Zidovudine therapy has been associated with a toxic myopathy with a clinical presentation very similar to polymyositis, with myalgias, proximal muscle weakness, and elevated creatine kinase levels.[235,236] There is a relationship between myopathy and cumulative dose of zidovudine, and the mechanism is thought to be due to mitrochondrial toxicity of the drug. Muscle biopsy may or may not show "ragged red" fibers characteristic of mitochondrial myopathy. The clinical abnormalities are reversible on withdrawal or even reduction of the zidovudine dose, and while biopsy may help distinguish this entity from polymyositis, if the clinical picture is not severe, withdrawal of medication may establish the diagnosis without reverting to biopsy.

STI/HIV in Reproductive Health and Pediatrics

This page intentionally left blank

78 Contraception, Contraceptive Technology, and STDs

Charles S. Morrison and Willard Cates, Jr.

INTRODUCTION

Using contraception has two main benefits[1–6]: prevention of unplanned pregnancies and protection against sexually transmitted diseases (STDs). Abstinence from sexual intercourse provides nearly absolute protection against both outcomes. For those choosing to be sexually active, contraception reduces, but does not eliminate, the risk of either pregnancy and/or STDs. Unfortunately the contraceptives with the best record for pregnancy prevention provide minimal STD protection. Some contraceptives may even raise the risk of certain infections.

Moreover, the interaction of contraception and STDs cuts both ways: Not only does the choice of contraception affect the risk of STDs, but also the perception of STD risk affects contraceptive choice. Thus, decisions about contraception by individuals, communities, and policymakers should involve balancing the relative need to prevent both unplanned pregnancies and STDs.

At the personal level, contraceptive use by couples is affected by the perceived risks and costs of STDs and/or pregnancy.[7] These involve such complex *individual* factors as rate of sex partner change, partner selection, relationship context (new vs. established and primary vs. secondary relationship), coital frequency, timing of coitus within the menstrual cycle, safety of the contraceptive method, availability and cost of the method, and acceptance of the method by the sex partner.[8]

At the community level, contraceptive *acceptance* is affected by the social norms of particular cultures.[9,10] This involves such complex *community* factors as the relative value of fertility within specific societies, local customs about sexual activity at early ages, community pressures on teenagers to bear children, societal norms about touching the genitals, and religious proscriptions against use of particular contraceptives.

At the policy level, contraceptive *emphasis* by policymakers is affected by the aggregate risks and costs of STDs and unplanned pregnancies in that particular society.[3] These involve such complex *public health* factors as the local prevalence of sexually transmitted infections (STIs) and unplanned pregnancies, the level of unprotected sexual activity, the political acceptance of individual choice over sexual and reproductive decisions, and the economic capacity of the society to support the existing population growth rate.

The choice of contraception is further complicated when considering its long-range reproductive implications. Contraceptive use has an influence not only on the acute risks of STDs and unplanned pregnancy but also on the eventual reproductive capacity of those making contraceptive decisions. Therefore, personal choices, community programs, and/or policy decisions made in the short run to prevent STDs and unplanned pregnancies can simultaneously improve (or harm) chances of planned procreation in the long run.[11,12]

THE EFFECT OF STD/HIV ON CONTRACEPTIVE USE

Concerns about STDs can affect contraceptive choice and family planning services from a variety of perspectives.[13] At the clinical level, the impact of managing a client with a potential acute STD depends on whether the infection is symptomatic or asymptomatic, whether the infection is curable, and what STD services are available from the family planning provider. If the infection is symptomatic, it should be diagnosed and treated during the same patient visit in which contraceptive services are requested; in the absence of laboratory facilities, clinical algorithms (albeit imperfect) have been recommended.[13,14] If no symptoms are present, the visit by sexually active women to family planning providers offers an opportunity to screen for asymptomatic infections that can be treated in the lower genital tract before they result in complications.

In developed countries, contraceptive providers already play a key role in detecting STDs. More STD screening occurs during routine family planning visits in the United States than through any other type of healthcare.[15] The benefit-to-cost ratio of STD screening in family planning clinics, especially in areas where STDs have a low prevalence, can be

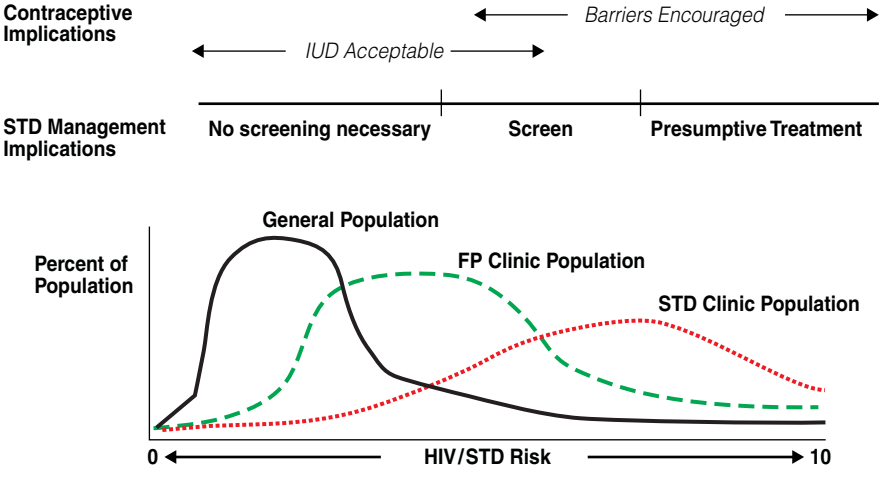
improved by using a variety of factors to increase yield.[16–18] For example, if the patient has a new sex partner, this should trigger both screening for current lower genital tract infection and also counseling regarding safer sexual practices to reduce future infection risk. If the woman is found to have a cervical infection such as chlamydia or gonorrhea, not only should she be immediately treated, but also barrier contraceptive methods should be encouraged, and insertion of an intrauterine device (IUD) at that time should be discouraged.

In resource-poor settings, the same criteria can be used to both initiate presumptive STD treatment and guide contraceptive choice (Fig. 78-1). The mix of demographic, behavioral, clinical, and epidemiologic factors that predict STD risk form a continuum to aid family planning providers in managing their clients more appropriately.[13] For example, clients with a high likelihood of being currently infected (symptoms, recent exposure to an infected partner) can be treated on epidemiologic indications. Likewise, clients without very high individual STI risk can generally be considered candidates for an IUD.[19]

At the operational level, the increasing provision of an array of health services by family planning providers has squeezed limited budgets.[20–22] During the past 20 years, federal funds for family planning services have declined making it a challenge to meet evolving needs. Inflation adjusted Title X funds have declined by 60% since the early 1980s forcing agencies to seek funding from multiple sources.[21,22] Today, many publicly funded family planning agencies offer a wider range of contraception methods, perinatal care, primary healthcare, education, and counseling along with integrating services for men, thus causing an increase in cost.[22] By 2000, almost all agencies test clients who meet screening criteria for bacterial STIs as well as treat infected patients for these infections. In addition, 85% test for HIV infection, 35% provide treatment for HIV positive clients, and at least two-thirds screen for UTI and HPV infection.[22] Because of these pressures to offer more clinical services to an increasing number of clients with decreasing funds, time, and money focused on contraceptive care has declined.[20,22]

At the community level, some hypothesize that STDs may have a negative impact on family planning programs.[17] High prevalence of STIs can serve to decrease acceptance and/or continuation of family planning methods directly and indirectly. (1) Directly—STDs, if perceived as a complication of contraceptive methods, may result in nonuse or discontinuation of the methods. For example, trends in IUD use have been directly related to adverse publicity and litigation about its risks of upper genital tract infection. In some countries the view that male condoms are primarily a device for STD protection has probably limited its acceptability as a contraceptive method. (2) Indirectly—STDs, by compromising healthy childbearing in a community, may hinder any willingness to delay initial childbearing or space out live births.[9] In addition, in regions with high HIV prevalence, perceptions of shortened duration of life expectancy may accelerate desires to achieve the desired family size at an early age although this may now be mitigated by the increasing availability of antiretroviral therapy (ART) in some countries.

These direct and indirect perceptions of STIs can be addressed by effective community health/education programs and by improvements in the quality of reproductive health services including family planning services. During



Lowest	Factors	Highest
• No symptoms/signs	• Clinical	• Symptoms/signs present
• No sexual activity	• Behavioral	• Unprotected sex with infected partners
• Older, married	• Demographic	• Younger, unmarried
• Low prevalence	• Epidermiologic	• High prevalence

FIGURE 78-1. Estimated levels of HIV/STD risk among different populations–implications on contraceptive and STD management. (Adapted from Cates W, Jr. A risk-assessment tool for integrated reproductive health services. *Fam Plann Perspect* 1997; 29: 41–43.)

the 1994 International Conference on Population and Development in Cairo it was emphasized that provision of clinical services to reduce STDs in family planning settings will be regarded as essential for ensuring a healthy reproductive future. In a recent UN report reviewing the progress made since the 1994 International Conference, the need for access to quality reproductive health services, including family planning, emergency obstetric services, and prevention and management of STI, remains a priority.[23,24]

THE EFFECT OF CONTRACEPTIVE USE ON STD/HIV

Recent scientific literature has been replete with reviews of the effects of different contraceptives on the risk of STDs/HIV.[1–6,25–28] In general, they all come to the same conclusion. Male condoms used correctly and consistently provide good protection against most STDs, both bacterial and viral. N9 spermicides alone provide no protection against bacterial or viral STDs. Mechanical barriers, such as diaphragms, may provide some protection against bacterial STD; their impact on HIV prevention is currently under study.[29] Hormonal contraception may enhance acquisition of some cervical infections, but its impact on *upper* genital tract infection and HIV is still unsettled. The IUD does not appear to be associated with STD acquisition (although evidence is weak) and appears to be associated with acute pelvic inflammatory disease (PID) only during the first 20 days postinsertion.[30]

The remainder of the chapter focuses on the relationship between highly effective contraceptive methods (hormonal methods, the IUD, and sterilization) and the acquisition of genital tract infections. We also discuss issues associated with contraceptive use by HIV-infected women and the clinical and policy implications of the dual needs for pregnancy and infection prevention. Chapters 93 and 94 will address the use of condoms and microbicides, respectively, for prevention of STI and HIV acquisition and transmission.

HORMONAL CONTRACEPTIVES

Hormonal contraceptives have an array of noncontraceptive health benefits, but their influence on STDs, HIV, PID, and eventual reproductive sequelae remains unsettled.

HORMONAL CONTRACEPTION AND STI ACQUISITION

Existing prospective studies suggest an increased risk of cervical chlamydial infection among oral contraceptive (OC) and depot medroxyprogesterone acetate (DMPA) users compared to nonusers. Six prospective studies have evaluated the association between use of combined OCs and risk of *Chlamydia trachomatis*, and three of these present statistically significant evidence of a harmful association (Fig. 78-2).[31–33] Three other studies found nonsignificant associations between OC pills and chlamydial infection: two reported risks suggestive of a harmful relationship,[34,35] while the third study suggested a modest protective association.[36] A meta-analysis that pooled results from 29 cross-sectional studies reported a crude pooled odds ratio (OR) of 1.9 (95% confidence interval [CI] 1.8–2.1) for the effect of OCs on the risk of chlamydial infection, compared to non-OC users.[37] When the meta-analysis compared pill users to barrier method users, the pooled OR rose to 2.9 (95% CI 1.9–4.6). This increase in risk may be due to the protective effect of condoms and demonstrates the importance of careful selection of a referent group for these studies. Three prospective studies have evaluated the risk of chlamydial infection associated with DMPA use (Fig. 78-3).[33–35] Each found a statistically significant association between DMPA use and the risk of chlamydial infection with hazard ratios (HR) ranging from 1.6 to 4.3.

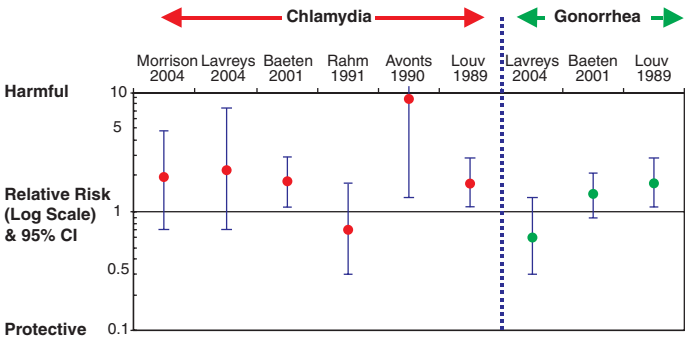


FIGURE 78-2. Prospective studies of OCs and Chlamydia and Gonorrhea acquisition.

Recent prospective research provides little evidence of an association between OC use and the acquisition of gonococcal infections (Fig. 78-2). Of the three studies that assessed this relationship cite mixed results, one produced a statistically significant harmful association for the effect of OC pills,[31] whereas the other two found no significant association between OC use and gonococcal infection.[33,35] Two of these prospective studies also investigated the effect of DMPA on risk of gonococcal infection; both found virtually no risk,[33,35] suggesting no association between DMPA use and acquisition of *Neisseria gonorrhoeae* (Fig. 78-3).

Previous research has suggested that the association between OC use and cervical infections may be mediated through cervical ectopy, which is commonly associated with OC use.[31,38,39] However, more recent studies suggest that while cervical ectopy may confer an independent risk for STI acquisition, it does not appear to be the primary mediator of increased acquisition of cervical infection among hormonal contraceptive users.[33,34] Other potential mechanisms for such an association are that both estrogen and progesterone

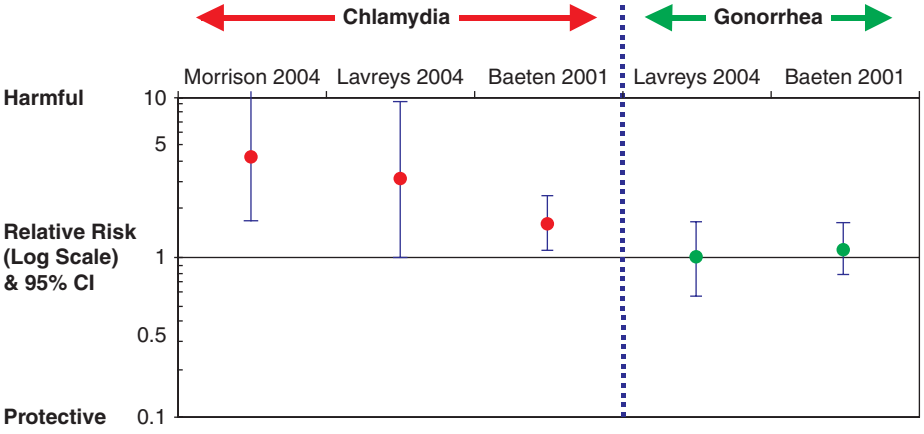

FIGURE 78-3. Prospective studies of DMPA and Chlamydia and Gonorrhea acquisition.

enhance the growth and persistence of *C. trachomatis* infections in animal models,[40] suppression of the local immune response by sex hormones,[41,42] and changes in vaginal flora associated with the hypoestrogenic effect as an outcome of DMPA administration.[43,44]

Studies of highly effective contraception and risk of trichomoniasis are inconclusive. Of the three prospective studies of OC use and risk of trichomoniasis, one study found a nearly null risk,[33] one found a statistically significant protective association,[45] and one found a nonstatistically significant protective relationship.[32] This third study compared IUD to OC users, and although only 10 cases of *Trichomonas vaginalis* were identified, IUD users appeared to be at substantially higher risk of infection than OC users. The single study of DMPA and trichomoniasis yielded a borderline statistically significant protective effect.[33] The relationship between trichomoniasis infection and other highly effective contraceptive methods cannot be established from the existing literature.

