment should be part of routine screening for all patients in most clinical settings. STI/HIV risk assessment could be accomplished in all patients if it were made part of a routine history and physical on a new patient and during an annual checkup for a patient in ongoing care. There are a number of additional circumstances under which STI/HIV risk assessment is especially important, for example, when a patient presents with the symptoms or signs of an STD- or HIV-related problem; when a patient is pregnant or wants to become pregnant; when a woman initiates contraceptive care; when a patient asks a question about an STI, or HIV or about sex; and when men initiate drug therapy for erectile dysfunction, given a possible association between use these drugs and STI/HIV acquisition, at least among MSM.[197,198]

Systematic methods to provide uniform STI/HIV risk assessment are an important component of identifying those at risk for infection. Systematic methods can include

approaches targeting clients, clinicians, or clinics. Approaches targeting clients can include routine written screening instruments given to all new clients; computer-based screening programs designed to identify risk and educate; and written educational materials available to those interested. Providing statements regarding confidentiality,[199] STI/HIV posters, and safer sex supplies in visible locations throughout the care setting demonstrates through visual clues that sexual health matters are an open and important part of the clinic climate. Approaches targeting clinicians include education in risk assessment methods, checklists or computer prompts to remind clinicians to assess risk, and the institutional expectation that risk assessment is a part of each new patient visit. System approaches can include all of the preceding methods when a clinic or health-care system formalizes these methods. Also important are dissemination of evidence-based practice guidelines for clinicians.

Given the importance of risk assessment and the difficulties that clinicians have in routinely providing this screening, one solution is to develop a screening instrument that could be administered to all individuals seen in a health-care setting. Such an instrument could be completed in a waiting room and used to signal clinicians that follow-up questions and voluntary HIV or other STI testing may be indicated. Many clinicians have a medical history intake form to which HIV or other STI risk assessment questions could be added. Some countries such as the UK and Australia have defined sexual health minimum data sets that will encourage standardization of data elements collected in settings that see people at risk for STI/HIV. In the United States, a set of standardized items for HIV behavioral surveillance (though not clinical risk assessment per se) has been developed.[200]

Several sample HIV risk behavior questionnaires have been published, but none with systematic input from the target population, and few have been formally validated. A 10-item HIV screening instrument for use in primary care settings was shown to have an internal consistency coefficient of 0.73; however, its predictive power was not tested for identification of actual HIV and it did not focus on screening for other STIs besides HIV.[201] An individual "potential risk index for STI" based on the reproductive rate formula (Fig. 48-1) has been developed but again, not validated for screening discrimination performance using STI biomarker outcomes.[202] A clinical prediction rule for HIV seroconversion among MSM developed in one STD clinic population and validated against a second, national sample found that five factors accurately predicted 65% of incident HIV acquisitions (area under the receiver operating characteristics curve 95% CI: 0.63–0.67).[203]

Risk assessment in the individual clinician–patient encounter requires that clinicians ask culturally sensitive, understandable risk questions and provide an environment that allows patients to reveal potentially embarrassing or even illegal information. It is important to be aware of culture-specific stigma issues, such as prohibition against same-sex behavior in the African American population, or concerns about family shame in some Asian populations.[204]

Ideally, assessing STI/HIV risk involves not just checking off a list of defined chart form elements but exploring with patients their sexual lives in the overall social and current life priorities context. Avoiding the tendency to focus on biomedical and pharmacologic approaches to sexual health necessitates understanding patient behaviors in regard to relational, psychosocial, cultural, and economic influences.[205] This "new view" approach to sexuality[206] is not the paradigm in which many clinicians were trained but is one that likely resonates with patients themselves, since it treats them as whole people rather than reducing them to a matrix of risk factors and specimen collection sites.

Figure 48-3 shows one suggested approach to a brief STI/HIV risk assessment involving a limited number of initial questions to be asked of all patients and follow-up questions when the initial questions suggest that risk is present.[207] There may be local or regional differences in language concerning sexual and drug use activity, and it behooves clinicians to know these variations in language to maximize the effectiveness and cultural relevance of their risk assessment.

FRAMING THE QUESTION IN RISK ASSESSMENT

Respondents who do engage in sexual risk-taking and who may even perceive this as risky may nonetheless not report risk-taking. Reasons for this at a clinical encounter may include fears that admitting risk could endanger employment or lead to other discrimination, in addition to the usual concerns about embarrassment and loss of face. It is helpful to use language, tone, and body language that suggests that the clinician is respectful, concerned about their patient's health, and will not be judgmental. Being empathetic, repairing problematic language by asking for clarification or by reframing one's questions, and being able to negotiate awkward moments while still persevering to elicit the patient's sexual health issues have been found to substantially improve patient-provider STI/HIV discussions.[208]

The sexual history should be conducted sitting at eye level, while the patient is still clothed. It is helpful to start by providing a rationale for the risk assessment. One approach is to tell the patients that risk assessment for HIV and STI is an important part of health-care delivery and that the clinician performs this type of risk assessment with all patients. For example, the California Chlamydia Action Coalition[209] recommends introductory statements tailored for teens and one for adults as follows:

- *For teens:* "Now I am going to take a few minutes to ask you some sensitive questions that are important for me to help you be healthy. Anything we discuss will be completely

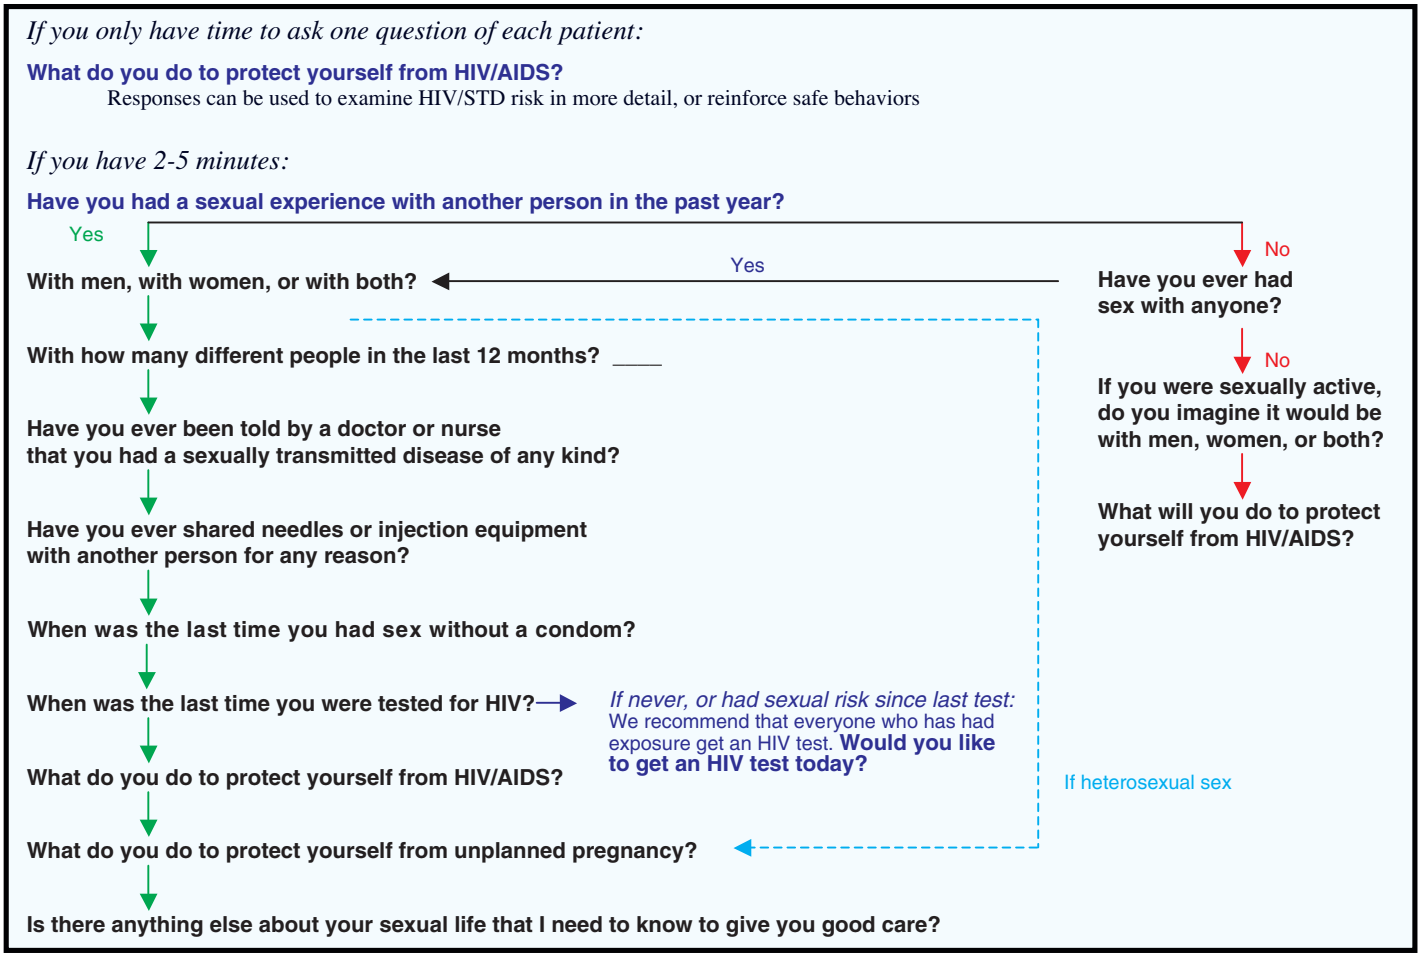

FIGURE 48-3. An abbreviated sexual history. (Adapted from Hatcher R, Trussel G, Stewart F, et al. *Contraceptive Technology*, 18th rev. edn. New York: Irvington Publishers, 2004; Nusbaum MR, Hamilton CD. The proactive sexual health history. *Am Fam Physician*. 2002; 66(9): 1705–1712.)

confidential. I will not discuss this with anyone, not even your parents, without your permission."

- *For adults:* "Now I am going to take a few minutes to ask you some direct questions about your sexual health. These questions are very personal, but it is important for me to know so I can help you be healthy. I ask these questions to all of my patients regardless of age or relationship status and they are just as important as other questions about your physical and mental health. Like the rest of this visit, this information is strictly confidential."

The goal of this introduction is to assure the patient that he or she was not singled out for risk assessment because of mannerisms, appearance, race, ethnicity, or some other factor.

Individual questions can be framed in a normalizing way to increase an individual's willingness to answer certain questions. For example, a clinician may say, "Many people have experimented with drugs such as cocaine or methamphetamine" before asking an individual about past amphetamine use. This type of framing is not necessary in all circumstances but may be helpful in some situations when a clinician believes that a patient may be reluctant to reveal risk behaviors. Kassler and colleagues offer a series of additional framing statements giving "permission" to discuss taboo topics and to introduce specific questions.[210] For example, "Many women find it difficult to get their men to use condoms; has this been a problem for you?" "Many men have sex with other men. Have you ever had sex with another man?"

It is useful to ask direct questions about specific behaviors.[211] Use of open-ended questions (e.g., "what are you doing to protect yourself from HIV and other STIs?") can yield substantive information regarding patient's risk perceptions and behaviors and may stimulate insights for both the patient and the provider.[212] In general, "how," "what" "where," types of question can be better used to explore behavior than asking "why" did you or "have you ever" [done this socially stigmatized behavior] sorts of questions.[213] Most clinicians are trained, however, and most clinical data forms are designed, to utilize closed-ended questions ("Did you use a condom?"). Both question types have their place when used to elicit specific information as well as to assess risk context and the need for personalized counseling.

The range and depth of questions asked in a risk assessment may vary depending on the venue and setting. For example, in outreach settings a brief but focused set of questions may be appropriate, whereas in primary care settings a more patient-centered focus on risk screening may be effective.[214]

SPECIFIC CATEGORIES OF INFORMATION NEEDED IN A COMPREHENSIVE STI/HIV RISK ASSESSMENT

Many sets of practice guidelines, including the evidence-based and influential Guide to Clinical Preventive Services, recommend STI/HIV preventive interventions that depend on risk assessment. The lack of specificity and validation of instruments for this purpose continues to represent the "Achilles heel" of such recommendations. Nonetheless, there are some common assessment domains that are reflected across many of these guidelines. Taken as a whole, and considering the epidemiological evidence related to STI/HIV risk, these may include assessment of the following:

- STI symptoms
- Sexual activity
  - Sex with men, women, or both.
  - Types of sex (vaginal, anal, oral).
  - Use of protective methods, especially condom consistency and correctness (assess user errors).
  - Number and type of recent sex partners (e.g., new, main, anonymous).
- Sex partners' risk, including HIV status, history of STDs, or IDU
- History of STDs
- Exchange of sex for money or drugs
- History of parenteral exposure (needle-sharing) and other substance use (such as amyl nitrites or crack cocaine)
- HIV testing and hepatitis vaccination history
- Among women, contraception usage including emergency contraception access; menstrual, obstetrical, and gynecologic history; cervical screening (Pap smear or HPV, any cervical dysplasia)

We now discuss elements that may be incorporated into an STI/HIV risk assessment, as conducted in a clinical sexual history. Assessment of risk may take into account consideration of the local epidemiology of STIs. Specific risk factors differ from one country or population to another, and providers and STI/HIV control programs should try to establish what demographic characteristics, behavioral risk factors, and clinical symptoms and signs are associated with the various STIs seen in their own settings.

Demographics

Key demographic data that may serve as potential markers for STI risk in some settings and are available on any clinical intake form include gender (male, female, transgender), area of residence, age, date of birth, and relationship status. Educational level and race/ethnicity (as a proxy measure) may also be helpful in some settings. All could be used to provide standard prompts to clinicians as to STI/HIV risk, and these alone could be sufficient in some settings to prompt screening or more comprehensive risk assessment for certain STIs.

Age

Young age (e.g., ≤25 years) is a risk factor in nearly all societies (especially true in females) both for physiologic reasons (cervical ectopy in the young female,[215] less immunity) and behavioral reasons (more partners, rapid partner change, less condom use negotiation power[216] or skills). Of note, age of the partner discrepant from that of the patient, has been found in some studies to be a risk factor for HSV-2[217] and for HIV infection.[218]

Race/ethnicity

There are no empiric data to suggest innate or biological reasons for the higher rates of STI/HIV seen among certain subpopulations in many settings such as in the United States. Reasons for this "racial" differential may include reporting bias,[219] reduced knowledge of and access to screening and treatment services,[220] high rates of incarceration[221] (and resultant disruption of the sex ratio[222] and social disorganization[223]), higher STI/HIV community or sexual network prevalence,[224] and assortative sexual missing by race,[225] in some populations (Chapter 7). The fact that in many settings minority populations have higher rates of STI/HIV, may support the need for improved screening and treatment services in these populations.

Relationship status

Partnership status (single vs. married or living with a regular partner) may or may not be a risk marker, depending on the local context. In many resource-poor settings, marriage is a significant HIV risk factor for women.[226] A meta-analysis of studies from non-Northern African countries found that the impact of socioeconomic status on HIV risk varies depending on whether the woman is married or unmarried.[227]

Sexual history: risk and satisfaction

Two main objectives of sexual history taking are assessment of STI/HIV risk and assessment of sexual function and satisfaction. The latter purpose may at times be overshadowed by an overly vigilant focus on the former.

The basic types of information sought include risk of exposure to STIs/HIV (whether or not the individual has ever had sex; the number and "riskiness" of sex partners; types of sex practices and "riskiness" of these practices) and the risks of acquiring STIs if exposed (methods and consistency of methods used to prevent STIs/HIV). Ascertaining both consistency and correctness of condom use is important, as user errors such as delayed application of a condom after sex starts, taking it off before sex ends, or putting it on backwards, occur even among regular condom users.[228] Incorrect condom use, including delayed application, has been associated with HIV seroconversion among MSM.[229]

The prevalence of sexual dysfunctions has been estimated from a review of 52 community sample studies at 0–5% for erectile dysfunction, 4–5% for premature ejaculation, and 7–10% for female orgasmic disorder.[230] Assessing individuals' satisfaction with their sexual lives and functioning is, therefore, an important component of a complete sexual history.[231] Furthermore, an overemphasis on STI and HIV risk can "pathologize" sexual behavior, neglecting the reality that people engage in volitional sex, even when it is high-risk, in order to feel pleasure and connection to others. A number of sexual function assessments have been developed though none of these are brief enough to be particularly useful in limited clinical encounters.[232] Simply asking a single question about sexual functioning[233] can be a starting point to elicit specific concerns.

Context of risk taking

A given sexual history may reflect high or low risk, depending on the ecological setting where sexual encounters occur (high or low STI prevalence in sexual network characteristics). Assessing the social context in which high-risk exposures occur (e.g., in substance-using situations, bar venues,[234] or bathhouses[235]) can provide the information needed to develop an individualized risk reduction plan.

STD history

The question, "Have you ever been told by a health-care provider that you had an STD of any kind?" identifies those who by definition have had high-risk exposure and should lead to probing to identify specific infections that can be reacquired by reexposure within the originally infected sexual network, as well as those who can be chronic or recurrent or carry a risk of late sequelae. A formal checklist of the major STDs for self-administered questionnaires may elicit positive responses not elicited by a more general question.

Partner risks, including HIV status

The question, "Have you ever felt that a sex partner put you at risk for any reason?" may uncover rape or abuse, as well as a history of a partner's high-risk behaviors (e.g., IDU, commercial sex, concurrent sex with others, multiple sex partners) or a history of an STD diagnosis or STD syndrome in a partner that should prompt STI screening.

It is crucial to ask the HIV status of sex partner(s) with whom there has been unprotected vaginal or anal sex, to ascertain whether or not that sex is seroconcordant and what might be the risks for primary or secondary HIV transmission.[236] Seroconcordant sex, sometimes called serosorting,[237] occurs when HIV-positive individuals choose to have unprotected sex with other HIV-positive people and HIV-negative individuals choose to have sex with other HIV-negative individuals. Another behavioral variant is negotiated safety, or strategic positioning,[238] wherein some HIV-positive MSM choose to be only the "bottom" or receptive partner in a sexual encounter,[239] on the assumption that HIV acquisition is less likely for the insertive partner, and transmission is less likely from the anal-receptive partner. Because this establishes a dead-end for viral transmission and limits HIV spread to susceptibles, HIV serosorting, if practiced exclusively, theoretically could potentially have population-level beneficial impact. However, this behavior still facilitates transmission of other STIs and may harm the individual(s) by putting them at risk of HIV superinfection[240] with other strains including drug resistant variants, thus complicating clinical management.

One critical presupposition of serosorting is that actual and truthful conversation about respective HIV status takes place prior to sexual exposure, two conditions that may not always be met. A South African study of recently HIV-diagnosed heterosexuals found that 78% had not disclosed their HIV serostatus to their sexual partners and 46% had no knowledge of their sexual partner's serostatus; nondisclosers were more likely to be male and to not use condoms.[241] Another study in the United States comparing the accuracy of HIV-infected persons' reported knowledge of their sexual partners' HIV status and the true infection status of partners found agreement of only 46% (κ −0.06), less than that expected by chance.[242] Those who have had negative HIV tests in the past are susceptible to new, acute HIV infection, and it is these persons who are most infectious. This probably helps explain why a substantial proportion of those with incident HIV infection report only having had sex with persons who reported being seronegative.

The universal challenges underlying HIV disclosure can be seen in studies that have shown in a variety of settings and populations that HIV disclosure may not always take place,[183] may be delayed until after sex has occurred,[243] or that unexamined assumptions regarding perceived HIV status still occur without any clear disclosure discussion or negotiation. Willingness to disclose may depend on the type of sexual partnership involved. Less willingness to disclose if the partner is anonymous or casual has been noted in some

studies of MSM,[244,245] whereas fear of violent partner reaction may be an impediment to HIV disclosure for others, particularly women. Thus, unprotected sex between people of discordant or unknown status obviously still occurs, accounting for an unknown proportion of incident HIV infections.[246] While the evidence on whether HIV disclosure results in more condom-protected sex is mixed,[247] a harm reduction approach for counseling with HIV-positive patients might follow this hierarchy:

- "If you are HIV positive, it is best to discuss your status with all sex partners, *and* to always use condoms correctly, to protect against passing HIV to others and to avoid getting STIs or other strains of HIV yourself." [disclose and use condoms]
- "If you are not going to discuss your HIV status with your sex partners, then always use condoms correctly in every sexual encounter." [if not disclose, then use condoms]
- "If you are not going to use condoms correctly in every sexual encounter, then at a minimum discuss each others' HIV status so that you can both choose what level of HIV transmission risk you and your partner(s) are willing to take." [if not use condoms, then disclose/negotiate]

Clinicians can assist their patients in this difficult area by encouraging strategies and skills for discussion of STI/HIV risk and sexual communication between partners.[248] Simply focusing attention on this issue may be effective; one randomized trial of 387 HIV-positive individuals who reported engaging in unprotected sex with HIV-negative or partners of unknown serostatus found that several counseling strategies (including a control condition) were equally effective in reducing the median number of unprotected sex acts from 14 to 4 at 12-month follow-up.[249]

STD symptom review

The routine review of symptoms should include questions about dysuria; past or current genital sores or lesions; abnormal vaginal discharge (i.e., increased amount, abnormally yellow color, or abnormal odor); vulvar pruritus or burning; low abdominal or pelvic pain in the female; testicular pain or swelling; and skin rash. In general, such symptoms, when presented spontaneously or in response to an open-ended question as the chief complaint or reason for visit, have a higher predictive value for STIs than when elicited in response to a specific query or checklist.[250]

STD history

A history of STDs or PID or of syndromic treatment for a reproductive tract infection predicts increased risk of current STDs, particularly if the partner was not treated or the underlying risk behaviors persist.[251,252] Even with partner treatment, the persistence and rediffusion of an STD within wider sexual networks may not be adequately addressed. When the patient is aware that the partner has had recent symptoms of an STD, such as urethral discharge, genital sores, or pain when urinating, several studies document increased risk in the patient. The prevalence of STIs is also increased in association with several symptoms or signs of STDs in the patient her- or himself, particularly those symptoms presented as a chief complaint or a response to a general open-ended question such as, "Do you have any new symptoms that make you think you might have a genital infection?," particularly those elicited by an experienced clinician who has had the opportunity for the educational feedback provided by repeatedly comparing examination findings with laboratory test results.[253–255]

Sexual behavior of the patient or patient's partner(s)

Having a new partner or more than one partner within the past 2 months, especially without correct and consistent condom use, has been associated with increased risk of STDs and HIV in many studies.[256] If patients perceive that their sex partner(s) are engaged in concurrency (i.e., sexual partnerships overlapping in time), this can be a risk factor for STI *acquisition* in the patient.[257] By the same token, if the index patient is him- or herself engaged in concurrent relationships, and has an STI, this is a risk factor for *transmission* to others that should be addressed with counseling.[258,259]

Psychological factors

A history of sexual abuse has been associated with STI/HIV risk behaviors in both women[260–262] and men.[263,264] Likewise, depression has been found to be associated with high-risk behaviors,[265] and for adolescent boys, may be a predictor of future STI incidence.[266] Depression is highly prevalent in some at-risk populations (39% in one study in the Baltimore public STD clinic[267]) and may complicate the ability to engage in behavior change or to adhere to antiretroviral medications.[268] If these items are assessed, resources or referrals should be made available to provide appropriate support for any sequelae and needed treatment.

Substance use

Injection drug use has directly and indirectly accounted for more than one-third (36%) of AIDS cases in the United States.[269] Not only is sharing syringes and other equipment for drug injection a well-known route of HIV transmission, but people who have sex with an IDU and their children are also at risk for infection. IDUs who do not enter treatment are up to six times more likely to become infected with HIV than are IDUs in treatment.[270] Racial and ethnic minority populations in the United States are most heavily affected by IDU-associated AIDS. In 2000, IDU-associated HIV

infection accounted for 26% of all AIDS cases among African Americans and 31% among Hispanic adults and adolescents, compared with 19% of all cases among white adults/adolescents.[269] Since the epidemic began, 57% of all AIDS cases among women have been attributed to injection drug use or sex with partners who inject drugs, compared with 31% of cases among men.[271] Those who inject methamphetamines are at highest risk for HIV, especially if they are also MSM.

Noninjection drugs (such as "crack" cocaine) also contribute to the spread of the epidemic. Some users trade sex for drugs or money to buy drugs. High-risk drug practices and sexual behaviors often are linked because drugs can make users feel less inhibited. One U.S. multisite study found that crack smokers were three times more likely to be infected with HIV than nonsmokers. When assessing STI/HIV risks it is necessary to understand and address the interconnectedeness and impact of substance use behaviors and sexual risk-taking.

EXAMPLE OF A COMPREHENSIVE STI/HIV RISK ASSESSMENT

The foregoing discussion illustrates the range of topics that could be addressed in an STI/HIV risk assessment, recapitulating how various agencies, professional groups, or experts suggest conducting STI/HIV risk assessment. Many of these recommendations have not yet been extensively evaluated in terms of objective prediction of STI/HIV infection. Figure 48-4 presents an example of a relatively comprehensive approach to individual-level STI/HIV risk assessment. The figure summarizes many of the key topics, offers ways they might be presented in a comprehensive face-to-face interview, and represents a point of departure for further work in this area. Although excessive for many clinical encounters, the more comprehensive approach may be appropriate for the patient who is positive for any of the risk factors elicited by the screening questions or by the selected priority questions highlighted in bold type in the table.

SELF-ADMINISTERED VERSUS FACE-TO-FACE

Few clinical settings other than STD clinics, which already know their patients are at potential risk of STI/HIV, could allow the time needed for a clinician to carry out such a comprehensive risk assessment during a face-to-face interview. Therefore, self-administered STI/HIV risk assessment questionnaires might be used to collect initial, or more comprehensive, information from patients. Particularly in primary care settings, an initial STI/HIV risk assessment could be integrated into an overall risk assessment that addresses risk for a variety of other medical and social problems. Computer-assisted self-interviews in clinical settings, using tablet, laptop, or handheld computers, may elicit more accurate or at least more complete information on sensitive topics than can face-to-face interviews.

Self-administered risk assessment need not be limited to clinical settings but can be included in confidential settings in schools or on websites or chat rooms on the Internet that are appealing to specific at risk-audiences.[272,273] Such sites encourage risk-takers to perceive the consequences of risk taking and to motivate behavior change or further health-care consultation.[274,275] Despite the challenges of conducting research on the Internet,[276] such approaches do appear to hold promise.

Whatever the method of administering questionnaires, important barriers to reporting sensitive risk behaviors exist. First, individuals who report high-risk sexual activities often do not perceive themselves at risk.[277] The magnitude of any STI/HIV risk perceived may be small relative to the hierarchy of other serious risks encountered by a homeless urban adolescent, for example. Thus, specific questions about specific behaviors are essential in conjunction with questions about subjective perception of risk. Identification of gaps between perceived risk and actual risk highlights the need to change risk perception as one potential outcome of risk assessment. In this regard, it is important to distinguish perceived risk from perceived susceptibility. Kowalewski and colleagues have critiqued current thinking on perceived risk and health behavior.[278]

Questions clinicians can use to identify the context of any risk-taking reported can encourage further patient insight and identify key avenues for counseling concerning skills, norms, misconceptions, and client-centered strategies for reducing risk. For example, the clinician or counselor can ask, "What happened the last time you had sex without using condoms?" "Were there any avoidable circumstances that put you at risk during that encounter (e.g., not using a condom with a casual partner)? Is there anything you can think of that would make it easier/harder for you to avoid taking that risk again?"

FUTURE RESEARCH AND TRAINING NEEDS

Ongoing research needs include local definition of risk factors for STIs/HIV and evaluation of optional questions and methods (face-to-face interview, self-administered questionnaire, audio-computer–assisted questionnaire) for eliciting information about these risk factors in clinical as well as in nonclinical settings. There is a need for particular emphasis on adolescents and young adults and sexual histories that include a focus on MSM—for development of instruments for risk assessment that not only integrate STI and HIV risk assessment but also integrate STI/HIV risk assessment with practical comprehensive social and medical risk assessment

DEMOGRAPHIC DATA: Date of birth/age, gender, race/ethnicity, relationship status, residential zip code

Framing Statement:
I am going to ask you some questions about your sexual health. I ask them of all my patients to help me provide the best possible care. What we discuss is confidential.

Screening Questions:
STD SYMPTOMS
Are you currently having symptoms that might be caused by a sexually transmitted disease, like a discharge from your [penis/vagina], pain, swollen glands, itching, rash, or sores on your [penis/vagina] or rectum? ☐ Yes ☐ No

STD HISTORY
Have you ever been told that you had any sexually transmitted diseases or any genital infections? ☐ Yes ☐ No
If yes, which:
☐ Gonorrhea
☐ Chlamydia; NGU; urethritis; cervicitis or cervical infection
☐ PID (pelvic inflammatory disease, infection of the uterus)
☐ Syphilis
☐ Genital herpes / Herpes simplex virus HSV-I/II
☐ Genital warts/human papillomavirus HPV
☐ Trichomonas
☐ Bacterial vaginosis (non-specific vaginitis)

Have any of your sex partners been treated for an STD? If yes, which one? _____

SEXUAL HISTORY
Do you have sex with men, women, or both? ☐ Men ☐ Women ☐ Both ☐ I haven't had vaginal, oral, or anal sex

How many sex partners have you had… in the past 2 months? # ___ Men # ___ Women
… in the past 12 months? # ___ Men # ___ Women

How long ago was the last time you had sex with your regular partner? #___ days ☐ Not applicable
- Types of sex: ☐ Vaginal ☐ Anal ☐ Oral
- What was the HIV status of that partner? ☐ HIV+ ☐ HIV Negative ☐ Don't know

How long ago was the last time you had sex with any other partner? # ___ days ☐ Not applicable
- Types of sex: ☐ Vaginal ☐ Anal ☐ Oral
- What was the HIV status of that partner? ☐ HIV+ ☐ HIV Negative ☐ Don't know

How long ago was the last time you had sex without using a condom? # ___ days/months/years ☐ Never used
When using a condom, have you ever had it slip/break; put it on after sex started, took it off before sex ended, put it on backwards, or other problem? ☐ No ☐ Yes *If yes*, ☐ Discussed correct & consistent condom use

We now recommend that all sexually active people in the US get a voluntary HIV test. **When was the last time you had an HIV test?** ___/___/___ Date of last test/ Result: ☐ Positive ☐ Negative ☐ Indeterminate ☐ Did not get result
___ Never tested
If never, or last exposure risk occurred after last test: ☐ Accepted offer of HIV test today
☐ Declined / Reason_____

Many people use a variety of substances to change their mood.
Have you ever used crack cocaine? ☐ Yes ☐ No
Have you ever used methamphetamine ("crystal")? ☐ Yes ☐ No
Have you ever shared needles to inject drugs, hormones, other? ☐ Yes ☐ No
Have you ever had sex with some one who injected drugs? ☐ Yes ☐ No
Have you ever had sex with a known HIV+ person? ☐ Yes ☐No
Have you ever exchanged sex for money or drugs? ☐ Yes ☐ No

(Continued)

Hepatitis vaccination history:
☐ A only ☐ B only ☐ Both A & B ☐ Neither A nor B ☐ If no B vaccination, offered or made referral

Are you trying to get pregnant/get your partner pregnant? ☐ Yes ☐ No
If no, what method(s) are you and/or your partner using to avoid pregnancy & reduce STD risk?_____
☐ None ☐ Condom ☐ Oral contraceptive ☐ Ring ☐ Patch ☐ Injectable ☐ IUD ☐ Diaphragm/Cap
☐ Tubal/Hysterectomy ☐ Vasectomy ☐ Other _____

For women:

Do you have access to emergency contraception? ☐ Yes ☐ No
Cervical screening (Pap smear or HPV, any cervical dysplasia) history:
HPV vaccination history:

For men who have sex with men:*
In the last 12 months…
Have you had receptive anal sex? ☐ Yes ☐ No

Exposure Status			Condom Use			
Partner Status	**Yes**	**No**	**Never**	**Sometimes**	**Usually**	**Always**
HIV+						
HIV -						
HIV Unknown						

Have you had insertive anal sex? ☐ Yes ☐ No

Exposure Status			Condom Use			
Partner Status	**Yes**	**No**	**Never**	**Sometimes**	**Usually**	**Always**
HIV+						
HIV -						
HIV Unknown						

Have you had any unprotected anal sex with a sex partner whose HIV status was different than yours, or was unknown to you, in the last 2 months? ☐ Yes ☐ No

If HIV+: How often do you tell anal sex partners your HIV status? ☐ Never ☐ Some ☐ Usually ☐ Always

For all:

RISK REDUCTION COUNSELING
What step do you think you could take to reduce your risk? This might include not having sex (abstinence), being only with one person (monogamy), using condoms correctly & consistently, getting HIV/STD testing, reducing alcohol or substance use, or some other plan. Your plan is: _____
☐ Counseling/Plan not done

SEXUAL FUNCTION/SATISFACTION
Have you noticed any problems in your ability to have and enjoy sex?_____

Is there anything else about your sexual health that you'd like to discuss today? _____

*Questions from Public Health Seattle-King County STD Clinic chart form, courtesy of Matthew Golden, MD, MPH. See Golden et al., *JAIDS* 2004; 36(2): 734-74

FIGURE 48-4. A comprehensive approach to individual-level STI/HIV risk assessment.

for general clinical use. Finally, the instruments and methods of administration should have demonstrated reliability and validity for predicting presence or absence of STI/HIV in a variety of clinical settings.

There remains a clear and ongoing need for improved performance of clinicians in assessing risk for STI/HIV infection. A starting point for this is to include STI/HIV and patient-centered communication skill content in medical, nursing, physician's assistant, pharmacist, and allied health professional school curricula.[279] The American Medical Women's Association has developed a reproductive health curriculum, for example, that covers sexual history-taking.[280]

Clinical workplaces can help improve the sexual health of their patients by identifying enabling and reinforcing factors in their systems, providing training, and making sexual history-taking elements part of their quality-improvement measurement (e.g., "percent of patients whose correct and consistent condom use was assessed"). One managed care organization that incorporated some of these approaches found that patient recall of provider discussion of STI/HIV risk assessment (OR 1.7, 95% CI 1.2–2.6) and personal risk reduction (OR 2.6, 95% CI 1.6–4.3) improved following this intervention.[281]

Information technology tools (guideline distribution by web[282] or PDAs, reminder prompts on electronic health record systems[283]) may help practicing clinicians in this fundamental task. Clinician–patient communication patterns have been evaluated using video trigger tapes to demonstrate assessment styles.[284] Epstein and colleagues have outlined ways to help clinicians learn to provide the rationale for STI/HIV discussions, to take a patient-centered approach, and to handle awkward moments and patient anxieties with empathy.[285] Available STI/HIV training resources include the AIDS Education and Training Centers, the STD Prevention Training Centers, and the International Training and Education Center on HIV.[286]

Helping clinicians and patients to communicate routinely about sexual health concerns and STI/HIV risk reduction will improve the health of individuals, their sexual partners, and communities.

49 Anatomy and Physical Examination of the Female Genital Tract

Daniel O. Graney and Claire C. Yang

INTRODUCTION

Any area of the body may be involved in STD syndromes or in the differential diagnosis of these conditions. Clearly there is no single, optimal method for conducting the history and physical examination. The critical areas of interest are determined by the history, other physical findings, and conditions considered in the differential diagnosis. Many critical anatomical points may be important in some contexts but irrelevant in others. Thus, this chapter is an attempt to present succinctly one approach to "the routine examination." This approach is selective but is based on clinical experience in developing an efficient method for evaluating a large number of patients in a timely manner. Accurate physical examination of the female genital tract can also be used as an integral part of developing and using syndromic management plans for care of STDs when laboratory support is either unavailable or prohibitively expensive.[1–3]

WHAT SHOULD BE INCLUDED IN THE ROUTINE EXAMINATION OF NONPREGNANT WOMEN FOR REPRODUCTIVE HEALTH CARE?

Several guidelines have been developed for the physical examination of women for routine preventive care, family planning, and STDs. These include the U.S. Preventive Services Task Force *Guide to Clinical Preventive Services*; the two-volume *Recommendations for Updating Selected Practices in Contraceptive Use*, produced jointly by the WHO, USAID, INTRAH (Program for International Training in Health, School of Medicine, University of North Carolina), and Pathfinder International; the *Guidelines for Adolescent Preventive Services*; the unpublished *Program Guidelines for Project Grants for Family Planning Services*, for recipients of the so-called Title X funding in the United States; and the pending *Reproductive Health Guidelines* being coordinated in the United States by the Centers for Disease Control and Prevention, the Office for Population Affairs, and certain professional societies.[4–7]

The U.S. Preventive Services Task Force recommends that screening examination of adult females includes periodic screening for hypertension every 2 years (for women aged 21 or older); measurement of height and weight and assessment for obesity; and screening of sexually experienced women for cervical cancer by Pap smear every 3 years.[4] The task force found insufficient medical evidence to support routine clinical breast examination in women younger than 50 years of age. Neither did they find medical evidence to support routine thyroid examination. No medical evidence was found to support routine pelvic examination to screen for ovarian cancer, or to recommend for or against breast self-examination.

Until recently, recipients of federal Title X funding for family planning in the United States were not allowed to defer pelvic examination longer than 3 months for women receiving hormonal contraception. More recently, because of concerns that some women were avoiding contraception to avoid pelvic examination, some agencies have decided to "delink" provision of hormonal contraception from the pelvic examination. For example, Planned Parenthood of America informed its affiliates in 1998 that they could defer pelvic examination for 3 months, 6 months, 1 year, or even longer—in order to remove the requirement for pelvic examination as a possible disincentive to the use of hormonal contraception. Women electing other forms of contraception, such as tubal ligation, diaphragm, or IUD obviously would need a pelvic examination for evaluation of uterine anatomy or properly fitting a diaphragm. Some adolescent medicine specialists have been outspoken about the lack of evidence for benefit of routine pelvic examination for adolescents receiving hormonal contraceptives. There are few data on this issue, except for one nonrandomized study that found no adverse effect from delaying pelvic examination of adolescents seeking hormonal contraception for up to 6 months.[8]

It should be noted that such guidelines have so far arisen from the family planning field, not the STD/HIV field, and efforts are underway to develop interdisciplinary reproductive health guidelines, which should have considerable

impact on what services are included in health-care services purchased for women, funded through insurance programs, and provided by managed care organizations.

Clearly, for women found to be at high risk for STD, based on risk assessment, and for those with symptoms or signs suggestive of an STD, the minimal physical examination should include the following:

Skin and hair (as indicated by symptoms or other findings), throat and mouth (as indicated by symptoms).

Inguinal examination for adenopathy.

External genitalia, including labia majora and minora, clitoris, introitus, perineum, anus, and perianal area.

Urethral meatus and Skene's glands.

Bartholin's glands.

Speculum examination, including vaginal walls and cervix (including Pap smear and tests for cervical and vaginal infection, as indicated).

Bimanual examination (with rectovaginal examination, as indicated).

Further, even for asymptomatic women without risk factors for STDs, medical visits for reproductive health care may be the only source of medical care. For such women, a comprehensive initial physical examination, including pelvic examination, should be strongly encouraged, and the patient should be counseled on the desirability for such examination, and on any risks of deferring the examination, with documentation of counseling and referral in the patients' medical record.

GENERAL CONSIDERATIONS IN EXAMINATION OF THE FEMALE GENITAL TRACT

For the female patient who presents to an STD clinic, few portions of the physical examination will yield as much information as the pelvic examination. In the female, the genital and urinary tracts, as well as the anus and rectum, can and should be examined together during the pelvic examination. Symptomatic pathology abounds and unsuspected pathology is found in a significant proportion of relatively asymptomatic women.

Rapport with the patient is always important in the physical examination but is especially critical with the female pelvic examination. Evidence of concern for a woman's problems at the initial interview will help provide needed rapport. The woman worried about STD expects to have a pelvic examination and is understandably concerned about the findings. She will usually be very cooperative. A little effort on the part of the examiner in regard to her well-being and comfort during the pelvic examination will maintain that cooperation and enhance the diagnostic yield.

Some specific suggestions to establish and maintain rapport are as follows. Prior to the examination always wash your hands where the patient can see you. Unless you are checking for incontinence, have the patient void before the examination, as a full bladder is uncomfortable and inhibits the examination. Obtain urine for analysis, culture, or nucleic acid amplification testing as indicated.[9–12] Recognize that the dorsal lithotomy position is one of vulnerability. The patient's comfort may be improved by elevating the backrest, suggesting that the patient wear her shoes so that the stirrups do not cause discomfort, and providing a drape if desired but not draping if that is the desire of the patient. The speculum should be kept warm in a warming drawer or warmed with water just before the examination. All the equipment necessary for the examination should be present in the examination room, which should be private and quiet.

You should tell the patient what you are doing at each step. It will help the patient's anxiety if she is told of normal structures and normal findings during the examination. A mirror should be available to demonstrate specific findings to the patient, as the more involved the patient becomes in her own care the more apt she is to return for subsequent visits and necessary treatments. The pelvic examination is an opportunity to teach the patient about her anatomy and about the transmission of infectious disease.

The comfort of the examiner should not be overlooked. Equipment should be readily available, lighting should be good, and the examination table and stool should be at the right height. Most often, the standard examination proceeds according to an orderly sequence. This has two advantages. First, the sequence of the examination limits the opportunity for errors of omission in a busy clinical situation. Second, there is minimal need for the patient to move. During the examination any needed specimens should be obtained, and following the examination the findings should be recorded and correlated with the patient's history and complaints. This chapter is further organized to follow this suggested pattern of evaluation. The relevant considerations in routine examination of the female will be presented for each section of the physical examination, and critical anatomical principles will be considered for that area. We will present the examination and anatomical descriptions according to our own opinions, recognizing that some of these opinions are controversial and that other anatomists and clinicians may hold alternative, equally valid viewpoints.

THE EXTERNAL GENITALIA AND PERINEUM

PHYSICAL EXAMINATION

Ordinarily, the examination is initiated by having the patient sit on the examining table. If indicated, head and neck examination, inspection, palpation, percussion, and auscultation

of the chest and examination of the breasts may be done in this position. Next, the patient is asked to lie supine. Skin, extremity, breast, cardiovascular, and abdominal examination may be conducted in this position, if indicated. Attention is then directed to the pelvic examination.

With the patient in the lithotomy position, the genital examination begins with palpation of the inguinal nodes and inspection of the mons pubis and the external genitalia. The quantity and location of pubic hair is noted. The amount of pubic hair varies greatly in different racial groups. Normal hair growth for a southern European would imply hirsutism from androgen excess in an Asian woman. Nits on the shaft of the pubic hair are indicative of lice infestation. Freckles that move are probably lice.

The labia are separated and the vaginal introitus is inspected. Redness or erythema signifies an irritation that may be owing to infection with *Candida*, *Trichomonas vaginalis*, herpes simplex virus (HSV), or certain bacteria (e.g., toxic shock syndrome, streptococcal cellulitis). A uniformly adherent homogeneous white or gray discharge at the introitus is suggestive of bacterial vaginosis. Small tender fissures in the mucous membrane should arouse suspicion of vulvovaginal candidiasis and genital herpes; many genital herpes occurrences do not form classic ulcerations. Pigmented or nodular areas on the vulva may be owing to human papilloma virus infection or carcinoma in situ. Use of a magnifying glass or colposcope may help delineate small lesions that would be difficult to detect without magnification. Multifocal carcinoma in situ (i.e., involving more than one site on the cervix, vagina, and vulva) is being found more frequently in young women, and biopsies of suspicious areas of the vulva are important to rule out this disease. Pigmented areas may also be benign nevi or malignant melanomas (see Chapter 62). A suspicious area that is darkly pigmented with irregular borders should be removed by excisional biopsy for histologic inspection. The inspection for such lesions should include the frenulum and clitoris.

While the vulva are held apart, the woman should be asked to strain, cough, or otherwise perform a Valsalva maneuver. This will allow observation of any vaginal relaxation or stress incontinence. At this time the urethra with its associated periurethral (Skene's) glands should be palpated and milked by gentle finger pressure from above downward. If infection or a urethral diverticulum is present, a small amount of discharge may be evident at the urethral meatus or at the orifices of Skene's glands.

The greater vestibular glands (of Bartholin) are located at approximately 5 and 7 o'clock on the face of the posterior fourchette (Fig. 49-1). When these regions are explored with gentle pressure between the thumb and forefinger, the normal gland cannot be palpated and the region is not tender. However, an infected gland is extremely tender. Occasionally a small asymptomatic Bartholin's duct cyst can be seen as a convexity of the posterior fourchette and felt as a discrete cystic nodule in the position of the Bartholin's gland. If any palpable mass is discovered in this area in a perimenopausal or menopausal woman, it should be removed for histologic examination, as the incidence of carcinoma increases with age.

ANATOMY OF THE PERINEUM AND EXTERNAL GENITALIA

The strict anatomical definition of the perineum is a diamond-shaped region bounded by the symphysis pubis anteriorly, coccyx posteriorly, and ischial tuberosities laterally. Projecting a line between the ischial tuberosities divides the diamond space into two triangles, the urogenital triangle anteriorly and the anal triangle posteriorly. Thus, both triangles share a common base with the apex of the urogenital triangle pointing anterosuperiorly and the anal triangle pointing posterosuperiorly. In lateral profile the floor of the perineum is shaped like a shallow V rather than appearing flat as implied by a two-dimensional drawing. The plane of the anal triangle is open and is filled only with fatty tissue. The plane of the urogenital triangle is closed or occupied by a thick triangular membrane, the perineal membrane that closes the anterior floor of the perineum and defines the anterior wall of the ischiorectal fossa.[13,14]

The region of the urogenital triangle contains two spaces, the superficial and deep perineal spaces (Figs. 49-2 to 49-5). The superficial space can be imagined as a pair of spaces lying between the perineal membrane and the skin of the labia majora. In fact, the two spaces are connected above the clitoris so that the space resembles an inverted U. It is bounded by the perineal fascia of the urogenital diaphragm that continues from the base of the diaphragm and reflects superiorly under the labial skin to join the membranous layer of superficial fascia of the abdomen above the symphysis pubis (see Figs. 49-2 to 49-4). Because of these fascial attachments, a hematoma in the labia majora, that is, superficial pouch, expands superiorly into the abdominal wall but neither laterally to the thigh nor posteriorly to the ischiorectal fossa.

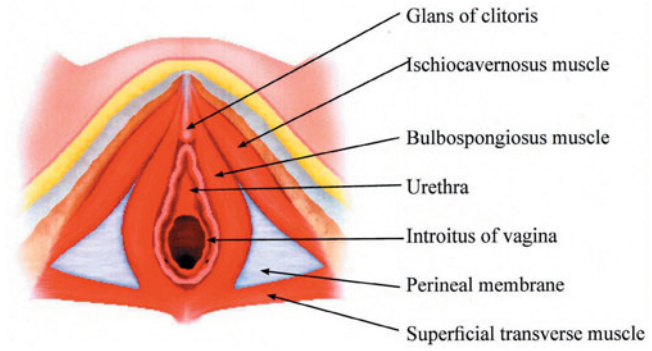

FIGURE 49-2. Muscles of the superficial perineal pouch. *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

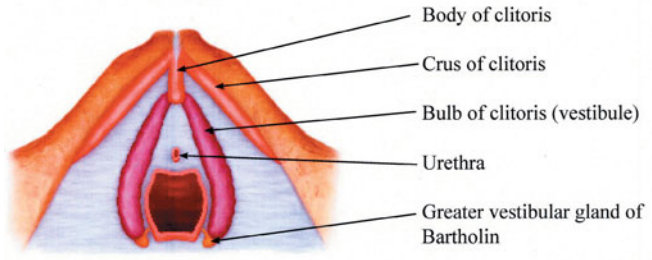

FIGURE 49-3. Erectile tissues of the superficial pouch. *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

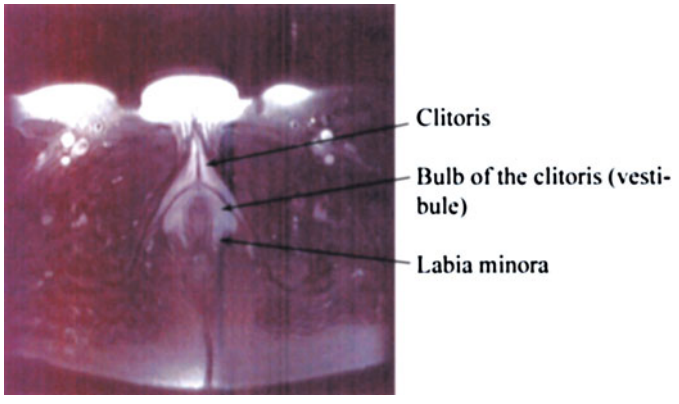

FIGURE 49-4. Magnetic resonance image of a female during sexual arousal illustrating increased blood flow in the erectile tissues of the clitorus and bulb.

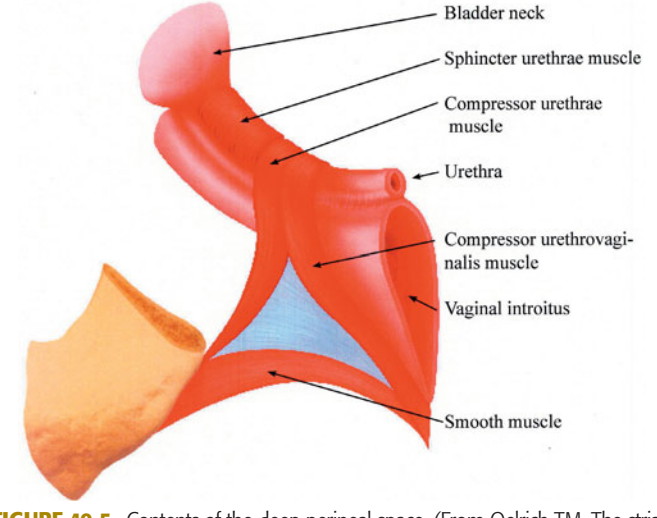

FIGURE 49-5. Contents of the deep perineal space. (From Oelrich TM. The striated urogenital sphincter muscle in the female. *Anat Rec* 1983; 205: 223–232.) *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

The contents of the superficial perineal pouch include the greater vestibular glands (Bartholin's), crura of the clitoris, bulbs of the vestibule, which are composed of elongated erectile tissue, and the overlying superficial perineal muscles. There have been several changes in the concepts and terminology of the perineal floor in both male and female which have been described in recent years [15,16]

Clitoris

The clitoris comprises two cavernous (erectile) bodies, arising from beneath the inferior rami of the pelvic bones. The lateral extensions of the erectile bodies, or the crura, meet in the midline and fuse to form the body of the clitoris. The body angles anteriorly away from the plane of the pubis. The distal-most aspect of the clitoris is the glans clitoris, which is the only visible portion of the clitoris. The glans is oftentimes covered by the clitoral hood, or prepuce. The labia minora arise from the ventral midline of the glans and extend laterally to outline the introitus.

Beneath the surface of the vulva, the clitoris has an inverted wish-bone shape, tilted to the plane of the pubic rami. The tips of the crura are covered in skeletal muscle, the ischiocavernosus muscle. The cavernous bodies are covered with a fibrous lining and filled with erectile tissue. This tissue fills with blood during sexual arousal.

Directly related to the clitoris are the bulbs of the clitoris, formerly known as the vestibular bulbs.[17] These mounds of erectile tissue are situated in the superficial perineal pouch, bounded by the crus of the clitoris dorsally and posteriorly; the lateral vaginal wall medially; the labia minora ventrally; and the bulbocavernosus muscle laterally. The bulbs are comprised of erectile tissue very similar to that of the clitoris, and also fill with blood during sexual arousal. There have been new studies in recent years detailing more specifically the anatomy and histology of the erectile tissues of the female perineum as well as imaging blood flow during sexual arousal with MRI[18–21] (Fig. 49-4).

The deep perineal space is a potential space limited inferiorly by the perineal membrane but incompletely closed by the pelvic fascia superiorly. In the female, the contents of the deep perineal space include striated muscles, the external urethral sphincter surrounding the urethra, the compressor urethrae, the urethrovaginal sphincter, and some smooth muscle fibers termed the *deep transverse perineal muscle* (see Fig. 49-5).[22]

Urethra

The female urethra measures 3–4 cm in length from the bladder neck to the meatus in the anterior vestibule of the vagina. Proximally, the mucosa is composed of transitional epithelium gradually becoming stratified squamous as it courses distally. The lumen appears stellate in cross section because of extensive longitudinal folding of the mucosa. Beneath the

mucosa is the lamina propria, rich in vascular and neural plexuses. The muscular coat, similar to other body tubes, is composed of a double layer of smooth muscle, with the inner fibers circularly arranged and the outer layer disposed longitudinally. As the urethra traverses the urogenital diaphragm, circularly arranged striated muscle fibers form an external sphincter of the urethra. These fibers are innervated by the internal pudendal nerve (somatic) in contrast to the internal urethral sphincter at the bladder neck, which is innervated by the pelvic splanchnic nerve (parasympathetic).

In essence, the entire length of the female urethra is paralleled by paraurethral glands that are tubuloalveolar outgrowths of the mucosa. Located in the lamina propria, these glands have their openings on the posterior and posterolateral wall of the urethra (see Fig. 49-6). At the distal end of the urethra there are usually two larger glands, commonly identified as Skene's glands, whose ducts are visible on the posterior wall. Both Skene's glands and the paraurethral glands are vulnerable to infection.

More extensive review of female pelvic anatomy and histology may be found in recent texts.[15,16,23,24]

VAGINA, CERVIX, UTERUS, AND ADNEXAL STRUCTURES

PHYSICAL EXAMINATION

Speculum examination and collection of specimens for microscopy and culture

A warm speculum should be inserted into the vagina and opened to reveal the cervix. It should be inserted at an angle directed toward the hollow of the sacrum (Fig. 49-7). Care should be taken not to apply pressure against the urethra and anterior bony arch of the pubis. With the speculum in place, specimens may be obtained for pH determination and wet mount examination of vaginal fluid; vaginal fluid Gram stain and selected cultures, if indicated; and endocervical Gram stain and cultures and Pap smear. If there are no symptoms or signs of abnormal vaginal discharge or of vaginal inflammation, no tests of vaginal fluid are usually done. If such symptoms or signs exist, a specimen of the vaginal discharge should be tested on pH paper to ascertain the vaginal pH, which is normally 4.5 or below. If the vaginal pH is above 4.5, it is suggestive of bacterial vaginosis or of trichomoniasis. Care should be taken to avoid mixing vaginal discharge with cervical mucus for determination of vaginal fluid pH, since cervical mucus has a pH of about 7. Vaginal discharge should also be mixed with saline for microscopic examination for motile trichomonads and clue cells; and with 10% potassium hydroxide for detection of a fishy, amine-like odor, characteristic of bacterial vaginosis, and for microscopic detection of fungal elements (see Chapter 55). A Gram stain of a thinly smeared slide of vaginal discharge is useful for confirming the diagnosis of bacterial vaginosis. With rare exceptions (e.g., toxic shock syndrome), bacterial cultures of vaginal fluid are not useful. However, for detection of *Candida* or *Trichomonas vaginalis*, vaginal cultures are more sensitive than microscopic examination of vaginal fluid, especially in the absence of abnormal vaginal discharge.

For Pap smear, separate samples should be obtained from the ectocervix, including the transformation zone, using an Ayre's spatula; and from the endocervix, using a cytobrush

(see Chapter 47). According to the U.S. Preventive Services Task Force, cervical cytologic screening should be performed at least every 3 years in sexually active women with a cervix.[5]

Specimens for culture for gonorrhea and diagnosis of *Chlamydia* by culture or antigen detection test can be taken from the endocervix. Nucleic acid amplification assays of urine or urogenital swabs may also be used to detect gonorrhea and chlamydial infection. A specimen of the endocervical mucus can also be obtained at this time, inspected for color (yellow color indicates increased numbers of PMN leukocytes), and used to prepare a Gram-stained smear for microscopic enumeration of PMN leukocytes in cervical mucus and for detection of gonococci. Nabothian cysts are a normal finding on the cervix (Fig. 49-8). They develop when squamous epithelium covers mucus-secreting columnar epithelium and the secretions cause the formation of a small cyst. These cysts rupture and reform throughout the reproductive years. While the speculum is still in place, colposcopy can be performed before and after applying dilute (3%) acetic acid or dilute Lugol solution to the cervix. Colposcopy enables one to better visualize cervical, vaginal, and vulvar abnormalities such as dysplasia or infection with human papilloma virus, as well as cervical ulcers caused by HSV, or "strawberry cervix" caused by *T. vaginalis*. Colposcopy is clearly helpful to select lesions or areas for biopsy when evaluating a cervix after Pap smears has shown dysplasia. The role of colposcopy as an initial screening procedure is debated.

Bimanual examination

After removal of the speculum, the first two fingers of the vaginal examining hand are lubricated and inserted into the vagina. The bladder should be compressed. This should cause no discomfort other than the sensation of needing to void. The cervix should be palpated and moved. Both the cervix and the attached uterine body should be freely mobile without pain. The body of the uterus is next located by providing suprapubic pressure with the abdominal hand to keep the uterus in the pelvic cavity. The two fingers of the examining vaginal hand should outline the uterus in its entirety. This is usually easy if the uterus is anterior. If it is in a mid or posterior retroflexed position, it will be more difficult to locate and may be best palpated on rectovaginal examination (Fig. 49-9). After noting the size, shape, position, mobility, consistency, and contour of the uterus, it is moved to the one side and the fingers of the examining hand are inserted into the right lateral vaginal fornix as far as possible (Fig. 49-10). The abdominal hand produces pressure on the right lower abdomen and the fingers of the vaginal hand are swept to the side to evaluate the adnexal structures consisting of the tube, ovary, round and cardinal ligaments, and the pelvic sidewall (Fig. 49-11). The same procedure is followed on the opposite side. (Some people prefer to change hands, using the left hand to examine the left side of the pelvis.) Only the ovaries should be palpable in the normal examination. Often they are not felt, especially if the patient is on birth control pills, which suppress the ovaries and decrease their size. A normal ovary in a menstruating nonsuppressed woman measures approximately $3 \times 3 \times 2$ cm^3. Any enlargement above 5–6 cm is an abnormal finding. Both pelvic sidewalls should be evaluated for enlargements of the lymph nodes. Tenderness of any of the pelvic structures is noted. The examination is concluded with a rectovaginal examination.

Rectovaginal examination

After the patient is informed of the procedure, a well-lubricated middle finger is placed in the rectum and the index finger is simultaneously placed in the vaginal vault. The patient can

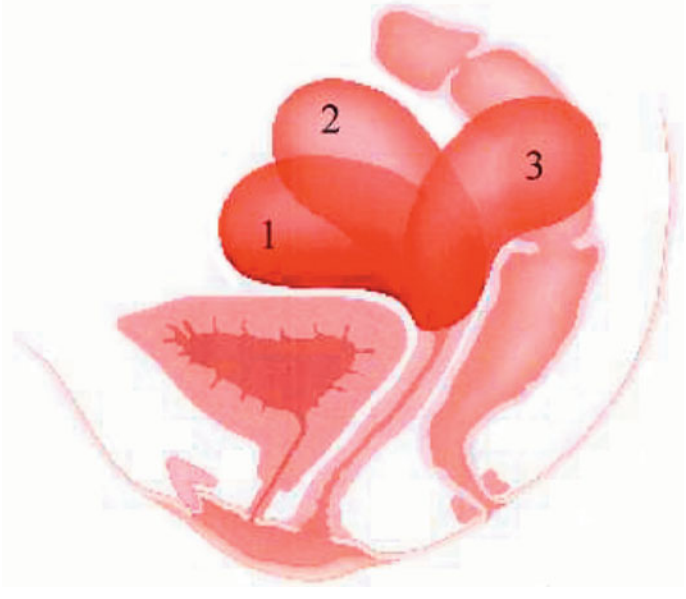

FIGURE 49-9. Positions of the uterus: (1) anteverted, (2) midposition, and (3) retroflexed. *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

FIGURE 49-10. Preparation for bimanual pelvic examination: placement of vaginal fingers (shaded). *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

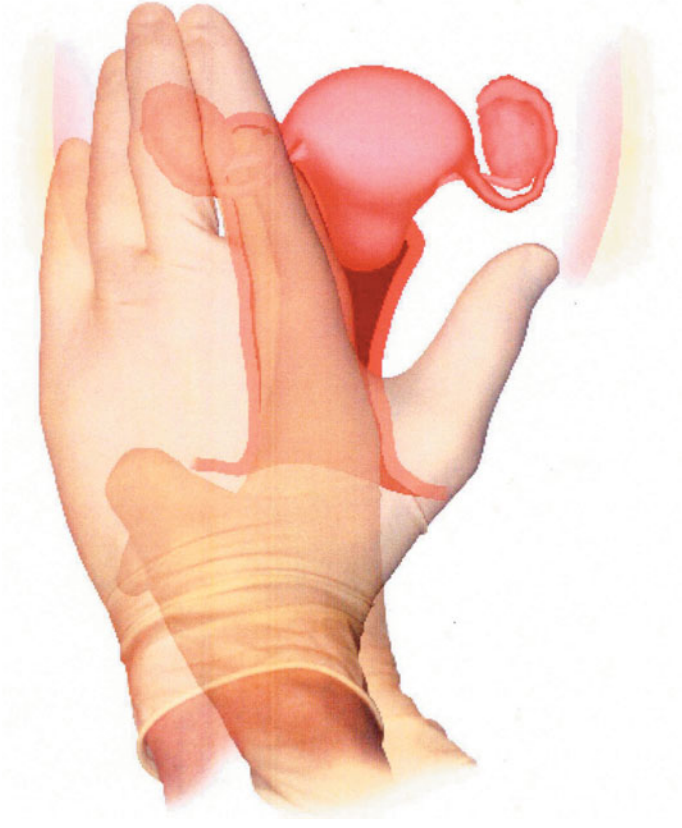

FIGURE 49-11. Bimanual examination: comparing position of vaginal fingers (shaded) and abdominal hand. *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

often facilitate the rectal examination by relaxing the pelvic muscles during insertion of the fingers. The rectal finger carefully evaluates the entire rectal wall for nodularity or polyps. It is then placed against the cervix, which is felt through the rectal and vaginal wall. Pressure from the abdominal hand brings the uterus down so that its entire posterior surface can be palpated with the rectal finger. This is the best method to examine the posterior wall of the uterus if it is in the mid or posterior position in the pelvis. The uterosacral and cardinal ligaments can be put on tension by elevating the cervix and palpated for nodularity such as may be found with endometriosis. The posterolateral sidewalls of the pelvis should be swept with the rectal finger, and a stool specimen can be obtained if indicated for evaluation of occult bleeding. The American Cancer Society recommends annual testing for gastrointestinal bleeding beginning at age 50.

Throughout the pelvic examination a mental image of the pelvic organs should be formed, noting size, shape, consistency, mobility, contour, and tenderness. Practitioners often confirm or supplement their findings in physical examination with a transabdominal or transvaginal ultrasound. Ultrasound may be especially helpful in patients who are difficult to examine because of pain, fear, or obesity, and in patients who have physical findings of uncertain etiology. It is not as accurate as laparoscopy for the diagnosis of pelvic inflammatory disease. Ultrasound is specifically beneficial in evaluating suspected ectopic pregnancy and differentiating ovarian from uterine tumors and can be used to evaluate other symptoms also.[25–27] All observations made should be accurately documented in the record. Correlation of the patient's complaints or historical data with the physical findings and the laboratory evaluation will often resolve the concerns of the patient and the questions of the examining physician.

ANATOMY

Vagina

The vagina is a fibromuscular tube whose anterior and posterior walls are normally in contact with one another. A longitudinal ridge is present along the mucosal surface of both the anterior and posterior walls; from these ridges, secondary elevations called rugae extend laterally. The vaginal wall consists of three layers: (1) the mucous membrane, composed of stratified squamous nonkeratinized epithelium and an underlying lamina propria of connective tissue; (2) the muscular layer, composed of smooth muscle fibers disposed both longitudinally and circularly; and (3) the adventitia, a dense connective tissue that blends with the surrounding fascia.

There are no glands in the vaginal wall. During sexual stimulation the marked increase in fluid production in the vagina is believed to be caused by transudation across the vaginal wall.

The stratified squamous epithelium of the adult vagina is several layers thick. The basal layer is a single layer of cylindrical cells with oval nuclei. Above this area are several layers of polyhedral cells that appear to be connected together much like those of the stratum spinosum of the epidermis. Above these are several more layers of cells that are more flattened in appearance and accumulate glycogen in their cytoplasm, the significance of which is discussed in the following. They also exhibit keratohyalin granules intracellularly. This tendency toward keratinization, however, is not normally completed in the vaginal epithelium, and the surface cells always retain their nuclei.

The most superficial cells are desquamated into the vaginal lumen where their intracellular glycogen is converted into lactic acid, probably by the bacteria normally resident in the vagina. The resulting acidity is believed to be important in protecting the female reproductive system from infection by most pathogenic bacteria (see Chapter 17).

Estrogen stimulates the production of glycogen and maintains the thickness of the entire epithelium. Before puberty and after menopause, when estrogen levels are relatively low, the epithelium is thin and the pH is higher than in the reproductive years (neutral before puberty and 6.0 or higher after the menopause). The thinness of the epithelium and the relatively high pH of the vaginal milieu are among the factors that are thought to render females in these age groups more susceptible to vaginal infections.

Uterus

The uterus has two major components: (1) the expanded upper two-thirds of the organ, the body of the uterus and (2) the cylindrical lower one-third, the cervix (Figs. 49-12 and 49-13). The fundus is the rounded upper part of the body, superior to the points of entry of the uterine tubes. The isthmus is the short, slightly constricted zone between the body and the cervix.

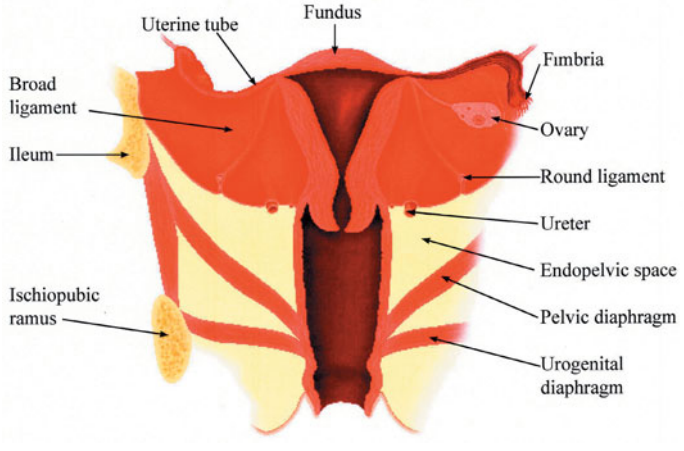

FIGURE 49-12. Coronal section of pelvis viewed from anterior surface illustrating broad ligament, endopelvic space, pelvic diaphragm, and urogenital diaphragm. *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

The two main components of the uterus are rather different from one another in their structure and function.

Cervix. The cervix consists primarily of dense collagenous connective tissue. Only about 15% of its substance is smooth muscle. In the isthmus, the uterine lumen narrows down to form the internal os. Below this point the lumen widens slightly to form the cervical canal (or endocervical canal). Finally, a constricted opening, the external os, at the lower end of the cervix provides communication between the lumen of the cervix and that of the vagina.

Inside the cervix, the endocervical mucosa is arranged in a series of folds and ridges. A longitudinal ridge runs down the anterior wall and another down the posterior wall; from each of these, small folds (the *plicae palmatae*) run laterally. The resemblance of this arrangement to a tree trunk with upward-spreading branches has given rise to the term *arbor vitae uterina* to describe the endocervical mucosa.

The part of the cervix that projects into the vagina (the *portio vaginalis*, or ectocervix) is covered by stratified squamous, nonkeratinizing epithelium. Usually, in older women, this type of epithelium extends for a very short distance into the cervical canal, where it forms a rather abrupt junction with the simple columnar epithelium lining the rest of the canal. The site of the squamocolumnar junction varies, however. It may occur higher up in the cervical canal, or the columnar epithelium may actually extend out beyond the external os where it forms small patches known as physiologic eversion, or ectopy, on the vaginal surface of the cervix. Ectopy is usually present in adolescents and decreases during the third and fourth decades of life.

The mucosa contains large branched endocervical glands. In reality, they are not true glands but are merely deep grooves or clefts (sometimes called crypts) that serve to increase the surface area of the mucosa tremendously. The epithelium of both the mucosal surface and the "glands" is of the simple columnar type in which almost all the cells are mucus secreting. A few ciliated cells are present. If the ducts of the glands become blocked, mucous secretion accumulates inside them to form small lumps just under the surface.

Unlike the mucous membrane of the body of the uterus, the endocervical mucosa does not slough off at menstruation. It does, however, respond to cyclic changes in the levels

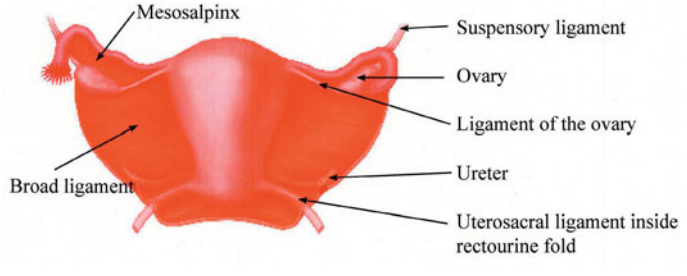

FIGURE 49-13. Posterior view of broad ligament and female reproductive organs. *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

of the ovarian hormones, estrogen and progesterone. It secretes up to 60 mg of mucus a day throughout much of the cycle, but near the time of ovulation (midcycle), when estrogen secretion reaches a peak, the secretion rate increases 10-fold and the abundant, clear mucus fills the cervical canal. It is less viscous than at other times during the cycle and is easily penetrated by spermatozoa.

The production of progesterone by the corpus luteum after ovulation (or during pregnancy) changes the quantity and properties of mucus produced. It becomes more viscous, less abundant, and much less penetrable by spermatozoa. It acts as a plug to seal off the uterine cavity.

The body of the uterus. The wall of the body of the uterus is composed of three layers: (1) the endometrium, a glandular mucous membrane; (2) the myometrium or smooth muscle layer; and (3) the serosa.

Endometrium. The function of the endometrium is to provide a suitable environment for the implantation and subsequent growth of the developing embryo. As such, it is a luxuriant mucosa with a large population of glycogen-secreting glands and a rich vascular network. However, if there is no developing embryo, most of the endometrium is sloughed off (causing the menstrual flow) and is regenerated again in the next menstrual cycle. This cyclic shedding and regeneration of the endometrium is under the control of the ovarian hormones, estrogen and progesterone. The rise and fall in ovarian hormone levels determine the rise and fall of the growth and shedding of the endometrium.

The endometrium varies from 0.5 mm to approximately 5 mm in thickness, depending on the stage of the menstrual cycle. It is at its greatest height a few days after ovulation, at about the time of expected implantation. It consists of a simple columnar epithelium and a highly cellular lamina propria (the endometrial stroma) in which there are large numbers of tubular uterine glands. The epithelium contains both ciliated and secretory cells.

The endometrium can be subdivided into a rather narrow, deeper layer next to the myometrium, the basalis, and a much thicker, more superficial layer, the functionalis. The latter receives its name because it is the portion that is shed during menstruation.

The arteries that supply the endometrium play an important role in the onset of menstruation. Circumferentially oriented arteries in the myometrium give off numerous branches toward the endometrium. As they enter this region, small basal arteries branch off to supply the basalis. The arteries then become highly contorted as they enter the functionalis and are known as coiled or spiral arteries. These arteries spasmodically contract late in the menstrual cycle that induces ischemia, necrosis, and eventually sloughing of the functionalis.

During the menstrual cycle, the endometrium passes through a number of phases. In the menstrual phase (approximately days 1 to 4 of a typical 28-day cycle) the functionalis is sloughed off; cellular debris and blood are discharged into the vagina. From day 5 until the time of ovulation (approximately day 14) the endometrium is in its proliferative phase. Epithelium in the persisting portions of uterine glands in the basalis grows out and covers the denuded surface. Estrogen from the growing follicles in the ovary promotes rapid proliferation of the epithelium, glands, and stroma. The endometrium may thicken by 2–3 mm at this time. Progesterone and estrogen from the corpus luteum stimulate the secretory phase (days 15–28), in which the epithelial cells begin to secrete. Accumulation of secretory products in the lumina of the glands, together with some edema of the stroma, causes the endometrium to increase further in height.

Late in the secretory phase, ovarian hormone levels drop and the changes that herald menstruation occur. Intermittent constrictions in the spiral arteries cause stasis of blood and ischemia of vessels and tissues in the area of supply. During the intervening periods of relaxation, blood escapes from the weakened vessels, promoting menstrual hemorrhage.

Myometrium. The myometrium consists of bundles of smooth muscle fibers separated by strands of connective tissue. Four layers of smooth muscle have been distinguished, but their boundaries are poorly defined owing to overlap between adjacent layers. In the innermost and outermost layers, most of the muscle fibers are disposed longitudinally, whereas in the middle layers there are rather more circular fibers.

Estrogen is essential for the maintenance of normal size and function in myometrial smooth muscle cells.

Serosa. The serosa is the peritoneal covering of the uterus; hence, only the pelvic portion of uterus has a serosa. The cervix has no serosa. The peritoneal reflections are discussed later in the chapter in the section on the broad ligament.

Uterine tubes

Fertilization and the earliest steps in development occur within the uterine tube. Therefore, these tubes must perform a number of tasks. As well as providing a suitable milieu for the gametes and transporting them to the site of fertilization in the midsection of the duct, they must also provide the nutritional support necessary for the embryo during segmentation and morula formation. In addition, transport mechanisms in the proximal portion of the oviduct must be such that the embryo arrives in the uterus at the appropriate time, both in terms of its own development and in terms of uterine receptivity.

General structure. The uterine tubes lie in the upper margins of the broad ligament. Each is composed of four parts. Beginning at the distal end these are (1) the infundibulum—the funnel-shaped end of the uterine tube that bears numerous delicate processes, the fimbriae, around the abdominal ostium; (2) the ampulla, or longest portion—it accounts for slightly more than half of the total length; (3) the isthmus—a narrow portion leading to the uterus; and (4) the intramural (or interstitial) portion—that part of the duct that extends through the wall of the uterus. At its end there is a minute ostium that connects the cavities of the uterus and uterine tube.

Three layers form the wall of the uterine tube: (1) the mucous membrane, characteristically composed of epithelium and lamina propria. The epithelium is of the simple columnar variety and contains two types of cells, ciliated and secretory. The lamina propria is loose connective tissue. (2) The muscular layer consists typically of two layers of smooth muscle, an inner circular and an outer longitudinal, but the boundary between the two is not distinct. In the intramural portion another longitudinal layer has been described, internal to the circular layer. (3) The serosa, which is typical of serosa elsewhere.

The mucous membrane and the muscular layer vary from one region of the duct to another. The structure and function of the various regions will now be discussed in more detail.

Infundibulum. When the oocyte leaves the ruptured follicle at ovulation, it is still surrounded by a mass of follicular cells that made up the bulk of the cumulus oophorus. The oocyte and its surrounding cells are now called the cumulus mass. The fimbriae of the infundibulum have the task of removing the cumulus mass from the site of follicular rupture on the ovary and transporting it into the ostium. Once contact is made, the cumulus mass begins to be transported over the fimbrial surface by ciliary action. The surface is richly ciliated and all the cilia beat toward the ostium. Since oocytes freed of cumulus cells are easily dislodged and are transported rather poorly, it is believed that the cumulus cells are essential for normal "pickup" and transport.

The epithelium of the fimbriae (and indeed, of the entire uterine tube) is sensitive to ovarian hormones. As estrogen concentration rises during the follicular phase of the cycle, the epithelium increases in height and reaches a maximum at midcycle. During the late luteal phase, cell height decreases. There is little evidence for deciliation and reciliation during the menstrual cycle in the human, but there is no doubt that withdrawal of estrogen will result in deciliation. The fimbriae of postmenopausal uterine tubes are largely devoid of cilia, whereas these from postmenopausal women who are on estrogen therapy are richly ciliated.

Ampulla. The mucous membrane of the ampulla is thrown up into an elaborate system of longitudinal folds. Most of the lumen is thus reduced to a system of fine channels between the folds. Less than half of the epithelial cells are ciliated and they beat toward the isthmus (Fig. 49-14).

Fertilization occurs in the proximal portion of the ampulla. There are potentially two mechanisms for transporting the cumulus mass to this site: ciliary activity and smooth muscle contraction. Although the role of the ciliated cells in the ampulla is fairly clear, the function of the secretory cells is less certain. Loss of cilia may be caused by infection, leading to poor gamete transport with resultant infertility or ectopic pregnancy. Infection may also occlude the tube and persisting secretion may result in hydrosalpinx.

Isthmus. The elaborate mucosal folds of the ampulla give way rather abruptly to simpler, lower folds in the isthmus. Concomitant with a decrease in complexity of the mucosal folds is a marked increase in the thickness of the muscle layer. The ciliated cells of the mucosa beat toward the uterus.

The isthmus is perhaps the least understood portion of the uterine tube. It has the capacity of transporting spermatozoa distally toward the site of fertilization and later, conducting the developing embryo proximally. It is not

FIGURE 49-14. Ampulla of the uterine tube from a 29-year-old woman in midcycle. Scanning electron micrograph illustrates distribution of ciliated and nonciliated cells. *(Courtesy Dr. Penny Gaddum-Rosse.)*

known how the isthmus (or perhaps the intramural portion) controls the passage of cleaving eggs into the uterus.

Intramural portion. The lumen of the uterine tube becomes extremely narrow in the proximal isthmus and intramural portions. The mucosal folds are reduced to low ridges. The muscular layer, on the other hand, becomes thicker than in any other part of the tube. The large amount of muscle in this region might suggest that a sphincter exists that could close off the uterine tube and help to prevent the spread of infection. However, there are no reported observations documenting the existence of an anatomical sphincter.

Broad ligament

The broad ligament represents a transverse double fold of peritoneum containing the uterus and the uterine adnexa (uterine tube and ligaments) as well as nerves, vessels, and lymphatics (see Figs. 49-12 and 49-13). Inferior to the sacral promontory, the peritoneum covers the anterior surface of the sigmoid colon and dips to its lowest point overlying the posterior vaginal fornix. From this position it reflects superiorly over the fundus and body of the uterus and then anteriorly to cover the dome of the bladder. At the level of the pubic symphysis it reflects superiorly again onto the anterior abdominal wall. From either side of the body of the uterus the folded peritoneum is carried laterally to the wall of the pelvis, forming a transverse vertical partition, the broad ligament. This divides the inferior peritoneal cavity into an anterior vesicouterine (pouch of Douglas) and posterior rectouterine space.

Suspensory ligament of the ovary

The suspensory ligament (infundibulopelvic ligament) is an extension of the most superior and lateral part of the broad ligament. It is misnamed, as it provides no support for the ovary or uterus. In reality, it is merely a fold of peritoneum raised by the underlying ovarian vessels, nerves, and lymphatics as they course between the ovary and the retroperitoneum. It provides a potential route for the spread of infection from adnexal structures to the retroperitoneum and para-aortic nodes.

Ovary. The ovaries have two major functions: to nurture and release the female gametes and to produce the female sex hormones, estrogen and progesterone. These functions entail considerable changes in ovarian structure, both cyclic changes during the reproductive years and long-term changes over the individual's lifetime.

The ovary is covered by a single layer of cells known as the germinal epithelium. This is actually a misnomer, since it does not give rise to germ cells, as was originally believed. The cells are cuboidal in the young individual but tend to become squamous with age. This epithelium is the source of most ovarian neoplasms. These masses may be detected on bimanual examination and can be confused with hydrosalpinx or more acute infectious processes, especially if the neoplasm undergoes torsion.

The substance of the ovary may be divided into an outer cortex and an inner medulla. The connective tissue stroma of the cortex contains many spindle-shaped cells that resemble fibroblasts and intercellular substance. In the outermost zone of the cortex, just under the epithelium, the ratio of intercellular material to cells is higher than elsewhere. The fibrous nature and relatively poor vascularity of this zone give it a whitish appearance that accounts for its name, the tunica albuginea. The stroma of the medulla is a loose connective tissue containing some smooth muscle cells, many elastic fibers, and large, tortuous blood vessels. The presence of elastic fibers and the convoluted nature of the blood vessels permits the ovary to adapt fairly readily to the large structural changes that occur in the organ during each menstrual cycle.

BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND INNERVATION OF THE PERINEUM AND EXTERNAL GENITALIA

BLOOD SUPPLY

The internal pudendal artery (Fig. 49-15) is an arterial trunk providing blood to all the perineal structures inferior to the pelvic diaphragm (see Figs. 49-12 and 49-16). It begins as a branch of the internal iliac artery located subperitoneally in the lateral pelvis. It exits the bony pelvis, crosses the sacrospinous ligament, and enters the ischiorectal fossa. At this point the artery along with the internal pudendal vein and nerve becomes enclosed by the obturator fascia forming the pudendal canal (of Alcock). As the artery enters the

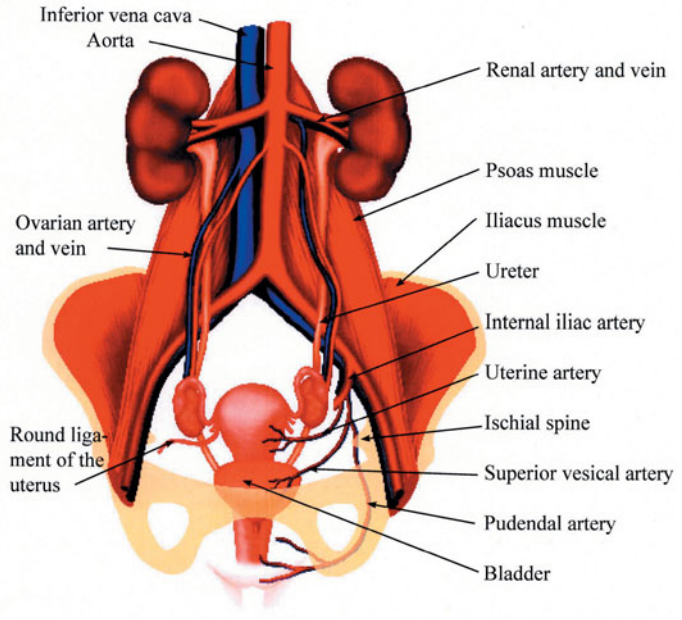

FIGURE 49-15. Blood supply of female reproductive tract. *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

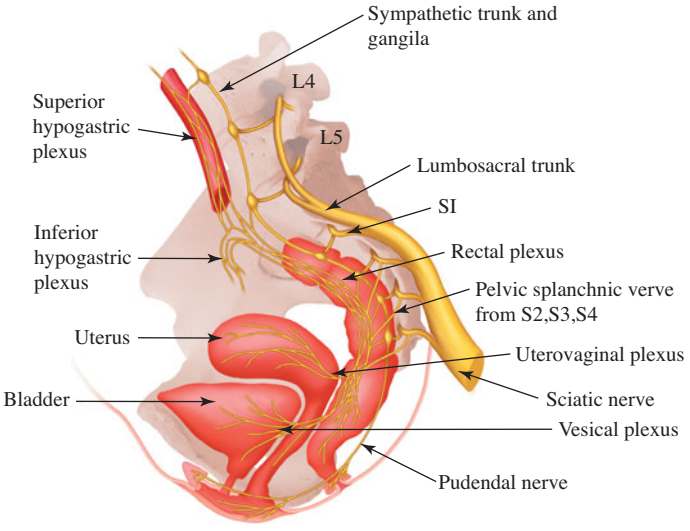

FIGURE 49-16. Innervation of female reproductive tract and pelvic plexuses. *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

pudendal canal it gives off an inferior rectal artery that supplies the anorectal junction. The remaining portion of the internal pudendal artery reaches the base of the urogenital diaphragm and gives off a series of perineal branches. These supply the contents of both superficial and deep perineal spaces, including the vagina and urethra and clitoris.

The venous drainage of both perineal triangles parallels the arterial supply. There is also a rich submucosal venous plexus in the distal vagina. Distension of these submucosal veins can produce vaginal or vulvar varices. The inferior rectal veins join the internal pudendal vein just as it leaves the ischiorectal fossa at the lesser sciatic foramen. Both the rectal and vaginal submucosal plexuses penetrate the pelvic diaphragm to communicate with the endopelvic space. Here, vaginal veins may anastomose with uterine veins and inferior rectal veins with middle rectal veins.