The prospective and cross-sectional studies report inconsistent findings about the effect of OC use on the risk of HPV acquisition. Three prospective studies have evaluated OC use as a risk factor for HPV acquisition: one study found a significant harmful effect,[46] a second study reported a significant protective effect,[47] and a third study found a nonsignificant protective effect.[48] A case-control study nested within a prospective cohort found that the risk of acquisition of oncogenic HPV subtypes was significantly increased both for women using OCs for less than and equal to or more than 6 years.[49] A review of 19 largely cross-sectional studies on OCs and HPV infection found no evidence for a strong negative or positive association.[50] One prospective study has evaluated DMPA as a risk factor for incident HPV, finding a statistically nonsignificant protective effect.[47] In addition, one cross-sectional study found a statistically significant elevated risk of prevalent HPV for current users of DMPA.[51] The same study reported a significantly increased risk of HPV for "ever use" of Norplant.

No prospective studies have evaluated the association between OC use and HSV incidence, though several cross-sectional studies have been conducted with mixed findings.[52–56] In addition, no prospective studies have evaluated the relationship between DMPA use and HSV incidence. One cross-sectional study[52] reported a nearly null association for DMPA users compared with pill users.

The data on hormonal contraceptive use and infection with *Treponema pallidum* is also scarce. One prospective study described earlier found statistically nonsignificant protective effects for both OCs and DMPA on syphilis risk.[33]

No prospective studies have evaluated the newer formulations of hormonal methods—the combined estrogen—progestin-releasing patch, ring, or injectables or progestin-only methods including pills, injectables other than DMPA, or implants—on the risk of acquisition of STIs.

HORMONAL CONTRACEPTIVE USE AND UPPER GENITAL TRACT INFECTIONS

The influence of OC use on the upper genital tract may be different from that on the lower genital tract; however, studies from Europe and the United States[57,58] have revealed that women using OCs are half as likely to be hospitalized for PID, compared with women who are sexually active but who do not use contraception. In a multicenter case-control study from the United States,[59] the protection was observed only among women who had been using OCs for more than 12 months. Past use of OCs conferred no protection. In Lund, Sweden,[60] OC use was associated with a significant reduction in the risk of gonococcal PID; the protective effect was not as strong for chlamydial PID. In Seattle, however, women using OCs apparently were differentially protected against chlamydial compared to gonococcal PID.[61] Whether these findings are real, or whether they represent an artifact of clinical detection of PID, is unclear. OC users tend to have milder upper genital tract infection with *C. trachomatis*, as manifested by antibody response[62] and laparoscopy.[63]

OC users also have increased risks of unrecognized endometritis.[64]

Possible mechanisms for the consistent protective effect of OCs on symptomatic PID remain speculative. The progestin component of combination OCs thickens the cervical mucus. Changes in either mucus composition or its immunologic properties might account for this protection. Likewise, the thinner endometrium and/or the decreased menstrual flow associated with OC use may play a role. Alternatively, if OC use tends to mask the symptoms of PID, they will appear protective even though unrecognized inflammation may be occurring.[64]

Consistent with this latter explanation, use of hormonal contraception seems to modify the acute clinical course of PID favorably. As judged by laparoscopic examination, women with PID who were using OCs had milder inflammation compared to women not using OCs.[63] Sex steroids can modify immunologic function[65] and so their impact on infectious inflammation is plausible, though still unproven.

HORMONAL CONTRACEPTIVE USE AND HIV ACQUISITION

Whether hormonal contraception, and in particular OC and DMPA use, alters the risk of HIV acquisition is a critical unresolved public health issue.[66,67] Animal models, using simian immunodeficiency virus (SIV) as the HIV surrogate, have raised concerns. Acquisition of SIV was increased nearly eightfold in monkeys with progesterone implants compared to monkeys challenged with SIV in the follicular phase of a normal menstrual cycle[68] and more than twofold compared to monkeys challenged randomly through a normal cycle.[69] This effect appears to be related to a state of estrogen deficiency that is associated with the use of progesterone including DMPA.[70] In a second study, 18 ovariectomized macaques received either progesterone or estrogen implants or no treatment followed by intravaginal SIV inoculation. All of the untreated macaques and five of six progesterone-treated macaques became infected, while none of the estrogen-treated animals became infected. In a follow-up study, 12 ovariectomized macaques were treated with vaginal estriol cream and 8 macaques with a placebo cream. Following vaginal challenge with SIV, 1 of 12 macaques treated with estriol and 6 of the 8 macaques receiving the placebo became SIV infected ($p = 0.004$). Use of the estriol cream was associated with significant cornification and thickening of the vaginal epithelium but appeared to have no systemic effect.[71] Finally, among macaques previously immunized with nonpathogenic simian-human immunodeficiency virus (SHIV89.6), treatment with DMPA led to a lower rate of protection after intravaginal challenge with SIV and higher acute postchallenge plasma SIV RNA levels compared with animals not treated with DMPA.[72] These studies raise the possibility that the progesterone component of various hormonal contraceptives may increase risk of HIV acquisition.

Epidemiologic studies in humans have produced equivocal results, however.[66] First, studies examining the effect of DMPA use on the thickness of human vaginal epithelium suggest no clinically important differences among women using and not using DMPA.[43,44,73] In addition, no RCTs have been performed of hormonal contraceptive use and HIV acquisition due to the ethical and practical issues related to randomizing some women to contraceptive methods, which may be less effective and are not their preferred method of contraception. This is an important issue because allowing women to use their preferred contraceptive method is associated with higher contraceptive continuation rates—an important methodologic consideration in such studies.[74]

Eleven prospective studies have examined OC use and HIV acquisition;[19,39,41,72,75–87] two found a statistically significant increased risk,[75,85] three a nonstatistically significant increased risk (risk ratios ≥1·8),[80,81,86] and six found no association.[76–79,82,84] (Fig. 78-4) Six prospective studies have addressed DMPA use and HIV acquisition;[79,81–85,88] two found a statistically significant increased risk,[79,83] one a nonstatistically significant increased risk,[88] and three found no association.[81,82,84] (Fig. 78-5)

Two reviews have been published with conflicting conclusions concerning the risk of HIV acquisition among OC users.[89,90] Most studies reporting an increased HIV risk involved high-risk populations, such as sex workers[75,79,81,83,85] or women attending STI clinics.[86]

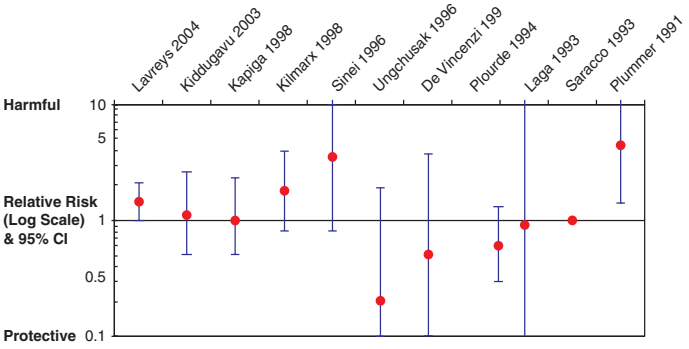

FIGURE 78-4. Prospective studies of OC use and HIV acquisition.

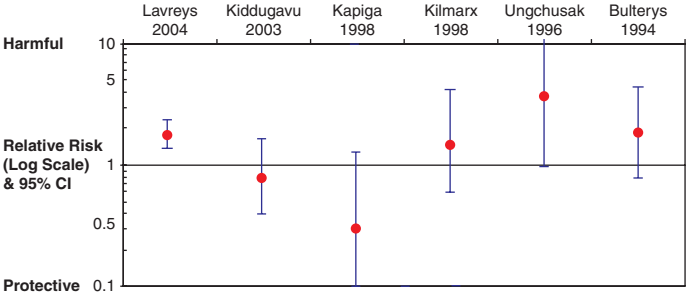

FIGURE 78-5. Prospective studies of DMPA use and HIV acquisition.

However, these studies were not specifically designed to assess the hormonal contraception–HIV relationship and most had important methodologic shortcomings, including poor measurement of contraceptive exposure (i.e., ever vs. never use), few hormonal contraceptive users, and therefore low power to detect differences between contraceptive groups, inaccurate measurement of the timing of contraceptive use versus HIV acquisition and poor follow-up. Also studies conducted among selected high-risk groups (e.g., sex workers) from a particular city or region have limited generalizability to women seeking family planning services worldwide.

A large, multi-country study was recently sponsored by the National Institute of Child Health and Human Development (NICHD) to specifically evaluate the relationship between hormonal contraception and HIV acquisition. Approximately 6100 HIV-negative women were recruited from 14 sites in Uganda, Zimbabwe, and Thailand. In this prospective cohort study, most women were recruited from the general population seeking reproductive health services. They were equally divided among three exposure groups: users of OCs, users of DMPA, and women not using hormonal contraception. Overall, the study found no statistically significant association between the use of either OCs or DMPA and HIV acquisition.[91]

The study also explored whether STIs modified the relationship between hormonal contraceptive use and HIV acquisition. Neither the presence of vaginal infections (trichomoniasis, bacterial vaginosis, and candidiasis) nor cervical infections (chlamydia and gonorrhea) modified this relationship. However, among the approximately half of African study participants testing negative for HSV-2 at enrollment, those who used either OCs or DMPA had a statistically significant increased rate of HIV acquisition compared to nonusers.[91] Because a biological mechanism for this finding is unclear and other studies have not examined it, further research is needed to validate this finding. Based on the preliminary results of this study, neither the World Health Organization nor the International Planned Parenthood Federation plan to change their guidelines for hormonal contraceptive use.

While the exact mechanism by which hormonal contraception might facilitate HIV infection is unknown, possibilities include increased cervical ectopy associated with OC use[31,39]; increased cervical chlamydial infection (and associated purulence)[31,33,34,86]; a hypoestrogenic effect associated with DMPA use resulting in a reduction in hydrogen peroxide producing lactobacilli and irregular uterine bleeding[43,44,50]; suppression of the local (cell-mediated) immune response[41,72,83,92]; and increased recruitment of inflammatory and other target cells to the genital tract[72,83,92,93] or through a direct effect on the infecting virus inoculum by upregulating HIV gene expression and associated viral replication.[72,83,92] In addition, the particular type and dosage of estrogens and progestins contained in OCs or injectable hormonal contraceptives may play an important role in any relationship between hormonal contraceptive use and HIV acquisition or transmission.[67]

INTRAUTERINE DEVICES

Current data suggest no association between IUD use and risk of STI acquisition (i.e., the risk of lower genital tract infections). One of the previously cited studies examined chlamydial infection in OC users compared to women with IUDs,[32] finding that IUD users were at significantly lower risk of chlamydial infection compared to OC users. More than 20 cross-sectional studies have also assessed the association between IUD use and chlamydia; none found significantly increased risks of chlamydia among IUD users compared to either OC users or to women using no contraception, and a review article concluded that the IUD was unrelated to cervical chlamydial infection.[94] Thirteen cross-sectional studies have assessed the association between IUD use and gonorrhea; none found significantly increased risks among IUD users compared either to pill users or to women using no contraception.[95–105]

The existing evidence suggests that IUD use does not increase the risk of HIV acquisition. Only three prospective and eight cross-sectional studies have examined this relationship. None of the prospective studies[80,82,83] found evidence of an increased risk of HIV acquisition associated with IUD use, and only two of the eight cross-sectional studies found an association between IUD use and prevalent HIV infection.[106–113]

However, again many of these studies had important methodologic limitations, including the lack of an appropriate comparison group (IUD users were often compared to users of OCs and DMPA). Moreover, IUD users in these studies were screened for lower risk of STI infection before IUD insertion, thus increasing the likelihood of selection bias.

The possible association between IUD use and the development of upper genital tract infection remains a controversial topic in contemporary contraception. Epidemiologic evidence from the 1980s showed the initial association between IUD use and PID found in the 1970s to be overestimated.[114] Three particular methodologic problems in the early studies contributed to their overly pessimistic assessment. First, women using barrier or OCs served as the comparison group in most studies.[115] Since these methods *reduce* the risk of symptomatic PID, such comparisons artifactually elevated the apparent risk associated with IUD use. Second, the PID diagnosis often rests on highly subjective symptoms and signs that are difficult to assess.[116] Since the putative association between IUD use and PID has been recognized since the 1960s, PID "diagnostic bias" might occur among IUD users. Third, early analyses did not adjust for type of IUD and the timing of its insertion. If either of these factors creates a disproportionate degree of PID risk, the overall crude risk for IUDs as a group is also spuriously elevated.

More sophisticated studies[30,117–119] have revised our understanding of the IUD–PID association. Current evidence suggests that the smaller, but still measurable, increased risk of PID associated with IUD use occurs around the time of insertion, and specifically in the 20 days following IUD insertion.[30] Thus, contamination of the endometrial cavity at insertion may be more responsible for IUD-related PID than the device itself.

Because of the association of PID to the timing of IUD insertion, short-term antibiotics might help reduce the risks. In Kenya,[120] Nigeria,[121] and the United States,[122] randomized clinical trials of antibiotics given at the time of IUD insertion were limited by rates of IUD-associated PID that were much lower than expected, even among the placebo group. Because of the infrequency of IUD-related PID and because of the limited size of the studies, they had insufficient power to distinguish any statistically significant differences among treatment and placebo groups. Nevertheless, the low prevalence of PID among IUD users both with or without the provision of antibiotics and in areas of high and low STI prevalence is reassuring.

Many perceive the IUD's safety today as vastly different from that a decade ago. With proper screening of clients, the IUD poses little, if any, added PID risk. Likewise, current evidence suggests no substantive impact of IUD use on subsequent fertility.[123] For example, a large case-control study compared women with primary infertility with documented tubal occlusion with women with primary infertility without tubal occlusion (infertile controls) and with primigravid women (pregnant controls). The study found no increase in the odds of previous IUD use among the women with tubal occlusion compared with either the infertile or the pregnant controls. However, the presence of antibodies to *C. tracomatis* was associated with infertility.[124] In another study, among women who had used copper IUDs and who had only one sex partner, no increase occurred in the risk of either PID or tubal infertility.[118]

Thus, the future challenge will be to establish criteria, based on a combination of demographic, behavioral, and clinical factors, to expand the proportion of women for whom the IUD is recommended.[13] Finally, some evidence suggests that the newer IUDs containing levonorgesterol are associated with even lower rates of PID.[123] If subsequent research confirms a preventive effect of the levonorgestrel IUD on PID risk, its use may be especially appropriate in populations with a high prevalence of cervical infections.

Based on recent research, the WHO has made important revisions in its *Medical Eligibility Criteria for Contraceptive Use* for IUD use by women with STIs or HIV.[19] In relation to STIs, only the presence of current purulent cervicitis or documented chlamydial or gonococcal infection definitively rules out an IUD insertion (but does not rule out ongoing IUD use). In addition, a high general STI risk (e.g., as when living in an area with high STI prevalence) does not rule out either an IUD insertion or ongoing IUD use. Finally, women with other STIs including vaginitis and HIV infection (unless the woman has AIDS and is not clinically well on ARV therapy) can generally either have an IUD inserted or continue the use of the ongoing IUD.

OTHER METHODS

Fertility awareness methods

Fertility awareness methods (FAM), also referred to as natural family planning, describe methods of planning or preventing pregnancy based on using naturally occurring signs and symptoms of the fertile and infertile phases of the menstrual cycle. Use of FAM for pregnancy prevention requires abstinence from intercourse on potentially fertile days. The pregnancy rates for this method vary widely, depending on the FAM approach used and the dedication of the users. No studies of the association between FAM and STD/HIV transmission have been conducted. Since these methods offer no obvious protection against infection, sexually active persons who wish to use FAM to prevent pregnancy and who are not having intercourse with partners known to be uninfected should be advised to use condoms for HIV/STD prophylaxis.

Lactational amenorrhea method

Breastfeeding, currently known as the lactational amenorrhea method (LAM), provides for another means of natural family planning. For some women, lactation-associated anovulation is a primary means of spacing births and avoiding pregnancies. Within the first 6 months following delivery, women who fully (or nearly fully) breastfeed have a low risk of pregnancy, 2% or less, prior to the return of menses.[125]

Breast milk is also an avenue for transmission of infectious agents, however. Both cell-free HIV and HIV-infected cells have been detected in breast milk, and more than one-third of cases of mother-to-child transmission among HIV-infected breastfeeding women are thought to occur through breastfeeding.[126–128] Several methods for reducing the risk of transmitting HIV through breastfeeding now appear promising including engaging only in exclusive breastfeeding,[129] limiting breastfeeding to the first six months of life,[130] and provision of antiretroviral treatment to breastfeeding women throughout the breastfeeding period.[131–132] Nevertheless, a complex trade-off exists between the contraceptive effect of LAM preventing an HIV-infected woman from becoming pregnant (and thus not at risk of transmitting HIV to her next child) versus the risk of transmitting HIV through breast milk to the child she is currently nursing.

For the mother who is uninfected, breastfeeding provides no protection against HIV or other STDs. Women who are using LAM as their contraceptive method, and who are at risk

of STDs/HIV, should use condoms to protect themselves against STI/HIV acquisition.

Tubal sterilization

Tubal sterilization protects against PID, but this protection is not absolute. Most typical cases of PID are thought to arise from ascent of cervical pathogens via the endometrial cavity; hence, disrupting the continuity of this passage should prevent inoculation of the distal fallopian tubes. Even though endometritis and proximal salpingitis are potentially possible, PID is rarely observed among women after tubal sterilization.[133] Anecdotal cases of PID and tubo-ovarian abscess continue to be reported. A more likely mechanism for poststerilization PID is the iatrogenic contamination of the tubes during the operative procedure; in the less developed world, where sterile conditions are more difficult to maintain, this risk may be further elevated.

Abortion

Women who have cervical infection with either *N. gonorrhoeae* or *C. trachomatis* have an increased risk of endometritis following induced abortion performed under proper hygienic conditions. The risk appears to be at least tripled with either organism.[134] A number of studies suggest that use of prophylactic antibiotics at the time of the abortion procedure reduces the risk of infection by one-half to two-thirds.[135] While preoperative screening for infection with these organisms is desirable, a brief perioperative course of an antibiotic such as azithromycin seems both safe and cost-effective and is recommended both by the WHO[136] and the American College of Obstetricians and Gynecologists.[137] Women later found to be infected by *N. gonorrhoeae* and/or *C. trachomatis* can be followed up with a full course of recommended antibiotics, with notification and treatment of their sex partner(s).

The greatest risk of upper genital tract infection associated with induced abortion occurs in circumstances where sterile conditions are not maintained. In countries where abortion services are restricted by law or practice, and especially in resource-poor regions where, even if legal, access to sanitary procedures is limited, postabortion infection poses risks not only to future fertility but also to the woman's life.[138] An estimated 67,900 annual abortion-related deaths occur worldwide with the highest rates in Africa, followed by South-central Asia and Latin America and the Caribbean. The global case-fatality rate associated with unsafe abortion is approximately 700 times higher than the case-fatality rate associated with legal abortions in the U.S. and over 99% of abortion-related deaths are due to unsafe abortions occurring in developing countries.[139]

In both the developed and less-developed worlds, carrying a pregnancy to term leads to greater risks of infection and death than terminating it through induced abortion.[140,141] Under sterile conditions, abortion is five to ten times safer than childbearing. Under less hygienic conditions, the risks of adverse outcomes for *both* abortion and term delivery increase, and the gap between the infection risks from abortion and childbirth probably narrows. In these circumstances, use of any method of contraception to reduce pregnancy has simultaneous effects on reducing pregnancy-associated infection (see later).

CONTRACEPTIVE USE AMONG HIV-INFECTED WOMEN

A number of international initiatives support the right of all persons, including HIV-infected women and men, to freely decide about their sexual and reproductive lives, including decisions about pregnancy and childbearing.[142,143] In addition to the direct health benefits conferred by prevention of unwanted pregnancies (reduction of maternal morbidity and mortality, reduction in abortions), offering high-quality and accessible family planning services to HIV-infected women and men provides additional important health and social benefits.

CONTRACEPTION AS AN HIV PREVENTION STRATEGY

From a public health perspective, the rationale for making highly effective contraception accessible to HIV-infected women who do not wish to become pregnant is strong. The use of effective contraception by HIV-infected women to prevent HIV sequelae remains one of the best-kept secrets in the field of HIV prevention. Most reviews of perinatal prevention strategies begin with the infected pregnant woman and emphasize antiretroviral prophylaxis to prevent transmission from the woman to her infant. However, earlier stages of prevention can be both more profound and more cost effective. The WHO has proposed a four-staged perinatal prevention strategy that includes the use of contraception as its second phase. The four-stage approach involves (1) preventing HIV in women overall, (2) preventing unintended pregnancies in HIV-infected women, (3) preventing transmission from an HIV-infected pregnant woman to her infant, and (4) providing support–and eventually treatment–for the mother and her family.[142,144]

A number of models have demonstrated that the impact of provision of family planning services to HIV-infected women who do not wish to become pregnant can have a dramatic effect on the number HIV-infected infants and orphans and is at least as cost-effective as providing ART to mothers and infants.[145–147] The differential impact of these strategies can be demonstrated by comparing stages 2 and 3, namely, providing effective contraception and delivering low-cost nevirapine to a population of 1000 HIV-infected women. Using assumptions based on the best available data, the number of infants infected with HIV either during delivery or the breastfeeding interval and the number of uninfected infants becoming

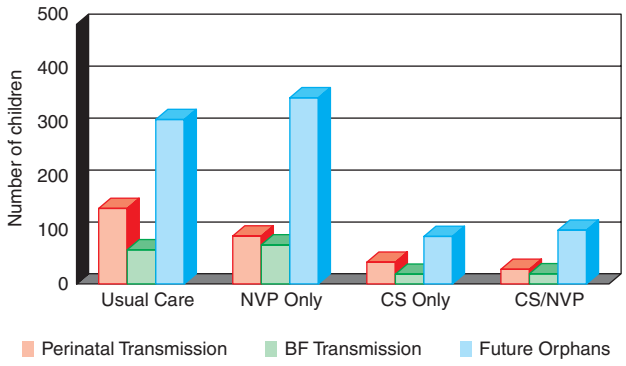

FIGURE 78-6. Comparative outcomes of providing single dose nevirapine (NVP) and effective contraceptive services (CS) to 1000 HIV-infected women during 1 year of service delivery.

orphans are shown in Fig. 78-6.[148] We compared four categories of care: (1) the "usual" standard of care (namely, no care in most resource-poor settings), (2) providing single-dose nevirapine as in stage 3 only, (3) providing contraception as in stage 2 only, or (4) providing both stages 2 and 3 sequentially.[148]

Focusing on the delivery interval, without any intervention, 150 infants would be infected with HIV. If nevirapine were available and chosen by pregnant, HIV-infected women, this number could be reduced to 82, which is the expected 47% decline. If effective contraceptive services were available to all HIV-infected women who did not wish to become pregnant, this number would be reduced to 49, and finally, if both these strategies were employed, we could further decrease the number of infected infants to 25.

During the breastfeeding interval, a paradoxical effect occurs with nevirapine compared to no intervention. Because the number of infants uninfected at birth rises with nevirapine, so does the denominator of HIV-uninfected babies exposed during the breastfeeding interval. Thus the number of infants infected during breastfeeding increases with the use of nevirapine. This does not occur with contraceptive services, since the pregnancies themselves are prevented.

Finally, the most dramatic effect of these two strategies is on the number of future infants orphaned because their mothers die of HIV infection. Without any intervention, 300 orphans will eventually be left behind by the death of their mother. Using nevirapine to prevent transmission again has the paradoxical effect of creating more orphans since a greater number of infants will be uninfected and live longer, whereas their mothers will die in the absence of antiretroviral treatment. However, with effective contraceptive services, the number of unintended orphans declines dramatically, to less than 100 since the unintended pregnancies themselves are prevented. When both strategies are used together, not surprisingly, the overall impact is the best.

Further estimates suggest that the current contraceptive use prevents over 173,000 HIV-infected infants each year in sub-Saharan Africa or 474 HIV-infants per day.[149] Moreover, given that the proportion of unintended births is about 25% in sub-Saharan Africa, provision of effective contraception to HIV-infected women who do not wish to become pregnant has the potential to prevent more than 160,000 additional HIV-infected infants annually.[149] These data are compelling. Providing effective and safe contraceptive choices to HIV-infected women who do not wish to currently become pregnant optimizes the prevention of HIV-infected births and the number of future orphans. Thus, the provision of family planning is a critical adjunct to prophylactic ART for reducing worldwide mother-to-infant HIV transmission.

Table 78-1. Issues Related to Contraceptive Use by HIV-Uninfected and Infected Women

Population	Issue
Uninfected	• HIV susceptibility
	• Contraceptive efficacy
Infected	• Changes in fertility desires
	• Breastfeeding issues
	• Changes in HIV infectivity
	• Impact on HIV disease progression
	• Contraceptive safety, side effects and efficacy (esp. with concomitant ART use)

For the HIV-uninfected woman the primary issues related to contraception and STDs are the complex trade-offs between pregnancy and infection prevention. For the HIV-infected woman the issues are even more complex (Table 78-1). These include (1) possible changes in fertility desires related to HIV infection status and the need for contraceptive choice to reflect these desires, (2) breastfeeding issues (as discussed above), (3) possible changes in her HIV infectivity related to contraceptive use (as measured by HIV genital shedding), (4) potential alteration in HIV disease progression related to the use of some contraceptive methods, and (5) possible differences in the safety profile, side effects, or efficacy of a contraceptive method when used by an HIV-infected woman, especially with concomitant use of ART.

DIFFERENCE IN FERTILITY AND FERTILITY DESIRES OF HIV-INFECTED WOMEN

Evidence suggests differences in fertility between HIV-infected and uninfected women. Such changes stem from possible reductions in fertility in HIV-infected women from a desire to avoid pregnancy,[150,151] decreased sexual activity,[152–154]

reduced fecundity from the infection,[155,156] and increased risk of pregnancy loss.[87,157,158] Nevertheless, fertility rates remain high among HIV-infected women—on the order of 11 to 20 births per 100 person-years.[153] Several studies in Africa suggest that about half of pregnancies occurring postpartum among HIV-infected women are unwanted with large numbers ending up with induced abortions.[159,160]

Nevertheless, many HIV-infected women want to continue childbearing. This desire is likely to become stronger as more highly effective antiretroviral regimens become available for both prevention of mother-to-child transmission and for treatment of the woman's chronic HIV infection.[161] Thus, access to highly effective reversible contraceptive methods is essential so that HIV-infected women may either avoid or delay pregnancy.

CONTRACEPTION AND HIV TRANSMISSION

A theoretical concern exists that hormonal contraceptive use by HIV-infected women might increase genital tract shedding of HIV and thus potentially increase HIV transmission to uninfected sex partners. The majority of reported studies have been cross-sectional and have provided conflicting data. For example in a study of 318 women attending an STD clinic in Kenya, use of both low-dose and high-dose OCs and DMPA was associated with an increased detection of HIV-1 DNA in endocervical secretions.[162] However, in a cross-sectional analysis of women participating in the Women's Interagency HIV Study (WIHS) Study from the United States, hormonal contraception was not associated with increased genital tract shedding of HIV-1 RNA.[163] The sole prospective study of the effect of hormonal contraceptive use on genital tract shedding of HIV, conducted among a population of family planning clients in Mombasa, Kenya, detected a significant but modest increase in the proportion of women with detectable HIV-1 DNA after initiation of various hormonal contraceptives (including low and high-dose combined OCs, DMPA and progestin-only OCs) compared with before initiation. Yet, no significant difference was detected in the concentration of cervical HIV-1 RNA (or in plasma HIV-1 RNA). This suggests the possibility that hormonal contraception does not affect HIV replication in the genital tract but instead increases the recruitment of HIV-infected cells from systemic compartments to the genital tract.[164]

The issue of factors associated with HSV-2 shedding among HIV-infected women has also been recently examined. In a cross-sectional study of 273 women seropositive for HSV-1, HSV-2, and HIV-1, hormonal contraception including both OCs and DMPA were significantly associated with cervical shedding of HSV infection.[154] However, in a subsequent prospective study of 200 women seropositive for HSV-2 and HIV-1, who were tested for HSV-2 shedding before and after initiation of combined OCs and progesterone-only contraception (pills and DMPA), no statistically significant differences were found in either the proportion of women exhibiting HSV-2 shedding or in the quantity of HSV in cervical secretions for either contraceptive group after as compared to before contraceptive initiation.[165]

Few data examine IUD use and HIV genital shedding. One prospective study from Kenyan family planning clinics found no increase in the prevalence of cervical shedding of HIV-1 DNA 4 months after insertion of an IUD compared to that before the IUD was inserted.[166] No studies have compared the levels of HIV-1 RNA from the genital secretions of HIV-infected women using and not using IUDs.

HORMONAL CONTRACEPTION AND HIV DISEASE PROGRESSION

Whether hormonal contraceptive use at or near the time of HIV infection affects disease progression is also of concern. In a prospective study of HIV acquisition among 1350 sex workers in Mombasa, Kenya—161 of whom were followed up for a median of 34 months after being infected with HIV—it was found that the use of DMPA at the time of infection was associated with a higher HIV viral set point.[167] This finding suggests that the use of DMPA at the time of infection may hasten HIV-related deterioration of the immune system and the natural course of HIV infection.[167] In a subset of these HIV-infected sex workers (82 of whom used any hormonal contraception and 68 of whom did not), hormonal contraceptive use near the time of HIV acquisition was associated with infection with multiple strains of the virus.[168] This relationship appeared to mediate the relationship between DMPA use and a higher viral set point. Moreover, infection with multiple strains appears to be related to a higher viral set point and faster CD4 decline, two key indicators of HIV disease progression.[169]

In a study conducted among the WIHS cohort in the United States, no differences were seen in plasma viral load either cross-sectionally (at baseline) or in changes in levels over time between women using hormonal contraception and those not using them. In contrast, the authors reported a statistically significant increase in CD4 lymphocyte counts among users of hormonal contraception both cross-sectionally and longitudinally when compared with women not using hormonal contraception. However, these increases were small, and the authors believe the difference not to be clinically relevant.[170]

Since much of the data on the possible impact of hormonal contraception on HIV disease progression has come from studies conducted among Kenyan sex workers, and some of the findings have not been corroborated by other studies, further research among other populations of women in diverse geographic locations is needed. Several ongoing studies of hormonal contraceptive use among various populations of HIV-infected women in Africa are expected to clarify this issue.