LYMPHATIC DRAINAGE

As a general rule, lymphatic drainage follows the blood supply of a region. The lymphatic drainage of the perineum differs in this respect because there is a dual pathway. Deep lymphatics course upward following the pudendal veins, draining the deep parts of both urogenital and anal triangles. However, superficial lymphatics from the skin overlying the vulvar and anal areas course to the medial thigh where they communicate with superficial inguinal lymph nodes. Adenopathy of superficial inguinal nodes is well known in many vulvar and anal infections as well as in carcinoma of these regions.

INNERVATION

The motor and sensory innervation of the perineum is via fibers from sacral roots S2, S3, and S4 forming the pudendal nerve (Fig. 49-16). Originating from the sacral plexus in the presacral region, the pudendal nerve exits the pelvis via the greater sciatic notch, crosses the sacrospinous ligament, enters the pudendal canal, and accompanies the pudendal vessels. The branches of the internal pudendal nerve are the inferior rectal, perineal, and dorsal clitoral nerves, supplying these respective areas.

BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND INNERVATION OF UTERUS AND VAGINA

BLOOD SUPPLY

The uterus and upper vagina lie within the endopelvic space, that is, between the pelvic peritoneum and the pelvic diaphragm. These structures as well as the adjacent rectum, bladder, and so on are all supplied by a single arterial trunk, the internal iliac artery (see Fig. 49-13). It arises by division of the common iliac artery at the junction of the sacrum and the ilium. Descending in the lateral pelvis subperitoneally it gives off a series of visceral branches, including rectal, uterine, and vesical. These course medially to enter the endopelvic space, at the base of the broad ligament. Before reaching the isthmus of the uterus the uterine artery crosses superior to the ureter and gives branches to the vaginal fornix and cervix. Turning superiorly in the parametrial space of the broad ligament, a series of arterial branches is given to the body of the uterus until the artery anastomoses with the ovarian artery at the uterotubal junction.

The uterine vein is usually plexiform, coursing laterally in the base of the broad ligament before reaching the lateral pelvic wall. Here the plexus of veins forms a series of tributaries entering the internal iliac vein, which in turn empties into the inferior vena cava. Other veins in the endopelvic space include middle rectal veins draining the rectum.

The normal route of rectal venous flow is into the internal iliac vein. During pregnancy, the fetus may partially occlude the inferior vena cava when the woman is recumbent, increasing venous resistance and diminishing pelvic venous flow into the inferior vena cava. Because the middle rectal veins also communicate with the superior rectal branches of the inferior mesenteric vein, there is the potential that pelvic blood can ascend via the portal circulation. None of the pelvic veins contains valves, allowing blood to take the pathway of least resistance. Middle rectal veins also communicate with inferior rectal veins; these veins are tributaries of the internal pudendal vein that drains into the iliac veins before entering the inferior vena cava. Increased blood flow in these vessels, particularly in the last trimester of pregnancy, is a well-known cause of hemorrhoids.

LYMPHATIC DRAINAGE

A plexus of uterine lymphatics parallels the course of uterine veins, entering regional lymph nodes along the internal iliac artery. From these nodes lymph trunks ascend to para-aortic nodes in the retroperitoneum.

INNERVATION

The endopelvic space is the primary pathway for both motor and sensory nerve fibers supplying the uterus (see Fig. 49-12). Sensory fibers from the uterine body descend in the parametrial space of the broad ligament to join other fibers from the cervix. These form a large plexus in the paracervical region termed the uterovaginal plexus or Frankenhauser's ganglion. In the endopelvic space these fibers commingle with visceral afferents from other pelvic viscera, before entering the inferior hypogastric plexus. Ascending the sacral promontory the fibers join the superior hypogastric plexus and enter the sympathetic trunk via lumbar splanchnic nerves.

From sympathetic ganglia white rami communicans conduct fibers to the dorsal roots of spinal nerves T10 to T12.The uterovaginal plexus also includes parasympathetic motor fibers from sacral roots that enter the endopelvic space directly, as well as sympathetic motor fibers that enter from the sympathetic trunk. Concentration of uterine sensory fibers in the uterovaginal plexus is the anatomical basis for a regional anesthetic procedure, paracervical block. It is accomplished by inserting the needle of a syringe into each lateral vaginal fornix and infiltrating the paracervical area with a local anesthetic. This will often provide adequate anesthesia for instrumentation of the cervix and uterus.

BLOOD SUPPLY, LYMPHATIC DRAINAGE, AND INNERVATION OF THE OVARY AND UTERINE TUBE

BLOOD SUPPLY

The ovarian arteries arise as lateral branches from the abdominal aorta, descend in the retroperitoneal space, cross the ala of the sacrum, and enter the suspensory ligament of the ovary (see Fig. 49-15). As the ovarian artery enters the lateral edge of the broad ligament it courses medially between the two layers of the ligament, giving branches to the ovary and uterine tube.

The venous drainage of the structures in the superior part of the broad ligament is via the ovarian vein, which parallels the ovarian artery as the vein ascends in the retroperitoneal space. On the right side the ovarian vein is a tributary of the inferior vena cava, whereas on the left side it drains into the left renal vein.

LYMPHATIC DRAINAGE

Afferent lymphatics from the ovarian and uterine tube accompany ovarian vessels to para-aortic lymph nodes in the retroperitoneum. The fundus of the uterus is drained in part by this same route but also sends lymphatic vessels anteriorly paralleling the course of the round ligaments of the uterus. This bilateral course carries afferent lymphatics to inguinal lymph nodes on both sides of the pelvis.

INNERVATION

The suspensory ligament of the ovary also contains the afferent neural pathway for the ovary and uterine tube (see Fig. 49-13). After reaching the retroperitoneum, these fibers join the superior hypogastric plexus, ascend briefly, and then enter a lumbar splanchnic to reach the sympathetic trunk. Ascending fibers leave the sympathetic trunk via rami communicans to enter spinal sensory roots T10 to T12.

50 Clinical Anatomy and Physical Examination of the Male Genital Tract

John N. Krieger and Daniel O. Graney

INTRODUCTION

Any area of the body may be involved in sexually transmitted disease syndromes or in the differential diagnosis of these conditions. Clearly there is no single, optimal method for conducting the history and physical examination. The critical areas of interest are determined by the history, other physical findings, and conditions considered in the differential diagnosis. There are as many correct ways of eliciting historical data and physical findings as there are clinicians. Similarly, there are many critical anatomical points that may be important in some contexts yet irrelevant in others. Thus, this chapter reflects our bias and represents an attempt to succinctly present one approach to "the routine examination." Pertinent genitourinary tract anatomy will be presented in the context of this examination. This approach is selective but based on our own clinical experience in developing an efficient method for evaluating a large number of patients in a timely manner.

Most often, the standard examination of a patient in our clinic proceeds according to an orderly sequence. The pertinent portions of the examination usually follow the outline in Table 50-1. Proceeding in this fashion has two advantages. First, there is an orderly sequence to the examination that limits the opportunity for errors of omission in a busy clinical situation. Second, there is a minimal need for the patient to move. Ordinarily, we initiate the examination by having the patient sit on the examining table. If necessary, head and neck examination and percussion and auscultation of the chest may be done in this position. Next, the patient is asked to lie supine. Cardiovascular examination may be conducted in this position, if indicated, and attention is directed to the abdominal examination. The patient is then asked to stand for examination of the groin and genitalia. Finally, the patient is asked to turn and bend over, placing his elbows on the examining table, for the rectal and prostate examination. In sum, there is minimal need for the patient to move from position to position if the examination is done in this order.

This chapter is organized to follow the suggested pattern of evaluation. The relevant considerations in routine examination of the male are presented for each section of the physical examination, then critical anatomical principles are considered for that area. Throughout, we emphasize a practical approach and minimize use of Latin terms. This means that we present the anatomy according to our own opinions, recognizing that some of these opinions are controversial and that other anatomists and/or clinicians may hold alternative, equally valid, viewpoints.

There are two major differences in anatomy and examination between male and female patients. First, in the male we are talking about genitourinary tract examination. In the female, there is a urinary tract and a separate genital tract. These two functions are combined in the male lower genitourinary tract in which the urethra serves as a common conduit for the excretory functions of the urinary tract and for the reproductive functions of delivery of semen. The second major difference is that the critical reproductive organs in the male are all easily palpable. In contrast, the reproductive organs in the female are located in the pelvis and, therefore, may be examined less readily than the comparable structures in the male. The clinical implication is that examination of the male lower urinary tract and the entire male genital tract is readily accomplished and is straightforward in most patients.

EXAMINATION OF THE ABDOMEN AND GROIN

ABDOMEN

Complete details of the abdominal examination are beyond the scope of this chapter. However, brief mention is necessary of the pelvic organs, specifically the urinary bladder. This may be distended in patients with bladder outflow obstruction caused by an enlarged prostate or urethral stricture, and occasionally in patients with neurological dysfunction, as may occur with herpetic infections. The normal bladder is not palpable or percussible when empty or nearly empty

Table 50-1. Routine STD Examination of the Male

- General Appearance

  - Other

because of its location in the pelvis. As the volume increases to approximately125–150 mL, the dome of the bladder rises out of the pelvis into the lower abdomen and may project above the symphysis pubis. As it continues to fill, the bladder rises progressively toward the umbilicus. When the bladder contains 400 mL or more, it may be identifiable by observation as a bulge in the lower abdomen. Percussion over a distended bladder may cause the patient to experience a desire to void and may result in a change of the normal resonance of the lower abdomen on percussion to a dull note. The distended bladder may be palpated as a firm, round, and tender mass in the lower abdomen.

GROIN

The groin, or inguinal region, should be examined for the presence of adenopathy while the patient is lying supine on the examining table. The patient is then asked to stand and the inguinal area is again examined for the presence of hernia by direct palpation of the area and again by insertion of the index finger through the neck of the scrotum following the spermatic cord. Both examinations are done with the patient standing quietly and again while he is coughing or straining.

GENITALIA

PENIS

Examination

It is critical that the clinic staff instruct patients to refrain from voiding, if possible, prior to examination because signs of urethritis may not be apparent if the patient has recently voided. In fact, in symptomatic patients who do not have objective evidence of urethritis on examination or on the urethral smear, it is our practice to repeat the examination before the first urination of the day. Initially, attention is directed to examination of the skin. Use of a good light source and a hand lens are strongly recommended for evaluating possible lesions.

Attention is then directed to examination of the penis. In uncircumcised patients, the foreskin should be retracted to rule out phimosis with an obstructing small opening. This maneuver may reveal balanitis, condylomata, ulcers, and, occasionally, tumor, as the cause of a foul discharge. The glans and inner surface of the foreskin should be inspected to rule out presence of ulcers, vesicles, or warts. The location of the meatus is determined and the urethra is examined for presence of spontaneous discharge. If the location of the urethral meatus is abnormal, it can usually be found by following the midline along the undersurface of the penis. This is the most common location for an abnormal orifice and is termed *hypospadias.* Hypospadias is associated with a prepuce that does not completely encircle the glans but is incomplete on the lower surface. This is commonly termed a "hooded prepuce." Patients with more severe degrees of hypospadias, in which the urethral opening is located at the base of the penis or on the perineum, often have bifid, or split, scrotums. Rarely, the location of the urethral meatus may be on the upper surface of the phallus, a condition termed *epispadias.* In either hypospadias or epispadias, there is likely to be

chordee, or an abnormal curvature of the phallus. Partial or complete duplication of the urethra may be noted. Commonly, patients with urethral duplications who present with urethritis have involvement of the accessory urethral meatus. The urethral meatus is examined by pinching the glans between the thumb and the forefinger at the 6 and 12 o'clock positions. This is important to exclude presence of meatal stenosis (or narrowing) and intraurethral lesions, such as condylomata.

The shaft of the penis is palpated, looking for firm fibrotic plaques (characteristic of Peyronie's disease that may result in discomfort and (or penile bending), and the urethra is palpated for evidence of induration. Induration is often secondary to infection, stricture (or scarring), or, rarely, tumor, abscess, or foreign body inserted by the patient. At this point, the urethra should be "milked" or stripped, beginning at the bulbous urethra (located at the perineal body, behind the scrotum in the midline) and proceeding to the meatus. This is necessary for evaluation for urethritis and may result in an expression of discharge at the meatus.

Anatomy

Major divisions. There are two parts of the penis: the base, which is attached to the pubis, and the pendular portion. Underlying the penile skin there are three cavernous erectile bodies, the paired corpora cavernosa that are primarily concerned with erection, and the corpus spongiosum that contains the urethra. These erectile bodies are separate structures at the base of the penis but become bound by fascia along the shaft of the penis (Fig. 50-1). Each corpus spongiosum is surrounded by a tough layer of white fascia. During erection, blood fills the muscular structure of the corpus spongiosum, causing it to expand while the outer covering expands minimally. The result is a rigid expansion of the penis. The corpora cavernosa are cylindrical bodies in the shaft region but taper markedly at the base where they attach to the pubic ramus and perineal membrane. The corpus spongiosum has three parts; beginning at the perineum, these are the bulb of the penis, the spongy portion, and the glans at the tip of the penis. The base and proximal portion of the penile shaft are covered by thin muscles (Fig. 50-1). The paired ischiocavernosus muscles overlie the crura and corpora cavernosa. Another pair of muscles, the bulbospongiosus, overlies the corpus spongiosum.

Urethra and glans. The urethra is named according to the part of the penis that it is traversing. Thus, in the penis the urethra is divided into bulbous, spongy, and glandular portions. The bulbous and spongy parts of the urethra are lined by a pseudostratified columnar epithelium, except at the tip of the penis, termed *the fossa navicularis,* which is lined by stratified squamous epithelium. The epithelium contains small acini of mucous cells (glands of Littré) as well as mucosal and submucosal glands, termed *urethral or periurethral glands* (Figs. 50-2, 50-3 and 50-4). These glands can become infected and form abscesses.

On the superior surface of the corona of the glans penis, as well as on the undersurface near the frenulum, there are sebaceous glands, the glands of Tyson. These glands secrete a white cheesy type of material, which with desquamating epithelial cells forms the smegma, a substance that accumulates between the prepuce and glans of uncircumcised men.

MALE CIRCUMCISION AND HIV AND STI

Presence of a foreskin has been related to an increased risk of HIV infection, chancroid, and perhaps other STIs.[1] This may be related to the relative lack of keratinization of the mucosal surface of the prepuce, to increased rates of inflammation and trauma, and to relatively poor hygiene of the prepuce. Increased risk of HIV infections may also be related to the density and positions of HIV target cells (CD4 lymphocytes,

macrophages, and Langerhan's cells) in the inner mucosal surface of the human foreskin[2] (Fig. 50-5). It is also possible that presence of a foreskin increases the duration and amount of retention and exposure to secretions containing HIV and other STI pathogens.

Circumcised men have more keratinized penile skin that may be more resistant to infection. The association between lack of male circumcision and an increased risk of HIV infection has led to three randomized clinical trials of adult male circumcision to prevent HIV infection. The first trial to be completed (from South Africa) found that male circumcision afforded about 60% protection against HIV infection.[3] In anticipation of potential widespread implementation of male circumcision, pending results of trials in Kenya and Uganda, the WHO is preparing a manual of male circumcision techniques appropriate for developing countries.[4]

SCROTUM

Examination

Skin. The scrotum and its contents are examined next. Palpation of the scrotal skin may reveal small sebaceous cysts. These structures may be multiple and, on occasion, become quite large or develop infections. Malignant tumors of the

scrotum are rare. In contrast, scrotal hemangiomas, bluish, vascular malformations are common and they may bleed spontaneously or following sexual activity. After the skin and subcutaneous tissues of the scrotum and perineum have been palpated, attention is directed to the intrascrotal contents.

Scrotal compartments. The scrotum has two compartments that are divided in the midline. Each side is the mirror image of the other, and an identical examination is carried out for each scrotal compartment. The testis is the most anterior intrascrotal structure and must be examined carefully. The second most important structure in the scrotum is the epididymis that lies immediately posterior to the testis.

Testis. Each testis should be palpated using two hands. Hard areas within the testicular parenchyma must be regarded as potentially malignant until proved otherwise. Testicular tumors are the most common genital urinary tract malignancy in men 20–40 years old. Transillumination of all scrotal masses should be routine. The patient is placed in a dark room and a strong light is applied to the back of the scrotum. Light is transmitted well through benign cystic structures, such as hydroceles or spermatoceles, but not through solid mass lesions, such as testicular tumors. Tumors may be nodular in consistency but are often smooth. The testis that has been replaced by tumor or damaged by a gumma is often insensitive to pressure, and the usual sick sensation produced by firm pressure on the testis is absent. The testis may be absent from the scrotum as a result of maldescent during development, a condition known as *cryptorchidism,* or as the result of abnormal mobility within the scrotal sac and inguinal ring, a condition known as *retractile testis.* An atrophic testis is small and flabby in consistency and may be hypersensitive. This may be congenital; following treatment of an undescended testes; the result of previous infection, such as mumps orchitis; or may follow torsion or previous surgery, such as hernia repair. Although sperm production may not occur in these organs, hormone production may continue. Very small (1.5×1×1 cm), abnormally firm testes in a young adult usually are attributable to Klinefelter's syndrome, a relatively common condition present in 0.2% of men and is usually associated with infertility. Klinefelter's syndrome is associated with one Y and two X chromosomes. On occasion, especially in adolescents and young men, the testis may twist within the scrotum, compromising its blood supply. This is *termed testicular torsion* and is one cause of acute scrotal pain and swelling requiring surgical intervention to prevent ischemic necrosis of the testis.

Epididymis. The epididymis is a comma-shaped organ that is usually applied closely to the posterior aspect of the testis. On occasion, however, the epididymis may be loosely applied to the testis. The epididymis should be carefully palpated for size, tenderness, and induration. Induration of the epididymis usually results from infection, as primary epididymal tumors are rare. It is often possible to feel the groove between the testis and the epididymis everywhere except superiorly, where the two structures are joined. During acute infections, the testis and epididymis are often indistinguishable, as both structures are involved in the inflammatory process. Tenderness is exquisite; swelling may be impressive and accompanied by an acute inflammatory hydrocele. In many men, a small, ovoid mass representing the appendix testis, a vestigial embryological structure, may be located near the groove between the upper pole of the testis and the epididymis. Occasionally, the appendix testis may twist, producing acute tenderness and swelling of the scrotum.

Spermatic cord. At the neck of the scrotum the cord structures should be palpated between the thumb and index finger. The solid, rope-like vas is usually identified easily and may be followed to its junction with the tail of the epididymis. Other soft, stringy structures in the spermatic cord may be palpable but are usually not clearly defined. Swellings in the cord are usually cystic in nature (e.g., hydrocele or hernia) and are rarely solid (e.g., connective tissue tumor). Varicoceles represent collections of dilated veins, are usually present on the left side of the scrotum, are best demonstrated with the patient standing, and feel "like a bag of worms."

Anatomy

Testis. The testis fulfills two main functions: it produces sperm and it secretes male hormones. Production of sperm takes place in the seminiferous tubules, whereas the production of testosterone, the major male hormone, takes place in the tissue located between the tubules. Each testis contains approximately 400–600 seminiferous tubules. Individual tubules are up to 70 cm in length and are coiled along most of their length in order to be accommodated in a fascial compartment of the testis. These compartments are extensions of the outer fibrous capsule of the testis, termed the tunica albuginea. The seminiferous tubules join to form the rete testis, which is the connection to the excretory duct system.[1,2] The lining of the seminiferous tubules contains two main types of cells, the developing sperm cells and the Sertoli cells, which support and presumably "nurse" the sperm cells during their development process. Sperm are continuously produced in the testis from puberty to senility following an orderly sequence of events. In the testis this process takes about 64 days.[2,3] However, when they leave the testis, the sperm cells are immature and are unable to fertilize an egg. The capability of fertilizing an egg is developed during transport of the immature sperm cells through the excretory duct system.

Excretory ducts. The excretory ducts transport sperm from the testis to the end of the male reproductive tract. The excretory ducts are composed of five elements, beginning from the testis: the efferent ducts, epididymis, vas, ejaculatory duct, and urethra.

Efferent ducts. There are approximately 12 efferent ducts, which are convoluted tubules connecting the rete testis to the

epididymis. The epithelium lining the ductules contains both ciliated and nonciliated cells. Ciliary movement helps propel sperm toward the epididymis. On electron microscopy, the nonciliated cells are found to be lined by tall microvilli. Surrounding the epithelium is a thin basal lamina, lamina propria, and smooth muscle fibers oriented circularly.

Epididymis. The epididymis receives the sperm and seminal fluid from each of the efferent ducts. The epididymis has three parts: the head, the body, and the tail. The initial segment of the epididymis is the head, which fuses with the efferent ductules. The epididymis continues inferiorly along the posterior surface of the testis as the body of the epididymis (Fig. 50-2). At the inferior pole of the testis, the epididymis thickens to form the tail. This convoluted tubule, if stretched, will be 6 meters in length.[1] It increases in diameter and thickness as it approaches the tail of the epididymis, where it becomes the vas.

Throughout its course, the epididymis is lined by tall, thin columnar cells with nonmotile stereocilia (Fig. 50-6). In electron micrographs the stereocilia are found to be exceptionally long filamentous microvilli. In addition, the fine structure of these cells is typical of a cell that is both secretory (abundant rough endoplasmic reticulum and Golgi cisternae) and absorptive (apical vesicles and tubules).[1,2]

Within the epididymis, sperm undergo progressive maturation during their movement from the head to the tail. As sperm emerge from the testis, they are infertile and relatively nonmotile. By the time they reach the tail of the epididymis, they are both motile and fertile.[1,2] The average time of sperm transit through the epididymis is 12 days.[4] Together, the sperm and epididymal fluid contribute about 10% of the ejaculate.

Vas. The vas is the continuation of the epididymal duct, with only slight modification of the epithelial surface but substantial thickening of the outer muscle coat. The thickness of the muscle coat produces the "whipcord" sensation when the vas is rolled between the thumb and forefinger during physical examination of the spermatic cord. The vas is 2–3 mm in diameter and about 18 inches long.[1]

From the inferior pole of the testis, the vas ascends in the spermatic cord within the scrotum, until it reaches the superficial inguinal ring. After traversing the inguinal canal, the vas enters the preperitoneal space at the internal inguinal ring, where it courses inferiorly into the pelvis lying between the pelvic fascia and peritoneum. The terminal portion, or ampulla, of the vas is more dilated and fuses with the seminal vesicle to form the ejaculatory duct.

Ejaculatory duct. The ejaculatory duct represents the short (about 2 cm), slender termination of the vas after it joins the duct of the seminal vesicle. Traversing the substance of the posterior wall of the prostate, the ejaculatory duct opens into the prostatic urethra at the verumontanum, an oval-shaped mucosal excrescence.

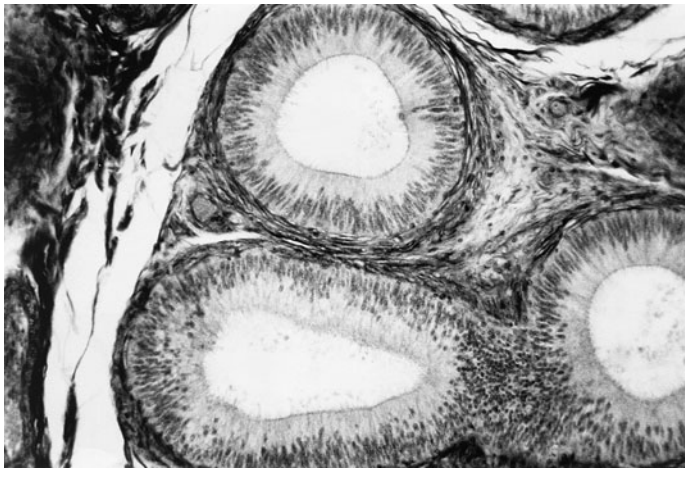

FIGURE 50-6. Light micrograph of the ductus epididymis. Epithelium is composed of pseudostratified columnar cells with stereocilia. Human, Mallory azan stain, ×135 in the original magnification.

LOWER GENITOURINARY TRACT SOURCES OF SEMINAL HIV

Coombs et al.[5] have studied 23 HIV seropositive men without urethritis or prostatitis in investigating genital tract sources of HIV by quantitative measures of HIV RNA in blood plasma, urethral fluid, preprostate massage urine, expressed prostatic secretions, and postprostate massage urine and by quantitation of HIV RNA and DNA in transrectal ultrasound biopsies from multiple prostate areas. Seminal HIV RNA levels are correlated with HIV RNA levels in urethral fluid and postmassage urine and with prostate biopsy DNA levels. However, distal genitourinary sources other than the prostate appeared to be the major source of HIV RNA in these men. The authors noted that, "Further localization of the source of HIV in semen could be pursued by analysis of split ejaculates, canulation of the ejaculatory ducts, or in situ detection methods." Similar systematic studies for localization of many other STI pathogens in the male genitourinary tract are largely lacking. HIV RNA levels did not reliably predict seminal plasma HIV RNA levels, suggesting the importance of the male genital tract as a distinct compartment for HIV replication.

RECTUM AND PELVIC ORGANS

Examination

Inspection may reveal presence of external hemorrhoids, rectal fissures, or fistulas. Internal examination is then carried out by inserting a well-lubricated, gloved index finger into the anal canal. The sphincter tone is evaluated and the canal is examined for undue tenderness or induration. Presence of induration, rectal stenosis, or mass lesions may indicate the need for additional studies, such as anoscopy or proctoscopy.

With the patient bent over the examining table, the prostate and seminal vesicles are palpated through the anterior rectal wall. The size of the normal prostate increases with age, and by palpation is about 4 cm in length and in width, about the size of the terminal segment of the thumb. The prostate is widest superiorly at the bladder neck. Two distinct "lobes" of the prostate are palpable, separated by a median sulcus, or indentation. Normally, the prostate gland is smooth, somewhat mobile, and nontender. The consistency is rubbery and resembles the tip of the nose.

One major problem in the prostate examination lies in differentiating firm areas. Differential diagnosis of a firm area in the prostate includes: cancer, calculi, infarction, granulomatous prostatitis, and nodular, benign hyperplasia. Even the most experienced examiner may have difficulty distinguishing among these possibilities on digital rectal examination.

Above the prostate it may be possible to feel soft, tubular seminal vesicles extending obliquely beneath the base of the bladder (Fig. 50-2). Usually, clear presence of seminal vesicles on rectal examination indicates a pathological process. Most commonly, these patients have pelvic tumors such as prostate cancer or acute infectious processes.

Determination of the prostate specific antigen (PSA) level can prove helpful in evaluating patients with an abnormal prostate examination. Findings such as nodules, asymmetry, or loss of distinct sulci, suggest the possibility of prostate cancer. An elevated PSA provides further support for the possibility of cancer. Prostate biopsy is necessary for diagnosis. Elevation of the PSA and firm areas in the prostate may also occur following acute lower urogenital tract infections, such as prostatitis. In this setting, reevaluation following antimicrobial therapy is appropriate.[5–7]

Some authorities recommend annual PSA determination and rectal examination for all men over 50 years old.[8–10] These evaluations are also suggested for men over 40 if they have a family history of prostate cancer. Other investigators suggest that there is little evidence that routine PSA screening, with biopsies and aggressive treatment has improved the overall outcome for patients with prostate cancer.[11] Lead-time and length-time biases may explain the results of many clinical series. Because aggressive diagnosis and treatment may be associated with considerable costs and morbidity, these authorities do not recommend routine screening.[8–10] Thus, the value of routine screening is debatable, but PSA testing is helpful for evaluating men with abnormal prostate glands on digital rectal examination.

Anatomy

Rectum. In the rectum, there are two to four permanent semicircular transverse folds of the mucosa, which are termed rectal valves. They neither serve as valves nor support the feces, as suggested by some investigators. These valves are readily observed during endoscopy and may be lacerated during blind instrumentation of the rectum.

Microscopically, the mucosa of the rectum is composed of columnar absorptive cells, although goblet-type mucous cells are interspersed among the absorptive cells. Invaginations of the epithelial surface form straight, tubular colonic glands equivalent to the glands of Lieberkühn seen in the small intestine.

Rectoanal junction. The rectoanal junction is not a discrete point but a longitudinal mucosal fold extending superiorly from mucosa that is paler and flatter (Fig. 50-7). This gives the appearance of a horizontal band with teeth, hence the term *pectinate line (Latin pecten,* "comb"). The mucosal ridges forming the tooth-like character of the line are termed *anal folds or columns* (of Morgagni). At the pectinate line between the base of the anal columns, the mucosa is redundant with outpockets to form the anal crypts. The epithelium of the anus, i.e., distal to the pectinate line, is characterized by stratified squamous cells of the nonkeratinizing type.

Accessory sex glands. The male accessory sex glands include the seminal vesicles, prostate, and bulbourethral glands (Cowper's glands).

Seminal vesicles. The seminal vesicles are paired, saccular glands with multiple foldings of their mucous membrane (Figs. 50-1 and 50-2). Embryologically, they begin as tubular buds from the vas. Hence, the seminal vesicles join with the vas, forming a common ejaculatory duct.

The seminal vesicles are lined by multiple foldings of columnar epithelial cells (Fig. 50-8) with abundant Golgi, rough endoplasmic reticulum, and secretory granules in the apical cytoplasm. The mucosal folds of the seminal vesicles are supported by a moderate lamina propria, containing collagen and elastic fibers. There is also a substantial muscular coat, which is important in the emission of secretions.

The seminal vesicles secrete an alkaline, slightly yellowish viscid fluid which constitutes 60–70% of the ejaculate volume.[3]

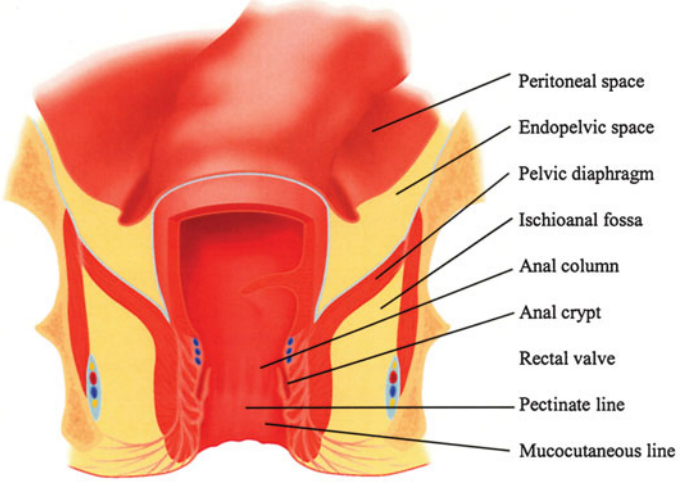

FIGURE 50-7. Coronal section of male pelvis and rectoanal junction. *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

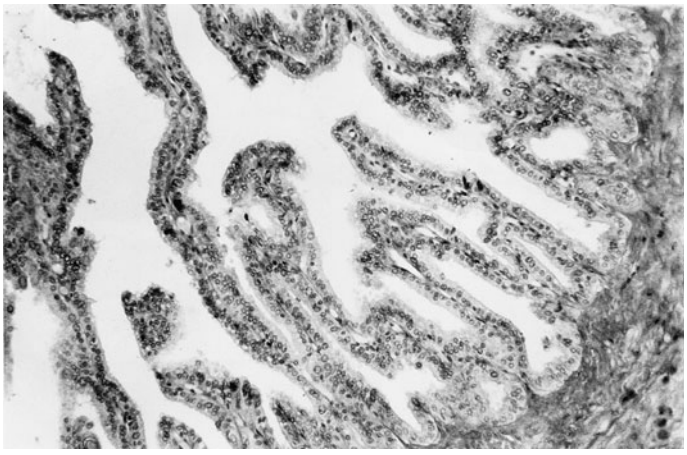

FIGURE 50-8. Light micrograph of the seminal vesicle, illustrating multiple compound foldings of glands. Human, Mallory azan stain, ×135 in the original magnification.

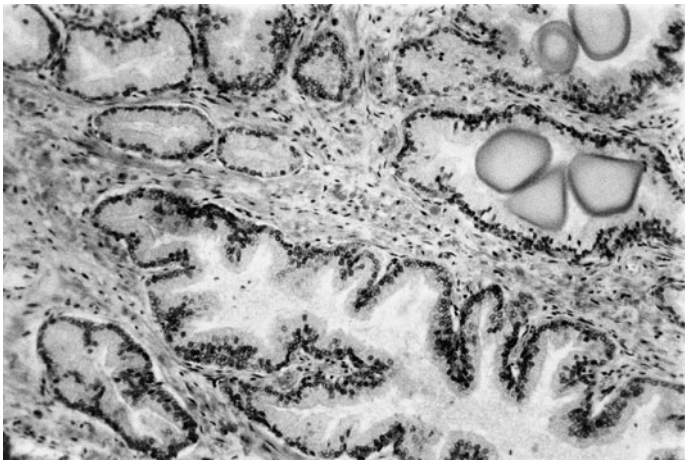

FIGURE 50-9. Prostate gland of older man showing prostatic concretions and columnar epithelium. Human, H & E stain ×135 in the original magnification.

Fractionation by "split-ejaculate" techniques shows that the semen consists of a presperm prostatic fraction, a sperm-rich fraction, and a postsperm vesicular fraction.[2] Fructose and a variety of prostaglandins appear to be formed specifically by the seminal vesicle.[2,3] Fructose is the principal energy source for sperm motility, but the role of prostaglandins in male fertility is uncertain.

Prostate. The prostate gland is located between the bladder neck and the urogenital diaphragm (Figs. 50-1, 50-2, and 50-3). The prostate completely encircles the urethra. The prostate measures about 3.5 cm transversely at its base and about 2.5 cm in its vertical and anterior posterior dimensions. Its normal weight is about 18 gm.[1]

Zones. The prostate gland is composed of three zones of tissue: a periurethral zone, surrounding the urethra; a wedge-shaped central zone, bounded by the ejaculatory duct, urethra, and base of the bladder; and a peripheral zone, composed of all remaining glandular tissue.[12–18]

The periurethral zone is composed of mucosal and submucosal glands penetrating the smooth muscle of the proximal urethra.[15–20] Benign hyperplasia originates in this region[15,21] and may lead to obstruction of urinary outflow from the bladder.

The central zone of the prostate is located between the urethra and ejaculatory duct.[12,16,22,23] This area appears to be least susceptible to development of inflammatory, hyperplastic, or neoplastic disease.

The peripheral, or outer, zone is the portion of the prostate that is palpable on rectal examination.[16,17,19,24] It is lined by multiple ducts (Fig. 50-9). The peripheral zone is also the region of the prostate that is most frequently involved in carcinoma and inflammation.[16,25]

Prostatic secretions. The prostate contributes approximately 30% of the ejaculate volume,[2,3] in the form of a thin, slightly opaque fluid. The prostate gland appears to be important in protecting the male lower urogenital tract against infection, in providing enzymes for "liquefying" the semen after ejaculation, and in providing other components of the seminal fluid. Normally the pH of prostatic fluid is around 7.[2,3,26] However, in men with well-documented bacterial prostatitis, the secretions alkalinize and may reach or exceed pH 8.25. Zinc, magnesium, citric acid, and acid phosphatase in the ejaculate appear to originate in the prostatic secretions.[2,26,27]

Bulbourethral glands (Cowper's glands). These paired, pea-sized glands are located in the urogenital diaphragm (Fig. 50-2). Their excretory ducts drain into the posterior urethra. The bulbourethral glands secrete a thin, mucoid material during the excitatory stage of sexual response, but the bulbourethral glands contribute only a minimal amount to the ejaculate. These glands are relatively immune to hyperplastic and neoplastic disease, although they can be involved in infections.[28]

BLOOD SUPPLY

ARTERIAL PATHWAYS (INTERNAL ILIAC ARTERY)

The pelvic organs in the male receive their blood supply from the internal iliac artery. The internal iliac artery arises at the pelvic brim from the common iliac artery and immediately divides into an anterior and posterior division.

Posterior division

The posterior division of the internal iliac artery provides small branches to the pelvic sidewall and has three branches that leave the pelvis, including the pudendal arteries.

The internal pudendal artery supplies the perineum (Fig. 50-10). This includes all structures located in the ischiorectal fossa and superficial and deep pouches. As it leaves the pelvis via the greater sciatic notch, the pudendal

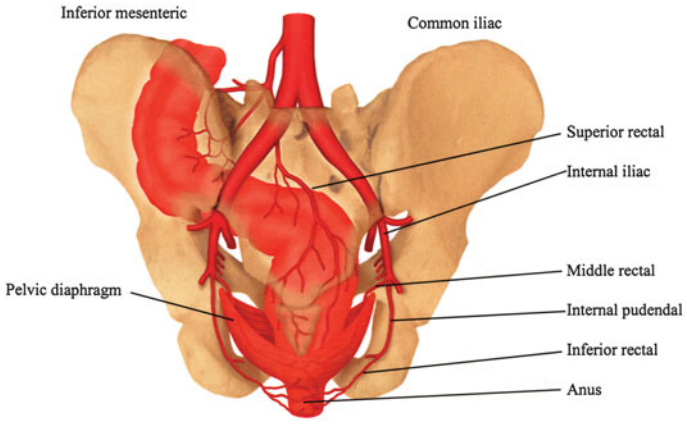

FIGURE 50-10. Branches of the internal iliac artery and the distribution of the internal pudendal artery. *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

artery gives off the inferior rectal artery and then enters the pudendal canal. The pudendal arteries have three areas of distribution: the anal canal, the perineum, and the phallus.

Anterior division

The anterior division of the internal iliac artery courses on the sidewall of the pelvis until it reaches the symphysis pubis, where it ascends the anterior abdominal wall. As it turns superiorly, the lumen of the vessel disappears and the vessel becomes a fibrous cord, the medial umbilical ligament. The internal iliac artery branches to form the middle rectal, superior, and inferior vesical arteries. The middle rectal artery supplies the rectum and has anastomosing branches with the superior rectal artery from the sigmoid. The superior vesicle artery supplies the fundus of the bladder whereas the inferior vesicle artery supplies the bladder neck, seminal vesicle, vas deferens, and prostate. All these vessels anastomose with their members from the opposite side.

VENOUS AND LYMPHATIC PATHWAYS

■ PELVIC ORGANS

Venous drainage

The pelvic organs have abundant venous plexuses which give rise to larger veins that parallel the arterial pattern. These veins return blood from the pelvic organs to the internal iliac vein that merges with the external iliac vessel to form the common iliac vein. This pathway joins the caval system of veins. Some blood in the perirectal region enters anastomotic channels in the mucosal plexus and ascends via the superior rectal vein to enter the portal drainage system.

Lymphatic drainage

The lymphatic pathways from the pelvic organs follow the venous pattern. The first series of regional node is along the proximal parts of the internal iliac artery. From these nodes, lymphatic channels ascend to the aorta and the para-aortic lymphatic chain before entering the thoracic duct.

The sigmoid lymphatics follow the superior rectal veins to inferior mesenteric lymph nodes near the aorta.

■ PERINEAL STRUCTURES

Venous drainage

Most structures supplied by the pudendal artery are drained by veins that enter the internal pudendal vein. This vessel returns along a similar route to enter the internal iliac vein. There are two exceptions to this pattern: the anorectal region and the dorsum of the penis.

In the anorectal region, blood may return via veins in the endopelvic space and eventually reach the vena cava through internal iliac tributaries or may continue superiorly to reach the superior rectal tributaries of the portal system. Increased venous pressure in this region, due to increased venous resistance in either the portal system or the caval system, can result in anorectal hemorrhoids. The anorectal submucosal venous plexus is also a pathway for the spread of infection from the perianal and rectal areas to the endopelvic space.

The second nonpudendal venous pathway from the perineum is via the dorsal vein of the penis to the prostatic venous plexus at the neck of the bladder. These veins cross the urogenital diaphragm from the perineum to enter the endopelvic space. The prostatic veins are tributaries of the internal iliac system.

Lymphatic drainage

The lymphatic drainage of the perineum differs from its venous drainage. In essence, all the skin and superficial structures of the perineum have lymphatics which course via the medial aspect of the thigh to the superficial inguinal nodes. Thus, anal and perianal ulcers caused by syphilis, chancroid, herpes simplex virus, or lymphogranuloma venereum cause inguinal lymphadenopathy. Channels from these nodes penetrate the fascia of the thigh at the saphenous opening to join the lymphatics from the leg. These lymphatic vessels course superiorly along the external iliac vein, then merge with para-aortic lymphatics.

An important exception is the lymphatic drainage of the testis, which does not follow the pattern described above. The testicular lymphatics course superiorly in the spermatic cord, traverse the inguinal canal, and then ascend in the retroperitoneum with the testicular vein. In this manner, the lymphatics reach the para-aortic lymph chain at the level of the renal vessels. This point is important clinically because metastases from testicular tumors do not cause inguinal adenopathy unless the usual lymphatic channels have been disrupted by infection or previous surgical procedures.

NERVE SUPPLY OF THE PERINEUM AND PELVIC ORGANS

The three neural components that must reach the perineal and pelvic structures are the somatic, parasympathetic, and sympathetic nerves.

Only the perineum is supplied by somatic fibers. These arise in spinal cord segments S-2, -3, and -4 and travel via the pudendal nerve to all the skins and structures of the anal and urogenital triangles (Fig. 50-11). The pudendal nerve leaves the pelvis along with the pudendal vessels, entering the pudendal canal after giving off the inferior rectal nerves. These supply the perineal skin, external anal sphincter, and the skin of the anal canal. The pudendal nerve then divides into a perineal branch, supplying the deep and superficial pouch structures, and the dorsal nerve of the penis, supplying the skin of the penis. Branches of the perineal division supply the urogenital diaphragm, superficial perineal muscle, and skin of the scrotum.

PARASYMPATHETIC NERVE SUPPLY

The parasympathetic innervation of the pelvic organs is also derived from spinal segments S-2, -3, and -4. However, these fibers originate from neurons in the intermediolateral gray rather than the ventral gray, which is the origin for fibers in the pudendal nerve. After these fibers leave the anterior sacral foramina, they join to form the pelvic splanchnic nerve (nervi erigentes), which contributes these fibers to the plexus surrounding the viscera. This is termed the pelvic plexus. These fibers traverse the plexus without synapsing and then enter the walls of the pelvic organs, rectum, bladder, and prostate, where they synapse in intramural ganglia. Short postganglionic fibers are then relayed to the muscle fibers.

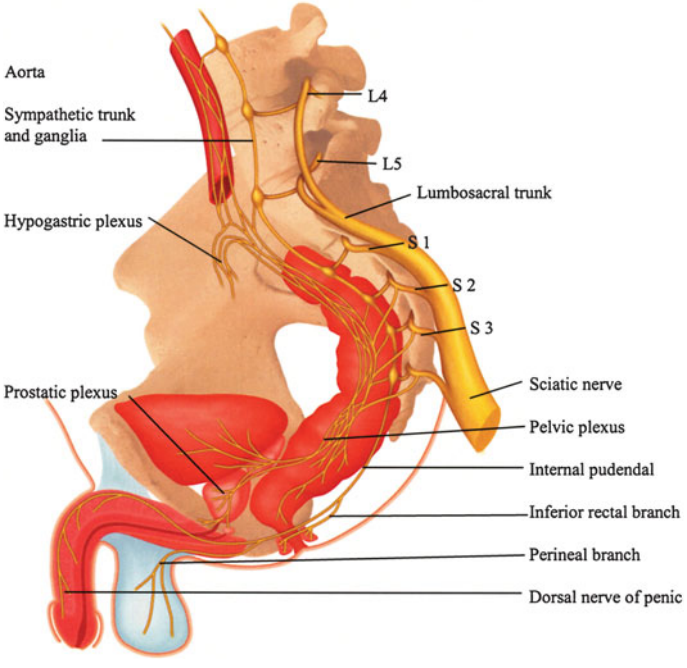

FIGURE 50-11. Innervation of the pelvic viscera. *(Artistic graphics by Robert Holmberg, Seattle, WA.)*

SYMPATHETIC NERVE SUPPLY

Sympathetic fibers to the pelvic viscera are believed to originate in the intermediolateral gray of the spinal segments T-12–L-2.

After joining a spinal nerve, they enter a sympathetic ganglion for that segment but do not synapse in the ganglion. The fibers descend briefly in the sympathetic chain and then course medially to enter the superior hypogastric plexus anterior to the aorta. The preganglionic fibers descend in the plexus to the inferior hypogastric plexus, which divides around the lateral sides of the pelvic organs and becomes the pelvic plexus (rectal, vesical, or prostatic). Synapses occur in the plexus or in the capsule of the organ innervated.

The pelvic plexus, therefore, is a mixture of parasympathetic and sympathetic fibers. At the lower aorta, much of the sympathetic input to the urogenital organs travels through the superior hypogastric plexus that lies anterior to the aortic bifurcation. Disruption of the nerve fibers during retroperitoneal dissection can cause loss of seminal vesicle emission and/or failure of the bladder neck closure, resulting in retrograde ("dry") ejaculation.[29–32] From the pelvic plexus, vesical branches emerge to proceed along the lateral sides of the bladder. A separate segment of the vesical plexus innervates the prostate, then forms the cavernous nerves to supply the penile erectile tissue.[33,34] These fibers contain both parasympathetic and sympathetic components. Detailed understanding of the precise anatomic relationships of these prostatic neurovascular bundles allows surgeons to routinely preserve potency during pelvic operations such as radical prostatectomy of radical cystectomy for pelvic cancers. [31,35–38]

ERECTION, EMISSION, AND EJACULATION

From many individuals' perspective, the most important physiological functions are the "three Es" related to reproduction: erection, emission, and ejaculation. Erection is the process of developing a phallus that is sufficiently rigid to allow intromission. Emission is deposition of the semen into the posterior urethra. Ejaculation is the process by which the semen is expelled from the urethral meatus. Intact anatomy is critical for each of these functions. The anatomy and physiology of erection have received intense research scrutiny over the past 2 decades. This massive effort has led to a much clearer understanding of the macroscopic aspects of erection and identification of many prominent causes of erectile dysfunction.

From the standpoint of neuroanatomy, there are three types of erections: psychogenic, reflexogenic, and nocturnal.[34,39]

(1) Reflexogenic erections occur in response to genital stimulation. Impulses reach the spinal erection center (S2–4 and T10–L2). Some impulses then follow the ascending tract, resulting in sensory perception, other impulses activate the autonomic nuclei to send messages via the cavernous nerves to the penis. This type of erection is preserved in patients with upper spinal cord injury. (2) Psychogenic erections occur after audiovisual stimuli or fantasies. Signals descend from the brain to the spinal erection center to activate the erectile process. This type of erection is preserved in only a small percentage of patients with complete sacral cord lesions, suggesting that the sacral erection center is the main locus of erectile nuclei. (3) Nocturnal erections occur during rapid-eye-movement sleep. Through an unknown mechanism, stimuli descend from the brain to the spinal cord to induce penile erections.

The corpora cavernosa may be considered vascular spaces. In essence, the process of erection involves increased arterial inflow into the corpora accompanied by decreased venous outflow. Because the relatively rigid outer covering of the corpora does not expand in proportion to the increased blood volume, the phallus becomes rigid. This complex erectile process requires an appropriate hormonal milieu, appropriate levels of enzymes such as phosphodiesterase-5, an intact nervous system, arterial inflow, and appropriate venous outflow. Problems with any of these factors result in erectile dysfunction.

The penile arteries arise from the paired internal pudendal arteries described above. The penile artery branches to form the cavernous arteries, which then provide helicine arteries supplying the erectile tissue of the corpora cavernosa. These helicine arteries are contracted and tortuous in the flaccid state but become dilated and straight during erection. The penile arteries and nerves penetrate the tunica albuginea surrounded by a sheath of loose, areolar tissue that protects them from compression during erection. In contrast, the emissary veins, however, are in direct contact with the tunica albuginea and are occluded easily by the shearing action of the tunical layers during erection.[34,39–41]

The key to the erectile process is the smooth musculature of the corpora cavernosa and penile arterial walls.[34,39,41] In the flaccid state, the intrinsic smooth muscle tone and the sympathetic discharge exert high resistance to incoming blood flow. The flaccid penis is in a moderate state of contraction. The critical event during erection is relaxation of these smooth muscles from neurotransmitters. This leads to decreased resistance to blood inflow to a minimum, trapping of the incoming blood by the expanding sinusoids, and expansion of the corpora cavernosa, resulting in increased intracavernous pressure. Thus, erection involves sinusoidal relaxation, arterial dilation, and venous compression. Contraction of the ischiocavernosus muscles produces the rigid erection phase by compressing the engorged corpora cavernosa, increasing the intracavernous pressure to several hundred millimeters of mercury. Rhythmic contraction of the bulbocavernosus muscle expels the semen down the narrowed urethral lumen resulting in external ejaculation from the meatus.

51 Principles of Treatment of Sexually Transmitted Diseases

H. Hunter Handsfield

Most treatment decisions for sexually transmitted diseases (STDs) seem straightforward, made on the basis of the clinician's past experience and general knowledge, often with reference to standardized guidelines such as those of the Centers for Disease Control and Prevention (CDC)[1] (see Appendix B), the Public Health Agency of Canada,[2] and the World Health Organization (WHO).[3] However, the benefits of treatment are maximized at both the patient and community level by understanding of principles that help place authoritative recommendations in context. This chapter reviews the theoretical underpinnings of the antimicrobial therapy of STDs.

APPROACHES TO TREATMENT

The approaches to treatment of persons with or at risk for STD may be conceptualized as *therapeutic goals, strategies,* and *practices* (Table 51-1).

THERAPEUTIC GOALS

From the perspective of the infected patient, the ultimate goal is *biological cure* or eradication of the causative pathogen. Biological cure is the norm for treatment of gonorrhea, chlamydial infection, trichomoniasis and chancroid, and the intent, often difficult to document, for treatment of syphilis, but it remains elusive for the viral STDs. Whether or not biological cure is attainable or practical, the *amelioration of clinical manifestations* and the *prevention of sequelae* are always desired goals and are often achievable even for the incurable viral STDs such as genital herpes, genital warts and human papillomavirus (HPV) infections, hepatitis B, and HIV infection. However, while biological cure usually results in resolution of all manifestations of disease, it cannot reverse anatomic complications, such as fallopian tube scarring or organ damage by syphilis.

A fourth goal is *prevention of transmission*. This goal may be independent of biological cure. For example, benzathine penicillin treatment for syphilis almost always promptly aborts infectivity but perhaps without biological cure; suppressive antiviral therapy helps prevent transmission of herpes simplex virus type 2 (HSV-2); and antiretroviral therapy may reduce the infectiousness of persons with HIV infection. Ablating genital warts and HPV-infected cervical or anal tissues infection probably reduces the likelihood of HPV transmission to infected persons' sex partners, but this effect might be related more to reducing viral load than to biological cure. Finally, preventing transmission is central to the fifth goal of therapy, *community-based prevention*. In the paradigm represented by the reproductive rate of infection in the community ($R_0 = (\beta cD)$ (Chapter 3), curative treatment shortens the mean duration of infection in the population (D), and suppressive antiviral therapy reduces the efficiency of transmission (β), either of which reduces the reproductive rate (R_0). In this context, biomedical approaches to diagnosis and treatment that are generally classified as secondary prevention at the individual level (i.e., resolution of infection and prevention of complications) represent primary prevention at the population level.

TREATMENT STRATEGIES

Strategies for STD treatment can be viewed as a continuum according to the timing of treatment in relation to exposure and acquisition of infection and the specificity of the diagnosis (see Table 51-1). *Prophylaxis* encompasses three overlapping strategies. *Preexposure prophylaxis* (PrEP), or true preventive therapy administered before exposure, is theoretically feasible and perhaps commonly used for the traditional STDs but little-studied. Informal reports suggest that PrEP usage may be frequent among persons expecting to have high-risk sexual encounters, perhaps especially among military personnel and commercial sex workers and occasionally among persons seeking to prevent genital herpes or HIV infection. PrEP with antiretroviral drugs may have promise as an HIV prevention strategy, although documenting efficacy and translation to routine use are challenging problems.[4] *Postexposure prophylaxis* (PEP) is treatment of an exposed or potentially exposed person to prevent infection, clinical disease, and secondary

transmission to new sex partners. Depending on the interval following exposure, most such use probably does not entail true prophylaxis but rather cures early subclinical infection. PEP with antiretroviral drugs following documented or suspected exposure to HIV infection is frequently employed following nosocomial exposure of health-care personnel and increasingly following sexual exposure. For the bacterial STDs, PEP is most commonly used in the guise of "epidemiologic" treatment of exposed sex partners.[5] Objective evidence of efficacy is scanty, but PEP is clearly effective in preventing urethral gonorrhea when administered within several hours of exposure to infected commercial sex workers.[6] *Periodic presumptive therapy* (PPT) is treatment at specified routine intervals, usually with long-acting antimicrobials such as azithromycin but sometimes using daily treatment with short-acting drugs. PPT can be considered a variation on both PrEP and PEP, since active infections are treated (PEP), and antimicrobial activity persists for varying periods while exposure to new infections may continue (PrEP). PPT has been shown to reduce the incidence of bacterial STDs in female sex workers.[7,8]

Etiology-based treatment of infected persons, directed toward a specific pathogen, is the modern historical norm in settings where etiologic diagnosis is practical, especially in industrialized countries. An etiologic diagnosis can be based upon laboratory tests, most of which have imperfect performance depending on the stage of infection and test characteristics; or upon clinical impression of probable etiology, conditioned on the specific infection, the clinical presentation, and the skill of the diagnostician. *Syndromic management*, of special interest in developing countries and other resource-poor settings, requires only determination of broad clinical manifestations together with risk assessment, followed by treatment of the main causes of the syndrome without attempting to identify the specific pathogen.[3,9–11] Examples include treating women with signs of mucopurulent cervicitis or men with urethral discharge for both gonorrhea and chlamydial infection; treating women with increased amount of vaginal discharge (without cervicitis) for trichomoniasis and bacterial vaginosis; and treating persons with genital ulcer disease for syphilis, chancroid, and, increasingly, genital herpes.[11] Some therapeutic strategies amount to a hybrid of etiologic and syndromic management, as when men with urethritis undergo Gram stain of urethral discharge as a diagnostic test for gonorrhea but regardless of the results of Gram stain may also receive treatment for nongonococcal urethritis (NGU) designed to eradicate chlamydial and *Mycoplasma genitalium* infection without attempting to identify these or other potential pathogens. Successful syndromic treatment requires knowledge of the etiologies of the syndromes treated and their local or regional epidemiology, as well as the susceptibility of the most common etiologic pathogens to locally available antimicrobial drugs. Although distinctly inferior to etiology based treatment,[10] syndromic management is a reasonable accommodation to the limited resources available in low and middle income countries and probably has contributed to improved STD control in such countries.[9] Syndromic management, including therapeutic recommendations for several syndromes, is addressed in chapters 47 and 48.

Mass treatment is the provision of therapy to entire populations known to have substantial prevalences of infection, without attempting to diagnose infection in individuals. Mass treatment can be *universal*, if applied to all persons in a population, or it may be selective. Selective mass treatment is the treatment of population subgroups with high prevalences of infection or with defined behavioral risks, such as sex workers. There have been few reported studies of mass treatment in STD control.[12] However, in the 1950s and 1960s, selective mass treatment was instrumental in almost eliminating yaws,

pinta, and endemic syphilis in several developing countries. More than 50 million persons in 46 countries were treated with various forms of long-acting penicillin and in some regions (e.g., Bosnia) one or more of these diseases were entirely eliminated.[13] Selective mass treatment, coupled with widespread serologic screening, also contributed to the near-elimination of syphilis in China in the 1950s and 1960s[14] and it might have helped curtail an outbreak of syphilis in sex workers and seasonal farm workers in California in the 1970s.[15] By contrast, in the Philippines a trial of selective mass treatment for gonorrhea in female sex workers resulted in only a modest, transient reduction in the prevalence of the infection in the treated women and had no significant effect on the rate of gonorrhea among U.S. military personnel who accounted for most of their partners.[12] In Greenland, selective mass treatment in communities with high rates of gonorrhea resulted in only transient benefits in the least populated areas and no measurable benefit elsewhere, and the program was abandoned.[16] More recently, selective mass treatment with azithromycin had a marginal and transient effect, if any, when tried as a measure to curtail the spread of syphilis in a high-risk population in Vancouver, Canada.[17]

As suggested by these examples, mass treatment usually has been directed toward a single STD or a few biologically similar infections, such as syphilis and other treponematoses.[13] However, the Rakai, Uganda trial of STD treatment as an HIV prevention strategy employed periodic selective mass treatment against a broader range of STDs.[18] In the intervention villages, all persons 15–49 years old were treated simultaneously for gonorrhea, chancroid, chlamydial infection, trichomoniasis, and bacterial vaginosis. In addition, periodic mass screening for syphilis was offered both in intervention and control villages, and penicillin therapy was given for those found to be seropositive. Only the prevalence of trichomoniasis was reduced to a significantly greater amount in the intervention villages than in control villages, and STD treatment was not associated with reduced transmission of HIV.[18]

On balance, the collective experience suggests that mass treatment has more potential against chronic, prolonged STDs like syphilis than against other bacterial STDs. Presumably, a prerequisite for greater success as a population-based control strategy probably is very widespread implementation in settings with limited population mobility and low potential for repeated reintroduction of infection. Mass treatment is unlikely to be effective in either the short or long term for any STD in open, mobile populations.

TREATMENT PRACTICES

STD treatment practices (Table 51-1) refer to the procedural aspects of therapy. *Directly observed treatment* (DOT) has been a central theme of STD management since the beginning of the antimicrobial era and preceded by several decades the adoption of DOT as a mainstay of treatment for tuberculosis. Multiple-dose, self-administered treatment for STD initially was problematical because only parenterally administered penicillin was available. Further, many clinicians and public health authorities considered patients with STDs to be inherently unreliable and unlikely to comply with unsupervised, multiple-dose regimens. This belief remained common even after orally administered antibiotics became available and access to health care improved. In reality, it is likely that persons with STDs are no less likely to comply with therapy than demographically similar people who have other medical conditions of similar severity or symptomatology. However, compliance with treatment is poor in most population groups, especially so among young persons with subclinical or mildly symptomatic infections. The need to promptly curtail transmission adds a strong public health rationale for DOT, which remains a high priority for the curable bacterial STDs. Accordingly, DOT is considered to be the standard of care in all clinical settings for gonorrhea, chancroid, chlamydial infection, NGU, and trichomoniasis, whether treatment is based upon a specific etiologic diagnosis or upon syndromic management in resource-poor clinical settings[1–3] (see Appendix B).

Prescriptive therapy, the normative practice for outpatient drug treatment for most indications, is the only practical approach when multiple dose regimens are required for STDs, such as treatment of chlamydial infection or NGU with doxycycline, and for all regimens employed against pelvic inflammatory disease (PID), genital warts using patient-applied therapies, genital herpes, and HIV/AIDS. Ideally, even multiple-dose therapy for STD should be dispensed in the clinical setting, with the health-care provider observing the patient ingesting or applying the first dose. In a study of women with PID diagnosed in a hospital emergency department, 28% of patients later acknowledged that they had not filled their prescriptions for doxycycline and only 31% completed the prescribed 10-day course.[19] Similarly, 223 patients given a 7-day course of doxycycline for chlamydial infection in two STD clinics were studied using a computerized system to monitor the timing and frequency with which their medication containers were opened. Even though the drug was given directly to patients in the clinic, 24% apparently took little or no doxycycline, only 25% completed treatment, and 51% had intermediate levels of compliance.[20]

Pharmacy-based treatment (PBT) refers to direct treatment of persons with self-diagnosed or suspected STD following recommendations by pharmacists or other pharmacy personnel, without clinical assessment by a personal health-care provider. PBT has evolved opportunistically in resource-poor settings, especially in developing countries, where infrastructural limitations are barriers to traditional clinical assessment and where local regulations or pragmatic policies permit anti-infective therapy without prescription. PBT can be

viewed as a variety of syndromic management based on the patient's self-assessment of symptoms that suggest STD, supplemented by assessment of symptoms by the pharmacy worker. For example, a person with urethral discharge or genital ulcer disease may describe his or her symptoms to a pharmacist, who then recommends and sells the patient a treatment regimen.

Although probably employed in some settings for many decades, PBT for STD has only recently come under systematic evaluation.[21,22] Not surprisingly, without specific training, pharmacy personnel in developing countries often fail to recognize or counsel customers that typical syndromes are sexually transmitted, and when STDs are recognized, they frequently offer inappropriate therapy. However, when STD syndromes are recognized as such, pharmacy personnel frequently suggest the use of condoms, and with systematic training PBT may have promise as an element of STD prevention in resource-poor settings.[21–24] In such settings, pharmacy workers may be linked with physician preceptors to learn about choice of antimicrobials. A large randomized trial in Peru evaluated training of pharmacy workers in STD recognition, treatment or referral, and on counseling patients about partner treatment and future condom use. The intervention resulted in dramatic and significant improvements in all aspects of management of simulated patients when they presented to pharmacies with scripted scenarios of urethral discharge, vaginal discharge, genital ulcers, or pelvic inflammatory disease.[23]

Expedited partner therapy (EPT) is the practice of treating the sex partners of persons with selected STDs without direct clinical assessment or professional counseling of the partners (Chapter 54). For the curable bacterial STDs, it has traditionally been recommended that patients' sex partners be examined, counseled, and treated, ideally by the provider or clinic that treats the index case. However, the success of this traditional approach in assuring partner treatment is limited by structural impediments (e.g., transportation barriers, insurance coverage), attitudes of exposed persons, such as disbelief that they might be infected when asymptomatic, and privacy concerns by both index patients and partners.[25] In the United States, local and state health authorities attempt to identify and treat the partners of fewer than 20% of persons with gonorrhea or chlamydial infection,[26] and although stronger efforts are made to assure evaluation and treatment of the partners of persons with infectious syphilis,[26] the effort usually is fruitless.[27,28] From a combination of spontaneous and assisted attempts by patients to notify their own partners, and occasional success through direct contact of partners by providers or public health authorities, it is likely that no more than half the partners of persons with gonorrhea or chlamydial infection are successfully treated through the traditional approach[27,29] (see Chapter 54).

EPT has evolved, first through spontaneous use by savvy practitioners and increasingly as a systematic approach to partner management, as one strategy to address the poor performance of the traditional approaches. EPT primarily employs patient-delivered therapy to his or her recent partner(s), but other strategies, less dependent on cooperation of the index patient, are also in evolution, such as postal delivery of medication and retrieval of drug at a health-care provider's office or public health clinic. Both randomized controlled trials and observational studies[27,29] (reviewed in Chapter 54) have documented the effectiveness of EPT as a partner management strategy for chlamydial infection and gonorrhea in heterosexual men and women. Effectiveness has been documented not only in significantly reduced rates of reinfection in index patients but also in process indicators, such as numbers of partners brought to treatment, reduced frequency of sex between index patients and untreated partners, and increased frequency of condom use in the weeks following treatment.[29,32] Somewhat surprisingly, a single trial did not document any benefit of EPT for reducing rates of recurrent trichomoniasis in index women,[30] perhaps because single-dose treatment with metronidazole is only about 90% effective against trichomonal vaginitis and perhaps still less effective among infected men.[33]

Thus, EPT has rapidly become a routinely recommended option to assure treatment of the partners of heterosexual men and women for chlamydial infection and gonorrhea, but the practice should be used with caution in the management of trichomoniasis (pending further data).[1,27,29,32,34] Clinical complexity and reliance on injection therapy or on multiple dose treatment regimens are challenges to the use of EPT for syphilis or the viral STDs. Studies are indicated to evaluate EPT in the syndromic management of genital discharge syndromes. Further research is also indicated for the use of EPT for trichomoniasis and on the utility of EPT for both syndromically and etiologically defined STDs in special populations, such as men who have sex with men (MSM) and pregnant women.[1,27,29,32,34]

CONCURRENT INFECTIONS

Concurrent STDs are common, and treatment guidelines for certain STDs have often recommended concurrent therapy for undiagnosed STDs likely to coexist with the primary infection. Treatment of gonorrhea with regimens that would eradicate undiagnosed or incubating syphilis was once considered a high priority, based on the belief that both infections were often acquired simultaneously. However, a controlled study in Miami, Florida, from 1985 to 1992, when gonorrhea was epidemic and syphilis resurgent, analyzed 98, 441 cases of gonorrhea treated either with drugs effective against syphilis (various regimens that included ceftriaxone, doxycycline, or erythromycin) or with spectinomycin, which is not active against *Treponema pallidum*. New cases of syphilis were rare

in the several weeks following treatment and were not significantly different according to the treatment given.[31] Thus, in recent years the activity of the selected antibiotic against *T. pallidum* and its efficacy against incubating syphilis have not been major determinants of the recommended treatments for patients with gonorrhea in the United States. Conversely, rates of treatable STDs other than gonorrhea, such as chlamydial infection, have not been assessed in persons with syphilis. Resurgence of syphilis among MSM in industrialized countries since 2000 has been accompanied by equally dramatic increases in gonorrhea and chlamydia morbidity in MSM.[35] Few pertinent data are available for developing countries. For the moment, the primary treatment strategy in persons with syphilis should be to routinely undertake screening laboratory tests for other common STDs, including HIV infection, but not to sacrifice the assurance of curing syphilis in order to treat other presumptive infections.

For 3 decades, recommendations for treatment of concurrent STDs have been influenced by the high prevalence of chlamydial infection in patients with gonorrhea. About 10–20% of men and 20–40% of women with gonorrhea in industrialized countries in the 1980s and 1990s were infected with *Chlamydia Trachomatis*.[36,37] According to the nationally representative, population-based National Health and Nutrition Survey, from 1999 to 2002 the prevalence of *C. trachomatis* was almost 50% among persons with gonorrhea.[38] Thus, it is universally recommended that all patients with gonorrhea be treated with regimens effective against *C. trachomatis* unless chlamydial infection has been excluded prior to treatment[1–3] (see Appendix B). The reverse is not the case: because of the differing population characteristics associated with the two infections, the prevalence of *Neisseria gonorrhoeae* in persons with chlamydial infection is typically below 5%, and treatment for chlamydial infection need not be routinely accompanied by treatment for gonorrhea. In any case, the recommended regimens against *C. trachomatis* usually will eradicate undiagnosed gonococcal infection. However, specific antigonococcal therapy should be considered in persons with chlamydial infection if local epidemiologic assessment suggests a high likelihood of dual infection.

Other combinations of simultaneous infections with treatable STDs are common but few if any systematic studies are available and no standard guidelines recommend routine treatment for other disease combinations. Among some women and men with trichomoniasis, 10–15% have gonorrhea, chlamydial infection, or both.[30] Infection with multiple pathogens, including HSV, *Haemophilus ducreyi*, and *T. pallidum,* has been reported in patients with genital ulcer disease in the United States and in developing countries.[39] Few data are available on the prevalences of gonorrhea or chlamydial infection among patients with genital herpes, genital warts, or other STDs. In the absence of definitive data, clinicians should screen patients with any of these infections for locally prevalent curable STDs. In some instances, presumptive therapy based on local epidemiologic data may be indicated for selected patients, such as those who are unlikely to return for follow-up.

POSTTREATMENT FOLLOW-UP

TEST OF CURE

Clinical follow-up and retesting to assess both the clinical and the microbiologic responses to therapy have been common practices in settings where funding and infrastructures permit. Syphilis in particular requires clinical and serological follow-up often for several months or years, when practical, in order to document cure[1–3] (see Appendix B). Clinical follow-up is generally recommended following treatment of chancroid, but prompt resolution of symptoms and signs are reliable indicators of cure so that retesting for *H. ducreyi* is rarely indicated. Likewise, the clinical response of gonococcal or chlamydial urethritis in men is usually a reliable indicator of bacteriologic cure, although subclinical persistence after initial clinical improvement sometimes occurs.[29,40] On the other hand, cervical, rectal, or pharyngeal infections with *N. gonorrhoeae* or *C. trachomatis* are commonly asymptomatic or have nonspecific manifestations, sometimes necessitating follow-up test of cure to assure eradication of the organism.

Nevertheless, in most industrialized countries the currently recommended treatment regimens for gonorrhea and chlamydial infection[1–3] are sufficiently reliable that routine test of cure soon after treatment is not cost-effective. Test of cure continues to be indicated when the treatment used has uncertain efficacy or if the potential consequences of persistent infection are especially severe, such as chlamydial infection in pregnant women. Test of cure is also recommended when the susceptibility of the pathogen, especially *N. gonorrhoeae,* is in doubt, or when compliance with therapy cannot be reasonably assured[1] (see Appendix B). In developing countries, where test of cure is most problematic both for financial and logistic reasons, it is especially important that highly effective DOT be used wherever possible.

When test of cure is employed following treatment of uncomplicated gonorrhea, retesting by culture 5–10 days after completion of treatment is probably reliable for detecting treatment failures. However, test of cure for either *C. trachomatis* or *N. gonorrhoeae* by nucleic acid amplification testing should be delayed until at least 3 weeks after completion of therapy because *C. trachomatis* DNA may persist for 2 weeks or occasionally longer after successful treatment.[1,29,40,41] In addition, some generally effective regimens, especially single-dose azithromycin, may transiently suppress but not eradiate *C. trachomatis,* resulting in falsely negative test results in the first few weeks after treatment.[29]

RESCREENING

Delayed posttreatment testing, or rescreening, is designed to detect both reinfection and, to a lesser extent, delayed treatment failure. Studies in the 1960s and 1970s showed that *N. gonorrhoeae* was reisolated from approximately 10% of women treated for gonorrhea several weeks earlier, primarily owing to reinfection. Accordingly, some authorities recommended routine rescreening of women with gonorrhea 1–2 months after treatment, and mathematical modeling suggested that rescreening women at high risk might contribute to control of gonorrhea. However, compliance was poor so that the use-effectiveness and cost-effectiveness of rescreening were low,[42] and this strategy was largely ignored and the recommendation was deleted from later treatment guidelines. Several recent studies, however, indicate that 10–20% of men or women treated for either gonorrhea or chlamydial infection have persistent or recurrent infection within the next year, with most cases detected within 4 months.[27,29,32] These results are consistent with the hypothesis that most reinfections are acquired from untreated sex partners or from reentry into partner networks with high infection prevalence. Rescreening also detects persistent infection resulting from treatment failure.[29,40] For these reasons, rescreening 3–4 months after treatment is now recommended routinely for all women with chlamydial infection[1] (see Appendix B), and many experts recommend its routine use for men with chlamydial infection and both men and women with gonorrhea.[29,43]

52 Principles of Laboratory Diagnosis of STIs

Jane Kuypers, Charlotte A. Gaydos, and Rosanna W. Peeling

INTRODUCTION

Laboratory diagnosis of sexually transmitted infections (STIs) involves the examination of material obtained from a patient to determine current or past infection with a sexually transmitted microorganism. This is accomplished by demonstrating either the presence of the organism or a marker of infection such as antigens, antibodies, nucleic acids, or metabolic products. Valid laboratory assays are necessary for accurate diagnosis of STIs because clinical signs and symptoms are frequently not reliable diagnostic parameters, and diagnoses based on the syndromic approach lead to both under and over treatment of STIs.[1–3] When patients present with similar manifestations for infections caused by dissimilar microorganisms, laboratory tests can provide a specific diagnosis and etiology. Laboratory testing plays a role in patient management to confirm diagnoses in symptomatic patients and to monitor antimicrobial susceptibility and the effectiveness of treatment. Accurate diagnoses will prevent unnecessary antimicrobial treatment and development of resistant organisms. Laboratory testing is perhaps most useful for detection of asymptomatic STIs to prevent transmission and complications, and for public health surveillance and interventions.

Laboratory diagnosis has undergone many changes in recent years due especially to the introduction of new technologies and to a lesser extent shifts in disease prevalence. For many STIs, improved methods for laboratory diagnosis have been developed and laboratory directors must evaluate these techniques with the view of adapting new equipment, reagents, and personnel training to their own settings. However, in some cases, older, conventional assays remain valid and should still be used. Deciding which tests to perform depends on factors unique to each individual laboratory environment. The most important attributes of a laboratory test are its ability to produce accurate and precise results consistently over extended periods with a turnaround time that is clinically useful. The characteristics of an ideal laboratory test are described in Table 52-1. Unfortunately, few tests meet this ideal.

This chapter will discuss the general established rules for the laboratory diagnosis of STIs, including gonorrhea, chlamydial infection, trichomoniasis, syphilis, chancroid, bacterial vaginosis (BV), and genital herpes simplex virus (HSV) infections. Testing strategies and approaches, methodology, and performance guidelines are presented. This information will help in making important decisions about laboratory testing of STIs, including when to test, whom to test, and which methodology to use.

TESTING STRATEGIES AND APPROACHES

The goal of laboratory testing is to provide information to the health-care provider regarding the etiologic agent responsible for the patient's symptoms and its antimicrobial profile. This information is then used to guide treatment and other management decisions. Current approaches to STI diagnosis rely upon a number of different but often complementary approaches.

ETIOLOGICAL APPROACH

Laboratory tests are used in this approach to identify the causative agent. This is the most accurate and, generally, the most costly approach to diagnosis. The complexity and scale of laboratory testing can be adapted appropriately for use at different levels of a health-care system, but even the most basic laboratory-based testing and diagnostic procedures (such as Gram stain or wet mount) depend upon the availability of trained personnel, infrastructure such as electricity to run microscopes and centrifuges, and reliable, ongoing supply sources of reagents. The more sensitive and accurate tests require a high level of technical expertise, expensive equipment, and testing is often batched to save cost of processing. The results of these tests are often not available the same day, so patients typically must return for their test results and treatment.

SYNDROMIC APPROACH

In the absence of laboratory services, the World Health Organization (WHO) has developed algorithms to allow

Table 52-1. Characteristics of an Ideal Laboratory Test

Specimen collection, transport, processing	
	Specimens easily obtained

health-care providers to identify and treat clinical syndromes caused by STIs.[4] Syndromic management aims to provide treatment for the most common infections linked to a particular cluster of symptoms. A man presenting with urethral discharge will be treated for the most common causes of genital discharge—chlamydial infection and gonorrhea. A person presenting with genital ulcers would be treated for syphilis, and chancroid, and perhaps for genital herpes. Syndromic management is relatively simple to use, and can be incorporated into all levels of public and private health-care systems. This approach has varying sensitivity and low specificity. To increase specificity, risk scores, generally based on sexual behavior, have been added but at the expense of lowering sensitivity.[5,6]

In settings where laboratory services are available, the two approaches may be combined. Thus, a patient with a suspected STI is presumptively treated for a clinical syndrome and appropriate specimens are collected for laboratory testing. Confirmation of infection by a diagnostic test for STI serves to reinforce the caregiver's clinical diagnosis and case management and allow partner notification to be initiated. An evaluation of treatment practice in Canada showed that 74% of all STI treatment provided in 1997 was for presumptive treatment of urethral and cervical infection or pelvic inflammatory disease (PID), of which 14.4% were confirmed by a positive test for chlamydia or gonorrhea.[7]

However, presumptive treatment for chlamydia and gonorrhea in women presenting with vaginal discharge, the most common symptom in women, can be problematic outside of high-risk populations. Women with vaginal discharge are often over-diagnosed and over-treated for cervical infection when they are in fact suffering from trichomoniasis or endogenous infections such as candidiasis or BV, or no infection at all. A study in rural Bangladesh showed that the syndromic approach to management of vaginal discharge led to as much as 98% overtreatment for chlamydia and gonorrhea.[8] Overtreatment carries not only financial implications, promotion of antimicrobial resistance, and needless risk of adverse drug reactions, but is also associated with social implications. Women diagnosed erroneously with an STI may be at risk of violence if they have to inform their sexual partners about their diagnosis and the need for partner treatment. Sensitive and specific rapid tests for chlamydia and gonorrhea are needed so that women with symptoms suggesting these infections can be treated appropriately at the first clinic visit. Although current point-of-care (POC) tests for chlamydia are less sensitive and specific than laboratory-based tests such as nucleic acid amplification tests (NAAT), a study at an sexually transmitted disease (STD) clinic showed that POCs led to more infected patients being treated than did NAATs when the population return rates for test results and treatment were low.[9]

SCREENING ASYMPTOMATIC INFECTIONS

A second, and perhaps more serious limitation of the syndromic approach is the fact it fails to identify individuals with STIs who have no overt or specific symptoms. Identification of asymptomatically infected individuals is important for the control of STIs to eliminate the reservoir of infection in the population and for the prevention of long-term complications in the infected individual. Screening is especially important in women, who bear a disproportionate share of the disease burden and may transmit the infection to their offspring.

Approaches to screening

Universal screening for STIs is not cost-effective as high concentrations of STI cases tend to be strongly correlated with a number of economic and social conditions, including poverty, inadequate and dysfunctional health systems, high rates of urbanization that create markets for sex work in cities, a demographic profile with a high proportion of young people, gender inequalities that result in a lower status for girls and women, and cultural and economic barriers to diagnostics and treatment access. For example, the economic and social upheavals caused by the break up of the Soviet Union have resulted in a significant increase in syphilis prevalence among adults in the new independent republics.[10] In China, the

change from socialism to a capitalist style market economy has led to changes in access to health services and rapid and uneven economic development that resulted in huge migration of the rural population into urban centers to seek employment. A sex industry has sprung up around booming areas. Migrants and sex workers are often stigmatized and marginalized from the health-care system. Syphilis incidence has increased approximately 20-fold from 1990 to 1998.[11]

Which STIs should screening programs target?

Priorities for STI screening should be made based on several considerations. They should include STIs likely to be transmitted to partners and newborns, those that enhance transmission of HIV and that are curable, ideally with single dose oral regimens deliverable on site. Affordable curative single dose oral treatments exist for chlamydial infection and gonorrhea, while syphilis requires one or more intramuscular injections of penicillin. STIs that can cause serious consequences if left untreated are especially important targets for screening. Such STIs of course include HIV infection (not the subject of this chapter), and others that can result in problems in pregnancy such as ectopic pregnancy, stillbirths, and prematurity; problems in neonates and infants, including blindness, pneumonia, congenital syphilis, and herpes encephalitis; and long term complications in infected sexually active men and women that include chronic pelvic pain, PID, infertility, and neoplasia (genital cancers including cervical cancer, and hepatocellular carcinoma).

Taking all the above factors into consideration, the highest priorities for STI screening remain the curable bacterial infections of syphilis, gonorrhea, and chlamydia. Most syphilis seroreactive individuals lack any clinical symptoms. Syphilis continues to be a serious public health problem where screening programs are not carried out. Infants born to infected mothers are at risk of acquiring the infection in utero. Primary and secondary syphilis during pregnancy will lead to fetal infection in virtually all cases with approximately 30–50% of pregnancies resulting in fetal death in utero, stillbirth, or death shortly after delivery.[12] These complications can be prevented if syphilis is detected and treated early in pregnancy.

We believe there is currently no widely accepted indication for screening asymptomatic women for vaginal infections such as *Trichomonas vaginalis, Candida* species, and BV; although one or more of these conditions have been associated in clinical epidemiologic studies with certain complications in pregnant and in nonpregnant women and with increased susceptibility to or vaginal shedding of HIV, (see Chapter 18) they are not usually treated unless patients are symptomatic. However, one review concluded that screening and treatment for BV before termination of pregnancy and hysterectomy significantly reduced the rate of complications.[13]

There is limited evidence to suggest that screening for viral infections other than HIV is cost-effective[14–16] (However, see Appendix A and Chapters 23, 24, 57, and 84 for further views on this topic).

The tests of choice for STI diagnosis of symptomatic patients, criteria and test choice for screening asymptomatic individuals, and the appropriate specimens to be collected are briefly summarized in Table 52-2.

Who should be targeted and how?

The serious morbidity and mortality associated with adverse outcomes of pregnancy in women infected with syphilis have led to policies for universal screening of all pregnant women in most countries. To prevent congenital syphilis, the U.S. Centers for Disease Control and Prevention (CDC) and European guidelines recommend prenatal screening in the first and third trimester and at delivery,[17,18] Apprendix A.

For chlamydia and gonorrhea, a targeted screening approach focused on high-risk populations is recommended. Studies of risk factors for infection have been translated into criteria for targeted screening. A number of guidelines have been developed to provide screening criteria for these three STIs.[19–21] For example, criteria for chlamydia screening vary but most include young age (<25 years of age), a change of sexual partner in the last 6 months, 2 or more sexual partners in the last year, unprotected sex, history of STDs, and diagnosis of another STD in the patient or diagnosis of an STD in a sexual partner. Screening following treatment for chlamydial infection, gonorrhea, or syphilis is also recommended to detect treatment failure or reinfection.

Previous screening approaches have suffered from a number of barriers including lack of access to populations at high risk of infection. Advances in diagnostic technology have resulted in a new generation of STD tests, NAATs, that not only have high sensitivity and specificity but also allow the use of noninvasive or minimally invasive specimens such as urine or self-collected vaginal swabs. These tests do not require the specimens to be viable and can thus be stored or transported at ambient temperatures. This has opened up a variety of screening options not previously thought possible. As shown in Table 52-3, in addition to traditional venues for screening at STD, prenatal, and obstetric and gynecological clinics, opportunistic screening is now possible at a variety of clinic settings where specimens for testing are obtained from women even if pelvic examination is not performed. Opportunities include screening for gonorrhea in emergency rooms and screening for chlamydia prior to termination of pregnancy (TOP).[22,23] Although it is a common practice to administer doxycycline to women undergoing TOP, concurrent testing for *Chlamydia trachomatis* can be recommended to guide partner treatment, if necessary.

Instead of waiting for individuals at risk to come to a clinic, a more proactive approach to screening is to take the testing to those at risk. This type of outreach program can be

Table 52-2. Testing Options for Diagnosis of Symptomatic Cases and Screening of Asymptomatic Individuals at Risk for STIs

	Diagnostic Testing		Screening		
Pathogen	**Test of Choice**	**Specimen**	**Target Population**	**Test of Choice**	**Specimen**
C. trachomatis	NAAT[a] EIA[a]	Urethral/ Cervical/ Vaginal swab Urine	Age < 25 High risk[b] Repeat screening after 3–6 months	NAAT EIA	Vaginal swab Urine
N. gonorrhoeae	Culture NAAT	Urethral/ Cervical/ Vaginal swab Urine	High risk	NAAT	Vaginal swab Urine
T. pallidum	Serology Darkfield DFA[a] PCR[a]	Blood Swab of lesion	Prenatal High risk	Serology	Blood
H. ducreyi	Culture	Swab of lesion[c]	Screening of asymptomatic individuals not recommended for these infections		
Bacterial vaginosis	Nugent Gram stain score	Vaginal swab			
T. vaginalis	Wet mount microscopy Culture	Vaginal swab			
HSV 1 and 2	Culture Antigen detection	Swab of lesion

[b]Definitions of high risk vary but generally include those individuals who exchange sex for money or drugs, have multiple sex partners, or have unprotected sex with an STI case.

[c]Except in high risk populations and during outbreak investigations.

conducted by collecting specimens at venues such as schools, youth centers, remand centers, prisons, or military units.[24–29] The specimens can be sent to laboratories for testing, or on-site testing can be offered if POC tests of sufficient sensitivity and specificity are available.

There have been other interesting developments in increasing access to STI services outside of clinic settings. In one scenario, pharmacists were trained to provide syndromic management of STIs, while in another, women aged 15–29 years, who bought contraceptives at a pharmacy, were offered a chlamydia screening kit for mailing a home-collected urine specimen to a laboratory.[30,31] Postal screening for *C. trachomatis* in asymptomatic men and women aged 20–24 randomly sampled from a population registry showed that this approach is cost-effective if prevalence exceeds 5.1% in women and 12.3% in men.[32]

In an increasing number of countries, STI services are being advertised on web sites where dating and anonymous sexual

encounters are arranged. A number of studies also show that sending specimens such as self-collected vaginal swabs and urines from home to laboratories for STI testing are also viable options (e.g., www.stdtest.org, www.iwantthekit.org).[33,34]

Which tests should be used?

Ideally, the screening test should have high sensitivity, and if possible, high specificity. For screening performed outside of clinic settings, the use of non-invasive specimens with tests that can be performed simply and efficiently at point of screening is ideal. This would allow test results and appropriate treatment to be given on site, as in settings where it may not be an option for patients to return.