SAFETY, SIDE EFFECTS, AND EFFICACY OF CONTRACEPTIVE USE AMONG HIV-INFECTED WOMEN

Few data exist on the side effects and efficacy of the use of highly effective reversible contraception by HIV-infected women. A study from Thailand conducted among 43 asymptomatic HIV-infected women reported that Norplant progestin implants appeared to be well tolerated with side effects and menstrual patterns similar to HIV-uninfected Norplant users. Likewise, no pregnancies occurred during 1 year of use among these women.[171] No evidence suggests reduced safety or efficacy of other hormonal contraceptives, including OCs and DMPA among HIV-infected women who are not using ART. Consequently, the WHO MEC guidelines include no restrictions or concerns for the use of hormonal contraception by HIV-infected women not using ART.

A study of IUD use among 649 women in Kenya (including 156 HIV-infected women) found no increased risk in either overall or infection-related complications among HIV-infected compared with uninfected women.[172,173] In contrast, women with chlamydial or gonococcal infections near the time of IUD insertion were at increased risk of both overall and infection-related complications. Given these findings and the finding that IUD use does not appear to increase genital shedding of HIV, the WHO MEC has changed its guidelines so that HIV-infected women can generally either have an IUD inserted or continue ongoing IUD use (unless the woman has AIDS and is not clinically well on ARV therapy).[19]

HORMONAL CONTRACEPTIVES AND USE OF ART

Hormonal contraception and many types of ART are metabolized in the liver and the same liver enzymes (cytochrome P450) are involved in the metabolism of both types of drugs. A number of NNRTI and protease inhibitors have been found to speed the metabolism of hormonal contraceptives and thus alter the steroid hormone levels in the blood. For example, studies have found that the use of nevirapine resulted in a 29% decrease in the levels of ethinyl estradiol and an 18% decrease of the levels of norethindrone among women using OCs.[174] Among women taking the protease inhibitor ritonavir, a 43% reduction in ethinyl estradiol was observed.[175] Because of these changes in hormonal levels, theoretical concerns exist about the possibility of decreased contraceptive efficacy of hormonal contraception, decreased efficacy of ART and/or an increase in side effects related to either the use of hormonal contraceptives or ART.

To date, no studies have examined the effects of simultaneous use of hormonal contraception and ART on contraceptive effectiveness, ovulation or breakthrough bleeding. However, given the reduction in blood hormone levels with coadministration of OCs and ART, some providers have recommended prescribing OCs containing 50 μg of estrogen instead of the low-dose OCs (20–35 μg of ethinyl estradiol) most commonly used. However, use of higher dose OCs carry an increased risk of severe side effects including deep vein thrombosis, heart attacks, and strokes. Currently, the WHO recommends that OC users may continue to use low-dose pills while on ART, but should also use condoms as a back-up contraceptive method.[19]

Only one published study has considered the effect of simultaneous use of hormonal contraception and ART on ART effectiveness. Among 77 hormonal contraceptive users and 77 nonusers matched for age, ethnicity, CD4 lymphocyte count, and HIV viral load who began using ART, no statistically significant differences were found in increases in CD4 lymphocyte count or in the proportion of women who had reduction in viral loads to undetectable levels.[176]

Based on the relatively sparse data on concomitant use of hormonal contraception and ART, WHO suggests that although women using ART can generally use OCs and other types of hormonal contraception, dual use of condoms is recommended.[19]

CLINICAL AND POLICY IMPLICATIONS

CONTRACEPTIVE/STD PREVENTION TRADE-OFFS

In ideal circumstances, consistent and correct use of male or female condoms can prevent *both* pregnancy and STDs. In typical situations of inconsistent use, however, they provide lower rates of protection against these conditions. Moreover, if couples choose to use contraceptive methods other than condoms, those with the best record for pregnancy prevention provide little STD protection. Thus, trade-off choices are necessary.

For those whose families are not completed, yet who do not currently wish to become pregnant, hormonal contraceptives and the IUD remain the most effective reversible methods available to prevent unintended pregnancy. However, they provide no protection against vaginal or cervical infection, and inserting the IUD carries temporary risks to the upper genital tract. Hence, for persons who are not mutually monogamous, addition of a barrier method, such as a condom, will help reduce the risk of STDs as well as unplanned pregnancies. Under typical conditions, however, barrier methods are substantially less effective in preventing conception than hormonal methods, yet they offer important protection against STDs. To maximize protection against both unintended pregnancy and STD, a barrier method should be used in conjunction with a hormonal method or IUD.

Worldwide, for couples whose families are complete, male or female sterilization is an increasingly popular method of contraception.[177] While these operations protect against upper genital tract infections in sterilized persons, they confer no protection against lower genital tract infections.

Alternatives to sterilization are hormonal implants or the IUD; both are effective methods of reversible contraception, but they offer no protection against cervical infection. Sterilized persons would still need to use barrier methods to protect against infections in the lower genital tract.

Because both mechanical and chemical barrier prophylaxes are coitally dependent, their efficacy in preventing either infection or unplanned pregnancy depends entirely on adherence by the couple. Some targeted high-risk populations have demonstrated high levels of barrier-method use. For example, in Thailand, a "100% condom policy" in commercial sex facilities has led to widespread use among the workers and their clients; this, in turn, has been associated with marked reductions in HIV and other STDs.[178,179] In the United States, women working in Nevada brothels have had similar success.[180] Unfortunately, to date, most heterosexual populations worldwide have not reported the same magnitude of condom use and have not experienced decreases in the traditional STDs.[181]

The reasons for relatively low global condom use rates vary. In many settings, a woman cannot insist on a male-dependent method such as a male condom. For example, in South Africa, female sex workers serving male truck drivers were unable to persuade most of their customers to use condoms; fear of economic loss and personal violence limited any ability to negotiate.[182] However, in Cameroon, sex workers provided with condoms and regular counseling reported using condoms with their clients in nearly 90% of sexual acts.[183] Moreover, cultural taboos against discussing sex limit the practical negotiations that can take place. In some societies, use of condoms is associated with commercial sex, which makes them unacceptable for use in any primary relationship. Finally, in all surveys, men consider condom use to be a major inhibition to their sexual enjoyment.

Another important aspect for assessing trade-off concerns is whether conditions exist for safe, sterile childbirth and/or abortion. If pregnancy itself, regardless of whether it is terminated or continued, carries markedly high "iatrogenic" risks of genital infection, then the pregnancy prevention efficacy of the contraceptive choice takes on greater weight. In addition, some studies suggest that pregnancy itself may increase the risk of HIV acquisition.[184] By preventing undesired pregnancies, the contraceptive method(s) simultaneously protect against pregnancy-associated infections of the reproductive tract. In the developing world, postabortal and puerperal infections are important causes of tubal infertility. In Africa, where the infectious etiology of infertility was most evident,[185] genital infections occurring both before and after the first pregnancy were associated with tubal occlusion. In Asia, abortion appeared to play a larger role than childbirth in contributing to infectious infertility, whereas in Latin America the reverse was found.[186]

DUAL METHOD VERSUS DUAL PURPOSE

Another complex issue for reproductive health providers serving clients at risk of STD/HIV is whether to encourage the use of dual methods—one to prevent pregnancy and the other to prevent STD/HIV.[5] Clinicians promoting dual use must weigh interacting factors such as extra cost and effect on user adherence, as well as the level of STDs in particular client populations. Moreover, clients may attach differing priorities to preventing either pregnancies or infections, and these priorities may change over time and among various relationships. Studies on dual-method use are limited and have focused on the use of the male condom added to other methods of contraception.[187–197] In general, based on investigations where participants were using primary methods other than the condom, the more effective the primary contraceptive method was in preventing pregnancy, the lower the level of consistent use of the male condom.

Several reasons can explain why concurrent condom use may decrease as perceived contraceptive effectiveness increases. First, many persons—even those with sexual behaviors putting them at risk of STDs—see pregnancy as a greater immediate threat. Thus, having taken proactive precautions against unintended pregnancies, they would be less motivated to undergo the extra effort and expense to use condoms. Second, situational differences in one's routine may exist between the adherence-independent contraceptive methods and the adherence-dependent methods, including both barriers and OCs. Those who are sterilized or who are using implantable or injectable hormones or IUDs do not have the coitally based requirements of barriers or the daily schedules of OCs to help keep them continually aware of, and prepared for, prophylactic needs. Without regular reminders of the need to protect against both pregnancy and STDs, individuals may be less likely to have condoms available when sexual opportunities arise.

A recent creative approach to the use of dual methods is based on the availability of emergency contraception (EC), which describes contraceptive methods that people can use after intercourse to prevent pregnancy.[198] Common methods of EC include using levonorgestrel (progestin-only) pills or a heightened dose of combined OCs. While EC in itself provides no protection against HIV or other STDs, making EC more widely available as a backup to barrier contraception may cause more couples to choose (and use) barriers as a *dual-purpose* method.[199] This dual-purpose approach, namely using condoms to protect against both unplanned pregnancies and STDs/HIV, needs to be investigated through operational research designs. To the extent that the availability of EC increases overall barrier-method use, it would have a positive impact on the overall level of STDs/HIV within the community.

More research is clearly needed on the best mix of contraceptives. Studies that examine the use of the female condom or the diaphragm, in conjunction with long-term methods will help clarify this issue. In addition, the patterns of dual-method use with different sex partners need to be evaluated. For example, if an individual uses one method with one partner and adds condoms with other partners, this might reduce the risk, even if the dual-method use is not consistent with the primary partner.

SERVICE INTEGRATION

The 1994 International Conference on Population and Development's Programme of Action highlighted the need for integrated reproductive-health services.[24] However, most publicly supported family planning, maternal/child health, and STD clinics were begun as independent entities rather than one integrated reproductive-health unit. In contrast, the women being served by these clinics frequently had overlapping health needs.[14] For example, in family planning clinics in developed countries, risk assessment surveys have found that approximately one-quarter of women report behaviors that put them at increased risk for HIV and the other STDs.[200] In STD clinics, up to half of the sexually active women of reproductive age report using no method of contraception,[201] despite most having histories of both STDs and unintended pregnancies.

In developing countries, the need for integrated care is even more acute. Since so few facilities are available for healthcare, they should not be fragmented.[14,202] Moreover, because access to health services is usually more cumbersome and time consuming in resource-poor settings, when patients make the effort to obtain one particular "categorical" service, the full range of clinical preventive care should be offered.

These overlapping needs have provided those interested in STD/HIV and family planning with a unique opportunity to deliver more broad-based reproductive healthcare. In the United States, this collaboration was initiated in the early 1970s, when family planning clinics became crucial allies for the federal gonorrhea control program.[203] In the 1980s, half of all women receiving family planning services were simultaneously screened for STD, primarily gonorrhea; this screening appropriately targeted those women who had the highest infection risks.[15] Moreover, efforts to screen for chlamydia in family planning settings have also been productive, especially when selective criteria are applied, such as age less than 24 years, more than one sex partner in the past 2 months, or signs of cervical infection.[204,205] The most successful of these has been the Region X chlamydia screening program, which led to a regional reduction in the prevalence of chlamydia.[206] The extension of STD services in family planning clinics has had its costs, however,[17] because the proportion of time and resources available for contraceptive care decreased.

In a reciprocal manner, some STD clinics increasingly have been providing rudimentary contraceptive services, especially barrier methods. Recent concerns with incurable viral STDs, especially HIV, have provided the necessary social environment and financial resources both to emphasize condom use during client-counseling sessions and to increase advertising of condoms in the media. The development of women-controlled mechanical or chemical barrier contraceptives may be of further value in reducing STD risks.[207,208] For this reason, diaphragms (which protect only the cervical os), female condoms, and eventually microbicides may play a wider role in upcoming efforts to prevent STDs/HIV.

The urgency of the HIV pandemic has hastened the need to integrate STDs and family planning services.[24] In the developing world, where heterosexual transmission predominates, family planning and maternal/child health facilities have increased their HIV/STD roles.[209] Agencies have begun both to counsel women on how to reduce their risks and also to provide services to diagnose and treat those STDs that themselves may further facilitate acquisition/transmission of HIV.[210] A strong case may also be made for the integration of family planning services into MTCT prevention programs.[211] The experience of integrating family planning services into VCT programs in Haiti and Rwanda has resulted in an increase in family planning users,[150,212] and a reduction in contraceptive discontinuation and the annual pregnancy rate among HIV-infected women.[150,211]

Client and service providers' knowledge of an individual's HIV status is becoming increasingly important in the provision of high-quality contraceptive services. Thus if the client's HIV status is known, more specific counseling is warranted. For uninfected women, culturally sensitive messages regarding ways to protect themselves from STD/HIV exposure are essential. For HIV-infected women, family planning choices involve complex personal, ethical, and policy issues. Providers need to ensure the woman's right to determine her reproductive future, improve her quality and duration of life, decrease the risk of perinatal HIV transmission, and decrease the risk of further HIV transmission within the community.[211]

CONCLUSION

Because contraception affects not only the risk of unplanned pregnancies but also that of STIs, the choice of particular methods is important to future fertility. Important trade-offs exist, however. Contraceptives with the best record of preventing pregnancy provide little protection against STDs and can, in some instances, even increase the risk of some genital tract infections. The provision of highly effective contraception to HIV-infected women wishing to avoid or delay pregnancy is an important and underused strategy in the prevention of

mother-to-child HIV transmission. While most forms of highly effective contraception appear appropriate for HIV-infected women receiving medical follow-up, more research related to contraception method use, HIV disease progression and possible interactions with the use of ART is warranted. Finally, epidemiologic studies are equivocal regarding the value of either recommending dual methods of contraception or relying on the condom alone to prevent both unplanned pregnancies and STDs. Continued biologic and behavioral research will be necessary to untangle these complex relationships.

79 Sexually Transmitted Diseases and Infertility

Harold C. Wiesenfeld and Willard Cates, Jr.

Sexually transmitted diseases (STDs) affect human fertility primarily through infections of the female upper genital tract and their sequelae. Except for the rare bilateral epididymitis and obstruction of the male epididymis or vas deferens, STDs produce infertility in men less frequently. Therefore, this chapter will focus on infertility resulting from sexually acquired infections that ascend to produce endometritis and salpingitis. Acute pelvic inflammatory disease (PID) has long been recognized as an important cause of tubal factor infertility, ectopic pregnancy, and chronic pelvic pain.[1] Despite this well-known relationship, there is a growing body of the literature suggesting that the greatest burden of postinfectious tubal infertility results from PID that is unrecognized by the patient and her physician. In this chapter, we will outline the historical evidence linking subclinical PID with adverse reproductive outcomes. Associations between lower genital tract infections and subclinical PID will be explored and the reproductive outcomes of women with acute and subclinical PID will be discussed.

DEFINITIONS

Infertility is typically defined as the inability to conceive after 1 year of regular intercourse without the use of contraception.[2] In the general population, the conception rate is 10–15% per cycle (Fig. 79-1), whereas in couples who have been infertile for 1 year, it is 5–6% per cycle. Approximately 10–15% of couples meet the clinical definition of infertility. Tubal infertility refers to infertility caused by damaged fallopian tubes. These fallopian tubes may be either blocked due to adhesions involving the external surfaces of the tubes, as in women with previous pelvic surgery or salpingitis, by distortion of the fallopian tube affecting tubal motility, as seen in women with pelvic adhesions or endometriosis, or due to blockage of the tubal canal due to salpingitis or congenital causes. We will address infertility only as it relates to salpingitis.

Salpingitis is an inflammation of the epithelial surfaces of the fallopian tubes caused by active infection with one or more of a number of organisms, of which most are either sexually transmitted or are components of vaginal microflora. These organisms ascend along mucosal surfaces from the cervix to the endometrium to the fallopian tubes and, in some women, to the peritoneum.[3] Acute PID is used to describe the symptoms and signs clinically associated with acute salpingitis, including patient report of pelvic pain and the finding of tenderness of pelvic organs on bimanual examination. Clinical criteria for the diagnosis of acute PID are inaccurate. Only about two-thirds of patients with a clinical diagnosis of PID actually have visual evidence of acute salpingitis by laparoscopy.[4] Further, as will be described in detail below, many women with upper genital tract inflammation experience an asymptomatic or minimally symptomatic infection. In this chapter, we will use the term subclinical PID to describe the condition of upper genital tract inflammation in women who fail to meet the classic criteria for acute PID.