Performance characteristics. The screening tests of choice for *C. trachomatis* and *Neisseria gonorrhoeae* are the NAATs. These tests are highly sensitive and specific and can be used with non-invasive specimens. Urine specimens can be used for screening chlamydial and gonococcal infections in men. Minimally invasive specimens such as self-obtained vaginal swabs are acceptable for detection of chlamydial and gonococcal infections in women. (Note, however that not all currently available NAATs are equally specific for *N. gonorrhoeae,* so that use of cerstain tests on specimens that contain other Neisseria sp., such as vaginal swab or throat specimens, is not recommended.) Vaginal swab specimens have a higher sensitivity than urine for the detection of chlamydia, gonorrhea, and *T. vaginalis* in women. These swabs can also be mailed to a testing center or deposited at a testing depot at a pharmacy without compromising specimen quality.

The screening test of choice for syphilis has traditionally been nontreponemal tests such as the Rapid Plasma Reagin (RPR) or Venereal Disease Research Laboratory (VDRL) tests. These tests usually require confirmation with a treponemal test such as the *Treponema pallidum* hemagglutination assay. Simple, rapid POC treponemal-specific tests that can use whole blood, require minimal training, no equipment, and cost U.S. $ 0.45–1.00 are now commercially available.[35] Several tests with sensitivities and specificities of 85–98% and 92–98%, respectively, compared to standard treponemal assays, are now available through the WHO Bulk Procurement Scheme (www.who.int/std_diagnostics). The affordability and portability of rapid tests will allow the design of innovative control programs outside of clinic-based settings. A disadvantage of these treponemal tests is that they cannot be used to distinguish between active infection and past treated infection as treponemal antibodies tend to persist for years.

Operational characteristics. A number of operational characteristics of tests are critical to the success of screening programs. Screening at venues where there is no electricity means the tests must be stable at ambient temperatures. Tests that are simple to perform in a few steps and give a visual result in less than 30 minutes allow treatment to be given and partner notification to be initiated on the same day. This is especially important in settings where the target population is unlikely to return for test results and treatment.

Cost-effectiveness

Syphilis. In settings with medium to low prevalence of infection, universal screening of STIs can be costly. For syphilis, the consequence of the disease is so serious that antenatal screening for syphilis is cost-effective even at very low prevalence. A recent analysis in the UK showed that universal prenatal screening was cost-effective even at 0.05% prevalence.[36] However, a recent 10- year retrospective analysis of universal antenatal screening for syphilis in Sweden showed that at a seroprevalence of 2.8 per 1000 live births (0.028%), this approach was no longer warranted. The screening focus should be shifted to regions of higher prevalence.[37]

Screening of pregnant women to prevent congenital syphilis can also be carried out within an essential antenatal care package. In areas where there is high HIV prevalence, integrating syphilis screening into Prevention of Mother to Child Transmission programs would not only be cost-effective but would also prevent the tragedy of babies avoiding HIV infection and dying of syphilis.[38,39]

***C. trachomatis* and *N. gonorrhoeae*.** Screening of genital chlamydial infections has been found cost-effective, even when expensive NAATs are used, when the prevalence of infection is between 3.1% and 10%.[40] However, with decreasing rates of genital chlamydial infections in recent years, the cost-effectiveness of screening using broad criteria such as screening asymptomatic sexually-active women aged <25 years needs further study. A recent review of cost-effectiveness showed that it continues to be cost-effective in the United States to offer annual screening of 15–25-year-old sexually-active females.[41] The frequency of reinfection in women has led to the recommendation to rescreen 4–6 months after the initial infection. More frequent screening should be considered in individuals with recent infection and among women <20-years old.[42]

The cost-effectiveness of using NAATs to screen young men at risk of genital chlamydial infection has not been as well studied as for women. At a prevalence of 5%, the use of a leukocyte esterase strip as a screening test, followed by a NAAT, was a cost-effective means of screening.[43]

Universal screening for chlamydia and gonorrhea in U.S. jails and detention centers was cost-effective,[24,25] as was a school-based screening program for genital chlamydial and gonococcal infection.[26] NAAT screening of women aged 15–29 presenting to urban emergency departments was found cost-effective and prevented substantial reproductive morbidity.[22]

Patients infected with *N. gonorrhoeae* are frequently co-infected with chlamydia. The U.S. CDC had previously recommended presumptive treatment for chlamydia in patients identified with gonorrhea. With declining chlamydia prevalence, this may no longer be cost-effective in some settings, where testing for both infections has become more cost-effective than routine presumptive treatment for chlamydia.[44,45]

Other means of improving the cost-effectiveness of screening include pooling of specimens to decrease test and reagent costs.[46–48] At a prevalence of approximately 5%, the savings can be as much as 39–56% of original costs. Batching so that multiple tests are processed in a single run decreases personnel costs.

METHODOLOGY

The type of diagnostic test ordered for each type of STI will vary with the individual infection in question as well as the type, experience, and capability of the laboratory performing the assay. If there is no laboratory and the clinician is performing the test, there are also specific considerations and constraints. This section will cover general principles for different diagnostic methods available for various STIs.

TYPES OF TESTS

Microscopy

Direct light microscopy can be a valuable and rapid method for the diagnosis of several STIs. Regular light microscopy can be used for wet preparations for *T. vaginalis* from vaginal swabs or urine pellets of male urine, but with lower sensitivity (~50%) than other methods.[49,50] Microscopy is useful for reading Gram stains of slides for *N. gonorrhoeae*, especially from symptomatic male urethral smears (sensitivity ~90–95%), but with less sensitivity for asymptomatic males and females (sensitivity ~50–70%).[51] Some serovars of *N. gonorrhoeae* have been noted to have reduced or negative Gram stain microscopy results.[52] Gram stain is not recommended for diagnosis of trichomonas. Older Giemsa's and iodine stains are no longer recommended for the diagnosis of chlamydial infection. Gram stains of female vaginal swabs can be used efficiently for the diagnosis of BV, a syndrome that can be transmitted sexually, using the standardized Nugent scoring system from 0 to 10, which is based on the number of lactobacilli, gram- negative to gram-variable bacilli, and gram- negative curved bacilli. Scores ≥7 indicate BV.[53]

Darkfield microscopy, although technically challenging, is most useful for visualizing motile treponemes for the diagnosis of primary syphilis from wet preparations of genital ulcer smears, but is not recommended for the diagnosis of oral or rectal lesions because of the presence of nonpathogenic treponemes.[54] Darkfield examinations must be done immediately after the specimen is taken (at least within 20 minutes) in order to maintain motility and morphology.

Fluorescent microscopy, which requires an epifluorescent microscope, can be used for the direct fluorescent antibody (DFA) staining of genital or ocular smears for several STIs. DFA for *C. trachomatis* has a sensitivity of approximately

80–85% with an experienced microscopist but is technically demanding and, although it provides rapid results, is no longer often used since the advent of molecular methods.[55] The DFA-*T. pallidum* is commonly used to detect organisms in primary or secondary lesion exudates.[54] The older Tzanck smear for multinucleated giant cells, stained by Wright or Giemsa's stain, is not widely used as the sensitivity is only ~40% for diagnosis of genital herpes when applied to ulcers.

Several commercial DFA and indirect FA stains are available for the detection and typing of HSV 1 and 2 viruses in cells from lesions. Staining patterns require an experienced microscopist to interpret. DFA is 10–87% sensitive compared to culture, with higher sensitivity for samples from vesicular lesions and poorer sensitivity for specimens from healing ulcers.[56]

Culture

Microbiologic culture is the oldest and original gold standard for the detection of several STI pathogens: *N. gonorrhoeae*, *C. trachomatis*, *T. vaginalis*, HSV 1 and 2, and *Haemophilus ducreyi*. Among the organisms associated with STIs that are nonculturable for practical purposes are *T. pallidum*, hepatitis B virus, HPV, and certain agents implicated in BV. Since *H. ducreyi* is rare in the United States and culture is technically difficult and not widely available, it is not usually routinely offered. Only research laboratories can perform culture for *T. pallidum* in rabbits (rabbit infectivity test), but it is the gold standard method to which other methods are compared.[54]

Culture of *N. gonorrhoeae* using modified Thayer-Martin medium is still the gold standard for the identification of the gonococci in genital and oral specimens with a sensitivity of ~90%,[57] although molecular testing methods are rapidly becoming more widely used since they can be used with urine samples and vaginal swabs.[55] Culture is especially desirable to obtain the isolate for susceptibility testing, since continued surveillance is necessary in light of the increasing antibiotic resistance of *N. gonorrhoeae* in the world and now in the United States.[58–61]

Culture for *C. trachomatis* was originally performed in embryonated chicken eggs. Growth and detection of chlamydia are now accomplished by staining chlamydial inclusions grown in tissue culture cells.[62,63] *C. trachomatis* is a biosafety level 2 agent and should be handled appropriately.[63] The cell line most commonly used is McCoy cells, but other cell lines, such as monkey kidney, HeLa, and HEp-2, have been employed. As culture is technically difficult and not as sensitive as molecular assays, it is rarely used except for sexual abuse cases, medicolegal matters, and samples from non-genital sites such as pharyngeal and rectal samples.[64,65] Recent studies have indicated that culture sensitivity compared to molecular techniques can range from 50% to 100% and is usually considered to average 85%, while specificity is considered to be 100%.[66] Antimicrobial susceptibility testing is not ordinarily performed for *C. trachomatis* isolates as they are uniformly sensitive to macrolides, but there have been rare reports of increasing heterotypic resistance.

Culture for *T. vaginalis* can be accomplished in Diamond's medium or using a culture pouch on a microscopic slide (InPouch TV test, Biomed Diagnostics), which has a reported sensitivity of ~70–78% compared to polymerase chain reaction (PCR) for females,[49,50,67] and of ~28% for urine from males.[68] There are some reports of metronidazole-resistant trichomonas isolates and antimicrobial susceptibility testing for this drug can be performed using special InPouch kits.

HSV cultures can easily be performed from genital and oral samples when cell cultures are available. Cell lines available commercially, in which typical cytopathic effects can be observed usually within 5 days, include human diploid fibroblasts such as WI-38, human foreskin fibroblasts, and MRC-5; human epidermoid carcinoma cell lines such as HEp-2 and A549; rhabdomyosarcoma cells; and mink lung cells.[69] Acyclovir resistant strains have been reported, but resistance testing is performed only by research laboratories.

Antigen detection

Nonculture antigen detection tests for agents of STIs became more widely used with the advent of the enzyme linked immunoassay (EIA) tests about 1990, especially for chlamydia. More recently, several EIAs have become available for HSV.

Chlamydia. For chlamydia, antigen detection using EIA was widely used before the advent of molecular tests, and the EIA is still one of the most prevalent nonculture detection tests.[70–74] There are several EIAs commercially available. The tests use either polyclonal or monoclonal antibodies to detect chlamydia lipopolysaccharide, providing theoretical detection of all species of chlamydia. However, they have been most extensively validated for urogenital *C. trachomatis*. The sensitivity of the EIAs ranges from approximately 53% to 76%, with specificities of about 95%, compared to newer molecular assays. Because these EIAs were originally compared to culture as a gold standard, the sensitivities reported in the older literature are inaccurate. A meta-analysis, adjusting the sensitivities of such assays based on a sensitivity of culture of 85% has been performed.[75] EIA tests are no longer the recommended method for chlamydia testing due to their poor sensitivity, although they continue to be widely used.[57]

HSV. An antigen detection test for HSV is available but is only 47–89% as sensitive as culture and is not in wide use clinically.[76]

Rapid tests. Rapid antigen detection assays employing antibody coated latex particles or immunochromatographic strip (ICS) tests have been marketed for several STIs. Older latex agglutination tests suffered from low sensitivity (52–85%). However, recent studies of a latex agglutination test for *T. vaginalis* (Kalon Biologicals) and an ICS test for

N. gonorrhoeae (NOW, Binax, Inc.) reported sensitivities of 98.8% compared to wet mount and culture in African women[77] and 94.1% compared to culture in male urine specimens,[78] respectively.

Microbial by-product detection

Recently, several commercial products have become available for the identification of microbial byproducts. These are mainly for the diagnosis of BV, a syndrome associated with adverse pregnancy outcomes, which is not exclusively considered an STD, but which has been demonstrated to be transmitted sexually.[79]

The BVBlue test (Gryphus Diagnostics, L.L.C.) is a chromogenic test based on the detection of elevated sialidase enzyme in vaginal fluid samples.[80–82] It is especially useful in venues where microscopic capabilities are unavailable for using either Nugent[53] or Amsel[83] criteria for the diagnosis of BV.[81] This assay had a reported sensitivity and specificity of 91.7% and 97.8%, respectively, compared to Nugent Gram stain criteria and 50% and 100%, respectively, compared to Amsel criteria by investigators in Canada.[81] Investigators in Australia reported sensitivities and specificities of 88% and 95%, respectively, compared to Nugent Gram stain criteria and 88% and 91%, respectively, compared to Amsel criteria.[80]

The FemExam test kit (Litmus Concepts) contains two small plastic cards; one card measures pH (4.7 or greater) and trimethylamine and the other measures activity of proline iminopeptidase from *Gardnerella vaginalis*.[84] Reported sensitivity and specificity compared to Nugent score were 91% and 61.5%, respectively.[84] Another recent study reported sensitivities of 88%, 41%, 89%, and 40% for a positive pH test, a positive amine test, a positive pH *or* amine test, and both pH *and* amine positive tests, respectively, while the corresponding specificities were 64%, 91%, 61%, and 95%, respectively, compared to Nugent Gram stain criteria.[85] In a resource poor setting, the pH test result was the most sensitive (94%) but not very specific (57%), while the combined result for both pH and amine was only 59% sensitive, but 92% specific.[86]

The Microbial analyzer (Osmetech, PLC) uses a vaginal swab placed in a sealed vial; the headspace is passed over an application-specific array of conducting polymer sensors, each of which has specific interactions to different volatile organic species based on their size, shape, and functional groups.[87] Reported sensitivity and specificity were 81.5% and 76.1%, respectively, compared to Amsel criteria and 82.9% and 77.3%, respectively, compared to Nugent Gram stain criteria.[87]

Antibody detection (serology)

Detection of antibodies to STIs is one of the main testing procedures for the diagnosis of syphilis and HSV infection. Many types of antibody tests are available: agglutination tests, neutralizing or complement-fixing antibody detection, microimmunofluorescence (MIF), indirect immunofluorescence, hemagglutination inhibition tests, EIA, Western blot, and rapid membrane-based immunoassay. Some tests can determine the type of the antibody, e.g., IgG, IgM, or IgA.

Syphilis. For syphilis, antibody tests become positive in response to infection with *T. pallidum*, and serological tests are used for diagnosis and to follow the clinical course of treatment. Tests can be divided into two types: non-treponemal and treponemal.

The nontreponemal screening tests, such as VDRL, RPR, automated reagin test (ART), toluidine red unheated serologic test (TRUST), and Spirotek EIA, which are inexpensive and widely available, measure reaginic antibodies that react with lipoidal particles containing the phospholipid cardiolipin.[54,88] These tests can be insensitive in the very early phase of primary syphilis and in very late syphilis cases. False positive reactions can occur due to cross-reacting antibodies in persons with autoimmune or collagen vascular diseases, acute viral illness, pregnancy, and intravenous drug use. The possibility of prozone reactions can occur if the titer is very high, with significant antibody excess in relation to the antigen, producing false negative reactions. Despite these limitations, these screening tests are in universal use. The titer of the serum that is reactive in the nontreponemal tests is the most useful assay for following the response to treatment, both in sera and cerebral spinal fluid in the case of neurosyphilis.[54] The nontreponemal tests can only be considered diagnostic when the clinical syndrome is highly suggestive of syphilis and are usually confirmed by a treponemal test. In the diagnosis of latent syphilis, a reactive nontreponemal test with a negative treponemal test is considered a false positive.[88] Results are usually reported as nonreactive or as reactive with the highest twofold dilution of serum giving a reactive result being reported.

The treponemal tests use *T. pallidum* as an antigen and are used to confirm a positive screening test. Types consist of FTA-ABS (fluorescent treponemal antibody absorption test), which is the most sensitive; the MHA-TP (microhemagglutination), which uses *T. pallidum* adsorbed to erythrocytes; and the TP-PA (particle agglutination), which uses particulate gelatin or latex. These tests are about 97% specific.[88] Recently, several rapid tests for *T. pallidum* antibody detection have become clinically available including INNO-LIA Syphilis (Innogenetics NV), RST (Quorum Diagnostics), and Determine Rapid Syphilis TP (Abbott). These ICS tests, utilizing *T. pallidum* antigens immobilized on membranes, have been 75–97% sensitive and 95–98.8% specific when compared to other treponemal tests.[89–91] Treponemal tests can be falsely reactive in nonvenereal diseases like yaws or pinta and in some cases of Lyme disease.[54] A persistently reactive treponemal test is common and does not indicate inadequate treatment, relapse, or reinfection.

HSV. Herpes simplex virus EIA tests are available for detection of antibody to the virus;, however, the older tests do not reliably distinguish between types 1 and 2 because nearly all HSV structural proteins have antigenic cross-reactivity.[56] EIA tests must be based on glycoprotein G (gG) to differentiate between the types.[92] For the diagnosis of antibody to HSV-2, the only FDA cleared EIA test meeting this requirement in the United States is the HerpeSelect 2 ELISA IgG test (Focus Diagnostics) with published sensitivities of 96–100% and specificities of 96–97%.[56,93] The HerpeSelect 1 ELISA can reliably detect antibody to HSV-1 with a sensitivity of 91–96% and a specificity of 92–95%.[56,93] These comparisons are with the gold standard of the Western blot assay at the University of Washington. It is important to note that genital herpes infections may be caused by HSV-1 in up to 30–50% of infections depending on the population.[88]

Recombinant-based gG HSV-2 serology tests have provided enhanced specificity over the older HSV crude antigen-based assays. However, even recombinant-based gG2 assays are not 100% specific. The HerpeSelect 2 assay had a low positive predictive value among a population with a relatively low prevalence of HSV-2.[94] Clinicians using the test in low prevalence populations should consider selectively using a higher index value to difine positivity based either on HSV-1 serostatus or on the presence or absence of clinical findings suggestive of genital herpes. Recently, a small protein segment at the distal end of the carboxyl terminal of gG2 has been discovered that contains at least two epitopes that are responsible for binding antibodies from sera that are negative for the presence of HSV-2 antibodies. Inhibiting the binding to these epitopes decreased the number of false positive HSV-2 antibodies by over 50% depending on the patient population being evaluated.[95] The blocking of antibody to the segment mentioned above does not appear to help in some populations (personal communication Dr. Wayne Hogrefe, Focus Technology).

A rapid POC test for detection of HSV-2 antibody from serum or capillary blood, originally known as the POCkit HSV-2 (Diagnology), is no longer available, but had high sensitivity of 93–100%.[56] It has since been bought and is now called BiokitHSV-2 (Biokit USA, Inc). Sensitivity and specificity compared to Western blot are listed in the package insert as 86–100% and 59–96.8%, respectively, depending on the population tested.

HSV type 2 EIA tests that perform well in industrialized countries may not perform well in other populations. When 13 commercial EIA kits were tested using sera from men and women in 4 African countries, the HSV Type 2 IgG ELISA kit (kalon Biologicals), though not FDA approved, had the best performance characteristics (sensitivity and specificity greater than 92%).[96]

Chlamydia. The MIF test for chlamydial antibody has been used in large population studies for determining the association of *C. trachomatis* with adverse outcomes of chlamydial disease such as PID or infertility but is not useful for the diagnosis of chlamydia urogenital disease.[97,98] MIF is, however, used for the diagnosis of respiratory infections with *Chlamydia pneumoniae*.[99]

Nucleic acid detection

Amplified and nonamplified tests are two types of assays that employ molecular methods for the detection of nucleic acids from organisms causing STIs. Nonamplified tests are simple hybridization assays using a DNA probe of short oligonucleotide sequences that will bind with the organism sequences of interest. Detection can be by colorimetric assay for probes having enzyme moieties, radioisotope detection for radiolabeled probes, or by chemiluminescence. Gen-Probe is a widely used commercially available assay for *C. trachomatis* and *N. gonorrhoeae*.[100] Also available are the Digene assays for HPV and *C. trachomatis* and *N. gonorrhoeae*, which are hybridization assays with amplification of the probe signal.[101–103]

The Affirm VP IIII test (Becton Dickinson) for the detection of *G. vaginalis*, *T. vaginalis*, and *Candida spp.,* etiologic agents in vaginal infections, uses synthetic nucleic acid capture probes and color development detection probes complementary to unique genetic sequences of the target organisms.[104] The capture probes are immobilized on a separate bead for each organism on an analysis card. The reported sensitivity and specificity for the diagnosis of BV were 73.2% and 97.1%, respectively, compared to modified Nugent criteria.[104] The Affirm test, originally designed for only *G. vaginalis* and *T. vaginalis*, was 90% sensitive for *G. vaginalis* compared to clue cells on wet mount and 95% sensitive for the detection of *G. vaginalis* in women with more than 5×10^5 colony forming units/mL by culture; 100% sensitive for trichomonas diagnosed by wet mount and 80% sensitive for trichomonas recovered by culture.[105] These nonamplified assays are of much lower sensitivity than amplified assays.[100,106,107]

Amplified assays are those which amplify the nucleic acid target itself up to a billion fold, so theoretically even a single target copy can be detected from a clinical specimen. Most commercially available assays amplify DNA but some convert RNA from a sample to cDNA, which is then amplified.[55]

Chlamydia and gonorrhea. The first STD for which there was a commercially available PCR assay was *C. trachomatis.*[108] Currently, several different types of NAAT technologies are commercially available for *C. trachomatis* as well as for *N. gonorrhoeae.*[66,109–111] These NAATs include PCR (Amplicor, Roche Molecular Diagnostics), transcription mediated amplification (Aptima Combo2, Gen-Probe), and strand displacement amplification (ProbTec, Becton Dickinson). These methods offer excellent sensitivity, usually well above 90%, while maintaining very high specificity.[51,112] However, studies have demonstrated that the specificity of the Amplicor PCR

assay for identification of *N. gonorrhoeae* is less than listed in the package insert.[113,114] One study showed that more than 40% of 122 genital specimens from Australian women positive for *N. gonorrhoeae* by Amplicor PCR were not confirmed as positive by a consensus of other molecular assays.[114] This high false positive rate for the Amplicor PCR emphasizes the importance of confirming all positive tests using a different, but equally sensitive, assay.

HSV. A PCR assay (Cepheid) that detects both HSV 1 and 2 is available as an analyte-specific reagent, which means it is not U.S. FDA cleared but can be validated by an individual laboratory for its own use. The manufacturer also markets a similar assay that can type the HSV as HSV-1 or HSV-2.

Other STIs. NAATs for other STIs for which commercially available amplified tests may soon be available include HPV and *T. vaginalis*. Presently only research assays are available.[49,115–119] Research PCR assays are also available for agents of genital ulcer disease (syphilis, chancroid, and HSV) but are not available commercially.[120,121] Several PCRs for syphilis have been published and used, especially for the diagnosis of early syphilis,[122,123] but currently are only available in research laboratories or from the U.S. CDC.[54]

Real-time PCR amplification and detection methods have the capability to be quantitative and are becoming widely available as research assays but are not yet commercially available. Real-time PCRs are designed so that the amplification product is detected in "real time" by a probe(s) while the PCR product is generated. Cycle threshold values are generated so that the assays can be quantified according to target input by comparison to standard curves resulting from controls of known target copy number or organism number. Several types of probes conjugated to various fluorescent reporter dyes are available, and the assays require a specialized PCR instrument like the LightCycler (Roche) or the ABI Prism sequence detection system (Applied Biosystems).

Confirmation of positive results generated by NAATs had not been recommended until recently. The CDC now recommends that in populations with low prevalence of disease and positive predictive values (PPV) less than 90%, confirmation of positive chlamydia and gonorrhea NAAT results should be performed.[57] Suggested ways include testing a second specimen with a different test using a different target, testing the original specimen with a different test using a different target or format, repeating the original test on the original specimen with a blocking antibody or competitive probe, or repeating the original test on the original specimen.[57] Confirmatory testing for NAATs in low prevalence populations where low PPV is a concern is presently controversial and deserves further study.[124,125] A less sensitive NAAT should not be used to confirm a more sensitive assay,[126] nor should a less sensitive type of assay such as an EIA be used to confirm an amplified test.[127] Recently, Gen-Probe has made available individual amplification tests for chlamydia and gonorrhea that can be used to confirm positive results from their Combo2 test or other amplification tests.[128]

SPECIMEN COLLECTION

Nothing is more important than the appropriate choice, collection, and handling of a diagnostic specimen for the diagnosis of an STI with regards to the accuracy of the laboratory test.[129] Many factors affect the choice of sample type. These include but are not limited to type of STI, location of collection venue, site of active disease, choice of serological diagnosis versus direct detection of disease agent, type of assays and equipment available in the laboratory, and even whether to perform a rapid, bed-side test such as a wet preparation for trichomonas or darkfield examination for primary syphilis.

Invasive vs. noninvasive specimen type

Specimens can be classified as either invasive, for which a clinician will collect a diagnostic sample by an invasive technique, such as a biopsy, a lesion or genital tract swab, etc.; or they can be classified arbitrarily as noninvasive, which generally includes those such as blood or serum, urine, self-collected vaginal or rectal sample, etc. Choice will be dictated by the disease, the patient population, the setting, and laboratory test availability. NAAT assays, with increased sensitivity, have opened the way for diagnostic samples that are less invasive, can often be collected by the patient,[51,55] and can be used for multiple analyses. For example, liquid cytology specimens routinely collected for preparing Pap smears have been used successfully to test for STIs.[130] Many of these noninvasive specimens are being used for the diagnosis of chlamydial infection and gonorrhea.

Transport and storage

Clinicians should pay particular attention to the collection, handling, and transport requirements for specimens on which they order a diagnostic test, as accurate results will depend on the quality of the diagnostic sample and the environmental transport of the specimen. Transport containers for clinical specimens and instructions for collection, handling, and transport of diagnostic samples are usually available from the laboratory. The etiologic agent(s) suspected usually dictate the collection method and conditions of transport.[129] There is a wide range of conditions for transport of samples for the diagnosis of STDs (Table 52-4). These range from transport of blood for serological diagnosis, which does not require special handling, to the necessity to provide rapid transport for wet preparations for trichomonas and darkfield for the examination of primary syphilis and to the need to provide environmental CO_2 for the culture of gonococci and a cold chain for the culture of chlamydia. Requirements for special handling for special environmental

Table 52-4. Collection and Transport Guidelines for Commonly Collected Specimens for Commercially Available Assays

Pathogen	Test Type	Transport Conditions[a] by Specimen Type					
		Blood	Genital Slide	Cervix	Vagina	Urethra	Urine	Lesion
Syphilis	Serology	Routine						
	Darkfield							Immed
C. trachomatis	EIA[b]			RT 4 d STM				
	DFA[b]		Routine					
	DNA probe			RT 4 d STM		RT 4 d STM		
	Culture			CC STM		CC STM

transport again are best obtained from the laboratory performing the assay.[129] The particular swab or tool for collection of the diagnostic sample often depends on the manufacturer of the particular assay, and the sample is not acceptable unless the required swab or collection kit is used.

Specialized environmental handling, time limitations, and temperature conditions are required for samples that must be mailed to a testing site.[129] Clinicians should follow guidance from the testing laboratory for the type of STD and the type of diagnostic test ordered.

INTERPRETATION OF RESULTS

Interpretation of the results of a laboratory test by a clinician depends on several parameters. Clinicians must understand how well the test performs with regard to sensitivity, specificity, PPV, and negative predictive (see next section). Often the laboratory, the package insert, or the medical literature can provide estimates of these statistics. In clinical practice, the predictive values of the test are probably the most useful parameters, providing guidance for the questions "if the patient has a positive test, how likely is he/she to have the disease" and conversely, "if the patient has a negative test, how likely is he/she not to have the disease."

Current vs. past infection

Whether the test being used measures current or past infection is an important consideration when interpreting the results of a diagnostic test. Often, a positive serological test result can indicate previous infection and not the presence of "active disease," as for the example, with syphilis and herpes virus infections.[54,56] In the case of NAATs, a positive test result can remain positive for a period, even up to 2 weeks after therapy is given and infectiousness is negative, and clinicians should be aware of this tendency, especially if they perform a "test-of-cure" assay.[131,132]

Confirmatory tests

Confirmatory tests are supplemental tests performed after a positive diagnostic or screening test result. Many screening or diagnostic tests (highly sensitive but of lower specificity) for STIs are considered presumptive positive results, which must be confirmed by another more specific test (very high specificity), as is the case with the RPR or VDRL tests for syphilis, which need to be confirmed by a specific treponemal test such as the TP-PA. Confirmatory tests are also required for *N. gonorrhoeae*. Tests for gonorrhea are considered "presumptive positive" if a Gram stain is performed on a genital exudate or a Gram stain and oxidase test are done on the culture isolate, while "confirmatory" tests such as carbohydrate utilization, nucleic acid amplification, rapid enzyme substrates, serological coagglutination, or fluorescent antibody tests are used to characterize the isolate as "definitive" and are more accurate in identifying the isolate as truly *N. gonorrhoeae*.[133,134]

Patient history

Patient history can profoundly influence the clinician's interpretation of a test result. The diagnosis of an STD has emotional and social implications for patients. Consideration of a false positive for an STI such as chlamydial infections in a woman who is not sexually active may lead the clinician to repeat the test, while consideration of a false negative result in a sexually active adolescent with a history of multiple partners and with signs of mucopurulent cervicitis (MPC) may lead to a decision to select an antimicrobial regimen effective for chlamydial infection as well as for other possible courses of MPC, when treating the adolescent, even if the test result for *C. trachomatis* is negative. Multiple reasons exist for erroneous test results: products used by patients such as douching agents, spermicides, or antibiotics result in culture-negative samples, and connective tissue diseases produce false positive results in syphilis screening. Ultimately the decision of how to interpret the STI test result is based on sound clinical judgment, the patient's history, knowledge of which particular assay is being used by the laboratory, the statistical parameters of the test itself, and the signs and symptoms of disease manifestations in the patient.

CHOICE OF DIAGNOSTIC TEST

The choice of which diagnostic test to use in various clinical settings will be determined by many characteristics, including but not limited to the geographical location of the laboratory, the level of capability of the laboratory, the cost of the assay, how much training is required for the person performing the test, and the availability of specific equipment required. Table 52-5 lists the types of tests used to diagnose the most common STIs and summarizes the important characteristics of each method. The assay complexity dictates whether a laboratory can offer a certain test, as well as the cost of reagents, and the availability and cost of the equipment. Sometimes the choice for a clinician is beyond his decision and will be dictated by the laboratory he or she is using. In a large facility, there may be many diagnostic options ranging from a simple Gram stain for the presumptive diagnosis of gonorrhea to a real time research PCR test for chlamydia. In a developing country, choice of laboratory test may be limited by the assay complexity, which may be ranked as easy, moderately complex, or highly complex. If equipment required for a particular test, such as a thermocycler for amplification assays for chlamydia, is not available or is cost-prohibitive, a clinician may have no choice but to use a less sensitive assay.

PERFORMANCE GUIDELINES

Laboratory testing at every level, whether simple or complex, must meet certain performance guidelines. Verification of the performance parameters of new tests before implementation

Table 52-5. Characteristics of Laboratory Methods of STI Diagnosis

Type of Test	Advantages	Disadvantages	Test of Choice for	Ease of Performance	Training	Equipment
Microscopy	Immediate result	Low sensitivity	Gram stain, darkfield DFA[a]	Easy	Extensive	Microscope
Culture	Highly specific	Low sensitivity	*N. gonorrhoeae* *T. vaginalis*	Moderate	Extensive	Incubators
Antigen detection	Inexpensive	Low sensitivity	*C. trachomatis* (if NAAT[a] unavailable)	Moderate	Moderate	Incubators, Plate washers O.D. readers
Microbial biproduct detection	Immediate result	Low sensitivity	BV	Moderate	Moderate	Reader
Antibody detection	Inexpensive	Detects previous infection	Syphilis, HSV	Moderate	Moderate	Rotator
Nucleic acid hybridization	Moderately sensitive	Low sensitivity	*C. trachomatis* *N. gonorrhoeae*	Moderate	Moderate	Luminometer
Nucleic acid amplification	Highly sensitive	Expensive	*C. trachomatis* *N. gonorrhoeae*	Complex	Extensive	Thermocycling equipment

and ongoing validation of established procedures must be performed. Calculation of test characteristics requires the use of a reference standard for determination of true positive and negative results. This section describes the important test performance parameters, considerations for the choice of a reference standard, guidelines for conducting or assessing a test evaluation, and recommended quality assurance procedures.

PERFORMANCE PARAMETERS

The characteristics that are important for evaluating the performance of a test are defined in Table 52-6.

Sensitivity and specificity

Sensitivity is the measure of a test's efficiency in detecting a specific infection and specificity is the measure of a test's efficiency in ruling out an infection. Together they determine a test's accuracy. No test has both 100% sensitivity and specificity when used to test a large number of unknown specimens. Sensitivity can refer to either analytical or clinical sensitivity. Analytical sensitivity, also called the limit of detection (LOD), is applied to tests that detect a quantifiable target. Analytical sensitivity is best expressed as the proportion of positive results among multiple replicate samples containing a known amount of target. For example, the number of target DNA molecules that can be detected in 15 of 16 replicate specimens by a PCR assay is the 95% LOD.

The sensitivity and specificity of tests that require the conversion of a continuously measured variable into a definitive positive or negative result can be manipulated by the choice of the test cutoff value. Relative operating characteristics (ROC) curves are used to determine the best cutoff value that will optimize assay performance in a particular population. ROC curves are generated by calculating the sensitivity and specificity of a test when different cutoff levels are used to define a positive value, using specimens with known results that were tested by a reference assay (Fig. 52-1). As the cutoff is varied, the sensitivity and specificity will move in opposite directions. The cutoff value that is chosen should reflect the way in which the test will be used, whether false negative or false positive results are more acceptable, and the population being tested. A cutoff value with 100% sensitivity can be used to rule out disease in patients with a negative test result (100% negative predictive value), while a cutoff value with 100% specificity can be used to rule in disease (100% PPV) (Fig. 52-2).[135]

Predictive values

The highest predictive values are desired when inappropriate treatment due to false positive or false negative results has serious clinical, emotional, epidemiological, public health, or economic consequences. Predictive values are

Table 52-6. Important Parameters for Test Evaluation

Binary Table Used to Calculate Parameters

New test results	Reference ("gold standard") test results		
	Positive	**Negative**	**Total**
Positive	True positive *A*	False positive *B*	Total positive new test *A* + *B*
Negative	False negative *C*	True negative *D*	Total negative new test *C* + *D*
Total	Total positive reference test *A* + *C*	Total negative reference test *B* + *D*	Total specimens tested *A* + *B* + *C* + *D*

Definitions and Formulas for Parameters

Parameter	Formula	Definition
Sensitivity	$A/(A + C)$	Ability of new test to identify people who are truly positive
Specificity	$D/(D + B)$	Ability of new test to identify people who are truly negative
Positive predictive value	$A/(A + B)$	Probability of a positive test being a true positive
Negative predictive value	$D/(C + D)$	Probability of a negative test being a true negative
False positive	B	True negative specimens that test positive
False negative	C	True positive specimens that test negative
Accuracy (agreement)	$(A + D)/(A + B + C + D) \times 100$	Percentage of correct results obtained by the new test compared to the results of the reference standard
Prevalence	$(A + C)/(A + B + C + D) \times 100$	Frequency of a disease in the population of interest at a given point in time
Precision (reproducibility)	Number of repeated results in agreement/number of specimens repeated $\times$ 100	Percentage of times the same results are obtained when the test is used to test the same specimens again

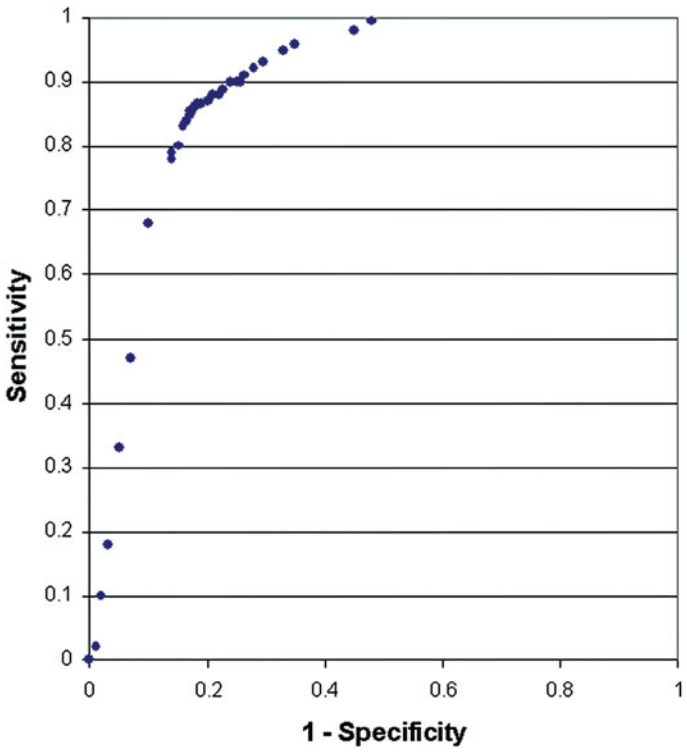

FIGURE 52-1. A hypothetical relative operating characteristics curve for samples tested by an ELISA. Each point represents the sensitivity and 1-specificity of the assay obtained at different optical density cutoff levels, using known positive and negative specimens.

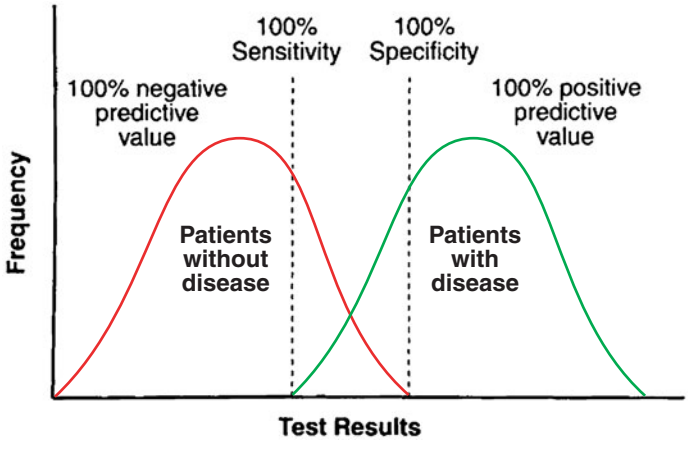

FIGURE 52-2. Relationship of choice of cutoff value to selected test parameters for converting a continuous valued test into a dichotomous test result. (With permission from Albritton WL, Vittinghof E, Padian NE. Human immunodeficiency virus testing for patient-based and population-based diagnosis. *J Infect Dis* 1996; 174(suppl 2): S176–S181.)

most meaningful in evaluating a test's performance in specific risk population groups because predictive values vary significantly with the prevalence of the disease or infectious agent unless the test is 100% sensitive (for negative predictive value, NPV) or specific (for PPV). As the prevalence of the disease in the population decreases, the PPV (the proportion of persons with a positive test having disease) decreases (Table 52-7), creating more false positives for the test in question. At low disease prevalence (<10%), small decreases in test specificity will result in a large decrease in the PPV, while changes in sensitivity have less effect on NPV. Even a test with a specificity of 99.5% will theoretically have a PPV of only 50% in a population of patients with a prevalence of 1%.

Table 52-7. Effect of Decreasing Prevalence on Positive and Negative Predictive Values for a Test with Sensitivity and Specificity of 95%

Disease Prevalence (%)	Positive Predictive Value (%)	Negative Predictive Value (%)
1	16.1	99.9
2	27.9	99.9
5	50.0	99.7
10	67.9	99.4
20	82.6	98.7
50	95.0	95.0
75	98.3	83.7
100	100	NA

Reproducibility

Reproducibility, also called precision, is a measure of the extent to which replicate analyses agree with each other. Reproducibility can be measured between operators or within the same operator. The reproducibility of an assay that provides a quantitative result can be expressed as the percent coefficient of variation, which is standard deviation/mean × 100. Automated processes are usually more reproducible than manual processes.

SELECTION OF A REFERENCE METHOD

A reference method or gold standard is used for assessing the performance characteristics of another test method. The test that is chosen to be the reference method should be the best available approximation of the truth; a test method currently accepted as reasonable but not necessarily 100% accurate. However, when the gold standard is imperfect, the results of the comparator test will be skewed. To improve the accuracy of the gold standard, the composite results of two or more assays or the results of more than one specimen collected from each subject can be used. In these situations, a specified

combination of positive results is defined as a true positive, and the reference method is referred to as an expanded reference or an infected-patient standard.

When using an expanded reference, how the reference is defined will alter the performance of the comparator test. The prevalence of *T. vaginalis* infection in men was underestimated when one specimen was used compared to an infected-patient standard using specimens from three sites.[136] When *C. trachomatis* infection was defined by using results from multiple tests performed on specimens from different sources, the sensitivity of any one test from a single specimen source was substantially lower than previously reported.[137] For the detection of *C. trachomatis* and *N. gonorrhoeae* by NAATs, the infected-patient standard reduced the sensitivity of the endocervical evaluation because some infected patients were positive only in a urine specimen, while specificities for single specimens improved because patients negative by the reference method for one specimen were positive by another.[138] Expanded reference or infected-patient standards are especially useful for evaluating the extremely sensitive NAATs. Martin et al. investigated how many test results run by different NAATs and what combinations of specimens comprised the best infected-patient gold standard. They recommended the following approach to evaluation of new diagnostic tests for *C. trachomatis* in women: a swab specimen compared to one urine and two swabs analyzed by two different U.S. FDA approved NAATs, or a urine compared to one swab and two urines. For men, the most efficient combination of infected-patient standard was a swab and urine analyzed by one FDA approved NAAT and a urine by a second NAAT. Any two positive of the three was defined as true positive.[139]

CONDUCTING A TEST EVALUATION

Many factors influence the performance of laboratory tests, including the characteristics of the target population, the resources of the testing laboratory or clinic, and the test method. A rigorous evaluation process is required to determine which type of test is most appropriate for a given setting. Laboratories that lack the resources to perform adequate evaluations of diagnostic tests on site should know how to assess evaluations performed by others. The Standards for Reporting of Diagnostic Accuracy (STARD) Iinitiative has developed a checklist for test evaluators to use that will improve the accuracy and completeness of reporting of studies of diagnostic accuracy. The information reported should allow readers to assess the potential for bias in the study and to evaluate its generalizability.[140]

The elements that are essential for evaluating a test's performance concern the objectives and design of the evaluation, the trial site, the selection of subjects, and specimen analysis. The objectives should be stated clearly and the study should be designed to meet them. An adequate number of subjects should be selected and tested in an unbiased manner from an appropriate population. A recognized, well-validated reference standard should be used and all specimens should be tested by both the test under evaluation and the reference method. Specimens should be tested by well-trained personnel, who are blinded to the results of all other tests. The performance parameters should be calculated accurately.

Discrepant analysis

In some test performance evaluations, when the new test is more sensitive than the reference test, a large number of specimens from infected persons may be classified as false positive (reference test negative, new test positive), producing a falsely low measure of the new test's specificity. In an effort to better estimate the performance of very sensitive new tests such as NAATs, test evaluators have used discrepant analysis to resolve areas of disagreement between the gold standard test and the comparator test. Discrepant analysis involves performing additional tests on the nonconcordant, usually false positive, specimens and acceptance of the comparator test results that are confirmed by the additional tests. Discrepant analysis is a controversial approach that introduces bias into the analysis, even when a perfect test is used to resolve the discrepant results,[141,142] because any test used to resolve the discrepant results can only improve or leave unchanged the original sensitivity and specificity. Any changes in the results can only favor the new test.[143] If performed, discrepant analysis should be done with a second, independent comparator test having sensitivity equal to the first but measuring a different target, and the data must be analyzed carefully. A better approach is to expand the gold standard to include the results of other tests or clinical information and use the same standard for all specimens. Alternatively, a random sample of concordant and all discordant samples can be tested by the resolving assay.

Operational characteristics

When evaluating currently performed techniques or considering the implementation of new procedures, laboratory directors must consider many factors as they apply to the population they are testing. Diagnostic tests must be evaluated in a clinically relevant population, because test performance varies across population subgroups (spectrum bias),[144] and performance can be affected by patient characteristics.[145] Although accuracy and precision are the main characteristics used for evaluating assay performance, other considerations include clinical relevance, cost, instrumentation, ease of performance, turnaround time, reagent stability, and specimen requirements.

QUALITY ASSURANCE

CQI (Continuous Quality Improvement) is an organizational philosophy and a process that promotes the improvement of

Table 52-8. Quality Assurance Measures in Clinical Laboratories: Each Practice Must Be Documented or Its Value Is Lost

Prior to test introduction
Method validation
Analyst training and qualification
Quality control assessment and plan
Following test implementation
Periodic analyst competency reassessment

patient care.[146] To minimize reporting of inaccurate results and to report results with a high degree of confidence, a system for continuously monitoring and improving the reliability, efficiency, and clinical utilization of laboratory tests must be followed. The concept of the quality assurance program is designed to monitor the elements of specimen quality, the transport of the sample, the correlation of the test methods with clinical data, the test performance, personnel, media and reagents, instrumentation, and result reporting methods.[146] Quality assurance measures encompass quality control and quality improvement practices, proficiency surveys, periodic validation of established tests, and verification of and training for new tests (Table 52-8).[147] Standardized protocols, continuing training, and accurate record keeping contribute to consistency of results and competent personnel. Laboratories in the United States are now bound by CLIA 88 (Clinical Laboratory Improvement Act) requirements and must follow guidelines for determining requirements for competency of laboratory personnel. Although a description of these programs in detail is beyond the scope of this chapter, programs such as these seek to improve the overall quality of test results for the clinician.

Quality control

Quality control in the laboratory is the process of monitoring and evaluating the analytical process. Procedures should be in place for reagent qualification, calibration and maintenance of equipment, and trouble shooting. Adequate control specimens should be analyzed including positive and negative controls for qualitative tests and controls to monitor test linearity for quantitative tests.

A necessary tool for assessing the performance of a laboratory, including personnel performance, is proficiency testing. Both internal and external programs are used. Repeat testing of in-house specimens ensures that a test is performing as expected over time. External programs, in which panels of samples that can be tested with all existing commercial and in-house methods and that resemble clinical samples are analyzed, ensure that the laboratory is reporting accurate results.

False positive and false negative results

Laboratory-caused false positive results are usually the result of specimen contamination due to improper sterilization, handling of contaminated material, and preparation of media and reagents. NAATs are at high risk for false positive results because of their high sensitivity. In a limited number of multicenter quality control studies of NAATs, the false-positive rate ranged from 9% to 57%.[148] The accuracy of these tests depends on use of specific procedures to prevent contamination (reviewed in 148).

Analytical false negative results are caused by interfering substances or inhibitors in the specimen or by improper specimen collection or processing. Some test systems include controls to detect inhibitors or sample degradation. Addition of control material directly to patient specimens can identify problems with sample storage and processing. However, this practice is controversial.[149] Biological false negative results may occur due to recent antibiotic use or incorrect timing of specimen collection.

FUTURE DIRECTIONS

The laboratory diagnosis of STIs has improved greatly in the past decade with the introduction of technologies that perform very sensitive detection of multiple organisms from single noninvasive specimen types. However, many challenges lie ahead for STI diagnostic testing. Unfortunately, the newer technologies and even many conventional laboratory procedures are beyond the reach of many health- care providers in resource- poor settings. As a consequence, syndromic management is practiced in many locations. Even when resources permit testing, the laboratory diagnosis of STIs is compromised when older technologies of limited sensitivity and specificity and often- substandard quality assurance practices are employed.

The availability of rapid, accurate, and inexpensive screening and diagnostic tests, especially for cervical infections in women, is sorely needed to improve patient management. Future directions for STI diagnostic tests should allow not only multiplex screening for all the causes of STI syndromes but also detection of mutations responsible for antibiotic resistance. The WHO and others who see this as a priority are working to develop and assess rapid and low cost diagnostics. Although home-based specimen collection, in which self-obtained specimens are

mailed to a laboratory, has been evaluated in some settings,.[150,151] home-based testing is not yet widely available. Home testing could provide STI diagnostic capabilities to some currently inaccessible populations.

The promise of better rapid tests lies in the rapidly evolving areas of nanotechnology and rapid detection technology. Complex nucleic acid amplification steps can be miniaturized on a nanoscale using microfluidic cartridges of the size of a credit card. This, combined with improved detection technology, will yield molecular rapid tests that can combine reasonable test performance with the operational characteristics of POC tests. Some tests are already in trials, but much work and innovation remains to be done before laboratory diagnosis of STIs is readily available to all those who need it.

53 Individual, Couple, and Small-Group Interventions to Reduce HIV and STI Acquisition

Thomas J. Coates

The NIH Consensus Statement on "Interventions to Prevent HIV Risk Behaviors" concluded:[1] "When we consider the available knowledge from the entire body of literature, we can reach a clear conclusion: Prevention programs significantly reduce HIV risk behaviors. This is true across a variety of risk behaviors and in a variety of populations at risk." The report went on to cite efficacy for individual and group-level interventions in terms of risk behavior reduction for men who have sex with men, men and women, and male and female heterosexuals. The Centers for Disease Control and Prevention (CDC) has formulated its own compendium of efficacious interventions[2,3] and has found individual and group intervention programs effective in reducing HIV risk behaviors among all the same populations as well. Because sexual transmission of HIV occurs through the same behaviors as sexual transmission of sexually transmitted infections (STIs), it is likely to assume that strategies for reducing sexual risk behaviors will affect both HIV as well as other STIs.

Many hundreds of studies have led to the NIH and CDC conclusions. Most of these studies, funded by the NIH and the CDC, use reported risk behavior as the outcome. This outcome might be regarded as a kind of a "surrogate" endpoint, as it is related to disease acquisition, but reductions in reported risk behaviors do not necessarily guarantee prevention of transmission for several reasons: because people forget or report erroneously, because behaviors were reduced but not sufficiently or consistently enough to prevent disease, or because the behaviors that were reduced were not those of greatest importance for disease prevention.[4] Thus, one can draw the conclusion that the data from these hundreds of studies using self-reported behavioral endpoints are interesting and promising, but that the results do not necessarily guarantee that such programs will prevent disease, and that individual and group interventions may not be sufficient to recommend changes in public health or clinical practice. In a very real sense, they can be regarded as Phase II studies.

Phase III studies are now needed. Changes in public health practice may require another level of evidence, namely, the demonstration that social and behavioral interventions to reduce risk behaviors result in clinically meaningful and sustained reductions in acquisition of new HIV or other STIs.

Manhart and Holmes[5] presented a review of randomized controlled trials of individual, population, and multilevel interventions to prevent STIs, with a focus on analysis of impact on disease endpoints. They found few individual-, couple-, or group-level behavioral interventions efficacious in reducing HIV or STI acquisition. In this chapter, we focus on those, as well as a few studies failing to demonstrate efficacy, in order to understand the benefits and limitations of these kinds of interventions, make suggestions about replications of extensions of these results into further research, and make recommendations regarding integration of these kinds of interventions into public health practice.

INDIVIDUAL LEVEL INTERVENTIONS

Project RESPECT was one of the most important studies examining an individual-level intervention with biological endpoints.[6] The study was completed in five sexually transmitted disease (STD) clinics (Baltimore, Denver, Long Beach, Newark, and San Francisco) between 1993 and 1996. A total of 5758 heterosexual HIV-negative patients presenting with symptoms at STD clinics were enrolled and randomized to one of four conditions: enhanced counseling consisting of four sessions, brief counseling consisting of two sessions, and the remaining two arms received two brief didactic messages. At the 12-month follow-up, participants in each counseling intervention had 20% fewer new STIs than those in the didactic message arms and this was consistent across study sites. Reduction of STIs was similar for men and women and greater for persons diagnosed with STIs at enrollment. The investigators concluded that short counseling interventions using risk reduction plans can prevent new STIs and can be incorporated into busy public clinics. A total of 82% of the participants completed all assigned intervention sessions but this was markedly lower in the four-session condition where only 72% completed all

sessions. People said that the sessions were "informative," "good," and "helpful."

Project EXPLORE[7–9] was similar to Project RESPECT in that it used an individual intervention. But in the case of EXPLORE, the intervention was far more intensive consisting of 10 one-to-one counseling sessions wherein assessments were made of the circumstances and other occasions in which an individual might engage in risk behavior, followed by tailored risk reduction plans to assist the individual in avoiding HIV acquisition. A total of 4295 men who have sex with men in six sites (Seattle, San Francisco, Denver, Chicago, Boston, and New York) were randomized to receive this intervention or semiannual voluntary counseling and testing delivered according to the CDC Project RESPECT model. Thus, Project RESPECT became the control for Project EXPLORE and this is consistent with ethical principles of randomized controlled trials. Thus, the evaluation of Project EXPLORE must take into account that it had to do substantially better than an intervention already proven efficacious. The individuals receiving the experimental intensive intervention also received quarterly maintenance sessions following the conclusion of the treatment sessions. Risk behaviors and HIV incidence were assessed but another important innovation was introduced. Average follow-up was 3.25 years, longer than has occurred in any other behavioral study.

The rate of acquisition of HIV was 18.2% lower in the intervention group than in the comparison group, but this effect was not significant (95% CI = –4.7–36%). Adjustment for baseline variables attenuated the effect further to 15.7% (95% CI = –8.4–34.4%).

Three other important findings emerged from this study. First, the intervention was effective in reducing overall risk behavior defined as unprotected anal intercourse with partners who were HIV-positive or unknown HIV status (20.5% reduction, 95% CI = 10.9–29%). Second, the effects of the intervention on HIV incidence appeared to be substantial in the first 12 months, with a 33% reduction in the first 6 months and a 39% reduction in the first 12 months. Had the study stopped at the time that other studies usually stop (i.e., 12 months), the intervention would most likely have appeared to be effective. Third, the intervention was effective in reducing certain risk factors for HIV (e.g., safer sexual norms, communication skills, self-efficacy) but not others (e.g., methamphetamine and other drug use, heavy alcohol use, depression) and these factors also predicted seroconversion among the entire cohort.

It is always a bit hazardous to generalize from an N of 2, but that is the sample we have at hand. Thus, we might conclude that it is possible, using individualized interventions, to reduce acquisition of new STIs and perhaps even HIV in the short run (e.g., up to 1 year postintervention). Nonetheless, the effect is likely to be modest and will not likely last beyond 12 months, at least given the evidence we have.

COUPLE-LEVEL INTERVENTIONS

The results for individuals inevitably give rise to the notion that it might make sense to involve others in the transmission chain, especially the partner giving the infection in the first place and perhaps regiving it after an infection has been cured (in the case of bacterial STIs). Further, investigations in the United States and other places have demonstrated that men are more likely to give HIV to women than vice versa,[10] but equal transmission has been observed in sub-Saharan Africa and is probably dependent on the viral load of the partner as well as other factors.

The potential of couple-level interventions to reduce HIV transmission was inspired by the early work of Allen et al. working in central Africa early in the HIV epidemic.[11] She and her colleagues demonstrated the potential of couples counseling and testing for HIV. They counseled and followed 60 serodiscordant couples. Condom use was reported by 3% of the couples at baseline and by 57% at 12 months follow-up. They reported an HIV seroconversion rate of 4 per 100 man-years of follow-up and 9 per 100 woman-years of follow-up. They determined that the absence of their program would have resulted in 22 new infections among serodiscordant couples. They also demonstrated a 50% reduction in incident gonorrhea when couples were tested together.[12]

Padian et al.[13] followed 175 serodiscordant couples in California. Among these couples, 32% reported consistent condom use at entry into the study and 75% reported consistent condom use as much as 9 years later. Again, this study was uncontrolled, but no new seroconversions were observed during 3000 couple-months of follow-up. Because these studies were observational, they were always subject to concerns of selection bias. The Voluntary Counseling and Testing Efficacy Study Group[14,15] tested the concept further in a randomized controlled trial and demonstrated that couples randomized to receive VCT, as compared to couples randomized to receive health education, reduced risk behaviors significantly more. This effect was especially pronounced in serodiscordant couples and was the most cost-effective of the interventions.[15] Unfortunately, we have no controlled data to demonstrate the efficacy of these counseling strategies in reducing disease acquisition when couples are counseled together.

SMALL GROUP INTERVENTIONS

Providing instruction, motivation, and skills training in small groups is a strategy employed widely, at least in studies of HIV and STI prevention. The National Institute of Mental Health of the NIH sponsored one of the largest trials using this kind of intervention strategy.[16] Entitled PROJECT LIGHT, the project was implemented in 37 inner-city, community-based clinics in five metropolitan areas: New York,

Baltimore, Atlanta, Milwaukee, and Los Angeles/Orange County, California. The sample was 74% African American, 25% Hispanic, and 58% female. A total of 3706 participants were randomized to a small-group, seven-session HIV risk reduction program, while the others were assigned to a control intervention consisting of health education. Those assigned to the intervention reported fewer unprotected sexual acts and higher levels of condom use than the control group.[17] They also reported fewer STD symptoms over the follow-up period, but there were also no overall differences in STD rates. However, among men recruited from STD clinics, those assigned to the intervention condition had a gonorrhea incidence rate one-half than that of those in the control condition.

Shain et al.[18] did find an effect on STI incidence. They recruited African American and Hispanic women from public health clinics in Texas and randomized them to receive either the control intervention (standard counseling about STIs) or a three-session sex- and culture-specific behavioral intervention. The intervention itself consisted of three small-group sessions of 3–4 hours each designed to help the women to recognize personal susceptibility, commit to changing their behavior, and acquire necessary skills. Rates of subsequent infection were significantly lower in the intervention group than in the control group in the first 6 months (11.3% vs. 17.2%, $p = 0.05$), the second 6 months (9.1% vs. 17.7%, $p = 0.008$), and over the entire 12-month study period (16.8% vs. 26.9%, $p = 0.004$).

Baker et al.[19] compared the effectiveness of two different 16-session group interventions for reducing new STD infections among heterosexual women. A total of 229 at-risk heterosexual women were randomly assigned to skills training based on the relapse prevention model or to health education. Participants in the skills training intervention were significantly less likely to be diagnosed with an STD in the year following intervention and demonstrated superior risk reduction skills at the 12-month follow-up.

Finally, Wingood et al.[20] evaluated the efficacy of the WILLOW Program, an intervention to reduce HIV transmission behaviors and STIs among women living with HIV. This is the first study to demonstrate reductions in incident bacterial STIs and reductions in risky sexual behavior among HIV-infected minority women. The intervention emphasized gender pride, maintaining current and identifying new network members, HIV transmission knowledge, communication and condom use skills, and healthy relationships. Over the 12-month follow-up period, women in the WILLOW intervention, relative to the control had a lower incidence of chlamydial infection and gonorrhea (OR = 0.19, $p = 0.006$). They also reported greater HIV knowledge and condom use self-efficacy, more network members, fewer beliefs that condoms interfere with sex, and fewer partner-related barriers to condom use. They also demonstrated greater skill in using condoms.

WHAT DO SUCCESSFUL INTERVENTIONS HAVE IN COMMON?

1. *Working with people recently diagnosed with HIV or an STI may increase the efficacy of social and behavioral approaches.* It may be the case that the surprise of a diagnosis of HIV or an STI may lead people to change behavior and reduce infection. There has been an emphasis recently within public health to identify people with very recent HIV infection, and the public health implications of such an approach could be enormous because of the heightened infectiousness associated with that period of the disease.[21,22] Such moments may also be teachable moments, as occurs when people seek nonoccupational postexposure prophylaxis,[23–25] that provide the opportunity to use both biological and social/behavioral strategies to enhance motivation and encourage behavioral change.
2. *Working with couples or sexual networks may increase the efficacy of social and behavioral approaches.* Working with couples or with entire sexual networks[26–30] may provide the opportunity both to intervene in and interrupt transmission chains and also build up social support systems to reinforce and support behavioral change.
3. *Interventions focusing on gender, racial/ethnic, or cultural issues might have promise.* Several of the successful interventions cited in this chapter[11,12,14,18–20] focused on issues of importance and relevance to the target populations, including those relating to gender, race/ethnicity, and culture. While we have no evidence that these elements were crucial in the success noted (and while other interventions might have focused on these issues and failed to find intervention effects on disease acquisition), nonetheless this feature is interesting and should be explored further as a potential ingredient of success. There is no specific science to determine which elements of gender or culture or race/ethnicity matter for a specific population, or how specifically to include those elements into an intervention. But the success of these interventions should be noted and, as others attempt to replicate and extend those findings, attempts should be made to use this strategy to the benefit of the participants.

RECOMMENDATIONS FOR RESEARCH

1. *We do not need a further abundance of Phase II types of individual, couples, or small group interventions that use self-reported risk behavioral endpoints.* Rather, focus should be placed on studies that demonstrate efficacy in reducing disease acquisition. The objective must be strategies that can and will be adopted by public health systems, and a level of evidence that demonstrates reductions in disease acquisition. With this in mind, it might be possible to examine the potential of other endpoints, such as HSV-2[31] or

HPV,[32,33] that occur with greater prevalence and incidence than chlamydial infection or gonorrhea.

2. *Systems studies are also needed.* While it is important to examine the efficacy of interventions using the highest and most rigorous design standards, it is also important to examine barriers and facilitators to systems' adoption of proven preventive strategies to ensure that efficacious strategies can be put into public health practice.
3. *Maintenance remains a problem and should be addressed specifically.* There is no evidence at present that the impact of any of these interventions lasts beyond 12 months. Examination of maintenance effects is needed along with focus on strategies that can carry changes beyond the end of that time period.
4. *Perhaps we need to change the paradigm.* The individual and small-group interventions follow a kind of brief psychotherapy or "inoculation" model. In this approach, individuals are counseled once and the impact is expected to last indefinitely. Perhaps the model that needs to be evaluated is a systems model in which prevention is incorporated into the fabric of HIV and STI care with multiple interventions employed—assessment, counseling, use of media, STI diagnosis and treatment on a regular basis, and HIV counseling and testing (including assessment of acute infection). Such models might be more comprehensive, and also more effective, in that the system is focused on prevention and individuals returning for follow-up care can be exposed to additional and maintenance doses of prevention.
5. *We should look more seriously at media-based interventions.* Media are important to youth and also represent a primary method by which certain individuals or groups seek out romantic or sexual partners.[34,35] Further, media strategies might be used beneficially in crowded public health settings where people have to wait for a long time to be seen.[36] We recommend that serious attention be paid to exploring more completely the benefits and efficacy of mediated approaches in reducing disease acquisition.
6. *Social and behavioral interventions typically do not address the role of substance use or mental health issues, and these issues may be at the heart of risk-taking and disease acquisition, at least with certain populations.* The role of methamphetamines and other drugs, as well as heavy alcohol use, in risky behavior is well documented.[37–39] Needed are strategies that can be incorporated into clinical settings that demonstrate efficacy in reducing drug use and the impact of those reductions on HIV or STI disease acquisition or transmission.
7. *Combination prevention strategies should be a priority and should be examined for efficacy.* We have alluded, in this chapter, to the potential of combining social and behavioral interventions with biomedical ones, as in the case of working with couples and using antivirals or antibiotics, or working with social networks and assessing acute HIV infection, or devising new strategies to reach potentially infected partners. It is time for the field to move beyond single discipline interventions and perhaps use more creative designs (e.g., factorial or other designs) to look at the synergistic effects of combined interventions to determine the ways to enhance the potential of social behavioral and biological interventions. For example, the combination of social/behavioral interventions with anti-retroviral medications (ARVs)[21] used either to control acute or established infection or used as preexposure[40] or postexposure prophylaxis[24,25,23] might be beneficial. The combination of social behavioral interventions with expanded partner therapy is another avenue ripe for investigation.[41] It might also be possible to examine the synergistic effects of social/behavioral interventions with anti-HSV-2 drugs.[42]

RECOMMENDATIONS FOR PUBLIC HEALTH PRACTICE

1. *Individual, couple, and small-group interventions CAN (but do not necessarily) lead to reductions in acquisition of HIV or STIs.* The studies using biological endpoints are few in number, but the positive findings are heartening. It is important to note, however, that other studies have examined impact on disease acquisition endpoints and have not found such effects. Thus, our conclusion is a bit muted and is qualified to indicate that such interventions CAN but do not necessarily affect disease endpoints. Thus, the evidence seems to indicate that the addition of individual, couple, and small-group interventions to routine STI treatment settings, and other clinical locations where high-risk individuals might present, could be beneficial.
2. *The potential of couples counseling and testing for HIV and STIs should be explored and enhanced.*[43] Disclosure of HIV serostatus, and presumably other diseases, remains a problem in HIV and STI prevention.[44] Strategies for enhancing disclosure might be a useful tool in the HIV/STI prevention armamentarium.

Reinfection with treated STIs or primary infection with viral STIs is common.[45] Some people presumably reacquire or acquire their STIs from primary partners; thus, innovative strategies for managing such encounters are essential. The literature reports some promising strategies for working with couples,[11–14] and we are beginning to understand some of the disease cofactors that lead to transmission.[46,47] Prevention studies in the field are testing the impact of antiretrovirals to prevent transmission of HIV to the uninfected partner, and also the impact of acyclovir to reduce HIV transmission in HSV+/HIV+ and to reduce HIV acquisition in HSV+/HIV– individuals.[42,48] Other innovative strategies for working with couples involve enhanced partner therapy, whereby the

infected person is given medications for their presumably infected partner(s).[41]

Given these developments, it might be useful to continue to examine the impact of couples counseling, with and without combination prevention strategies (such as ARVs and other antivirals or antibacterials) in controlled trials. It might also be useful to examine, in controlled studies, the impact of various strategies for encouraging or increasing disclosure from the diagnosed individual to his or her partner(s). Again, the utility of strategies might be enhanced if such social and behavioral interventions are combined with biological or chemotherapeutic ones.

3. *Some interventions can be effective with minority women.* This can be a heartening finding, given the feminization of the epidemic.[49] The studies by Shain,[18] Wingood,[20] and Baker[19] demonstrated beneficial effects on new STI acquisition among heterosexual women, and these studies worked with substantial numbers of minority women. These results demonstrate the potential of social and behavioral approaches for working with women and suggest that such interventions might be employed routinely for such populations. Interestingly, the interventions in all three studies addressed gender and racial/ethnic/cultural issues, and working with these issues may be vital in securing any intervention effect with these populations. It is also possible that naturally occurring social support systems among women facilitate greater behavioral change and maintenance of those changes to achieve the reductions in disease acquisition noted.

CONCLUSION

The evidence suggests that individual, couples, and small-group social/behavioral interventions can be successful in preventing disease acquisition with some people, and that these interventions are relatively low-cost. We encourage the field to apply now what we know can be effective and, simultaneously move forward to expand the range of strategies at our disposal. In expanding the range of options, the goal should not necessarily be more studies such as reviewed here, but rather expansion to new paradigms and ways of thinking about influencing behavior and disease acquisition or transmission.

54 Partner Notification for Sexually Transmitted Infections Including HIV Infection: An Evidence-Based Assessment

Matthew R. Golden, Elisabeth Faxelid, and Nicola Low

Partner notification, previously referred to as contact tracing, is the process of informing the sex partners or needle-sharing contacts of persons with sexually transmitted infections (STI), including HIV infection, of their potential exposure to an infectious disease and ensuring their evaluation and/or treatment. Partner notification has been a component of public health STI control efforts since at least the eighteenth century, when Danish priests collaborated with local governmental authorities to "notify persons known or suspected of being infected" with syphilis.[1] Similar measures were introduced in Sweden in the nineteenth century and, as in Denmark, linked partner notification to compulsory treatment and free medical care. Public health partner notification programs were incorporated into U.S. and British syphilis control efforts in the 1930s and 1940s and were subsequently expanded in some areas of the United States and Europe to affect persons with gonorrhea, chlamydial infection, and HIV.[2–4]

In this chapter, we describe the rationale for partner notification for STI, approaches to STI partner notification in clinical practice, and the evidence supporting the efficacy and effectiveness of these different approaches. Because these approaches vary depending on the resources available and the organization of health service delivery, we discuss partner notification in high-income and low-income nations separately.

RATIONALE FOR PARTNER NOTIFICATION

Partner notification has been justified as a means to reduce ongoing STI transmission, improve the health of individuals, and as a societal obligation to fulfill a duty to warn those potentially exposed to infection. Insofar as partner notification leads to the treatment of infected partners, it has the potential to advance the health of individual patients, and several recent studies of gonorrhea and chlamydial infection have reported reduced rates of index patient reinfection as a consequence of outreach for partner treatment.[5–7] The value of partner notification as a means to improve the health of individual patients is further supported by studies reporting that it is a cost-effective means to avert the complications of chlamydial infection,[8,9] though some investigators have questioned the parameters used in these cost-effectiveness analyses and their failure to incorporate the dynamic effects of interventions in STI incidence.[10] Moreover, many interventions found to be cost-effective from a societal perspective are too costly for widespread implementation with existing public health resources.

Mathematical models of both gonorrhea and chlamydial infection suggest that increased treatment of sex partners can substantially reduce the prevalence of these infections in the population, particularly when partner notification effectively identifies STI transmitters.[11–15] A single dynamic model found that partner notification for chlamydial infection is also cost-effective.[16] However, little empirical data exist to support these findings, and public health partner notification programs have not been shown to affect the prevalence or incidence of STI in the population. Intensified partner notification efforts have occasionally been temporally associated with declines in rates of STI in individual cities or counties that were not observed in areas without intensified partner notification,[17–19] but such studies are essentially anecdotal and the utility of partner notification as a means to prevent STI in the population is uncertain. Some public health authorities have also argued that the insights gained through partner notification programs yield indirect benefits that advance disease control efforts.[20]

Partner notification programs are primarily justified as a societal good, an effort that diminishes the burden of disease in the population and improves the health of exposed partners. Inherent in this justification is some tension between the welfare of the population and exposed partners and the liberty and right to privacy of persons infected with STIs. The emergence of HIV in the 1980s challenged the traditional view of the balance between these competing concerns. Many patients, HIV political activists, civil libertarians, and some public health authorities concluded that the invasion of privacy and potential to stigmatize persons with HIV

outweighed any potential public health benefits that might be achieved through partner notification.[21–24] Compared with bacterial STI, identifying the contacts of HIV-infected persons conferred little individual benefit on partners who could not be effectively treated or cured, and the risk of stigmatizing those infected was substantially greater. Increasing social acceptance of homosexuality, data on the acceptability and efficacy of HIV partner notification,[25] the introduction of effective treatment for HIV and opportunistic infections, and the advent of effective means to prevent mother to child transmission have all substantially altered the balance of risk and benefits related to partner notification for HIV. However, the fundamental dilemma of balancing the public good and individual rights persists, and public health authorities and clinicians need to remain mindful that partner notification is accomplished in a manner that ensures the voluntary cooperation of infected persons and rigorously safeguards their privacy.

TERMINOLOGY, TYPES OF PARTNER NOTIFICATION

An extensive vocabulary has evolved over the last 60 years to describe different approaches to partner notification and the indices used to measure partner notification program process outcomes. These terms are summarized in Table 54-1.

Three primary approaches to partner notification are now recognized as follows:[26–29]

- *Patient referral*: Responsibility for partner notification is left to the index patients themselves. This process sometimes involves an interview to elicit the names of contacts. At times, the process may be enhanced through counseling or the provision of referral cards.
- *Provider referral*: A clinician or health department employee interviews an index patient, elicits information about the identity of their sex partners, notifies the identified sex partners, and attempts to ensure their treatment without revealing the identity of the index case.
- *Conditional referral*: Public health staff elicit contact information about index patients' partners but only notify those partners if the index patient does not ensure the partners' treatment within some agreed on time period.

Although these terms provide a basis for describing partner notification, in practice the line between approaches is often blurred, and partner notification activities described with the same term often vary. In particular, patient referral, when implemented within a public health partner notification program, sometimes includes an interview with a health worker to elicit a sexual history and follow-up to ascertain outcomes. When undertaken by individual clinicians, patient referral is more likely to involve only the advice to index cases to inform their sex partners. Recently, some investigators have divided patient referral into simple patient referral and supported patient referral to differentiate between patient referral in which no assistance is offered (simple patient referral) and patient referral involving contact slips, or some education, interview, enhanced counseling, or follow-up (supported patient referral).[4]

CONTACT PERIODS

Contact periods are the time periods used to define which of an infected person's sex partners are at risk for STI and require evaluation and treatment. These periods are based on what is known about the incubation periods and natural history of each STI, as well as empirical data on case-finding yields observed using different periods. Table 54-2 presents the contact periods recommended by the U.S. Centers for Disease Control and Prevention (CDC) and the British Association for Sexual Health and HIV. Before publication of the UK guidelines, different UK genitourinary medicine (GUM) clinics appeared to employ different contact periods; 3 months was the most commonly used period for gonorrhea and chlamydial infection, and 6 months the most common period for HIV.[30] The impact of the UK guidelines on harmonizing contact periods has not yet been assessed.

The adequacy of different contact periods for gonorrhea and chlamydial infection have been evaluated in studies using 120 and 180-day periods for the two infections, respectively.[31,32] In both studies, public health staff attempted to test all index patients' partners for these periods to define the total population of potentially infected partners. (The study of chlamydial infection attempted to test at least two partners for each index person, using a period longer than 180 days if the patient reported only one partner during the 180-day period.) Among persons with gonorrhea, 30, 60, and 90-day contact periods identified 84%, 96%, and 99% of infected partners, respectively. A 30-day period identified 91% of infected partners of male index cases treated for symptomatic urethral gonorrhea. Among persons with chlamydial infection, 30, 60, and 90-day contact periods identified 79%, 88%, and 92% of infected partners, respectively. These studies suggest that relatively little is accomplished by extending contact periods for these infections beyond 60 days.

PUBLIC HEALTH PARTNER NOTIFICATION PRACTICES IN HIGH-INCOME NATIONS

The role of public health authorities in partner notification varies considerably between countries and among the different STIs. In the United States, health department staff routinely attempt to interview all patients reported with syphilis and typically employ provider referral. In contrast, the approach to other STIs, including HIV, is much more tentative. A survey of partner notification practices in 60 high STI

Table 54-1. Commonly Used Terms in Partner Notification Practice and Research

Term	Alternative Term	Definition
Index patient	Index case, original patient (OP)	The patient who presents for medical care with a newly diagnosed STI
Partner	Contact	Individuals who have been exposed to the index patient through sexual intercourse or needle sharing
Contact period		The time periods used to define which of an infected person's sex partners are at risk for STI and require evaluation and treatment
Contact slip	Referral card	Printed material that clinicians or public health staff give to index patients to give to their sex or needle-sharing partners. Contact slips advise recipients to seek care and are sometimes used to track the number of partners treated.
Partner notification staff		
Disease Intervention Specialists (DIS)	Public health advisors	U.S. health department staff performing PN activities
Health advisers	Contact tracers	UK health professionals performing partner notification, usually in genitourinary medicine clinics
Public health nurses		Dutch health professionals performing partner notification (amongst other duties), based in Municipal Health Services
Types of partner notification		
Patient referral		Index patient is encouraged to notify partners themselves
Provider referral		Health worker notifies partners
Conditional referral		Health worker notifies partners if index case has not done so within an agreed time period
Expedited partner therapy		Goal term of practices that involve treatment of sex partner's without the partner's mandatory prior examination by a clinician
Patient delivered partner therapy (PDPT)		Diagnosed patient is given medication or a prescription for medication to give to their sex partner(s)
Measures of program productivity		
Contact index		Number of contacts for whom information is elicited/number of persons with STI interviewed
Epidemiologic index	Treatment index	Number of contacts treated/number of persons with STI interviewed
Case-finding index	Brought-to-treatment index	Number of infected contacts treated/number of persons with STI interviewed

morbidity U.S. areas found that in 1999, only 17% of persons with gonorrhea and 12% of those with chlamydial infection were interviewed for purposes of partner notification; partner notification services for gonorrhea and chlamydial infection were largely restricted to patients seen in STD clinics, and, when provided, typically involved simply offering to notify patients' partners with no routine follow-up if that offer was refused.[3] In 2001, only 33% of persons reported with newly diagnosed HIV infection in high morbidity parts of the United States were interviewed for purposes of partner notification. As with gonorrhea and chlamydial infection, partner notification services were typically restricted to persons tested in publicly financed HIV testing sites, though some areas routinely attempted to contact all persons with

Table 54-2. CDC and British Association for Sexual Health and HIV Recommended Contact Periods for Pn[143–146]

Disease	United States	UK
Gonorrhea	Symptomatic–60 d prior to onset of symptoms Asymptomatic–60 d prior to treatment	Symptomatic–2 wks prior to the onset of symptoms Asymptomatic–3 mo prior to treatment[12]
Chlamydial infection	Symptomatic–60 d prior to onset of symptoms Asymptomatic–60 d prior to treatment	Symptomatic–4 wks prior to the onset of symptoms Asymptomatic–6 mo prior to treatment[11]
Primary syphilis	90 d prior to date of onset of primary lesion	90 d prior to the onset of the primary lesion
Secondary syphilis	6.5 mo prior to date of onset of secondary symptoms	Up to 2 yrs prior to treatment in cases of clinical relapse[a]
Early latent syphilis	1 yr prior to start of treatment	2 yrs prior to start of treatment[a]
HIV	1 yr prior to date of positive test (extended interview period may be warranted in some circumstances). 10-y period for current or any previous spouse	No guideline

[a] In the UK, early latent syphilis is defined as a new positive serological test for syphilis with no clinical evidence of treponemal infection within 2 years of infection.

Interview periods may be modified if a history of symptoms, a negative test result, or an incidental treatment are documented. Maximum periods are used if symptom history is uncertain. If a patient reports no partners during the interview period, the most recent partner should be notified.

newly reported HIV.[33] A Canadian survey of public health partner notification practices found that most provinces provided partner notification services to the majority of persons with bacterial STI, but that only 33% of health units provided partner notification services to most persons with HIV; provider referral was employed in approximately 50% of instances when partner notification services were provided.[34]

Partner notification practices in the European Union are highly variable and in many nations somewhat ill-defined.[4,35] Infected patients and diagnosing clinicians in Sweden and Norway are legally required to notify the sex partners of persons with reportable STIs. Provider referral is used for at least some cases of STI in Scandinavia, the UK, and Ireland. Most other European countries do not have sexual health services that are distinct from their systems of primary medical care and rely on patient referral. Patient referral in some countries involves some sort of interaction with public health authorities, but the nature of that interaction and the proportion of patients that are contacted by public health authorities are not known.

In the UK, a national network of specialist GUM clinics provides free and confidential care for people with STIs. These clinics are thought to treat most diagnosed cases of HIV, syphilis, and gonorrhea, but not chlamydial infection, and most employ specialized staff (health advisors) to undertake partner notification. Patient referral, including an interview to elicit a sexual history, advice about how to inform partners, and education about reducing the risk of reinfection, is the preferred strategy for syphilis, gonorrhea, chlamydial infection, and HIV infection in over 80% of clinics. Conditional referral is used in almost all other instances,[30] and provider referral is very rarely used as an initial approach. Contact slips were formerly used in the UK as a fundamental aid to patient referral and follow-up.[27] Sexual contacts could attend any GUM clinic with a contact slip and the slip would be returned to the issuing clinic so that treatment could be recorded in the index patient's notes. Contact slips are not used for HIV partner notification and their use for other infections is diminishing. Clinicians in primary care settings, where increasing numbers of cases of chlamydial infection are being diagnosed, often advise patients to notify their partners but do not necessarily provide risk reduction counseling or follow up the outcomes. A minority of primary care providers send patients with chlamydial infections to GUM clinics[36,37] and many patients who are referred do not attend.[38]

In Sweden, the main method for PN is conditional referral. At specialized dermatological and venereological clinics (mainly in the big cities), trained social workers are responsible for partner notification. At primary care clinics, diagnosing clinicians are responsible for partner notification.

Program statistics on PN yields have recently been compiled from published data from the United States between 1995 and 2003 and from both published and unpublished data from the UK from 1995 to 2002 (Table 54-3).[39,40] The U.S. study compiled data on brought-to-treatment indices, while the UK review evaluated the epidemiologic index (see Table 54-1 for definitions). Assuming that approximately 50% of partners of persons with gonorrhea or chlamydial infection are infected, the results of these reviews are roughly similar, indicating that 3–5 persons with gonorrhea, chlamydial infection, or syphilis need to be interviewed to identify one new infection in a partner, though recent data on syphilis in men who have sex with men (MSM) suggest that current case-finding yields, like those for HIV, are probably lower.[41] The absence of clearly defined partner notification procedures across these studies makes them difficult to interpret or compare, though they provide some basis on which to assess partner notification program success.

Health departments' relatively infrequent application of intensive partner notification efforts for HIV, the most important STI, merits particular discussion. At the outset of the AIDS epidemic, several U.S. states instituted routine PN efforts linked to named-based HIV reporting. Early evaluations of these efforts reported reasonable case-finding yields, with 2–11 index patients interviewed to identify one new case of HIV infection.[42–48] A small randomized, controlled trial conducted in the early 1990s found that conditional referral was superior to patient referral, when patient referral involved only an interview with public health authorities and no follow-up.[49] The case finding success of HIV partner notification was subsequently evaluated in a study of 6394 persons receiving public health HIV partner notification services in 23 U.S. cities or states; 13.8 index patients needed to be interviewed (Number Needed To Interview [NNTI]) to identify one new case of HIV infection. HIV partner notification success was highly variable across different health departments (NNTI ranged among areas from 1 to 196), with fewer new cases identified in areas with higher proportions of AIDS cases occurring in MSM.[33] A multicenter European study reported very similar results, with 28 new cases of HIV infection identified as a result of interviewing 356 index cases (12.7 index cases interviewed to identify one new case of HIV infection).[50]

Despite this evidence, in the United States and UK, relatively little public health effort was devoted to HIV partner notification during the first 2 decades of the AIDS epidemic.[24,33,51] The failure to more widely employ partner notification likely reflects a combination of concern about the stigma of HIV and potential deleterious effects of partner notification; political considerations, with civil libertarians and community-based organizations (CBOs) purporting to represent MSM frequently opposing the process;[21–23] the paucity of effective therapies for HIV infection to benefit those with HIV infection identified early in the epidemic; and the culture of HIV-related public health activities, which has often placed a premium on client satisfaction and counseling rather than on more traditional disease control objectives, such as case-finding.[3,27,52] Recent observational studies have not identified an elevated risk of domestic violence or partnership dissolution associated with HIV partner notification and have found that condom use increases following partner notification.[53,54] Moreover, persons with HIV, including MSM, typically believe that some form of public health-facilitated partner notification should be routine.[25,55] Since 2003, CDC has begun to place greater emphasis on HIV partner notification,[56] and it seems likely that U.S. HIV partner notification programs will expand in the coming years.

Table 54-3. Partner Notification Indices from Reviews of Recent U.S. and UK Data

	United States[39] Median Brought-to-Treatment Index[a] (range)	UK[40] Pooled Epidemiologic Index[b] (range)
Gonorrhea	0.25 (0.09–0.58)	0.58 (0.47–0.71)
Chlamydia	0.22 (0.05–0.53)	0.61 (0.55–0.66)
Syphilis	0.22 (0.05–0.53)	NA
HIV	0.13 (0.03–0.75)	NA

[a] Brought to treatment index = Number of infected contacts treated/number of persons with STI interviewed.

[b] Epidemiologic index = Number of contacts treated/number of persons with STI interviewed.