HISTORY

An association between gonorrhea, PID, and tubal infertility was first reported in the preantibiotic era.[5,6] Upper genital tract infection, especially severe tubo-ovarian abscess, was a feared consequence of gonococcal infection and rates of postgonococcal tubal obstruction of up to 70% were reported.[7] With the advent and use of sulfonamides and penicillin in the 1940s, both lower- and upper-genital tract infection caused by gonococci could be treated more effectively and their sequelae were reduced.

The classic cohort studies of Westrom and colleagues in Lund, Sweden in the 1960s demonstrated the impact of STD and salpingitis on subsequent tubal infertility.[1,8,9] These studies contributed data on such crucial topics as

1. the clinical difference between PID and salpingitis;
2. the importance of chlamydia (in addition to gonorrhea) as a cause of tubal infertility;
3. the effects of different risk factors on fertility;

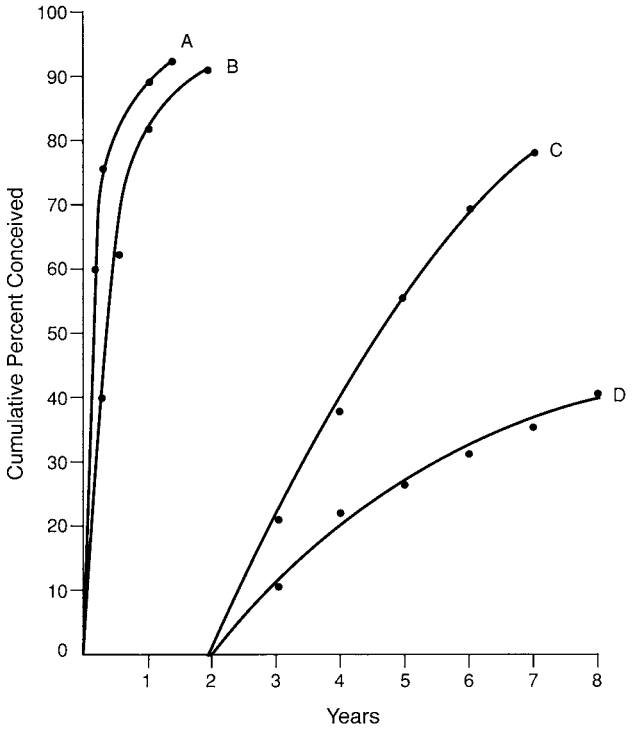

FIGURE 79-1. The conception rates of a normal population of parous, **A.,** and nulliparous, **B.,** women are compared with the cumulative conception rates of apparently normal women with secondary infertility, **C.,** and primary infertility **D.** No conceptions occurred before the 2- to 3-year interval in the infertile groups, as this was part of the selection criteria for these patients. From Lenton EA, et al.: Long-term follow-up of the apparently normal couple with a complaint of infertility. *Fertil Steril* 1977; 28: 913. Used with permission in STD 3rd Edition.

4. the effects of different antibiotic regimens used for treatment of acute PID on fertility;
5. the impact of PID severity on fertility outcome; and
6. the importance of timely therapy to preserve fertility.

During the 1970s, the polymicrobial etiology of PID, and especially the role of *Chlamydia trachomatis,* became increasingly appreciated.[10,11] The influence of contraceptives on both PID and tubal factor infertility has become clearer (Chapter 78). Intrauterine devices, especially the Dalkon Shield®, appeared to increase the risk of PID and infertility, whereas more modern IUDs do not substantially increase the risk of PID aside from the brief period around insertion.[12] Further, barrier methods, both mechanical and chemical, appear to be protective.[13–15] Finally, an increased understanding of the role of subclinical PID as a prelude to tubal obstruction has emerged from recent studies.[16]

DEMOGRAPHIC EFFECTS OF STD-RELATED INFERTILITY

In areas of the world where *Neisseria gonorrhoeae* and *C. trachomatis* infection are common, tubal infertility is also more frequent.[17,18] Particularly, strong data link the epidemiology of gonococcal infection with infertility. For instance, in

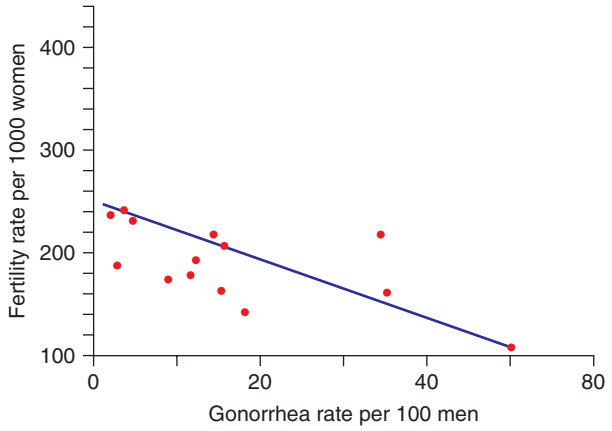

FIGURE 79-2. Correlation between the annual reported incidence of gonococcal urethritis in men and the general fertility rate, Uganda health districts, 1960s. (Data from Griffith HB: Gonorrhea and fertility in Uganda. *Eugen Rev* 1963; 55: 103.)

Uganda, 15 districts recorded a significant inverse correlation between the annual reported incidence of gonococcal urethritis in men and the general fertility rate (Fig. 79-2).[19] A subsequent population-based study conducted in two rural districts of Uganda demonstrated that the rate of gonococcal infections in females and males was inversely related to the general fertility rates in the population, even after controlling for the effects of maternal nutrition and malaria.[20,21]

To explore the potential relation between gonococcal and chlamydial infections and human population growth, mathematical models have been developed that combine epidemiologic and demographic data.[22,23] These models predict that in areas where untreated gonococcal and chlamydial infections are prevalent, STD-related infertility has a major impact on fertility and, concomitantly, on net population growth. Gonococcal infection was predicted to exert a greater demographic impact than chlamydial infection because of its greater incidence and higher prevalence of postinfection infertility.[24] Specifically, the models concluded that a 10% prevalence of gonorrhea in sexually active adults would result in a 25% reduction in net population growth; a 10% prevalence of chlamydia in sexually active adults would result in a 10% reduction in net population growth.[22,23] Because demographers have raised valid questions regarding the assumptions underlying the mathematical models, additional demographic research into the recent expansion of world population is needed.[24]

Further information on the association between STDs and infertility derived from the WHO-sponsored investigation on infertility that evaluated infertile couples from 33 countries from the developed and developing world.[25] This monumental effort enrolled participants from 1979 to 1984 and utilized a standardized approach to the evaluation of infertility and completed the infertility investigation for over 5800 couples. Self-reported frequency of a history of STDs was more common in couples from Africa than in couples

from developed and other developing regions (Asia, Latin America, and Eastern Mediterranean). The great majority of African women suffered from infertility that was most attributable to prior infection, whereas prior infection was deemed responsible for infertility in only a minority of women from the other regions (both developed and developing). These results are likely explained by the high prevalence of *N. gonorrhoeae* and *C. trachomatis* infections in African populations. Thus, STD-related infertility may be a major and underrecognized demographic factor affecting the rate at which populations expand.

PREVALENCE OF TUBAL INFERTILITY

The prevalence of infertility can be assessed by measuring the absence of recent pregnancies in noncontracepting sexually active couples.[26] Using these definitions, rates of infertility have ranged from 1% to 16% of couples, with considerable regional variation.[27] When the denominator is confined to women who have actually attempted to become pregnant, about one in four had experienced infertility for at least 1 year and about 4% had never achieved a pregnancy.[28–30]

The presence of tubal damage can be identified only in women who undergo gynecologic evaluation by a specialist. In the United States, couples in the middle to upper classes are more likely to seek such evaluation.[31] Because STD and salpingitis occur less frequently in these populations, the prevalence of tubal infertility is probably underestimated. In Bristol, England, where medical care is less subject to this bias, an average of 1.2 couples per 1000 population annually requested infertility advice from a specialist.[32] At this rate, approximately one in six couples (with an average length of infertility of 2.5 years) would seek help from a specialist at some time in their lives. Tubal damage was demonstrated in 14% of these infertile couples. In a representative Denmark population, nearly half of infertile couples had sought infertility services. One in five were diagnosed with tubal infertility, with older women (age >35 years) having higher rates.[28]

Internationally, the WHO multicenter study compared STD-related infertility in five different regions of the world.[25,33] More than 8000 infertile couples were enrolled in the study and more than 6000 (71%) completed evaluation of the fallopian tubes. Almost two-thirds of infertility in African women was attributed to infection, including 49% with bilateral tubal occlusion and 24% with pelvic adhesions (Table 79-1). The prevalence of tubal occlusion in Africa was more than three times that of any other region. Developed countries had an 11% prevalence of tubal occlusion in infertile women. Non-African developing areas had higher rates of tubal occlusion than developed countries, although well below those of Africa. Across various regions worldwide, the burden of female infertility due to infection is considerable. In studies in Israel, Australia, and India, tubal damage, often attributed to prior salpingitis, has been documented to be present in one in five women with infertility.[34–36] In cohorts of infertile couples in Western Siberia and Mongolia, tubal damage was present in one-third of women and was the most frequent cause of female infertility.[37,38]

Table 79-1. Cause of Female Infertility, by Region

Categories	Percent of Cases Associated with Each Cause			
	Developed Country	Africa	Asia	Latin America
No demonstrable cause	40	16	31	35
Bilateral tubal occlusion	11	49	14	15
Pelvic adhesions	13	24	13	17
Acquired tubal abnormalities	12	12	12	12
Anovulatory regular cycles	10	14	9	9
Anovulatory oligomenorrhea[a]	9	3	7	9
Ovulatory oligomenorrhea	7	4	11	5
Hyperprolactinemia	7	5	7	8
Endometriosis	6	1	10	3
Total[b]	115	128	114	113

[a]Includes amenorrhea.

[b]Total greater than 100 percent due to the presence of more than one factor in some women.

Adapted from Arya OP, Nsanzumuhire H, Taber SR. Clinical, cultural, and demographic aspects of gonorrhoea in a rural community in Uganda. *Bull World Health Organ* 1973; 49(6): 587–595.

Another approach to estimating the prevalence of tubal infertility utilizes extrapolation from the annual reported incidence of STDs. For example, approximately 2.8 million cases of chlamydia and over 700,000 cases of gonorrhea are estimated to occur each year in the United States.[39] More than half of these infections occur in young people under the age of 25 years, those with many years of future reproductive potential. Assuming 30% of these cause salpingitis, and that 17% of salpingitis lead to tubal occlusion, an estimated annual incidence of 125,000 cases of STD-related infertility occurs each year in the United States.[40–42] Converting these to cumulative numbers, we estimate that approximately 2 million reproductive-age women (range 200,000–2.7 million) currently have tubal occlusion in the United States. However, only about one-half may desire more children and a smaller percentage will seek infertility services.[43]

Although the preceding estimates are crude, they are internally consistent with the annually reported number of STDs, the number of ambulatory and hospitalized cases of

PID, the number of infertility visits to private clinicians' offices, and the cross-sectional number of self-reported cases of PID and infertility in the American population of reproductive-age women.

ACUTE PELVIC INFLAMMATORY DISEASE AND INFERTILITY

Acute PID has long been associated with fallopian tube damage and subsequent infertility. The greatest body of knowledge concerning PID-related infertility stems from the longitudinal cohort study of women with acute PID in Lund, Sweden.[1] This study documents the long-term reproductive outcomes of 1844 women with laparoscopically diagnosed acute PID. Overall, approximately 11% of women with laparoscopically confirmed acute PID subsequently became infertile due to occluded fallopian tubes, compared to none of the women without PID. Among a cohort of 28 Finnish women with laparoscopic-proven acute PID who were subsequently attempting to conceive, Heinonen and Leinonen documented an infertility rate of 10.7%.[44] Less robust data from American cohorts support the association between PID and infertility. Using the National Survey of Family Growth, Cycle III, infertility was observed in twice as many women with a self-report of PID than in women without PID (44% compared to 21%).[45] Another US-based study described an infertility rate of 35% following the diagnosis of acute PID.[46]

What has also become evident from the Swedish and other studies is that there are a number of factors that predict outcomes (Table 79-2). First, the greater the number of episodes of acute PID that a woman experiences, the greater the risk of subsequent infertility. The infertility rate following one episode of acute PID was 8%, while a second and third episode of acute PID exponentially increased the subsequent rates of infertility to 19.5% and 40% respectively.[1] Second, the severity of inflammation directly correlated with subsequent infertility. Those women with severe cases of acute PID had a 21% rate of infertility, while 6.2% of those with moderate infertility suffered from infertility. However, the rate of infertility in women with mild cases of acute PID was only 0.6%. A later analysis of the Lund data demonstrated that earlier treatment is associated with improved reproductive outcomes. Women treated for PID within 2 days of onset of symptoms were 2.6 times less likely to develop infertility compared to women treated later in the course of PID (8.3% vs. 19.2%)[47] Taken together these data, which demonstrate improved reproductive outcomes in women with less frequent, milder PID and in those treated earlier in the course of infection, indicate that fertility is optimized with earlier recognition and treatment of PID.

Table 79-2. Rate of Tubal Infertility Among Women Trying to Conceive, by Age, Number of PID Episodes, and Severity of PID—Lund, Sweden, 1960–1984

Number of PID Episodes	Age <25	Age ≥25	Total
One	7.7	9.1	8.0
Mild	0.8	0.0	0.6
Moderate	6.4	5.6	6.2
Severe	20.1	25.0	21.2
Two	18.4	25.9	19.5
Three or more	37.7	75.0	40.0
Total	11.2	12.0	11.4

PATHOGENESIS OF PID-ASSOCIATED TUBAL INFERTILITY

NEISSERIA GONORRHOEAE

Unraveling the complex etiologic relationships between STDs, PID, and infertility is complex and largely remains unknown. The paradigm of STDs leading to infertility is demonstrated in Fig. 79-3. The antecedent condition is the presence of microbial pathogens in the lower genital tract that commences the pathogenic chain of events culminating in microbe-influenced inflammation and damage of the fallopian tubes. As noted earlier, clinical features of acute PID relate to the risk of developing infertility, including previous episodes of salpingitis, severity of illness, and timeliness of treatment.[1,47] Not all women diagnosed with PID will suffer impaired fertility, and the protective elements and factors causing damage on the cellular or tissue level remain to be fully characterized.

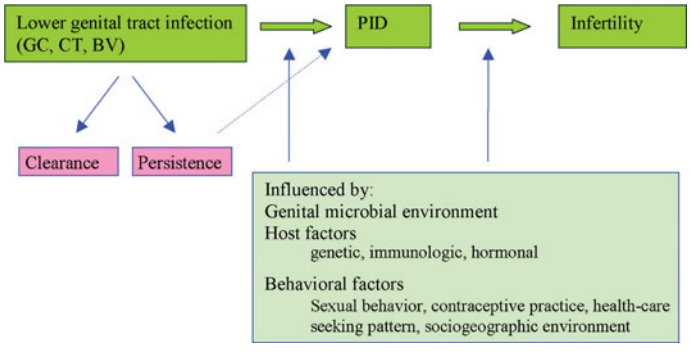

FIGURE 79-3. Relationships among STDs, PID, and tubal infertility.