HOW CLINICIANS AND PATIENTS APPROACH PARTNER NOTIFICATION

Since public health efforts in most high-income countries affect small numbers of persons and often rely on patient referral, the success of partner notification is often a question of how well diagnosing clinicians and their patients assure partners' evaluation and treatment with little or no assistance. Studies conducted in the United States and Europe have found that clinicians treating patients for STIs typically make very limited efforts to treat partners and seldom know whether their patients' partners are treated. For example, in a U.S. study conducted in King County, Washington, in which clinicians were interviewed about their management of a specific case of *Chlamydia trachomatis* they had reported to the health department, 90% stated that they had told the patient to notify their sex partners but only 17% knew that all of their patient's partners were treated.[57] Studies surveying

providers about their typical practices have found similar results. A study of a national probability sample of 7300 American physicians found that over 80% reported routinely telling patients to notify their sex partners and advise those partners to seek medical care, but fewer than one-third routinely followed up with patients to inquire about partner treatment.[58] A 1994 survey of British general practitioners found that only 30% referred patients with chlamydial infection to GUM clinics and that only 30% of providers who did not refer to such clinics routinely treated their patients' partners or referred them elsewhere for treatment.[36]

Although relatively few clinicians seem to actually examine their patients' sex partners, many give their patients medications or prescriptions for medications to give to their sex partners, a practice called patient-delivered partner therapy (PDPT). Approximately half of all U.S. physicians treating persons with gonorrhea or chlamydial infection report at least occasionally using PDPT, though most studies have found that 25% or fewer use it half or more of the time.[57,59–61] The practice has been less well-studied outside of the United States. A survey of European public health officials reported that PDPT was uncommonly employed.[4] However, a Danish study of provider practices that included information on how specific patients were managed found that 34% of women and 12% of men treated for *C. trachomatis* were given prescriptions for their current partner.[62] PDPT also appears to be used relatively commonly in Australia.[63] PDPT for gonorrhea and chlamydial infection has been instituted as part of a population-based public health program in a single U.S. city[64] and is now being promoted in California and in Washington State but is of uncertain legal status in much of the United States[65] and possibly in Europe. In the UK, PDPT is under investigation and is legal if a health professional (including a pharmacist) has assessed whether such therapy is suitable for a partner, and the doctor prescribing the therapy takes responsibility for the partner. The CDC has issued preliminary advice to state and local health departments suggesting that U.S. health departments should have PDPT available as an option.[66] Data and controversies related to PDPT have recently been reviewed.[67] CDC has recently issued guidance related to EPT.[66]

Since health departments frequently do little to promote partner notification, and, in the absence of PDPT, most clinicians do little more than advise patients to notify their sex partners, patients are typically left to assure their partners' treatment with little assistance. Defining the success of patient referral is difficult since ascertaining whether partners have been treated is either dependent on index patient report, which may not be valid, or confirming partners' treatment at a specific clinic, which may fail to ascertain treatment received under an alias or at other venues. In addition, the content of patient referral is variable, reports on patient referral outcomes have used different contact periods, and health department staff is likely variably successful in defining the number of potentially exposed sex partners used as denominators to calculate the percentage of partners notified or treated. Despite those limitations, numerous studies have attempted to define the success of patient referral, mostly for gonorrhea or chlamydial infection (Table 54-4). Overall, these studies suggest that probably fewer than half of partners of persons with gonorrhea or chlamydial infection are treated. Factors associated with more successful referral of partners include female gender of index patient;[68–70] steady, recent and ongoing partnership;[68,69,71–73] chlamydial infection (vs. gonorrhea);[68,73] index patients having fewer sex partners;[57,68,73] nonuse of condoms;[72,74] index patient self-efficacy[70]; and diagnosis by a private sector clinician as opposed to clinicians in an STD clinic, public health clinic, or an emergency room.[73] Index patient age has not been consistently associated with patient referral success.

COMPARATIVE STUDIES OF PARTNER NOTIFICATION

Given the long history of partner notification, there are relatively few studies comparing different approaches to partner notification and very few randomized, controlled trials (Table 54-5). Between 1994 and 2002, three systematic reviews of the partner notification literature were conducted.[26,28,75] These studies and reviews suggest several conclusions:

(1) Provider referral or conditional referral conducted by public health professionals among male STD clinic patients with gonorrhea or NGU, and possibly among persons with HIV, increases the proportion of partners who are identified or treated compared to patient referral. Limited existing data do not support the efficacy of partner notification interventions by public health professionals when applied outside of STD clinics. The efficacy of partner notification undertaken by public health professionals is supported by two randomized controlled trials conducted among mostly male STD clinic patients with gonorrhea[76] and NGU,[9] as well as by a small randomized trial among persons with HIV.[49] In addition, a study that compared partner notification outcomes in one U.S. city during two time periods found that brought-to-treatment indices were higher during a period of intensified partner notification involving provider referral than they were during a period of "perfunctory" disease intervention specialist (DIS) partner notification efforts.[77] In contrast, a randomized trial conducted in the UK among persons with chlamydial infection found that brief partner notification counseling by nurses in primary care clinics or physicians' offices with telephone follow-up was at least as effective as referring patients to receive

Table 54-4. Studies Evaluating Patient Referral Success

Location (y)	Number Index Patients Studied	STI	% Partners Notified or Treated	PN Procedures and Outcome Ascertainment
Colorado Springs (1977)[78]	93	GC	51	All patients received a routine follow-up call. Partner treatment status based on confirmed treatment in STD clinic
Colorado Springs (1985)[77]	3368	GC	62	"Perfunctory" PN interviewing performed with no follow-up. Partner treatment status based on confirmed treatment or evaluation
Nova Scotia (1992)[147]	37	CT	68	Partner notification status based on index patient report (treatment outcome not reported)
London (1994)[71]	254	CT	53	Index patients had ocular CT infection. Treatment status based on confirmed treatment
Amsterdam (1997)[68]	440	GC/CT	40	Patients given referral cards. Partner treatment status based on confirmed in STD clinic or elsewhere
Rotterdam (1998)[72]	250	GC/CT	41	Patients routinely counseled by public health nurse and given referral cards. Partner treatment status based on confirmed treatment in STD clinic or elsewhere
Houston (2000)[148]	54	GC/CT	55	Partner treatment status based on index patient report–percentage reflects any partner having been treated
Seattle (1999)[57]	76	CT	51	Partner treatment status based on index patient report
Seattle (2001)[64]	698	GC/CT	51	Partner treatment status based on index patient report
Indianapolis (2002)[70]	241	GC/CT/NGU/TV	65	Partner notification status based on index patient report (treatment outcome not reported)
France (2002)[69]	145	Any STD	49	Partner notification status based on index patient report (treatment outcome not reported)

GC = gonorrhea, CT = *C. trachomatis,* NGU = nongonococcal urethritis, TV = trichomonas.

partner notification assistance from health advisors in GUM clinics.[38] Also, one small, nonrandomized trial did not find that provider referral was superior to patient referral,[78] and an observational study comparing periods in which DIS services were provided or not provided to patients with gonorrhea found no difference in the proportion of cases of infection identified through PN.[79] Possible reasons for disparities across studies include (a) patient referral may be more effective in women, meaning that DIS assistance among women has a smaller effect;[80]

Table 54-5. Experimental and Comparative Studies of Different Approaches to PN

Author (y)	Population	Design	Intervention	Outcome	Comment
Gonorrhea, Chlamydia, and NGU Cleveland (unpublished)[76]	1898 Dade county STD clinic patients with gonorrhea (94% male, 71% African American)	Randomized controlled trial Test of cure (TOC) performed at 2–5 d Rescreening performed 28 d after treatment (excluded those with positive TOC)	3 arms: (1) Referral cards and instructions to refer partners with no contact elicitation interview (PR) (2) Informational pamphlet, contact elicitation interview, and referral cards (IP) (3) Conditional referral with referral cards (CR)	Epidemiologic Index: PR = 0.37 IP = 0.37 CR = 0.62 Brought-to-treatment index PR = 0.25 IP = 0.24 CR = 0.37 Test of cure (67% tested) PR = 3.5% IP = 2.6% CR = 3.6% Rescreening (54% tested) PR = 6.3% IP = 7.7% CR = 7.2%	Costs per case identified 3.6 × higher in CR than in PR. Statistics to assess significance of PN indices cannot be calculated due to nonindependance of data. No significant difference in TOC or infection at rescreening
Hammer (1972)[80]	669 STD clinic patients with gonorrhea in Uppsala, Sweden.	Comparison of two time periods	Routine follow-up PN interviews performed during an intervention period. Only an initial interview was performed to elicit partner names during the control period.	Proportion of index cases with at least one infected contact increased from 63% to 74% among men ($p = 0.03$), but decreased from 78% to 68% among women ($p = 0.05$).	The probability of finding the source partners was believed to be higher in men during the intervention period.
Potterat (1977)[78]	187 El Paso, Colorado male STD clinic patients with gonorrhea	Controlled nonrandomized trial	Conditional referral (CR) vs. patient referral with referral cards (PR) DIS interviewed subjects in PR arm but did not elicit names or contact information	Epidemiologic Index: PR = 1.15 CR = 1.27 Brought-to-treatment index[a] PR = 0.53 CR = 0.53	Excludes partners treated prior to notification[a]
Judson (1978)[79]	Denver STD clinic patients with gonorrhea	Comparison of two time periods	One period involved DIS interviews with some follow-up provided to 30% of patients. The comparison period involved provision of contact slips to patients by clinicians without any DIS interview	The percentage of all gonorrhea cases diagnosed in the STD clinic as a result of PN did not differ between the DIS and no DIS periods (19.2% vs. 19.4%)	DIS PN procedures ill-defined
Woodhouse (1985)[77]	Gonorrhea in Colorado Springs, USA	Comparison of two time periods	Study period (1980–82)—intensive PN involving at least some provider referral control period (1977–79)—"perfunctory" patient interviewing	Brought to treatment index increased from 0.17 to 0.28.	Decline in gonorrhea incidence in Colorado Springs was greater than elsewhere in Colorado state (−12.9% vs. −6.6%)

Table 54-5. (*Continued*)

Author (y)	Population	Design	Intervention	Outcome	Comment
Katz (1988)[9]	678 Indianapolis male STD clinic patients with nongonococcal urethritis	RCT	3 arms: (1) Patient referral (PR)—nurses caring for subjects advised them to notify partners and gave them referral cards (2) Patient referral with DIS interview (PRD)—DIS elicited contact infor mation but no follow-up done and no referral cards given (3) Provider referral (PrR)—DIS elicited contacts and attempted to contact them	Epidemiologic Index: PR = 0.22 PRD = 0.18 PrR = 0.72	
Solomon (1988)[91]	902 mostly African American (99%) male STD clinic patients	RCT	Intervention: 10 min soap-opera style videotape that emphasized the importance of notifying partners and of returning for test-of-cure followed by DIS interview and receipt of referral cards. No routine DIS follow-up was provided. Control subjects were interviewed by DIS and received referral cards	No difference in PN outcomes as measured by DIS case dispositions or number of partners presenting with referral cards	No numbers presented on PN outcomes. One or more referral cards returned by partners of only 13% of subjects
Montesinos (1990)[88]	65 university students (74% male) with gonorrhea or nongonococcal urethritis at Southern Illinois University	Two 6 mo periods compared. The first offered counseling only (arm 1) to all subjects, the second randomly assigned subjects to arms 2 and 3	3 arms: (1) Counseling with partner elicitation interview (2) Counseling with partner elicitation interview + referral card + free care for patient and partner (3) Counseling with partner elicitation interview + referral card + follow-up call	More identified partners of persons in arm 3 (90%) sought care than in arm 1 (56%) or arm 2 (62%) ($p < 0.05$)	50 students excluded because they did not have a partner who was also a student at the university. Only 2/19 subjects in arm 3 were called for follow-up. Uncertain if statistical methods accounted for correlated data
Alary (1991)[149]	104 persons with gonorrhea or chlamydial infection (74% female) in Quebec, Canada.	Comparison of number of contacts elicited and number infected contacts	Persons receiving public health PN were interviewed by a PN nurse and managed with conditional referral. Those who refused public	Mean number of contacts elicited was 2.55 in the public health PN group and 1.59 in the physician group ($p = 0.004$). Brought-to-treatment	Acceptance higher among women, though difference in number of contacts identified was higher among those

Table 54-5. (*Continued*)

Author (y)	Population	Design	Intervention	Outcome	Comment
Gonorrhea, Chlamydia, and NGU	Includes persons diagnosed by general practitioners	identified among persons accepting and refusing public health interviews	health PN had partners elicited by the reporting physician	index higher among persons receiving public health PN (0.66 vs. 0.26)	accepting public health PN after adjustment for gender
Andersen (1998)[150]	96 Danish women with *C. trachomatis* diagnosed in general practices	RCT	Counseling patient to refer partners vs. providing women with home sampling urine specimen container for male partners	68% of partners in home sampling group and 28% in control group tested ($p < 0.01$)	Completeness of ascertainment of male partner evaluation uncertain
Brewer (2001)[81]	158 MSM (49%), HIV testers, or injection drug users in Seattle, Washington	Comparison of number of partners named before and after use of supplementary techniques. Different supplementary techniques compared in randomized trial	Free recall of sex partners in past year vs. free recall enhanced with supplementary interviewing techniques	Supplementary techniques increased number of sex partners acknowledged by 40% and number of IDU partners acknowledged by 123%	Prompting using alphabetic and locations for meeting partners as cues were most effective
Wright (2002)[94]	424 heterosexual GUM clinic patients with chlamydial infection in London	Comparison of two 2 month time periods during which different contact slips were used	Contact slip naming chlamydial infection as the index patient's STI diagnosis with attached informational brochure compared to standard contact slip alone	Contacts attending GUM clinics per index patient increased from 0.3 to 0.8 ($p < 0.0005$)	No data provided on number men and women. Significantly, more patients issued slips during time period when experimental slip was used
Brewer (2005)[82]	123 persons (43% male) receiving PN services for gonorrhea, chlamydial infection (90%) or syphilis in Colorado Springs, CO.	Comparison of number of sex and needle-sharing partners acknowledged before use of supplementary techniques and after. Different supplementary techniques compared in randomized trial	Location/alphabetic/network/role cues compared to first-name cues and individual characteristic cues (control)	Location/alphabetic/network/role cues resulted in elicitation of 21% more partners and a 0.11 mean increase in partners located	Enhanced elicitation techniques increased number of partners found by 12%

Table 54-5. (*Continued*)

Author (y)	Population	Design	Intervention	Outcome	Comment
Ostergaard (2003)[83]	1826 persons with *C. trachomatis* randomized prior to enrollment; 562 (74% women) enrolled	Randomized controlled effectiveness trial	Enrolled patients sent home urine specimen collection kits to give to partners; controls received a kit that required them to go to an office for testing	26% of home sampling and 12% office sampling had at least one partner treated ($p < 0.0001$). Among persons enrolled, 67% of home sampling and 34% of office sampling subjects had at least one partner treated	Uncertain how many partners may have been treated outside of study
Schillinger (2003)[5]	1787 women treated for chlamydial infection in diverse clinical settings in 5 U.S. cities	RCT	Azithromycin PDPT vs. patient-referral	Chlamydia diagnosed in 12% PDPT vs. 15% self-referral at 1 or 4 mo follow-up (OR 0.80, 95% CI 0.62–1.05). NNT to prevent one case of CT = 33	Study did not achieve goal enrollment. Proportions of partners treated not reported
Apoola (2004)[89]	800 patients with chlamydial infection at Birmingham, U.K. GUM clinic	Comparison of two time periods	2001—patients interviewed by health advisor asked to return to clinic for routine follow-up in 2 wks 2002—patients interviewed by health advisor and 2 wk follow-up telephone call scheduled	Number of contacts treated per case higher in 2002 than 2001 (0.57 vs. 0.45, $p = 0.0006$)	Statistical tests did not account for nonindependence of events
Golden (2005)[6]	2751 persons (24% men) reported with gonorrhea or chlamydial infection in King Co., WA	RCT	Expedited partner treatment (EPT) vs. standard partner referral. 9% EPT partners treated following direct contact with study staff. Standard partner referral involved patient referral with an offer of assistance notifying sex partners	Infection at 10–18 wk follow-up detected in 9.9% of subjects who received EPT and 13% who received standard partner referral (RR 0.76, 95% CI 0.59–0.98). Partners reported treated 64% EPT vs. 52% standard partner referral	Excluded index patients who reported all partners treated at time of study interview. EPT significantly more effective for gonorrhea (RR 0.32, 95% CI 0.13–0.77) than for chlamydia (RR 0.82, 95% CI 0.62–1.07)
Kissinger (2005)[7]	977 men treated for urethritis in New Orleans STD clinic; 60% infected with gonorrhea and 20% chlamydial infection	RCT	3 arms: PDPT with azithromycin + ciprofloxacin or cefixime, information booklet (BR), or patient referral (PR)[a]	Infection at follow-up detected in 23% PDPT, 14% BR, and 43% PR ($p < 0.001$). Partners reported treated 56% PDPT, 44% BR, and 34% PR ($p < 0.001$)	Follow-up Interviews performed on 79% of men. STI testing performed on 38% of men interviewed
Low (2005)[38]	140 patients with chlamydial infection (44% men) diagnosed	RCT	Patient referral by practice nurse (PN) with telephone follow-up by health adviser vs. referral	Partners reported treated PN 65%, HA 53%, difference 12% (95% CI −2–27%. $p = 0.087$)	31% of patients referred to genitourinary medicine clinic did not attend

Author (y)	Population	Design	Intervention	Outcome	Comment
	in primary care practices in Bristol and Birmingham, UK		to health adviser at genitourinary medicine clinic (HA)		Persons randomized to HA were interviewed a mean time of 13 d after treatment Cost of two strategies similar
Syphilis					
Peterman (1997)[152]	1966 patients with syphilis (76% early latent) in Florida or New Jersey	RCT	3 arms: (1) Conditional referral (CPR) (2) Provider referral (PR) (3) Provider referral with bloods drawn from partners in the field (PR+)	Epidemiologic index : CR : 0.67 PR : 0.61 PR+ : 0.62 Cost per partner treated: CR: $317 PR: $362 PR+: $343	Most contacts in CR arm notified by DIS. Cost estimates likely underestimates due to incomplete recording of time spent on activities other than interviews
Trichomonas					
Kissinger (2005)[93]	463 New Orleans STD clinic patients with Trichomonas	RCT	3 arms: PDPT with metronidazole, information booklet (BR), or patient referral (PR)[a]	Infection at follow-up detected in 9.4% PDPT, 9.0% BR, and 6.3% PR ($p < 0.001$) Partner treatment reported by 76% PDPT, 58% BR, and 70% PR	81% women tested at follow-up
HIV					
Landis (1992)[49]	74 persons newly diagnosed with HIV (76% MSM) in publicly funded HIV-testing programs in North Carolina	RCT	Conditional referral (CR) vs. patient referral (PR). DIS attempted to notify partners in patient referral arm after 1 mo	Partners notified and tested 50% in CR arm and 6.5% if PR arm ($p < .001$)	Enrolled subjects constituted 14% of all persons with HIV-positive tests during time period; 46% of those offered participation enrolled

PDPT = Patient delivered partner therapy.

(b) patient referral may be more effective among patients with chlamydial infection than among those with gonorrhea; (c) the quality and intensity of health department-mediated partner notification may have varied substantially between studies; and (d) studies employed different methods to define whether partners were treated, with recent studies showing no benefit associated with conditional referral relying more on index patient report of partner treatment status, and older studies relying exclusively on confirmed partner treatment, mostly in STD clinics. It should be noted that provider or conditional referral has not been compared

to patient referral in randomized trials involving patients with syphilis, and that the conclusion that conditional referral is superior to patient referral for HIV is based on a single study of only 74 people in the era before highly active antiretroviral medication was available.49

(2) Specific cues can be used to increase the number of part ners elicited when interviewing index patients. This finding is supported by two randomized controlled trials.[81,82] To date, the interviewing techniques studied in these trials have not been widely applied, and the feasibility of widely using these cues and their effectiveness when used outside of a study is unknown.

(3) Providing women with chlamydial infection with urine self-collection kits to give to their male sex partners increased the number of partners tested and treated in two randomized controlled trials conducted in Denmark.[63,83] The extent to which self-collection may have increased ascertainment of partner treatment more than total partner treatment in these trials is uncertain.

(4) PDPT or other means to treat partners without requiring the partners to seek prior medical evaluation increases the proportion of partners treated and decreases STI reinfection rates in persons with gonorrhea or chlamydial infection. This conclusion is based on findings from three randomized controlled trials,[5–7] all of which reported increased proportions of partners treated per index patient report and two of which found significantly lower rates of infection at follow-up among persons given PDPT. The third trial found a nonsignificant trend toward lower rates of infection at follow-up among women given PDPT. Findings from two observational studies also support this conclusion.[84,85] Of note, the benefits of PDPT in women with trichomonas are less clear; a randomized controlled trial of PDPT for trichomonas found no difference in reported partner treatment or infection at follow-up in women randomized to PDPT compared to those who were managed with counseling and patient referral of partners.[86] In contrast, a randomized controlled trial among women treated for trichomoniasis with tinidazole found that routine treatment of the male partners significantly decreased rates of reinfection in the female index patient compared to no such treatment of male partners, demonstrating that effective partner notification for trichomonas does affect index patient reinfection rates.[87]

Other low-intensity interventions include routine follow-up calls and contact slips for patients to give to their sex partners. A randomized controlled trial conducted among 65 college students in a rural Midwestern town in the United States found that routine follow-up calls could increase the proportion of partners treated,[88] a finding that is supported by a UK study in which routine telephone follow-up with index patients with chlamydial infection appeared to result in more partners seeking care, compared to asking index patients to return to the clinic.[89] Although contact slips are a longstanding component of PN programs, relatively little has been done to evaluate them. Published data on this subject suggest that fewer than 50%, and often less than 20%, of contact slips distributed to index patients are typically returned to STD clinics.[38,78,90–92] Three recent studies have investigated the utility of contact slips that include some counseling or educational message. In two randomized controlled trials, Kissinger found that using a contact slip that contained a small amount of information about the STI was superior to patient referral alone in men with NGU[7] but was inferior to patient referral alone in women with trichomoniasis.[86,93] Wright compared two different contact slips used during different time periods among persons with chlamydial infection in a London GUM clinic; one contained disease specific information and the other did not. She found that more partners attended the clinic when a contact slip with infection specific information was used.[94]

INTERNET-BASED PARTNER NOTIFICATION

Since the mid-1990s, the Internet has emerged as an important avenue through which persons with STI, particularly MSM, meet sex partners.[95–97] DIS have successfully used the Internet to trace the sex partners of persons with syphilis,[98,99] and many patients are interested in using the Internet to notify partners without direct assistance from public health staff.[100] An Internet site, inSpot (http://www.inspot.org/), developed by a nonprofit group with funding from the San Francisco Department of Health, has been used to allow persons with STIs to anonymously or confidentially notify their sex partners. During a 3-month period in 2005, 2216 persons sent 3562 notification cards using the Internet site. In 1 month, at least 5 persons seen in the San Francisco STD clinic reported receiving an email notification card.[101] It is uncertain whether the Internet site increased the numbers of partners notified or treated.

NETWORK APPROACHES TO PARTNER NOTIFICATION

Over the course of the last 2 decades, partner notification studies have been used to better understand sexual networks, with the implied idea that such an understanding might help direct disease control interventions.[102] To date, new network insights have helped inform modeling efforts but have probably had relatively little practical impact on disease control activities. However, the notion that risk networks might be

exploited for the purpose of STI case-finding has a long history in partner notification programs, many of which have included efforts to test cases' nonsexual contacts (i.e., "suspects") as well as the social and sexual contacts named by uninfected persons initially identified through partner notification activities (i.e., "associates"), a process called cluster tracing or cluster case finding.[103] More recently, increasing research on sexual networks has prompted renewed interest in focusing on social networks as a means to identify persons with undiagnosed syphilis or HIV.[102] Such efforts have met with mixed success. Studies conducted in the 1990s reported interviewing between 9.1 and 500 syphilis cases in order to identify one new case of syphilis among suspects or associates.[104–108]

Peer referral is a variant on traditional cluster tracing and involves recruiting persons from an at-risk social network to refer other members of the network for HIV or STI testing. To the extent that recruited peers are given an opportunity to become recruiters, it is similar to respondent driven sampling, a procedure sometimes used to sample hard-to-reach populations.[109] Peer recruiters are typically given some incentive for referring others. A small study of HIV-positive patients treated in an inner city Los Angeles HIV clinic suggested that this approach might be effective. In that study, 31 HIV-positive patients referred 79 peers for testing and counseling, of whom 37 (47%) tested HIV positive.[110,111] More recently, a preliminary evaluation of nine small, CDC-funded peer referral programs conducted by community-based organizations (CBOs) reported that 46 (5.7%) of 814 peers referred by 133 recruiters had previously undiagnosed HIV infection.[112] A study of peer referral in Seattle, WA, identified 22 new cases of HIV among 438 peers referred over a 29-month period and reported that peer referral was cost-effective relative to other approaches to HIV case-finding.[113]

CONCLUSIONS

The approach to partner notification in high-income nations is now in flux. The emergence of *C. trachomatis* as the most common bacterial STI, the continued HIV epidemic, rising rates of syphilis among MSM, and increased skepticism about the effectiveness and feasibility of applying traditional, labor-intensive approaches to partner notification to all persons with STI have prompted a renewed interest in partner notification research that emphasizes applying variable approaches to larger populations. Although existing data supporting the efficacy of HIV partner notification are limited, they suggest that resource-intensive efforts spearheaded by public health professionals should prioritize persons with HIV. The role of public health professionals in partner notification for other STIs is less certain. Because the number of syphilis cases in most high-income nations remains small, efforts involving intensive investigations by health department staff are feasible. But the efficacy of such efforts among MSM, now the majority of all early syphilis cases in the United States, is uncertain.[41] Approaches to partner notification that rely on traditional, intensive interviews with public health staff cannot be applied to all persons with gonorrhea or chlamydial infection in most nations. How to best use tools such as PDPT, mailed specimen collection for partners, and less-intensive clinic-based counseling efforts is uncertain, but these tools offer promise as a means to improve partner notification outcomes.

PARTNER NOTIFICATION IN LOW-INCOME NATIONS

Relatively little data are available on current partner notification practices or the efficacy of partner notification in low-income nations. One study, conducted in Chennai, India, found that only 27% of patients diagnosed with STIs in diverse health-care facilities were advised to notify their partners.[114] A second study, conducted by the same investigators in Chennai compared how providers and simulated patients reported that a case of STD was managed. Eighty-eight percent of clinicians reported telling patients to notify their partners, but only 33% of patients reported discussing partner notification with their diagnosing clinician; 22% of simulated patients were prescribed medication to give to their partners.[115] Studies utilizing simulated STD patients conducted in Peru, Gambia, and Ghana found that pharmacy workers advised fewer than 50% of patients that their partners required treatment or medical evaluation.[116–118]

Studies evaluating the efficacy of partner notification practices for bacterial STIs or STD syndromes have usually focused on patient referral, typically aided by the use of contact slips, in patients seen in STD clinics or prenatal care clinics. Investigators have generally ascertained outcomes by counting the number of contact slips returned. Summarizing the findings of these studies is complicated by the fact that some investigators have reported epidemiologic indices (for definition, see Table 54-1) as outcomes, while others have reported the total proportion of partners treated. Results from studies evaluating patient referral have been highly variable, with epidemiologic indices varying from 0.13 to 0.7[119–123] and the proportion of partners treated ranging from 20% to 67%.[124–131] As in high-income nations, patient referral appears to be most successful among female index cases and in persons in more stable relationships.[121,127,128,131,132] Studies have also associated greater patient referral success with pregnancy[121] and with genital ulcer disease as opposed to other STD syndromes.[130] A study conducted in China found that feeling stigmatized by an STI was associated with a reduced willingness to notify spouses.[131]

Virtually all studies evaluating partner notification for HIV conducted in low-income nations have involved women seen in antenatal or postpartum care clinics in sub-Saharan Africa. Results have been variable, with 17–86% of

women reporting that their partners were notified. Most studies have reported that index patients inform half or fewer of the partners of their possible exposure to HIV,[133–137] and that fewer than half of partners believed to have been notified are known to have been tested.[138,139] Successful HIV partner notification has been associated with greater use of antiretroviral drugs to avoid perinatal HIV transmission, greater adherence with advice to avoid breastfeeding, and higher levels of condom use[140] and could potentially increase a couples' interest in subsequent contraception. Commonly cited barriers to notifying partners include fear of abandonment, rejection, discrimination, violence, or being accused of infidelity.[136] A review of nine studies assessing the outcomes of HIV partner notification among women in low-income nations found that adverse events occurred in 4–28% of cases, with violence reported by 4–15% of women. These studies did not report how often these women were victims of domestic violence before disclosing their HIV status to their partners, making the results difficult to interpret.[136,137] To date, studies of HIV partner notification in women have not included efforts to promote disclosure to partners, and it seems likely that women who notify their partners do so because they feel safer in their relationships than women who do not notify partners. As a result, encouraging more women to disclose their HIV status to partners could result in higher levels of domestic violence. The existing literature on HIV partner notification in low-income nations is notable for the absence of data on how often men notify their partners of their infection, and for the paucity of data from continents other than Africa.

Table 54-6 summarizes studies comparing different approaches to partner notification in developing nations. All but

Table 54-6. Experimental and Comparative Studies of Different Approaches to Partner Notification in Developing Nations

Author (Year)	Population	Design	Intervention	Outcome	Comment
Ogunbanjo (1986)[153]	64 male STD clinic patients with gonorrhea in Ibadan, Nigeria	RCT	Counseling by health advisor vs. counseling by health advisor plus 5–7 min of additional counseling by a physician	Five partners in counseling group and 10 in experimental counseling group evaluated at clinic	Poor power to detect a difference
Hira (1990)[154]	110 RPR positive women receiving prenatal care in health centers in Luska, Zambia	Comparison of birth outcomes in three intervention and three control clinic populations	Health education intervention	Partners treated in 29/74 (39%) intervention clinic women vs. 3/36 (8%) control clinic women	Although populations of clinics were similar overall, partner notification data before the intervention is not presented
Njeru (1995)[132]	254 Kenyan patients at General medicine or family planning clinic (37% men)	Comparison of PN outcomes in two time periods	5–10 min of individual counseling and collection of names of sex partners. All patients asked to return	33% of partners confirmed as having been treated during intervention period vs. 15% in preintervention period	Data for intervention period limited to 93 (37%) or 254 persons recruited for study, possibly biasing results Index patients reported they notified 58% of partners, and that 40% of partners were treated

(*Continued*)

Table 54-6. (*Continued*)

Author (Year)	Population	Design	Intervention	Outcome	Comment
Faxelid (1996)[151]	386 Zambian STD clinic patients (76% men) with gonorrhea, chancroid, LGV, syphilis, or trichomonas	RCT	10–20 min of individual counseling, contact slips, and offer of provider referral vs. advice to refer partner for treatment	Per index patient report, more partners were notified (87% vs. 63%) and treated (82% vs. 55%) in the intervention group than in the control group	Index patients not typically given treatment if they did not refer a partner. Impact appeared greater for male index patients
Nuwaha (2000)[141]	383 STD clinic patients with STD syndromes in Kampala, Uganda, (52% men). Women with only bacterial vaginosis or candida excluded	RCT	Patient referral with contact slips vs. PDPT	74% of PDPT reported treated vs. 34% of patient referral partners seen in clinic	Primary study outcome ascertained by different mechanisms for two arms of study
Harrison (1999)[142]	Five pairs of clinics in the Hlabisa health district, South Africa	Clinic-level randomized trial	Clinician training and supervision to improve syndromic management and use of syndrome specific treatment packets that included partner referral cards	Proportion of clinic patients who reported being asymptomatic partners of persons with STD higher in control clinics (8% vs. 5%, RR 0.79, 95% CI 0.68–0.92)	Difference between intervention and control clinics not significant in multivariate analysis. Intervention improved other aspects of STD care
Mathews (2002)[155]	335 STD clinic patients (40% male) with STD syndromes in Kwazuku Natal, South Africa	Comparison of two time periods	Educational video shown in clinic waiting area, nurse educational training, and referral cards compared to referral cards alone	Epidemiologic index in intervention vs. control period were 0.27 vs. 0.20 (95% CI for difference −0.05–0.17)	
Garcia (2003)[116]	Seven pairs of districts in Lima, Peru	Community-level randomization of pharmacy workers. Workers in 884 intervention pharmacies participated. Outcomes ascertained using simulated patients	Pharmacy worker training in STD syndromic management	At 3 mo follow-up, 46% of simulated patients in intervention pharmacies and 15% in control pharmacies were advised that partners needed treatment ($p = 0.004$)	Impact on partner treatment in real patients not evaluated

one of these studies was undertaken in sub-Saharan Africa. Five studies evaluated brief counseling or educational interventions, four of which reported significant improvements in the proportion of partners treated or a trend toward such an improvement. A study of PDPT undertaken in Uganda reported higher rates of partner treatment in persons given medication for their partners compared to persons who were simply advised to refer their partners for care but employed different methods to ascertain outcomes in intervention and control groups, possibly biasing the result.[141] Two clinic or community-level trials have evaluated partner notification as part of larger, more complex interventions trials. Harrison evaluated an intervention designed to improve clinicians' syndromic management of STI that involved training and the use of syndrome specific treatment packets; slightly lower proportions of clinic patients presented as asymptomatic partners of persons with STI in intervention than in control clinics,[142] suggesting that the intervention did not increase partner notification. Garcia evaluated an intervention designed to improve pharmacy workers' syndromic management of STI in Lima, Peru. She found that trained workers were more likely to advise simulated patients to refer partners than workers randomly assigned to a control training unrelated to STI.[116]

In summary, due to resource limitations, patient referral is often the only feasible partner notification method in low-income countries. Limited data suggest that the outcomes can be improved through appropriate counseling and the use of contact slips. The information on these slips should be easy to understand and issues of confidentiality should be emphasized, since some persons in low-income countries are illiterate and might seek reading help from relatives and friends. Given the low specificity of vaginal discharge as an STD syndrome, it seems reasonable to prioritize HIV, urethritis, and genital ulcer disease for scarce partner notification resources in countries where microbiologic diagnoses are not available. Particularly as antiretroviral medications become more widely available, improving partner notification for HIV should be a public health and research priority.

PART 9

Management of STD Syndromes in Women

This page intentionally left blank

55 Lower Genital Tract Infection Syndromes in Women

King K. Holmes, Walter E. Stamm, and Jack D. Sobel

Differences in male and female anatomy and reproductive physiology account for the greater risk of complications of certain STDs in women and also for the greater difficulty in differential diagnosis of urogenital infections in women. In fact, the difficulty in diagnosing sexually transmitted urogenital infections in women undoubtedly results in delay of proper therapy, which further contributes to the higher risk of complications in women and to the further spread of infection in the community.

In heterosexual men, gonococcal and chlamydial infections appear limited to the anterior urethra in most cases, although the frequency of extension of infection to the posterior urethra and genital adnexae has not been well studied. Symptoms and signs of urethral discharge readily recognizable by both the patient and the clinician have come to represent the most monotonous aspect of venereology; knowledge of variations on this theme is limited.

On the other hand, in women several STD pathogens, including *Neisseria gonorrhoeae, Chlamydia trachomatis*, and herpes simplex virus (HSV), have predilection for infection of the urethra, cervix, and rectum simultaneously, producing more variable symptom patterns, each with a wide range of differential diagnostic possibilities. Furthermore, infections at any one site can produce poorly localized symptoms easy to erroneously ascribe to involvement of a contiguous site. For example, infections of the bladder, urethra, or vulva can produce similar symptoms, such as dysuria or dyspareunia. Finally, lack of appreciation of the differing clinical signs of specific genital infections in women can often be attributed to inadequate inspection of the genitalia because of poor clinical skills, paucity of speculums in many developing countries, or simple reluctance to perform the examination (Fig. 55-1). These factors account for the vague terms still used to describe some of the urogenital syndromes in women, such as "nonspecific genital infection" and "lower genital tract infection"—terms that pose a barrier both to understanding these syndromes and to accurate clinical diagnosis and therapy.

The positive predictive values of symptoms or signs for having an STI is a function both of the prior probability of STI in the individual being tested, and of the validity of the symptoms or signs as indicators for such infections. The prior probability of STI in the individual can be measured by risk assessment (see Chapter 48), addressing individual-level risk factors such as history of an STI; history of exposure to an STI; history of individual-level risk behavior(s); age and gender; of partnership-level characteristics such as marital status; and of sexual network and population-level risk, often assessed indirectly through sociodemographic risk markers, such as ethnicity, place of residence, etc. The validity of symptoms and signs as indicators is a function both of (1) the validity of the symptom or sign per se as predictive of one or more specific STIs (e.g., profuse urethral discharge or genital ulceration on physical examination by an STD clinical expert are both highly predictive of certain STI, whereas symptoms of generalized rash, lower abdominal pain, and vaginal bleeding are not) and (2) the validity of ascertainment of the presence of particular symptoms or signs, based on the experience, skill, biases, and efforts of the clinician.[1]

Improved detection of gonococcal and chlamydial infections in women by new laboratory tests represents one of the major advances in gynecology and STD during the past 25 years. Beginning in the 1970s, diagnosis of gonorrhea in women by culture became widely available in industrialized countries; and during the past 15 years newer tests for chlamydial and gonococcal infections have also become increasingly available. However, in developing countries there is still almost total reliance on syndromic management and on contact tracing to detect and reduce the "female reservoir" of these infections. Because of the expense and limited availability of facilities for specific detection of *N. gonorrhoeae* or *C. trachomatis* in developing countries, there has been an unwarranted sense of futility about the prospects for diagnosis of lower genital infections in women. Uncertainty about the usual etiologies of inflammatory conditions of the urinary tract, vulva, vagina, and cervix in women, the lack of consistent

FIGURE 55-1. Pelvic examination performed by a clinician not trained in sexually transmitted diseases.

application of available laboratory testing where needed, and the failure to exclude coinfections when analyzing the clinical manifestations of any one particular infection add to the confusion and vagueness concerning classification of urogenital inflammation in women. Clinicians experience further difficulty in differentiating true inflammatory conditions from noninflammatory conditions, including functional, psychosomatic genitourinary complaints.

Although the etiology of certain genitourinary and anorectal inflammatory conditions in women is still not well understood, it is becoming increasingly possible to presumptively identify many common and potentially serious STDs in women on the basis of clinical observations of symptoms and signs, supplemented with selective use of relatively simple screening and confirmatory laboratory tests. More precise diagnosis of urogenital infection in women could make a major contribution to improved control of several important STDs in the community, and should lead to improved management strategies for genital infection in the individual patient. An etiologic classification of urogenital inflammatory and "pseudoinflammatory" syndromes in women is presented in Table 55-1; also, each syndrome is further discussed in this chapter. Chapter 49 introduces an approach to the anatomy and physical examination of the female genital tract and provides useful background for this chapter. Chapters 42, 43, and 45 discuss the three most common nonviral vaginal infections (bacterial vaginosis [BV], trichomoniasis,

Table 55-1. Etiologic Classification of Lower Urogenital Inflammatory or "Pseudoinflammatory" Syndromes in Adult, Premenopausal Women

Syndrome	Usual Microbial Etiology	Other/Idiopathic
Cystitis	Coliform bacteria *S. saprophyticus*	Interstitial cystitis
Urethritis	*N. gonorrhoeae* *C. trachomatis* HSV	
Vulvitis	HSV *C. albicans*	Vulvar papillomatosis Vulvar vestibulitis Essential vulvodynia Vulvar necrotizing fasciitis
Bartholinitis	*N. gonorrhoeae* *C. trachomatis* Facultative or anaerobic bacterial infection	
Vaginitis/Vaginal discharge	*T. vaginalis* *C. albicans* *G. vaginalis*, mycoplasmas, and anaerobic bacteria	Desquamative inflammatory vaginitis Toxic shock syndrome Intravaginal use of detergents, certain microbicides, chemicals, physical agents. Chronic tampon use, other retained foreign bodies Allergic vaginitis
Endocervicitis	*C. trachomatis* *N. gonorrhoeae* *M. genitalium* HSV	
Ectocervicitis	HSV *T. vaginalis* *C. albicans*	

and vulvovaginal candidiasis, respectively), which are therefore not covered in detail here.

CYSTITIS AND URETHRITIS

EPIDEMIOLOGY AND ETIOLOGY

In the United States, women with symptoms of lower urinary tract infection (UTI) account for an estimated 7 million office visits to physicians in office practice each year.[2] In a community-based study in England, symptoms of dysuria and frequent urination occurred in as many as 20% of women per year.[3] A prospective study of young women in Seattle initiating contraceptive use demonstrated an incidence of acute cystitis of 0.5–0.7% per year.[4] Thus, this infection is exceedingly common and its incidence is probably underestimated by surveys dependent on office visits. In addition, recurrent infection is common, occurring in 25% of young women following a first UTI.[5]

Symptoms of dysuria or frequency in women can usually be attributed to acute bacterial cystitis, urethritis, or vulvitis. The incidence of acute bacterial cystitis is highest in women 20–25 years of age, and this condition is a particularly common cause of urinary symptoms among sexually active young women. Recent studies have identified sexual intercourse, spermicide or diaphragm-spermicide use, a history of a prior UTI, and recent antimicrobial exposure as independent risk factors for acute cystitis.[4,6,7] Almost identical risk factors are seen in young women with pyelonephritis.[8] Among 263 women presenting to the Seattle STD clinic with urinary symptoms alone, or with both urinary and vaginal symptoms, but without clear signs of vaginal infection, 69 (26%) had "significant" bacteriuria ($\geq 10^5$ organisms(mL of urine).[9] A separate study of female students at the University of Washington showed that the traditional criterion of $\geq 10^5$ uropathogens per mL of urine is insensitive for diagnosis of acute bacterial cystitis in women who present with dysuria, frequency and pyuria.[10] This criterion was originally established in studies of women with acute pyelonephritis, and in surveys of asymptomatic women who have a low prevalence of bladder infection. However, among female students with symptoms of dysuria, specimens obtained by suprapubic aspiration or urethral catheterization usually confirmed the presence of bladder infection, when voided urines contained lower concentrations of bacteria, ranging from 10^2 to $<10^5$ bacteria per mL.[10] Subsequent studies have confirmed these observations and it is now accepted that among women with dysuria and frequency, from one-third to one-half of those with acute bacterial cystitis have "low-count" bacteriuria, with cultures yielding uropathogenic bacteria in concentrations between 10^2 and $<10^5$ organisms per mL of urine. Almost all episodes of bacterial cystitis, irrespective of the urinary colony count, are accompanied by pyuria, and about 20% of patients have gross hematuria. The etiologic agents in women with acute uncomplicated cystitis are highly predictable, with *E. coli* causing 80% of cases. *S. saprophyticus* is the second most common pathogen, causing 5–15% of cases.[11] This organism has a seasonal variation in incidence (summer fall) and preferentially infects adolescents. Infections due to *E. coli* and *S. saprophyticus* cannot be distinguished clinically. *Proteus mirabilis, K. pneumoniae*, Enterobacter and enterococci collectively cause about 10% of cystitis cases.

The syndrome of dysuria and frequency in women whose urine does not contain $\leq 10^2$ of the preceding uropathogens has been called the "urethral syndrome" or, in the presence of pyuria, the "dysuria-sterile pyuria syndrome."[12–14] In a 1980 study of female university students with the urethral syndrome who had sterile bladder urines, the etiology was found to be related to the presence or absence of pyuria. Infection with *C. trachomatis* was demonstrated in 10 of 16 women with pyuria but in only 1 of 16 women without pyuria ($p = 0.002$).[12] Pyuria was defined as more than eight leukocytes per mL of uncentrifuged midstream urine, approximately equivalent to 10 leukocytes per 400× microscopic field when 10 mL of urine have been centrifuged and the sediment resuspended in 1 mL of urine for microscopic examination under a coverslip. *N. gonorrhoeae* was not associated with the urethral syndrome in this population of university students.

However, in a 1970s study of indigent women attending a hospital emergency room, gonococcal infection was significantly correlated with dysuria, accounting for 8 (61%) of 13 cases whose urine samples contained $<10^5$ uropathogens per mL.[15] Cultures for *C. trachomatis* were not obtained in that study. The role of *Mycoplasma genitalium* in women with dysuria and pyuria remains undefined, though one recent Swedish study of STD clinic patients and their sex partners[16] found a significant association of *M. genitalium* with urethritis (mostly nonsymptomatic pyuria), as well as with cervicitis in women. In another study,[17] a nonsignificant trend toward an association with increased numbers of polymorphonuclear (PMN) leukocytes in urethral smears was found. Thus, among young women with the urethral syndrome, and without bladder infection by uropathogens, the relative importance of gonococcal and chlamydial infection probably depends on the relative background incidence of these two infections in young women. HSV infections (especially primary infection), although not commonly found among women with the urethral syndrome, clearly can produce urethritis, dysuria, and pyuria in young sexually active women, and can be mistaken for bacterial cystitis if vulvar lesions are not prominent or carefully sought. Dysuria in women who do not have bacteriuria or urethral infection with STD pathogens is often attributable to vulvar inflammation caused by genital herpes or candida vulvovaginitis.[18–20] For example, Komaroff et al. reported that in

young women, dysuria was attributable to vaginitis more often than to UTI because vaginitis was so much more common than UTI.[20,21]

DIAGNOSIS AND THERAPY

The characteristic features that help to differentiate the three major conditions that can result in dysuria in women are summarized in Table 55-2. The medical history, physical examination, and simple laboratory tests are all helpful in the differential diagnosis of dysuria. The optimal diagnostic approach to dysuria and/or frequency varies, depending on the clinical setting and the likelihood of STD. Thus, in STD clinics, family planning clinics, teen clinics, or other settings where the prevalence of STDs is high, speculum exam is warranted to rule out STDs. In clinical settings or individual patients where the likelihood of an STD is low, the pelvic exam can be omitted. Urinalysis should be performed in all women with dysuria or frequency to detect pyuria. Microscopic examination of unspun urine by using a hemocytometer or calibrated chamber is the most sensitive and specific test for the presence or absence of pyuria.[22] Alternatively, leukocytes can be counted after centrifugation of the urine followed by resuspension of the sediment in 1 mL of urine and enumeration of white cells in one to two drops of urine placed on a microscope slide under a coverslip. This method is slightly less accurate than the first method. Another simple test for pyuria involves the use of a "dipstick" to detect leukocyte esterase in urine. Although the sensitivity of the leukocyte esterase test appears lower than that of the chamber microscopy method for detection of pyuria, the simplicity and low cost of the test make it useful for screening women with dysuria in the clinic.[22,23] Among women with dysuria, pyuria usually is indicative of acute bacterial cystitis in women at low risk for STDs and may indicate either cystitis or urethritis in women at high risk for STDs. If pyuria is found microscopically or by leukocyte esterase test, the urine can also be examined microscopically for bacteriuria, either by (1) preparation of a Gram's stain of a fresh, midstream, clean-catch, uncentrifuged urine specimen and examination with an oil immersion lens (the presence of one bacterial organism per field is correlated with quantitative isolation of $\geq 10^5$ bacteria per mL of urine); or (2) by examination of unstained, centrifuged urinary sediment of fresh urine under high dry objective (detection of 100 organisms per field also correlates well with isolation of $\geq 10^5$ bacteria per mL of urine). These simple procedures should be readily available in any clinic. However, bacteria present in concentrations of

Table 55-2. Characteristic Features That Differentiate the Three Major Causes of Dysuria in Women

	Acute Bacterial Cystitis	Urethritis	Vulvitis
Predisposing factors	Previous cystitis Spermicide onset of symptoms within 24h after intercourse	New sex partner	History of genital herpes Partner with genital herpes Antibiotic use History of recurrent vulvovaginal candidiasis
Symptoms	Internal dysuria Duration of symptoms ≤4 days Frequency and urgency Gross hematuria	Internal dysuria Duration of symptoms often ≥7 days with chlamydial urethritis	External dysuria Vaginal discharge Vulvar irritation, burning, pruritis, or lesions
Signs	Suprapubic tenderness	Endocervical mucopus Vulvar lesions (with herpes)	Vulvar lesions Vulvitis Curdlike vaginal exudate
Laboratory	Pyuria Microscopic hematuria Rapid nitrite test Urine Gram stain Urine culture	Pyuria Urethral discharge or bartholinitis Endocervical exudate Cervical and urethral tests for *C. trachomatis* and *N. gonorrhoeae* Test lesion for HSV	No pyuria Test lesion for HSV Test vaginal discharge for *C. albicans*

$<10^5$ per mL of urine are not likely to be seen on Gram's stain; hence this is not a sensitive test for bacteriuria. The use of urine cultures to confirm the diagnosis of acute cystitis, once universally recommended for all suspected cases, is now considered unnecessary for most women. In women with typical symptoms and signs of acute cystitis and a low risk of STDs, the uropathogens that would be identified by culture and their antimicrobial susceptibility profiles are highly predictable, obviating the need for culture (see Table 55-2). Cultures are most useful to confirm the diagnosis in cases of persistent or recurrent symptoms of UTI, when there are signs of pyelonephritis or other complications, or when there is a history of recent use of antimicrobials. If the patient has pyuria without bacteriuria and is considered to be at risk for STD, or has signs of mucopurulent endocervicitis, specimens from the endocervix and urethra should be tested for *N. gonorrhoeae* and *C. trachomatis.*

The diagnosis of urethritis owing to *C. trachomatis, N. gonorrhoeae*, or HSV rather than the diagnosis of bacterial cystitis is favored by a recent history of acquiring a new sex partner. Genital herpes is suggested by history of genital herpes, exposure to a partner with genital herpes, or the presence of genital lesions (which can also result in external dysuria). Symptoms or signs of abnormally yellow vaginal discharge, or pelvic pain or tenderness, or other signs of pelvic inflammatory diseases (PIDs) in the woman with internal dysuria suggest gonorrhea or chlamydial infection. Infection with *N. gonorrhoeae* or *C. trachomatis* is suggested by the presence of expressible urethral discharge (Fig. 55-2), inflammation of Skene's glands (Fig. 55-3), bartholinitis (Fig. 55-4), mucopurulent cervicitis (MPC) (Figs. 55-5 and 55-6), or proctitis. Findings that favor cystitis rather than urethritis include a history of previous cystitis, history of onset of symptoms within 24 hours after sexual intercourse, prominent frequency or urgency as well as dysuria, and history of gross hematuria.[7,12] Cystitis is also suggested by a history of current spermicide or diaphragm use, which appear to increase the risk of cystitis in young women by altering the vaginal bacterial

FIGURE 55-2. Urethritis in a female caused by *N. gonorrhoeae*. Pus can be expressed from the urethral orifice by compressing the urethra against the pubic symphysis.

FIGURE 55-3. Purulent discharge from Skene's gland. This can be caused by *N. gonorrhoeae or C. trachomatis.*

FIGURE 55-4. Acute batholinitis caused by *N. gonorrhoeae*. Pus is expressesd from the orifice of Bartholin's duct, which opens in the posterior portion of the labia minor and runs posteriorly toward the rectum.

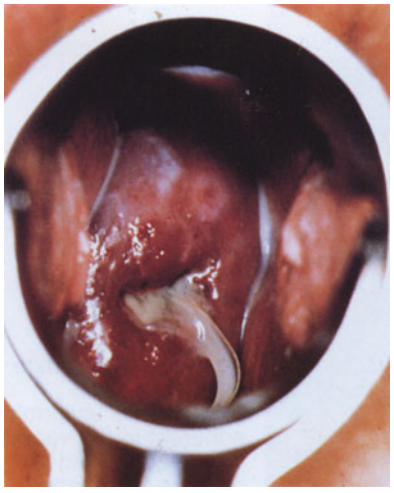

FIGURE 55-5. Mucopurulent cervicitis caused by *C. trachomatis*. Note pus mixed with mucus (indicating source from the endocervix); also note ectopy, edema, and bleeding.

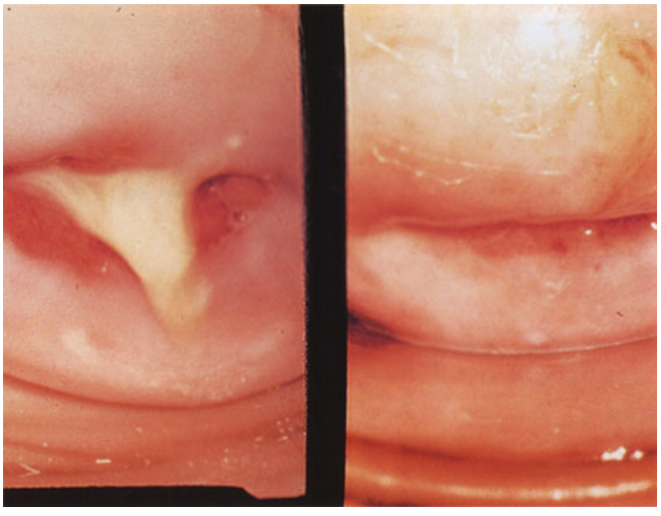

FIGURE 55-6. Mucopurulent cervicitis caused by *C. trachomatis*, before and after treatment with doxycycline.

flora,[4,6] but which may be associated with decreased risk of cervical infection. Acute onset of severe dysuria leading to consultation within 4 days after onset favors a diagnosis of bacterial cystitis (or perhaps gonococcal urethritis), whereas a history of gradual onset of milder symptoms and long duration of symptoms before seeking therapy (≥7 days) suggests chlamydial urethritis.[12] Suprapubic tenderness and microscopic hematuria are also highly suggestive of cystitis in the acutely dysuric patient.[12]

External dysuria (vulvar burning during urination) owing to vulvitis is produced most commonly by genital herpes or by vulvovaginal candidiasis.[19,20] Perhaps the less common conditions discussed in Chapters 62 and 64 can also produce this symptom. With trichomoniasis, no significant correlation was found with dysuria or frequency, after adjustment for coinfections.[24] The patient with external dysuria should be questioned about history of genital herpes or exposure to herpes, or about risk factors for vulvovaginal candidiasis, such as recent antibiotic use, or history of VVC.

Women with clinical findings suggestive of uncomplicated bacterial cystitis (or with microscopic evidence of pyuria and bacteriuria as well) should generally be treated with a 3-day course of antimicrobial therapy.[25,26] If the temperature exceeds 38.3°C (101°F), symptoms have been present for longer than 1 week, or there is costovertebral angle pain or tenderness, the presence of pyelonephritis should be considered, and longer treatment is needed.[26] Over 25% of coliform isolates from women with acute cystitis are currently resistant to sulfonamides, ampicillin, tetracyclines, and first-generation cephalosporins. These organisms, as well as *S. saprophyticus*, generally remain susceptible to sulfamethoxazole-trimethoprim, trimethoprim alone, nitrofurantoin, the fluoroquinolones, or amoxicillin-clavulanic acid.[27] However, an increasing proportion (now up to 15–20% in the United States and even higher in southern Europe, Asia, and Israel are now resistant to TMP/SMX, which limits the effectiveness of this agent in those areas where resistance is frequent.[28] Resistance to fluoroquinones among *E. coli* strains causing acute cystitis remains infrequent in the United States but has increased to 5% or more in the same areas in which TMP resistance has increased.[29,30] Thus, the clinician needs to know the epidemiology of resistance among *E. coli* strains causing cystitis in order to select empiric therapy.[31] Three days of treatment with TMP, TMP/SMX, or a fluoroquinolone provides excellent results when treating acute cystitis caused by uropathogens sensitive to those drugs.[25] TMP or TMP/SMX should be used as the preferred empiric regimen in areas in which the prevalence of resistance does not exceed 20%.[31] Specific regimens include trimethoprim (100 mg PO q12h); TMP/SMX (160 plus 800 mg q12); ciprofloxacin (250 mg q12h); or levofloxacin 250 mg daily).[26] These 3-day regimens are more effective than single-dose therapy and are as effective as 7 days of therapy. Further, both cost and rates of side effects are lower than those seen with 7 days of therapy. However, β-lactams and nitrofurantoin generally provide better cure rates with 7 days of therapy than with 3 days. Despite appropriate antibiotic therapy, recurrent infections occur in 25–35% treated women, most commonly among women given amoxicillin or amoxicillin-clavulanic acid.[5,27]

Recurrent infections should likewise be treated with a 3-day regimen of TMP/SMX or a fluoroquinolone such as ciprofloxacin or levofloxacin. There is no benefit in investigating most such women urologically or with imaging procedures as almost all are normal. If recurrences continue to occur, low dose antimicrobial prophylaxis is effective.[32]

Women suspected of having urethritis owing to chlamydia (because of pyuria without microscopic evidence of bacteriuria, together with other compatible clinical or epidemiological findings) should be treated with azithromycin (1.0 gm) or with

a tetracycline regimen such as 100 mg doxycycline twice daily for 1 week while urine cultures are pending. The latter regimen was significantly more effective than placebo in curing symptoms of the urethral syndrome in women with pyuria and would also be adequate in many bladder infections caused by common uropathogens.[12] Male sex partners of women with suspected or confirmed gonococcal or chlamydial urethritis should be examined and tested to exclude urethral infection, or should be treated for exposure to these agents.

VULVOVAGINITIS AND VAGINAL DISCHARGE SYNDROMES

AGE-DEPENDENT DIFFERENCES IN VAGINAL ANATOMY, PHYSIOLOGY, AND FLORA

The normal anatomy, physiology, and microbial ecology of the vagina are age-dependent, and there are also obvious age-dependent differences in the source and microbial etiology of vaginal infections (see Chapters 8 and 42).[33] These factors account for very different etiologies of vaginitis in neonates, infants and toddlers, prepubertal girls, and pre- and postmenopausal adults.

During the first month of life, the neonatal vagina, still under the influence of maternal estrogen, is lined by stratified squamous epithelium. From about 1 month of age until puberty, the vagina is lined by cuboidal cells, and the pH of vaginal fluid is normally about 7. After puberty, under the influence of estrogen, the vagina becomes lined by stratified squamous epithelium containing glycogen (Fig. 55-7). With growth of facultative H_2O_2-producing species of lactobacillus, such as *L. crispatus* to concentrations of approximately 10^9(mL of vaginal fluid, lactic acid is produced from glycogen, and the pH falls to between 4.0 and 4.5 in normal adult women. The fall in pH, as well as the H_2O_2 production, are considered important in regulating the vaginal flora (see Chapter 18).[34,35] The oxidation–reduction potential (Eh) at the surface of the vaginal epithelium is approximately 0 ± 50 mV in the absence of BV, but is much lower in BV.[36]

FIGURE 55-7. Normal adult vaginal epithelium, showing the basal cell layer with overlying stratum spinosum. Note the absence of an overlying stratum corneum. The transit time for cells moving from the basal layer to the superficial surface of the vaginal epithelium has been estimated to be about 4 days, perhaps one-third that of normal epidermis.

The relative concentration of vaginal microbes has not been extensively characterized in neonates, infants, or prepubertal girls, but the facultative flora most often includes diphtheroids, *S. epidermidis*, γ-hemolytic streptococci, lactobacilli, and coliforms.[37,38] Coliforms are more common in the vagina before puberty (especially among toddlers still in diapers) than after puberty, whereas the reverse is true for lactobacilli, which dominate the vaginal flora of normal postpubertal women.

VAGINITIS IN PREMENARCHAL GIRLS

The neonatal vaginal squamous epithelium resists perinatally transmitted *N. gonorrhoeae* and *C. trachomatis* but is susceptible to perinatally transmitted vaginal candidiasis. Among older infants, the cuboidal vaginal epithelium is susceptible to *N. gonorrhoeae* and *C. trachomatis* but is resistant to candidiasis. Vaginal shedding of *C. trachomatis* does indeed sometimes appear after about 1 month of age in infants who were exposed perinatally but is not generally associated with overt signs of vaginitis in young infants. Vaginal infection by *N. gonorrhoeae* is rare among infants, and with few exceptions it is thought to represent postnatal acquisition.[39]

Among older premenarchal girls, the etiology of vaginal symptoms is correlated with puberty status and with the presence or absence of objective signs of abnormal vaginal discharge. For example, in a study of 54 premenarchal patients with suspected vaginitis and 52 age-matched controls, a microbial pathogen was isolated from the vagina from 14 of 26 with abnormal vaginal discharge, none of 26 with suspected vaginitis who had no vaginal discharge, and none of 52 control subjects (Table 55-3).[40] *N. gonorrhoeae* accounted for one-third of cases of abnormal discharges in prepubertal girls, whereas *C. albicans* or "yeast" was isolated only from those premenarchal girls who were considered to be pubertal (Tanner stages II, III, or IV) on the basis of breast growth.

Streptococcus pyogenes (group A β-hemolytic streptococci) and *Shigella* sp. are also recognized as causes of purulent or bloody vaginal discharge in prepubertal girls.[41–44] Any species of *Shigella* may cause vaginitis in children, but *Shigella flexneri* has been most often implicated and represented a significantly higher proportion of isolates from the vagina than from all other sites in one retrospective study.[43] Shigella vaginitis is often chronic, causes a bloody vaginal discharge in about 50% of recognized cases, and is associated with

diarrhea in only about one-quarter of cases. The predilection of shigella for prepubertal rather than adult vaginitis may be partly attributable to poor survival of this organism below a pH of 5.5.

The etiologic roles of group B *Haemophilus influenzae* and coagulase-positive staphylococci in prepubertal vaginitis are controversial. Group B streptococcal vulvovaginitis has been described in a case series of 13 adolescents and young adults.[45] As indicated in Table 55-3, no specific bacterial pathogen is found in a large proportion of prepubertal girls with abnormal vaginal discharge. However, intravaginal foreign body and poor perineal hygiene are among the leading predisposing factors in young girls, among whom *Enterobius vermicularis* (pinworm) is an acknowledged cause of vulvovaginitis. Although *C. trachomatis* has not been implicated as a common cause of prepubertal vaginitis, this agent was isolated from the vagina from about one-quarter of girls with gonococcal vaginitis and appeared responsible for postgonococcal vaginitis following penicillin treatment in such cases.[46] The occurrence of *C. trachomatis* infection in prepubertal sexually abused girls has been documented in several studies (see Chapter 105).

VULVOVAGINAL SYNDROMES IN ADULT WOMEN

Vaginal infections in adult women ranked among the 25 most common reasons for consulting physicians in private office practice in the United States in a 1979 report from the U.S. CDC. The three most common types of vaginal infections in adult women are BV, vulvovaginal candidiasis, and trichomoniasis (see Chapters 42, 43, and 45).[47]

In the United States, the number of initial visits to private physicians' offices for trichomonal vaginitis declined slowly from an estimated 579,000 in 1966 to 190,000 in 1988, remaining fairly stable since then, with 165,000 visits in 2005.[48] However, the estimated number of new cases of trichomoniasis in the United States, is much higher—7.4 million cases in 2000.[49] Initial visits for other conditions classified as "vaginitis" (presumably including BV, not generally regarded as true vaginitis, vulvovaginal candidiasis, and undiagnosed cases of trichomoniasis) increased from an estimated 1,155,000 in 1966 to nearly 4.5 million per year during 1989, then declined to 3.1 million in 1997 followed by a steady increase to 4.1 million in 2005.[50] (Fig. 55-8) (Genital herpes is discussed in Chapter 24 and vulvovaginal papillomavirus infections in Chapter 28.)

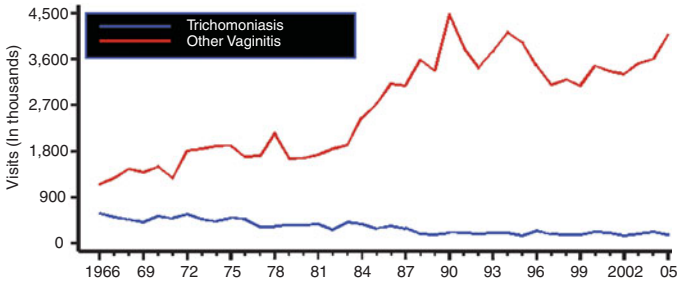

FIGURE 55-8. Trichomoniasis and other vaginal infections in women – Initial visits to physicians' offices: United States, 1966–2005. (Source: Adapted from CDC and IMS Health)

Other types of relatively well-characterized vaginitis syndromes in adults are attributable to microbial or chemical toxins or those associated with physical agents. The most serious and important to rule out is a destructive type of ulcerative vaginitis associated with vaginal infection by toxic shock syndrome (TSS)-associated *Staphylococus aureus*[51,52] and currently attributed at least in part to the action of the TSS toxin 1 on vaginal epithelial cells, upregulating several chemokine and cytokine genes, with influx of lymphocytes into vaginal tissue.[53] Vaginal ulceration and mixed infections have also been associated with the use of vaginal tampons or other retained foreign bodies.[54,55] Cervical caps, detergent spermicides, such as nonoxynol-9, or a vaginal antiseptic preparation actually still sold commercially to consumers in some countries containing policresulin (a condensation product of metacresol sulfonic acid and formaldehyde) can cause vaginitis and vaginal ulceration,[56] as can various chemicals used in douching.[57–59] Vaginal inflammation also has been associated with the use of various traditional vaginal preparations in some developing countries.[60–62]

In postmenopausal women, vaginal symptoms are very prevalent, and the usual forms of vaginal infection need to be considered and differentiated from symptoms attributable to vaginal atrophy.[63,64] Postmenopausal women have a relative depletion of vaginal lactobacilli, which in turn is associated with a higher frequency of vaginal colonization by *E. coli*.[65] The vaginal epithelium becomes thin with estrogen withdrawal, with decreased glycogen and increased pH. Lubrication occurs less often with sexual arousal, the introitus narrows, and the depth of the vagina decreases. These atrophic changes have been negatively correlated with frequency of intercourse and with circulating concentrations of gonadotrophins and androgens in postmenopausal women.[66] Treatment with intravaginal or systemic estrogen is effective. A possibly related syndrome, puerperal vaginal atrophy with dyspareunia, occurs postpartum in relation to the duration of breast-feeding and is sometimes treated with topical estrogen.

A number of other perplexing, chronic vulvovaginal syndromes tend to involve women older than those most often affected by STD.[50,67] These include desquamative inflammatory vaginitis, a syndrome associated with purulent vaginal discharge, massive vaginal cell exfoliation with increased numbers of parabasal cells on vaginal smear, elevated vaginal pH, and gram-positive cocci on Gram's stain of vaginal fluid; this syndrome often responds to intravaginal 2% clindamycin cream.[68] Some experts view this syndrome as the most severe manifestation of what may represent a continuum of vaginitis caused by facultative or aerobic microbial pathogens. Various other forms of irritant or allergic vulvovaginitis have also been described, including those caused by various intravaginal medications, spermicidal products, personal hygiene products, local anesthetics, components of lubricants, latex condoms, and occasional instances in which vulvovaginitis seems to follow intercourse with a particular sex partner.[69] There is some published evidence from small case series for localized vaginal hypersensitivity to human seminal plasma;[70–74] and even for penicillin-induced anaphylactic reactions attributed to sexual exposure to partners who are taking penicillin.[75] Vulvar vestibulitis and essential vulvodynia are other poorly understood vulvovaginal syndromes. Since the etiology of these syndromes remains unknown, treatment is empiric and should be as conservative as possible. Vaginal aphthae, like oral and esophageal aphthae, have been described among women with HIV infection. Among women who present vulvovaginal symptoms with or without dyspareunia, but without objective physical evidence of vulvitis or vaginitis, psychological factors may sometimes be involved.[76] In a recent analysis of a prospective clinical data base of women with chronic vaginitis, the most common diagnoses were contact dermatitis (21%), recurrent vulvovaginal candidiasis (20.5%), atrophic vaginitis (14.5%), and vulvar vestibulitis syndrome (12.5%).[77] Women with desquamative inflammatory vaginitis were older; those with vulvar vestibulitis more often complained of dyspareunia. Psychiatric disorders (44%) and atopy (43%) were common.

DIFFERENTIAL DIAGNOSIS AND MANAGEMENT OF VAGINAL DISCHARGE

Symptoms or signs of abnormal vaginal discharge are usually attributable to vaginal infection. As shown in Table 55-4, in analyses adjusted for detection of cervical or vaginal infections, signs of increased profuse vaginal discharge among STD clinic patients were associated only with isolation of *T. vaginalis;* foul or fishy odor volatilized after adding 10% KOH to vaginal fluid was associated strongly with BV and also with with *T. vaginalis*; and yellow color of vaginal discharge was significantly and independently associated with detection of HSV, *T. vaginalis, N. gonorrhoeae*, and *C. trachomatis*.[18] The relationship of symptoms or signs of abnormal vaginal discharge to cervical infection has undergone reevaluation in recent years. Few recent studies have found statistically significant associations between symptoms of vaginal discharge and cervical infection; and where found, such associations could represent coincidental sexual acquisition of cervical infection together with trichomoniasis or BV. Several studies have demonstrated no association of cervical gonococcal or chlamydial infection with symptoms or signs of abnormally increased amount or abnormal odor of vaginal discharge.[18,78,79]

In contrast, and not surprisingly, symptoms and signs of abnormal vaginal discharge have been predictive of vaginal infections. For example, in a large 1998–1999 survey of healthy women in rural Peru, over half of the women with symptoms of malodorous vaginal discharge, or signs of abnormal discharge, or both had BV or trichomoniasis[80] and thus could benefit from metronidazole therapy.

Modified with permission from Ryan CA, Courtois BN, Hawes SE, Stevens CE, Eschenbach DA, Holmes KK. Risk assessment, symptoms and signs as predictors of vulvovaginal and cervical infections in urban U.S. STD clinic: implications for use of STD algorithms. *Sex Transm Infect* 1998; 74(Suppl 1): S59–S76.

The initial assessment of the patient for vulvovaginal infection ideally should begin with an open-ended question about the reason for the clinic visit (i.e., the chief complaint), since a chief complaint of vaginal discharge is most predictive of vaginal infection. An alternative or intermediate step is a semistructured but nonleading question (e.g., "Do you have any abnormal genital symptoms?" or "Do you have any new symptoms that make you think you might have a vaginal infection or an STD?"). A leading question, such as "Do you have a vaginal discharge?" generates very nonspecific responses of low predictive value for vaginal infection. More specific questions concerning abnormal vaginal discharge, as a follow-up to an initial open-ended question should probe the following three main types of abnormality and focus on recent changes in symptoms to further increase specificity of positive responses, such as "Have you recently developed (1) an abnormal increase in the amount of vaginal discharge? (2) an abnormal and unpleasant odor of vaginal discharge? (3) an unusually yellow color of vaginal discharge?" Unfortunately, the terminology commonly used in clinical practice (i.e., "leukorrhea," "physiologic leucorrhea," or the equivalents in other languages) may have little utility.

Specific questions directed toward vulvar disease also should focus on the main types of vulvar abnormality and on recent changes in symptoms, such as (1) "Have you recently developed abnormal itching or burning pain at the opening of the vagina (the vulva)? (2) any open sores or painful lesions at the opening of the vagina? (3) any lumps or swellings at the opening of the vagina?" Positive responses should lead to probing about past history of such symptoms, because of the recurrent nature of genital herpes or vulvovaginal candidiasis, and the chronicity of other conditions described above.

Vulvar and perineal inspection and speculum examination are indicated to detect signs of vulvovaginitis, and also to identify other types of ectocervicitis (e.g., herpetic ulcerations, and "strawberry cervix" with trichomoniasis), and to identify manifestations of cervico-vaginal HPV infection, epithelial dysplasia, and cancer; to detect vulvovaginal ulcers, and less common types of severe vulvovaginal pathology (see the following); to establish the presence or absence of MPC; and to obtain specimens to test for specific microbial pathogens.

The amount, consistency, and location of the discharge within the vagina should be noted. A sample of discharge should then be removed with a swab from the vaginal wall, avoiding contamination with cervical mucus. The color of vaginal discharge should be noted in comparison with the white color of the swab. The pH should be determined directly by rolling the swab containing the specimen onto appropriate pH indicator paper, which should show color variation with pH above and below 4.5. An additional specimen should be removed with a swab and mixed first with a drop of saline, then with a drop of 10% KOH, on a microscope slide. Any abnormal fishy (amine) odor released after mixing the specimen with KOH is noted, and separate coverslips are placed on both the saline and KOH wet

mounts for microscopic examination to detect the presence and quantity of normal epithelial cells, clue cells, PMN leukocytes, motile trichomonads, or fungal forms, especially fungal hyphae. The presence of any three of the four criteria described by Amsel et al. (homogeneous adherent white discharge, pH >4.5, clue cells and amine odor after mixing the discharge with 10% KOH) provides the usual basis for a clinical diagnosis of BV.[81] Where microscopic examination of vaginal fluid is not possible, various rapid point-of-care tests can be used by the clinician to screen for BV.[82,83] For example, the QuickVue Advance® test for pH ≥ 4.7 and amines;[84] the QuickVue Advance® test for proline aminopeptidase; and the OSOM BV Blue test for sialidase have correlated fairly well in a few studies with results of the Amsel criteria and with Gram stain criteria for diagnosis of BV. Gram stain criteria or oligonucleotide probe testing are used on an increasing but still very limited basis for laboratory diagnosis of vaginal conditions (see Chapter 42).

Although the sensitivity and specificity of individual symptoms and signs as outlined above and in Table 55-5 are not high, in many patients, symptoms and signs combined with risk assessment and with pH and amine tests and microscopic wet mount findings correspond to a consistent pattern, and further diagnostic tests are unnecessary. However, when symptoms or signs suggest a vaginal infection that cannot be confirmed by microscopic wet mount examination, further microbiological studies are indicated. Depending on the clinical findings, these further studies may include culture for *C. albicans,* culture for *T. vaginalis*, or Gram's stain of vaginal fluid to differentiate between normal flora and the flora characteristic of BV or other forms of vaginitis.[18,19] In women with prominent vaginal symptoms but no abnormal findings, all three of these additional microbiological tests may be indicated to differentiate vaginal infection from other causes of vaginal symptoms, including psychosexual factors.[76] Although evaluation and treatment of sex partners is not currently recommended for partners of women with BV or vulvovaginal candidiasis, male partners of women with vaginal trichomoniasis should be treated with metronidazole 2 gm single oral dose (probably this should also be offered to any female partners); and recent progress in diagnosis of trichomoniasis in men[85] has improved the likelihood of detecting trichomoniasis in the male partner.

A proposed pH based algorithms for diagnosing vaginal infections

Because of the lack of specificity of clinical symptoms and signs in allowing practitioner-based diagnosis, or self-diagnosis, a pH based algorithm has been suggested[86] as a practical guide for practitioners in facilitating diagnosis and therapy of vaginitis which is no longer based on empiricism (Fig. 55-10). This transition from symptom- or sign-based (syndromic) clinical assessment to an objective data-driven process represents a further step towards specific diagnosis. The pH based system rests on the premise that during acute vulvovaginal candidiasis whether uncomplicated or complicated, the vaginal pH remains unchanged and within the normal range of 4–4.5. It further utilizes the remarkable stability of the vaginal pH at 4–4.5 found in healthy women throughout most of the menstrual cycle, although an elevation does occur during menses. While it is recognized that a variety of physiologic and nonphysiologic short- and long-term causes of altered pH can occur in the absence of infection, the measurement of the vaginal pH represents a useful, simple signpost directing clinical decision making.

Vaginal pH is best measured by avoiding cervical mucous as well as not using the vaginal secretions that normally accumulate in the lower blade of a speculum. The most reliable method requires using a conventional swab to rub the middle third of the vaginal walls until the cotton swab becomes moist. The pH should be immediately determined using conventional techniques with pH paper. Several commercial interests are attempting to expedite measurement of pH by the practitioner as well as by patient self-interpretation of a self-obtained specimen. Physiologic causes for an elevated pH in excess of 4.5 include menses, bleeding from any source, the presence of semen for up to approximately 8–12 hours, recent and particularly prolonged use of systemic and local antibiotics, which may deplete the physiologic vaginal flora, as well as pH elevation in the absence of estrogen. Thus, an elevated pH in a postmenopausal woman is an early indicator of local vaginal estrogen deficiency. The normal vaginal pH reflects the production of vaginal organic acids, which include lactic acid. The local production of organic acids by indigenous vaginal flora is predominantly attributable to lactobacilli but also, potentially, partially attributable to other bacterial species. The substrate for the lactic acid production is predominantly glycogen. Another frequent cause of elevated vaginal pH includes recent and perhaps chronically repeated vaginal douching.

Accordingly in a symptomatic patient, the finding of a normal pH usually indicates the absence of BV, trichomoniasis, or atrophic vaginitis (Fig. 55-9). This also serves to exclude a number of rare causes of inflammatory vaginitis of noninfectious etiology e.g., desquamative inflammatory vaginitis

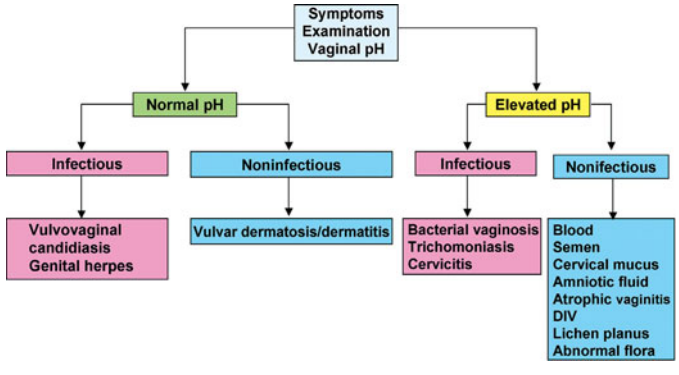

FIGURE 55-9. pH-based algorithm for diagnosing vaginal infection. (Modified from Nyirjesy P, Sobel JD. Advances in diagnosing vaginitis: development of a new algorithm. *Curr Infect Dis Rep* 2005; 7: 458–462.)

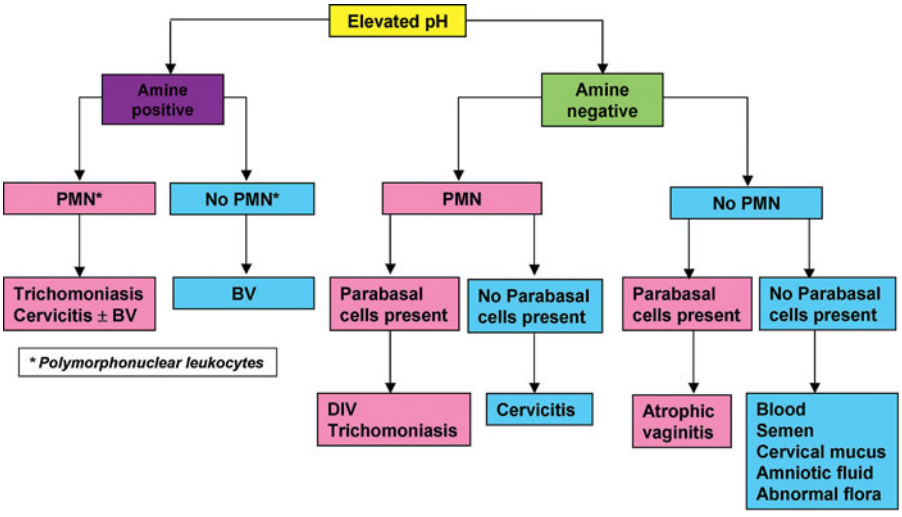

FIGURE 55-10. Use of vaginal pH and amine test, and of screening for polymorphonuclear leucocytes (PMNs) and para basal cells, in diagnosis of vaginal infections. (From Nyirjesy P, Sobel JD. Advances in diagnosing vaginitis: development of a new algorithm. *Curr Infect Dis Rep* 2005; 7: 458–462.)

(DIV). In contrast, an elevated pH while not excluding *Candida*, increases the likelihood of BV or trichomoniasis. Little additional information is gleaned from quantitation of the pH once it is elevated above 4.5. (i.e., a pH of 6 appears to be of no greater diagnostic specificity than a pH of 5.)

With vaginal pH >4.5, a positive amine or "whiff" test further increases the likelihood of abnormal bacterial flora as found in BV and trichomoniasis. A positive amine test does not reliably differentiate BV and trichomoniasis, which frequently coexist. In this diagnostic algorithm, with an elevated pH and positive amine test, the finding of increased PMN leukocytes by microscopic examination of vaginal fluid mixed with saline, strongly suggests trichomoniasis rather than BV. Saline microscopy is also useful in identifying motile trichomonads.

Lactobacillus depletion may follow many types of systemic or local antibiotic therapy—especially after topical intravaginal clindamycin therapy—and a conventional course of therapy with clindamycin may result in an elevated pH for several weeks. The accompanying algorithms have not been validated in prospective studies for diagnosing the cause of vulvovaginal symptoms but reflect the clinical experience of one of the authors (JS) of this chapter.

Treatments recommended in the CDC 2006 STD Treatment Guidelines[87] (see Appendix B and Chapters 42, 43, and 45) for vaginal infections including newer approaches to managing; and chronic or recurrent vaginal infections are briefly summarized in Table 55-5. It is still a common practice to prescribe metronidazole for BV only for those who have complaints related to this condition, despite the associations of BV with PID, preterm delivery, and increased risk of HIV acquisition (see Chapter 42).

Vulvar symptoms

Symptoms of vulvar pruritis or burning, of painful vulvar lesions, and of external dysuria, are most often associated with isolation of HSV or *C. albicans*. Primary genital herpes with cervicitis may also produce symptoms of increased or yellow vaginal discharge, whereas such symptoms do not typically seem to occur with vulvovaginal candidiasis (see Table 55-4).[18]

■ BARTHOLINITIS

Bartholin's gland infection can involve the main duct (which opens near the junction of the anterior two-thirds and posterior one-third of the labia majorum) as well as the minor ducts and glandular acini. Ductal inflammation and obstruction can lead to Bartholin's abscess or cysts, which can reach 1–8 cm in diameter. The etiology of bartholinitis commonly involves *N. gonorrhoeae*, or *C. trachomatis*; abscesses often contain enteric and vaginal gram-negative rods and anaerobes.[88–91] The role of *M. genitalium* has not yet been assessed. The potential role of BV as a risk factor for Bartholinitis (analogous to the role of BV or PID) remains undefined. Unusual etiologies include the respiratory pathogens *Streptococcus pneumoniae* and *Haemophilus* species.[92–94] Ductal exudate or aspirates from abscesses or cysts provide material for microbiologic diagnoses. The differential diagnosis of cysts includes benign tumors such as adenomas and hamartomas as well as carcinoma, especially in postmenopausal women. Treatment of Bartholinitis and Bartholin's abscess probably should cover gonococcal and chlamydial infection, as well as anaerobic bacteria—analogous to treatment of PID. Drainage of abscesses, and excision or marsupulization of cysts are commonly employed.

■ CERVICITIS

Two types of cervicitis can be distinguished—*endocervicitis* (also known as *mucopurulent cervicitis* [MPC]) and *ectocervicitis*. Causes of endocervicitis include *C. trachomatis*, *N. gonorrhoeae*, and herpes simplex virus. Several recent

Table 55-5. Diagnostic Features and Usual Management of Vaginal Infection in Premenopausal Adults

	Normal Vaginal Examination	Yeast Vaginitis	Trichomonal Vaginitis	Bacterial Vaginosis
Etiology	Uninfected; *Lactobacillus* predominant	*Candida albicans* and other yeasts	*Trichomonas vaginalis*	Associated with *G vaginalis*, various other cultivable and non cultivable anaerobic bacteria, and mycoplasma
Typical symptoms	None	Vulvar itching or irritation	Profuse purulent discharge	Malodorous, slightly increased discharge
Discharge:				
Amount	Variable; usually scant	Scant to moderate	Profuse	Moderate
Color[a]	Clear or white	White	Yellow	Usually white or gray
Consistency	Nonhomogeneous, floccular	Clumped; adherent plaques	Homogeneous	Homogeneous, low viscosity; uniformly coating vaginal walls
Inflammation of vulvar or vaginal epithelium	None	Erythema of vaginal epithelium, introitus; vulvar dermatitis common	Erythema of vaginal and vulvar epithelium; colpitis macularis	None
pH of vaginal fluid[b]	Usually ≤4.5	Usually ≤4.5	Often ≥5.0	Usually ≤4.7
Amine ("fishy") odor with 10% KOH	None	None	May be present	Present
Microscopy[c]	Normal epithelial cells; lactobacilli predominate	Leukocytes, epithelial cells; yeast, mycelia, or pseudomycelia in up to 80%	Leukocytes; motile trichomonads seen in 80–90% of symptomatic patients, less often in the absence of symptoms	Clue cells; few leukocytes; lactobacilli outnumbered by profuse *mixed flora, nearly* always including *G vaginalis* plus anaerobic species, on Gram stain
Usual treatment	None	Miconazole, clotrimazole, or other imidazoles (See Chapter 45)	Metronidazole or tinidazole 2.0 g orally (single dose) Metronidazole 500 mg orally twice daily for 7 days	Metronidazole 500 mg orally twice daily for 7 days Intravaginal metronidazole gel or clindamycin cream
Usual management of sex partners	None	None; topical treatment if candidal dermatitis of penis is present	Examine for STD; treat with metronidazole, 2 g po	Examine for STD; no treatment if normal

[a]Color of discharge is determined by examining vaginal discharge against the white background of a swab.

[b]pH determination is not useful if blood is present.

[c]To detect fungal elements, vaginal fluid is digested with 10% KOH prior to microscopic examination; to examine for other features, fluid is mixed (1:1) with physiologic saline. Gram's stain also is excellent for detecting yeasts and pseudomycelia and for distinguishing normal flora from the mixed flora seen in bacterial vaginosis, but is less sensitive than the saline preparation for detection of *T. vaginalis*.

studies have also implicated *Mycoplasma genitalium*.[16,95–97] HSV infection can also be associated with ectocervicitis, and will be discussed separately in the following. The presence of cervical infection is not synonymous with the term "cervicitis," since not all infections are associated with demonstrable inflammation, and vice versa. For example, a positive test for *C. trachomatis* in an endocervical specimen leads to a diagnosis of chlamydial infection of the cervix, not of necessarily to a diagnosis of chlamydial "cervicitis."

MPC caused by *C. trachomatis* or *N. gonorrhoeae* must be differentiated from endo- and ecto-cervicitis caused by HSV, from ectocervicitis caused by *T. vaginalis*, from vaginitis, and from simple cervical ectopy without inflammation, a common condition (Fig. 55-11). Columnar epithelium lies in an exposed position on the ectocervix in the majority of adolescent girls at the onset of menarche. The prevalence of ectopy gradually declines through young adulthood.[98] The term ectropion has also been used to describe the patulous parous cervix, which opens as the blades of a vaginal speculum are spread, to expose the endocervix. Ectopy or ectropion, when not associated with visible or microscopic evidence of mucopurulent exudate, or with colposcopic epithelial abnormalities, is a normal finding and requires no therapy. Recurrent genital herpes involving the cervix alone produces lesions of the endocervical columnar epithelium and the ectocervical squamous epithelium. Ectocervicitis caused by trichomoniasis and vulvovaginal candidiasis are generally associated with vaginitis, as discussed below.

■ ENDOCERVICITIS

Urethritis in men represents the tip of the iceberg of infections caused by *C. trachomatis, N. gonorrhoeae*, and probably by *M. genitalium*. Endocervical infection, together with subclinical urethral infections in both sexes, represents the portion of the iceberg that often goes unrecognized. The fact that urethritis in the male can result in detection and treatment of cervical infection led to the old adage in venereology: "The man who develops a discharge after sex with a woman could become that woman's best friend." At present, in most of the world, control of these infections unfortunately is based largely on the clinical diagnosis of urethritis in the male and on treatment of the female sex partners of men with urethritis. This is particularly so in the poorest developing countries, where specific laboratory tests for *N. gonorrhoeae* and *C. trachomatis* are rarely available. Because endocervicitis produces symptoms less often than male urethritis, and symptoms of endocervicitis that may occur (e.g., yellow vaginal discharge) are less distinctive than symptoms of urethritis, the careful assessment of clinical signs of MPC, and the appropriate use of laboratory tests for confirming the microbial etiology of MPC, as well as for screening for subclinical infection of the female, are of paramount importance in the control of gonococcal and chlamydial infections.

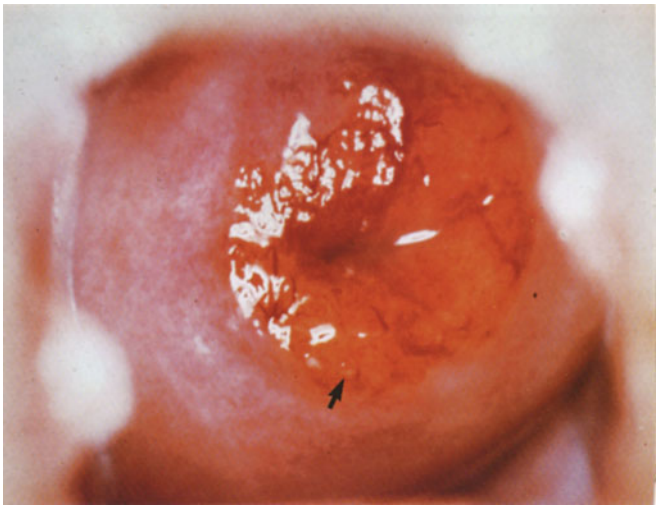

FIGURE 55-11. Cervical ectopy. Endocervical columnar epithelium is present in an ectopic position on the exocervix, giving a bright-red circumoral appearance. Note that the cervical mucus is clear, not purulent. However, also note the small vesicle (arrow) indicative of a very early primary HSV lesion, within the zone of ectopy.

Infection of the cervix represents a reservoir for sexual or perinatal transmission of pathogenic microorganisms, and also might lead to at least two possible types of complications in the female: (1) ascending intralumenal spread of pathogenic organisms from the cervix, producing endometritis and salpingitis; (2) ascending infection during pregnancy, resulting in chorioamnionitis, premature rupture of membranes, premature delivery, amniotic fluid infection, and puerperal infection.

The lack of widely recognized objective signs of cervical inflammation is illustrated by the confusing nomenclature for endocervicitis. Terms such as acute and chronic cervicitis, cervical erosion, cervical discontinuity, MPC, papillary cervicitis, follicular cervicitis, and hypertrophic cervicitis have all been used. This confusion results in part from the changes that occur in the cervix over the reproductive period and in part from difficulty in differentiating normal ectopic columnar epithelium from endocervicitis.[98–101] The latter differentiation is complicated by the fact that cervical ectopy (Fig. 55-11) has been correlated with the detection of cervical infection by *C. trachomatis* in most studies.[98,102–104] Ectopy is present in the majority of younger teenage girls, and decreases steadily in prevalence with increasing age. Further, ectopy is significantly positively correlated with oral contraceptive use, and inversely correlated with smoking, independent of age.[98]

In this chapter, the term *mucopurulent endocervical discharge* (or *endocervical mucopus*) refers to yellow endocervical exudate or increased numbers of neutrophils in endocervical mucus as demonstrated by Gram's stain (see the following). The yellow color is thought to be caused by the presence of the "green enzyme" myeloperoxidase contained within PMN neutrophils.

Mucopurulent endocervicitis refers to the appearance of the inflamed endocervix on physical examination—optimally by colposcopy—with manifestations such as yellow endocervical discharge, edema and erythema of the zone of ectopy, and easily induced endocervical bleeding. *Endocervicitis* refers to histopathologic features of endocervical inflammation.

Definition and etiology of mucopurulent cervicitis

Rees et al.[105] and then Brunham et al.[106] initially established the relationship of *C. trachomatis* to MPC.[105] Brunham studied randomly selected women attending an STD clinic in Seattle for the correlation of selected cervical abnormalities with isolation of *C. trachomatis, N. gonorrhoeae*, and HSV.[106] *C. trachomatis* was isolated from 22%, and *N. gonorrhoeae* from 16%. The presence of yellow endocervical exudate, confirmed by the simple identification of yellow exudate on a white cotton-tipped swab specimen of endocervical secretions, correlated only with isolation of *C. trachomatis*. Mucopurulent secretions were present in 62% of women with cervical chlamydial infection and 12% of women with no cervical pathogen. Bleeding produced by collection of culture specimens from the endocervix, erythema (owing to increased vascularity), and edema of the zone of ectopy were also more common among women with *C. trachomatis* infection (Fig. 55-12). Examples of some of these findings are also shown in Figs. 55-5 and 55-6. Microscopic detection of increased numbers of neutrophils demonstrated by Gram's stain within the faintly pink strands of endocervical mucus, collected after first removing ectocervical vaginal cells with a large swab, and examined as described in the following, was also correlated with isolation of *C. trachomatis* (Figs. 55-13 and 55-14).

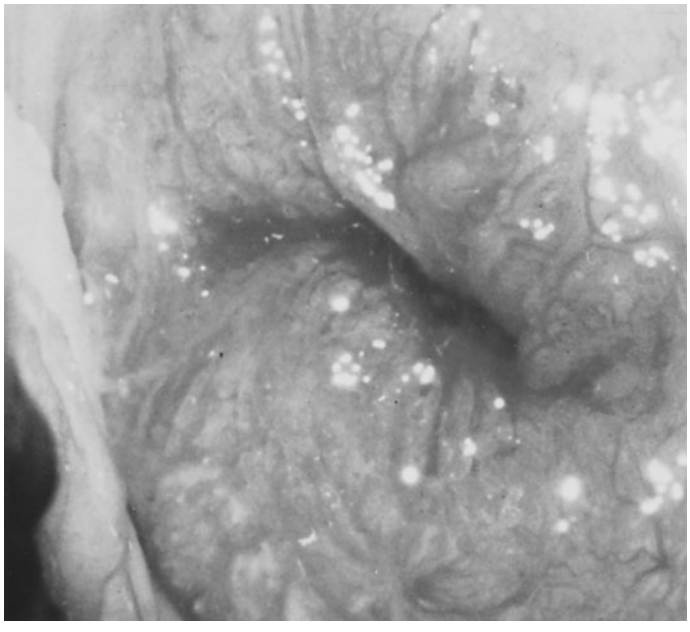

FIGURE 55-12. Colpophotograph of the cervix infected with *C. trachomatis*, showing proliferation and dilation of subepithelial capillaries in the zone of ectopy.

In a 1984–1986 study of a larger series of 779 consecutive women attending the Seattle STD clinic, when the prevalence of endocervical chlamydial and gonococcal infection by culture were 15% and 14%, respectively, we found that the presence of yellow mucopus collected from the endocervix and visualized on a white swab was independently correlated not only with isolation from the cervix of *C. trachomatis*, but also with isolation of *N. gonorrhoeae* and of HSV from the endocervix, and with isolation of *T. vaginalis* from the vagina.[18] A subsequent retrospective analysis of endocervical specimens from 719 of these 779 patients studied during 1982–1984 also found that *M. genitalium* was associated with MPC. We identified *M. genitalium* by PCR in 24 (11.2%) of 215 patients with MPC (defined either as visible mucopus or $\geq$ 30 PMNs) versus 26 (5.2%) of 504 patients without MPC.[95] (Fig. 55-15) displays the proportion of women with endocervical mucopus in that study found to have *N. gonorrhoeae, C. trachomatis*, HSV, *T. vaginalis*, or *M. genitalium* alone or in mixed infections; 36% of those with MPC had none of these pathogens. In populations with lower prevalence of these pathogens (including the same

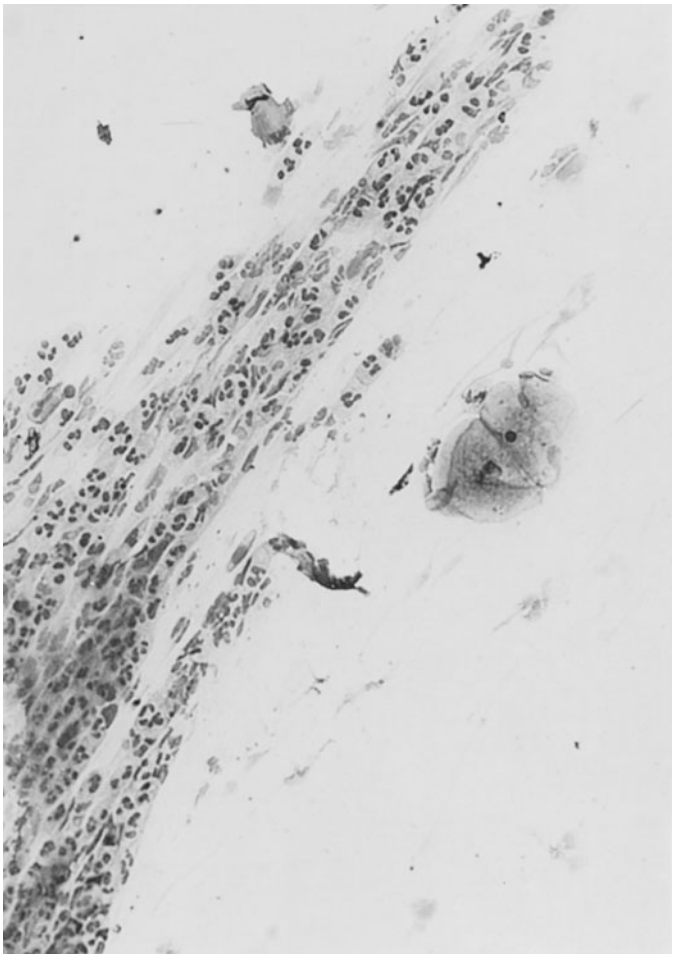

FIGURE 55-13. Satisfactory smear of endocervical mucus from chlamydial mucopurulent cervicitis, showing many neutrophils in strands of mucus, with few contaminating vaginal squamous cells or bacteria.

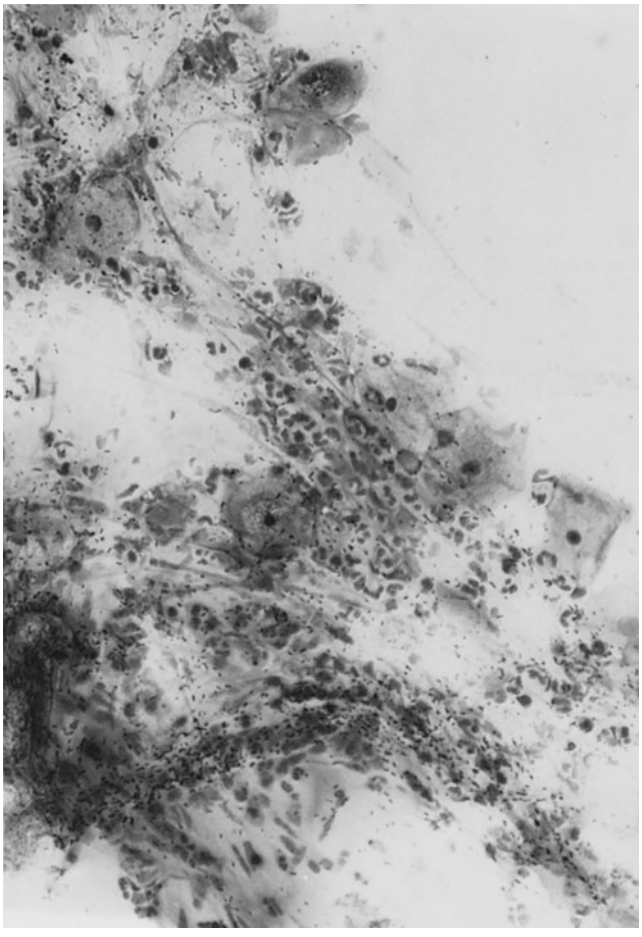

FIGURE 55-14. Unsatisfactory smear of cervical mucus. Although moderate numbers of neutrophils are seen, the presence of many vaginal squamous cells and bacteria makes it difficult to tell whether the neutrophils originate in the cervix or the vagina.

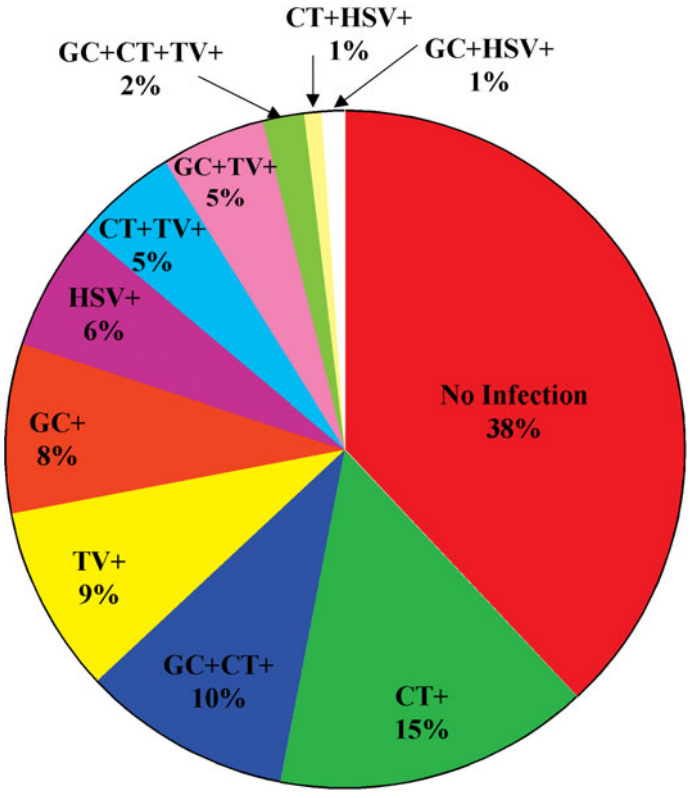

FIGURE 55-15. Among 779 consecutive female STD clinic patients, 182 (23.4%) had signs of endocervical mucopus. This pie chart shows the percentage of those with endocervical mucopus no cervical infection, or cervical infection by *C. trachomatis* (CT), *N. gonorrhoeae* (GC), herpes simplex virus (HSV), or *T. vaginalis* (TV).

Seattle STD Clinic today[107]), smaller proportions of those with mucopus would have these infections. *N. gonorrhoeae* or *C. trachomatis* were isolated from 45% of those with endocervical mucopus and 14% of those without endocervical mucopus in this 1982–1984 study. By multivariate analysis adjusting for other infections, chlamydial infection was also significantly associated with cervical ectopy and with cervical bleeding that was easily induced with a dacron swab (commonly mistermed cervical "friability," see Table 55-4.) Gonococcal and chlamydial infection, cervical HSV infection, and trichomoniasis all were also associated with signs of yellow vaginal discharge on speculum examination, but neither gonococcal nor chlamydial infection was associated with objective signs of profuse vaginal discharge.

Initial efforts to develop clinical algorithms for syndromic management of STDs were based on the premise that symptoms of vaginal discharge could identify women with increased risk of gonococcal and chlamydial infection, and that this could be the basis for improved control of these infections in the population. When this approach failed to identify women with increased prevalence of cervical infection, especially after adjusting for the presence or absence of BV or trichomoniasis, which tend to be associated with gonococcal or chlamydial infection, a modified approach was proposed by the World Health Organization, in which risk assessment was added to try to identify a subset of women with vaginal discharge who might have a higher prevalence of cervical infection, sufficient to warrant presumptive treatment for cervical infection. In general, although various locally derived strategies for risk assessment did help to identify those with increased prevalence, the positive predictive values for cervical infection were still too low to warrant routine treatment in most settings; the basic flaw was the lack of correlation of symptoms of an increased amount of vaginal discharge with cervical infection in most studies.[108] The question then arises: If endocervical mucopus or easily induced cervical bleeding are the true clinical manifestations of cervical infection, would addition of risk assessment *after detection of mucopus*, help to further discriminate those with from those without cervical infection; and prove more useful for syndromic management algorithms in which speculum examination was performed? Applying this more logical approach to the above data set for 779 Seattle women who had an overall prevalence of cervical gonococcal or chlamydial infection of 24%, the prevalence of

Table 55-6. Performance of Risk Assessment (RA) in Identifying Gonococcal and Chlamydial Infection Among Women With and Without Signs of Endocervical Mucopus

	Endocervical Mucopus Present		Endocervical Mucopus Absent	
	RA Positive	RA Negative	RA Positive	RA Negative
	(N = 119)[a]	(N = 63)	(N = 314)	(N = 283)
% GC+	35%	10%	14%	5%
% CT+	37%	27%	12%	7%
% GC or CT+	57%	21%	23%	11%
Sensitivity[b]	78%		70%	
Specificity[b]	45%		51%	
Positive P.V.[b]	57%		23%	
Negative P.V.[b]	69%		89%	

[a]Risk assessment positive = partner with gonorrhea or chlamydia or 2 or more of the following: age <21, no use of barrier contraception, new partner in past 30 days, multiple partners in past 30 days.

[b]Sensitivity, specificity, and positive and negative predictive values for detection of GC and/or CT are presented separately for those with, and those without endocervical mucopus.

cervical gonococcal or chlamydial infection was 57% among those with mucopus and positive risk assessment versus only 11% among those with no mucopus and negative risk assessment (Table 55-6). Such an approach might prove useful in various settings for deciding who to treat empirically and when to initiate presumptive partner treatment as well, who to test while deferring treatment, and who to offer neither treatment nor testing nor partner treatment.

In various published studies, the recommended cutoff value indicative of MPC for the number of PMN leukocytes per 1000× microscopic field in endocervical mucus on Gram's stain for diagnoses of endocervical mucopus has been ≥10, ≥20, or ≥30. As shown in Table 55-7, in our study of 779 women, cutoff values of ≥10 neutrophils and ≥30 neutrophils per 1000× field in endocervical mucus both were significantly and independently associated with isolation of *N. gonorrhoeae, C. trachomatis*, and HSV, but only the lower value (≥10) was also associated with isolation of *T. vaginalis*.[13] With respect to detection of *N. gonorrhoeae* or *C. trachomatis*, the finding of ≥10 PMN(1000× field in cervical mucus had a sensitivity of 80.4%, a specificity of 48.3%, and a positive predictive value of 33% in this population, with its 24% prevalence of either infection. The finding of ≥30 PMN had a lower sensitivity of 46.6%, a higher specificity of 80.2%, and higher positive predictive value of 43%. Neither finding was as accurate as detection of yellow endocervical mucopus, which had a sensitivity of 52%, specificity of 82%, and positive predictive value of 48%.[18]

Changing prevalence and etiology of mucopurulent endocervical discharge

In recent years, at the Public Health Seattle-King County STD Clinic at Harborview Medical Center the proportion of new problem male visits associated with a diagnosis of urethritis has fallen, as has the proportion of men with urethritis who have associated with gonococcal or chlamydial infection. Similarly, among 6230 women visiting Seattle STD clinics from 1995–1999[107] (i.e., 12–15 years after the 1982–1984 study of MPC, when the prevalence of gonorrhea or chlamydial infection or both was 24%) the prevalence of either or both of these infections had fallen to 10%. Endocervical gonococcal or chlamydial infection were independently associated with age less than 25 years, endocervical mucopus or induced bleeding, or >30 PMNs on endocervical Gram stain, but the positive predictive value of any of those signs of endocervicitis was considered high enough to warrant presumptive treatment only in those younger than 25 years of age—with results of specific laboratory tests now recommended to guide treatment for women 25 years of age or older.[107]

Several published studies on the prevalence of endocervical gonococcal and chlamydial infections, and on the prevalence of endocervical mucopus on speculum examination, are summarized in Table 55-8, in relation to the year and type of population studied.[18,106,109–125] Some but not all of these studies enrolled only women with symptoms,

Table 55-7. Percentage of Infection Among 779 Randomly Selected Female STD Clinic Patients With and Without Increased Concentrations of Polymorphonuclear (PMN) Leukocytes in Cervical Mucus or Vaginal Fluid[a]

	% Infected with Finding	% Uninfected without Finding	Unadjusted OR (95%CI)[b]	Adjusted OR (95%CI)[b, c]

[c]Mucopus defined as yellow or "brown" cervical mucus in this study.

such as abnormal vaginal discharge or lower abdominal pain; many did not test for HSV or *T. vaginalis* infection. The prevalence of gonococcal or chlamydial endocervical infection ranged from as low as 2.7% in the U.S. Region X family planning clinics in 1995–1996 to as high as 37% in female sex workers (FSWs) in Cebu City, the Philippines.[121] The reported prevalence of endocervical mucopus observed by speculum ranged from 2.8% in Cebu FSWs (perhaps representing insensitive screening for mucopus) to 50.7% (probably representing nonspecific detection of mucopus) in Moroccan family planning clinics enrolling women with symptoms of vaginal discharge or lower

abdominal pain.[78,121] This wide range reflects the importance (and difficulty) of training health-care providers to accurately screen for this finding. It is also not surprising that surveys of healthy women in the general population (as opposed to studies of women seeking care for genital symptoms or exposure to an STI) have shown only weak correlations of symptoms and signs of cervical inflammation with detection of *C. trachomatis* or *N. gonorrhoeae*.[80] Nonetheless, of the 19 studies cited, 16 found significant associations of endocervical mucopus (usually defined as a positive "swab test," meaning yellow color of endocervical discharge visualized on a white swab) with endocervical gonococcal or chlamydial infection (with odds ratios [OR] ranging from 2.1 to 5.5); and the remaining three (all done in family planning or antenatal clinics) did find associations with increased numbers of PMN leukocytes in cervical mucus, or with induced endocervical bleeding. Some studies also assessed and found associations of endocervical gonococcal or chlamydial infections with yellow vaginal discharge, or with increased numbers of leukocytes in vaginal smears. [18,115,118,126] This finding may be easier for clinicians to demonstrate in some settings than the demonstration of endocervical mucopus, but can reflect vaginal trichomoniasis as well. Many of these studies found no relationship of symptoms of vaginal discharge to presence or absence of endocervical gonococcal or chlamydial infection, as discussed earlier.

Although MPC has been significantly correlated with endocervical infection in most of these studies, the sensitivity, specificity, and predictive value have varied in different settings. [18,106,111–125,127–129] It is difficult to assess to what extent the variability is attributable to differences in patients, to differences in assessing MPC, or to differences in detection of infection. Our experience suggests that the correlation of detection of *C. trachomatis* or *N. gonorrhoeae* in the cervix with detection of mucopurulent (yellow) endocervical discharge by an inexperienced clinician is initially low (in which case identification of increased numbers of neutrophils in cervical mucus by an experienced laboratory technician is more reliable); but with training and experience, the correlation improves.

In the absence of proven gonococcal, chlamydial, *M. genitalium* or HSV infection or trichomoniasis, the causes of MPC remain uncertain. Various other genital pathogens have been implicated in single studies, and it is likely that false negative tests for *C. trachomatis, N. gonorrhoeae*, or HSV account for some cases. Just as new microbial etiologies of urethritis and cervicitis (such as *M. genitalium*) have been discovered, it seems likely that further causes will be identified in the future. Hence, the positive predictive values of clinical manifestations of MPC for the detection of *N. gonorrhoeae* and *C. trachomatis* may greatly underestimate the predictive value for infection per se, and may even underestimate the proportion that would respond to syndromic treatment with currently recommended antimicrobial therapies. Similarly, the specificity of signs of cervical inflammation, in terms of cervical infection, are likely to be understated when gonococcal and chlamydial infections are the only infections considered. In addition, it remains possible that oral contraceptive use and cervical ectopy per se, and perhaps some vaginal infections,[130] may be associated with endocervical inflammation.

■ ECTOCERVICITIS

Routine colposcopic examination of female STD clinic patients has shown that cervical HSV infection is highly correlated with cervical ulcers or necrotic lesions (Fig. 55-16), whereas trichomoniasis is correlated with colpitis macularis ("strawberry cervix"), and both *C. trachomatis* and cytomegalovirus infection of the cervix are correlated with colposcopic features of immature metaplasia.[131] Immature metaplasia has been defined as faint acetowhite epithelium (white after application of acetic acid) with diffuse distal borders, occurring as finger-like projections within the transformation zone, at the central margin of a squamocolumnar junction advancing centrally into the zone of ectopy. In a further analysis, colpitis macularis Fig. 55-17 was identified without magnification in only 2 (2%) of 108 women with trichomoniasis; but by colposcopy was identified in 49 (45%) of the 108 with trichomoniasis versus only 6 (1%) of 509 without trichomoniasis.[24] In the 1984-Seattle study of 779 women mentioned above, cervical ulcerations or necrotic lesions were detected by colposcopy in 22 (65%) of 34 women with positive cervical cultures for HSV, and 11 (1.5%) of 745 with negative cultures for HSV.[132] *C. albicans*, like *T. vaginalis*, also can produce ectocervicitis, but both are associated with other manifestations of inflammation of the contiguous stratified squamous vaginal epithelium (Figs. 55-18 and 55-19).

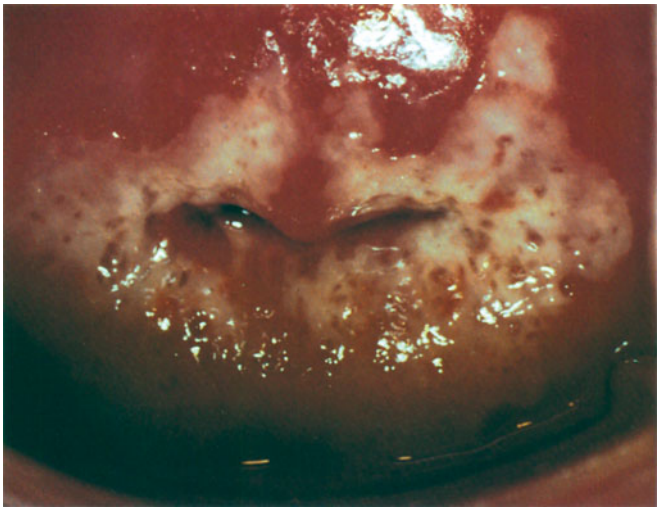

FIGURE 55-16. Severe primary HSV-2 cervicitis. HSV-2 produces both endocervicitis and ectocervicitis.

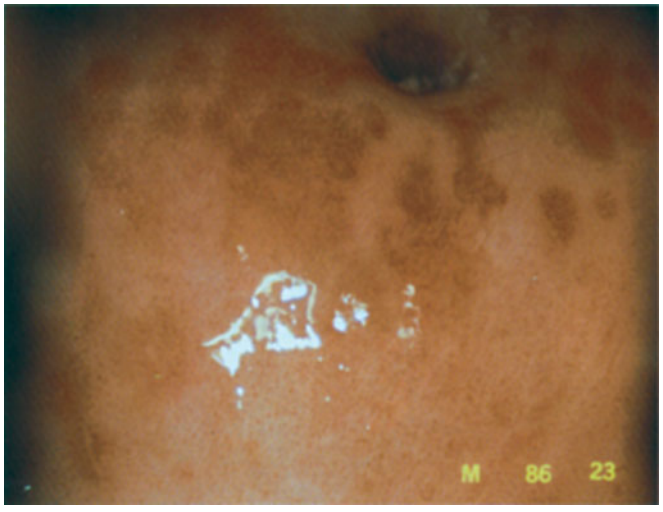

FIGURE 55-17. Colpophotograph of "strawberry cervix" showing petechiae on the ectocervix in a patient with trichomonal vaginitis and ectocervicitis.

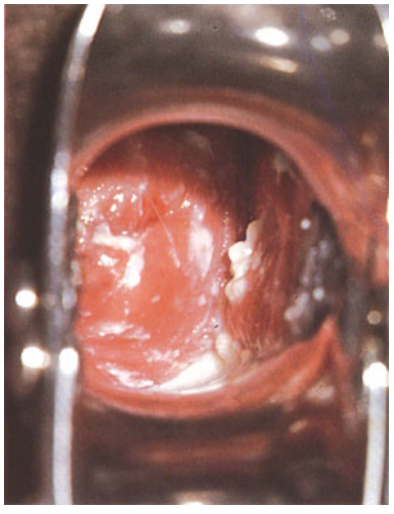

FIGURE 55-18. Cervical-vaginal candidiasis. Note the white nonhomogeneous curd-like, clumped exudates characteristic of candida infection.

Special diagnostic procedures for cervicitis

The presence of endocervicitis can be confirmed by a variety of supplementary diagnostic procedures, most of which should be available to clinicians specializing in treatment of genital infections of women. These include Gram's stain of endocervical mucus, cervical cytology, colposcopy, and cervical biopsy. The gonococcal etiology of endocervicitis can be presumptively established when Gram's stain of endocervical mucus shows gram-negative diplococci; the microbial etiology of cervicitis can be further substantiated by isolation of *C. trachomatis, N. gonorrhoeae*, or HSV, by detection of specific microbial antigens, or by detection of specific nucleic acid sequences from these pathogens or from *M. genitalium*.

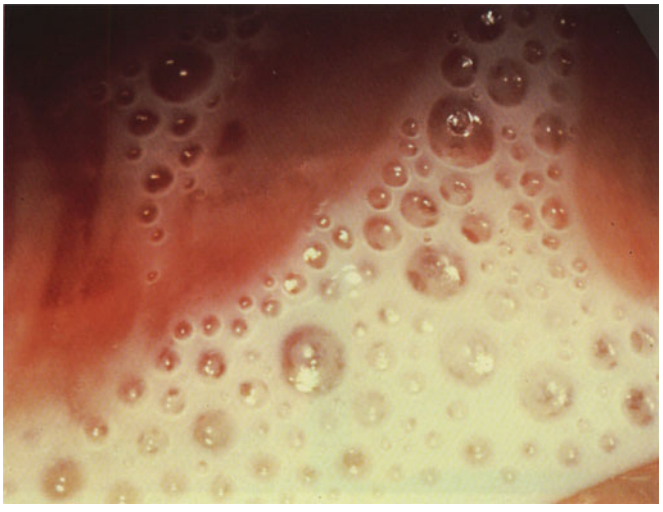

FIGURE 55-19. Profuse purulent vaginal discharge due to trichomoniasis. Color is yellow when viewed on a white swab. Appearance is occasionally frothy, as seen here.

Endocervical Gram stain

Just as sputum is difficult to evaluate microscopically when contaminated by oropharyngeal cells and flora, the endocervical mucus is difficult to evaluate microscopically when contaminated by vaginal cells and flora. The ectocervix is therefore generally wiped clean with a large swab before endocervical mucus is obtained for microscopy. (NOTE: this is recommended to facilitate microscopic examination of endocervical secretions, not necessarily to improve sampling for other specific diagnostic tests such as culture or nucleic acid amplification tests.) Mucus is then obtained from the endocervical canal, rolled in a thin film over a slide, heat-fixed, and stained by Gram's stain. The slide is screened at low magnification (×100) to identify strands of cervical mucus containing PMN, as well as to evaluate the extent of contamination by vaginal squamous cells, and to select representative areas of cervical mucus for closer examination with the oil immersion lens. The number of PMN neutrophils per ×1000 field (oil immersion magnification) within strands of cervical mucus should then be counted in several representative fields. The presence of increased concentrations of PMN in mucus strands supports the diagnosis of cervicitis, unless heavy contamination by vaginal squamous cells (e.g., > 100 squamous cells per slide) and by vaginal flora (e.g., > 100 bacteria per 1000× field overlying cervical mucus) suggest that the neutrophils may have originated in the vagina rather than in the endocervix. Common mistakes are to search areas of the smear other than cervical mucus strands to enumerate PMNs, or to enumerate mononuclear leukocytes rather than PMN. Contamination of the specimen with vaginal flora can also obfuscate the detection of gonococci in endocervical mucus by Gram's stain. As discussed elsewhere, detection of gram-negative diplococci within neutrophils in properly

collected endocervical mucus is highly specific, but gonococci can be identified by Gram's stain in only about 50–60% of women with cervical gonococcal infection.

CYTOPATHOLOGY

An estimated 50 million cervical Pap smears are performed by physicians in private office practices in the United States each year for detection of cervical neoplasia. Cervical cytological screening also can help identify women with cervicitis who require further microbiological studies.

The correlation of cervical intraepithelial neoplasia with human papilloma virus infection is described in Chapter 57. Cytological studies in STD clinic patients and in pregnant women have shown that *C. trachomatis* infection is significantly correlated with certain other epithelial cell changes and inflammatory cell patterns.[133] The epithelial cell changes include so-called reactive changes of metaplastic cells and endocervical cells. Inflammatory changes, which are significantly correlated with *C. trachomatis* infection include the presence of transformed lymphocytes and of increased numbers of histiocytes and plasma cells, as well as increased numbers of neutrophils. Large, inclusion-containing vacuoles in endocervical and metaplastic cells also are correlated with *C. trachomatis* infection, but they are relatively nonspecific and are not present in the majority of women with chlamydial infection. Use of cytopathology to identify cervical inflammation in addition to cervical neoplasia, represents a potential but little used approach to control of cervical infections. This can now be facilitated by nucleic acid amplification testing of liquid Pap smear media.[134,135] "Reflex testing" by nucleic acid amplification for cervical pathogens of specimens yielding inflammatory cervical Pap smears should be viewed as analogous to reflex testing for HPV of liquid Pap smear medium specimens when Pap smears show atypical squamous cell changes of uncertain significance (ASCUS).

COLPOSCOPY

Colposcopy has been increasingly used to evaluate women who have cervical cytological smears consistent with cervical intraepithelial neoplasia, and to obtain directed biopsies of colposcopically visible lesions. Colposcopy has potential utility for use in high-risk patients (e.g., in STD clinics) for screening examinations for cervical dysplasia, and for cervical infection.[131] Colposcopic features of papillomavirus infection and of dysplasia, and the use of simple techniques for visual screening for cervical dysplasia and cancer in developing country settings, where cytology and colposcopy may not be available, are described in Chapter 57. Colposcopic features of MPC are described in the preceding and are illustrated in Figs. 55-16, 55-5, 55-6, 55-18, 55-17, and 55-13.

HISTOPATHOLOGY

In patients with endocervicitis due to *C. trachomatis*, cervical biopsy may show intraepithelial inclusions, which are located in columnar or metaplastic cells. Such inclusions are best demonstrated by immunofluorescence or immunoperoxidase staining (Fig. 55-20). By electron microscopy with special stains, these can be shown to contain typical elementary and reticulate bodies of *C. trachomatis* (Figs. 55-21 and 55-22). Inflammation surrounds endocervical glands in a patchy distribution, and lymphoid follicles, containing germinal center cells (transformed lymphocytes) can be identified in about two-thirds of patients (Fig. 55-23). The majority of cervical biopsy specimens from patients with chlamydia-positive endocervicitis show superficial focal endocervical micro-ulcerations, reactive endocervical cellular changes, stromal and epithelial cellular

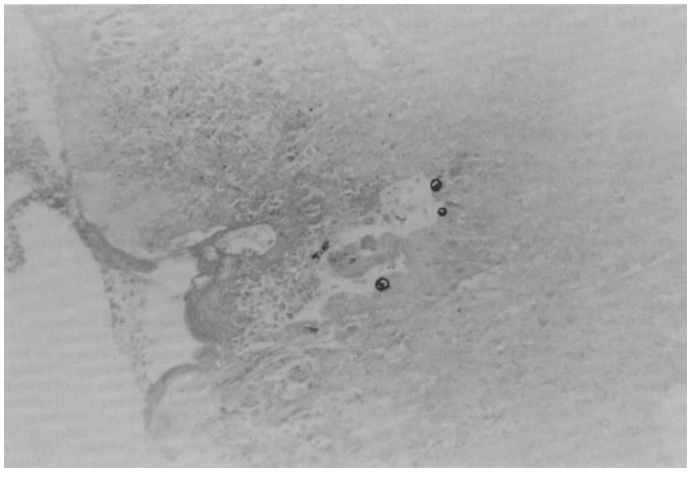

FIGURE 55-20. Immunoperoxidase stain of a cervical biopsy specimen using monoclonal antibodies to *C. trachomatis* showing cervical intraepithelial chlamydial inclusions. (*Courtesy of N. Kiviat.*)

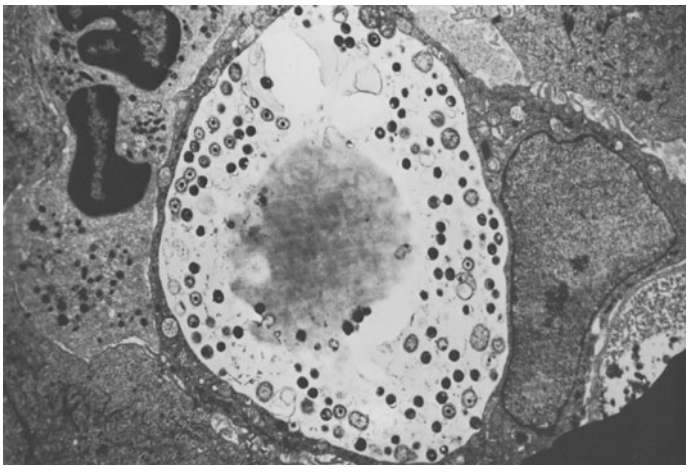

FIGURE 55-22. Electron micrograph of a chlamydial inclusion in cervical biopsy tissue, showing compact elementary bodies, larger reticulate bodies, and intermediate forms that resemble bull's eyes. Uranyl acetate, lead citrate, 12,000× magnification. (*Courtesy of J. Swanson*.)

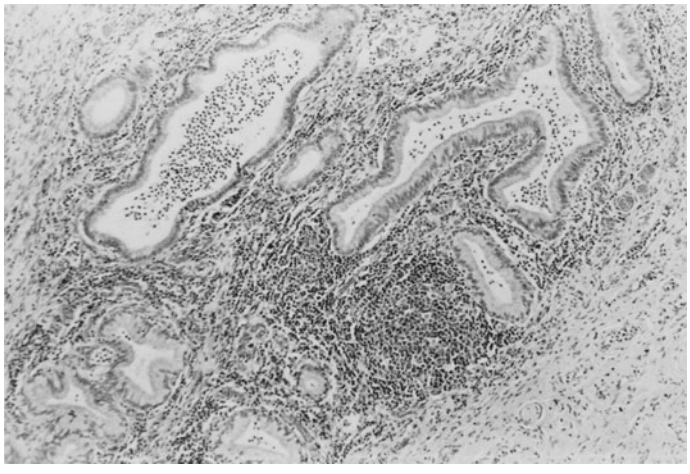

FIGURE 55-23. Endocervical biopsy showing patchy periglandualr Inflammation associated with chlamydial infection. Several gland lumena are filled with neutrophils, with intraepithelial infiltration by neutrophils, and are surrounded by mononuclear cells, predominantly plasma cells. A rounded germinal center containing transformed lymphocytes is present.

edema, dilatation and proliferation of subepithelial capillaries, and stromal inflammatory infiltration, predominantly by plasma cells.[136] These changes resemble those described in ocular trachoma.

There is surprisingly little recent information on the histopathology of cervical infection with *N. gonorrhoeae* or of initial and recurrent episodes of HSV cervicitis, or on the histopathology of cervical *M. genitalium* infection. We have observed that HSV infections differ from chlamydial and gonococcal infections in showing deep, necrotic ulceration with stromal infiltration predominantly by lymphocytes; whereas chlamydial cervicitis differs from gonococcal or HSV cervicitis in showing germinal centers and stromal infiltration predominantly by plasma cells.[136]

CONFIRMATORY MICROBIOLOGICAL STUDIES

To provide the best guide to therapy, patient counseling, and management of sex partners, a specific microbiological diagnosis is desirable in patients with cervicitis. This can be accomplished by isolation of *N. gonorrhoeae, C. trachomatis*, HSV, or *T. vaginalis*; by immunologic detection of microbial antigens; or increasingly by use of nucleic acid probes or DNA amplification/detection methods. A Gram stain of endocervical mucus is useful in patients with suspected endocervicitis, for detection of gram-negative diplococci associated with neutrophils, as well as for quantitation of neutrophils. However, even if gonococci are identified by Gram's stain, confirmatory testing for *N. gonorrhoeae* is desirable, and culture testing has the advantage of allowing tests for beta-lactamase production, and antimicrobial sensitivity. The presence of cervical lesions suggestive of HSV infection warrants confirmatory testing for HSV (see Chapter 21). Viral isolation and nucleic acid amplification tests can permit differentiation of HSV-1 from HSV-2, which has prognostic importance, since HSV-1 is less likely than HSV-2 to cause recurrent genital herpes. If colpitis macularis is seen, wet mount examination for motile trichomonads is usually positive.

TREATMENT FOR MUCOPURULENT CERVICITIS

The 2006 Centers for Disease Control Guidelines for Treatment of STD[87] (see Appendix B) recommend "the results of sensitive tests for *C. trachomatis* and *N. gonorrhoeae* (e.g., nucleic acid amplification tests) should determine the need for treatment subsequent to the initial evaluation." A negative endocervical Gram stain for *N. gonorrhoeae* does not exclude gonorrhea. The guidelines also recommend that management of sex partners of women with MPC should be "appropriate for the identified or suspected STD," and should include examination and treatment for that STD; and further note that management of persistent MPC is unclear, since infection is not often found, and the need for or benefit of further treatment is unproven.

However, among women with coexistent gonococcal and chlamydial infection of the cervix, persistence of *C. trachomatis* has been more common after single-dose ampicillin therapy than after therapy with trimethoprim-sulfamethoxazole; and persistence or development of cervicitis after therapy was correlated with persistence of *C. trachomatis*.[137] Treatment of women with gonococcal infection with 4.8 million units of procaine penicillin G plus probenecid was associated with a significantly higher rate of post-treatment cervicitis and PID than was treatment with drugs effective against *C. trachomatis* (tetracycline or trimethoprim-sulfamethoxazole).[138] Treatment of cervical *C. trachomatis* infection with effective therapy for this pathogen (e.g., 500 mg of tetracycline hydrochloride four times daily for 7 days) has eliminated

mucopurulent endocervical discharge in nearly all women within 3 weeks after completion of therapy.[139] In another small study, women with mucopurulent cervical discharge who also had BV, were all treated with doxycycline plus ofloxacin, and were additionally randomized to also receive treatment either with metronidazole gel for 5 days or with placebo gel. The MPC resolved in 24 (89%) of 27 given the metronidazole gel, versus 15 (62.5%) of 24 given placebo ($p = 0.03$). This small study raises the question as to whether MPC was related as cause or effect to BV, or whether metronidazole might have activity against other organisms involved in causing MPC.[130] The emerging data in treatment of *M. genitalium*-associated cervicitis is reviewed in Chapter 40.

PREVENTION OF LOWER GENITAL TRACT INFECTION IN WOMEN

When used correctly, consistent and correct condom use can be regarded as highly effective in preventing sexual transmission of pathogens that infect the columnar epithelium of the urethra and endocervix (e.g., *N. gonorrhoeae, C. trachomatis*);[140] and recent prospective studies also indicate effectiveness in reducing sexual acquisition of pathogens that can infect the squamous epithelium of the vulva and penis (e.g., HPV and HSV[141,142]); although undoubtedly ineffective in reducing sexual transmission of ectoparasites pathogens that infect the cornified skin or the cutaneous appendages (i.e., *Sarcoptes scabiei, Phthirus pubis*) (see Chapter 47). The efficacy of other intravaginal barrier contraceptives, such as the diaphragm, in reducing transmission of *N. gonorrhoeae* and *C. trachomatis* is being evaluated.

OBSTETRIC, GYNECOLOGIC, AND SYSTEMIC COMPLICATIONS OF LOWER GENITAL TRACT INFECTIONS IN WOMEN

A high index of suspicion for local complications or systemic disease is essential in evaluating women with symptoms or signs of lower genital tract infection.

The differential diagnosis of vulvovaginitis, or Bartholinitis includes potentially catastrophic diseases, including toxic shock syndrome (TSS) and necrotizing fasciitis of the vulva.[143–153] TSS associated with tampon use and menses is associated with temperature >38.9°C; systolic blood pressure <90 mm Hg; rash with subsequent desquamation—especially on palms and soles; involvement of ≥3 of the following organ systems: GI, muscular, mucous membranes (vagina, conjunctiva, pharynx), renal, liver, blood (thrombocytopenia), or central nervous system; and negative tests for causes of similar illnesses (e.g., measles, leptospirosis, Rocky Mountain spotted fever).

Necrotizing fasciitis of the vulva arises from obstetrical or other trauma or episiotomy, vulvar abscess, or Bartholin's abscess, with predisposition for diabetic, alcoholic, or otherwise immunocompromised patients.[143–153] The process involves the superficial fascia and subcutaneous tissue (as opposed to necrotizing cellulitis, which occurs beneath deep fascia and involves muscle). Symptoms and signs often begin with severe tenderness, swelling, and erythema, progressing to an ecchymotic appearance with bullae and skin breakdown, eventually leading to anesthesia and loss of pain following destruction of superficial innervation. The etiology generally is either group A *Streptococcus pyogenes* or anaerobic plus/minus facultative anaerobic species that can produce gas in the tissue with foul odor. The histopathology includes PMN infiltration, with necrosis of fat and superficial fascia, microabscesses and thrombi, and the presence of causative organisms visualized with special stains. Superantigens produced by β-hemolytic streptococci may contribute to local and systemic manifestations. Diagnosis is prompted by a high index of suspicion, and best confirmed by surgical exploration. Management is guided by the phrase, "Be bloody, bold, and resolute" with surgical debridement; together with prompt antimicrobial therapy that covers streptococci and staphylococci, gram-negative pathogens, and anaerobes. In particular, clindamycin is commonly used, and some clinicians use hyperbaric oxygen or immunoglobulin therapy, although the benefits of these adjunctive approaches warrant further study.

Perhaps the most important aspect of the differential diagnosis of MPC is careful evaluation for complicating endometritis or salpingitis. As discussed in the following and in Chapter 49, endometritis, manifested by midline abdominal tenderness or menorrhagia, often with elevation of the erythrocyte sedimentation rate, C-reactive protein, or peripheral white count, and with characteristic histopathological evidence of endometritis, is often present among women with MPC. Among STD clinic patients with MPC studied at the University of Washington, at least 40% had histopathological evidence of plasma cell endometritis.[154] The classic study of Jacobsen and Westrom required the presence of purulent discharge in the vagina (leukocytes must outnumber other cell types) for the diagnosis of salpingitis.[155,156] It seems likely that such discharge is probably attributable to MPC in most if not all cases. Jacobsen and Westrom once stated they had never seen salpingitis laparoscopically in a patient who did not have a purulent vaginal discharge.[157] In contrast, U.S. gynecologists have not required the presence of MPC as a criterion for salpingitis, and in fact guidelines developed for diagnosis of salpingitis by a group of U.S. gynecologists and approved by the Obstetrics and Gynecology Infectious Disease Society did not include this criterion.[158] Nonetheless, detection of MPC is useful in increasing the odds that symptoms of lower abdominal or pelvic pain are attributable to PID (see Chapter 56), or that upper abdominal pleuritic pain is attributable to perihepatitis.

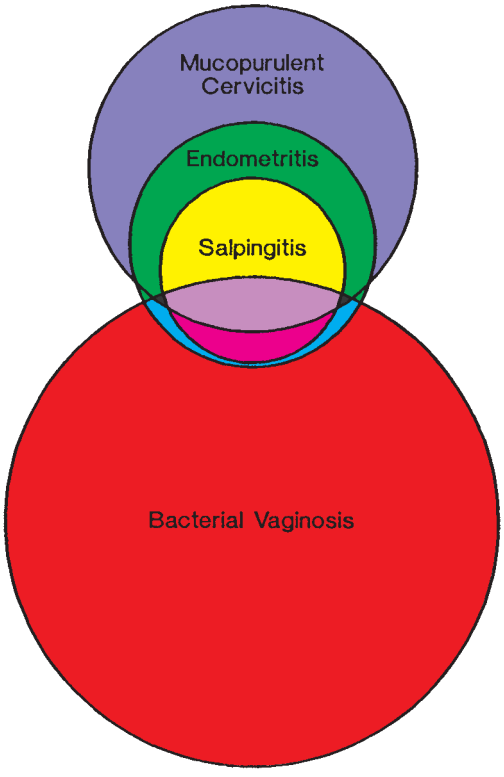

FIGURE 55-24. Hypothetical relationship of upper genital tract infections to lower genital tract infection. In this model, among women with mucopurulent cervicitis, upper tract infections are attributable to *C. trachomatis* and *N. gonorrhoeae*, while among women with bacterial vaginosis, upper tract infections are attributable to bacterial vaginosis-associated vaginal organisms. Upper tract infections in women with both bacterial vaginosis and mucopurulent cervicitis may be owing to either or both sets of organisms. A second hypothesis advanced here is that salpingitis complicating mucopurulent cervicitis or bacterial vaginosis is associated with endometritis.

BV may also predispose to endometritis and salpingitis caused by those pathogens characteristically found in the vagina in BV.[159] Among the set of randomly selected 1984–1986 Seattle STD clinic patients described in the preceding, BV was significantly associated with a clinical diagnosis of PID; and even after adjusting for coinfections and other potential confounders, BV was significantly associated with moderate to severe adnexal tenderness.[160] The role of MPC and the potential role of BV in predisposing to endometritis and salpingitis are illustrated in Fig. 55-24. Simultaneous MPC and BV may be responsible for mixed tubal infections caused by the cervical pathogens (*N. gonorrhoeae, C. trachomatis*), together with the BV-associated organisms. HIV infection with immunosuppression may increase the risk of PID, given cervical chlamydial or gonococcal infection or BV; and may increase the risk of tuboovarian abscess among women who develop PID. Evaluation of these and other possible models for the interrelationship between upper and lower genital tract infection could lead to clearer understanding of the pathogenesis of salpingitis. As discussed in Chapter 81, there is also a great deal of evidence for the importance of cervical and vaginal infection in causing complications of pregnancy, including chorioamnionitis and premature delivery; and evidence for a beneficial impact of detecting and treating such infections early in pregnancy. Increasing emphasis on proper management of these lower genital tract infections in pregnant women can be anticipated. Finally, there is ample evidence that mucopurulent endocervicitis, and endocervical gonococcal and chlamydial infections, are associated with increased risk of acquiring HIV infection, and with increased cervical shedding of HIV; and considerable evidence for an association of BV, trichomoniasis, and vulvovaginal candidiasis with acquisition of HIV. Cervicitis has also been associated with increased probability of shedding of human T-lymphotrophic virus type 1 (HTLV-1)[161] among HTLV-1 seropositive sex workers. It is likely that the quantitative shedding of endocervical pathogens per se is also greatest among women with cervicitis, and that quantitative shedding of *T. vaginalis* is greatest among women with vaginal inflammation. Therefore, as with men, early detection and treatment of women with lower genital inflammatory syndromes associated with their LGTI would likely have a greater, impact per case detected—both in terms of the women's individual benefit and the population benefit—than would screening and treatment for subclinical, nonsymptomatic LGTI in women.

56 Pelvic Inflammatory Disease

Jorma Paavonen, Lars Westrõm, and David Eschenbach

DEFINITION

Pelvic inflammatory disease (PID) comprises a spectrum of upper genital tract inflammatory disorders among women, which includes any combination of endometritis, salpingitis, tuboovarian abscess, and pelvic peritonitis.[1] Use of the term *pelvic inflammatory disease* is restricted to infections of the upper genital tract caused by microorganisms that ascend from the cervix or vagina; the term excludes blood-borne infections such as tuberculosis. Infections following delivery or induced abortion are also categorized separately as puerperal or postabortion infection.

Salpingitis, or infection of the fallopian tubes, is the most important feature of PID, and the terms *PID* and *salpingitis* are often used synonymously. In this chapter, the term *salpingitis* is reserved for women with visual confirmation of fallopian-tube infection. About two-thirds of women with a clinical diagnosis of PID in fact have salpingitis, while the remaining one-third have either other conditions or normal pelvic organs when laparoscopy is used to confirm a clinical diagnosis of PID.[2] A small proportion of women with clinical PID have infection and inflammation of the endometrium and/or blood vessels and lymphatics adjacent to the uterus, but without visually recognized salpingitis.[3]

Women with salpingitis/PID present with a vast array of clinical manifestations that range from virtually none to severe. No symptom, clinical sign, or laboratory result or combination thereof is pathognomonic for PID. In most women with mild or uncharacteristic manifestations, the diagnosis of salpingitis is just not made. In fact, about two-thirds of cases of PID are probably unrecognized.[4] Attempts were made to sharpen the diagnostic criteria for PID and to grade the severity of clinical manifestations,[5,6] but there are no accepted criteria or classification in the clinical diagnosis of salpingitis/PID. Chronic PID is an even more poorly defined entity that is often used for patients with chronic pain or infertility, caused by pelvic adhesions and other abnormalities from a prior episode of PID. Thus, the term *PID* has different meanings in various settings.

HISTORICAL REVIEW

In ancient Greece, Aetius described surgical drainage of pus through the vagina, indicating that early physicians not only diagnosed pelvic abscesses but also provided surgical treatment.[7] In the seventeenth and eighteenth centuries, when direct observations and dissection of human cadavers became acceptable, Mauriceau described inflammatory tumors of the uterine adnexa in puerperal infections in 1683.[8] In the 1700s, "adnexitis" was described in autopsy reports.

Noeggerath was the first physician to link sexual transmission with infertility in 1876,[9] 3 years before Neisser identified the gonococcus. In the late nineteenth century, advances in bacteriology, pharmacology, anesthesiology, asepsis, and surgery opened the era of modern medicine. By the turn of the century, a number of important observations were made with respect to PID; some immediately increased our understanding, but others were not fully understood until half a century later. Von Bumm established the sequence of cervical gonorrhea progression to endometritis, salpingitis, and pelvic peritonitis in 1887.[10] Between 1892 and 1914, Wertheim, Schauta, Kelly, Martin, Schottmüller, and Barfuth isolated a variety of aerobic and anaerobic bacteria from the fallopian tubes and pelvic cavities of women with PID.[11]

Nocard and Roux in 1898 identified the causative organism of pleuropneumonia in cattle, later to be named *mycoplasmas*.[12] Kelling described the fundamentals of laparoscopy in 1902, and Jacobaeus reported laparoscopy in humans by 1910–1912.[13] In 1907, Halberstaedter and von Prowazek described inclusion conjunctivitis in experimental primate infections,[14] and in 1910 Fritsch et al.[15] linked inclusion conjunctivitis with genital infection, later recognized as chlamydia. Successful attempts at conservative treatment of PID began in the 1920s[16] and were generally accepted by the 1930s. Sulfonamides were first used to treat PID in the 1930s.

In 1937, mycoplasmas were first isolated from the human genital tract.[17] By 1946, Falk clearly demonstrated the ascending route of spread in PID,[18] and Ruddock in the United States and Palmaer in Paris pioneered modern laparoscopy.[13]

Chlamydia trachomatis was identified by T'ang and coworkers in 1957,[19] and by 1959 the organism was isolated from the human genital tract.[20]

During the 1960s, laparoscopy was systematically used to provide an accurate diagnosis of salpingitis, and the vast array of clinical presentations became apparent.[2] Laparoscopy made possible accurate studies of the microbial etiology of salpingitis, and laparoscopy became the gold standard for diagnosis and research in PID. Mycoplasmas in 1970[21] and chlamydia in 1977[22,23] were isolated from the fallopian tubes of women with PID, and in 1975 the polymicrobial etiology of PID was described.[24] Echoing Noeggerath's theories, Westrōm in 1975[25] quantitated the incidence of infertility and ectopic pregnancy (EP) following salpingitis. During the 1980s and first half of the 1990s, our understanding of PID further increased due to progress in microbiology, immunology, epidemiology, experimental animal models, and social and behavioral sciences.

In recent years, many societies and organizations have published practice guidelines to diagnose and treat PID. Since PID is the only preventable cause of infertility and adverse pregnancy outcome, increased efforts are now focused on PID prevention.

MICROBIAL ETIOLOGY

PID is caused when microbes ascend from the vagina/cervix into the endometrium, fallopian tubes, and contiguous structures. Since a large number of species colonize the vagina and cervix, the microbial etiology of PID is best established by direct culture of upper genital tract tissue. Specimens potentially contaminated by vaginal/cervical flora include endometrium obtained by transcervical biopsy,[26,27] peritoneal fluid obtained by cul-de-sac puncture,[28] or material from transvaginal abscess drainage.[26] Direct uncontaminated specimens can be obtained from the pelvic cavity at laparoscopy or laparotomy.[21,26,29,30] Specimens from the cul-de-sac or peritoneal cavity may also contain microorganisms not necessarily present in infected tubes.[30,31] Further, comparisons among studies is difficult because of marked differences in the sample method (tissue biopsy, scraping, swabbing, and aspiration), specimen transport (media, time, and temperature), laboratory culture techniques, and spectrum of microorganisms sought.[2] Finally, modern DNA technology is only now being used for PID.[32]

Isolates from the upper genital tract and abdominal cavity in PID are usually classified into sexually transmitted organisms (those never normally isolated from the genital tracts) and endogenous organisms (those often present in the lower genital tract), some of which may also be sexually transmitted.[31]

SEXUALLY TRANSMITTED ORGANISMS

C. trachomatis and *Neisseria gonorrhoeae* both cause PID, while the role of genital mycoplasmas remains unclear. Herpes simplex virus (HSV),[21,33] cytomegalovirus, and *Trichomonas vaginalis*[29,34] occasionally are isolated from the pelvis, but systematic studies provide no convincing evidence that viral pathogens or protozoa cause PID, although HSV may rarely cause peritonitis.

Isolation of more than one sexually transmitted pathogen from the lower genital tract is common in acute PID. From one-fourth to three-fourths of young women with acute PID have *N. gonorrhoeae* and/or *C. trachomatis* isolated from the lower genital tract, although these bacteria are isolated less frequently from the upper genital tract of women with PID.[21,24,29,30,35,36] *Mycoplasma hominis*, *Ureaplasma urealyticum*, and *T. vaginalis* are also commonly present in the lower genital tract in PID.

N. GONORRHOEAE

N. gonorrhoeae is the "classic" bacterial cause of PID. *N. gonorrhoeae* has been recovered from the cervix, endometrium,[31,37] fallopian tubes,[29,33,35,37] peritoneal fluid,[10,11,24,37] and serosal surface of the liver[38–40] in women with PID. The organism is not isolated from normal fallopian tubes. Koch's postulates to establish an organism as the causative agent of disease are not fulfilled because of difficulty to infect animals with *N. gonorrhoeae*.[41] *N. gonorrhoeae* causes a cytotoxic effect[42,43]; gonococcal endotoxin causes tubal cilia damage in human organ culture experiments.[44]

Ten percent to 19% of women with *N. gonorrhoeae* in the cervix have clinical signs of acute PID.[45–47] Certain characteristics of *N. gonorrhoeae* appear to predispose to tubal infection, including specific auxotypes and penicillin resistance,[48,49] the formation of transparent colonies on agar,[50,51] and certain serovars.[51,52] Women with *N. gonorrhoeae* and PID tend to have the onset of pain in the first part of the menstrual cycle, suggesting rapid ascent of *N. gonorrhoeae* into the upper genital tract after cervical mucus is lost with menses.[53] In women with cervical *N. gonorrhoeae* and PID, the rate of recovery of gonococci from the upper genital tract is inversely related to the duration of symptoms.[29,54,55]

The endometrium serves as a transition zone between uncomplicated cervical infection and salpingitis. Cervical infection is frequently asymptomatic, and symptomatic gonorrhea may occur only when the organism reaches the upper genital tract. Ultrastructural studies of the pathogenesis of gonococcal endometrial infection indicate that gonococci utilize multiple mechanisms to associate with endometrial epithelial ciliated and secretory cells.[56] Thus, gonococcal endometritis is a well-characterized clinical syndrome. CDC guidelines include endometritis as well as salpingitis, tuboovarian abscess, and pelvic peritonitis—as manifestations of PID.[1]

In (Table 56-1), 42% of 185 women with cervical *N. gonorrhoeae* and PID had *N. gonorrhoeae* isolated from

Table 56-1. Rates of Isolation of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* from the Cervix, and *N. gonorrhoeae* from Fallopian Tubes Among Women with Acute Pelvic Inflammatory Disease

fallopian-tube or cul-de-sac specimens.[22–24,53,57–71] Many women with PID and *N. gonorrhoeae* also have *C. trachomatis* in the cervix or other bacteria isolated from the fallopian tubes or peritoneum.[24] Thus, mixed infections are common.

In populations with high endemic rates of gonorrhea, a high proportion of PID is associated with gonorrhea. *N. gonorrhoeae* can be isolated from the lower genital tract in up to 70–80% of women in such populations with acute PID (see Table 56-1).[70,71] In regions with reliable statistics, the proportion of PID associated with gonorrhea increased in the 1960s, leveled, and then decreased in the 1980s, paralleling changes in the incidence of gonorrhea (Fig. 56-1).[46,47,72] In

many U.S. populations, gonorrhea was found in 40–50% or more of patients with PID (Table 56-1). However, in current populations in the United States and elsewhere without endemic gonorrhea, less than 5% of young women with PID have gonorrhea (Fig. 56-1).[47,72] For example, gonorrhea is now uncommon in most European countries. In addition, the rapid decrease of endemic gonorrhea paralleled reduced hospitalization rates for patients with PID. One explanation is that gonogoccal PID tends to clinically manifest as peritonitis and be severe enough to require hospitalization.

C. TRACHOMATIS

C. trachomatis is now an established important etiological agent in PID. *C. trachomatis* has been isolated from the cervix, endometrium,[27,72–75] fallopian tubes,[22,23,62,75,76] and the liver capsule of women with PID.[77] Specific serum IgM and IgG antibody and titers increase significantly with primary PID associated with chlamydia.[24] In experimental infection of human fallopian-tube organ culture, *C. trachomatis* can be recovered for 5–7 days, and inclusions contain all forms of chlamydia in ciliated and nonciliated tubal cells for 72 hours

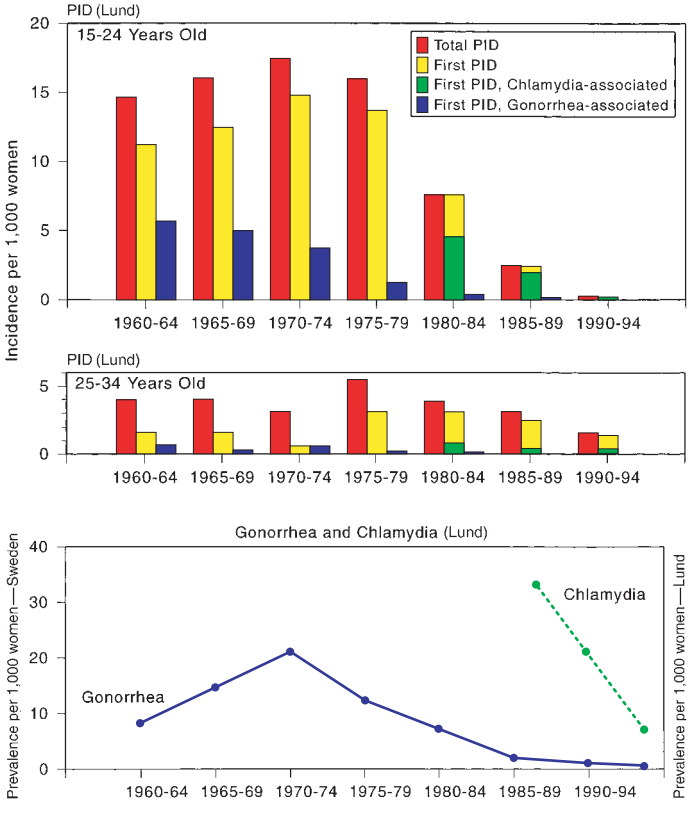

FIGURE 56-1. Mean annual incidences of PID in women 15–24 and 25–34 years of age during 5-year periods 1960–1964 through 1990–1994 in the city of Lund, Sweden, as well as the prevalences of gonorrhea in Swedish women less than 25 years of age from 1960 to 1994 and of genital chlamydial infection in women in Lund from 1987 to 1994.

after inoculation.[78,79] Disruption of cell junctions and rupture of the cell occur with the release of elementary bodies.[79] Experimental chlamydial infection in primates produces salpingitis.[80,81] A single inoculation of *C. trachomatis* directly into the oviducts produces acute infection for several days, after which the organism is no longer recovered and inflammation subsides. The cellular response is complex, and severe inflammation can result, particularly with repetitive *C. trachomatis* infection.[81] Repeat infection contributes to development of a delayed hypersensitivity response, resulting in severe tubal epithelial inflammation and damage with frequent sequelae.[82]

In contrast to gonorrhea, which tends to produce severe symptoms with mild tubal disease, chlamydial salpingitis tends to produce only mild clinical manifestations with severe tubal disease. The age distribution of women with chlamydia-associated PID parallels that of uncomplicated cervical chlamydia in the same population, with a peak incidence in sexually active teenagers. An estimated 10% of *C. trachomatis* cervical infections ascend to cause PID, although this proportion is less well established than with *N. gonorrhoeae.* In a population-based study, the mean annual incidence of infection per 1000 sexually active teenagers was 97 for genital chlamydial infection and 14 for symptomatic chlamydial PID; among women aged 25–29 years, the annual incidence was 46 for genital chlamydial infection and 3 for chlamydial PID.[83]

Incidence rates of PID following cervical chlamydial infection may also have decreased in recent years, because of improvement in clinical diagnosis and treatment, including use of sensitive nucleic acid amplification test (NAAT)-based diagnosis and a single-dose azithromycin-containing regimen to treat *C. trachomatis*. Prior diagnostic studies used cervical culture, which required a relatively high bacterial load for detection of *C. trachomatis*. NAAT detects chlamydia at a low bacterial load that may not be associated with ascending infections at as such a high rate. Further, opportunistic screening programs detect more asymptomatic uncomplicated chlamydial infection, which may help explain why the rate of PID associated with chlamydial cervical infection has decreased.

Among women with PID in (Table 56-1), *C. trachomatis* was isolated from the cervix of 29% of 1528 (range 5–51%); by comparison, *N. gonorrhoeae* was isolated from the cervix of 26% of the 1891 women (range 5–80%). Patients in studies with high rates of cervical *C. trachomatis* tended to have low rates of cervical *N. gonorrhoeae* and vice versa. However, 20–30% of patients with *C. trachomatis* also have *N. gonorrhoeae*, and a similar percent with *N. gonorrhoeae* have *C. trachomatis*.[60,63–66,84] The combined results of most studies from Europe during the 1970s and 1980s indicated that *C. trachomatis* was isolated from 25–50% of women with PID, while *N. gonorrhoeae* was found only in 5–25%. American studies at the time showed higher rates of gonorrhea and lower rates of chlamydial infection than the European studies. A fourfold or greater

change in IgG antibody titer to *C. trachomatis* was present in 25% of women with laparoscopically verified PID.[24,84]

In acute salpingitis, *C. trachomatis* was isolated from the tubes/abdomen in 39% of those with cervical *C. trachomatis* infection, a percentage similar to that for recovery of *N. gonorrhoeae* from tubes of PID patients with gonorrhea (see Table 56-1). *C. trachomatis* was isolated from the fallopian tubes of women with "chronic PID"[31,85–87] and occasionally from normal-appearing fallopian tubes.[87–89] *C. trachomatis* is uncommonly recovered from the cul-de-sac.[90]

MYCOPLASMAS AND UREAPLASMAS

M. hominis has been isolated from the cervix, the endometrium,[91] and the fallopian tubes of women with laparoscopically verified salpingitis (Table 56-2).[21,24,59,71,90] The microbe has not been isolated from normal fallopian tubes.[21,91] Direct inoculation of *M. hominis* into the oviducts of grivet monkeys provoked oviductal infection,[92,93] and a cytopathogenic effect was demonstrated after inoculation of human fallopian-tube organ culture with *M. hominis*.[94]

M. hominis is recovered frequently from the cervix[21,91,95,96] but infrequently (0–17%) from the upper genital tract of women with PID (see Table 56-2). Twenty percent to 40% of women with acute PID had significant change of antibody to *M. hominis* demonstrated by enzyme immunoassay (see Table 56-2).[96–98] In contrast to PID associated with *N. gonorrhoeae* and *C. trachomatis*, PID associated with *M. hominis* was evenly distributed in all age groups.[95]

On the other hand, *M. hominis* is frequently isolated from the lower genital tract of sexually active women[21,99] and is associated with bacterial vaginosis (BV) (see Chapter 42). BV has been implicated as a risk factor for PID. Thus, *M. hominis* may be either a risk marker or an independent risk factor for PID.

Mycoplasma genitalium is associated with nongonococcal urethritis.[100] *M. genitalium* produces oviductal infections in marmosets, grivet monkeys, and baboons.[101,102] *M. genitalium* adheres to human fallopian-tube epithelial cells in organ cultures.[103] Using a polymerase chain reaction (PCR) assay, *M. genitalium* can be detected in vaginal, cervical, and endometrial specimens.[104,105] *M. genitalium* has been associated with cervicitis[106] and with clinically diagnosed PID[107] and was more common in women with (16%) than without (2%) symptomatic histologic endometritis.[108] Among women with laparoscopically confirmed acute salpingitis, *M. genitalium* was identified by PCR in the cervix or endometrium of 7% and in the fallopian tubes of one.[109]

U. urealyticum has been isolated from the fallopian tubes from 2% to 20% of women with PID (see Table 56-2), and a significant increase of serum metabolism-inhibiting antibody to *U. urealyticum* was documented in 20% of women with acute PID.[24] However, attempts failed to produce tubal infection in monkeys with *U. urealyticum* failed.[93] *U. urealyticum* is commonly found in the lower genital tract of sexually active women, and isolation rates are similar in healthy women and women with PID.[21,91,99,110] The role, if any, of *U. urealyticum* in PID appears minimal.

HUMAN IMMUNODEFICIENCY VIRUS

There is no evidence that human immunodeficiency virus (HIV) infection per se causes PID. Infection with HIV does influence the clinical manifestations of PID, as discussed below in the section "Epidemiology and Risk Factors."

ENDOGENOUS AND OTHER ORGANISMS

Facultative and anaerobic bacteria are commonly isolated alone or together with *N. gonorrhoeae* or *C. trachomatis* from the endometrium, fallopian tubes, cul-de-sac, and/or abscesses of women with acute PID.[21,24,30,53,111–113] *Bacteroides* spp. (*disiens*, *fragilis*, and *melaninogenicus*), *Prevotella bivius*, *Escherichia coli*,

Gardnerella vaginalis, *Peptostreptococcus* spp. (*asaccharolyticus*, *anaerobius*, and *magnus*), staphylococci, group B–D streptococci, *Actinomyces israeli*, *Campylobacter fetus*, clostridiae, and others have all been isolated from the upper genital tract of women with acute PID. Most of these bacteria are also found in normal vaginal flora, and several occur more often and in increased concentrations among women with BV. Even respiratory pathogens such as *Haemophilus influenzae*, *Streptococcus pneumoniae*, and group A streptococci occasionally cause salpingitis.[24,30,31] Often more than one species from the vaginal flora are isolated from the patient, leading to the concept of "polymicrobial" PID.[24]

Microbial species associated with BV are frequently recovered from upper genital tract or cul-de-sac specimens of women with acute PID and deserve special mention.[114] BV has been associated with a clinical diagnosis of PID[115] and with histologic endometritis.[116] For example, the presence of cervitis among women with BV was associated with the absence of H_2O_2-producing *Lactobacillus*. The presence of BV flora may increase the susceptibility of both the cervix and the upper genital tract to bacterial invasion by the local production of enzymes, such as sialidase and cytokines that enhance both the invasion and the susceptibility of cells to the effect of bacteria.[117] Among patients with a clinical diagnosis of PID, "BV-associated" bacteria were associated with histologic endometritis even when controlling for gonorrhea or chlamydia.[118] "BV-associated" bacteria were also isolated from the upper genital tract of women with gonorrhea and PID in a polymicrobial infection.[24,111] More efficacious screening and treatment of BV may reduce PID rates.[119] BV is almost three times more prevalent among black women than among white women.[120] However, more research is needed on adverse sequelae of BV. Isolation of "endogenous" bacteria from the upper genital tract appears more common in older women[29] and may be associated with severe suppurative disease,[24] intrauterine device (IUD) use,[121] recurrent PID,[53] and tuboovarian abscess.[24,111] Tuboovarian abscesses virtually always contain a mixture of facultative and anaerobic bacterial species.[122] In contrast, women with early mild salpingitis at laparoscopy generally have no anaerobic bacteria recovered from the upper genital tract.[31]

These observations could indicate a dynamic infectious process that evolves over time, where a large proportion of cases of PID initially are ascending gonococcal or chlamydial infections. If not treated, such infections might be followed days or weeks later by a "polymicrobial" stage and eventually by abscess formation. Alternatively, endogenous bacteria may ascend into the upper genital tract without a preexisting cervical infection. At present, it is not fully known how or under what circumstances endogenous, predominantly vaginal, bacteria cause infection in an otherwise healthy fallopian tube, or if the tube needs to be "primed or compromised" by an earlier pathological process to enhance tissue invasion.

PID OF UNKNOWN ETIOLOGY

Although many different microbial species can be recovered from the upper genital tract in acute PID, no microorganisms are recovered from 20–30% of patients in recent studies. In one study, 30 (20%) of 151 women with laparoscopically verified acute salpingitis had no evidence of microbial infection. In comparison to patients with PID of proven etiology, those with unknown etiology were older, had a longer average duration of pelvic pain, and relatively mild inflammation at laparoscopy.[123] Study of the microbiology of PID also is hampered by what appears to be a large number of unculturable species in the genital tract, which are only identifiable by DNA techniques. The microbial picture in the fallopian tube may well mirror that of the vagina; species identified in the vagina of women with BV in the highest quantity in recent research were unculturable bacteria identified only by PCR.[124] Newer diagnostic techniques, such as PCR and antigen detection assays, may help refine the etiology of PID.

PATHOGENESIS

By definition, PID associated with sexually transmitted infections (STIs) is caused by spread of microbes from the lower to the upper female genital tract.[1] The spread is canalicular, along mucosal surfaces from the vagina/cervix through the cervix to the endometrial cavity, the fallopian tubes, and into the abdominal cavity. The initial infection involves the mucosa and not the muscularis.[80] *N. gonorrhoeae* and *C. trachomatis* are demonstrated by culture or antigen detection in epithelia of the cervix, endometrium, and fallopian tube in women with salpingitis.[75,125] Interruption of the fallopian tubes by cornual resection prevents salpingitis.[18]

Some observations indicate that intermittent ascent of microbes into the endometrial cavity and even fallopian tubes might be a physiological phenomenon.[2,126] Spermatozoa, dyes, and particulate matter are rapidly transported from the vagina/cervix into the pelvic cavity.[127–129] With menses, the cervical mucus plug is lost, potentially allowing bacteria access to the endometrium. Endometrial blood is commonly present in the abdomen at menses.[130] Observations in animal experiments also suggest that microbes may be transported through the genital tract without causing infection.[131] The fate of such microbial ascent would depend on their virulence and load, as well as on local defense mechanisms.

The immunopathogenesis of *C. trachomatis* infection is an important focus of recent research. As an intracellular pathogen, *C. trachomatis* induces an antigen-specific cell-mediated immune response. Some individuals are more susceptible to *C. trachomatis* infection and associated sequelae than others, suggesting involvement of genetic factors. Specifically, chlamydial heat shock proteins (CHSP60) are major targets of both humoral and cell-mediated immune

mechanisms. The outcome of *C. trachomatis* infection may depend not only on its virulence but also on the host response. CHSP60-specific cell-mediated immune response is associated with specific HLA types and IL-10 polymorphism, which may reduce the Th1 response needed to eradicate *C. trachomatis*.[132–134]

Comparisons of immune markers in individuals with noncomplicated and complicated chlamydial infection are needed to further understand risk factors or including immunologic factors, associated with the development of long-term sequelae of *C. trachomatis* infection.

FACTORS INFLUENCING ASCENDING CANALICULAR SPREAD

COITUS-RELATED FACTORS

PID is rare in virgins,[135] and the frequency of sexual intercourse appears related to PID among monogamous women.[136] The role of spermatozoa in the active transport of microbes in PID is unknown. However, "bacteriospermia" occurs, and spermatozoa with adherent microbes migrate through cervical secretions.[137,138] Spermatozoa with attached *C. trachomatis* were identified in cul-de-sac fluid of women with salpingitis.[139] Experimental *C. trachomatis* infection in the cervix of pig-tailed macaques produced plasma-cell infiltrates in the tubes of mated but not of unmated animals, suggesting that coitus helped introduce chlamydia to the tubes.[140] On the other hand, symptoms of PID may begin weeks following sexual intercourse, and the use of condoms in women already infected with *N. gonorrhoeae* or *C. trachomatis* does not protect against PID.[136]

IATROGENIC PROCEDURES

Diagnostic and therapeutic procedures that disrupt the protective cervical barrier—such as dilatation and curettage, induced abortion, IUD insertion, and hysterosalpingography—introduce bacteria into the endometrial cavity. These procedures preceded the onset of acute PID in up to 12% of women with PID.[2]

The association of BV with iatrogenic PID or with upper tract infections after hysterectomy or induced abortion has led to a common strategy to treat such patients with prophylactic antibiotics, including use of metronidazole to cover BV-associated organisms.[118]

SEXUAL STEROID HORMONES

Sexual steroid hormones might influence the pathogenesis of PID. Cervical mucus provides a barrier against ascent of microbes into the endometrial cavity; mucous production and characteristics are highly influenced by such hormones. During the estrogen phase of the menstrual cycle, cervical mucus is watery, with glycoprotein molecules arranged in parallel rows, allowing penetration by spermatozoa.[141] In contrast, during the progesterone-dominated luteal phase, the water content of the secretion is low and glycoprotein molecules are arranged in an interlacing network that inhibits spermatozoa penetration.[141] Thus, the likelihood of microbes spreading from the cervix to the endometrium might be higher in follicular- than in luteal-phase mucus. In ovulating women, gonorrhea has been diagnosed more often in the follicular than in the luteal phase of the menstrual cycle,[142] and symptoms of STI-associated salpingitis more often start at menses or shortly thereafter than in the luteal phase; this suggests that retrograde menstruation may play a role to transport bacteria into the fallopian tubes.[130,143,144]

In women not using oral contraceptives, subendometrial myometrial contractions increase in frequency and amplitude at midcycle ovulation, and most contractions move toward the fundus. This pattern is essentially reversed in the luteal phase.[145] These observations underline the pivotal role of ascending infection in the pathogenesis of PID.

Combination oral contraceptive pill (OCP) use is associated with protection against acute salpingitis.[146] The 36-month PID-related discontinuation rate was lower in women using levonorgestrel-medicated IUDs than among women using copper IUDs.[147] In vitro, progesterone suppresses the growth of *N. gonorrhoeae*,[148] while 17-β-estradiol enhances the adherence and growth of *C. trachomatis* in a dose-dependent manner in human endometrial cells.[149] However, the addition of contraceptive progestins (and ethinyl estradiol) to cell cultures had no effect on the replication of *C. trachomatis*.[150]

In animal experiments, it has beeen found that administration of estradiol to ovariectomized guinea pigs prolonged genital infection with the guinea pig inclusions conjunctivitis agent and thus promoted upper genital tract infection.[151] Mestranol/norethynodrel enhanced the course of the infection and produced ascending infection not seen in untreated animals.[152] Progesterone alone given to the animals prevented acute endometritis.[153] By contrast, the duration of experimental *C. trachomatis* infections in monkeys was not influenced by combined OCPs.[154]

The apparent protective effect of progestins against ascending infection may be explained by the production of luteal-type cervical mucus, which inhibits bacterial penetration, and by the production of an inactive endometrium, which may inhibit bacterial attachment. OCPs appear to protect against PID in women infected with *C. trachomatis* but not in those with gonorrhea.[146] Thus, the mechanism of protection by sex steroid hormones remains unclear, but protection against overt *C. trachomatis* salpingitis raises the possibility that sex steroids may also downregulate the immune response to *C. trachomatis*.

OTHER FACTORS

The ecological disturbance in the vaginal flora of women with BV includes a significant increase in the concentration of potentially pathogenic species (see Chapter 42), which may predispose to upper genital infection if the cervical barrier is breached. An increased risk of PID was documented among women who douche.[155,156] Induced abortion also predisposes to PID,[157] presumably by the introduction of pathogenic cervical or vaginal bacteria into the upper genital tract.

The role of the IUD in the ascending spread of infection in the female genital tract remains controversial. A majority of epidemiological studies report higher incidences of PID in IUD-using women than in nonusers. With IUD insertion, bacteria from the vagina/cervix are introduced into the endometrium along with the IUD.[158] The risk for PID appears mainly increased during the first 3 months after IUD insertion.[159] However, bacteria are also found to colonize both the string and the main body of the IUD months to years after insertion.[160] IUDs also enhance cervical colonization by bacteria such as actinomyces,[161] predispose to BV,[162] and cause impressions in the endometrium,[163] all of which should increase the risk for PID.