The ciliated epithelial cells of the fallopian tube function to transport the ovum to the ampullary portion of the fallopian tube for fertilization and then transport the fertilized ovum to the uterus for implantation. Damage to the delicate cilia of these tubal epithelial cells impairs tubal transport, resulting in infertility or ectopic pregnancy formation. In the fallopian tube, *N. gonorrhoeae* initiates its attack by attaching to the nonciliated mucosal cells but its dominant impact on tubal damage is by sloughing of ciliated mucosal cells.[48] This epithelial damage may be toxin-mediated, as sterilized supernatant from gonococcal infection results in fallopian tube damage similar to direct infection with the gonococcus.[49] In a fallopian tube organ model, experimental challenge with *N. gonorrhoeae* induced expression of the proinflammatory cytokines IL-1ά, IL-1ß, and TNF-ά.[50] TNF-ά appears to play an important role in mediating mucosal damage from *N. gonorrhoeae* infection.[51] TNF-ά induces apoptosis of fallopian tube epithelial cells, which may represent a host defense protecting against tubal damage The gonococcus appears to be able to modulate and inhibit TNF-ά mediated damage and possibly permit ongoing infection.[52] Lipopolysaccharide (LPS) expressed on the surface of gonococci can be toxic to epithelial cells but its role in salpingitis is largely unknown.[53] Other characteristics of *N. gonorrhoeae,* including transparent colony phenotype and serotype have been associated with salpingitis.[54,55]

CHLAMYDIA TRACHOMATIS

Seroepidemiologic study of women with tubal infertility has shown that women with *C. trachomatis*-associated infertility have antibody to a distinctive chlamydial antigen of 57,000 Daltons molecular mass.[56] Molecular study showed that this antigen was a highly conserved heat shock protein 60 (Hsp-60) whose homologs are widely found in both bacterial and eucaryotic cells.[57] Hsp-60 has been shown to be a potent T-cell antigen capable of eliciting an intense inflammatory response when applied to the mucosal surfaces of the fallopian tube of immunologically primed animals.[58,59] These characteristics are highly suggestive of the hypothesized chlamydial hypersensitivity antigen implicated in chlamydial immunopathology and tissue fibrosis.[60]

Chlamydial Hsp-60 antibodies are associated with acute PID and correlate with severity of infection and tissue damage. In a cohort of women with laparoscopically confirmed PID by Eckert et al., chlamydial Hsp-60 antibodies were found in the sera of 80% of women with occluded fallopian tubes and in only 19% of women with patent tubes ($p < 0.001$).[61] Further, higher titres have been observed in women diagnosed with PID who have severe pelvic adhesive disease and perihepatitis.[62] As there is considerable homology between human and chlamydial Hsp-60, an autoimmune response may occur during chlamydial PID, whereby chlamydial Hsp-60 antibodies cross-react and target fallopian tube mucosa, causing damage and scarring.[63]

The host's inflammatory response to *C. trachomatis* salpingitis plays an essential role in resultant tubal damage.[64,65] A T-helper (Th-1) cytokine response is seen following experimental chlamydial salpingitis.[65] And while IFN-γ demonstrates chlamydial killing and clearance in experimental models, IFN-γ can promote fibrosis[66–68] A Th-2 response is also observed during chlamydial infection, with higher levels of IL-10 secretion observed from chlamydia Hsp-60-stimulated peripheral blood mononuclear cells obtained from women with tubal factor infertility than from women infertile from other reasons.[69] Whether the antiinflammatory cytokine response suppresses host clearance and allows for persistent infection is unclear.

The exponential increase in tubal damage and infertility following repeated episodes of PID as demonstrated in the Swedish cohort (see above) lend support to the importance of an immunologic basis for tubal damage.[1] In the animal model employing the pig-tailed macaque, Patton et al. demonstrated that a single inoculation with *C. trachomatis* causes a self-limited infection of the lower genital tract.[70] Repeated inoculation in this animal model results in fallopian tube obstruction. In another monkey model study, development of peritubal adhesions was related to increased number of cervical inoculations with *C. trachomatis.*[71] Similar fibrosis is observed in the macaque subcutaneous salpingeal pocket model after repeated chlamydial infections.[65] Experience in humans corroborates animal data suggesting that repeated *C. trachomatis* infections cause considerably greater damage to the fallopian tubes than single infections.

RECENT TRENDS ON SEVERITY OF PELVIC INFLAMMATORY DISEASE

Between 1979 and 1988, hospitalizations for acute PID in the United States decreased by 36%, and in the subsequent decade from 1990 to 2000, the number of such hospitalizations further dropped by approximately one-half.[72,73] The same findings were seen in an analysis of hospitalizations for acute PID in Norway, where a 35% reduction in hospitalized cases of acute PID was observed comparing two time periods separated by 10 years (1990–1992 and 2000–2002).[74] Provider behavior was likely not a factor in this decline in rates of inpatient treatment of acute PID, as there were no changes in policy regarding admission criteria for acute PID. Despite this observed decline in hospitalization for acute PID, the number of ambulatory visits to physicians' offices for PID remained stable over the same period. While practice patterns have changed in recent years, focusing on ambulatory treatment to reduce medical costs, it is likely that the decline in hospitalization rates for acute PID reflects the evolving trends in the microbiologic etiology of PID in

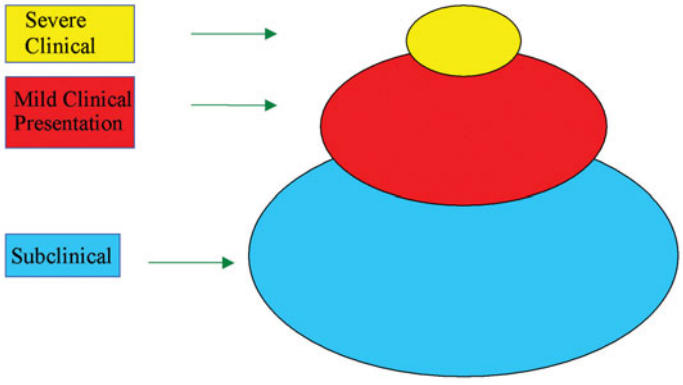

FIGURE 79-4. Spectrum of clinical presentation of pelvic inflammatory disease (PID).

many populations. Specifically, the recent decline in the rate of *N. gonorrhoeae* in the United States, which has not been observed with the prevalence of *C. trachomatis* infection, may have resulted in fewer cases of PID associated with gonorrhea and a relative increased proportion of cases associated with chlamydia. As PID involving *N. gonorrhoeae* istypically a more clinically severe condition than PID caused by *C. trachomatis,* decreased hospitalizations for acute disease would be expected if most cases of PID are nongonococcal in etiology. As the trends in clinical presentations of PID are evolving toward less severe clinical presentations, much attention is focused on milder forms of pelvic infection, recognizing that atypical, silent, or clinically unrecognized cases of PID are commonplace. Despite the absence of clinical evidence of an acute inflammatory response, these cases of subclinical or silent PID are believed to be associated with reproductive health risks. The new paradigm of PID reflects the shifting spectrum of clinical presentations from acute, symptomatic illness to subclinical disease (Fig. 79-4).

EVIDENCE LINKING INFERTILITY WITH PRIOR EPISODES OF SUBCLINICAL PELVIC INFLAMMATORY DISEASE

The body of the literature linking subclinical PID with infertility has largely involved retrospective analyses, given the challenges in arriving at the diagnosis at the time of occurrence. Tubal factor infertility ranks among the most common causes of infertility in women worldwide. Many of these women do not have an obvious current explanation for fallopian tube damage such as endometriosis or post surgical adhesive disease. While PID can cause tubal damage and subsequent infertility, many women with otherwise unexplained tubal factor infertility do not report a history of acute PID (Figs. 79-5 and 79-6). Investigations of these women have examined serologic evidence of remote infection in women with fallopian tube damage and have implicated subclinical PID as a possible cause of tubal obstruction.

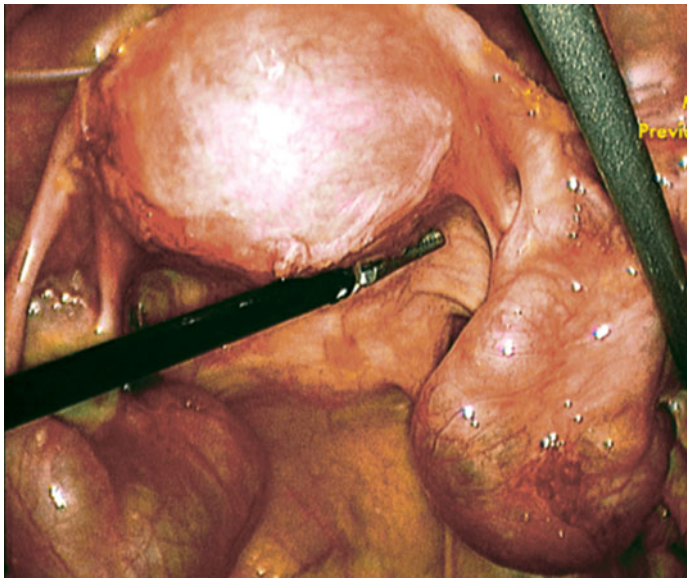

FIGURE 79-5. Laparoscopic view of the pelvis of a 28-year-old infertile woman with a prior history of gonorrhea but denied a history of acute PID. Both fallopian tubes are obstructed and dilated.

SEROLOGIC EVIDENCE OF PRIOR CHLAMYDIAL INFECTION IN WOMEN WITH INFERTILITY

A number of studies among women from various communities worldwide have examined sera from women with tubal damage to determine the prevalence of antibodies to *C. trachomatis.* Moore et al. tested sera from infertile women for *C. trachomatis* antibody by micro-immunofluorescence.[75] Distal occlusion of the fallopian tubes was evident by laparoscopy in 33 infertile women. Twenty-four (73%) of these women were seropositive for *C. trachomatis* antibodies, compared to 0/35 infertile women without tubal disease. In the Netherlands, Tjiam performed a similar study of 53 women who were infertile for at least 18 months. All subjects had undergone an evaluation that included documentation of fallopian tube patency by hysterosalpingography (HSG) and laparoscopy.[76] Among women with tubal factor infertility, antibodies to *C. trachomatis* were detected in 7 (21.2%) of 33, whereas none of the 20 infertile women without tubal disease tested positive for chlamydial antibodies. In a U.S. cohort of 218 infertile women who underwent HSG and laparoscopy, Meikle et al. reported that *C. trachomatis* antibodies were present in the sera of 68 (78%) of 87 women with tubal disease, whereas only 36% of infertile women without tubal disease had antichlamydial antibodies.[77] Another U.S.-based study of 210 infertile patients examined the association between antichlamydial antibodies and fallopian tube damage.[78] Only 9% of this cohort reported a prior history of chlamydial infection or PID, yet 40% were seropositive for *C. trachomatis.* Among those women undergoing laparoscopy, all 43 (100%) with high titres of *C. trachomatis* IgG antibodies had tubal disease, compared to 19 (30%) of 63 seronegative women ($p < 0.001$).

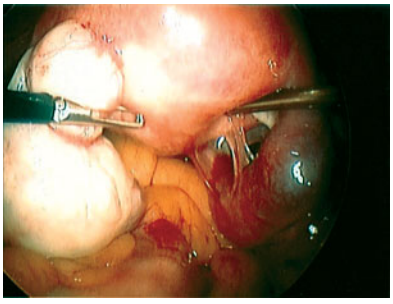

FIGURE 79-6. Laparoscopic view of the pelvis of a 23-year-old woman with an ectopic pregnancy in the right fallopian tube. The right fallopian tube is distended by the ectopic gestation. Adhesions are readily evident. This patient had a prior history of chlamydia but no history of PID.

Bilateral tubal blockage was 3 times more common in women with high titres compared to seronegative women. Similar results were found by the WHO's Task Force on the Prevention and Management of Infertility multicenter case-control study of women reporting at least 12 months of infertility performed in Thailand, Slovenia, and Hungary. Antichlamydial antibodies (using an enzyme-linked immunosorbent assay) were present in 32 (71%) of 45 women with bilateral tubal occlusion detected either by HSG or laparoscopy, compared to this finding in 31 (32%) of 96 women with other etiologies for infertility.[18] Rather than comparisons to women with other etiologies of infertility, some studies have used cohorts of fertile women as the comparison group to evaluate seroprevalence. Sellors et al. compared the seroprevalence of antibodies to *C. trachomatis* (measured by enzyme immunoassay) of women with tubal factor infertility to the rates in two control cohorts, women undergoing tubal sterilization, and women undergoing hysterectomy.[79] The seroprevalence of *C. trachomatis* in the two fertile control groups was 34%. In contrast, three of four women (32/43, 74.7%) with tubal factor infertility had serologic evidence of prior infection with *C. trachomatis.* The authors concluded that women with evidence of prior chlamydial infection are approximately 6 times more likely to develop tubal factor infertility than women without prior infection. Results from numerous other investigations add considerably to the findings of an association of tubal factor infertility with *C. trachomatis* antibodies (Table 79-3).

SEROLOGIC EVIDENCE OF PRIOR GONOCOCCAL INFECTION IN WOMEN WITH INFERTILITY

Gonococcal PID is also an important cause of fallopian tube damage. While fewer data are available linking serologic evidence of past *N. gonorrhoeae* infection and tubal factor infertility than with *C. trachomatis* in cohorts of women without a history of PID, the data are noteworthy for their consistency (Table 79-4). Tjiam et al. measured antibodies to *N. gonorrhoeae* pili antigens by ELISA in a Dutch cohort of infertile women who underwent HSG and laparoscopy to determine fallopian tube status.[76] Antigonococcal antibodies, indicating remote infection with *N. gonorrhoeae,* were identified in 20 (60.6%) of 38 women with fallopian tube damage and in only 5 (25%) of 20 infertile women with normal fallopian tubes. In the WHO study mentioned earlier, antibodies to the pili of *N. gonorrhoeae* were present in 28 (62.2%) of 45 infertile women with bilateral tubal occlusion compared to 36 (37.5%) of 96 women with other etiologies of infertility and without tubal occlusion (p <0.01).[18] Miettinen et al. did not identify prior gonococcal infection in any infertile women without fallopian tube damage, yet serologic evidence of past gonococcal infection was found in 14% of women with infertility and fallopian tube abnormalities.[80] Finally, among a cohort of 172 women in Thailand, serum antibodies to the alpha pili of *N. gonorrhoeae* were more commonly seen among infertile women with tubal damage, as assessed by laparoscopy, than among infertile women with normal fallopian tubes and fertile controls.[81] Robertson et al., however, found no such relationship between serologic evidence of prior *N. gonorrhoeae* infection and infertility.[82]