TUBAL INFLAMMATION

The presence of *N. gonorrhoeae* and *C. trachomatis* on genital mucosal surfaces starts a cascade of events involving humoral and cellular defense mechanisms. These mechanisms either can clear the infection and/or provoke tissue damage. This damage can have important reproductive consequences by interfering with fallopian-tube function. In a human fallopian-tube culture model, *N. gonorrhoeae* selectively adheres to and enters nonciliated cells, leaving ciliated cells uninfected. However, the ciliated cells soon undergo ciliostasis and sloughing.[42,43,164] Ciliary activity of tubes is significantly reduced within 24 hours of initiation of gonococcal infection, as well as after exposure to gonococcal supernatant,[44] suggesting that the reduction of ciliary activity is mediated by a toxic cell-free product. Reduced tubal ciliary activity also occurs from purified *N. gonorrhoeae* lipopolysaccharide[165] and from monomeric peptidoglycan fragments of *N. gonorrhoeae*.[166] Once inside nonciliated cells, gonococci are protected from immune-defense factors, traverse the cells, and eventually are released from the basal surfaces of the cells by exocytosis.[42,43]

In the natural disease, antibody binding to gonococcal lipooligosaccharide molecules and peptidoglycan in the fallopian tubes activates complement and initiates the prostaglandin cascade,[144] resulting in an intense acute inflammatory reaction that includes purulent secretion, edema, vasodilatation, and tissue destruction. Gonococcal infection may produce more severe inflammation and symptoms that lead women to seek health care quickly, while other pathogens may produce more indolent symptoms that result in delayed seeking of health care.[123,167]

Immunological defense mechanisms induced by a gonococcal infection appear to offer some defense against recurrent gonococcal salpingitis. Antibody against the principal outer-membrane protein of *N. gonorrhoeae* was associated with reduced risk of PID among women with recurrent gonococcal infection in a small 1970s study,[52] and antibodies to gonococcal opacity proteins reduced gonococcal salpingitis among prostitutes.[168]

C. trachomatis attaches to tubal epithelium and is engulfed by endocytosis in a membrane-lined vacuole.[78] *C. trachomatis* replicates within the cell, protecting it from immune recognition. Infectious *C. trachomatis* elementary bodies are eventually released from the cytoplasmic inclusions into the fallopian-tube lumen.[78] In human fallopian-tube organ culture, elementary bodies replicate with inclusion formation in both ciliated and nonciliated cells, during a 5–7-day maintenance period of the cultures.[79] Similar findings occurred in the oviducts of mice infected with murine-*C. trachomatis*.[169] Both cilia and ciliated cells are lost in chlamydial salpingitis of the pig-tailed macaques.[80]

Chlamydial infections induce cytokines, including tumor necrosis factor (TNF), interferon (IFN), and interleukins (IL).[170–172] In PID, monocytes produce increased levels of IL-1 and IL-6, which in turn can induce scarring and tissue damage.[173] IFN-γ is present in cervical secretions of women with chlamydial cervicitis[174] and in the sera of women with acute PID.[175] IFN-γ may elicit a further increase in monokine production, and it may induce expression of major histocompatibility complex (MHC) class II molecules on epithelial and endothelial cells and on macrophages. Expression of MHC II-bound exogenous antigens on epithelial cells activates an immune response that in salpingitis could result in tubal cell destruction, analogous to that demonstrated in ocular trachoma.[176]

Genital chlamydial infection also elicits a humoral immune response of local and serum antibodies. Serum IgG antibody to *C. trachomatis* is detected up to 6 years after chlamydia-associated PID.[177] Partial protection against reinfection with *C. trachomatis* is present in animal experiments,[178–180] but this protection appeared both short lived and serotype specific.[181] On the other hand, studies on mice[182,183] indicate that cell-mediated immune mechanisms rather than antibody play a dominant role in the resolution of chlamydial infection.

In experimental studies of primates and mice, repeated *C. trachomatis* inoculations produced progressive tubal scarring.[81,184] A single direct tubal *C. trachomatis* inoculation in previously uninfected pig-tailed macaques produces a self-limited infection with edema that leaves no tubal scarring.[81] By contrast, tubal inoculation after either repeated cervical or tubal inoculations causes tubal occlusion and peritubal

adhesions.[80] These findings are analogous to clinical and experimental findings after repeated infection in ocular trachoma,[185,186] suggesting damage from an immunologic response to chlamydial antigens.[82] A cytokine response involving INF-γ and IL-2, IL-6, and IL-10 occurs with experimental fallopian-tube infection.[187] While INF-γ helps eradicate *C. trachomatis*, it also stimulates macrophages to intensify the inflammatory response. With acute infection, about 60% of the lymphocytes were CD8 cytotoxic lymphocytes.[187] Repetitive inoculation of *C. trachomatis* appears to result in severe permanent tissue damage from immunopathogenic T-cell responses.

Since CD4 T-cell loss induced by HIV infection increases the risk of *C. trachomatis* salpingitis, it may be that CD8 T cells are relatively more important in immunopathology than are CD4 T cells. This is supported by the observation that chlamydial salpingitis in humans is associated with an increased number of individuals with HLA-A31.[188] HLA-A31 is an HLA class I molecule that presents cytoplasmically processed peptide antigen to CD8 cells.

CD4 T cells may also play a role in immunopathology by T-cell delayed-type hypersensitivity (DTH). In experimental ocular trachoma, DTH was reproduced by placing a 60-kilodalton (kD) chlamydial heat shock protein (CHSP–60) on the conjunctiva of previously infected animals.[189] A human 60–kD heat shock protein (HHSP–60) is present in humans, and both heat shock proteins share extensive amino-acid sequence homology.[190] A proliferative response by lymphocytes to conserved epitopes CHSP–60 and HHSP–60 was demonstrated in five of 10 women with two or more episodes of PID, one of nine with a single episode of PID, and one of 32 control women.[190] Preexisting antibody to CHSP–60 was associated with a fivefold increased risk of developing chlamydial PID.[188] Antibody to CHSP–60 is also associated with severe tubal disease at acute infection[191] and perihepatitis,[192] infertility,[193] and tubal pregnancy.[194] These findings support the likelihood that *C. trachomatis* PID is, in part, an immune-mediated disease, where particularly severe inflammation results from an immune response to CHSP–60.[82,195]

Antibody response to CHSP–60 appears to be genetically determined.[196] Several mechanisms could explain the role of CHSP-60 in the immunopathogenesis of chlamydial PID. First, antibody to CHSP-60 could reflect a shift in the immune response to a Th-2-dominant response away from a protective cellular immune response. Second, immune complexes involving CHSP-60 antibody could stimulate excessive tissue inflammation. Third, because of the homology between CHSP-60 and human HHSP-60, antibody to CHSP-60 could initiate an autoimmune response to self-HHSP-60, precipitating further tissue injury.

In summary, clinical and experimental studies suggests a profound difference in host-parasite interactions of tubal infections caused by *N. gonorrhoeae* compared to *C. trachomatis*. *N. gonorrhoeae* appears to induce an acute neutrophilic inflammatory response, while *C. trachomatis* often results in a more indolent, cell-mediated lymphocytic response, possibly a DTH response. In naturally occurring chlamydial salpingitis, however, neither a DTH nor a human heat shock protein expression on tubal cells has been confirmed.

TUBOOVARIAN ABSCESS

Abscess formation is a late manifestation of PID. Neither *N. gonorrhoeae* nor *C. trachomatis* alone produces abscesses in animals or humans.[197] Instead, tuboovarian abscess typically results from a mixture of facultative and anaerobic bacteria, where facultative bacteria dominate the early phase of infection and bacterial metabolic products produce an environment of low oxygen tension that favors the growth of anaerobic bacteria.[122,197] Anaerobic bacteria dominate the infection in tuboovarian and pelvic abscesses.[24,34,122]

TISSUE REPAIR

In the repair process, the replacement of dead tubal epithelial cells by ingrowing fibroblasts causes tubal scarring and eventual tubal function impairment. Tubal deciliation,[80] intraluminal adhesions,[198] tubal occlusion, and peritubal adhesions occur after both natural infection in women[199] and experimental infections in animals.[197,200–202] These sequelae appear irreversible and can lead to infertility or tubal pregnancy (see below).

Tubal infection and scarring can be rapid; tubal infection and inflammation are initiated within hours for gonorrhea and within days for chlamydia, and tubal scarring begins within days of infection. In follow-up studies of women with STI-associated salpingitis, a delay in seeking care for more than 2 days after the onset of pain was associated with a threefold increase in infertility or EP.[167] Infertility after chlamydial salpingitis in mice was inversely proportional to the time between inoculation and the start of tetracycline treatment.[201]

EPIDEMIOLOGY AND RISK FACTORS

We do not usually accurately know the incidence and prevalence of acute PID in a population, and considerable variation between populations occurs. Patient surveys, outpatient visits, hospital discharge rates, retrospective self-reporting, and extrapolations from incidence figures of gonorrhea and chlamydia were used to study the epidemiology of PID. PID is not a notifiable disease, and different methods have been used to obtain information, including the use of ICD codes, reporting agencies, and self-reporting. Further, accurate

clinical criteria do not exist for the diagnosis, and the diagnostic accuracy of a clinical diagnosis (as assessed by laparoscopy) is only about 65%.[2] In addition, about two-thirds of women with PID have so few or such mild symptoms that the diagnosis is not even made. These latter cases are only identified if and when the late complications of tubal infection become evident. Thus, published figures on the epidemiology of PID are difficult to compare. A number of factors influenced trends in the incidence of PID over time, most importantly the prevalences of STIs in the population. Other influential factors include demography (parous and/or married women have a lower incidence of PID than nulliparous, single, divorced, or widowed women[29]), economics, health-care characteristics of the population, sexual risk-taking behavior, douching, smoking and drug habits, and contraceptive use.

REPORTED INCIDENCES AND TRENDS

In the United States, widely divergent figures on the estimated incidence of PID illustrate the difficulties with such estimates. In the 1980s, the annual estimated number of cases of PID varied from 857,000 cases[203] to 1,477,000 cases (based on average numbers of hospitalized cases in 1987–1988 and outpatient cases in 1985–1989)[204] to 2,000,000 cases (a 1984 community survey).[205] Hospitalization occurred in 30% of cases of PID in the 1980s, falling to 9% by 2001.[206,207] Of U.S. women 15–44 years, 14.2% in 1982 and 10.8% in 1988 reported that they had received treatment for PID.[208]

American data indicate a particularly high incidence of PID among young, nonwhite, single, or divorced urban women .[203–206,208] Between 1972 and 1981, hospitalized cases of PID per 100,000 women per year had decreased among African American teenagers from 1000 to 750 and had increased among white teenagers from 250 to 300 cases.[209] Since 1980, the number of hospitalizations of women for acute PID peaked in 1992 at nearly 200,000; the number has fallen fairly steadily since then, to less than 90,000 in 1993 and 70,000 in 2001 (Fig. 56-2).[207,210] The number of initial visits to physicians' offices for PID peaked in the mid-1980s at over 450,000 visits; the number has fallen sharply since 1993 (Fig. 56-3).[210] From 1993 to 2001, annually, an estimated 769,858 women 15–44 years of age were diagnosed with PID.[207,211]

In England and Wales, hospital admissions for PID in women 15–44 years of age increased from 11,300 to 16,000 between 1975 and 1985. The incidence per 1000 women increased from 1.3 to 1.8 in the 20–24-year age group and from 1.1 to 1.2 in the 25–29-year age group but was virtually constant among teenagers and older women.[212]

In Sweden, hospital discharge rates for PID peaked in 1977 and have significantly decreased since.[72] The incidence of PID was followed from 1960 in one region in Sweden, where one gynecological department cared for the female population, and about 90% of all cases were verified by laparoscopy. The total incidence of PID per 1000 women 15–24 years of age increased to a peak of 17.5 in the mid-1970s and subsequently decreased to less than one in 1990–1994 (Fig. 56-1).[213] Only minor changes in the incidence of PID occurred in the 30–34-year age group over this time. The incidence of gonorrhea-associated PID per 1000 women 15–24 years of age decreased from six in 1960–1964 to none in 1990–1994, paralleling a significant nationwide drop in gonorrhea rates after 1975. The incidence of chlamydia-associated PID per 1000 women 15–24 years of age decreased from 6.3 in 1977 to less than one in 1994, in parallel with a local chlamydial-control program that markedly reduced chlamydial infection in women. Additionally, recurrent episodes of PID decreased from 21% of the total in 1960–1964 to 4% in 1990–1994, possibly from a lower risk of gonorrhea and chlamydia.[213] Thus, trends in STIs significantly influence the epidemiology of PID.

In developing countries, hospital admissions for PID provide a crude marker of PID as a public-health problem. PID

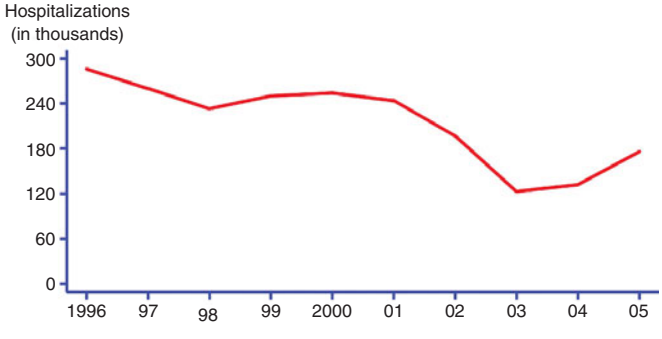

FIGURE 56-3. Pelvic inflammatory disease. Hospitalizations of women 15 to 44 years of age: United States, 1996–2004. *Note*: The relative standard error for these estimates of the total number of acute unspecified PID cases ranges from 8% to 11%. The relative standard error for these estimates of the total number of chronic PID cases ranges from 11% to 18%. Data only available through 2004. (*Source*: National Hospital Discharge Survey. National Center for Health Statistics, CDC).

has accounted for 17–40% of all gynecological admissions in the sub-Saharan region of Africa, for 15–37% in Southeast Asia, and for 3–10% in India.[214] However, the exact proportion of PID associated with STIs is not known, because postpartum and postabortal infections are also common.

As expected, tubal infertility is common in developing countries. Some sub-Saharan communities reported that up to 80% of infertility was associated with previous PID and that 30–50% of reproductive-age women are infertile.[215] EP was the most common surgical emergency in one center in Nairobi.[216] The ratio of ectopic to intrauterine pregnancy prior to 1980 was 1:88 in Benin and 1:91 in Kampala,[217] compared with 1:133 in Finland.[218] In summary, limited data indicate that PID and its consequences are common in most developing nations. Poverty, urbanization, lack of education, prostitution, and the low status of women constitute formidable challenges to control STIs and PID.

RISK MARKERS AND RISK FACTORS

Risk factors for PID that are possibly in the causal pathway after acquiring an STI include age, contraceptive use, coital frequency, douching, invasive diagnostic procedures, health-care behavior, and HIV infection. Knowledge of how risk factors cause PID could allow reduction of PID through education, counseling, or treatment.[136] By contrast, risk markers are variables associated with PID, which in themselves do not cause the acquisition of microbes that cause PID, nor do they cause the ascent of microbes into the upper genital tract. Risk markers for PID include age, socioeconomic status, smoking, and drug and alcohol abuse. Risk markers and risk factors are interrelated to form a complex network.

SEXUALLY TRANSMITTED DISEASES

Risk factors for the acquisition of STIs are discussed in Chapter 4. As discussed above, gonorrhea, chlamydial infection, and probably BV represent the most important risk factors for PID, based on epidemiologic and etiologic studies.[47,136] A genital infection was diagnosed in about 50–65% of sexual partners of young women with PID, irrespective of the etiology of PID.[69,219] Declining rates of PID parallel control of gonorrhea and chlamydial infection in Sweden (see Fig. 56-1) and the United States. In Wisconsin, the institution of a chlamydial treatment program was followed by a drop in the rate of PID.[220] In Seattle, a randomized trial of screening high-risk women for chlamydial infection coupled with chlamydia treatment demonstrated a 60% reduction in the rate of PID, compared to a control group of high-risk women assigned to receive usual care without chlamydia screening.[221]

AGE

Age is associated with PID, probably as a risk marker rather than a causal risk factor.[49,210] The risk to acquire acute salpingitis is 1:8 for sexually active 15–year-olds, 1:16 for 16–year-olds, and 1:80 for women 24–year old.[222] The high number of sexual partners in younger women is associated with more frequent acquisition of STIs in this group. Women 20–24 years of age have the highest incidence of both STIs and PID, closely followed by teenagers.[222] After adjusting for sexual activity, however, sexually active teenage females have higher incidences of both gonorrhea and chlamydial infection than any other age group. The incidences of both STIs and PID decrease significantly with increasing age beyond the age of 24 years. Additionally, age is no longer associated with PID after adjusting for gonorrhea and chlamydial infection, which further suggests that young age is related to PID through increased rates of these two STIs.[223] The impact of history of these STIs on risk of PID should be viewed as a risk factor independent of the physiologic attributes of age per se.

CONTRACEPTIVE USE

The magnitude of the effect of contraception on PID is difficult to ascertain. Experimental studies of the influence of contraceptives on the pathogenesis of PID have been cited above. The use of different methods of contraception influences the risk of acquiring STIs, as well as the risk of progressing to PID. Some contraceptives, such as barrier methods, reduce the acquisition of STIs, while oral contraceptives may enhance the acquisition of chlamydial infection yet reduce the development of PID among those who have acquired chlamydial infection.[146] Use of IUDs has no known influence on STI acquisition, but it enhances the movement of bacteria from the cervix to the uterus/tubes. Behaviors that influence both contraceptive choice and PID potentially confound studies of the association of contraceptives with PID. Women using no contraception may tend to take sexual risks and pregnancy risks and have poor health-care utilization, which in concert can increase the rates of STIs, PID, and pregnancy. Contraceptives have not been randomly assigned to women to examine the influence of contraception per se on PID, so the influence of contraception on PID is generally assessed from case-control studies.

Barrier methods, such as condoms and probably diaphragms, decrease the acquisition of STIs by women. Spermicidal agents offer a partial protection against cervical pathogens by a direct inhibitory effect on bacteria. Thus, barrier and spermicidal use has been associated with modest reduction in PID.[136,224]

Overall, OCP use has generally been associated with a reduction of 40–60% in the rate of PID.[136] Among women with chlamydial infection, OCP use was associated with a 70% reduction in risk of PID,[146] but OCPs do not appear to protect women with gonorrhea from PID.[146] The protective

effect of OCPs on chlamydial PID, but not other forms of PID, raises the possibility that OCPs might influence the immune response to chlamydial infection and thereby reduce fallopian-tube inflammation. This hypothesis is consistent with the finding that OCP users have had less severe damage of the fallopian tubes when PID is visualized laparoscopically, compared to IUD users or women who use no birth control.[225] Women in these studies used first- and second-generation combination OCPs with higher doses than most OCPs used today, however, and there is a complex interaction of OCP use with age, ectopy, and cervical infection, and perhaps with health-seeking behavior and health-care access as well.[226]

At least 20 controlled studies from the 1960s through the 1980s reported a two- to fourfold increased risk of PID or consequences of PID among users of IUDs, compared to women using other or no contraceptives.[227,228] Women who use IUDs clearly have an increased risk of PID in the first 1–3 months following insertion of the device, probably related to the introduction of bacteria into the uterus during insertion.[159] After this immediate postinsertion period, the rate of PID decreases but remains above that of non-IUD users, based on data from case-control studies of PID,[229] tubal infertility,[230,231] and EP.[232] Later infections are probably related to the long-term colonization of the IUD and string surface demonstrated by bacteriologic and scanning electron microscope studies.[160,233] Uncontrolled prospective cohort studies of IUD users report low rates of PID, but since they lack non-IUD-using controls, they fail to examine the sensitivity to detect PID.[228] Thus, prospective cohort data are not consistent with case-control study data. Women who use IUDs appear to have more non-STI-associated PID than do non-IUD users.[234,235] The rate of PID among IUD users can be reduced by screening for gonorrhea and chlamydia before insertion and by recognizing early signs of infection such as abnormal vaginal discharge, vaginal bleeding, and mild abdominal pain. Progesterone-releasing IUDs may reduce the rate of PID compared to copper or nonmedicated IUDs.[147]

Studies of the association of prior IUD usage with tubal infertility and EP are not subject to the bias of underdiagnosis or misdiagnosis of PID. Women using only copper IUDs have a threefold increased rate of tubal infertility, after adjustment for variables associated with infertility.[236] Copper IUD users also had a threefold increased rate of EP following IUD removal and after adjustment for variables associated with EP.[232] The data on tubal infertility and EP following IUD use are consistent with the increased rates of salpingitis noted in case-control studies of IUD users.

DOUCHING AND BV

In the United States, douching is practiced more commonly among African Americans and is associated with low socioeconomic status. Women with PID report frequent douching more commonly than controls, even after adjustment for gonorrhea and chlamydial infection.[155] A recent confirmation of the link between douching and PID and a link between douching and EP[237] raises the possibility that douching upsets the vaginal ecology or in some way enhances bacterial invasion of the uterus.

Among women undergoing induced abortion, those with BV have a threefold increased rate of postabortion PID compared to those without BV. The increased rate of PID was reduced to baseline in a randomized treatment trial of BV.[157] Frequent intercourse has been implicated as a risk factor for PID.[136] BV, with its 1000-fold increased concentration of a variety of bacteria in the lower genital tract, might interact with the frequency of intercourse to cause ascending infection.

SURGICAL PROCEDURES

Surgical procedures such as dilatation and curettage, hysterosalpingography, and IUD insertion spread microbes to the upper genital tract, by breaching the protective cervical barrier. Such procedures preceded the onset of PID in about 12% of cases.[2]

SMOKING, ALCOHOL, AND ILLICIT DRUG ABUSE

Cigarette smoking was related to a twofold relative risk of PID.[136,238] However, a dose-response relationship was not observed,[238] and the relationship between smoking and PID is not consistent. The association between alcohol and illicit drug use, particularly cocaine and the risk of PID, may occur because of high STI rates in this population.[136]

HIV INFECTION

Patients with HIV infection may have increased risk of PID, although several potential biases could distort the recognition and incidence.[239] The seroprevalences of HIV were 15–17% among patients with PID compared to 2–3% among control women in two U.S. studies,[240,241] and they were elevated in patients in Nairobi with PID.[242] HIV infection may also influence the course and clinical manifestations of PID, particularly among patients with markedly suppressed immunity. Patients with PID who were also HIV positive tended to have more abscesses[243,244] and more frequent surgical intervention,[244,245] compared to HIV-seronegative women with PID. The Centers for Disease Control and Prevention (CDC) recommends early hospitalization and intravenous antibiotics for HIV-infected women with PID.[246]

CLINICAL MANIFESTATIONS

In response to the spread of microbes from the lower to the upper genital tract and, in some instances, the abdominal cavity, inflammatory mediators cause endometritis, salpingitis, peritonitis, or perihepatitis. Different etiologic agents

(*N. gonorrhoeae*, *C. trachomatis*, etc.) tend to cause different clinical presentations, ranging from mild to severe (Fig. 56-4). Mild symptoms may not prompt patients to seek care and may allow physicians to miss the diagnosis. About two-thirds (range 30–75%) of infertile women with postinfection tubal obstruction report no history of prior PID,[4,247–250] indicating that subclinical infection accounts for the majority of PID and tubal infertility following PID. On the other hand, many patients with suspected PID have other conditions. When a clinical diagnosis of PID is made, the specificity of any one clinical and laboratory diagnostic procedure is low; in general, the clinical diagnosis of PID is incorrect about one-third of the time. Up to one-third of women with pain and other clinical findings suggestive of PID, in fact, have other diseases or no disease.[251–257]

SUBCLINICAL DISEASE (ATYPICAL PID, "SILENT" PID)

Historically, low abdominal or pelvic pain was regarded as the symptom sine qua non to suspect acute PID.[2] However, as noted above, individuals with apparent subclinical infection identified in studies of postinfection sequelae of salpingitis, such as tubal occlusion, hydrosalpinx, infertility, and EP, often give no past history of treatment for PID. On the other hand, in detailed focused interviews of infertile women with "no history of PID," medical visits for abdominal pain were reported by 60% of those with tubal occlusion, compared to only 19% of those without tubal disease.[258] Thus, many who recall no treatment for PID, nevertheless, may have experienced symptomatic PID and even have sought medical care.

Inflammation or microbes in the endometrium and fallopian tubes, and abnormal tubal ciliary function, can be found in women with no or few symptoms of PID. Histopathologic evidence of endometritis (≥ 10 plasma cells in any of six tissue sections) was found in 45% of women with mucopurulent cervicitis (MPC), including 65% of those with chlamydia-associated MPC.[27] Some of these patients had abnormal uterine bleeding or mild uterine tenderness, but no overt signs of salpingitis. Other studies demonstrated *C. trachomatis* in the endometrium in 26% of asymptomatic infertile women with serum antibody to chlamydia,[259] and in the fallopian tubes of 15% of infertile women without clinical or laparoscopic evidence of acute salpingitis.[260] Among asymptomatic women undergoing laparoscopic sterilization, plasma cells were present in the tubal mucosa of 47% of IUD users and 1% of those who have never used IUDs.[250]

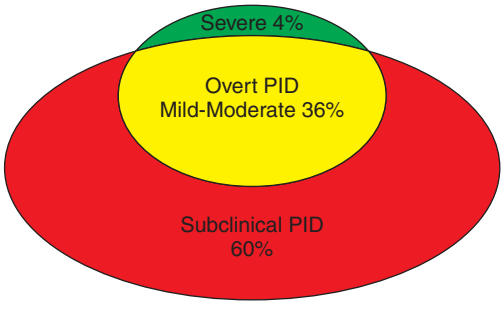

FIGURE 56-4. Illustration of the probable proportions of clinical manifestations of PID.

Some evidence suggests that *C. trachomatis* infection can persist without symptoms in fallopian tubes after treatment. In one study, *C. trachomatis* DNA and/or antigen was detected in fallopian-tube biopsy specimens of 19 of 24 women undergoing surgery for postinfection tubal factor infertility (TFI).[85] Eight women had been treated for PID and six for chlamydial cervicitis. However, these data have not been confirmed.

Another study suggests that tubal pathology from prior PID appears unrelated to presence or absence of history of previous clinical symptoms. Among 59 women with TFI, abnormal ciliary-beat frequency in fallopian-tube specimens and structure measured by scanning and transmission electron microscopy were identical in women with and without a history of overt PID.[261]

Thus, ascending infection can cause endometrial and tubal inflammation, resulting in tubal scarring, impaired tubal function, tubal occlusion, and infertility, even among those who report no prior treatment for PID. *C. trachomatis* is particularly implicated in subclinical PID, on the basis of (1) lack of prior history of PID among chlamydia-seropositive women with tubal damage,[4,247] (2) detection of chlamydial DNA or antigen among asymptomatic women with tubal infertility,[85] and (3) mild clinical manifestation when acute PID infection occurs in symptomatic PID, as discussed below. These data further imply that the best method to prevent PID and its sequelae is the surveillance and control of lower genital tract infection, particularly chlamydia and gonorrhea. Promotion of early symptom recognition and healthcare seeking may also reduce the sequelae of PID.

Endometritis is generally thought to represent an intermediate phase of PID. However, endometritis has also been described as a distinct pathologic syndrome. Among women with suspected PID, the histopathologic manifestations of endometritis are associated with clinical manifestations of infection and specific risk factors that were intermediate in frequency between women with salpingitis and women with neither endometritis nor salpingitis.[262] The potential for the progression to salpingitis would seem to warrant antimicrobial therapy, although the natural history of endometritis with or without treatment remains unclear. In particular, the frequency with which endometritis clears with menstruation, persists without spreading to the fallopian tubes, or progresses to salpingitis needs further study.

The PEACH study was a multicenter randomized clinical trial designed to compare the effectiveness of inpatient and outpatient treatment for mild-to-moderate PID. PEACH investigators also studied the association between endometritis and reproductive morbidity. Surprisingly, endometritis was

not associated with reduced pregnancy rates, recurrent PID, or chronic pelvic pain.[263,264] The conclusion from the PEACH study was that, among women with clinically suspected mild-to-moderate PID treated with standard antibiotics, endometritis was not associated with reproductive morbidity. These findings suggest that, although endometritis can accompany salpingitis, endometrial inflammation alone does not predict future morbidity among women with acute PID. Alternatively, endometritis and PID may be separate clinical entities and not necessarily different aspects of the same disease condition. Another PEACH report addressed clinical predictors of endometritis in women with symptoms and signs of PID. The finding most highly associated with endometritis was a positive test result for *C. trachomatis* or *N. gonorrhoeae*. It is clear that not just one or a few clinical criteria are enough to accurately diagnose upper genital tract infection. Combinations of clinical criteria can increase predictive values for PID. Sensitivity is increased by using the presence of adnexal tenderness as a minimal criterion to diagnose PID. Criteria that support the probability of endometritis include abnormal cervical or vaginal discharge, elevated temperature, elevated leukocyte count, and positive test results for *N. gonorrhoeae* of *C. trachomatis*.[265]

MILD AND MODERATELY SEVERE PID

Most laparoscopically verified cases of overt PID have mild-to-moderate symptoms and physical signs (see Fig. 56-4).[29] Up to 75% of women with mild or moderate PID are sexually active, are less than 25 years of age, and have gonococcal or chlamydial infection.[47,222]

In (Table 56-3), consecutive women routinely laparoscoped because of assumed PID all had low abdominal or pelvic pain for less than 3 weeks, cervical motion tenderness, and an increase of inflammatory cells in the cervical/vaginal secretion on microscopic wet mount.[2,29] Salpingitis was identified at laparoscopy in 65% of those with a clinical diagnosis of PID, but some of the remaining women without salpingitis had lower genital tract infection.[2] The prevalence of selected symptoms in (Table 56-3) was similar among women found to have salpingitis and those with no salpingitis; no symptom helped to distinguish the group with salpingitis.

Various combinations of symptoms and signs are also given in (Table 56-4), for the proportions of 2220 women in the Swedish study with and without salpingitis. A minimum of clinical and laboratory abnormalities (lower abdominal pain plus signs of a lower genital tract infection and cervical motion tenderness) was present in 16% of women with salpingitis. Sixty-one percent of women with salpingitis and 39% without salpingitis had these minimum abnormalities. The addition of an elevated ESR or temperature or an adnexal mass (especially two to three of these abnormalities) increased the possibility of salpingitis. In fact, 84% of the women with salpingitis had the minimum criteria and at least one of the three additional abnormalities; however, so did 36% of those with no salpingitis.

The general condition of the patient with mild or moderately severe PID is good. Pain associated with PID is usually subacute and slow in onset, bilateral, and dull in character and present in the lower abdomen or pelvis. Of women with PID who experienced pain within 7 days of the first menstrual day, 81% had gonococcal or chlamydial infection compared to 66% of those with premenstrual onset of pain.[143] A short period of pelvic pain (<3 days) at time of presentation to the clinic was significantly correlated with gonorrhea-associated PID and with age >30 years.[29] Women with chlamydia-associated

Table 56-3. Percent Prevalence of Symptoms, Signs, and Laboratory Abnormalities Among 807 Women Subjected to Laparoscopy Because of Clinically Suspected Salpingitis

	Laparoscopic Diagnosis			Laparoscopic Diagnosis	
Symptoms	Salpingitis, % (n = 623)	No Salpingitis[a], % (n = 184)	Signs and Laboratory Abnormalities	Salpingitis, % (n = 623)	No Salpingitis[a], % (n = 184)
Abnormal discharge	55	56	Temperature > 38.°C	41	20
Irregular bleeding	36	43	Palpable mass	49	25
Dysuria	19	20	ESR ≥ 15mm/h	76	53
Vomiting	10	9	WBC > 10,000/mL blood[b]	59	33
Anorectal symptoms	7	3	Acute phase reactants[c]	79	24
			Decreased isoamylases[d]	90	20

[a]Normal intraperitoneal findings; assumed to have lower genital tract infection or endometritis.
[b]WBC was determined in 186 cases of salpingitis and 54 controls with no salpingitis.
[c]Antichymotrypsin, orosomucoid, or acute-phase reactants including CRP, determined in 40 cases of salpingitis and 15 controls with no salpingitis.
[d]Determined in peritoneal fluid in 57 cases of salpingitis and 20 controls without salpingitis.

Table 56-4. Correlation of Clinical and Laboratory Abnormalities with Laparoscopic Findings in 2220 Cases, Given a Clinical Diagnosis of Acute Salpingitis

Clinical and Laboratory Abnormalities	Laparoscopic Salpingitis, %	Diagnosic Normal or Other, %	Percentage of Women with Salpingitis Presenting the Symptoms or Signs
Low abdominal pain plus signs of an LGTI[a] plus cervical motion tenderness	61	39	16
As above plus one or more of the following: ESR ≥ 15 mm/h; temperature > 38.0°C; palpable adnexal mass:			
+ one of the above abnormalities	78	22	28
+ two of the above abnormalities	90	10	39
+ all three abnormalities	96	4	17
		75	100

[a]LGTI = lower genital tract infection, as defined by the presence of inflammator cells outnumbering other cellular elements on wet-mount examination of vaginal fluid.

Table 56-5. Prevalence of clinical and Laboratory Abnormalities in Women with Laparoscopically Verified Acute Salpingitis Associated with Cervical Infection with *Neisseria gonorrhoeae, Chlamydia trachomatis*, or Neither Organism

Clinical and Laboratory Abnormality	Prevalence of Clinical and Laboratory Abnormalities Gonorrhea, % (*n* = 19)	Chlamydia, % (*n* = 68)	Neither, % (*n* = 64)
Duration of pelvic pain:			
≤ 3 days	32	15	38
> 10 days	21	41	27
Temperature > 38.0°C	52	22	30
Palpable adnexal mass	52	25	20
ESR ≥ 30 mm/h	32	65	19
Irregular bleeding	25	40	30

PID more often reported a period of pain exceeding 1 week in duration (Table 56-5).[123] Deep dyspareunia is frequent in women with PID.[29]

A fever was reported by about one-half of women with gonorrhea-associated PID, but only by 22% of those with chlamydial PID (Table 56-5). A palpable mass occurred slightly more often in women with gonorrhea than the other groups, and ESR >30 mm/h was associated with *C. trachomatis*. Irregular vaginal bleeding was also common and significantly associated with chlamydia-associated PID (Table 56-5).[123] Abnormal bleeding appears to be a manifestation of endometritis. Bleeding is often the only symptom (other than pelvic pain) of chlamydial PID.[258] One-fifth of women with PID reported dysuria,[2,29] reflecting the urethritis caused by gonorrhea and chlamydial infection. Nausea and vomiting are infrequent in mild-to-moderate PID and, if present, should raise suspicion of an appendicitis or a ruptured EP.

Despite increased inflammatory cells in the cervical/vaginal discharge of all cases in the Swedish series, only slightly more than one-half of the patients with PID reported symptoms of increased or changed vaginal secretion (see Table 56-3).[29] Thus, symptoms of lower genital tract infection preceding PID go unnoticed or are not present.

Clinical symptoms and signs do not accurately predict the extent of tubal disease observed at laparoscopy.[266] Patients with tubal occlusion or moderate-to-severe tubal adhesions are fairly equally distributed among patients with mild-to-moderate and severe clinical symptoms and signs.[25,249,267]

SEVERE PID

Clinical manifestations of severe PID correspond to classic textbook descriptions of PID, but severe manifestations occur in only 5–10% of those with overt PID, at least in industrialized settings. Severe PID has two general etiologic categories: (1) young patients with florid peritonitis, usually from gonorrhea, and (2) older patients with an abscess and no STI-associated disease.[2,29,222,267] In fact, severe PID was diagnosed in only about 3–4% of all patients with PID in Swedish and American studies.[29,222,267] This group represents only the tip of the iceberg of PID cases (see Fig. 56-4).

Patients with peritonitis appear very ill, usually with a short duration of symptoms (e.g., <3 days), fever, chills, purulent vaginal discharge, nausea, vomiting, abdominal guarding, and other signs of diffuse peritonitis. The white blood count (WBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) are usually elevated. Patients with an abscess have a more varied duration and severity of pain, but they are usually febrile with clinical or ultrasonographic evidence of an abscess.

CLINICAL MANIFESTATIONS OF EXTRAGENITAL INTRA-ABDOMINAL SPREAD OF *N. GONORRHOEAE* AND *C. TRACHOMATIS*: PERIAPPENDICITIS AND PERIHEPATITIS

Both *N. gonorrhoeae* and *C. trachomatis* may enter the abdominal cavity and cause inflammation of serosal surfaces.[268,269] Spread of gonococci from gonococcal salpingitis, causing periappendicitis, was described by Moritz in 1912,[270] and gonococcal perihepatitis was described in 1930 by Curtis[271] and in 1934 by Fitz-Hugh.[38]

Periappendicitis is serositis not involving the intestinal mucosa. Periappendicitis alone is found in 1–15% of appendices removed because of a preoperative diagnosis of acute appendicitis.[272] The majority (32/41) of patients with periappendicitis in one study were young women, and eight of the 32 had "tubal abnormalities."[273] Periappendicitis must always be kept in mind; when an appendix is removed from a young woman, the appendix should be opened and the mucosal surface inspected. A normal-looking mucosal surface strongly suggests periappendicitis secondary to salpingitis. All seven appendices removed from 112 women with bilateral salpingitis had histologically confirmed periappendicitis, and all had chlamydial salpingitis. The appendix was adherent to the right fallopian tube in six women, indicating a direct spread of organisms from the infected tube to the appendiceal serosa, but *C. trachomatis* was not detected in the removed appendices.[274] By contrast, an inflammatory mass of both the appendix and the right tube with a normal left tube indicates primary appendicitis.[29]

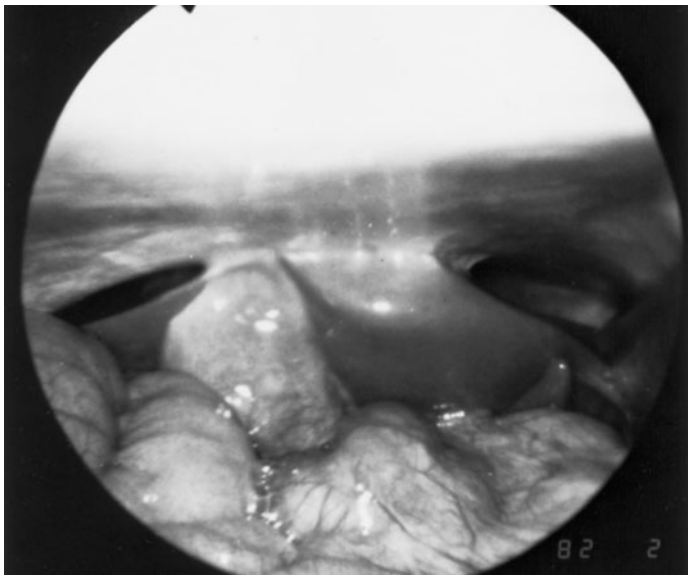

FIGURE 56-5. Laproscopic view of an early-stage Fitz-Hugh–Curtis syndrome with the liver surface closely adherent to the anterior abdominal wall.

Perihepatitis involves inflammation of the liver capsule and the adjacent peritoneum associated with PID. The liver parenchyma is normal.[38,269] In acute perihepatitis, filmy fibrinous deposits develop on the reddened liver capsule ("pepper-and-salt appearance"), and avascular, initially soft, adhesions form between the liver capsule and the adjacent parietal peritoneum under the ribs (Fig. 56-5).[275,276] The adhesions eventually form dense "violin-string" adhesions between the liver capsule and the abdominal wall (Fig. 56-6); dense adhesions indicate prior perihepatitis.[276]

Although some women with laparoscopic perihepatitis report no local symptoms,[276] acute severe pleuritic right-upper-quadrant abdominal pain is a cardinal clinical sign of perihepatitis.[269,276] Its sudden dramatic onset mimics pleuritis or cholecystitis. Right-upper-abdominal tenderness, guarding, and slight liver enlargement on palpation are present. A friction rub is occasionally auscultated over the liver.[38]

The results of conventional laboratory tests (ESR, WBC, and CRP) with perihepatitis usually are within the ranges seen in other cases of acute salpingitis.[192,276] Liver enzymes are usually normal.[192,275–277] A small amount of basal pleural fluid may be found on X-ray.[278] Ultrasonic examination of the gall bladder is normal in perihepatitis but should be performed to differentiate perihepatitis from gall-bladder disease.

Perihepatitis has been observed by laparoscopy in 5–15% of patients with acute salpingitis,[279,280] although a smaller proportion have clinical signs of perihepatitis.[275–280] Twenty-four of

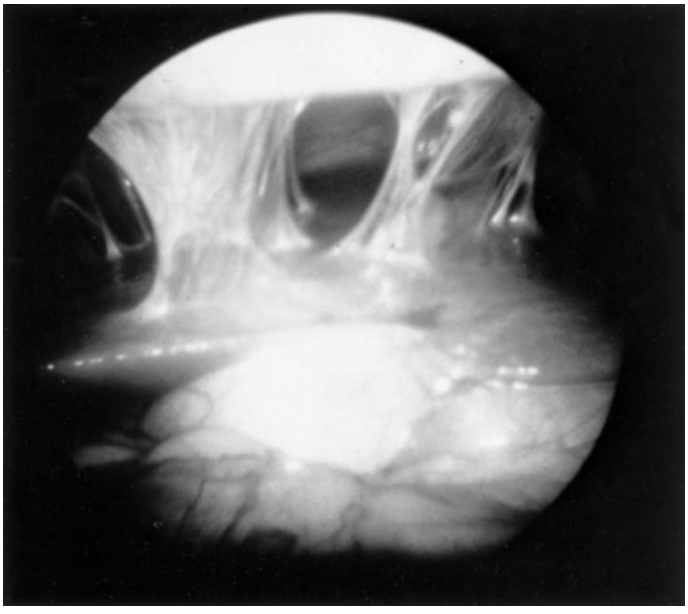

FIGURE 56-6. Laproscopic view of a later-stage Fitz-Hugh–Curtis syndrome demonstrating fibrous adhesions, including "violin-string adhesions," between the liver surface and the anterior abdominal wall.

38 women with laparoscopic signs of perihepatitis and salpingitis had right-upper-quadrant abdominal pain.[279] Other conditions can cause upper-quadrant pain, and laparoscopy can establish a definite diagnosis of acute perihepatitis.

Perihepatitis was initially associated with gonococcal PID,[38,211] but in most recent reports it was associated with *C. trachomatis*.[269,277,280–282] *C. trachomatis* was isolated from the liver capsule in women with perihepatitis.[276,282] An elevated serum antibody to *C. trachomatis* of ≥ 1: 32 occurs in 70–75% of women with perihepatitis[269,277,280]; the geometrical mean titer of *C. trachomatis* antibody is higher among women with perihepatitis than among those with salpingitis alone.[277]

The pathogenesis of perihepatitis remains unclear. Fluid and particulate matter in the cul-de-sac rapidly move to the subdiaphragmatic spaces.[283] As suggested by the recovery of *N. gonorrhoeae* and *C. trachomatis* from the liver capsule in perihepatitis, microbes may move with this fluid film. An additional factor might involve a delayed hypersensitivity reaction to CHSP-60 or other chlamydial antigens, analogous to the proposed role of DTH in chlamydial salpingitis. Antibody to CHSP-60 was associated with laparoscopically verified perihepatitis.[192] In addition to the particularly high levels of antichlamydial serum antibody, noted above, women with perihepatitis are more likely to have serologic evidence of a prior infection with a heterologous chlamydial immunotype,[277] and less frequent use of OCPs,[256,276,278] which may reduce the cellular immune response.[284]

The clinical importance of perihepatitis lies in the differential diagnosis. Many women with perihepatitis lack or do not report symptoms from concomitant genital infection. Perihepatitis should always be considered in a young woman presenting with right-upper-quadrant abdominal pain or right-sided pleuritic pain. Chest X-ray, ultrasonographic examination of the gall bladder, and gynecological examination, including tests for *N. gonorrhoeae* and *C. trachomatis*, can exclude other disease and reveal salpingitis and predisposing cervical infection.

DIAGNOSIS

As mentioned, no symptom or sign is pathognomonic of PID, and, in fact, all symptoms have a low positive and negative predictive value for the diagnosis of PID.[2,29,252–256]

CLINICAL SIGNS

An increase in the inflammatory cells in the vagina is common in PID. However, this criterion is imprecise, lacks an accepted definition, and can reflect either cervical or vaginal inflammation. MPC is correlated with cervical infection[285,286] and, therefore, is a more logical sign for the presence of upper genital tract infection in women with pelvic pain. However, MPC is common in populations at high risk of gonorrhea and chlamydia, where it has a low positive predictive value for diagnosis of PID. By contrast, in a primary-care setting, where cervical infection is less common, the clinical diagnosis of cervicitis among 95 women presenting with pelvic pain was 75% sensitive and 95% specific to diagnose PID.[254] Since PID usually arises from lower genital tract infection, the absence of MPC or inflammatory cells is a valuable negative predictor to exclude PID. In fact, none of the Swedish patients with laparoscopically documented PID had both an entirely normal vaginal wet mount and a clear cervical secretion.[2,29] Similarly, in women with histologic endometritis but without symptoms of PID, finding vaginal neutrophils was 91% sensitive, although only 26% specific.[287]

A vaginal wet mount with three or more WBC per high-powered field was more sensitive (87%) but less specific (38%) than the ESR, CRP, or peripheral WBC, among patients with signs of overt PID documented by endometrial biopsy or laparoscopy.[266] Vaginal wet mount and endocervical Gram stain for white blood cells are most useful for the presumptive diagnosis of chlamydial or gonococcal infection, only in settings with a relatively high prevalence of infection or when taken together with other predictors that can increase the likelihood of infection.[288]

In a meta-analysis of data from 14 studies on the diagnosis of PID, adnexal tenderness had a sensitivity of 95% but a low specificity of 74%; a palpable adnexal mass had a sensitivity of 48% and a specificity of 75% in predicting PID.[257] Other physical findings were even less predictive.

Simple pragmatic clinical algorithm may be useful in practice to lower the risk of under- or overtreating PID (Fig. 56-7). If pelvic examination findings suggest PID in a patient with a negative pregnancy test, the presence of MPC or an increased number of WBCs on a wet mount of vaginal fluid (e.g., number of WBCs exceeds number of epithelial cells) suggests PID, and treatment should be initiated. However, PID is unlikely if the patient is not sexually active or if the wet mount shows normal lactobacilli and no WBCs.

LABORATORY TESTS

Most laboratory tests used to diagnose PID are nonspecific. Further, the sensitivity and specificity of laboratory tests have not been compared with the laparoscopic diagnosis in large series. No laboratory test is either highly sensitive or specific for PID. However, a pregnancy test is required in all cases of suspected PID to exclude possible EP, which represents a life-threatening complication.

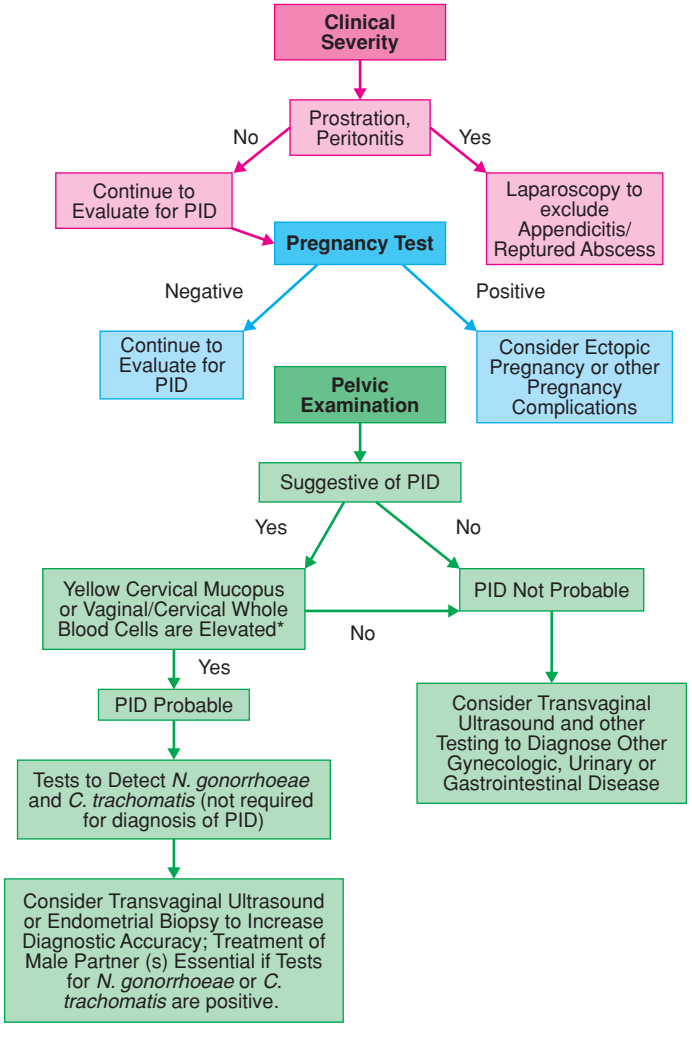

FIGURE 56-7. A stepwise algorithm in the differential diagnosis of acute PID.

Laboratory findings from Jacobson and Westrõm's study of Swedish women with PID are presented in (Table 56-3).[2,29] An ESR >15 mm/h was present in 76% of patients with, but also in 53% of patients without, laparoscopically verified PID. An elevated ESR was significantly associated with laparoscopic staging of the inflammatory reactions (mild 60%, moderate 84%, and severe 89%)[29] and, in another data set, with chlamydia-associated PID.[123]

Elevated levels of CRP had a sensitivity ranging from 70% to 93% and a specificity ranging from 67% to 90% for PID.[251,289–291] The level of CRP also appears to reflect the severity of laparoscopically proven PID. The mean CRP was 47 mg/L (range 32–63) for mild tubal abnormalities and 83 mg/L (range 65–103) for severe tubal disease.[290] An elevated CRP is a more sensitive and specific predictor of PID than an elevated ESR.[290] Further, changes in CRP more accurately reflect the course of the infection and the effect of treatment than changes in ESR.

In the Jacobson–Westrõm study, the peripheral WBC exceeded 10,000 mm^3 in 59% of patients with laparoscopically verified PID and in 33% of patients with no PID.[2,29] The WBC was normal in 63% of patients with laparoscopically mild disease and in 20% of those with severe disease.[29] An elevated WBC was particularly associated with gonococcal PID in a Seattle study.[267]

Other serum markers examined in patients with PID remain investigational. Antichymotrypsin levels were increased (>140% of a reference pool) in 23 of 40 patients with PID and in none of 15 control women.[29,291] Ovarian cancer-associated tumor markers, both CA125 and tumor-associated trypsin inhibitor have been elevated in one-fourth to one-third of patients with proven PID.[245,292,293] Specific genital isoamylases (SGI) are produced in fallopian-tube epithelium and are present in peritoneal fluid.[294] The SGI level is high in peritoneal fluid of healthy women but is diminished or absent in tubal infections and pregnancy.[295] Ratios of the level of nonpancreatic isoamylases in peritoneal fluid and serum (P/S quotient) <1.5 were found in 45 of 56 of patients with PID, in none of 22 women with lower genital tract infection, and in one of 18 control women.[295] This commercially available test is easy to perform, but it demands a cul-de-sac puncture. Larger studies are needed to confirm these results.

Since the diagnosis of PID is extremely difficult, a search for accurate diagnostic tests continues. One recent small study found enhanced erythrocyte aggregation in PID.[296] Erythrocyte aggregation testing is simple, rapid, and of low cost, but it should be further evaluated. Another recent study found an association between elevated neutrophil defensin levels and endometritis.[297] High levels of neutrophil defensins in the vagina were associated with endometritis. Neutrophil defensins process antimicrobial properties and are elevated in body fluids from patients with severe infections such as meningitis, sepsis, or intrauterine infection in pregnancy.

INVASIVE DIAGNOSTIC TECHNIQUES

CULDOCENTESIS

Peritoneal fluid can be obtained by culdocentesis, which is easy to perform, especially with vaginal ultrasonography to guide the needle.[298] An increased WBC level in peritoneal fluid indicates intra-abdominal inflammation. Combining two studies,[29,298] 21 out of 24 patients with proven PID and none of 36 control women had WBC counts >3100/mm in cul-de-sac fluid. Pure nonclotting blood in the aspirate indicates intra-abdominal bleeding and usually is an indication for laparoscopy or laparotomy to exclude EP or ruptured ovarian cyst.

Microbiological results on peritoneal fluid obtained by culdocentesis must be interpreted with caution, because of potential contamination from vaginal organisms or unrecognized bowel puncture. Additionally, species recovered by culdocentesis in PID have often been different from those recovered from tubal specimens obtained simultaneously by laparoscopy.[30,31] *C. trachomatis* is rarely isolated from peritoneal fluid even in chlamydial salpingitis,[31] although detection of *C. trachomatis* antigen or DNA in peritoneal fluid has not been evaluated.

In recent years, culdocentesis became less common to diagnose PID.

ENDOMETRIAL BIOPSY

Endometrial biopsy is a simple outpatient procedure.[298] Histologic evidence of endometritis includes polymorphonuclear leukocytes (PMNs) migrating through the endometrial epithelium and present within lumina of endometrial "glands," dense infiltration of the subepithelial stroma by plasma cells and lymphocytes, and germinal centers within the stroma.[37] Demonstration of histologic endometritis, based on detection both of plasma cells and of intraepithelial PMNs, had a sensitivity of 92% and a specificity of 87% with respect to detection of salpingitis by laparoscopy.[298] However, the distribution of endometrial inflammation may be patchy, and results are not immediately available. Still, endometrial biopsy has been increasingly used for the outpatient diagnosis of PID.[299–301]

It should be emphasized that plasma cells are also found in small numbers in the endometrium of healthy women, suggesting that plasma cells alone may not signify upper genital tract infection.[302] One central question in management of endometritis is whether endometritis and PID are different aspects of the same disease or separate clinical entities. The answer is not straightforward, and whether endometritis alone requires treatment[303] has been thoroughly assessed in the PEACH study.[301] Clearly, endometritis can be a distinct clinical syndrome requiring treatment in symptomatic women,[300] but evidence is not available for or against screening and treatment of endometritis in asymptomatic women.[303]

LAPAROSCOPY

Laparoscopy was introduced to study PID in the 1950s. After a series of publications during the 1960s through the 1980s,[2,23,252,253] laparoscopy became the gold standard to diagnose PID and obtain specimens directly from the fallopian tubes.[113] Criteria used to define salpingitis observed through the laparoscope include tubal erythema, swelling, and exudate.[2] Laparoscopy is a valuable research tool to study the accuracy of the clinical diagnosis of PID, to correlate symptoms and signs with laparoscopy findings, and to study the microbiology, pathology, and prognosis. However, laparoscopy is not practical for the majority of women with PID. Interpretation of laparoscopic findings is subjective and in need of interobserver and intraobserver reproducibility; the procedure has slight risks, and it is costly. Still, laparoscopy is valuable in selected circumstances; about 5% of women with clinically suspected PID have serious surgical conditions such as EP, appendicitis, or a ruptured abscess.[2,29,30] Laparoscopy has been used to guide the percutaneous placement of catheters to drain abscesses or to directly puncture a tuboovarian abscess.[304] Laparoscopy also benefits patients unresponsive to antibiotics, where the only objective finding is pelvic tenderness; such patients usually have no active infection, and laparoscopy identifies other conditions such as endometriosis.

The true accuracy of laparoscopy in the diagnosis of PID has never been formally validated. Although generally considered as the gold standard, observer agreement may be poor. In one study, where histopathologic diagnosis based on endometrial biopsy and fimbrial mini biopsy were used as the gold standard, laparoscopy had a sensitivity of 50%.[254] This study was performed among primary-care physicians referring patients with suspected PID to gynecologists for laparoscopy and suggested that the clinical diagnosis of PID was no more accurate than chance. In addition, specificity of 80% suggested only a modest agreement between clinical, visual, and histopathologic assessments.

A recent observer-agreement study also showed low accuracy of the laparoscopic diagnosis of PID, when histopathologically proven PID was used as the gold standard. The overall accuracy of the laparoscopic diagnosis of PID was 78%, the sensitivity was 27%, and the specificity was 92%.[305] The intraobserver reproducibility of the diagnosis of PID was only modest, and the interobserver reproducibility was only fair. When specific diagnostic features such as tubal erythema, edema, adhesion, or cul-de-sac fluid were separately analyzed, the results were not different, suggesting only poor-to-fair reproducibility. However, in this study, experienced gynecologists performed better than residents in training. These studies suggest that while the clinical diagnosis of PID is extremely difficult, laparoscopy seems to only partially solve the diagnostic problem.

ULTRASONOGRAPHY

Ultrasound provides a noninvasive test to diagnose and follow the course of severe PID. Findings in cases of severe PID include tuboovarian abscess, dilated fallopian tubes suggestive of pyosalpinx, excess fluid in the cul-de-sac, and enlarged polycystic ovaries.[306,307] These ultrasound findings were consistent with PID in 94% of patients with proven severe PID, in 80% of patients with moderate PID, but in only 64% of patients with mild PID.[307] Transvaginal ultrasound, which found dilated tubes, thickening of the wall of the tube, or fluid within the tube, was 85% sensitive and 100% specific, compared to plasma-cell endometritis among outpatients with pelvic pain.[308]

Transvaginal power Doppler sonography (TVS) is increasingly used among women admitted for suspected PID. Specific TVS findings, including wall thickness above 5 mm, cog-wheel sign, incomplete septa, and cul-de-sac fluid, best discriminate women with acute PID from women with hydrosalpinx formation.[309] Power Doppler TVS also reveals hyperemia in women with acute PID, which is not usually present in women without acute inflammation. Power Doppler TVS is hampered by motion artifacts and the need for a high level of expertise. Ultrasonography may also be used to guide needles for the drainage of tuboovarian abscess in selected cases.[310,311]

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) has been extensively used in the characterization of adnexal masses, but only a few studies have used MRI to diagnose gynecologic infection. Recent development of fast MRI technology shortens the imaging time. In one study, MRI turned out to be more accurate than transvaginal ultrasound to diagnose PID among patients who underwent laparoscopy. Thus, MRI is useful not only to establish the diagnosis of PID but also to detect other processes such as tubal torsion or severe endometriosis. Although transvaginal ultrasound is far more cost effective than MRI, MRI may still be cost effective if proper therapy can be provided early and laparoscopy is avoided.[312]

COMBINATIONS OF SYMPTOMS AND SIGNS IN THE DIAGNOSIS OF PID

Individual symptoms and signs of PID have a low diagnostic accuracy. Two comprehensive surveys on the diagnosis of PID[255,257] used a syndromic approach to evaluate the diagnosis of PID. As expected, increasing the number of positive indicators of PID increased the specificity but decreased the sensitivity, and a high sensitivity and good specificity were achieved only by integrating laparoscopy into the logistic models.[257] Still, in clinical practice, even in developed countries, a syndromic approach supplemented by simple laboratory tests for WBC and CRP and for pregnancy, together with vaginal wet mount examination and cervical tests for gonorrhea and chlamydial infection, remains the usual practice.

In conclusion, the diagnosis of PID remains difficult. In the absence of laparoscopy, the most obvious challenge is to discriminate whether or not a genital infection has extended to the fallopian tubes. In the future, TVS ultrasound and analyses of vaginal, cervical, and endometrial specimens seem to offer the best combination to diagnose PID without the use of laparoscopy.

High diagnostic accuracy is essential for effective patient management. Unfortunately, there is insufficient evidence from clinical research to support the existing commonly used diagnostic criteria for PID. Thus, a new evidence base is urgently needed; this will require either new studies of the association between clinical presentation and PID based on gold standard diagnoses or the development of new innovative diagnostic tests. However, a new major study of the clinical presentation of proven PID would be costly and time consuming.[313]

DIFFERENTIAL DIAGNOSIS

PID is one of many diagnoses that must be considered in women with abdominal or pelvic pain. In the largest series of 814 consecutive women laparoscoped because of a clinical diagnosis of salpingitis, 12% had intra-abdominal disorders other than PID.[2] The differential diagnosis of PID includes other gynecological conditions and disorders of the gastrointestinal and urinary tract. EP and acute appendicitis are the most serious intra-abdominal conditions to exclude. Despite the limitations of a direct microscopy of vaginal secretion, a completely normal wet mount argues strongly against PID.[29]

GYNECOLOGICAL CONDITIONS OTHER THAN PID

EP is the most common and important differential diagnosis in PID.[314,315] It is difficult to differentiate between an unruptured EP and mild-to-moderate PID on clinical criteria alone. Thus, a pregnancy test should be done in all potentially fertile women with acute abdominal/pelvic pain, and it also should be performed irrespective of contraception use.

Other common gynecological diagnoses to consider include rupture, bleeding, or torsion of an ovarian cyst. In such instances, the pelvic pain is usually acute in onset, unilateral, and severe. Laboratory tests are generally normal, and ultrasound most often reveals a pelvic mass or fluid in the cul-de-sac. Pelvic endometriosis may mimic PID, but the history of pelvic pain is often of longer duration than in PID. The microbiologic tests will be normal, but CRP may be elevated, and only laparoscopy will establish the diagnosis.

GASTROINTESTINAL DISEASES

Acute appendicitis is the most important differential diagnosis to exclude in this group. The clinical signs and laboratory test results overlap between appendicitis and PID, and up to 3% of women treated for PID have appendicitis.[2] A brief period of abdominal pain, pain originating in the central abdomen and moving to the right lower quadrant, nausea and vomiting, favoring a supine position, pallor, and abdominal guarding suggest appendicitis. If appendicitis cannot be excluded, laparoscopy should be performed and expectant management should not be considered.

Mesenteric lymphadenitis, *regional ileitis*, *enteritis*, and other manifestations of *inflammatory bowel disease* are other considerations in the differential diagnosis of PID.

URINARY TRACT DISORDERS

Urinary tract infection and colic from renal or ureteral stones are unusual differential diagnostic problems in PID. Microscopy and culture of urine usually will reveal the diagnosis. About 20% of women with STI-associated PID have urinary symptoms.[2]

A STEPWISE ALGORITHM

A simple stepwise algorithm for the differential diagnosis of PID includes the following: (1) A patient with prostration and signs of peritonitis needs hospitalization and an exploratory laparoscopy to exclude appendicitis or a ruptured abscess. (2) A positive pregnancy test in patients with pelvic tenderness points to EP or other pregnancy complications. (3) If a pelvic examination suggests PID in a patient with a negative pregnancy test, but the patient is sexually inactive or the wet mount or Gram stain of cervical/vaginal secretions is normal (i.e., shows no increase in PMNs or evidence of BV [see Chapter 42]), consider ultrasonography to diagnose other gynecological conditions, or a gastrointestinal/urinary disorder. (4) If the patient is sexually active and there is yellow cervical mucopus or the wet mount reveals WBCs outnumbering the number of epithelial cells, PID is probable, but other intrapelvic conditions are not completely excluded; consider TVS and endometrial biopsy to increase the accuracy of diagnosis. Testing for *N. gonorrhoeae* or *C. trachomatis* in the cervix or urine by nuclear amplification testing is indicated, and a positive test for either strongly increases the probability of PID.

TREATMENT

Antimicrobial therapy is required to treat infection present in PID. As previously noted, early antibiotic treatment in the first 3 days after the onset of symptoms reduced tubal infertility.[167] The choice of antimicrobial is empiric. The ideal to provide antimicrobial therapy, based on the isolation, identification, and antimicrobial susceptibility of the offending pathogen, is rarely achieved, because collection and microbial testing of fallopian-tube specimens are not practical in the majority of cases and test procedures are still too slow to guide initial therapy. Thus, the antimicrobial regimen must cover at least the most frequently expected microbes, including *N. gonorrhoeae*, *C. trachomatis*, and common aerobic and anaerobic isolates. At least two drugs are recommended by the CDC for syndromic treatment of PID (Table 56-6).

Guidelines for the hospitalization of patients are available.[1] A randomized trial has compared clinical and long-term outcomes with inpatient versus outpatient PID therapy. Among 831 women with clinical signs and symptoms of mild-to-moderate PID, there was no difference in reproductive outcomes of women randomized to inpatient treatment with intravenous cefoxitin and doxycycline versus outpatient treatment of a single intramuscular injection of cefoxitin and oral doxycycline.[301] Short-term clinical and microbiologic improvements were similar for inpatient versus outpatient treatment. After a mean 35 months of follow-up, pregnancy rates were nearly equal between groups. No statistically significant differences occurred between groups in the time to become pregnant or the proportion of women with recurrent PID, chronic pelvic pain, or EP.[301]

Large numbers of women are hospitalized for PID each year, but, without an apparent difference in effectiveness, the large cost savings gained by treating women with PID outside hospital certainly favors outpatient management of those with symptoms of mild-to-moderate PID.

Comprehensive assessment of the efficacy of antimicrobial treatment of acute PID must include (1) evaluation of the clinical response to acute infection, (2) elimination of at least *N. gonorrhoeae* and *C. trachomatis*, (3) evaluation for subsequent relapse and/or recurrence, and (4) incidence of late sequelae, including infertility, EP, and pelvic pain. The vast majority of studies have evaluated only the initial clinical response to infection. Factors that influence efficacy, besides the interval between symptoms and treatment, include the presence of *N. gonorrhoeae* (which is associated with better clinical outcome), abscesses, and prior PID (associated with worse clinical outcome).

A report summarizing the rates of clinical cure for inpatient and outpatient regimens found that clinical cure rates ranged from 60% to 100%.[316] Only five inpatient studies reported clinical cure rates less than 84%. Of these, one used metronidazole and penicillin, two used metronidazole and doxycycline, one used cefoxitin-doxycycline, and the other used sulbactam-ampicillin-doxycycline. In a meta-analysis of 21 studies that met inclusion criteria, pooled cure rates were similar for the multiple-drug inpatient regimens, which consisted of clindamycin-aminoglycosides (92%), cefoxitin-doxycycline

Table 56-6. Inpatient and Outpatient PID Treatment Regimen

Inpatient

Regimen A

Cefotetan 2 g i.v. every 12 h or cefoxitin 2 g i.v. every 6 h
plus
Doxycycline 100 mg orally or i.v. every 12 h

Regimen B

Clindamycin 900 mg i.v. every 8 h
plus
Gentamicin loading dose i.v. or i.m. (2 mg/kg of body weight) followed by maintenance dose (1.5 mg/kg) every 8 h. Single dosing may be substituted. Because of pain with infusion, doxycycline should be administered orally, when possible.
The intravenous regimen should be continued for at least 24 h after substantial clinical improvement, then followed by doxycycline 100 mg orally twice daily or clindamycin 450 mg orally four times daily for a total of 14 d of therapy.
Alternative parenteral regimens include ofloxacin or levofloxacin (with or without metronidazole) or ampicillin/sulbactam plus doxycycline.

Outpatient

Regimen A

Ceftriaxone 250 mg i.m. in a single dose or Cefxitin 2 g i.m. plus probenecid 1 g orally administered concurrently as a single dose or other parenteral third-generation cephalosporins (e.g., ceftizoxime or cefotaxime)
plus
Doxycycline 100 mg orally twice daily for 14 d with or without metronidazole 500 mg orally twice daily for 14 d

Regimen B

Ofloxacin 400 mg orally twice daily for 14 d or levofloxacin 500 mg orally once daily for 14 d
with or without
Metronidazole 500 mg orally twice daily for 14 d

From Centers for Disease Control and Prevention. Sexually transmitted disease guidelines 2002. *MMWR* 2002;51(RR6):1–80.

(93%), cefotetan-doxycycline (94%) and ciprofloxacin (94%).[316] Thus, the CDC-recommended regimens A and B (Table 56-6) have provided virtually identical clinical cure rates. Metronidazole-doxycycline had a pooled cure rate of only 75%. Single reports of multiple-drug inpatient regimens combining other cephalosporins (ceftizoxime and cefotaxime) or sulbactam ampicillin with doxycycline and ofloxacin alone also provided clinical cure rates of 88–100%.[316] Quinolones could also be combined with doxycycline and metronidazole for coverage. However, note that all of these studies were carried out before the widespread and continuing emergence of gonococcal resistance to fluoroquinolones.

In a review of trials between 1980 and 1990, the overall clinical cure rate was 90.4%. Six antibiotic regimens (clindamycin-aztreonam, cefoxitin-doxycycline, ticarcillin-clavulanic acid, moxalactam alone, clindamycin-aminoglycoside, and cefoxitin alone) provided clinical cure rates of 91–98%.[317] All the regimens achieved over a 90% clinical response rate, as reported in three or more papers, and all had significantly greater clinical response rates than penicillin combined with tetracycline, aminoglycosides, or metronidazole. Superior regimens, judged on the highest clinical response rates, lowest toxicity, and adequate coverage of *C. trachomatis*, included clindamycin-aztreonam and cefoxitin-doxycycline, where the clinical response rates were 98% and 95%, respectively.[317]

One recent trial compared azithromycin 500 mg IV daily for 1–2 days with or without metronidazole to combinations of doxycycline, cefoxitin, and metronidazole, and doxycycline and amoxicillin/clavulanic acid in 309 hospitalized patients in whom laparoscopy confirmed the diagnosis in 75%. Cure rates ranged from 95% to 98%, and *N. gonorrhoeae* and *C. trachomatis* eradication did not differ between groups.[318]

Currently, no single intravenous drug provides satisfactory coverage of both *N. gonorrhoeae* and *C. trachomatis*; two drugs must be used to cover these two bacteria. As shown in (Table 56-6), most facultative and anaerobic bacteria found in

PID are effectively treated by the cephalosporins in regimen A, and by gentamicin and clindamycin in regimen B. Intravenous clindamycin provides adequate but not optimal coverage of *C. trachomatis*.[319,320] Microbiologic cure rates were over 85%, with the exception of two studies: one of metronidazole-doxycycline-gentamicin (71% microbiologic cure) and one of cefoxitin-doxycycline (85% microbiologic cure).[316]

Outpatient regimens recommended by the CDC for the treatment of PID are also listed in (Table 56-6). As with the intravenous regimens, they are designed to provide excellent *N. gonorrhoeae* and *C. trachomatis* inhibition and some aerobic and anaerobic coverage. Metronidazole could be added to improve coverage of anaerobic bacteria. Physicians must ensure that those treated as outpatients comply with treatment. In the UK, a significant improvement in the clinical cure rate of outpatient management of PID was observed following a change in therapy that added ceftriaxone. (In the UK, many genitourinary medicine clinics had used oral doxycycline and metronidazole to treat PID.) Ceftriaxone 250 mg intramuscularly was added to cover quinolone-resistant gonorrhea. Women receiving ceftriaxone, doxycycline, and metronidazole had a clinical cure rate of 72%, compared with 55% among women who received only doxycycline and metronidazole. This UK study, reported in 2005, suggests that doxycycline and metronidazole alone are not a suitable regimen to treat PID.[321]

Little data exist on the effectiveness of azithromycin for PID treatment in the outpatient setting. Nonetheless, azithromycin might be more effective than doxycycline for eradicating persistent in vivo infection[322] and appeared to reduce upper genital tract inflammation in experimental primate infection.[323]

As expected, microbiologic cure rates of *N. gonorrhoeae* and *C. trachomatis* in the cervix are high with all regimens.[316] Virtually no valid data on microbiologic cure rates at the fallopian-tube site exist following therapy.

Also, few studies have followed patients for more than a few weeks to provide reliable data on relapse and recurrence of infection after therapy. Further, few studies assessed infertility, EP, and chronic pain after therapy.[199,263,301,324,325] Westrõm found that the subsequent infertility rate was 11–13% among patients treated with regimens such as penicillin-streptomycin, penicillin-chloramphenicol, ampicillin, and doxycycline.[326] The data suggested that most of the permanent damage occurred before antibiotic therapy was given, reinforcing the finding that the most important predictor of subsequent infertility is the degree of tubal damage when the infection was first observed and treatment was initiated.[25,326] However, more data are needed on tubal patency following therapy. In one small study reported in 1985, patients given doxycycline-metronidazole had a higher post-treatment rate of tubal patency based on hysterosalpingogram than those given penicillin-ampicillin-metronidazole.[327]

Women with an IUD should have it removed, usually after some interval of antibiotic therapy. All recent male sexual contacts of women with acute STI-associated salpingitis, including those who are asymptomatic, should be empirically treated for both gonococcal and chlamydial infection.

Radical surgery during the acute phase of PID has decreased significantly. Immediate surgical exploration is necessary to prevent septic shock in patients with a ruptured pelvic abscess. Early operative transvaginal drainage is the preferred method of treating a fluctuant pelvic abscess that becomes attached to the vagina in the midline of the cul-de-sac. More difficulty arises when an abscess that is not attached to the vagina requires transperitoneal drainage. Because even large masses do not always represent abscess formation, our current recommendation is to start antibiotic therapy that includes effective coverage of anaerobes and continue antibiotics if the mass size declines. Surgical exploration can then be delayed unless a definite abscess is identified by the clinical course, when the patient fails to improve clinically or the mass remains unchanged in size. If an abscess is of substantial size (greater than 6 cm in diameter), as demonstrated by TVS, transabdominal drainage may provide a shorter hospitalization and reduce recurrences.

If surgical drainage is required, laparoscopy is used to guide percutaneous placement of catheters into the large abscess. A catheter is used to drain pus and gently irrigate the abscess cavity. The catheter may be left to drain for 24–48 hours or until drainage decreases and the patient's condition improves. Care must be taken to avoid bowel injury and to identify multiloculated abscesses. About 90% of large abscesses can be cured with drainage[328,329] plus appropriate antibiotics with the advantage of obviating extensive surgery. For more complex clinical courses, simple drainage or even removal of a unilateral abscess at laparotomy without removal of the opposite tube and ovary and the uterus is usually successful when a patient receives an adequate antibiotic regimen that includes antibiotics to inhibit anaerobes. This conservative approach is particularly mandatory for young women with a first episode of acute PID who may desire children in the future. A limited number of patients with salpingitis suffer persistent abdominal pain without evidence of an abscess or adnexal pathology, except for mild tenderness. If pain continues, diagnostic laparoscopy should be performed.

PROGNOSIS AND SEQUELAE

PROGNOSIS

The vast majority of women have a complete clinical recovery, regardless of treatment.[326] The clinical course of acute PID is protracted in only a few women. In the industrialized countries, mortality from PID is unusual. In the United States, the mortality rate for PID was 0.29 per 100,000 female population 15–44 years of age in 1979.[330] The most common cause of

death is rupture of an abscess with generalized peritonitis, a condition still capable of causing death.[331,332]

SEQUELAE

Despite prompt diagnosis and treatment, sequelae are common. The most-feared complication of PID for women is tubal infertility (Fig. 56-8).[25,213,332–335] Tubal and peritubal damage after PID can result not only in infertility but also in EP, chronic pain, and other gynecological morbidity. Appropriate, timely antibiotic treatment helps to reduce these complications. The mean pregnancy rates in women attempting pregnancy after conservatively treated PID were 28% in 1026 patients before antibiotics and 73% in 954 patients after antibiotic therapy.[199]

In the United States and Europe, an estimated 15% of married and cohabiting couples fail to conceive after 1 year of unprotected sexual intercourse.[336] Among infertile couples, a global study reported a wide range in prevalence of postinfection tubal occlusion from a low number to over 50% of women, with wide geographical variations.[335–338] In studies from industrialized countries, 10–15% of women in infertile couples have tubal abnormalities and/or pelvic adhesions.[339] The corresponding figure in African women has been up to 64%.[337]

As mentioned, many tubal infections severe enough to cause tubal infertility have no or mild symptoms. In 23 seroepidemiologic studies of IgG antibody to *C. trachomatis* among infertile women, a serum antibody titer of ≥ 1: 8 was present in 68% of 1466 women with, and 27% of 1544 women without, TFI.[249] IgG antibody was found in about 33% of 1130 fertile controls. A titer of ≥ 1: 32 was present in 75% of those with tubal infertility and 21% of those with other reasons for infertility.[249] In these studies, 30–60% of the infertile women reported no history of PID.

The most extensive prospective follow-up study on reproductive events after overt PID was conducted at the University of Lund in Sweden, over the 25 years from 1960 through 1984.[25,29,213,249,326,333,340] In a brief review of these studies, 1730 women underwent routine diagnostic laparoscopy because of clinical suspicion of acute salpingitis. PID was diagnosed in 1282 and entirely normal conditions in 448 women. The latter group served as controls. Women exposed to pregnancy during the follow-up, and who either conceived or consulted because of infertility were compared to controls. Details of the methods are given in Ref. 199 and the results are provided in (Table 56-7).

Fertility

In this series, 96% of the controls and 78% of the patients with salpingitis developed an intrauterine pregnancy following the index laparoscopy. Among those with intrauterine pregnancies, no difference was observed between patients and controls in the proportion resulting in normal-term delivery, preterm delivery, stillbirth, and induced or spontaneous abortions.[25]

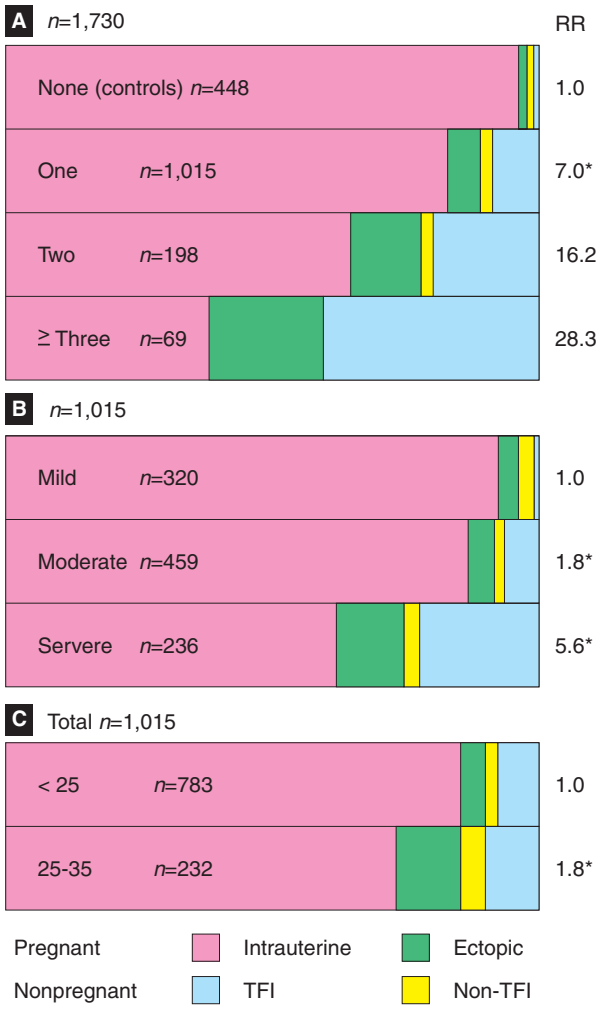

FIGURE 56-8. Fertility and infertility after PIDs: **A.** related to the number of PID episodes in one and the same woman; **B.** related to laparoscopic severity of the inflammatory reactions in women with only one episode of PID; and **C.** related to the age of the patient at the time of her only episode of PID.

Infertility

Among patients with salpingitis at laparoscopy, 12.1% had postinfection TFI and 2.1% were infertile for other reasons (Table 56-7). The corresponding figures in controls were 0.9% and 1.1%. An independent and significant risk factor for post-PID TFI was both the number of PID episodes (Fig. 56-8A)[25,326] and, among women with only one PID episode, the severity of the infection determined at laparoscopy (Fig. 56-8B).[25,326] Mild tubal disease was observed significantly more often at laparoscopy among women who used OCPs than among women who did not use contraception or used other methods.[341] With noncontraceptors as a reference group, tubal infertility after salpingitis was reduced by one-third ($p < 0.01$) in women who used combined OCPs at the time of the index laparoscopy, one-half in IUD users ($p < 0.05$), and not at all in users of barriers or other

Table 56-7. First Pregnancies (Uterine and Ectopic) and Infertility (Tubal and Nontubal Factor Infertility) in 1282 Patients and 448 Control Women Followed After Index Laparoscopy Related to Number of PID Episodes, Severity of Infection, and Age at Infection

		Pregant		Infertile		
		Uterine[a]	Ectopic[a]	TFI[b]	Other

[c]RR = Relative risk of postinfection tubal dysfunction (TFI/ectopic pregnancy).

methods.[326] These results should be interpreted with caution, because there was no information on the contraceptive method used after the PID episode. In an analysis of 443 women with STI-associated PID in this series, women who consulted after ≥ 3 days of abdominal pain had a 2.8-fold (95% confidence interval 1.3–6.1) increased risk of impaired fertility (tubal infertility or EP), compared with those who consulted within 3 days.[167]

Among women with only one episode of PID, post-PID TFI did not correlate with the antibiotic treatment administered.[326] A more favorable prognosis may have occurred after gonorrhea-associated PID than after nongonococcal PID,[25] but no such difference was observed in other reports.[249,333,342,343] *C. trachomatis*-associated PID has produced high rates of infertility in other studies,[193,334] and recent reanalysis of the series from Lund also indicated increased infertility after chlamydia-associated PID than after PID without genital chlamydial infection.[343] However, no difference was observed between women with chlamydia- and gonorrhea-associated PID in a prior report from that same group.[342]

Women less than 25 years of age have an overall better fertility prognosis after PID than older women (Fig. 56-8C). There was no difference between the age groups in tubal infertility after PID; however, the difference was accounted for by a higher proportion of fertility from other causes and from EP in older women, factors only partly related to PID (Fig. 56-8C).

Among women with one episode of PID with severely damaged tubes, fertility nonetheless remained in 62.7% (Table 56-7). Similarly, fertility was preserved in 63% in a series of women treated by colpotomy for pelvic abscess.[344] Thus, even in women with severely diseased tubes, fertility is preserved in over one-half.

Seroepidemiological studies of infertile and fertile women suggest significant causal roles for *N. gonorrhoeae*,[345–347] *C. trachomatis*,[247,342,345–348] and possible roles for *M. hominis*[348,349] and *M. genitalium*) in TFI.[348,350,351]

Since *C. trachomatis* is the leading cause of permanent tubal damage world wide, chlamydia antibody testing (CAT) is increasingly used in the evaluation of infertility.[352–354] Detection of past chlamydial infection using serology is noninvasive, simple, and quick. Also, chlamydial antibodies persist for years as serologic evidence of past infection. Further, a linear trend exists between serum CAT results and the likelihood of tubal damage.[354] However, the choice of cut-off level used for CAT screening depends on the prevalence of chlamydial infection in the population and the antibody test used. By using CAT more extensively, it may be possible to reduce the use of laparoscopy to diagnose TFI. In many infertility clinics, CAT is already an integral part of the infertility work-up. Medical history alone or transvaginal ultrasound appearance are insensitive to detect TFI in infertile women.[355] Cost-effectiveness studies suggest that the diagnostic work-up to detect tubal pathology should start with CAT.[356] One study from a university-based tertiary care infertility clinic reported that CAT was more accurate than hysterosalpingography in predicting TFI.[357]

Ectopic pregnancy

The ratio of EP to intrauterine pregnancy is related to the prevalence of fertile women exposed to pregnancy and the presence of risk factors for EP. Risk factors for EP besides salpingitis include older age, past and current use of an IUD, postoperative tubal damage, and other tubal pathology.[218,358] Since 1970, significant increases occurred in EP in industrialized countries.[359–362] A 64% increase in annual hospital admissions for EP was observed in one study between 1970–1974 and 1980–1984.[361] In the United States, hospital admissions for EP continued to increase until 1989 and then began to fall (Fig. 56-9). The decline may reflect a growing trend toward outpatient management of EP rather than a true decline in incidence; nearly half of all women with EPs in the United States are treated as outpatients.[362] Thus, the estimated number of EPs in the United States in 1992 was 108,800 (19.7 cases per 1000 pregnancies), the highest level in more than two decades.[362]

The epidemic increase in EPs until the early 1990s was explained by better diagnostic methods, increased use of IUDs, postponing the first pregnancy to an older age, and the epidemic of STIs. The impact of any individual factor is difficult

to evaluate, but, in one report, the increase in EP paralleled an increase in STIs in the 1980s, and the risk increased with the number of episodes of salpingitis.[363]

In the series from Lund, the first pregnancy after documented salpingitis was ectopic in 7.8% of patients compared to 1.3% of the control women. The ratio of EP to intrauterine preg-nancy in all first pregnancies was 1:73 among control women, and 1:15, 1:6, and 1:2.6 after one, two, and three episodes of salpingitis, respectively (Table 56-7; Fig. 56-8A). In women with only one episode of salpingitis, the corresponding figures were 1:36, 1:25, and 1:5.4 after mild, moderately severe, and severe PID, respectively (Table 56-7; Fig. 56-8B).

Age is consistently related to EP.[358,360] Women who used an IUD in the past have an increased rate of EP.[232] In seven sero-epidemiological case-control analyses, the mean prevalence of chlamydial serum antibody was 60% (range 32–71) in patients with EP and 24% (range 4–39) in control women.[249] PID has a "carryover" effect for increased risk of EP, even if the first pregnancy was intrauterine, such that an increased percentage of EP was parallel to the severity of tubal damage (observed by laparoscopy) and the number of episodes of prior salpingitis.[363] If the first pregnancy was ectopic, the risk for an EP in the following pregnancies was about 20%.[363]

Chronic pain

Abdominal or pelvic pain lasting longer than 6 months occurred in 17–18% of patients after one or more episodes of PID, compared to only 2–5% in control women.[29,199,253,364] Chronic pain is related to the number of PID episodes, occurring in 12% with one episode, 30% with two episodes, and 67% after three or more episodes of PID.[364] In patients with chronic pain after PID, peritubal and periovarian adhesions at a second-look laparoscopy revealed that pain occurred in 9% with no visible adhesions and 91% in those with extensive adhesions.[364] Chronic pelvic pain correlated better with the extent of pelvic adhesions than to the number of PID episodes.[364]

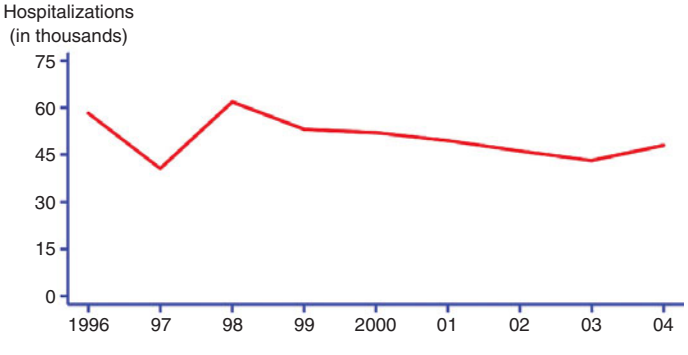

FIGURE 56-9. Ectopic pregnancy. Hospitalizations of women 15 to 44 years of age: United States, 1996–2004. *Note*: The relative standard error for these estimates ranges from 10% to 14%. Data only available through 2004. (*Source*: National Hospital Discharge Survey. National Center for Health Statistics, CDC).