SEROLOGIC EVIDENCE OF PRIOR STDS IN WOMEN WITH ECTOPIC PREGNANCY

While tubal factor infertility is the most common complication of PID, another important late sequela is ectopic pregnancy. A number of studies have outlined the relationship between previous infection with *C. trachomatis* and ectopic pregnancy (Table 79-5). In 1983, Gump and colleagues examined 204 infertile women for an association between *C. trachomatis* and infertility.[83] Eleven (14%) of the 76 women who subsequently became pregnant were diagnosed with an ectopic pregnancy. Prior history of chlamydial infection was far more common in the ectopic pregnancy group. Among women diagnosed with an ectopic pregnancy, the prevalence of antichlamydial antibodies was 82% (9/11), while only 29% (19/65) of women with an intrauterine pregnancy were seropositive for *C. trachomatis.* Svensson and associates reported a case control study of 112 women with ectopic pregnancies. One-half were determined to have prior episode(s) of PID based on operative findings of the presence of tubal adhesions. Sixty-five percent (73/112) of women with ectopic pregnancies were seropositive for antichlamydial antibodies, statistically greater than the rate of 21% seen in the control group of pregnant women (p <0.001).[84] Brunham et al. divided a cohort of 50 women with ectopic pregnancy into two groups according to the presence or absence of ectopic pregnancy risk factors (tubal ligation or intrauterine contraceptive device) and compared these two groups to a group of 49 women with an intrauterine pregnancy.[85] Serologic evidence of prior *C. trachomatis* infection was present in 18% of women with known risk factors for

ectopic pregnancy and 22% of women with intrauterine pregnancy. Thirty-two women with ectopic pregnancy in this cohort had no identifiable risk factor for ectopic pregnancy (they did not use an intrauterine contraceptive device and did not previously undergo a tubal ligation) and 56% of these women were positive for *C. trachomatis* antibodies. Many in this group of women who lacked known risk factors for ectopic pregnancy were believed to have previously experienced subclinical infection of the fallopian tubes. While most investigations examining the relationship between chlamydia and ectopic pregnancy used pregnant women as their control groups, other researchers

have classified women with ectopic pregnancies into groups with and without prior PID based on the gross appearance of the fallopian tubes at the time of surgery. For example, adhesions of the contralateral fallopian tube in women with ectopic pregnancy would be suggestive of remote pelvic infection. In a study of women undergoing laparotomy as treatment for ectopic pregnancies, Hartford et al. demonstrated that antichlamydial antibodies were present in 50% (5/10) of women with damage of the contralateral fallopian tube compared to 0% (0/14) of women with normal-appearing contralateral tubes.[86] Sheffield et al. similarly reported nearly a doubling of prevalence rate of antichlamydial antibodies among women with ectopic pregnancies who had damage of the contralateral fallopian tube compared to women with ectopic pregnancies and normal tubes.[87]

A recent population-based study from Norway linked women with a hospital discharge or outpatient diagnosis of ectopic pregnancy with a county database containing information on prior *C. trachomatis* testing.[88] Among women aged 20–34, prior *C. trachomatis* infection was associated with a twofold increase in risk for ectopic pregnancy. Such a relationship was not observed in a Danish population-based study.[89] The Norwegian study further suggested a dose-response relationship with the number of prior chlamydial infections.[88] Similarly, Hillis and colleagues, examining data from a chlamydia prevention program and hospital discharges in Wisconsin USA, found that recurrent chlamydial infections increase the risk of hospitalization for ectopic pregnancy.[90] Compared to women with a history of one reported chlamydial infection, those with two and three or more reported infections were 4 times and 11 times as likely to be diagnosed with an ectopic pregnancy. Overall, retrospective and population-based studies support an association between *C. trachomatis* infection and ectopic pregnancy formation.

The association between prior genital infection with *N. gonorrhoeae* and ectopic pregnancy has also been recognized, albeit the data is less extensive. Robertson detected antibodies to gonococcal pili in 16 (32%) of 50 women with ectopic pregnancy, while only 2 (4%) of 50 fertile women with intrauterine pregnancies had serologic evidence of prior gonococcal infection ($p < 0.001$).[91] Similarly Ville et al. demonstrated that in a cohort from Gabon, gonococcal pili antibodies were evident twice as often (49% vs. 23%) in women with ectopic pregnancy than in pregnant women.[92]

PERSISTENT UPPER GENITAL TRACT INFECTION

Evidence that pathogens can infect the upper genital tract in the absence of classic signs or symptoms of acute PID would add substantially to the argument that many cases of PID are clinically subtle or silent. A number of studies have revealed that PID-type pathogens can be recovered from the upper genital tract in women in the absence of symptoms of acute PID. Among the earliest observations was a report by Henry-Suchet in 1980 describing the isolation of *C. trachomatis* from the abdomen in 6 of 23 infertile women without pain or other evidence of acute pelvic infection.[93] A larger study further expanded on this preliminary series, documenting that in women undergoing laparoscopy for infertility, a large proportion had evidence of upper genital tract infection.[94] Among these women without clinical evidence of acute PID, *C. trachomatis* was recovered from the abdominal cavity from 23.3% of women with tubal damage and laparoscopic evidence of chronic inflammation. The chlamydial isolation rate among women with tubal damage but without inflammation was 15.4%, while only 2% of women without tubal damage had evidence of chlamydial infection. Sweet and colleagues' study of women with acute PID added to the evidence that *C. trachomatis* can persist in the upper genital tract in the absence of symptoms.[95] Despite clinical resolution of symptoms, endometrial cultures following treatment were positive for *C. trachomatis* in 12 of 13 women treated with a cephalosporin agent, which does not have activity against this pathogen. These early findings suggest two important features about PID: first, the need for antichlamydial therapy for acute PID, and second that *C. trachomatis* infection of the upper genital tract can occur in

the absence of symptoms of acute PID. In an elegant study of fallopian tube specimens from women with laparoscopic-confirmed postinfectious tubal infertility, Patton et al. searched for evidence of *C. trachomatis* by culture, in situ hybridization, immunoperoxidase staining, and transmission electron microscopy.[96] Persistent infection with *C. trachomatis* was evident in nearly 80% of women by these techniques. Taken together, these studies provide strong evidence to suggest that *C. trachomatis* can cause a persistent and clinically silent infection of the upper genital tract.

PREGNANCY LOSS–DOES ENDOMETRITIS PLAY A ROLE?

An inflammatory process of the endometrium would pose a challenge to the implantation of the embryo and may cause pregnancy loss. To that end, the influence of inapparent chlamydial infections on the success of embryo implantation has been studied. Licciardi et al. examined *C. trachomatis* IgG antibodies in the sera of 145 women undergoing in vitro fertilization (IVF).[97] Spontaneous abortion was strongly associated with the presence of chlamydial IgG antibodies. While there were no active *C. trachomatis* infections detected in this cohort, remote chlamydial infection was nearly 3 times more common among those experiencing pregnancy loss. Antichlamydial antibodies were found in 20 (69%) of 29 women who experienced a spontaneous abortion compared to 9 (24%) of 38 women with successful pregnancies (p <0.001). A nonsignificant relationship was observed by Keltz et al., who found a pregnancy loss rate of 35% (6/17) among women positive for serum *C. trachomatis* IgG antibodies compared to a rate of 17% (8/47) observed in seronegative women.[78] Witkin and colleagues identified an association between undetected and untreated chlamydial infection and both failure to conceive and spontaneous abortion in women undergoing IVF.[98] Other data conflicts with this theory. Spandorfer did not find an association between IVF outcome and antibodies to either chlamydial 10 kDa heat shock protein 10 (Chsp 10) or chlamydial surface antigen.[99] Claman found a similar lack of association among women attending a university-based IVF program.[100] Similar conflicting data concerning prior chlamydial infections have been observed when examining women with recurrent pregnancy loss. High titre antichlamydial antibodies were found in 13.5%, 12.8%, 12.1%, 41%, and 60% of U.S. women with zero, one, two, three, or four spontaneous abortions, respectively (p < 0.01), linking recurrent pregnancy loss with prior chlamydial infection.[101] However, immunoglobulin G antichlamydial antibodies were not associated with recurrent pregnancy loss in cohorts of women from the UK and Finland.[102,103] Similarly, a prospective study of women undergoing miscarriage found no relationship between antichlamydial antibodies and miscarriage.[104] As endometrial sampling for inflammation is impractical at the time of, or in the days leading to implantation, the mechanisms of pregnancy loss in these women remain to be determined. One plausible theory is that low-level persistent chlamydial infection, and its associated inflammation of the endometrium, adversely affects implantation. Alternatively, immune activation could interfere with implantation, perhaps via production of antibody to the chlamydia heat shock protein, which has similar features as mammalian heat shock proteins. Such immune activation may cause an autoimmune-type of hostile response to the embryo. Clinical data examining active *C. trachomatis* infection and pregnancy loss are limited. Studies of women diagnosed with chlamydial infections in pregnancy have provided conflicting results regarding a link between *C. trachomatis* and preterm birth (Chapter 80).[105,106] No data are available on the influence of active chlamydial infections on early pregnancy outcomes. Another theory is that remote chlamydial infection may have caused irreparable damage to the endometrium, prohibiting successful implantation. While the mechanistic explanation for upper genital tract inflammation and pregnancy loss is lacking, the association between remote chlamydial infection and pregnancy loss suggests that upper genital tract inflammation creates a hostile environment for embryo implantation.

HISTOPATHOLOGY OF SUBCLINICAL PID

Further light has been shed on the devastating impact of subclinical PID on fertility by studies examining the pathologic findings of the fallopian tubes in women with acute and subclinical PID. Patton et al. examined the morphologic changes of the fallopian tube mucosa from women undergoing salpingostomy to repair distal tubal occlusion.[16] These women were divided into two groups based on the presence or absence of a clinical history of salpingitis (overt PID and subclinical PID, respectively) and compared to a control group that consisted of women with normal tubes undergoing hysterectomy. One-half of the women in each of the two PID groups had serologic evidence of prior chlamydial infection, while antichlamydial antibodies were not identified in any of the control women. Fallopian tube damage was assessed by light, scanning, and transmission electron microscopy, assessing for evidence of flattened mucosal folds, deciliation, and damage to the secretory epithelial cells (Figs. 79-7 and 79-8). The findings of this study clearly demonstrate that the morphologic damage to the fallopian tube was very similar among women with acute PID and subclinical PID. Further, the characterization of the damage was strikingly similar, suggesting very similar pathophysiologic mechanisms. The investigators further asse-ssed tubal damage by measuring ciliary beat frequency. The beat frequency was similar in the tubes from women with acute and subclinical PID; the beat

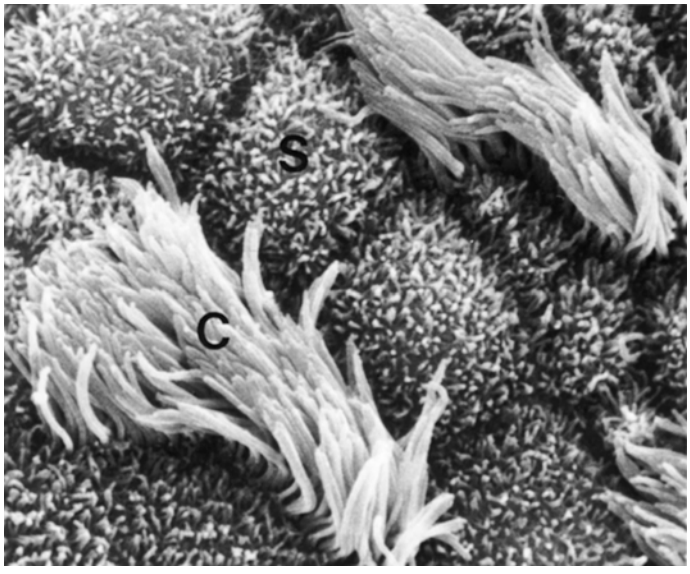

FIGURE 79-7. Normal fallopian tube. Secretory cells (S) with abundant microvilli are surrounded by clumps of long, slender cilia (C) atop the ciliated cells. 4800×. (*SEM provided by Dr. Dorothy L. Patton, Departments of Obstetrics and Gynecology and Biological Structure, University of Washington.*)

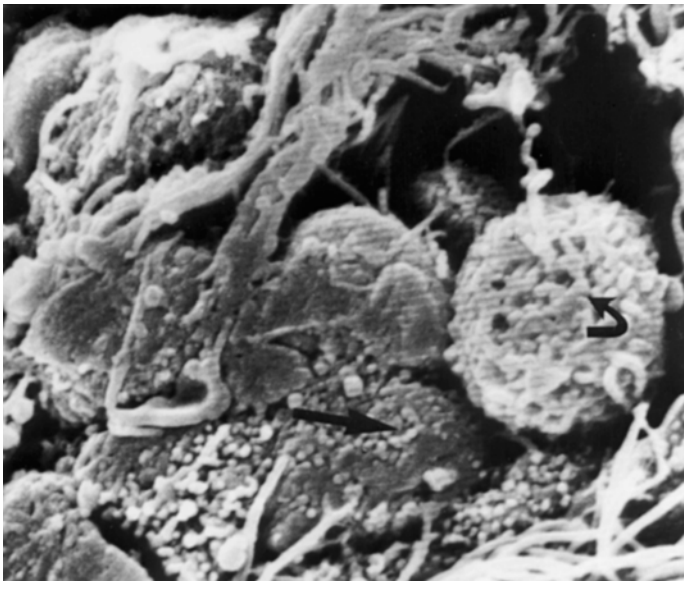

FIGURE 79-8. Infertile fallopian tube following infection. Pronounced deciliation (straight arrow) of the ciliated cells and clubbing of the microvilli on the secretory (curved arrow) cells are evident in this biopsy taken from a distally occluded fallopian tube. 5200×. (*SEM provided by Dr. Dorothy L. Patton, Departments of Obstetrics and Gynecology and Biological Structure, University of Washington.*)

frequency was 3 times faster in the fallopian tubes of the control women than the tubes from either the women with acute or silent PID. Thus, both the histologic appearance of the fallopian tube is altered and the function of the tube is impaired. The results from this important work highlight that fallopian tube damage from acute and subclinical PID is nearly identical. Subclinical PID is responsible for considerable damage to the structure and function of the fallopian tube with the possible adverse impact on fertility potential.

LIMITED UTILITY OF HISTORY TAKING IN TUBAL FACTOR INFERTILITY

As *N. gonorrhoeae* and *C. trachomatis* are important causes of acute PID, one can surmise that the serologic data linking these two sexually transmitted organisms with infertility and ectopic pregnancy reflect prior episodes of acute PID. However, many of these women do not recall being diagnosed with acute PID. Studies of women with tubal factor infertility have shown the inaccuracy of patient recall.[107] Studies of women with infertility have consistently shown that only approximately one-third report a history of a prior diagnosis of acute PID.[17,56,83] Further, recall of past PID was unrelated to chlamydial serology.[79] Similar findings were noted among infertile women with damaged fallopian tubes and antibodies to *N. gonorrhoeae,* with only 45% of women reporting a history of prior PID.[80] In the WHO study investigating the relationship between chlamydia and gonorrhea serology and infertility, only one-third of women with bilateral tubal occlusion and serologic evidence of past gonococcal or chlamydial infection reported prior symptoms suggestive of acute PID.[18] It is probable that recall bias may explain some of these discrepant findings. However, the great discrepancy between suspected prior PID and recall of such a history lends credence to the argument that a large proportion of infection-mediated tubal damage is subclinical; the high frequency of antibodies to *C. trachomatis* and *N. gonorrhoeae* in women with infertility or ectopic pregnancy reflects prior acute PID in only a minority of women. Fallopian tube damage that occurs as a result of chlamydial or gonococcal infections indicates that many cases of postinfectious tubal damage arise from subclinical PID rather than acute PID.

SUBCLINICAL PID IN WOMEN WITH CERVICITIS AND VAGINITIS

The sexual pathogens *N. gonorrhoeae* and *C. trachomatis* are considered to be the etiologic agents of a substantial proportion of acute PID cases (see Chapter 56). A growing body of the literature suggests that these pathogens are implicated in the pathogenesis of subclinical PID. In one of the earliest studies examining a small cohort of 35 women with suspected cervicitis, Paavonen identified histologic endometritis in 40%, and that endometritis was correlated with the presence of chlamydial or gonococcal cervicitis.[108] Korn et al. studied 111 women with lower genital tract infection.[109] Using criteria of the presence of any plasma cells in the endometrial specimen, 56% of women (15/27) with gonorrhea and 57% of women with chlamydia (17/30) had plasma cell endometritis.