General gynecologic morbidity

In a study of 1200 women hospitalized for PID and followed for 6.5–8.5 years, compared to 10,507 control women, there was a 4.5–9.8-fold increased risk of hospitalization for abdominal pain, "gynecologic" pain, endometriosis, hysterectomy, and EP.[365] The rate of total gynecological operations (excluding laparoscopy for repeat PID) was 0.8 procedures per woman in 415 patients after PID, compared to 0.1 per woman in 100 controls followed for 6–14 years.[25,366]

It is evident that many long-term sequelae can result from PID. It was estimated that one in four women with acute PID will suffer from one or more of the following: tubal infertility, EP, chronic pelvic pain, or PID-related gynecological surgery. Apart from the economic and public-health consequences of PID and its sequelae,[211] the human suffering is enormous in terms of a lowered quality of life and childlessness.

PREVENTION

Because treatment of PID has so far had only a limited impact upon sequelae of PID, prevention of PID is a high priority. Prevention of PID would not only reduce the morbidity and costs from acute infection, but it would also potentially offer large lower cost savings of treating sequelae. Widespread clinic-based screening for chlamydial infection reduces the prevalence of chlamydial infection at the population level, and public-health efforts to control gonorrhea and chlamydia reduce the rate of PID. In fact, recent data indicate that control programs for chlamydia have a major impact on reducing PID rates.[220,221,367]

One report demonstrated that women randomized to chlamydia screening subsequently experienced only half the rate of PID in half compared to an unscreened control group.[221] Another randomized trial from Denmark screened 5500 female high-school students for *C. trachomatis* by home sampling, with an overall uptake of 42%. The relative risk reduction for PID also was 50%.[367]

It is apparent that screening and treatment of asymptomatic women for *C. trachomatis* reduce the prevalence of chlamydial infection in the population and lower the risk of acute PID for the individual. As a result, the CDC, the U.S. Preventive Services Task Force, and several international agencies recommend chlamydia screening of sexually active women less than 26 years of age.[368] Despite these recommendations, U.S. women aged 16–26 years had only a 26% screening rate in commercial health plans and a 38% screening rate in Medicaid plans in 2001.[368] While about one-half of women with acute PID have *C. trachomatis* identified by culture, NAATs increase the detection of chlamydia by about 30%.[369] Thus, chlamydia-associated PID probably causes greater morbidity than currently estimated, because, until recently, the proportion of all cases of PID associated with

C. trachomatis had been determined only by culture. Because *C. trachomatis* is also particularly likely to produce mild symptoms[115] and may cause a disproportionate amount of unrecognized PID,[256] tubal infertility,[342] and EP[194,249] a more widespread adherence to recommended screening is called for.

Unfortunately, *C. trachomatis* infection is still not controlled in most populations. Efforts to control chlamydia in the United States and elsewhere are increasing very slowly. Some barriers to *C. trachomatis* control relate to indecisiveness about who to screen. While *C. trachomatis* causes specific clinical manifestations in women such as cervicitis[285] and the urethral syndrome,[370] most *C. trachomatis* infections in women are asymptomatic or produce only nonspecific or mild symptoms,[371] resulting in a large reservoir of asymptomatic *C. trachomatis* infection. Effective control programs require screening of both men and women, rather than reliance only on the identification and treatment of syndromes related to chlamydial infection.

CONTROL STRATEGIES

Disease prevention can be primary, secondary, or tertiary. Clinicians and other health-care providers have an important role in the primary prevention of STI. Primary prevention occurs through lifestyle counseling and health education, asking questions about risk-taking sexual behaviors, encouraging screening tests for those at risk, ensuring the proper management of sex partners, and counseling about safe sex practices. Partner notification and expedited treatment of sex partners are important but often ignored steps to prevent further sexual transmission of infections. Many sex partners of individuals with gonorrhea or chlamydial infections go untreated, leading to reinfections and further transmission. Strategies for expedited partner treatment, for example, by giving patients undergoing treatment for gonorrhea or chlamydial infection, have been found in a randomized trial to decrease rates of such infections in the index patient at follow-up—presumably by preventioing reinfection from an untreated partner.[372]

Screening for *C. trachomatis* infection represents secondary prevention at the population level, leading to early treatment and reduced further transmission, and also represents secondary prevention of complications and sequelae at the individual level. Because *C. trachomatis* is a major cause of upper genital tract infection and tubal damage, it is logical to focus a major prevention effort on chlamydia. Chlamydial infection fills all prerequisites for disease prevention by screening, because chlamydial infections are prevalent, associated with significant morbidity, readily diagnosed, and effectively treated. Current screening programs are important steps to limit complications of chlamydial infection. Major long-term reductions in the prevalence of chlamydial infections in the population seem unlikely unless men also are targeted, clinic-based screening is maximized, and innovative strategies are developed to encourage young people to be screened.[373] Prevention of PID is also clearly a testing issue. To date, screening rates are surprisingly low among sexually active young people, which can be explained by specific system, provider, and patient factors.[366,374] System factors include lack of availability of urine-based screening tests, which eliminate the need for gynecologic examination, insufficient reminder systems about screening, and inadequate organizational commitment to increase the availability of this preventive service. Provider factors include lack of awareness of high chlamydia prevalence in adolescents, misperceptions that adolescent patients are not sexually active, discomfort with discussing or lack of time to assess sexual activity, and lack of knowledge of the availability of urine-based chlamydia screening tests. Patient factors include the stigma associated with STIs, lack of awareness of the high prevalence of asymptomatic chlamydial infection, and fears about breaches of confidentiality regarding sexual health services or diagnoses in medical records.[368] One intervention that increased screening from 5% to 65% involved informing providers about high chlamydia prevalence and providing urine tests and monthly provider feedback on screening rates.[374] Another intervention, which included routine placement of chlamydia specimen collection materials next to Pap test collection kits, increased screening from 61% to 83%.[368]

COST EFFECTIVENESS OF PID PREVENTION

Cost-effectiveness analyses strongly support *C. trachomatis* screening to prevent PID.[375] By screening men and women between age 15 and 24 years, the prevalence of asymptomatic infections in women can be reduced from 4.2% to 1.4% over 10 years.[376] In particular, school-based screening programs are likely to be cost effective.[377] The average per person lifetime cost of PID ranges between $1060 and $3180. This suggests that successful PID prevention efforts may save substantial costs. These redefined estimates of the average lifetime cost of PID may improve future cost-effectiveness analysis.[378]

In many countries, reported rates to chlamydial infection have increased several fold since the early 1990s. An increasing incidence of genital *C. trachomatis* infection might be expected to lead to a rise in the incidence of PID. However, on a population level, trends in the incidence of PID generally do not parallel those of reported chlamydia rates. Such ecological disassociation may be surprising and should be interpreted with caution. For example, in Australia, chlamydia rates increased fourfold at a time when admission rates for PID significantly decreased.[379] This obvious discrepancy can be explained in many ways; one explanation is that the proportion of women with PID admitted to the hospital has decreased over the same time.[380] Further, early detection and treatment may prevent PID. Increased use of azithromycin

may improve compliance and prevent more complications. Population-level ecological data cannot show that chlamydia screening is directly responsible for a declining PID rate. In Sweden and many other European countries, despite continued screening, chlamydia rates have actually increased since early 1990s. In British Columbia, Canada, it has been argued that a resurgence in reported chlamydial incidence and rise in rates of *C. trachomatis* reinfections might reflect waning population-level immunity to *C. trachomatis* attributable to early detection of infection and attenuation of the average duration of infection to a period too short to generate protective immunity.[381] Nonetheless, increasing screening appears to be at least temporally associated with decreasing rates of PID in recent years and continued scale-up of screening seems warranted, while simultaneously pursuing other approaches to alter sexual networks. Ecological, time series analyses should be interpreted with caution.[382]

57 Cervical Neoplasia and Other STD-Related Genital Tract Neoplasias

Akhila Balasubramanian, Joel M. Palefsky, and Laura A. Koutsky

PAST SUCCESSES AND CURRENT CHALLENGES FOR PREVENTION AND TREATMENT OF GENITAL TRACT NEOPLASIA

It is now well established that specific types of sexually transmitted human papillomaviruses (HPV) play a central role in the pathogenesis of most squamous cell cancers and adenocarcinomas of the male and female genital tract. This makes HPV an STD with potentially life-threatening consequences. Fifty years ago, cervical cancer was considerably more common in the United States and other developed countries than it is today. This success is primarily due to the establishment of early detection through cytology-based screening programs. Such programs are only rarely available in much of the developing world, where cervical cancer continues to be the most common cause of cancer-related mortality among women. Worldwide, it is second only to breast cancer.[1]

In the last decade, our rapidly expanding knowledge of HPV carcinogenesis (reviewed in Chapter 27) and epidemiology (reviewed in Chapter 28) has allowed us to make great strides in our approach to control cervical cancer. As discussed in Chapter 58, HPV DNA testing is now recommended for use in cervical cancer screening programs in both developed and developing countries. At present, however, neither HPV DNA testing nor cytological screening have been recommended for early detection of other HPV-related genital cancers, in part because such cancers are less common than cervical cancer. More recently, a prophylactic recombinant HPV vaccine aimed at preventing cervical cancer as well as other HPV-related cancers and genital warts was approved in many countries for use in young women (reviewed in Chapter 28). The challenge of the next decade will be to implement and sustain HPV immunization programs that optimize public health benefits in both developed and developing countries.

This chapter summarizes recent trends in the incidence of invasive cervical and other anogenital tract cancers (vagina, vulva, penis, and anus), and discusses evidence that links genital and anal cancers with HPV and with other factors including behavioral and biological characteristics of the host. Practical guidelines for diagnosis and early treatment of genital and anal precancers and cancers are also provided.

DEFINITIONS AND CLASSIFICATION OF LESIONS

INVASIVE SQUAMOUS CELL CANCER

A variety of different types of malignancies occur at all genital and anal sites, but the majority of tumors are of the squamous cell type (Table 57-1). As discussed below, all have been associated with HPV infection. Squamous cell lesions of the anal and genital tract that are felt to be neoplastic in nature are generally divided into (1) invasive cancer and (2) noninvasive or preinvasive lesions. The term *invasive* refers to tumors in which the malignant cells have penetrated the underlying basement membrane and have infiltrated into the stroma. Invasive squamous cancers are graded as well, moderately, or poorly differentiated. Grade 1, or well-differentiated carcinoma, most resembles normal squamous epithelium, with many keratinizing cells and keratin pearls present. Grade 2, or moderately differentiated cancer, shows less keratin formation, with greater nuclear polymorphism and more mitoses present. Grade 3, or poorly differentiated squamous cell cancer, is composed of cells with a high nuclear/cytoplasmic ratio and many mitotic figures, but no keratin formation.[2] Invasive cervical cancers are further classified as being either frankly invasive or microinvasive. The Society of Gynecologic Oncologists (SGO) guideline defines microinvasive cervical lesions as those in which the malignant cells have not penetrated more than 2 mm below the basement membrane and in which lymphatic or vascular invasion is absent. More recently, it has been proposed that lesions in which the malignant cells have penetrated to a depth of 5 mm without vascular and/or lymphatic invasion, or lesions in which malignant cells penetrate to a depth of 3 mm but where vascular and/or lymphatic invasion is present, should be classified separately as *occult carcinoma*.[3] The term *microinvasive vulvar cancer* has also been introduced.

Table 57-1. Distribution (Percent) of Genital and Anal Cancers by Histologic Type Surveillance, Epidemiology, and End Results (SEER) Program, United States, 1993–2002

Total *N*	Cervix 35876	Vagina 2663	Vulva 7634	Female Anus 4130	Male Anus 2706	Penis 2418
Histologic types:*

NONINVASIVE SQUAMOUS CELL EPITHELIAL LESIONS

Histologic classification and natural history of noninvasive squamous cell epithelial lesions of the cervix

The concept of precancerous lesions was first developed around the beginning of the 1900s, when it was noted that the normal cervical epithelium cells adjacent to invasive squamous carcinomas were often replaced by a full-thickness layer of cells morphologically identical to invasive tumor cells.[4,5] Such areas were termed *carcinoma in situ* (CIS). On the basis of retrospective studies of women with invasive squamous cell carcinoma in whom prior biopsies showed CIS,[6] as well as on the basis of prospective studies,[7] it became widely accepted that such lesions represented incipient cancers. In fact, the exact proportion of cases that would progress from CIS to invasive cervical carcinoma (ICC) if left untreated is still unknown, because virtually all women with CIS are treated. Estimates of progression (based on eight studies) range from 0% to 71%, with a median of 34%.[7] However, median follow-up for these prospective studies has been less than 5 years, which is not sufficient time to accurately estimate rates of progression to invasion, persistence, or clearance. As discussed below, it is quite likely that most CIS lesions would persist or progress if left untreated, and therefore, cervical cancer control today is based on detection and subsequent treatment of women harboring such lesions.

Other types of cervical lesions composed of less worrisome cells were subsequently described. The significance of these lesions was even less clear, but because the cells in these lesions shared some morphologic features of cells seen in CIS, it was proposed that these lesions (initially called *dysplasias*, and later termed *cervical intraepithelial neoplasia or squamous intraepithelial lesions*) represented the earliest morphologic changes associated with cervical cancer. Despite the fact that little was known about the natural history of such lesions, several hierarchical systems for their classification were developed, which supposedly reflected their potential biological behavior. In the most popular of these classification schemes, noninvasive cervical epithelial lesions were classified as mild, moderate, or severe dysplasia or CIS. Subsequently, natural history studies in which women with varying degrees of dysplasia were followed by cytology alone (as it was felt that biopsies might alter the natural history) were undertaken to clarify the nature of these lesions and to provide a basis for clinical management of women harboring such lesions. As summarized in Table 57-2, with the exception of the Richart and Barron study, most investigators reported extremely low rates of progression of mild dysplasia to CIS. Nevertheless, on the basis of results from this natural history study, the investigators concluded and popularized the idea that "dysplasia is simply an early cervical

Table 57-2. Development of Carcinoma In Situ Among Women with Cytologic Evidence of Dysplasia: Summary of Four Studies

Principal Author, Year	Cytologic System[a]	Cytologic Entry Criterion	Cohort Definition	Number in Cohort	Months of Follow-Up	% Progressing to ≥ Carcin In Situ
Richart, 1969[b]	O[c]	3 dysplastic smears	Mild dysplasia	NS[d]	Projected progression at 60 mo (life table analysis)	50
			Mod. dysplasia	NS		70
			Severe dysplasia	NS		95

Data from SEER (the Surveillance Epidemiology and End Results Program of the National Cancer Institute).

neoplasm and ... although some spontaneous regressions do occur in the mild lesions, the vast majority of dysplasias ultimately evolve to carcinoma in situ and invasive carcinoma".[8] This view of dysplasia is inherent in the *cervical intraepithelial neoplasia* (CIN) classification scheme for cervical lesions, and the concept that mild, moderate, and severe dysplasia and CIS represent a morphologic and biologic continuum of progressive, consecutive stages in the development of invasive cancer. Lesions are classified as cervical intraepithelial grade lesion 1 (CIN1), cervical intraepithelial grade lesion 2 (CIN2), cervical intraepithelial grade lesion 3 (CIN3), or carcinoma *in situ* (CIS), according to the proportion of epithelium occupied by basaloid, undifferentiated cells (cells resembling the basal cell layer of the epithelium). CIN 1 lesions are conceptualized as having neoplastic, basaloid cells occupying the lower third of the epithelium, while in CIN 2 lesions, basaloid cells occupy the lower third to two-thirds of the epithelium, and in CIN 3, the full thickness of the epithelium is occupied by undifferentiated basal-type cells. The belief inherent in this system is that these are successive stages in development of invasive cancer and that most CIN 1, if left untreated, will progress to CIS. This view of the natural history of CIN 1 is dramatically different from that suggested by most natural history studies (see Table 57-2), which provide support for the view that mild dysplasia is generally a benign self-limited lesion with little malignant potential. The high rate of progression of CIN 1 detected in the

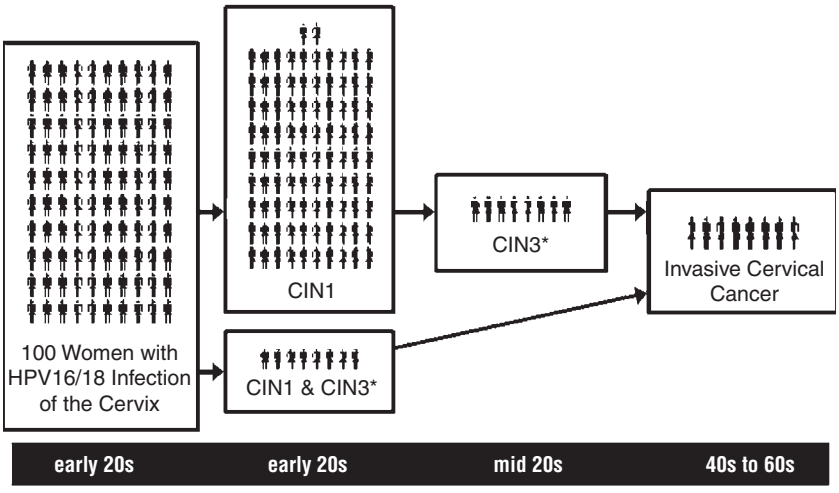

FIGURE 57-1. Natural history of HPV16/18-related cervical cancer in the absence of screening.

Richart and Barron study most likely resulted from the specific study entry criteria and the unique cytologic classification scheme employed. The fact that only women who had had three consecutive Pap smears showing mild dysplasia during the previous 12 months were eligible for enrollment in Richart and Barron's study that biased the study population toward women with mild dysplasias that were unlikely to regress. Furthermore, the Okagaki cytologic classification used in Richart and Barron's study differed markedly from that used today or from that used in the other studies shown in Table 57-2. Nevertheless, over the last 30 years, the CIN classification system has been widely used for histologic classification of cervical pathology, and has served as the basis for clinical management of women with cervical epithelial abnormalities. The view of carcinogenesis inherent in the CIN classification system has led to aggressive treatment of all lesions classified as CIN. Such an approach is increasingly being questioned in the light of what we have learned about the role of HPV as a common, self-limited, sexually-transmitted viral infection as well as the etiologic agent of most genital tract neoplasia.

All genital HPV types appear to be capable of causing CIN1, which is now widely accepted as the transient manifestation of a productive cervical HPV infection. Even without treatment, most CIN1 clears within less than 12 months.[9,10] CIN3, which is caused by oncogenic HPV types, is the precancerous cervical lesion that, if left untreated, is more likely to persist or progress to invasion than to spontaneously clear.[11,12] CIN2 is a histologically ambiguous presentation of CIN1 or CIN3. Current evidence indicates that regardless of the patient's age at detection, CIN3 requires treatment because spontaneous clearance is unlikely, and long-term persistence with the potential for invasion is likely. CIN2 is also treated because current technologies do not distinguish between lesions that will spontaneously clear and those that will persist and progress.

Recent knowledge of the role of oncogenic HPV in the pathogenesis of cervical cancer has led to the consideration of a new natural history paradigm (Fig. 57-1). This figure depicts the course of infection for 100 young women with HPV-16 or HPV-18 infection of the cervix. As in the analysis of Goldie and colleagues,[13] the estimated lifetime risk of cervical cancer in the underlying population of infected and uninfected women is estimated to be ~3.6%. Another feature of this paradigm is that all women with a cervical HPV-16 or HPV-18 infection are shown to develop CIN1. Although others[14] suggest that only about 20% of cervical HPV infections result in CIN1, it is probably closer to 100% because CIN1 is the lesion that produces infectious virions. A CIN1 lesion may never be detected because it is small and located outside of the transformation zone or in a glandular crypt, and because it is transient and often resolves before it is identified on a Pap test (median duration of CIN1/LSIL is 6 months or less[10,15]). Also, some HPV DNA that is detected in a cervical swab sample is from a vaginal, not a cervical infection and, thus, would not be expected to cause CIN.[16] While natural immune surveillance usually clears infectious virus, which leads to resolution of the associated CIN1 lesion and regeneration of uninfected (virally quiescent?) epithelium, immunity appears to be relatively ineffective at clearing the proliferating immature cells of CIN3.

Although the natural history of HPV at genital sites other than the cervix is less well understood, both productive and precancerous HPV-related lesions of the vagina, vulva, anus, and penis have been described.

Histologic Classification and Natural History of Noninvasive Squamous Cell Epithelial Lesions of the Vagina, Vulva, Anus, and Penis

The nomenclature for the precancerous states of vaginal, vulvar, anal, and penile squamous epithelium is similar to that of the cervix,[17] being termed as vaginal intraepithelial neoplasia

(VaIN 1, 2, 3), vulvar intraepithelial neoplasia (VIN 1, 2, 3), anal intraepithelial neoplasia (AIN 1, 2, 3), and penile intraepithelial neoplasia (PIN 1, 2, 3). It is preferable to avoid using terms such as "Bowen's disease" or "Bowenoid papulosis." Although there appears to be a remarkable morphologic similarity between CIN3 and VIN3, the risk for progression of VIN3 to invasive carcinoma is thought to be much lower than for CIN3, with less than 10% progression among young women with normal immune systems.[18–20] Given this apparent low risk of progression, the management of patients with VIN should be as conservative as possible. Similarly, management of VaIN and PIN is conservative. Invasive vaginal carcinoma is rare, and less is known about the relationship between intraepithelial and invasive disease. VaIN is most often found in the upper third of the vagina, and the lesions are usually multifocal. In one study, approximately one-half of the lesions were associated with concomitant cervical or vulvar intraepithelial neoplasia. Progression to invasive vaginal carcinoma occurred in two cases (9%), persistence of VaIN occurred in three (13%), and regression of VaIN occurred in 18 (78%).[21] Perianal high-grade AIN has a well-defined rate of progression to invasive anal cancer.[22] Intra-anal high-grade AIN has also been demonstrated to have precancerous potential but the progression rate is not well defined.[23]

INCIDENCE AND PREVALENCE

■ INVASIVE CERVICAL CANCER

International Trends

Carcinoma of the uterine cervix is the second most common cancer in the world among women, and the most common cancer among women in many developing countries of Africa, South and Central America, Asia, and the Pacific, with crude incidence rates ranging from 4 cases per 100,000 in western Asia to 35 per 100,000 in the Caribbean.[24] In 2002, it was estimated that there were 493,000 new cases and 274,000 deaths from cervical cancer detected worldwide. It was the seventh most common cancer among both sexes, preceded by cancers of the lung, breast, colon/rectum, stomach, prostate, and liver.[1] Figure 57-2 shows the incidence of cervical and penile cancer estimated from the data collected from tumor registries that were maintained in several countries in the years 1968–1972 and 1993–1997 (figure taken from Partridge and Koutsky [2005][25]). The incidence of cervical cancer declined in all of the areas shown except Israel and Zaragoza, Spain, whereas the incidence of penile cancer increased in many areas between the two periods studied. Although the overall incidence of cervical cancer has been declining in countries with organized screening programs, rates of cervical adenocarcinomas have been on the rise.[26–28] This could be due to the fact that cervical cytology testing has a relatively low sensitivity for adenocarcinoma compared to squamous cell carcinoma.[24]

US Trends

Data on the incidence, mortality, and survival rates of invasive cancer in the United States come from the Surveillance, Epidemiology, and End Results (SEER) Program, the part of the Surveillance Program at the National Cancer Institute (NCI) that routinely collects cancer data from nine population-based cancer registries located throughout the United States. The National Center for Health Statistics (NCHS) provides cancer mortality data for the entire United States. The

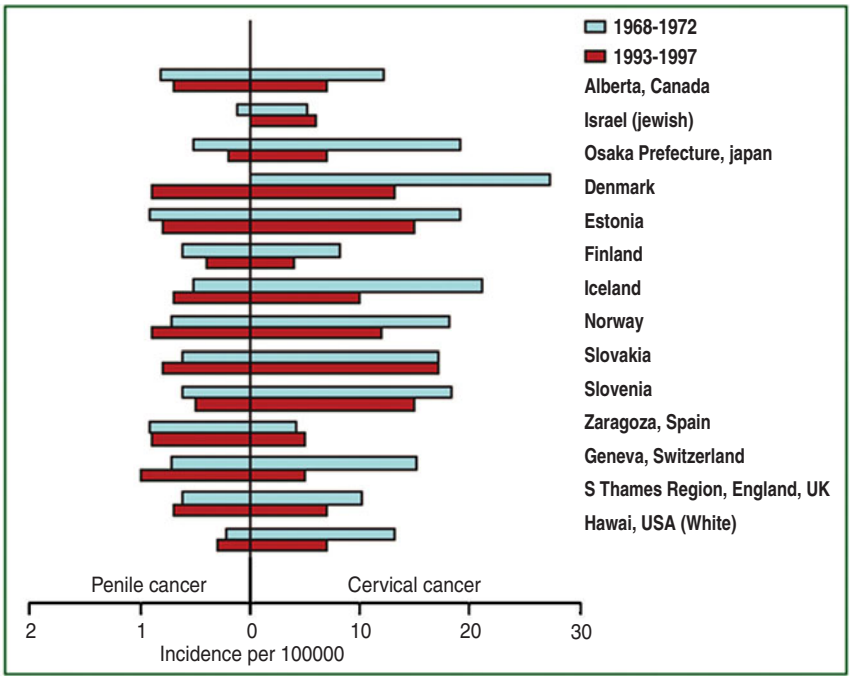

FIGURE 57-2. Age-adjusted incidence of cervical and penile cancers in countries with tumour registries during the years 1968–972 and 1993–1997. (Reprinted from Partridge JM, Koutsky LA. Genital human papillomavirus infection in men. *Lancet Infect Dis Jan* 2006; 6(1): 21–31.)

SEER data presented below are calculated only for women and are age-adjusted to the 2000 U.S. standard population.

From 1950 to 1991, the incidence of cervical cancer in the United States declined by 76.6% among white women, with an estimated annual percentage change of about 3.3.[29] The incidence has continued to decline, with an estimated annual percentage change of 4.5 for all women of all ages between 1997 and 2003. From 1975 to 2003, mortality from cervical cancer declined by 53.2% among whites and 64.7% among blacks. The 5-year relative survival among white women has increased from 58% (1960–1963) to 74.6% (1996–2002); among black women it has increased from 47% (1960–1963) to 66.3% (1996–2002).[30] The development and implementation of Pap smear screening for early detection of precancerous cervical lesions in the 1950s has generally been credited with a major portion of the dramatic decline in incidence and mortality.

The changes in incidence of cancers of the cervix, vagina, vulva, penis, and anus since 1973 are shown in Table 57-3. While rates of cervical cancer have generally declined, the incidence of carcinomas at each of the other genital sites has remained relatively low and steady over the past two decades, at least five times lower than the rates of cervical cancer, despite the fact that there is no routine screening for such lesions. Thus, the combined incidence of cancers of the vagina, vulva, and penis equaled 29.5% of the incidence of cervical cancer in 1973–1982, increasing to 44.1% in 1993–2002. On the other hand, the incidence of anal cancer has risen substantially in both men and women.

In 2002, there were an estimated 12,085 new cases and 3952 deaths from invasive cervical cancer in the United States.[31] The U.S. age-adjusted mortality rate (2000–2002) for cervical cancer was 2.6 per 100,000 women per year (standardized to the 2000 population), and for women diagnosed between 1996 and 2002, the 5-year relative survival rate for 17 SEER geographical regions was 71.6%. With an incidence of 8.8 cases per 100,000 during 2000–2003, cancer of the cervix uteri was the third most common female genital tract malignancy, following cancers of the corpus uteri (23.3 per 100,00) and ovary (13.7 per 100,000). In comparison, the incidence of breast cancer among women was considerably higher (129.1 per 100,000). The incidence of cervical cancer declined during the 1975–2003 period by 52.0%, cancer of the corpus uteri declined by 32.7%, and cancer of the ovary declined by 19.0%, but the incidence of breast cancer rose by 18.3%.[30]

Although carcinomas of the cervix, penis, vagina, vulva, and anus are morphologically similar and share a common sexually transmitted etiology, the incidence of cervical cancer is 5 to 50 times higher than other genital tract cancers (Table 57-3). The exception is anal cancer among homosexual men. While anal cancer was rare among the general population even prior to the advent of HIV, the incidence of anal cancer among homosexual men at that time approached that of cervical cancer prior to Pap screening (i.e., 36/100,000).[32] Why cervical cancer and anal cancer in homosexual men are so much more common than the other HPV-related genital tract cancers is unclear. Interestingly, however, both of these cancers arise in areas where HPV commonly infects metaplastic epithelium. Metaplasia is the process by which much of the mucus-secreting columnar epithelium in a particular anatomic location is replaced by stratified squamous epithelium. As shown in Fig. 57-3, the surface epithelium of the endocervix and ectocervix undergoes dramatic changes (squamous metaplasia) throughout a woman's lifetime, presumably as a

Table 57-3. Age Adjusted Genital and Anal Cancer Incidence for 1973–1982, 1983–1992, and 1993–2002, All Races; Surveillance, Epidemiology, and End Results (SEER) Program, United States

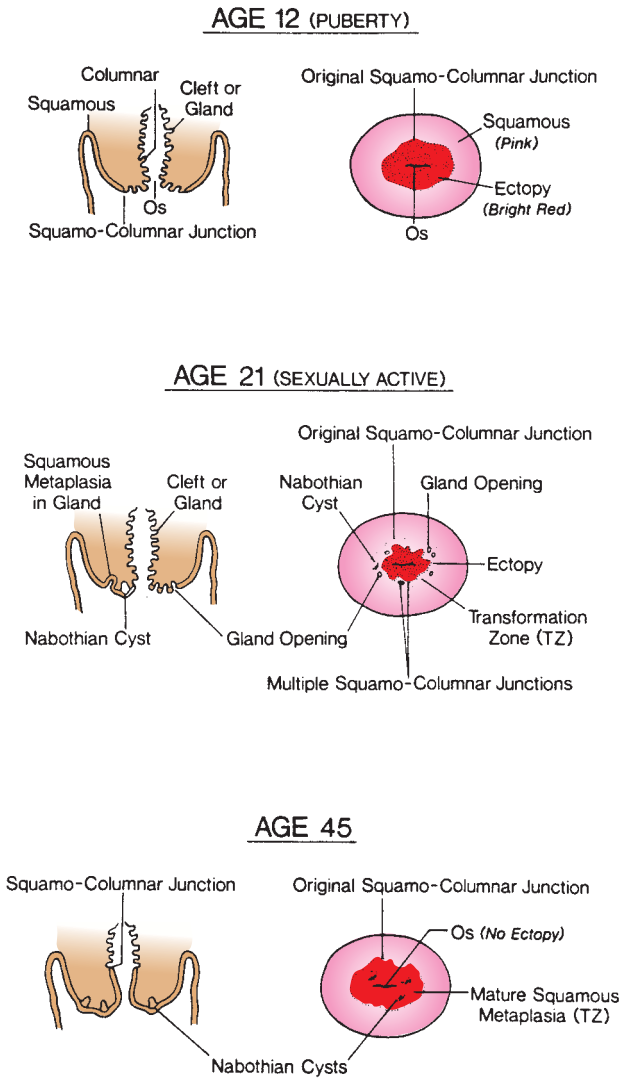

FIGURE 57-3. These diagrams show the change in location of the squamo-columnar junction on the uterine cervix from menarche (12 years) through initiation of sexual activity (21 years) and menopause (45 years).

result of hormonal and physical influences as well as infection with various agents, including HPV. As this change occurs, the point at which the squamous epithelium abuts columnar epithelium (termed the squamocolumnar junction) progressively recedes up into the endocervical canal. The area of the cervix where the native mucus-secreting columnar epithelium has been replaced by squamous epithelium is termed the transformation zone, and it is within this area of metaplastic epithelium that most cervical pathology, including early cancer, occurs. A similar zone of active epithelial metaplasia has been observed in the anal canal.

Age-specific rates in the US

Between the years 2000–2003, the median age of diagnosis for carcinoma of the cervix was 48 years, about 20 years younger than the median age of diagnosis of carcinoma of

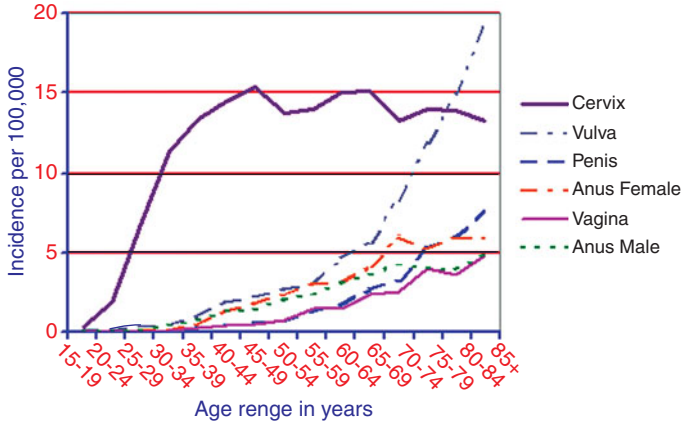

FIGURE 57-4. Age- and sex-specific incidence of invasive cancers of the cervix, vulva, penis, anus, and vagina in the United States. (Data from the Surveillance, Epidemiology, and End Results (SEER) Program, United States, 1993–2002.)

the vagina (68 years), vulva (69 years), anus (females, 63 years; males, 58 years), and penis (68 years).[30] As shown in Fig. 57-4, the incidence of all genital tract and anal cancers increases with age. The incidence of invasive cervical cancer increases with age, rising sharply to 11 per 100,000 between the ages of 30 and 34 years (premenopausal years), then fluctuating around 13–15 cases per 100,000 through the ninth decade of life. The age-specific incidence for other HPV-associated genital tract and anal cancers increases much more slowly and remains relatively low throughout life, except that of vulvar cancer, which increases sharply among women 60 years of age or older, up to about 20 cases per 100,000 for those in their 80s.

Ethnic Comparisons in the US

For all genital tract cancers except cancer of the vulva, the incidence is higher and the 5-year survival rate lower among African Americans than among whites. Overall in 2003, the incidence of carcinoma of the cervix was 10.5 as compared to 6.6 per 100,000 for black and white women, respectively. The disparity in cervical cancer incidence between white and black women is greatest among those over 50 years of age.

Mortality rates for HPV-related genital tract cancers have also remained considerably higher among African Americans of all ages since the early 1970s. This may be related to the fact that compared to cervical tumors diagnosed in black women, tumors diagnosed in white women are more likely to be localized at the time of diagnosis.[30] These racial differences in age and stage of cancer diagnosis may be related to varying access to and utilization of screening and treatment. However, the fact that survival is better for white women than for black women for each diagnostic stage of cancer[30] suggests other factors are also important. Regardless of race, women among lower

socioeconomic groups (lower income and education level), who until recently have had less access to Pap screening and gynecological services, have a higher risk of cervical cancer.[33,34]

CERVICAL CARCINOMA *IN SITU*

In countries with early detection programs, the incidence of cervical carcinoma in situ (CIS) is much higher than the incidence of invasive cervical cancer through the fourth decade of life. The estimated age-specific incidence rates of CIN 3/CIS and invasive cervical cancer (CC) are shown for three European cancer registries (Fig. 57-5). As seen in the figure, CIN 3/CIS has a younger age distribution than CC, with incidence rates peaking in the 25–30 years age group in all three countries. The incidence of CIN 3/CIS peaked at about 400 per 100,000 women in the UK and Iceland, thus being at least 400-fold greater than the incidence of CC. In Finland, which has a long-standing, centralized cervical screening program, the incidence of CIN 3/CIS is an order of magnitude lower, peaking between 25 and 30 per 100,000 women at the highest. Similarly, the population-based ratio of CIN 3/CIS to invasive cancer calculated over all ages is lowest in Finland. In all three countries, a second mode of CIN 3/CIS and CC cases is seen in the 50–65 years age group. The reason for this second mode is uncertain. It is possible that screening coverage may be poorer or cytology screening may have decreased sensitivity at older age groups. Alternatively, immunosuppression in older women may induce activation of latent HPV infections. Finally, the possibility of newly acquired HPV infections during middle age cannot be ruled out.[24]

It is likely that CIN3/CIS is often established at an age earlier than is depicted in Fig. 57-5. CIN3/CIS is asymptomatic and, therefore, will only be detected with screening followed by histological diagnosis. Delays in detection occur for the following reasons (1) in the United States women are screened only once every two years on average;[35] (2) Pap testing is only about 60% sensitive;[36] (3) cells from CIN3 lesions are difficult to identify on Pap tests when there is coexisting CIN1/LSIL, which is a common occurrence in young women;[37,38] (4) diagnostic biopsies often are not scheduled until after two or more abnormal Pap tests;[39] and (5) the lesion is initially misdiagnosed as normal, atypia, CIN1, or CIN2.[40] Moreover, in European countries, routine screening may not begin until the age of 25 or 30, and recommended screening intervals tend to be longer than in the United States.[41–43]

There is little information on the incidence of intraepithelial neoplasia of the vagina, vulva, anus, or penis in the general population, but it is likely that these lesions are less common than cervical neoplasia. VaIN 2–3 in the upper vagina usually represents a distal extension of CIN.[44,45] A recent report indicates that the incidence of vulvar in situ carcinoma increased more than 400% in the United States between 1973 and 2000.[46] The rate also appears to be increasing worldwide.[47]

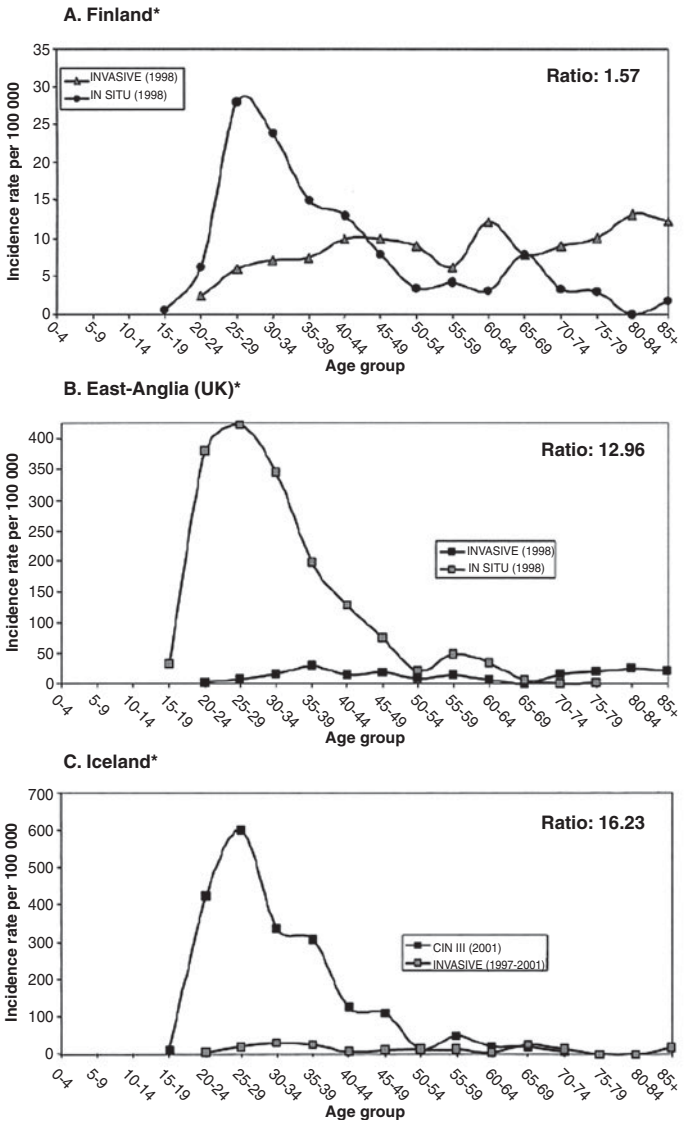

FIGURE 57-5. Age-specific incidence rate of CIN 3/carcinoma in situ and of invasive cervical cancer in selected populations. Ratio: Number of cases of CIN 3/in situ carcinoma of the cervix over the number of cases of invasive cancer diagnosed in the same population over the same time period across all age groups. (From Bosch FX, de Sanjose S. Human papillomavirus and cervical cancer–burden and assessment of causality. *J. Natl Cancer Inst Monogr* 2003; 31: 3–13.)

HISTORICAL OVERVIEW of ETIOLOGY: EPIDEMIOLOGICAL DATA SUGGESTING THAT CERVICAL CANCER IS AN STD

The association between cervical cancer and sexual activity was noted as early as 1842, when Rigoni–Stern reported that cancer of the uterus (site unspecified) occurred less frequently among cloistered nuns than among married women.[48] Since this initial report, other studies have con-

firmed the association between various measures of sexual exposure and development of squamous cell neoplasms of the cervix,[49] anus,[32] and vulva.[50] Since 1950, at least three studies have documented a low incidence of mortality from cervical cancer among nuns.[51–53] In contrast, subsequent wives of husbands whose previous wife had cervical cancer are at an increased risk.[54] In most studies, total number of sex partners is strongly associated with the risk of cervical neoplasia.[55,56] In 1981, Buckley et al. reported that among women reporting only one lifetime sex partner, those whose husbands reported six or more sex partners appeared to have approximately a fourfold higher risk of cervical neoplasia than women whose husbands reported having had fewer than six partners.[57] Zunzunegui showed that among South American women residing in California, the occurrence of invasive cervical cancer was highly associated with the total number of sex partners of the husband but not with the woman's sex partner history.[58] Studies have reported an increased occurrence of cervical cancer in partners of men with penile carcinoma.[59–61] Increased numbers of sex partners has also been associated with carcinoma of the anus[32] and penis.[62]

The epidemiologic evidence correlating sexual behavior with CIN and ICC, as well as with cancers of the penis and anus[32,56,63,64] led to an extensive search for specific STD agents acting as carcinogens in genital and anal cancers. Until the 1980s attention had shifted from one organism to another about every ten years, from syphilis in the 1940s[65,66] to gonorrhea[67–70] and trichomoniasis.[71–75] Other pathogens implicated in one or more studies include mycoplasmas, *Gardnerella vaginalis*, cytomegalovirus,[76–81] and Epstein–Barr virus.[82–85] The relationship of other sexually transmitted bacterial, chlamydial,[79,86–89] protozoan, and fungal infections to genital tract neoplasia has also been evaluated, and although it is now clear that they are not independent causes of genital and anal cancers, their capacity to induce chronic inflammation or to produce mutagenic metabolites[90] may increase the risk of genital and/or anal carcinogenesis.

During the 1970s and early 1980s, there was considerable interest in HSV 2 and cervical cancer.[56,91,92] The major problem in most seroepidemiologic studies linking cervical cancer to various STDs, including HSV, has been the lack of careful matching of cases and controls for potential confounding factors, most importantly sexual behavior. With HSV 2 there was the additional difficulty in initial seroepidemiologic studies of discriminating between serum antibody responses to HSV 1 and HSV 2.[93–96] Epidemiologic and laboratory-based studies suggest that once HPV is taken into account, there is little evidence of an important role for HSV in the pathogenesis of cervical cancer,[97,98] but that it may act as a cofactor by enhancing host susceptibility to HPV-induced neoplastic changes.[99,100]

HPV TYPE AND GENITAL TRACT CANCERS

Within the taxonomic family of papillomaviruses, there are many species of HPVs, and within each species, the numerous HPVs are classified into types, subtypes, or variants based on DNA homology.[101] Clinical epidemiologic studies undertaken during the last two decades have strongly supported the central role for specific types of HPV in the pathogenesis of squamous cell cancers of the genital tract. In addition, as discussed in Chapter 27, the molecular and biochemical evidence supporting a link between specific types of HPV and cancers of the genital tract and anus is quite strong.

Bosch et al. examined over 1000 cases of invasive cervical cancers from 22 countries from around the world for HPV DNA by PCR, using the L1 consensus primer and 26 type-specific probes. Over 93% of cancers in this series were positive for HPV DNA[102] (Fig. 57-6)[103]. It was hypothesized that the failure to detect HPV DNA in 7% of the samples may have been an indication of false-negative PCR results rather than the absence of HPV. Integration of HPV DNA into the host genome can disrupt the L1 open reading frame or the PCR primer sequences, leading to negative PCR results. Amplification of the E6 or E7 region of HPV DNA avoids this problem. With this in mind, the HPV DNA-negative samples were retested by type-specific E7 PCR targeting 14 HPV types. Combining the data from the two studies, HPV DNA was found to be present in 99.7% of cervical carcinomas.[104]

A number of case-control studies examining the association between specific HPV types and invasive cervical cancer have been performed, with most studies reporting relative risks for the association of HPV DNA and invasive cervical cancer ranging from about 10 to over 40 for PCR-based studies.[105,106] Recently, a pooled analysis was conducted that included 1918 squamous cell cervical cancer cases and 1928 controls taken from 11 case-control studies from around the world. All the studies included had used PCR-based methods to detect HPV DNA. Detection of HPV of any type was associated with a 158-fold increased risk for cervical cancer. Thirteen HPV types were classified as "high-risk" types because the odds ratios for cervical cancer associated with these types exceeded 45. These types were HPV-16, -18, -31, -33, -35, -45, -51, -52, -56, -58, -59, -68, and -73. In addition, types 39 and 82 were also classified as "high-risk" because they were detected in some cases but no controls. HPV types 26, 53, and 66 were classified as "probable high-risk" because they were detected in only a few cases and in no controls. HPV-16 was associated with the highest risk for squamous cell carcinoma (OR = 435, 95% confidence interval 278–679). In general, HPV types that are phylogenetically related to HPV-16 and HPV-18 conferred the highest risk.[101,107] Prospective studies of HPV infection and risk of CIN2 or worse show similar findings.[10,108–117]

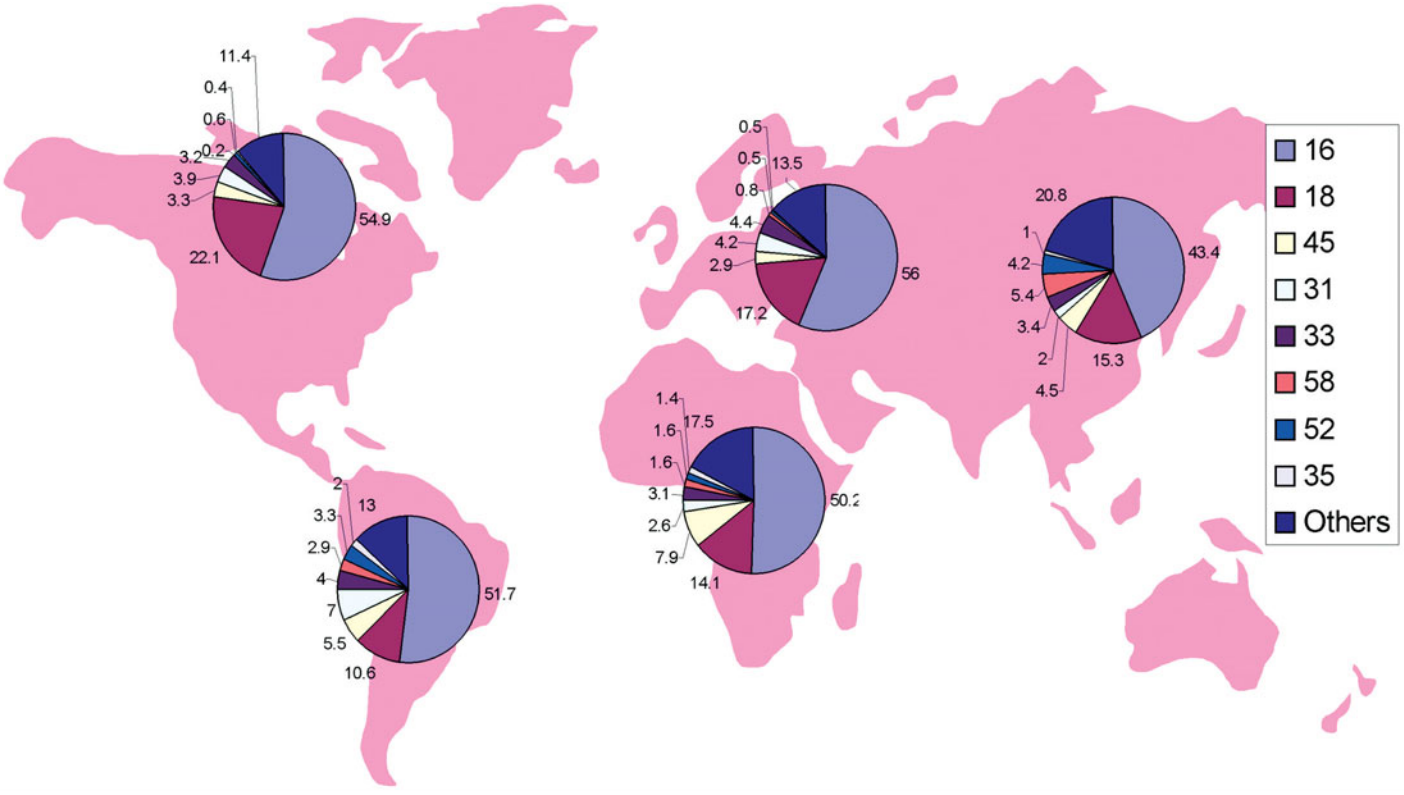

FIGURE 57-6. Detection of HPV types in cervix cancers from different regions of the world. (Data from Clifford GM, Smith JS, Plummer M, Munoz N, Franceschi S. Human papillomavirus types in invasive cervical cancer worldwide: A meta-analysis. *Br J Cancer* 2003; 88(1): 63–73.)

The overall distribution of HPV types in cervical cancer is similar across the world (Fig. 57-6). In a meta-analysis, Clifford et al. found that HPV DNA is significantly more likely to be detected in squamous cell carcinomas (SCC) than in adenocarcinomas, but HPV-16 is the predominant type in both types of cancers. Throughout the world, HPV-16 and HPV-18 were the first and second most common types present in SCC, accounting for about two-thirds of the cases worldwide. In North and South America, Europe, and Australia, HPV-45 and HPV-33 were the next most prevalent types in SCC. In Africa, HPV-45 was more than twice as prevalent as HPV-31 or HPV-33, while in Asia HPV types 58 and 52 were found more commonly than HPVs-45, -31, and -33.[103]

The role of HPV in anal carcinoma has been extensively studied and is now well established.[118] There is no clear distinction between HPV-positive and HPV-negative tumors. Basaloid anal cancers are similar to squamous cell anal cancers with respect to prevalence of HPV DNA, and are more likely to be a histologic variant rather than a separate entity. HPV has also been shown to substantially increase the risk of other anogenital cancers. In a case-control study, Carter et al. investigated the effect of HPV seropositivity on the risk of cervical, vulvar, vaginal, penile, and anal invasive and in situ cancers among men and women in western Washington state. HPV-16 seropositivity was associated with an increased risk of all the anogenital cancers, with risk estimates ranging from 1.8 for cervical adenocarcinoma to 5.9 for vaginal cancer. HPV-18 seropositivity was associated with an increased risk of cervical, vulvar, vaginal, and anal but not penile cancer. HPV DNA was detected in >80% of all anogenital cancers tested.[119] Bjorge and colleagues performed a nested case-control study, using data from a cohort of individuals in Norway and Finland who developed noncervical anogenital cancers.[120] HPV-16 seropositivity was associated with a significantly increased risk of vulvar and vaginal cancers. HPV-18 seropositivity was associated with a significantly increased risk of preinvasive lesions at these sites. Nonsignificant but elevated risk for penile cancer was associated with seropositivity for HPV-16 and HPV-33. The fact that this study is based on prospectively collected data adds further credence to the role of HPV in these anogenital cancers. In contrast to cervical and anal cancer, however, HPV DNA is not as frequently detected in all other genital cancers. In penile tumors, HPV DNA positivity varies from 42% to 80%.[62,121–123] Similar findings have been made for vulvar tumors.[25] The relationship between HPV and penile cancer resembles vulvar cancer more than cervical cancer. Warty and basaloid cancers of the penis have a higher prevalence of HPV infection than verrucous and keratinizing cancers of the penis. Verrucous carcinomas are associated with low-risk HPV types.

COFACTORS FOR HPV CARCINOGENESIS

Because only a minority of women infected with oncogenic types of genital HPV go on to develop cervical neoplasia, investigators have studied other factors that may work in conjunction with HPV to contribute toward an increased risk of neoplastic behavior. These factors can be broadly classified as (1) viral cofactors; (2) host cofactors; and (3) environmental cofactors.

VIRAL COFACTORS: VIRAL PERSISTENCE, VARIANT, VIRAL LOAD AND INTEGRATION

Persistent detection of infection

The majority of genital HPV infections appear to be transient,[124–128] with most new infections being detectable for less than 2 years.[124,125,128,129]

While it has been generally accepted that persistent HPV infection is crucial for development of neoplasia, uncertainties and controversies remain. Long-term persistence (that is, repeated detection of the same HPV type on two visits at least 5 years apart) is about the same for high-risk and low-risk HPV types, with the possible exception of HPV-16.[108] Furthermore, in a longitudinal study with active biannual follow-up,[111] risk of a precancerous cervical lesion was greatest within 6 months of the first positive HPV test, not after 12 or more months of persistent HPV infection. Results from another natural history study[10] and from 3.5 years follow-up post-dose 3 of the placebo arm of the monovalent HPV-16 vaccine trial[130] are similar. Thus, as Woodman and Collins[131] have discussed, persistence per se does not appear to predict progression. Rather, it is likely that a persistent high-risk HPV infection is more of a "risk marker" for underlying CIN3 than a "risk factor" for future development of CIN3.

HPV variants

HPV viruses are classified into separate "types" if they differ by more than 10% in the nucleotide sequences of specified regions of the genome.[101,132,133] Viruses that differ by 2–10% in these regions are considered "subtypes" while those that differ by less than 2% in these regions are considered to be "variants."[101,132,133] Because only a minority of women infected with oncogenic HPV types go on to develop cervical cancer, there is now considerable interest in the idea that different HPV variants might have differing biological behaviors. Although most of the research in this area has tended to focus on HPV-16, investigators have begun expanding their studies to include other oncogenic HPV variants as well.

The first HPV-16 to be cloned was from a cervical cancer removed from a German patient. This HPV is considered the HPV-16 prototype variant, and is the variant commonly used in molecular studies of HPV. Nucleotide sequencing of E6, L1, L2, and the long control region (LCR) of viruses in different parts of the world revealed the existence of multiple HPV variants, which segregate geographically, suggesting that the virus coevolved with its human host.[132–140] Based on their suspected origin, HPV-16 variants have been classified into five phylogenetic lineages: European (E), Asian (As), Asian American (AA), African-1 (Af1), and African-2 (Af2). Yamada et al. examined invasive cervical cancers from 22 countries and found that 92% belonged to previously reported HPV-16 lineages, with 7.8% of cancers harboring HPV-16 variants with novel hybridization and/or nucleotide changes. Most variants from European and North American samples were phylogenetically classified as European prototype (E), while samples from Africa were primarily classified as African.[137] Stewart et al. examined 135 invasive cervical cancers from the same 22 countries, in addition to 11 cancers from New Mexico, for variations in the genomic sequences of HPV types -18, -33, -35, -39, -45, -51, -52, -58, -59, -68, -73, and -82. They found that within a given HPV type, nucleotide sequence varied from 0.2% to 2.9% and amino acid diversity was between 0% and 5.1%.[139]

It is possible that differences in certain amino acid sequences might have functional importance for biologic properties related to the development of malignancy. As discussed in Chapter 27, E6 and E7 genes of HPV are vital to oncogenic transformation. Their gene products interact with various cellular proteins involved in cell-cycle regulation, most notably p53 and Rb, respectively. Transcription of E6 and E7 genes is controlled by promoter and enhancer elements in the long control region and by the E2 protein of HPV. Thus, nucleotide sequence variation in E6, E7, E2, and LCR genes may have functional significance that impacts the malignant potential of the different variants. Evidence of this has begun to emerge from *in vitro* studies. HPV-16 E6 variants have been observed to have varying abilities to generate differentiation-resistant human foreskin keratinocyte (HFK) colonies and to target the degradation of p53.[133,141] Nucleotide alterations in the noncoding region of HPV-16 have been shown to enhance promoter and transcriptional activity[142–145] or alter oncogenic potential in the presence of *ras* oncogene and hormone.[146] The influence of variant differences on promoter activity of E6/E7 has also been observed in vitro for HPV-18.[147]

Early epidemiologic studies of the association between HPV variants and risk of neoplasia (reviewed in Ref. 132) yielded conflicting findings. It is now accepted that the early data were rather homogeneous, being predominated by European variants.[132] Thus, significant differences in the risk of neoplasia were not always observed in the variants included in these projects. Later studies, conducted largely in North and South America, demonstrated that the non-European lineages of HPV-16 confer higher risk of cervical neoplasia.[144,148–152] In a

cohort study in Seattle, we found that compared to women infected with prototypelike (PL) variants of HPV-16, women infected with non-prototypelike (NPL) variants are at increased risk of developing CIN2-3.[144,151] This finding was also seen in a cohort study performed in Brazil.[150]

A few studies[150,153,154] have provided evidence that as with HPV-16, NPL variants of HPV-18 confer increased risk of developing high grade cervical neoplasia. The limited epidemiologic data on variants of other oncogenic HPV types have so far indicated that certain polymorphisms of HPV-33[155] and HPV-58[156] may be associated with CIN3 and invasive squamous cell carcinoma.

It is possible that the oncogenic potential of HPV variants may vary in different populations if certain amino acid changes present in certain variants, in association with specific host HLA haplotypes, influence the host immune response to different HPV types or variants.[149,157–162] It has also been suggested that specific HPV variants might work in concert with certain p53 polymorphisms to increase a woman's risk for cervical cancer[163] or risk of transitioning from CIN3 to invasive cancer.[164] Such data are currently sparse and suffer from low sample sizes, but suggest that the oncogenic potential of HPV could be determined by the particular combination of molecular factors present in the cellular milieu.

Viral load

Several studies have shown that HPV-16 viral loads are higher among women with cervical neoplasia than among those without,[165–169] but a similar trend has not been reported for other oncogenic HPV types.[170] In a nested case-control study conducted in Sweden, viral load measured using quantitative PCR was able to predict CIS even in samples collected 13 years before diagnosis.[171] Repeated detection of high viral load was associated with risk of incident CIS, but the magnitude of this risk decreased with increasing length of time between HPV testing and diagnosis of CIS.[166] In another study using quantitative PCR, women with high viral loads had increased likelihood of developing CIN 2–3 and decreased risk of viral clearance. Furthermore, among women with Pap abnormalities, a consistently high viral load was predictive of progression to a higher grade lesion.[165] Although the relationship between high HPV-16 viral load and cervical neoplasia is consistent, the association is not strong enough to propose the use of HPV-16 viral load as a screening test for cervical cancer.

Viral integration

In vitro studies with HPV-16 have shown that cell populations in which the virus is integrated into the host genome possesses a growth advantage compared to cells in which the virus is retained in its episomal form.[172] During integration, the E1 and/or E2 genes of HPV are often disrupted, while the E6 and E7 oncogenes are retained. The disruption of the open reading frame of E2 is thought to augment the levels of mRNAs encoding E6 and E7. The proteins expressed by the latter two genes are critical in HPV carcinogenesis through their interactions with p53 and Rb proteins in the host, respectively. Thus, disruption of E2 during the viral integration process may be an irreversible step that leads to a chain of events resulting in genomic instability and cell immortalization.[172] HPV-16 integration has been reported to occur to different degrees in variously graded cervical lesions, from low-grade lesions to invasive cancer.[172–182] Some studies show that the frequency of integration increases with increasing disease severity,[176–179] and integration has also been linked with poorer prognosis of cervical cancer.[183,184] These findings have not been confirmed in other investigations, and the importance of integration in development of neoplasia is still being debated.[172,180–182] As was the case with the early studies of the role of HPV DNA in cervical neoplasia, much of the reason for this uncertainty may lie in the limitations of laboratory assays to measure integration. Methodologic challenges include the fact that HPV often coexists in integrated and episomal form, and that the sites of integration are highly variable. Also, assays that measure levels or relative levels of E2 and E6 or E7 DNA without taking into account the inherent variability of the nucleotides for different variants of a given HPV type are likely to provide inaccurate results.

HOST FACTORS: ASSOCIATIONS BETWEEN HLA HAPLOTYPE AND RISK OF HPV-RELATED CANCER

Since human leukocyte antigen (HLA) molecules are responsible for presenting foreign antigens to the immune system, there was a strong a-priori hypothesis that HLA molecules may influence the risk of developing neoplasia mediated by clearance of HPV infection. Most research on the association of HLA molecules with cervical neoplasia has focused on HLA Class II molecules, which present antigenic peptides to $CD4^+$ T-helper cells to initiate cell-mediated immunity.[132] The most consistent findings to date point toward a decreased risk of CIN3/CIS and SCC associated with HLA Class II DRB1*13 (DRB1*1301-5) and DQB1*0603 alleles (these two alleles are in linkage disequilibrium and, therefore, often occur on the same haplotype).[185–202] In a recent study, Sastre-Garau et al. observed that after controlling other factors including HPV-16/-18 infection, the DRB1*13 allele is associated with increased probability of regression of CIN 1 lesions.[203]

ENVIRONMENTAL FACTORS: MEASURES OF SEXUAL BEHAVIOR, HORMONE AND CONTRACEPTIVE USE, SMOKING AND DIET

After taking into account HPV, the previously reported associations of cervical cancer with many risk factors, such as

number of sex partners, early age of first intercourse, parity, or other infectious agents, disappear or are greatly reduced. Likewise, while several case control studies during the 1980s linked current cigarette smoking with cancers of the cervix,[55,204] vulva,[50] anus,[32] and penis,[205] these studies did not adequately take into account confounding sexual exposures not measured by the number of sex partners, or (most importantly) laboratory evidence of HPV infection. Recent studies have evaluated the independent effect of smoking on neoplasia by restricting analyses to include only women who are HPV-infected. These studies have indicated that smoking imparts a 1.5-fold to 5-fold increased risk for high grade cervical neoplasia and invasive cancer, and that there is a trend of increasing risk associated with increasing amounts of exposure to tobacco smoke, as measured by the duration or intensity of smoking.[206–214] Interestingly, investigators are beginning to find that this elevated risk for squamous cell cervical cancer is not seen for cervical adenocarcinoma.[210,215,216] There is evidence that cervical mucus from cigarette smokers is more likely than mucus from nonsmokers to contain carcinogens.[217–219] Various mechanisms have been proposed for the pathway through which tobacco smoke might induce neoplastic changes. Exposure to tobacco may suppress one's immune response to HPV infection, allowing the virus to persist for a longer period of time, as cigarette smokers have a reduced Langerhans cell population in the cervix.[220,221] A prospective study has provided evidence that compared to nonsmokers, smokers take longer to clear oncogenic HPV infections.[222] Cigarette smoke has also been shown to directly induce malignant transformation in HPV-infected cells.[223–225] Finally, it has been proposed that smoking alters normal epithelial cell proliferation by increasing cell division and inducing metaplasia.[207]

As regards hormonal contraceptives (HC), a recent meta-analysis of HC use and cervical cancer among women with HPV infection showed a 2.5-fold increased risk of cervical cancer for long-term users.[226] While this finding supports a causal association, the hormonal contraceptives that were available to many of these women during their reproductive years, which mostly coincided with years in the 1960s and 1970s, contained levels of hormones that were much higher than those of present-day hormonal contraceptives. Other studies among HPV-infected women have shown either no significantly elevated risk or significant associations limited to particular histologic types or only in subgroups of the study participants.[208,211,212,214,227,228] (For a detailed discussion on the possible reasons for these conflicting findings, refer to the cited studies or to a review by Castellsague and Munoz.[229])

There also appears to be an increased risk for high grade cervical neoplasia and cervical cancer among women with high parity compared to those with low parity or nulliparous women, even after restricting the analyses to HPV-infected women.[211,214,228] In studies in North America and Denmark, significant associations were not seen with parity,[208,212,228] but this may be because most participants in these studies had low parity. High parity may increase a woman's risk for cervical neoplastic changes by maintaining the transformation zone exposed on the exocervix for a longer duration of time, thus increasing the likelihood of exposure to HPV. Hormonal changes during pregnancy could also play a role, particularly given the observed association with hormonal contraceptive use. Increased levels of estrogen and progesterone during pregnancy could reduce the immune response to HPV. Further, estrogen could promote HPV-related malignant transformation in cervical cells by facilitating viral integration into the host genome and stimulating transcription of E6 and E7 oncogenes of HPV.[229] Such hormone-induced mechanisms would explain the associations with high parity and hormonal contraceptive use.

As mentioned earlier in this chapter, other sexually transmitted infections could enhance host susceptibility to HPV-induced changes by causing chronic inflammation, which can result in the production of reactive oxygen species that can cause DNA damage. Recent epidemiologic evidence points to HSV-2 and Chlamydia trachomatis as cofactors.[99,230] Lastly, after HPV infection is taken into account, it does not appear that specific nutritional factors or combinations of factors affect cervical cancer risk; however, such studies have only been conducted in populations with adequate nutrition.[231]

IMMUNOSUPPRESSION, INCLUDING HIV-INFECTION-RELATED IMMUNOSUPPRESSION

The importance of immune surveillance for prevention of HPV-associated neoplasia of both the skin and genital tract has been well documented.[232–234] For example, patients with a rare genetic defect of cell-mediated immunity, epidermodysplasia verruciformis, are particularly prone to developing multiple common skin warts, with up to one-third of these individuals going on to develop skin cancers at the site of such lesions.[235] Renal transplant patients also have increased risk for various manifestations of HPV infection, including genital warts and cervical neoplasia[233,234,236,237]

The prevalence of HPV is high among women with HIV infection.[238–245] Some studies indicate that HPV infection is more likely to occur at higher viral loads[246] and with multiple types of HPV[246] in HIV-positive as compared to HIV-negative women. Follow-up studies have also shown that HPV infection is more likely to be persistently detected in HIV-positive women.[247–251] Infection with HIV has also been associated with a higher prevalence of cytologic abnormalities and histologically confirmed CIN.[239,240,242–245,249,250,252–257] In longitudinal studies, HIV infection has been associated with a greater incidence and persistence of CIN.[247,258,259] There have been few studies on the natural history of CIN in HIV-infected women, but it appears that lesions are more

likely to progress and less likely to regress in the presence of HIV.[259,260] Detection of HPV, as well as the frequency of detecting CIN, increases with worsening immunosuppression as measured by CD4 cell counts.[240–242,247,251,253,256,258,259] Other mechanisms such as HIV-targeting of specific genes and direct viral–viral interactions may also play a role in HPV-related neoplasa.[261,262]

The association with HIV infection has also been demonstrated for other HPV-related genital neoplasias including anal[263–268] and vulvovaginal intraepithelial neoplasia.[269,270] While the effect of HIV has been clearly demonstrated for precancerous HPV-related lesions, its relationship with HPV-related genital cancers is not as firmly established despite the addition of invasive cervical cancer to the list of AIDS-defining illnesses. The association between prevalence of HIV and invasive cervical cancer varies from country to country, being influenced by a number of factors including access to cervical screening and follow-up care and life expectancy following HIV infection. In North America, Europe, and Australia, no significant change was seen in the incidence of cervical cancer between 1992 and 1999.[271] Similarly, no increase in cervical cancer was seen among HIV-positive women in Kenya.[272] On the other hand, an increase in cervical cancer incidence was observed in South Africa.[273] Some studies in the United States and Southern Europe have also shown an increased risk of cervical cancer among HIV-positive women.[274–276]

It is not yet clear whether using highly active antiretroviral therapy (HAART) to control HIV replication alters the course of HPV-related lesions. A number of studies have explored this issue, with mixed findings.[277–282] Although current findings are based on studies with relatively short-term follow up, any effect of HAART on reducing the risk of HPV and/or CIN appears to be modest.[283]

THE ROLE OF COLPOSCOPY IN CERVICAL CANCER CONTROL

During the last 50 years, colposcopy has been used to evaluate women with atypical cervical cytology or with vaginal and vulvar intraepithelial neoplasia, to determine where to carry out biopsy and to follow the evolution of lesions over time.[284] Colposcopic identification of epithelial pathology is possible because as cancers or intraepithelial lesions develop, the normal epithelium is replaced by a proliferating and crowded epithelium that is characterized by an altered optical density and an abnormal vasculature. With the cervix, the colposcopist first determines whether the colposcopic examination is adequate (i.e., whether the squamocolumnar junction and the whole lesion are visible). If the entire squamocolumnar junction cannot be seen (because a portion or the entire junction lies within the endocervical canal), the colposcopic examination is termed inadequate or unsatisfactory. This situation occurs in approximately 15–20% of women, especially older women, and requires endocervical curettage for diagnosis of any pathology present. Next, severity of the lesions is estimated and biopsies obtained from what appear to be the most serious lesions. Colposcopic criteria for diagnosis of different pathologic diagnoses have been established, and the reader is referred to the American Society for Colposcopy and Cervical Pathology website (http://www.asccp.org/) for resources that provide visual presentations and detailed discussions of this issue. Generally, the size of the lesion, its appearance with and without the application of acetic acid, and its vascular pattern (best assessed with the use of a green filter) are used to classify changes. If a two-stage or greater discrepancy exists between colposcopically directed biopsies and cervical cytology, in which the severity of the cytology is greater than that of the biopsy, it is important to consider diagnostic or therapeutic conization by performing large-loop excision of the T zone (LLETZ). Colposcopy has also been used to aid in evaluation of cervicitis and other cervical vaginal infections. A major problem with colposcopy is poor accuracy and reliability even among experienced colposcopists.[285,286] However, even with these shortcomings, colposcopic examinations are needed to guide practioners to areas of abnormality that require biopsy and histopathological diagnosis.

COLPOSCOPIC EXAMINATION OF THE PENIS AND ANUS

Colposcopic examination of the penis and anus has been used for evaluation of intraepithelial neoplasia at these locations.[266,287–289] Colposcopic examination of the penis is usually performed after application of 5% acetic acid to the penis, whereas 3% acetic acid is used in the anal canal. There have been reports that application of 5% acetic acid and colposcopy augment the detection and diagnosis of subclinical HPV infections and PIN. Common manifestations of subclinical HPV infection of the penis, including PIN, include sharply demarcated, slightly raised macules, and papules with fine punctation. Detection of acetowhite epithelium, although useful for clinical examination, is not sufficiently specific and should not be used as a screening tool for penile lesions or as a sole criterion for the diagnosis of HPV infection.[290]

When used to assess anal disease, the technique, known as high resolution anoscopy (HRA) has been recommended by some experts to visualize anal intraepithelial neoplasia (AIN). Similar to assessment of CIN, HRA is used to direct biopsies to establish the histologic grade of the lesion to guide treatment.[291]

TREATMENT OF GENITAL SQUAMOUS CELL NEOPLASIA

■ CERVICAL INTRAEPITHELIAL NEOPLASIA (CIN)

Once invasion has been ruled out by histologic examination of tissue and the extent of a lesion has been accurately established

by colposcopy, the lesion can be destroyed by a variety of methods, including excision or ablation. Although treatment of CIN by various methods may be followed by recurrence of CIN, subsequent development of invasive cancer is quite rare.

Local biopsy excision

Local biopsy excision is appropriate for excision of a small, single focus of CIN 1 completely visualized by colposcopic examination, but it is not appropriate for multifocal disease or for lesions which extend into the endocervical canal.

Hysterectomy

Hysterectomy is an alternative treatment for CIS, if fertility is not important and when concomitant gynecologic indications for hysterectomy are present.

Cold-knife or CO2 Laser Conization

Cold-knife conization has been widely employed as a definitive therapy for CIN in the past, but it has recently been replaced by simple outpatient procedures such as CO_2 laser conization, and most recently by loop electrosurgical excision procedure (LEEP). The recurrence rates after cold-knife or CO_2 laser conization are generally low if margins are negative; however, there is a relatively high complication rate, including postoperative hemorrhage, cervical stenosis and scarring, increased risk for subsequent preterm deliveries, and infertility. Both procedures offer the opportunity of histopathologic evaluation for degree of pathology and margins.

Electrocautery

Although electrocautery was popular in the past, this approach is no longer recommended because of frequent complications and failure to eradicate lesions with deep crypt involvement.

Cryocautery

Introduced by Townsend and Ostergard[292] 25 years ago, cryocautery involves liquid nitrogen freezing of lesions. Treatment usually involves one or two 2–3 minute applications of a cold probe, which causes necrosis of the targeted area. Cryocautery is virtually painless and bloodless, and total reepithelialization is complete in 7–10 weeks. The value of cytology and colposcopy after treatment may be reduced as a result of scarring and of the fact that the squamocolumnar junction often recedes high up into the endocervical canal after squamous metaplasia during reepithelialization. Published failure rates (i.e., persistence of disease) after initial cryotherapy for CIN range from 4% to 24%.[293] Failure is especially common among women with a positive endocervical curettage specimen (ECC), inadequate colposcopic examination, extensive lesions, or glandular involvement. Given the high rate of treatment failures, cryotherapy is no longer considered the treatment of choice for CIN lesions and is contraindicated in patients with CIN who have inadequate colposcopy, positive ECC, or extensive lesions.

CO2 laser

Laser vaporization treatment of CIN can be performed as an outpatient procedure, and allows for precise tissue destruction under colposcopic guidance, minimal damage to surrounding tissue, low risk for postoperative hemorrhage, rapid healing with practically no scarring, and decreased risk for postoperative infections. A new squamocolumnar junction is formed at the external os and usually remains visible colposcopically, facilitating posttreatment cytologic and colposcopic evaluation. Concomitant multifocal intraepithelial lesions in the vagina or vulva can easily be treated simultaneously. However, relative to cryotheraphy, CO_2 laser vaporization is costly and requires more training and skills. Failure rates have ranged from 4% to 30%,[293] with the best designed studies showing a failure rate of 17%.[293]

Large-loop excision of the T zone (LLETZ)

Large-loop excision of the T zone (LLETZ) is also called LEEP.[294–298,295] This Procedure uses a fine wire loop diathermy for biopsy or excision of the whole T zone. This is a safe, effective, inexpensive, easily mastered outpatient procedure,[299–302] which provides excellent quality tissue for histologic evaluation.[297] Reported recurrence rates have ranged from 5%, when lesions involved only one quadrant, to 26% when the lesions involved all four quadrants.[297] Morbidity of this procedure, as with laser or cold-knife cone biopsies, is related to the volume and depth of endocervical tissue excised. Potential problems include intra- and postoperative bleeding in 4–7% of women treated,[299–303] a figure well below the average complication rates reported with cold-knife conization or CO_2 laser conization,[304] and removal of excessive amounts of tissue, which can result in an increased risk of preterm delivery and low birth weight.[305–308] Although there was initially a great deal of enthusiasm for a "see and treat" approach using the LLETZ, this approach has led to the overtreatment of minor cytological abnormalities, with recent reports showing that 5–41% of "see and treat" LLETZ specimens are free of disease[296,299,301,309]

Topical chemotherapy

Topical chemotherapy (bleomycin, 5-fluorouracil, beta-all-trans-retinoic acid, or interferons) has been used in the treatment of CIN with relatively poor success rates, due to its inability to eradicate CIN involving glandular crypts.

VAGINAL AND VULVAR INTRAEPITHELIAL NEOPLASIA

Although during the 1960s, vulvectomy, and more recently skinning vulvectomy, were the standard treatments for vulvar

carcinoma in situ (VIS), the high rate of spontaneous regression of VIN has prompted less aggressive treatment modalities. Excisional biopsy and CO_2 laser treatment have now largely replaced skinning vulvectomy in the treatment of VIN, including VIS. The CO_2 laser is useful because it is an efficient treatment of multifocal disease to a depth that allows for rapid healing with minimal scarring.[310]

PENILE AND ANAL INTRAEPITHELIAL NEOPLASIA

The spontaneous regression rate of PIN and specifically Bowenoid papulosis (PIN 3) is not known; however, these lesions appear to have a low risk of progression. Lesions suggestive of PIN should be biopsied, and preferably treated with local ablation using CO_2 laser surgery or cryotherapy under colposcopic guidance.

Treatment of anal lesions depends on the location and extent of the lesions.[291] Although it has not yet been confirmed, it is presumed that treatment of high-grade AIN will reduce the risk of progression to invasive anal cancer, analogous to the reduction in cervical cancer due to treatment of high-grade CIN. Small internal lesions may be treated with 85% trichloroacetic acid (TCA) and small external lesions may be treated with cryotherapy or 85% TCA. Perianal condyloma may also be treated by patients themselves with imiquimod or podophyllotoxin. Larger lesions inside the anal canal may be treated in the office with infrared coagulation (IRC).[311] Lesions too large for IRC may be treated in an outpatient surgical setting with electrocautery, laser or cold scalpel excision.[312]

Lesions that are too diffuse may be difficult or impossible to remove without causing excessive morbidity, and some experts recommend that patients with high-grade AIN be monitored on a regular basis for development of invasive anal cancer.

CERVICAL CARCINOMA

Treatment for early microinvasive carcinoma ranges from cervical conization to radical hysterectomy with pelvic node dissection and radiotherapy or chemotherapy. The overall recurrence rate is approximately 1%, regardless of the criteria used for case definition or the method of treatment. Hysterectomy with excision of the vaginal cuff is the current treatment of choice in cases with less than 3 mm invasion depth, without evidence of stromal or vascular involvement, and in which there is no confluence of tongues of invasive cells. Treatment of other forms of invasive cervical carcinoma (ICC) is based on the stage of disease defined by the International Federation of Gynaecology and Obstetrics (FIGO) classification.

VAGINAL AND VULVAR CARCINOMA

Treatment of vaginal cancer is more difficult because of anatomic considerations. The selection of treatment is based on the stage of the disease, the tumor volume, and location within the vagina. Most superficial lesions can be treated with vaginectomy. However, in general, surgical treatment can rarely be conservative because of the close proximity of the rectum and the bladder. Hence, ultraradical surgery with pelvic exenteration is often necessary. Cure rates are generally poor except in stage I disease. During the 1960s, VaIN was treated by partial or total vaginectomy with or without radiation. Currently, less traumatic treatment modalities are used, including colposcopically directed excisional biopsies, cryotherapy, laser therapy, and topical 5-fluorouracil (5-FU). Laser therapy has reported cure rates of 85–90%, whereas 5-FU has a high recurrence rate and can result in local toxicity, with frequent development of genital ulcerations.

ANAL AND PENILE CARCINOMA

In the past, anal cancer was usually treated by excision of the rectum and anus and formation of a permanent colostomy. More recently, first-line therapy is a combination of chemotherapy and radiation therapy, with abdomi–operineal resection usually reserved for recurrent anal cancer. As with cervical cancer, the success rate of therapy varies inversely with the stage at which the cancer is diagnosed. Although often successful, this regimen is frequently complicated by radiation proctitis, with anal pain and bleeding that may last for years. Treatment of HIV-positive men and women may be particularly challenging due to inability to tolerate a full course of therapy. Recent data suggest, however, that patients successfully treated with antiretroviral therapy are often able to tolerate a complete course of therapy. Cancers at the earliest stage of invasion may potentially be treated with wide local excision, but the outcome of this approach has not yet been determined.

Treatment of localized, stage I penile cancer has a high cure rate. If the cancer is on the glans, its treatment may involve fluorouracil cream and microsurgery (removal of the cancer). If the tumor begins in the glans and involves other tissues, its treatment may involve partial penectomy and lymph node removal, external radiation therapy, and microsurgery. If the cancer is limited to the foreskin, its treatment is likely to be wide local excision and circumcision. Stage II cancers are often treated with partial, total, or radical penectomy, or radiation therapy followed by penectomy. Stage III involves cancer that has spread beyond the penis, and in addition to penectomy, lymph node removal on both sides of the groin, radiation therapy, and chemotherapy may be required. Treatment of Stage IV cancer may involve chemotherapy and radiation therapy for palliation.

PREVENTION OF HPV-RELATED CANCERS

Primary prevention of cervical and other HPV-related genital cancers relies on preventing HPV acquisition. Secondary prevention, which requires screening and treatment for

precancerous lesions or early cancers, is discussed in Chapter 58. Certain behavioral interventions including lifelong mutual monogamy and use of male condoms with sex partners can be undertaken to reduce one's risk of acquiring or transmitting HPV (see Chapter 28). Condoms have also been shown to reduce the risk of high-grade cervical neoplasia and cervical cancer, as well as to increase the regression rate of cervical and penile lesions.[313–316]

A prophylactic vaccine designed to prevent infection by four HPV types (HPV-6, HPV-11, HPV-16, and HPV-18), was recently approved in many countries for immunizing young women aged 9–26 years of age (discussed in Chapter 28). Briefly, among an HPV-16 and HPV-18 susceptible population, this vaccine was highly effective (>90%) in preventing infection with these four HPV types, as well as in HPV-16/-18-related precancerous lesions of the cervix, vagina, and vulva. Similarly, high efficacy was observed for prevention of HPV-6/-11-related genital warts.[317] Clinical trials of a bivalent HPV-16/-18 prophylactic vaccine[318] with encouraging early results are ongoing and licensure is expected in 2007. Both vaccines have the potential to reduce the global incidence of cervical and anal cancers by about 70%, the incidence of vaginal, vulvar, and penile cancers by about 30%, and the incidence of oral and oral-pharyngeal cancers by about 15%. Due to the long latency period between infection and cancer, it will take decades of high vaccine coverage among preadolescents to achieve such reductions. Whether high levels of vaccine coverage will be achieved in the future depends on information developed over the next decade concerning societal acceptability, long-term durability and safety profiles, and pricing schemes that allow for cost-effective vaccination strategies in all countries, particularly in developing countries where the need is the greatest.

58 Screening for Cervical Cancer

Stephen E. Hawes and Nancy B. Kiviat

INTRODUCTION

Over the last 30 years we have gained important insights into the pathogenesis of cervical cancer.[1] It is now well established that specific types of sexually transmitted human papillomaviruses (HPV) play a central role in the pathogenesis of the essentially all squamous cell cancers of the cervix, most of those of the vagina and vulva, as well as many of the adenocarcinomas of the endocervix.[2] In the United States and other industrialized countries, the incidence and mortality of the most important HPV-related cancer, invasive cervical cancer (ICC), have dramatically decreased, presumably as a result of cytologic detection and eradication of preinvasive cervical lesions, termed *intraepithelial lesions* or *cervical dysplasia*. However, worldwide cervical cancer remains the second most common malignancy in women, with 83% of cases occurring in the developing world, where Pap screening is only rarely available.[1] Further, while the incidence of ICC has markedly decreased in the United States, the cost of cervical cancer control has dramatically increased over the last decade due to the practice of referring up women with atypical squamous cells of undetermined significance (ASCUS) and cervical intraepithelial neoplasia grade 1 (CIN-1) findings for additional follow-up, colposcopy, biopsy, and often treatment. As a result, it was recently estimated that the yearly cost of cervical cancer prevention and treatment of HPV-associated disease in the United States exceeds $4 billion.[3]

In the past decade, HPV testing has become available and gained widespread acceptance as an adjunct to cytology in developed nations,[4] while other low-technology approaches, such as visually aided inspection, have been proposed for use in less developed areas.[5] While these approaches may improve and extend cervical cancer control efforts, the recently developed HPV vaccines are likely in the long term to be central to cervical cancer control. However, for the reasons explained below, some form of continued screening and treatment of cervical cancer precursor lesions will be required for at least the next 50 years. Importantly, as an increased proportion of the population becomes immunized for those types of HPV most commonly associated with cervical cancer, we will need to identify new approaches to cervical cancer screening.[6] The challenge of the next decade will be to develop new cost-effective approaches for screening in the developed world and to bring inexpensive screening and vaccination programs to areas without current screening programs.

This chapter reviews the successes and failures of the current approaches to cervical cancer control and of our current histologic and cytologic classification systems. We also present an overview of emerging technologies that have recently been proposed for the identification, diagnosis, and management of these lesions in the future. Lastly, we examine the changing epidemiology of cervical cancer screening in the setting of the new HPV vaccines.

BURDEN OF DISEASE

CURRENT INCIDENCE AND MORTALITY OF ICC GLOBALLY

Cervical cancer remains the second most common cancer in women, being exceeded only by breast cancer, and represents the third most common cause (after breast and lung cancer) of cancer-related mortality. Worldwide, nearly 500,000 new cases of cervical cancer arise each year, and approximately 275,000 deaths from cervical cancer occurred in 2002.[1,7] The incidence of ICC varies dramatically across populations, in large part, as discussed below, depending on the availability of screening and treatment of cervical cancer precursor lesions. Since genital HPV, the acknowledged cause of cervical cancer,[2,8–11] is a very common sexually transmitted disease, factors such as sexual behavior and reproductive history are also of importance,[12–14] Over 80% of cases of ICC now arise in the developing world, where cervical cancer remains the leading cause of cancer-related death in women[15] and accounts for 15% of female cancers, with an estimated cumulative risk of 1.5% before age 64 years. The highest rates occur in sub-Saharan Africa, Melanesia, Latin America, and South Central Asia (Fig. 58-1), which suffer incidence rates of

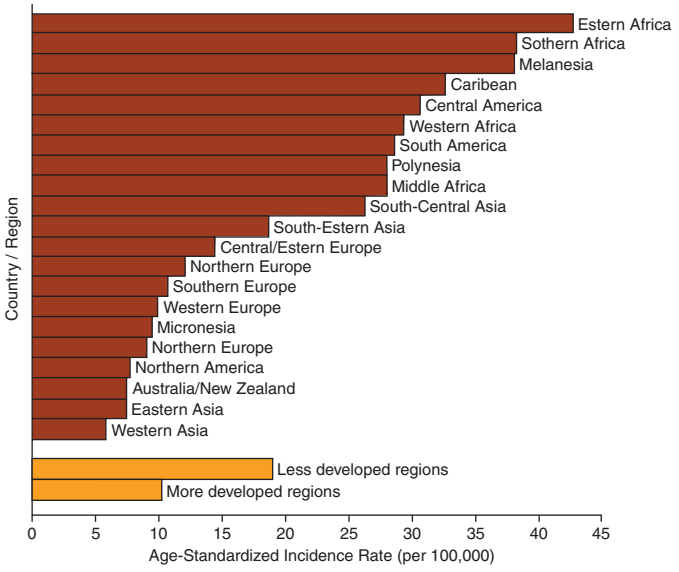

FIGURE 58-1. Age-standardized incidence for cervical cancer, per 100,000 women. GLOBOCAN 2002, International Agency for Research (IARC).[1,7]

greater than 25 cases per 100,000 women and lifetime risks of cervical cancer as high as 6–7%.[16] In contrast, in developed countries where cytology-based screening is widely available, cervical cancer accounts for only 3.6% of new cancer cases, with a cumulative lifetime risk of 0.8%. Country-specific factors associated with high rates of cervical cancer include lacking adequate public health infrastructure, having a low number of doctors per capita, high rates of fertility, sexual activity, early age of birth of first child, and high rates of HIV infections.[17]

Survival from cervical cancer is strongly associated with stage at diagnosis and varies substantially by region: 21% in sub-Saharan Africa, 42% in India, 51% in Eastern Europe, 55% in South America, 65% in Japan, 66% in Western Europe, and 70% in the United States.[1] Women with localized cancer experience over 90% 5-year survival, as compared to less than 15% survival with distant disease.[18] In sub-Saharan Africa, patients typically seek care only when their cancer is advanced, resulting in poor prognosis.[19,20] Dramatic improvements in cervical cancer survival rates can result from improvements in health service infrastructure and accessibility, as has been observed in Singapore, where 5-year age-standardized survival increased from 45% to 65% in a recent 20-year time period.[21]

INCIDENCE AND MORTALITY IN THE UNITED STATES

In the United States, as Pap smear screening has increased over the past few decades, the incidence and mortality of ICC has steadily declined. In 2005, 9710 new cases of ICC occurred, with 3700 deaths.[22] The probability of developing cervical cancer during a woman's lifetime is approximately 1 in 135 (0.74%).[23] Five-year survival rates in women diagnosed with ICC in the United States rose slightly from 69% in 1974–1976 to 73% by 2001, with 92.4% and 54.7% 5-year survival of women with local and regional disease, respectively. Survival is considerably lower among women with distant disease (16.5%).[18] In the United States, incidence is higher in African Americans and Hispanics compared to Asian, whites, and native Americans. Likewise, survival rates tend to be higher for white (75%), compared to African American (66%) women.

CLASSIFICATION OF DISEASE

HISTOLOGIC CLASSIFICATION OF CERVICAL NEOPLASIA

Cervical neoplasia is classified as either *invasive* or *intraepithelial*. A lesion is classified as ICC if the neoplastic (i.e., cancer) cells have extended through the basement membrane into the underlying tissue. In contrast, in CIN, the neoplastic cells remain limited to areas normally populated by epithelial cells and are not found below the basement membrane. Our current approach to cervical cancer control is based on the concept that ICC arises from intraepithelial precursor lesions termed *cervical intraepithelial lesions grade 3* (CIN-3) and/or *carcinoma in situ* (CIS) and that treatment of these precursor lesions prevents progression to invasive cancer.

CLASSIFICATION OF ICC PRECURSOR LESIONS

ICC precursor lesions include CIN grades 1, 2, and 3, and CIS. This classification system was developed over 45 years ago, prior to any understanding of the importance of HPV infection in the pathogenesis of ICC.[24] At that time, it was believed that CIN grades 1, 2, and 3 represented a morphologic and biologic continuum of progressive, consecutive stages in the development of invasive cancer. It was thought that the majority of women with CIN-1 would progress to CIN-3 and, if untreated, to ICC.[25] As we have gained insights into the molecular pathogenesis of ICC and the central role of infection with "oncogenic" or "high-risk" (HR) types of HPV in this process, the relationship of CIN-1, CIN-2, CIN-3, CIS, and ICC has been reassessed. It has become apparent that most CIN-1 lesions simply represent morphologic manifestation of infection with HPV and that the overwhelming majority of such legions regress within 1–2 years.[26–28] Further, previous studies as well as data from the recent large multicentral ASCUS/low-grade squamous intraepithelial lesions (LSILs) triage study (ALTS) suggests that, in many cases, morphologic changes that are classified as CIN-2 and CIN-3 are found early after infection with "oncogenic" types of HPV.[9,29] CIN-3 and CIS are considered to be the immediate precursors of ICC. This idea is supported

by the fact that these lesions are often present adjacent to invasive cancers and, in the few prospective studies that were undertaken prior to our understanding of the malignant potential of these lesions, untreated CIN-3/CIS were the lesions that appeared to be most likely to progress to ICC.[30] Available data concerning the risk of development of invasive cancer associated with untreated CIS come primarily from a small series of women with CIS who inadvertently were not treated, and several series undertaken before ablative treatment became the accepted standard of care, from women repeatedly undergoing biopsies rather than definitive treatment.[30,31] These data suggest that, if left untreated, 12–40% would develop invasive disease within the span of a normal lifetime.[28,32,33] Pathologists do not routinely attempt to differentiate between CIN-3 and CIS, as such morphologic differentiation is known to be difficult and nonreproducible.[34] and the clinical management of these lesions is similar. Unfortunately, using morphology (microscopy), we are unable to differentiate those cases of CIN-3/CIS, which, if untreated, would progress from those that carry little or no risk of progression, and therefore all such lesions are treated. It is likely in the future that ICC precursor lesions will be defined by the presence of specific cancer-associated molecular changes. Interestingly, studies have demonstrated that the molecular profiles (expression and methylation profiles) of ICC resemble those of a subset of approximately 30% of CIN-3 and CIS lesions, with such changes being only rarely present in CIN-1 lesions.[35,36]

The classification of CIN lesions as grade 1, 2, and 3 or CIS described in 1968[24] was originally based on the proportion of the epithelium that was replaced by abnormal, less differentiated cells. While many CIN-3/CIS lesions do appear to be comprising a full-thickness layer of poorly differentiated cells under the microscope, molecular studies demonstrate that CIN-1 lesions also are composed of a full-thickness layer of abnormal cells. Other criteria for classification of these lesions include the presence of dividing cells (i.e., mitotic figures) at different levels of the epithelium. Normally, mitotic figures are limited to the basal epithelial cells; however, they are present throughout the full thickness of CIN-3/CIS lesions but are less frequent and only present at lower levels in lesions classified as CIN-1 or CIN-2.[32]

ADENOCARCINOMA

Historically, cervical adenocarcinoma has been relatively uncommon,[37] constituting approximately 5% of all ICCs.[38] However, over the last 25 years, there has been both an increase in the proportion of cancer cases attributable to adenocarcinoma and an increase in the overall rate of adenocarcinoma.[38–46] In the United States (Fig. 58-2), the age-adjusted rate of adenocarcinoma increased 29.1% between 1973–1977 (1.34 per 100,000 women) and 1993–1996

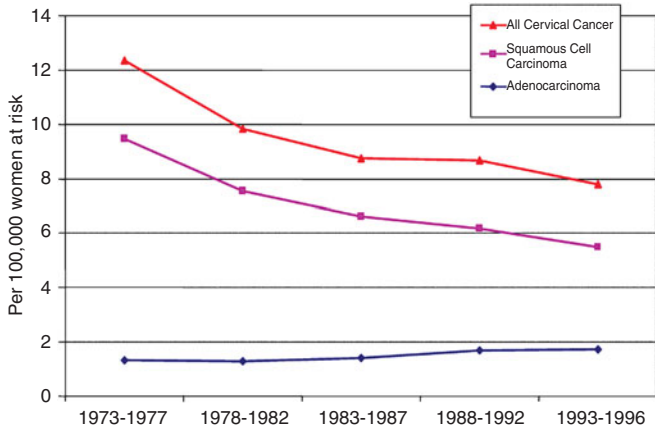

FIGURE 58-2. SEER age-adjusted incidence rates of invasive cervical cancer, by histologic type, in the United States 1973–1996.[38]

(1.73 per 100,000 women), while the proportion of incident ICCs, which were adenocarcinomas, nearly doubled from 12.4% to 24.0%.[38] Similar patterns of increasing adenocarcinoma with decreasing squamous cell carcinoma rates have been observed in Canada[42] and Europe.[39,47] Presently, adenocarcinoma accounts for approximately 20% of all ICCs.[38,48,49] Such changes may be related to the fact that although current screening practices target squamous cell cancer precursor lesions, they are much less sensitive for detection of adenocarcinoma precursor lesions.[42,43,50,51] As in squamous cell cervical carcinoma, HPV is central to the pathogenesis of cervical adenocarcinoma, with HPV 16 and 18 accounting for the majority of adenocarcinoma cases.[52–54]

CYTOLOGY-BASED CERVICAL CANCER CONTROL

HISTORY

The Pap smear was first described in 1928,[55] and, while it is generally agreed that cytology-based screening for, and treatment of, CIN is highly effective for prevention of ICC,[56] cytology-based cervical cancer control requires the establishment and maintenance of an extensive clinical and laboratory infrastructure, and thus extensive screening has largely been limited to industrialized countries. European countries generally implemented organized screening programs in the early 1960s, while in the United States, opportunistic screening has been in effect since the 1950s, with most of the population being screened by the 1970s.[57] A recent national population-based survey found that 93% of American women have had at least one Pap smear in their lifetime,[58] although this varies somewhat by geographic region.[59] In contrast, less than 5% of women in developing countries have been screened for cervical dysplasia in the past 5 years.[22]

IDENTIFICATION AND TREATMENT OF LESIONS TO PREVENT PROGRESSION TO ICC

It is also well established that a single Pap test is insensitive for CIN 2–3/CIS, detecting from 30–87% of underlying CIN-3 lesions.[60,61] Effective identification of the great majority of women harboring lesions at HR for progression has traditionally been achieved by repeated (annual) Pap testing over long periods of time. This approach is possible because progression from CIN-3/CIS to ICC is extremely slow, with transit times from CIN 2–3/CIS occurring over an average of 10 or more years.[62] Furthermore, these lesions increase in size (and presumably increase shedding of abnormal cells) over time. Importantly, CIN-3/CIS lesions are easily removed without significant morbidity, with such treatment being highly effective in preventing progression to invasive cancer.

CLASSIFICATION OF ABNORMAL CELLS: BETHESDA SYSTEM OF CLASSIFICATION

The morphologic changes Papanicolaou originally used decades ago on vaginal aspirates to make a cytologic diagnosis of invasive squamous cancer are the same used today and include the presence of cells with characteristic nuclear and cytoplasmic changes in a background containing necrotic debris, old blood, and inflammation. Over time, to support clinical management of women with Pap smear abnormalities, a number of different schemes have been developed to attempt to classify the other abnormal, but not malignant, cells identified. In 1988, the Bethesda system was introduced to attempt to standardize nomenclature and improve inter- and intrapathologist reproducibility.[63] Using this system, which was updated in 2001,[64] abnormal squamous cells are classified as suggestive of the presence of invasive squamous cell cancer; high-grade squamous intraepithelial lesion (HSIL), which now encompasses moderate and severe dysplasia, i.e. CIN 2–3/CIS (a comment is added, if necessary, to alert the clinician to the possibility of invasion); or LSIL, which encompasses changes associated with HPV and mild dysplasia/CIN-1. Abnormal cells that are not definitively dysplastic are termed *atypical squamous cells of uncertain significance*, and if such equivocal atypical cells are thought to possibly arise from a CIN 2–3/CIS, they can be classified as *atypical squamous cells, cannot exclude HSIL* (ASC-H) (Table 58-1). Although the traditional cytologic diagnoses of moderate and severe dysplasia are now regrouped with CIS into HSILs, a corresponding revision of the histologic classification system has not formally occurred, although some pathologists have adapted such an approach.

EFFECTIVENESS OF CYTOLOGY-BASED CERVICAL CANCER CONTROL

Although it is widely accepted that the implementation of cervical cancer control based on cytologic identification of, and treatment for, women with CIN 2–3/CIS has been responsible for the decrease in the incidence of cervical cancer in the developed world over the last 50 years, there have never been clinical trials verifying the effectiveness of this approach.[66] The fact that the incidence of cervical cancer strongly reflects the availability of routine screening strongly supports the contention that identification and treatment of precursor lesions are central to the observed decline in cervical cancer incidence. Age-standardized incidence rates of ICC declined by 27–77% in 11 of 17 populations after the introduction of screening,[67] and cervical cancer incidence rates are now below eight cases per 100,000 in Western Asia, China, Australia/New Zealand, North America, and Japan, where most women regularly undergo Pap screening. In the United States, the age-adjusted incidence of cervical cancer decreased from 17.2 to 7.2 cases per 100,000 between 1973 and 2002 (Fig. 58-3), and cervical cancer mortality has fallen from 7.7 (1969) to 2.5 deaths per 100,000 in 2002. Cervical cancer is currently only the 14th most common type of cancer in U.S. women.[68] It is estimated that 93% of American women aged 18 years and older have had at least one Pap smear in their lifetime, with over 80% of women in the United States having had a Pap test in the last 3 years, and over half participating in annual Pap testing.[58,59,69,70] The lack of Pap smear screening is now the most important risk factor for development of ICC in the United States, with most cases of ICC developing in women who did not undergo regular screening[71–73] or who did not receive appropriate follow-up.[74,75]

Factors associated with lack of screening include low family income, low educational attainment, and a lack of a usual source of health care or insurance.[69,76,77] In an attempt to increase screening, since 1990, cervical (and breast) cancer screening and diagnostic services have been provided in the United States to low-income women without health coverage, through The National Breast and Cervical Cancer Early Detection Program (NBCCEDP). Nearly 2 million Pap tests have been performed as part of the program; however, this

Table 58-1. The 2001 Bethesda System (Abridged)

Specimen Type: *Indicate conventional smear (Pap smear) vs. liquid based vs. other*

Specimen Adequacy

- Satisfactory for evaluation (*describe presence or absence of endocervical/transformation zone component and any other quality indicators, e.g., partially obscuring blood, inflammation, etc.*)
- Unsatisfactory for evaluation (*specify reason*)
  - Specimen rejected/not processed (*specify reason*)
  - Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (*specify reason*)

General Categorization (*optional*)

- Negative for intraepithelial lesion or malignancy
- Epithelial cell abnormality: see interpretation/result (*specify 'squamous' or 'glandular' as appropriate*)
- Other: see interpretation/result (*e.g., endometrial cells in a woman ≥ 40 years of age*)

Interpretation/Result
Negative for Intraepithelial Lesion or Malignancy (*when there is no cellular evidence of neoplasia, state this in the General Categorization above and/or in the Interpretation/Result section of the report, whether or not there are organisms or other non-neoplastic findings*)

Organisms:

- *Trichomonas vaginalis*
- Fungal organisms morphologically consistent with *Candida* spp
- Shift in flora suggestive of bacterial vaginosis
- Bacteria morphologically consistent with *Actinomyces* spp.
- Cellular changes consistent with Herpes simplex virus

Other Non-Neoplastic Findings (*Optional to report; list not inclusive*):

- Reactive cellular changes associated with
  - inflammation (includes typical repair)
  - radiation
  - intrauterine contraceptive device (IUD)
- Glandular cells status post hysterectomy
- Atrophy

Other

- Endometrial cells (*in a woman ≥ 40 years of age*) (*Specify if 'negative for squamous intraepithelial lesion'*)

(*Continued*)

Table 58-1. *(Continued)*

Epithelial Cell Abnormalities

Squamous Cell

- Atypical squamous cells
  - of undetermined significance (ASCUS)
  - cannot exclude HSIL (ASC-H)
- Low-grade squamous intraepithelial lesion (65) encompassing: HPV/mild dysplasia/CIN 1
- High-grade squamous intraepithelial lesion (HSIL) encompassing: moderate and severe dysplasia, CIS/CIN 2 and CIN 3
  - with features suspicious for invasion (*if invasion is suspected*)
- Squamous cell carcinoma

Glandular Cell

- Atypical
  - endocervical cells (NOS *or specify in comments*)
  - endometrial cells (NOS *or specify in comments*)
  - glandular cells (NOS *or specify in comments*)
- Atypical
  - endocervical cells, favor neoplastic
  - glandular cells, favor neoplastic
- Endocervical adenocarcinoma in situ
- Adenocarcinoma
  - endocervical
  - endometrial
  - extrauterine
  - not otherwise specified (NOS)

Other Malignant Neoplasms: (*specify*)

Educational Notes and Suggestions (*optional*)

Suggestions should be concise and consistent with clinical follow-up guidelines published by professional organizations (*references to relevant publications may be included*).

represents fewer than 15% of women eligible to participate in the program.[78] Further, in 2000, the Breast and Cervical Cancer Prevention and Treatment Act (BCCPTA) offered states Medicaid coverage for treatment services for women screened under the NBCCEDP.[79]

Similar to decreases described in the United States, decreases in the age-adjusted incidence rates of invasive squamous cervical cancer as a result of screening have been noted in Canada,[42] Australia,[80] and Europe (including Scandinavia).[40,41,67,81] Screening intervals and the age of onset of screening vary

across programs; however, screening every 3 years of women aged 20–60 years is the most common approach used.[82] Estimated coverage varies from 30–40% in Hungary and Luxemburg to 93% in Finland, with most countries falling in the 70–85% range.[82–84] Few Asian countries have established routine screening programs, although in Singapore, high-level opportunistic screening has taken place since 1987, resulting in increased survival in cervical cancer patients, presumably due to increased awareness and utilization of prevention measures resulting in early detection.[21] More recently in Vietnam, a grassroots effort has attempted to establish a nationwide Pap smear cervical cancer prevention program in 10 districts in south and central Vietnam.[85]

COST EFFECTIVENESS OF CERVICAL CANCER SCREENING PROGRAMS

Cytology-based cervical prevention and treatment programs are extremely expensive. In the United States alone, over 55 million Pap smears are performed each year,[86,87] and while actual costs incurred remain unknown, total direct costs for the prevention of HPV-relative disease were estimated to be U.S. $3–4 billion in 2000.[3,88] In 1998, a large U.S. health plan estimated annual cervical cancer prevention and treatment costs to be $26 per female enrollee, with 63% of the costs being attributed to screening, 17% attributed to management of CIN, 10% attributed to treatment of cervical cancer, and 9% attributed to costs associated with false-positive results.[89] Costs associated with the now widespread use of HPV testing and thin-layer cytology were not included.

Various mathematical models have been developed to assess the cost effectiveness of different cervical cancer-screening strategies,[87,90–103] including a number evaluating the cost effectiveness of HPV DNA testing for triage of equivocal cytologic abnormalities, primary HPV testing in countries with existing screening programs, and the introduction of various screening strategies in nations without current screening programs.[104] Most studies suggest that screening intervals of 3–5 years are the most cost effective.[96] Increased screening frequency generally leads to detection and treatment of greater numbers of low-grade lesions, which generally regress without intervention.[104] It is thought that the cost efficiency of existing screening programs can be increased by increasing the age of onset of screening and/or by lengthening the screening interval.[96] The benefit of screening appears to decline rapidly in women over 65[104]; however, determining the upper-age limit for discontinuing cervical cancer screening is controversial. Modeling studies suggest that cessation of screening of women over age 50 years with a recent history of negative smears might provide an approximate 25% cost savings; however, this approach is also predicted to increase in cancer incidence by 16–21%.[105] If withdrawals began later, at age 60 years, screening costs were reduced about 4.0%, with a less than 2% increase in cancer rates, suggesting that terminating screening after age 60 years would not lead to a substantial saving in resources,[106] and therefore there is no reason to impose an upper-age limit for cervical cancer screening.[107]

CYTOLOGY-BASED CERVICAL CANCER CONTROL IN THE DEVELOPING WORLD

Cytology-based screening programs are rare outside the industrialized world. Further, while a few developing countries in Central and South America established screening programs during the 1970s, these programs have had limited success.[108] For example, a cervical cancer screening program established in the early 1970s screened over 80% of married women in Chile at least once, while a 5-year program initiated in Columbia in 1990 trained nurses, gynecologists, and pathologists to provide cytology screening, follow-up, and treatment to over 60% of women aged 25–69 years. Nevertheless, cervical cancer mortality data suggest that cancer rates remained unchanged. In Cuba, over 80% of women aged 20–60 years have been screened at least once, without a reduction of cervical cancer.[108] In Mexico, a national annual cervical screening program has been in place since 1974, but the lack of sufficient infrastructure led to screening of less than 30% of women in rural areas.[109] Further, an evaluation of cervical cytology testing showed that >50% of the smears were of insufficient quality.[110] Perhaps not surprisingly, there has not been a decline in mortality from cervical cancer in Mexico.[111] A key barrier to establishing effective screening programs appears to be difficult in establishing and maintaining high-quality Pap screening. In part, this is due to a shortage of well trained cytology technicians and cytopathologists.[112] Encouragingly, however, in Costa Rica nationwide cytology services have been available since the 1970s, with 85% of eligible women receiving screening. While cervical cancer rates remained unchanged from 1983 to 1991, a more recent decline has been observed.

Currently, there are no organized or opportunistic screening programs for cervical cancer prevention in sub-Saharan Africa. A recent situational analysis of cervical cancer services in five African nations (Kenya, Lesotho, Uganda, Tanzania, and Zimbabwe) reported a serious lack of both supplies and qualified staff (gynecologists, pathologists, and cytotechnicians) necessary for carrying out screening, biopsy, and treatment.[113] Our experience in West Africa over the last 20 years is similar: There is a severe lack of qualified cytology screeners, pathologists, and colposcopists, as well as a lack of necessary materials. In South Africa, an attempt in the late 1980s to organize the infrastructure for mass screening of women in Soweto resulted in poor participation. The South African government has adopted a policy of three lifetime smears,

at ages 30, 40, and 50 years, and it has been suggested that, while the necessary infrastructure is in place, the necessary funds are not, as the government perceives other health problems, such as malnutrition, diarrheal diseases, tuberculosis, and HIV/AIDS as more urgent.[20] While screening services are widely available, a recent survey found that 80% of women had never been screened.[114] In India, which accounts for one-fifth of the world burden of cervical cancer, there are no organized or opportunistic screening programs for cervical cancer, although as discussed below, visual inspection-based approaches to cervical cancer screening have been extensively investigated.[115]

The introduction of annual screening in developing countries could reduce cancer incidence by up to 93% (Table 58-2) but would require performing 45 tests per women to identify 33 cases of cancer for every 100,000 tests.[116] Every 3-year screening would result in significantly fewer tests (approximately 15 tests per woman) to identify 96 cases for every 100,000 Pap smears performed[116] and could reduce the cumulative incidence of ICC by at least 75%.[116,117] Thus, as compared to annual screening, every 3-year screening would significantly reduce the cervical cancer burden in a more economic fashion.[116] The effectiveness of a 3-year interval is supported by a study of 25,000 Dutch women, in which incidence of squamous cervical cancer declined from 0.38 per 1000 to zero within 12 years.[118] Mathematical models suggest that once per lifetime cytology or HPV testing in women 30–59 years old would lead to a 23–30% reduction in annual incidence of ICC, given 80% coverage.[91] In a modeling study in Hong Kong, compared with no screening, opportunistic screening using cytology was predicted to reduce lifetime risk of cervical cancer by 40% but would be less effective than cytology at 3-, 4-, or even 5-year intervals, which was associated with 90%, 87%, and 83% reductions, respectively.[119] For all cytology-based screening strategies, organized screening programs were less costly and more effective than opportunistic screening. In simulations utilizing data from Thailand, well-organized screening programs reduced cervical cancer mortality at low costs.[94] However, as discussed below, given the recent development of highly efficacious vaccines for prevention of infection with those HPV types most frequently associated with development of cervical cancer, it is unclear whether such an approach would be cost effective.

Table 58-2. Reduction in Cervical Cancer Incidence with Effective Screening

Screening Frequency	Potential Reduction,[a] IARC, 1986	Potential Reduction,[b] Goldie, 2001	Potential Reduction,[c] Mandelblatt, 2002
Every year	93.5%	90–93%	NA
Every 2 yr	92.5%	86–91%	NA
Every 3 yr	90.8%	75–88%	NA
Every 5 yr	83.6%	NA	8–52%
Five times lifetime	NA	61–74%	NA
Every 10 yr	65.1%	NA	5–32%
Three times lifetime	NA	35–55%	NA
Two times lifetime	NA	29–42%	2–11%
One time per life	NA	17–32%	1–6%

LIMITATIONS OF CYTOLOGY-BASED CERVICAL CANCER CONTROL

Despite the past proven successes, primary screening based on cytology has serious shortcomings. Most importantly, cytology has low *test sensitivity* (i.e., the sensitivity of a single test) for CIN 2–3, with a single Pap smear detecting as few as 47–62% of these lesions.[60,120–123] Traditionally, to increase the overall *program sensitivity,* women undergo repeated Pap testing. Further, any women having abnormal cells detected on their smear, regardless of whether such changes were only weakly associated with an increased risk of cancer, were referred for additional testing. Thus, all women with cytologic diagnosis of CIN were referred for colposcopy and biopsy, while those with atypia (ASCUS) returned for repeat Pap testing and, if the abnormality did not resolve, for colposcopy and biopsy. Since ASCUS is diagnosed in 5–15% (over 3 million) of the over 5.5 million U.S. women undergoing Pap screening each year,[86] considerable numbers of women were required to undergo additional testing. Further, Pap smear-based identification and classification of cervical abnormalities is characterized by poor inter- and intraobserver reproducibility.[34,86,124] This is especially true for a cytologic diagnosis of ASCUS. This approach, although successful in terms of decreasing the incidence of cervical cancer, was becoming increasing costly and burdensome.

Over the last 20 years, a number of changes have been made to attempt to increase the sensitivity of Pap-based screening. Liquid-based cytology (LBC) for screening for cervical cancer was developed in the 1960s and approved by the Food and Drug Administration (FDA) in 1995, for use in the United States as an alternative to conventional cytology. There are currently two commercially available liquid-based preparation technologies: ThinPrep (Cytyc Corp., Boxborough, MA) and SurePath (TriPath Imaging Inc., Burlington, NC). Unlike conventional cervical smears, LBC cell samples are rinsed into a vial of liquid to produce a suspension of cells to produce a thin monolayer on slides, thus reducing the clustering of cells, which may obscure abnormalities. This technique is designed to reduce the number of inadequate smears and increase the sensitivity for the detection of SIL.[125–127] Additionally, the method provides for enough cells for the detection of infectious agents, including HPV as well as *Neisseria gonorrhoeae, Chlamydia trachomatis,* and herpes simplex virus, through molecular biology techniques.[128] Presently, approximately 80% of the estimated 55 million Pap smears performed annually in the United States currently utilize LBC[129] and the UK has also incorporated LBC into screening programs.[130] However, Canada, New Zealand, and Australia have been reluctant to adopt LBC without more conclusive clinical evidence as to its accuracy and cost effectiveness. Numerous studies have compared the adequacy, accuracy, and/or cost effectiveness of LBC to that of conventional cytology.[60,130–135] Cells on thin-layer preparations appear to be more easily viewed, making smear less frequently inconclusive,[131] and a study from the UK National Institute for Clinical Excellence reported that the percentages of unsatisfactory slides decreased from 9.1% to an average of 1.6% with the introduction of LBC,[136] although whether there is an overall improvement in adequacy remains unclear.[130,132,133]

Another far-reaching change has been the introduction of testing for HR types of HPV. With the understanding of the central role of HPV in the pathogenesis of cervical cancer, assays for detection of HR types of HPV have become available and, as discussed below, are now widely used as an adjunct to cytologic screening. Lastly, another shortcoming of our current morphology-based approach (i.e., cytology and histology) to identification of women at risk of cancer is the fact that, although all HSIL are treated, it is expected that a minority of women with CIS would eventually have progressed to invasive cancer if untreated. Cytology- and histology-based cervical cancer control is unable to identify those women who are truly at risk of progression to invasive disease. However, as discussed below, this is also an important limitation of HPV DNA testing.

ALTERNATIVE APPROACHES TO IDENTIFICATION OF WOMEN AT RISK OF ICC

HPV TESTING INCERVICAL CANCER SCREENING

HPV as an adjunct to cytology

As noted above, a major shortcoming of cytology-based identification of women with CIN 2–3/CIS is the low sensitivity of a single smear and the need to refer the large number of women receiving an ASCUS diagnosis for additional testing. The ASCUS/LSIL triage study, or ALTS, recently examined the potential of HPV testing to aid in the clinical management of women with an ASCUS or an LSIL diagnosis by identifying those who truly at HR of CIN 2–3. Women in this study either were randomized to repeated cytology with referral to colposcopy on the basis of a cytologic HSIL diagnosis, immediate colposcopy, and biopsy or were triaged to colposcopy and biopsy on the basis of HPV testing (i.e., referred to colposcopy if they tested positive for HR types of HPV DNA). HPV testing was noted to be of little benefit among women with LSIL, as 83% of women with LSIL were positive for HPV DNA, and thus women receiving an LSIL diagnosis are directly referred to colposcopy without HPV testing.[137] Referral of women solely on the basis of a positive HPV DNA test allowed identification of approximately 90% of CIN 2–3/CIS lesions.[138] This trial demonstrated that triage of women with ASCUS to colposcopy on the basis of testing

for HR types of HPV testing was not only highly sensitive for identification of women with CIN 2–3/CIS, but importantly, using this strategy, approximately 50% of women with ASCUS (i.e., those who test negative for HR HPVs) were returned to normal screening without undergoing unnecessary colposcopy or additional Pap smear testing.[139] Testing for HR types of HPV is currently being used in many settings as an adjunct to cytology-based screening to support the clinical management of women with ASCUS. In 2000, the U.S. FDA approved HPV DNA testing with the Digene Hybrid Capture 2 (HC2) test for triage of all women with equivocal Pap smears,[66,140–142] and in 2003, HPV testing was approved as an adjunct to Pap screening in women aged 30 years and above.

The cost effectiveness of the three management strategies examined in ALTS were recently analyzed.[87] Management costs per ASCUS case for HPV testing ($183) fell between those associated with conservative management strategies with one or two follow-up cytology visits ($100 and $179, respectively) and immediate colposcopy ($196) or conservative management with three visits ($252). HPV testing had the highest sensitivity (66%) for CIN-3, compared to 51% or less for the other strategies; conservative management with a single cytology was the least sensitive (37%) strategy. HPV DNA testing appeared to be the most cost-effective strategy for management of ASCUS. However, while this approach may be among the most sensitive and cost-effective approaches currently available, its lack of specificity is problematic. While millions of U.S. women with HPV-positive ASCUS can undergo colposcopy and biopsy each year, relatively few (7–20% in the ALTS multicenter trial[137]) have significant underlying disease.[62,143] While women with ASCUS cytology who were HPV 16 DNA positive at baseline had 2-year cumulative absolute risk for CIN-3 or worse of 32.5%, women with ASCUS who were positive by HC2 for the other oncogenic HPV types combined had an 8.4% risk for CIN-3 or worse, which was similar to the risk posed by having ASCUS (8.8%) without knowledge of the oncogenic HPV DNA status.[144] Further, HPV testing is likely to be of little benefit among young sexually active women initiating sexual behavior, many of whom experience sequential self-limited infections with different HPV types. Use of this approach in such a population could result in overtreatment of HPV-positive women, who most likely have self-limiting, transient infections, which would clear with no clinical effects within months.[145–148] Further, while using HPV testing as an adjunct to cytology-based screening is of interest for the developed world, as discussed above, this approach is not currently practical in resource-poor settings. Cervical cancer control strategies, which involved referral of women with cytologic abnormalities, would be particularly ineffectual in areas with endemic HIV infection, given that the rate of CIN-1 and ASCUS is much higher among women with, as compared to those without, HIV infection.[149–151] Thus, while, in the setting of a cytologic diagnosis of ASCUS, detection of HPV 16 appears to be useful, this may not be the case for detection other HPV types.

HPV testing for primary screening

Given the central importance of HPV in the development of cervical cancer, primary screening on the basis of HPV detection is theoretically of considerable interest. In the last 15 years, several large cross-sectional studies have evaluated HPV DNA detection of HR HPV types as a primary screening method and have compared HPV testing to cytology been completed (Table 58-3).[169–171] In these studies, HR HPV viral DNA has been detected either by PCR-based research assays using consensus primers MY09/MY11 or GP5+/6+ or by the commercially available and now FDA-approved HC2 test (Digene Corp, Gaithersburg, MD), which uses RNA-based probes and detects 13 types (HPV 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68). Both assays are widely accepted to be reliable for detecting HPV in clinical samples.[172,173]

HPV DNA testing has extremely high sensitivity for detecting CIN-2 lesions or worse, with a mean sensitivity in the 19 studies of 89%, a median sensitivity of 91%, and an interquartile range (IQR, defined as the 25th to 75th percentiles) of 84–97%. In comparison, conventional Pap smear cytology testing had a mean sensitivity of 62%, a median of 63%, and an IQR of 46–78%, varying greatly by study population. In no study was the sensitivity of HPV testing less than that of the Pap smear. Further, the median increase in test sensitivity of HPV testing in paired comparisons to conventional cytology in the 19 studies was 23%, with an IQR of 16–34%. In contrast, the specificity of the Pap smear was consistently high and usually greater than that of HPV testing. In these studies, the mean specificity of conventional cytology was 93%, with a median of 96% and an IQR of 94–98%. In comparison, the mean specificity of HPV testing was 85%, with a median of 88% and an IQR of 82–98%, varying somewhat across populations and by HPV detection method. Only in one study in Finland[167] was the specificity of HPV testing greater than that of cytology, and in that study, the specificity values were somewhat low and not substantially different from each other (78% compared to 77%, respectively). Overall, the median increase in specificity of cytology compared to HPV testing across the 19 studies was 6%, with an IQR of 3–13%.

The relative performance of primary HPV testing in screening for cervical cancer precursors tends to vary by age. In a combined summary of eight European and North American studies assessing cytology and HPV testing, Cuzick et al.[174] demonstrated a similar sensitivity for CIN-2 or greater (96%) for HPV testing across all age groups (<35, 35–49, and 50+ years), whereas the specificity of HPV testing with respect to CIN increased with increasing age (87%, 93%, and 95%, respectively). In contrast to what was seen in HPV testing, the

sensitivity of cytology testing increased with increasing age group (49%, 55%, and 79%, respectively). Similar to HPV testing, the specificity of cytology increased with increasing age (95%, 97%, and 98%, respectively).

Given that infection with HR types of HPV is exceedingly common, with a 2-year cumulative HPV prevalence of up to 80%,[175] it is not surprising that a single HPV screening is sensitive but not specific with respect to presence of CIN, especially among young sexually active women. Many studies suggest that women with persistent infections with HR HPV are at greatest risk of developing cervical precursor lesions and carcinoma.[176–180] Two HPV tests, for example, at a 6-month interval, might be an effective way to differentiate transient HPV infections from those that will persist and develop into relevant precursor lesions. However, such a strategy is associated with other problems (such as the need for additional follow-up). Given the inability of a single HPV assay to distinguish transient infection from infection associated with neoplasia, there has been a reluctance to have HPV testing replace cytology as a method for primary screening.[145] HPV

testing may have a role in primary screening, if it can reliably distinguish between women who would benefit from more intensive Pap testing (more frequent, different technologies, or extended over longer periods) and women for whom screening can be less intensive or even discontinued.

It is important to keep in mind that in these cross-sectional studies, the sensitivity of the screening tests may be overestimated and the specificity underestimated due to verification bias, since in most study designs, only women with a positive test result by one of the tests were referred for colposcopy and biopsy, preventing an unbiased estimate.[169] However, in some of these studies, verification bias was averted by use of the gold standard (colpo/biopsy) on all study subjects[166,181] or by extrapolation of results from a subset of negative testers undergoing colpo/biopsy[138,155,158] to the entire study population. A further limitation of these studies is that, thus far, none have reported on long-term follow-up for incident high-grade lesions, and none were randomized controlled trials.

Other randomized controlled trials of HPV testing alone (by PCR or HC2) or with cytology compared to cytology alone (conventional or liquid based), with long-term follow-up, are currently being conducted in Europe and North America.[174,182] The largest of these, the Finnish Randomised Public Health Trial, will ultimately randomize 200,000 women aged 25–65 years to HPV or Pap smear screening and was initiated in 2003.[183] In Canada, the Canadian Cervical Cancer Screening Trial (CCCaST)[184] enrolled 9667 women between 2002 and 2004, randomizing the order of Pap and HPV testing within study subjects. Another randomized study comparing HPV to cytology is being conducted in Mexico.[165] The remaining trials study HPV as an adjunct to cytology in comparison to cytology alone. One such population-based study, POBASCAM (Population Based Screening Study Amsterdam), is taking place in the Netherlands and has enrolled 44,102 women.[185] Additional trials are taking place in Sweden (Swedescreen),[186] the UK (ARTISTIC—a Randomised Trial in Screening to Improve Cytology,[187] and HART (HPV in Addition to Routine Testing[163])), as well as Italy (NTCC—New Technologies for Cervical Cancer screening[188]), and all will be completed by 2010.

Cost effectiveness of HPV-based screening

Most cost-effectiveness studies suggest that the HPV testing costs per quality-adjusted life-year are less than for repeat cytology[95,98,189,190] and that the costs associated with screening strategies combining HPV testing and cytology (either for primary screening or triage of ASCUS) are within the range of acceptability, as compared to screening for other cancers.[191,192] However, small changes in specificity can greatly influence the outcome of cost-effectiveness modeling, and, as described above, since HPV DNA testing is 25–30% more sensitive but 5–10% less specific than cytology for high-grade lesions, the true cost effectiveness of such approaches remains unknown. Mathematical models indicate that adoption of recent guidelines to include HPV testing with cytology as a screening option for women aged 30 years and over is likely to be cost effective[192] but only with an increase of the routine screening interval.[96,104]

As discussed below, immunization against infection with HR types of HPV will become increasingly available. However, some form of screening will likely need to be carried out for the next several decades. The decreasing prevalence of CIN 2–3/CIS in the population may make cytology- as well as HPV-based screening for identification of women at risk of cervical cancer even less efficient. Development of novel, molecular-based biomarkers for identifying women at true risk of cervical cancer will be necessary. As described below, a number of new approaches have recently been developed to try to overcome the problems associated with cytology-based screening.

DETECTION OF HPV IN SELF-COLLECTED VAGINAL SPECIMENS OR URINE

Detection of HPV DNA by testing of self-collected vaginal samples has been proposed as an alternative to testing of clinician-collected cervical samples.[193–196] Two published studies have compared HPV DNA testing of self-collected samples with clinician-collected samples for conventional Pap test screening and HPV testing and with biopsy findings. Among 1415 previously unscreened black South African women,[157] the sensitivity of an HPV test of the self-collected vaginal swab sample for detecting CIN 2–3 (66.1%) was similar to that of the conventional Pap test (67.9%), but both had lower sensitivity than the clinician-collected HPV sample (83.9%). However, comparison of these test indices may be misleading because of verification bias, since women who had negative HPV test results were not followed up for colposcopic assessment with the same intensity as those who had positive HPV test results. In another study of 200 Canadian women,[196] the sensitivity of the self-collected vaginal sample for detecting CIN 2–3 was 86.2%, compared to 77.6% for the Pap test and 98.3% for the clinician-collected HPV sample.

Developing urine-based cervical cancer control is of interest, as it offers the possibility of freeing screening from the need of a clinic visit and pelvic examination. Most studies, thus far, have focused on detection of HPV DNA in urine as a biomarker for cervical neoplasia or cervical HPV infection. HPV DNA is detected less frequency in urine than at the cervix.[196–201] For example, Brinkman[197] detected any HPV DNA in 58% of cervical and 48% of urine specimens. However, concordance of any, HR, or low-risk type of HPV in urine and the cervix was high (70%, 71%, and 78% women, respectively, for the distributions of any, low-risk, and HR HPV in the cervix and the urine, respectively), and detection of HPV DNA in urine was associated with an

abnormal Papanicolaou smear to the same extent that detection of HPV DNA in a cervical swab specimen was. HPV DNA was detected in 89% of nine cervical cancer cases, 45% of 29 HSIL cases, and 13% of 39 LSIL cases identified in Greece,[202] with the relative sensitivity of urine compared to cervical HPV detection being 89% in cancers, 77% in HSIL cases, and 46% in LSIL cases. HPV types were 100% concordant in cases where both cervical swab and urine samples were HPV DNA positive. However, in a study of 80 sexually active adolescents,[199] detection of HPV was significantly higher in the cervix (90.0%) than in urine (75.0%), and HR HPVs were 50% more common in the cervix than in urine. With recent techniques, urine HPV DNA detection is 100% specific for cervical HPV DNA, and there are no positive urine samples when the cervical sample was negative,[202,203] although, historically, this is not universal.[198] In summary, detection of HPV DNA in urine samples is generally lower than in cervical samples, but it is generally considered more acceptable than self-collected vaginal sampling.[196] The main advantage is that urine sampling allows for self-collection of the specimen, which may be valuable in resource-limited settings.[202]

While detection of HPV DNA by itself in urine appears to have limited sensitivity and specificity for CIN 2–3, the sensitivity and specificity of urine-based approaches to cervical cancer control might be increased by combining detection of HPV DNA in urine with other biomarkers for cervical cancer. For example, in a recent study Feng[204] examined the potential utility of detection of hypermethylated genes in combination with the detection of HR types of HPV for cervical cancer screening in urine. Urine samples from Senegalese women with, and without, same-day biopsy-proven cervical neoplasia were examined for the presence of HR HPV and hypermethylation of four genes that we have previously shown to be associated with cervical neoplasia.[35] Hypermethylation of at least one of the four genes identified 62% of ICC and 28% of CIN 2–3/CIS and was present in only 4% of CIN-1 or normal urines. HR HPV DNA was detected in urine in 70% of those with biopsy-proven ICC, 59% of those with CIN 2–3/CIS on biopsy, 44% of those with CIN-1 on biopsy, and only 11% of women negative for cervical neoplasia on biopsy. Urine-based detection of either HR HPV and/or hypermethylation of any of the four genes (DAPK1, RARB, TWIST1, and CDH13) identified 84% of ICC, 64% of CIN 2–3/CIS, 44% of CIN-1, but only 19% of women negative for cervical neoplasia. The sensitivity for detection of CIN 2–3/CIS/ICC by HR HPV DNA and/or aberrant DNA methylation of four genes appears to be comparable to that of an exfoliated cervical cytology.

SCREENING BASED ON VISUALIZATION OF THE CERVIX

Since it is not currently feasible to set up and maintain the extensive laboratory and clinical infrastructure necessary for cytology-based cervical cancer screening in many resource poor settings, there have been numerous attempts to identify "low-technology" approaches to cervical cancer screening and prevention. One approach that has received a great deal of attention is visual inspection, with or without low-level magnification. Detection of cervical abnormalities by visual examination with magnification has been practiced for over 75 years, with the use of a colposcope.[205] In the early 1930s, Schiller added the use of a topical iodine solution to dissolve mucus and promote vasoconstriction to facilitate identification of cervical abnormalities.[206] Several other "low-technology" methods of visual inspection have been described (recently summarized by Wright[207]), including direct visual inspection (DVI), (also called direct visual inspection with acetic acid (VIA), aided visual inspection (AVI), the vinegar or acetic acid test, or cervicoscopy), visual inspection with acetic acid involving a low-level magnification device (VIAM), and visual inspection with Lugal's iodine (VILI). The International Academy of Cytology task force recommends the term DVI to be used to refer to inspection of the cervix with the naked eye after application of acetic acid.[104] DVI involves examination of the cervix after application of a 3–5% solution of acetic acid. Several countries have begun prevention programs that include immediate treatment of women with positive examination by DVI or VIAM. Ablative treatment of CIN-3 or CIS lesions with cryotherapy is simple and may prevent subsequent development of cervical cancer in many cases. However, since cryotherapy results in wide areas of cervical ulceration, which is known to increase risk of HIV transmission,[208,209] such an approach to treatment would be appropriate only if the primary screening approach was highly specific for identification of women with CIN-3/CIS.

A number of large clinical trials have been conducted to evaluate DVI alone or compared with the performance of cytology and/or HPV testing (Table 58-4). Definitions of a positive DVI test have varied across studies, as have the thresholds for cervical disease (LSIL or HSIL). Training techniques have varied as well. Most studies have used a cross-sectional design and have been limited by verification bias, in that the gold standard (usually colposcopy or biopsy) has only been applied to those with positive tests.[210] This bias results in an overestimate of the specificity of DVI, since test-negative subjects are assumed not to have disease. In addition, this bias also results in an overestimation of the sensitivity, since test-negative cases with disease are not identified.

DVI is generally associated with a high rate of test positivity, similar to HPV testing. In the 26 studies summarized above, the median percentage of subjects testing positive by AVI was 21%, with the middle 50% of the studies (IQR) reporting positivity rates between 13% and 30%. Results of

previous studies in resource-poor settings have shown a wide range of sensitivity and specificity for visual inspection methods. Median sensitivity across the published studies was 77%, with an IQR of 65–88%, while the median specificity was 82%, with an IQR of 75–89%. These wide ranges may reflect the relative subjectivity of DVI and differences in the training and experience of observers.[207] The median positive predictive value (PPV) of studies evaluating DVI was 14%, with half of the studies observing values between 11% and 23%. In the 10 studies that have eliminated ascertainment bias by conducting colpo/biopsy on all study subjects, the median percentage of test positives was 28%, and studies had a median sensitivity of 77%, a specificity of 78%, and a PPV of 12%.

Similar to other screening methods, test performance varies with the age of women screened. In the IARC study, specificity of DVI for HSIL generally increased with increased age,[115] from specificity for HSIL being 83% in women 25–29 years old and 87% in women 50–59 years old. However, increased specificity was associated with a loss of test sensitivity, with the sensitivity of DVI for HSIL being 89% in young women as compared to only 72% of in older women. VIA may be less effective in older women, reflecting the tendency for the transformation zone and associated lesions to recede into the endocervical canal, making inspection difficult.[235] Although the specificity of VIA was significantly lower in HIV-positive women,[222] the test performance of DVI does not appear to vary with the presence of most other sexually transmitted infections. Magnification does not appear to substantially improve the accuracy of VIA but may reduce specificity.[222,236]

DVI has been reported to have a higher sensitivity but lower specificity for high-grade cervical lesions. For example, in a study in Zimbabwe, the sensitivity of VIA (77%) was considerably greater than that of cytology (44%), although the specificity of VIA was lower than that of cytology (67% vs. 91%).[218] Similarly, in a South Africa-based study,[224] the sensitivity of VIA was greater than that of cytology (79% vs. 53%), while specificity was much lower (49% vs.95%). A Nicaraguan study found that while VIA detected twice as many HSIL lesions and cancers than did

cytology, for every additional true-positive case identified, there were eight false-positive cases, all of which had to be referred for additional examination.[227] In contrast, a study of over 4000 women in India found that the sensitivities of VIA, cytology, and HPV testing were similar (near 60% for all methods), while the specificity of cytology (99%) was greater than that of HPV testing (93%) or VIA (88%).[230] Finally, in a multicenter study in Latin America, VIA had a sensitivity (50–53%) similar to that of cytology but had a lower specificity (99% vs. 90%). In that study, HPV detection by hybrid capture had a considerably higher sensitivity (83%) with a lower specificity (86%).[233] The PPV of cytology was considerably higher (73%) than the PPV of HPV testing (9%) or VIA (7%). HPV DNA testing tends to have higher sensitivity and similar (low) specificity as compared to DVI.[207,237]

Visual screening strategies, combined with immediate ablative treatment of visually identified lesions, without confirmation of the presence of disease, have been widely advocated for use in resource-poor settings,[150,238] as these eliminate the need for cytology and histology. However, given the low specificity of visual screening approach, on average, for every woman with HSIL or worse treated who is correctly identified by visual screening, seven women *without* disease would receive treatment. This approach may have some merit in areas where HIV infection is rare. However, ablative therapy creates large areas of cervical/endocervical ulceration, which may, in populations with a high HIV prevalence rate, result in increased rates of HIV acquisition or transmission to offspring or sexual partners.[208,209]

In summary, compared to conventional cytology, visual inspection methods generally have similar sensitivity but lower specificity. Because of the low specificity and PPVs, concerns exist regarding diagnostic workups and/or unnecessary treatment of the large numbers of women with false-positive tests, and it remains to be seen if test specificity can be improved by improved reporting or training, without undue loss in sensitivity.[115] As a number of these studies have involved highly trained staff with quality control procedures in place, it seems unlikely that even the level of performance observed in these studies would be obtained in a routine service setting in the developing world.[207] Nonetheless, despite these limitations, mathematical modeling studies have suggested that visual inspection is likely to be more cost effective than cytology or HPV testing for cervical cancer screening in the developing world.[94,102,117] In a recent cost-effectiveness study in five developing countries, once per lifetime screening with a one- or two-visit strategy involving VIA reduced lifetime risk of cancer by 25–31%, similar to that of HPV DNA testing, and was somewhat better than two- and three-visit cytology.[100] However, real-life evidence regarding the long-term programmatic performance and effectiveness of VIA-based programs does not currently exist,[239] and the results of ongoing prospective trials and actual programs will help determine the potential utility of this screening method for more widespread use worldwide.

NON-HPV RELATED MOLECULAR MARKERS

As discussed above, once it became apparent that HPV infection played a central importance in the pathogenesis of cervical cancer, a number of proposals for incorporating HPV into cervical cancer control were put forth and tested. Testing for HR types of HPV is now widely used as an adjunct to cytology, whereby women with ASCUS are either triaged to colposcopy and biopsy or returned to routine screening on the basis of detection of HR types of HPV. This approach has the limitations discussed earlier, especially in young women. Similarly, primary screening based on detection of HR types of HPV may be sensitive, but not adequately specific for detection of CIN 2–3. Given the limitations of HPV-based testing, it is of great importance to develop other sensitive and specific markers for detection of women at risk of development of ICC. Further, for reasons discussed below, development of such markers will become increasingly important in the era of HPV vaccines. A number of different molecular markers have been proposed for cervical cancer control screening, including antigens involved in cell proliferation, tumor suppression, DNA repair, apoptosis, and other aspects of the cell cycle (PCNA, Ki-67, cdc6/mcm5, telomerase, cyclin E, and P16), and markers related to control of gene expression, which are also briefly reviewed below.

PCNA

Many of the proposed biomarkers for HPV-associated cervical neoplasia, including proliferating cell nuclear antigen (PCNA), are molecules involved in cell cycle control and thus cellular proliferation. PCNA is an S-phase-associated nuclear protein, which is a cofactor of DNA polymerase.[240] Monoclonal antibodies to PCNA have been used in a variety of assays, including flow cytometry and on paraffin-embedded tissue.[241,242] On immunohistochemical staining, normal cervical epithelium shows only rare intranuclear staining of basal epithelial cells. A number of tissue-based studies report that the level of PCNA-positive nuclei staining correlates with the increasing severity of dysplasia.[43,243–245] However, HPV infections induce cell proliferation so that this marker is generally positive in the setting of HPV infection, and PCNA can be used as a surrogate of HPV gene expression.[246] Thus, in relation to HPV testing, PCNA does not provide any significant gain in specificity for CIN-3.[247] The utility of this marker is also limited by the fact that the number of basal cells staining is markedly increased in the presence of inflammation (without neoplasia), and in normal squamous metaplastic epithelium, but not atrophic epithelium.[248]

Ki-67 (MIB-1)

Detection of intranuclear Ki-67 (MIB-1) antigen, a nonhistone protein expressed in all active parts of the cell cycle, but not in G0,[249] has gained popularity for identification of proliferating cells. As with PCNA, in normal mature squamous epithelium, Ki-67 staining occurs only in rare basal cells (second and third cell layers). Hence, Ki-67 has been proposed as a biomarker for identification of cervical neoplasia. Since HPV infection activates host cell cycle progression, Ki-67 staining is increased in the presence of HPV infection. Although all HPV-related neoplasia stains positive, some studies suggest that the pattern of Ki-67 staining differs with increasing grade of neoplasia,[250–252] and increased Ki-67 may have prognostic value for progression.[253] In LSILs, some studies report that staining is located in the areas of cytopathic effect (i.e., in upper epithelial layers), while staining is more diffuse with a higher index of cell nuclei in HSIL. However, the index of Ki-67-positive cells changes throughout the menstrual cycle (i.e., is hormone dependent), increasing in the luteal, as compared to the follicular phase, and increasing during pregnancy.[254] Atrophic epithelium stains at a lesser level, so it has been speculated that Ki-67 may be useful in cases of ASCUS in postmenopausal women.[255] However, although there appears to be no significant difference in Ki-67 expression with and without inflammation, recent studies suggest other serious limitations of this marker, including the fact that criteria for a positive result are subjective (defined as staining in the upper two-thirds of the epithelium) and false positives are common in tangentially sectioned tissues.[256] These problems make this marker of limited use for cervical cancer screening or classification.

cdc6 and mcm5

Since cdc6 and minichromosome maintenance 5 (mcm5) have been used as markers of active DNA replication, they might be of interest for cervical neoplasia.[185,257,258] These are both proteins involved in regulating DNA replication and have been shown to mark dysplastic cells. However, similar to Ki-67, these markers cannot precisely distinguish dysplastic cells from normal proliferating cells.[259]

Telomerase

Telomeres are repetitive DNA sequences at the ends of eukaryotic chromosomes, which are shortened with each cell division. Decreased length of telomeres is associated with instability and cell death. Telomerase is a ribonucleoprotein enzyme that plays an important role in maintaining telomere length during normal cell proliferation.[260] Since telomerase has been noted to be upregulated in most cancers, detection of this enzyme has been proposed as a potential cancer biomarker. The clinical utility of this marker has been somewhat limited by its low level of expression, making it difficult to detect with conventional immunohistochemical methods. More importantly, with regard to identification of women with CIN-3, HPV 16 E6 oncoprotein expression has been shown to induce telomerase activity by a p53-independent mechanism,[261] so that HPV cervical infections and HPV-related neoplasia resulting from HR types of HPV are all positive for telomerase. Thus, while greater than 90% of HSILs are positive for telomerase, approximately 50% of LSILs, 56% of reactive atypias, and 18% of normal cervical mucosa samples are also positive,[262] making this marker of limited interest for cervical cancer screening by itself. Recently, telomerase activity has been suggested as a possible adjunct to cytology or HR HPV,[263,264] although the utility of this approach has not been extensively studied.

Cyclin E

Cyclin E is a regulatory protein that complexes with the cyclin-dependent kinase (CDK) cdk2 to control the G1–S-phase transition in the cell cycle. The intervention of the cyclin E–cdk2 complex during S phase is required for progression through the cell cycle. The oncogenic E7 gene of HPV 16 has been shown to upregulate cyclin E activity. Cyclin E also interacts with the E1 gene of HPV 16, which is involved in viral replication. Thus, in the presence of oncogenic HPV types such as HPV 16, overexpression of cyclin E not only deregulates the cell cycle but also facilitates viral replication.[265,266] In tissue-based studies, cyclin E staining is associated with preinvasive and invasive cervical neoplasia, with some studies reporting increasing levels of immunohistochemical staining for cyclin E, with increasing severity of diagnoses. However, other studies report that 95% of LSILs also show nuclear staining.[267] This, along with difficulty in interpretation as a result of high background staining of inflammatory cells and cervical stromal cells, makes this marker of limited interest.[256]

$p16^{INK4a}$

$p16^{INK4a}$ is the gene product of cyclin-dependent kinase inhibitor type 2A (CDKN2A), which inhibits cdk4/6 interaction with cyclin D1 to prevent progression through the cell cycle G1–S transition checkpoint. In normal cells, accumulation of E2F-1 induces transcription of $p16^{INK4a}$, thus limiting G1 kinase activity by feedback inhibition. It is well established that the p16 CDKN2A gene is frequently altered (decreased) in many cancers. In contrast, in HPV-related cervical cancers and precursor lesions, nuclear and cytoplasmic $p16^{INK4a}$ protein immunoreactivity is normally present and increased. Although it is not known why $p16^{INK4a}$ overexpression occurs in HPV-associated lesions, it is thought that a positive feedback linked to increase in E2F transcription factor is a likely cause.[268] A number of studies have used histologic or cytologic immunostaining methods to evaluate the

presence of p16 in normal and dysplastic cervical biopsy or cytology samples.[269–280] In general, the proportion of p16-positive cases has been closely associated with severity of diagnosis, with 0–18% of normal, compared to 81–100% of high-grade and nearly 100% of squamous cancer cases.[281] Staining is highly correlated with the infection with HR types of HPV, and, not surprisingly, the majority of both CIN-1 and CIN 2–3 lesions associated with such HPV infections stain positively. In a study of 400 subjects comparing identification of cervical neoplasia by HC2 HPV testing and $p16^{INK4a}$ staining, HC2 had somewhat greater sensitivity, while $p16^{INK4a}$ had greater specificity for HSIL/CIN 2–3.[279] $p16^{INK4a}$ was positive in 78% of HSIL specimens, 42% of LSIL specimens, and 36% of ASCUS specimens, whereas HC2 was positive in 92% of HSIL specimens, 81% of LSIL specimens, and 45% of ASCUS specimens.[279] However, high levels of $p16^{INK4a}$ expression have also been noted in endocervical and metaplastic cells,[272] and a number of studies have reported a lack of positive staining from a subpopulation of CIN 2–3 and ICC cases. Labeling of normal cells and bacteria may preclude the use of $p16^{INK4a}$ in automated screening or nonmorphologic assays.[279]

While it is generally now agreed that $p16^{INK4a}$ staining is not likely able to distinguish CIN-1 from CIN 2–3, several recent studies have attempted to correlate $p16^{INK4a}$ expression with risk of disease progression.[184,280] A retrospective analysis of $p16^{INK4a}$ expression on cervical biopsy samples from women with LSIL reported that those with diffuse $p16^{INK4a}$ staining on biopsy had a significantly higher tendency to progress to a high-grade lesion than $p16^{INK4a}$-negative cases. Importantly, the presence of HR types of HPV in the LSIL was not considered. Wang et al. also explored the potential of $p16^{INK4a}$ as a marker of risk of progression and assessed its relationship to the presence of HR HPV infection. $p16^{INK4a}$ was highly associated with oncogenic HPV infection. Risk of progression of LSIL was associated with $p16^{INK4a}$ staining, when the presence of HPV was not taken into account.[43] In a larger study,[277] $p16^{INK4a}$ was associated with detection of HR HPV, and there was a significant linear relationship between the lesion grade and intensity of $p16^{INK4a}$ staining, but $p16^{INK4a}$ staining did not predict clearance or persistence of HR HPV after treatment of CIN. Similarly, despite a slightly more favorable survival in women with strong/intense $p16^{INK4a}$ staining in univariate analysis, $p16^{INK4a}$ expression was not an independent prognostic predictor in multivariate survival analysis. In summary, $p16^{INK4a}$ has emerged as a promising complementary marker in the detection of CIN[282,283] and may improve the diagnostic accuracy of HPV and cytology screening[284] but, like most other markers, appears to have limited usefulness in cervical cancer screening on its own.

Epigenetic changes

As discussed above, assays based on detection of antigens involved in cell cycle are generally positive in the setting of oncogenic HPV infection and thus do not provide any clear advantage over HPV testing, which is sensitive but not specific for CIN 2–3/ICC. An alternative strategy is development of biomarkers based on changes that are highly associated with oncogenesis, rather than with cell proliferation or HPV infection. Such changes include various genetic mutations, and/or *epigenetic* changes (heritable changes in gene expression without alterations of the primary nucleotide sequence), associated with loss and/or gain of function of genes regulating tumor suppression, DNA repair, apoptosis, or facilitating development of malignancy. Epigenetic changes, especially DNA promoter hypermethylation,[285,286] have been of particular interest, as such changes are believed to be an early event in carcinogenesis and are often present in the precursor lesions of a variety of cancers, including cervical cancer.[27,35,287–292] Further, while mutations found in cancers from different individuals occur at many different locations in a specific gene, DNA hypermethylation of genes always occurs in the same region (the promoter region). This makes development of a clinical assay, based on detection of DNA promoter hypermethylation, considerably easier than development of an assay based on mutations. A variety of different genes have been found to have aberrant DNA hypermethylation in ICC, including genes related to cell cycle, tissue differentiation regulation (*CDKN2A, p16, p14ARF, CDKN2B, CCND2, TP73, RB1 RASSF1 RARB TWIST1, PRDM2, SFN, HIC1, APC, BRCA1*, and *MYOD1*), genes related to cell growth regulation (*SOCS1, SOCS2, CALCA, VDR, RNR1, HSD17B4, PGR, TYMS, TGFBR2,* and *ESR1*), genes related to DNA repair, detoxification, and chromosomal stability (*MGMT, MLH, BRCA1, GSTP1, FHIT, TERT, FANCF,* and *PTGS2*), and genes related to metastasis and invasion (*CDH1, TIMP3, TIMP2, APC,* and *CDH13*).[204,293–307] In the largest study thus far, Feng et al. reported that a panel of three genes (*DAPK1, RARB,* and *TWIST1*) detected 73.9% of 92 cases of ICC and 56.5% of 23 CIN-3/CIS cases, while 95.0% of 181 with CIN-1 or less were negative for all three genes.[35] These gene methylation markers may have great potential as surrogates of clinical disease or as indicators of risk during follow-up.[308]

HPV VACCINES

■ VACCINE DEVELOPMENT

It is now clear that the development of ICC requires infection with HR types of HPV[2,54]; therefore, vaccines preventing HPV infection have the potential to dramatically reduce the incidence of cervical cancer and its precursor lesions.[309] In June 2006, a Merck (Whitehouse Stations, NJ, USA) vaccine (Gardasil®) for prevention of infection with HPV types 16 and 18, which together account for approximately 70% of all cervical cancer, was approved by the U.S. FDA for use in girls and women aged 9–26 years and has been approved by the European Medicines Agency (EMEA). Gardasil® also protects

against infection with HPV 6 and 11 types, which are associated with 90% of genital warts but not with cervical cancer. Another vaccine (Cervarix™), manufactured by GlaxoSmithKline (Philadelphia, PA, USA) for prevention of HPV 16 and 18, is also now under review in Europe, and the company hopes to apply for U.S. FDA approval by the end of 2007.[310] Three proof-of-principle randomized controlled trials have assessed the efficacy of these vaccines to prevent HPV infection and cervical abnormalities to date[311–313] and demonstrated high levels of efficacy (at least 89%) for prevention of incident/transient, persistent HPV infections as well as for prevention of type 16 or 18 high-grade disease.[178,314,315] In the Merck-sponsored monovalent type 16 HPV vaccine study,[311] 1533 U.S. women aged 16–23 years and without a history of cervical abnormalities were enrolled and followed for up to 48 months after receiving an HPV 16 virus-like particle capsid vaccine (or placebo). No serious side effects were observed, and antibody titers were 60 times greater in those vaccinated compared to titers that occur in natural genital HPV infection. Similarly, in the GSK-sponsored study,[312] 1113 women aged 15–25 years in the United States, Canada, and Brazil were vaccinated with a bivalent (HPV 16 and 18) VLP capsid vaccine (or placebo). Again, serious side effects were not noted, and antibody titers were 50–80 times greater in vaccines compared to individuals with naturally acquired HPV 16 or 18 infection. Most recently, the approved Merck quadrivalent vaccine, Gardasil®, containing L1 protein antigens from HPV types 6, 11, 16, and 18, showed 90% efficacy against persistent infection or disease. Ongoing clinical studies are expected to provide further evidence of efficacy in preventing high-grade CIN. It is important to note that these vaccines did not prevent development of HPV 16 or 18 related CIN 2–3 in women who were infected or who had baseline evidence of serum antibodies to HPV 16 or 18.

While these vaccines will clearly lower the incidence of cervical cancer and will be of tremendous importance for cervical cancer control, many questions must be addressed, including what additional HR HPV types should be included in future vaccines, whether development of vaccines containing many HPV types is achievable, and whether there is any cross protection between different related HPV types. More than 40 HPV types infect the genital tract and at least 15 of these are significantly associated with progression to ICC.[316,317] A recent meta-analysis of HPV types in over 10,000 cases of squamous cervical cancer worldwide[53] showed that 69% of cases were associated with HPV 16 (51%) or 18 (16%), making inclusion of these types logical for first-generation vaccines. HPV types 45, 31, 33, 58, and 52 each accounted for less than 10% of all invasive cancers and collectively accounted for 18% of cases. While a majority of ICC was associated with HPV 16 or 18 in all regions, the distribution of other types in ICC varied by region. A vaccine that contained the seven most common HPV types could potentially prevent approximately 87% of cervical cancers worldwide, with little geographic variation. Gains in type coverage rapidly diminish beyond inclusion of four HPV types and potentially cause increased manufacturing challenges.[318] Similar findings have been observed in adenocarcinoma, where HPV 16 (52%) and HPV 18 (39%) were detected in a vast majority of cases across eight studies.[52] Which HPV types in addition to 16 and 18 will be added to future vaccines is unclear, as early studies show some evidence of cross protection among certain HPV types.[319] However, the extent of such cross protection will be defined by larger ongoing studies.

Other issues that will need to be addressed are the duration of protection and the cost effectiveness of various vaccination strategies. At present, for example, it is not clear whether young adolescent females or both young females and males should be vaccinated. Natural history studies have reported that HPV infection occurs shortly after the onset of sexual activity,[320] necessitating early vaccination of individuals before they become sexually active. Sexually active males and females both become infected with HPV[321,322] and transmit HPV between each other, so it has been suggested that vaccination should be considered for both genders. Males have been included in clinical trials only recently, to determine whether vaccination protects them from penile and anal infections and potentially from cancers, caused by HPV 16 and 18; this would then be expected to also protect their female partners from cervical cancer. Vaccinating males could thus help reduce HPV infection transmission through herd immunity, especially since vaccine coverage of women is likely to be less than 100%.[323] However, recommendations for male vaccination will require data from research studies of prevention currently underway.[324] Unfortunately, the duration of vaccine efficacy is unknown and remains a key issue that will have a major impact on the timing of vaccination regimens and affordability.[325] Presently, both vaccines have shown proven immunization for up to 5 years, and there is strong evidence that the protective effect of the vaccines will be long lasting, but it is still unknown whether both vaccinees will require booster shots.

The impact of these vaccines will obviously be highly significant. In the developed world, where full implementation of cervical cancer screening has shifted the burden of HPV infection from cervical cancer mortality to management of precancerous lesions, HPV vaccination might decrease the costs associated with management of abnormalities detected by Pap testing and CIN.[313] Inclusion of HPV 6 and 11, which are not causally associated with ICC, in a vaccine could diminish the incidence of genital warts and low-grade CIN, which are benign but costly to treat.

Theoretical models suggest that an HPV vaccine will have the greatest effect where screening programs are not in effect.[326] In the developing world, the logistics of delivering a new vaccine will be formidable, particularly since the present vaccines require multiple injected doses and are likely to

target adolescents, a group that is not currently reached by any global health-care program.[327] Public health-care systems are generally understaffed and underfunded, and the health-care community faces numerous challenges in organizing implementation of HPV vaccine programs of the future.[324] The WHO, the Bill and Melinda Gates Foundation, IARC, and PATH (a Seattle-based NGO) are all involved in facilitating implementation of vaccination programs in the developing world and are hopeful that the introduction of HPV vaccination will bring about greatly needed reductions in cervical cancer incidence.

SCREENING IN THE AGE OF HPV VACCINES

Vaccine implementation will have important implications for cervical cancer screening protocols in countries with established screening programs. The currently available vaccines will protect uninfected women from infection with HR types HPV 16 and 18 and from development of HPV 16- and 18-related HSIL and (presumably) cancer. However, HPV 16 and 18 only account for approximately 70% of all cervical cancers, and the current vaccines probably will not provide protection from infection and development of pathology related to the many other oncogenic HPV types. If many HPV 16- and 18-associated lesions and cancer will be avoided, it is possible that lesions caused by other HR types not included in a vaccine might increase in frequency.[323] Further, the current vaccines are not therapeutic and hence will not protect women already infected with HPV 16 or 18, from subsequent development of related HSIL and cancer.[328] Thus, many sexually active women will not derive any benefit from these vaccines. In light of these problems, some sort of cervical cancer screening will be needed for the foreseeable future.

Mathematical modeling of the impact of an HPV vaccine on screening for cervical cancer suggests that the interval for Pap smear screening in vaccinated women could be lengthened as a result.[99,309,329] HPV vaccination might decrease the costs associated with management of abnormalities detected by Pap testing and CIN.[313] Inclusion of HPV 6 and 11, which are not causally associated with ICC, in a vaccine could diminish the incidence of genital warts and low-grade CIN, which are benign but costly to treat. Vaccination will likely affect HPV DNA testing and screening practices and result in changes to screening time intervals and clinical management algorithms.[330] The current approach of frequent screening using cytology may prove too expensive and inefficient for many countries as they implement HPV vaccination, particularly for those that publicly fund most of their health care; countries that introduce HPV vaccination may eventually switch to HPV DNA testing as the primary screening test, and HPV genotyping will allow for monitoring long-term vaccine protection.[328] The impact of vaccination on these issues will need to be evaluated prospectively and will depend on the timing of regional vaccine implementation, the extent of coverage, whether other HR HPV types are added to future vaccines, and the duration of vaccine protection. A significant reduction of cervical cancer rates as a result of vaccination in young girls will not be observed for years to come, and it is clear that countries will need substantial resources to support both vaccination and screening programs at the same time for years to come.[331]

CURRENT SCREENING RECOMMENDATIONS

Cervical cancer screening recommendations have been issued by a variety of organizations, including the American Cancer Society[66] and the American College of Obstetrics and Gynecology (ACOG).[332] These guidelines are summarized below, but the reader is referred to these original publications for the evidence-based rationale and a broader discussion of these recommendations.

ONSET OF SCREENING

It is recommended that cervical cancer screening start 3 years after first vaginal intercourse or no later than 21 years of age. However, cervical cancer screening should not be the only basis for the onset of gynecologic care, with all adolescents being given information on preventive health care, counseling regarding health risks, contraception, along with screening and treatment of sexually transmitted diseases.

DISCONTINUATION OF SCREENING

Women 70 years of age or older who have had three or more normal Pap tests in a row and no abnormal Pap test results in the last 10 years may choose to stop having cervical cancer screening. Women with a history of cervical cancer, DES exposure before birth, HIV infection, or a weakened immune system should continue to have screening as long as they are in good health.

SCREENING AFTER HYSTERECTOMY

Women who have had a total hysterectomy (removal of the uterus and cervix) may choose to stop having cervical cancer screening, unless the hysterectomy was performed for treatment of cervical cancer or precancer. Women who have undergone hysterectomy for treatment of CIN2/3 should continue screening until they receive three consecutive, satisfactory normal/negative cervical cytology tests and no abnormal/positive cytology tests within a 10-year period. Those with a history of treatment of cancer and/or a history of in utero diethylstibesterol (DES) exposure should continue

screening after hysterectomy for as long as they are healthy. Women who have had a hysterectomy without removal of the cervix should continue to follow the guidelines below.

SCREENING INTERVAL

Cervical screening should occur annually if conventional cervical cytology smears are used or every 2 years with LBC. For women 30 years or older, those with three prior consecutive, satisfactory normal/negative cytologies may be screened every 2–3 years (unless they have a history of in utero DES exposure, are HIV+, or are immunocompromised by organ transplantation, chemotherapy, or chronic corticosteroid treatment).

HPV DNA TESTING WITH CYTOLOGY FOR SCREENING

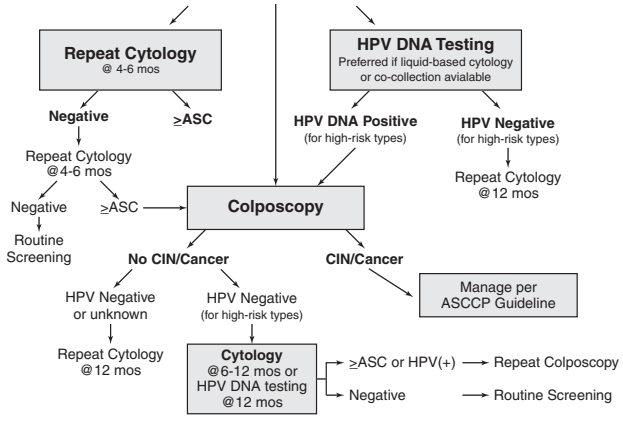
Some have advocated HPV DNA testing with cytology for primary cervical cancer screening for women over 30 years. This is an option for women over 30 years, since Digene-based detection of HPV DNA has been approved for primary screening with cytology for women aged 30 years. As an alternative to cervical cytology testing alone, cervical screening may be performed every 3 years (but not more frequently), using conventional or LBC combined with a test for DNA from HR HPV types.

MANAGEMENT OF ABNORMAL CYTOLOGY RESULTS

As discussed above, approximately 3.5 million women are diagnosed with cervical cytologic abnormalities each year. To encourage standardized clinical care, the American Society for Colposcopy and Cervical Pathology (ASCCP) hosted a consensus conference in 2001[333] to develop evidence-based guidelines for clinical management of the women with abnormal cytologic findings (http://www.asccp.org). These recommendations are summarized below.

MANAGEMENT OF WOMEN WITH ASCUS

Repeat cervical cytological testing, immediate colposcopy, HPV DNA testing for HR types, or combined repeat cervical cytological testing with another adjunctive method are all acceptable methods for managing women with ASCUS (Fig. 58-4). Reflex HPV DNA testing (automatic testing of the original specimen if cytology shows ASCUS) is of interest, as it eliminates the need for an additional clinical examination for specimen collection and reduces by 40–60% the number of women with ASCUS who are referred for colposcopic examination. Further, a negative test essentially



ASCCP=American Society for Colposcopy and Cervical Pathology; CIN=cervical intrapithelial neoplasia; HPV=human papillomavirus

FIGURE 58-4. Management of women with atypical squamous cells of undetermined significance (ASCUS).[338]

eliminates the presence of a significant cervical neoplastic lesion and allows the women to return to normal screening. All women who test positive for HPV DNA should be referred for colposcopy and biopsy. The use of excisional loop electrosurgical excision procedure (LEEP) as a means of diagnosis is not recommended in women with ASCUS on cytology, as this is likely to result in overtreatment of large numbers of women. Women positive for HR types of HPV, but without CIN on colposcopy and biopsy, should have either repeat HPV DNA testing at 12 months or cytological testing at 6 and 12 months. Those with a cytologic diagnosis of ASCUS or greater, or a positive HPV test should be referred back to colposcopy. If women with ASCUS are followed by cytology, repeat cytological testing should be performed at 4–6-month intervals until they receive two consecutive "negative" results, at which time women can be returned to routine screening. Those with ASCUS or greater on the repeat tests should be referred for colposcopy. If immediate colposcopy is used to manage women with ASCUS, those who are not found to have CIN should have repeat cytology at 12 months. Women with CIN on biopsy should be managed according the 2001 Consensus Guidelines for the Management of Women with Cervical Histological Abnormalities.[334] Postmenopausal women with ASCUS may be managed by a course of intravaginal estrogen followed by a repeat cervical cytology with subsequent management, based on these results. All immunosuppressed women with ASCUS should be referred for colposcopy.

MANAGEMENT OF WOMEN WITH ASC-H

Women with ASC-H should be directly referred for colposcopic evaluation. If no lesion is found on colposcopy, cytology, colposcopy, and histology, results should be reviewed, and if ASC-H is confirmed, HPV DNA testing at 12 months or repeat cytology at 6 and 12 months should be performed.

MANAGEMENT OF WOMEN WITH LSIL

Women with LSIL on cytology should be referred for colposcopic evaluation. HPV DNA testing and LEEP are not considered useful for the initial management of women with LSIL, as most women with LSIL are HPV positive and LEEP is frequently normal.

MANAGEMENT OF WOMEN WITH LSIL BUT NO CERVICAL LESIONS

Few data are available regarding management of women with LSIL on cytology in whom CIN is not identified after satisfactory colposcopic examination. While some such women do have underlying CIN, the risk of missing a significant lesion in this situation is relatively low.[335] Endocervical sampling lowers the risk of missed endocervical lesions in women with LSIL, with or without satisfa ctory colposcopic examinations. Endocervical sampling is acceptable for nonpregnant women with satisfactory colposcopic findings and a lesion identified in the transformation zone but is preferred for those without identifiable lesions. Women in whom CIN is not identified can be managed by either repeat cytology at 6 and 12 months with referral to colposcopy if ASCUS or greater is diagnosed or HPV DNA testing at 12 months with referral for colposcopy if testing is positive for an HR HPV.

MANAGEMENT OF POSTMENOPAUSAL WOMEN WITH LSIL

Postmenopausal women with LSIL can be managed as above, or alternatively with either repeat cytology at 6 and 12 months with referral for colposcopy for ASCUS or greater, or with HPV DNA testing at 12 months with referral for colposcopy if positive for HR types of HPV. Women with LSIL, who have clinical or cytological evidence of atrophy, and who are without contraindications to use of intravaginal estrogen, can be managed by a short course of intravaginal estrogen treatment with repeat cytology approximately a week after completion of estrogen therapy. Those with ASCUS or greater should be referred to colposcopy, while those with a cytologic diagnosis of "negative for intraepithelial lesion or malignancy" should have repeat cytology in 4–6 months. Patient can return to routine cytological screening, if both repeat cytology test results are "negative for intraepithelial lesion or malignancy." Women should be referred for colposcopy if either repeat result is ASCUS or greater.

MANAGEMENT OF ADOLESCENTS WITH LSIL

Adolescents with LSIL can be managed without initial colposcopy with either repeat cytology at 6 and 12 months or of HPV DNA testing at 12 months. Those with ASCUS or ASC-H on repeat cytology, or who are positive for HR HPV DNA should be for referral for colposcopy.

MANAGEMENT OF PREGNANT WOMEN WITH LSIL

For the recommended management of pregnant women with a diagnosis of LSIL, see the "HSIL in Special Circumstances" section.

MANAGEMENT OF WOMEN WITH HSIL

Women with HSIL on cytology should be referred for colposcopy with endocervical assessment. Repeat cytological testing or triage by HPV DNA testing is unacceptable. Omission of endocervical sampling is acceptable when a diagnostic excisional procedure is planned. The approach of managing nonpregnant women with HSIL by immediate LEEP of the transformation zone (i.e., "see and treat") has been shown to be safe; however, studies of women undergoing immediate LEEP for cytological abnormalities show that histologically confirmed CIN will frequently not be present (reviewed by Wright),[333] so this approach should be reserved for populations with an HR of being lost to follow-up and for older patients where effects of LEEP on fertility does not have to be considered.

Women with a cytologic HSIL, which cannot be identified on colposcopy and biopsy, need additional consideration, as up to 35% of such women have been found to have high-grade lesions after additional workup.[336,337] Therefore, in situations where a woman has an HSIL cytology without a high-grade lesion on biopsy, a careful re-review of the colposcopic, biopsy, and cervical cytology results should be undertaken to confirm the initial HSIL diagnosis. Nonpregnant patients in whom the cytological diagnosis of HSIL is upheld after review can be managed by a diagnostic excisional procedure. Ablation is unacceptable in this situation.

HSIL in pregnant women also requires special attention. Lesions suspicious for high-grade disease or cancer should be biopsied, while biopsy of other lesions is acceptable. Colposcopic evaluation and detection of HSIL are sometimes more difficult in the setting of pregnancy, and endocervical sampling is proscribed. Pregnant women with unsatisfactory colposcopic findings should have a repeat colposcopic examination 6–12 weeks after an unsatisfactory colposcopy, as colposcopy may become satisfactory as the pregnancy progresses. If invasive disease is not present, the patient should have additional colposcopic and cytological examinations, with biopsy only of lesions whose appearance has worsened or when cytology suggests invasive cancer. A diagnostic excisional procedure is recommended only if invasion is suspected. Reevaluation with cytology and colposcopy should take place no sooner than 6 weeks postpartum.

Young women of reproductive age with HSIL on cytology but in whom biopsy-confirmed CIN 2–3 is not identified on (satisfactory) colposcopy and biopsy (including negative endocervical sampling) can be managed by observation with colposcopy and cytology at 4–6-month intervals for 1 year, and the patient accepts the risk of occult disease. Cytologic persistence of HSIL or colposcopic progression to high grade should be handled by a diagnostic excisional procedure.

MANAGEMENT OF WOMEN WITH AGC AND AIS

Glandular cell abnormalities less severe than invasive adenocarcinoma include (1) atypical glandular cells endocervical, endometrial, or "glandular cells" not otherwise specified (AGC NOS), (2) atypical glandular cells, either endocervical or "glandular cells" that favor neoplasia (AGC "favor neoplasia"), and (3) endocervical adenocarcinoma in situ (AIS).

Women with all subcategories of AGC, with the exception of women with atypical endometrial cells, should initially be evaluated by colposcopy with endocervical sampling. Those with atypical endometrial cells should initially be evaluated with endometrial sampling. In younger women with AGC with unexplained vaginal bleeding and in women older than 35 years with AGC, endometrial sampling should be performed in combination with colposcopy. Women with AIS on cytology should undergo endocervical sampling. Repeat cytologic testing is not an acceptable management strategy for women with AGC or AIS. Further, it is not known whether HPV DNA testing has a role in the management of women with AGC or AIS.

WORKUP OF WOMEN WITH AGC OR AIS IN WHOM LESIONS ARE NOT IDENTIFIED

If initial colposcopic examination and endocervical sampling do not identify invasive disease, women with AGC "favor neoplasia" or endocervical AIS should undergo a diagnostic excisional procedure, preferably cold-knife conization for women with AGC or AIS. Biopsy-confirmed CIN (of any grade) identified during the initial workup for AGC NOS should be managed as are other CINs. Women with AGC NOS without neoplasia on initial workup should be followed by repeat cervical cytological testing at 4–6-month intervals until four consecutive "negative for intraepithelial lesion or malignancy" results are obtained, at which point the woman may return to routine screening. If ASC or LSIL is diagnosed on any of the repeat cytology, repeat colposcopic examination or referral to a clinician experienced in the management of complex cytological situations is appropriate.