Wiesenfeld et al. performed a cross-sectional study evaluating the relationship between lower genital tract infection and subclinical PID among 556 women between 15 and 30 years of age who were attending STD and ambulatory

clinics.[110] Lower genital tract infections were common in this cohort, with 57 diagnosed with cervical *N. gonorrhoeae* infection, 103 women were infected with *C. trachomatis,* and 377 were diagnosed with bacterial vaginosis. None of the participants had clinical evidence of acute PID. Using endometrial histology criteria for subclinical PID as validated by Kiviat et al., the diagnosis of subclinical PID required the presence of neutrophils and plasma cells in the endometrial sample.[111] Subclinical PID was detected in 27% of women with *C. trachomatis* infection and in 26% of women diagnosed with gonorrhea. The odds ratio for subclinical PID among women with chlamydial cervicitis was 3.4 (95% confidence interval 1.8, 6.3), while that for gonococcal cervicitis was 2.4 (95% confidence interval 1.1, 5.1). Thus, it is apparent that clinically inapparent upper genital tract inflammation, also termed subclinical PID, is found in a substantial minority of women with seemingly uncomplicated gonococcal or chlamydial cervicitis.

Bacterial vaginosis has been implicated as an important cause of ascending pelvic infection, with studies demonstrating associations between bacterial vaginosis and preterm labor and premature rupture of the fetal membranes (much of which is related to ascending infection), postcesarean section endometritis, and PID.[112–114] Bacterial vaginosis is found in a high proportion of women diagnosed with acute PID and bacterial vaginosis- associated microorganisms have been isolated from the upper genital tract of women with PID.[115,116] Given the relationship between bacterial vaginosis and PID, several investigations have explored whether women with bacterial vaginosis are at risk for subclinical PID. Korn et al. studied the relationship between bacterial vaginosis and plasma cell endometritis in women without signs or symptoms of acute PID.[117] Twenty-two women with bacterial vaginosis but without *N. gonorrhoeae* or *C. trachomatis* infection were compared to an uninfected control group of 19 women. Plasma cell endometritis was present in 10 (45%) of 22 women with bacterial vaginosis and in only 1 (5%) of 19 controls ($p < 0.05$). As evidence of clinically inapparent ascent of vaginal microflora to the upper genital tract, these investigators recovered bacterial vaginosis-associated organisms from the endometria more frequently from those women with bacterial vaginosis than those without bacterial vaginosis. Moreover, these organisms were isolated nearly twice as often from women with plasma cell endometritis than from those without endometritis, suggesting that the microbiologic findings from the endometrium did not reflect contamination from the lower genital tract. In a later study published by the same group of investigators comprising women attending an inner-city hospital or an STD clinic, plasma cell endometritis was found in 42% of 57 women with bacterial vaginosis and in only 13% of the 24 women without BV.[109] In women without clinical evidence of acute PID, Wiesenfeld et al. identified plasma cell endometritis in 39% of women with bacterial vaginosis, which was significantly greater than the 29% rate of endometritis in women without bacterial vaginosis; this difference was not found to be significant after adjustment for confounding variables.[110] However, using stricter histopathologic criteria (the presence of both neutrophils and plasma cells), endometritis was statistically associated with bacterial vaginosis. As with the sexually transmitted pathogens *C. trachomatis* and *N. gonorrhoeae,* bacterial vaginosis is not only implicated in the pathogenesis of acute PID but is suspected in the development of subclinical PID.

As detailed above, substantial retrospective data associated prior PID with infertility. Despite the virtual unanimity of these observations, there are no prospective data published to date on the risk of infertility in women with gonococcal or chlamydial cervicitis or bacterial vaginosis. Current prospective studies are underway examining whether women with subclinical PID are at risk for tubal factor infertility, and preliminary data indicate that women with subclinical PID are at increased risk for subsequent involuntary infertility.[118]

ENDOMETRIAL PATHOLOGY OF SUBCLINICAL PID

The current gold-standard diagnostic test for confirming the presence of PID is direct visualization of the pelvic organs (via laparoscopy) but the cost and surgical risks limit the widespread utility of this approach. Rather, endometrial ampling is a much safer office procedure that is becoming more widely employed to identify upper genital tract inflammation. Histopathologic interpretation typically takes 2 days or more, precluding its use to timely influence therapeutic management. However, its utility in confirming or refuting the presence of upper genital tract inflammation is a considerable advantage and offers important prognostic information to the patient and clinician.

Lack of consistent criteria for endometritis has posed challenges both in clinical care and in research investigations. Investigators have used several different histologic criteria to define endometritis. The presence of plasma cells in the endometrium, referred to as plasma cell endometritis, has been associated with lower genital tract infection in cohorts of women at risk for STDs.[109,117] Some investigators rely solely on the presence of a single plasma cell in the entire endometrial specimen.[117,119,120] Paukku et al. studied the association between *C. trachomatis* infection and plasma cell endometritis by reexamining paraffin-embedded endometrial biopsy specimens for the presence of *C. trachomatis* by PCR and immunohistochemistry.[121] Detection of *C. trachomatis* within the biopsy specimen was performed using DNA extraction and PCR of paraffinized endometrial tissue to amplify *C. trachomatis* DNA and by immunohistochemistry. Overall, 5 (24%) of 21 samples with plasma cell endometritis (at least one

plasma cell per 120x field) were positive for *C. trachomatis,* compared to 1 (4%) of 28 specimens that did not have plasma cell endometritis. This study is limited by its small size and by potential selection bias. Further, more than one-half of women whose biopsies revealed plasma cell endometritis were febrile and had lower abdominal pain, suggesting that many of these women had acute rather than subclinical PID. Contradicting these results, Stern et al. did not find an association between the presence of plasma cells in the endometrium and chlamydial infection in a study using nested PCR to detect the presence of *C. trachomatis.*[120] Paavonen compared endometrial pathology with laparoscopy-confirmed PID among 27 women with suspected acute PID.[108] While the sensitivity of the finding of plasma cells for the diagnosis of acute PID was 89%, the specificity was only 67%; one-third of women with plasma cell endometritis did not have laparoscopically-confirmed acute PID.

What is the significance of endometrial plasma cells? Traditionally, plasma cells have not been considered as normal constituents of the endometrium.[122] The presence of plasma cells in the endometrial sample may be unappreciated, perhaps because their appearance is similar to lymphocytes and stromal cells. As such, special stains, particularly methyl-green pyronine, are useful to highlight the presence of plasma cells. Plasma cells appear to be commonly found in the endometrium, and their presence in low numbers and in the absence of other inflammatory cells (e.g., neutrophils), may not signify an ongoing inflammatory process. Among women 3 months postpartum, Andrews et al. identified plasma cell endometritis in 39% of 506 specimens.[123] This high rate of plasma cell endometritis in post partum women raises the suspicion that this endometrial histopathologic diagnosis may not represent a pathogenic process. In Wiesenfeld's study of 556 women without clinical evidence of acute PID, infections with *N. gonorrhoeae, C. trachomatis* or bacterial vaginosis were not associated with plasma cell endometritis.[110] A cross-sectional study of women with proven fertility undergoing tubal ligation (i.e., low risk for PID) found that endometrial plasma cells were identified in one-third of the asymptomatic fertile women and were not associated with lower genital tract infection.[124] A further analysis of the postpartum cohort by Andrews et al. did not demonstrate an association between bacterial vaginosis and plasma cell endometritis; in fact, nearly identical proportions of women with and without bacterial vaginosis had plasma cell endometritis (39.8% and 39.2%, respectively).[125] Thus, plasma cells can be commonly found in endometrial samples from healthy women and their presence (at least in small numbers) may not represent ongoing upper genital tract inflammation.

The most comprehensive evaluation of endometrial histopathology in women with PID has been performed by Kiviat et al.[111] Sixty-nine women with clinically suspected acute PID underwent endometrial biopsy, laparoscopy, and endosalpingeal cytology along with cultures from the cervix, endometrium, fallopian tube, and cul-de-sac. Several histologic features of the endometrium were analyzed according to the presence of upper genital tract infection and salpingitis. The best histologic criteria that predicted upper genital tract infection and salpingitis was the combined presence of at least five neutrophils per 400x field in the endometrial surface epithelium and one or more plasma cells per 120x field of endometrial stroma. These stringent criteria had a sensitivity of 92% and a specificity of 87% for predicting PID. A number of studies utilizing endometrial histology in PID studies have used these criteria to diagnose endometritis.[110,126–128] In Wiesenfeld's study of women without acute PID, lower genital tract infection with gonorrhea, chlamydia, or bacterial vaginosis was associated with endometritis using the criteria described by Kiviat et al. but was not associated with plasma cell endometritis.[110] As these criteria are the best validated, future studies should examine the endometrium for the presence of both neutrophils and plasma cells as previously outlined.[111] Histopathologic changes in the endometrium of women with subclinical PID need to be correlated with long-term outcomes (i.e., infertility) to determine the optimum histologic criteria of subclinical PID.

CLINICAL FINDINGS IN WOMEN WITH SUBCLINICAL PID

The clinical diagnosis of acute PID is imprecise, with the sensitivity of clinical criteria of approximately 70%.[129,130] Given the difficulty in confirming acute PID, the task to identify women with subclinical pelvic infections is challenging. Cates et al. attempted to identify clinical predictors of subclinical PID by comparing characteristics of women with tubal infertility who had a history of overt PID to characteristics of those with infertility without a prior known history of acute PID (subclinical PID).[131] Sociodemographic characteristics of women with subclinical PID were more similar to those of fertile women than of women with post-PID infertility. Reports of number of sexual partners, illicit drug use, and douching were identified in women with subclinical PID at rates intermediate between the rates in fertile women and women with infertility due to overt PID. Wiesenfeld et al. also conducted a study comparing the characteristics, clinical findings, and microbiology of women with subclinical and acute PID. Several demographic characteristics of women with subclinical PID were found at intermediate rates between those in women with acute PID and without PID, including age, race, and education. However, no strong predictors were found that could aid in the identification of women with subclinical PID.

Given the broad range and severity of symptoms of acute PID, clinical findings have limited predictive value for acute PID.[3] Some have suggested that subtle symptoms and signs of PID may be present and can alert the clinician to con-

sider the diagnosis of subclinical PID. To elucidate these clinical findings, Wiesenfeld et al. compared cohorts of women with acute PID, subclinical PID, and controls.[132] Subclinical PID was identified in women lacking the diagnostic symptoms of acute PID but who had lower genital tract infection (gonorrhea, chlamydia, or bacterial vaginosis) and had histologic evidence of upper genital tract inflammation. Abdominal pain was reported at slightly higher levels in women with subclinical PID compared to women without PID. Adnexal tenderness was uncommon (11%) in women with subclinical PID but more often found than in controls (3%). While 4–5 times more common in women with subclinical PID than in women without subclinical PID, pelvic organ tenderness was nonetheless uncommon in women with subclinical PID. Microbiologic findings in women with subclinical PID fall between those seen in acute PID and in women without PID. Specifically, endometrial recovery of *C. trachomatis* among women with acute PID, subclinical PID, and controls was 20%, 10% and 2%, respectively (p for trend <0.001). A similar relationship was seen with endometrial *N. gonorrhoeae* (9%, 3%, and 0.3%, p for trend <0.001). The hidden nature of subclinical PID makes the identification of this disease very difficult, even by experienced clinicians.

ENDOMETRITIS IN HIV-INFECTED WOMEN

It may be expected that women with immune dysfunction may be at risk for upper genital tract inflammation. Eckert et al. characterized histologic endometritis in a cohort of human-immunodeficiency virus infected women who did not have clinical evidence of acute PID.[127] None of the 42 women enrolled in the study were infected with *C. trachomatis* or *N. gonorrhoeae* and 29% had bacterial vaginosis. Histologic endometritis was identified in 16 (38%) of 42 women in the cohort, indicating a high rate of subclinical PID in this cohort of HIV-infected women. These results suggest that subclinical PID in HIV-infected women may be related to pathogens other than (or in addition to) *N. gonorrhoeae* and *C. trachomatis,* or that these women may have altered immune function predisposing to upper genital tract inflammation. Further work is needed to determine the impact of HIV on subclinical PID and the sequelae of subclinical PID in HIV-infected women.

DO ANTIBIOTICS CLEAR ENDOMETRIAL INFLAMMATION?

Further evidence of the abnormal nature of histologic endometritis in women without PID stems from a treatment study of women with subclinical PID by Eckert et al.[128] This prospective trial enrolled women without clinical evidence of PID who presented for evaluation at an STD clinic or who had abnormal uterine bleeding. Endometrial biopsies were performed prior to oral antibiotic treatment, which consisted of single doses of cefixime and azithromycin and a 1 week course of metronidazole. Of the 48 women who had endometrial biopsies before and after treatment, 18 had histologic endometritis before treatment, while only two had endometritis following therapy (p <0.001). A study from Alabama demonstrated that antimicrobial therapy impacts microbial flora of the endometrium.[133] In a secondary analysis of a trial evaluating the effect of antibiotic therapy on recurrent preterm birth, treatment with metronidazole and azithromycin resulted in enhanced endometrial eradication and reduction of acquisition of *Gardnerella vaginalis* and other gram-negative rods. These results demonstrate that antibiotic therapy can alter the microbial environment and possibly eliminate inflammatory changes of the upper genital tract in women without clinical evidence of acute PID. Moreover, these data indicate that such histologic changes are not normal findings in otherwise healthy women and imply that these histopathologic findings represent ongoing upper genital tract inflammation.

REPRODUCTIVE SEQUELAE OF SUBCLINICAL PID

The data available to date on subclinical PID reveals that this disorder is commonly found in women with seemingly uncomplicated lower genital tract infection. Moreover, the presenting symptoms are nearly uniformly vague and mostly absent. Likewise, physical findings of pelvic infection are absent, making the identification of this condition difficult. There are substantial retrospective data that strongly imply that subclinical PID is associated with subsequent fallopian tube damage, as many women with tubal factor infertility or ectopic pregnancy have evidence of remote infection. Current prospective studies are underway examining whether women with subclinical PID are at risk for tubal factor infertility. Preliminary data indicate that women with subclinical PID are at increased risk for subsequent involuntary infertility.[118] Should this hypothesis be proven in a prospective manner, subsequent research would be focused on determining the most favorable therapeutic regimen to optimize fertility in women with subclinical PID. Subclinical PID is present in a substantial proportion of women with otherwise uncomplicated gonococcal or chlamydial cervicitis and bacterial vaginosis. Given the STD epidemic worldwide, far more women may be at risk for infertility from subclinical PID than from acute PID.

80 Bacterial Sexually Transmitted Infections in Pregnancy

Jane Hitti and D. Heather Watts

As the spectrum of bacterial sexually transmitted infections (STI) has broadened, the medical and social consequences of STI in pregnancy have become more apparent. Ectopic pregnancy, spontaneous abortion and stillbirth, prematurity, congenital and perinatal infections, and puerperal maternal infections represent outcomes of pregnancy in which bacterial sexually transmitted infectious agents play important etiologic roles. The incidence of many bacterial STI has increased during the last three decades, and the number of pregnancies per year is also increasing; the superimposition of the one factor on the other can be expected to further amplify the effects of bacterial STI on pregnancy and neonatal morbidity.

In general, bacterial STI appear to pose a much greater problem in pregnant adolescents and young adults (less than 25 years) compared to older pregnant women who are more likely to be involved in a stable monogamous sexual relationship at the time of conception. Adolescents have miscarriages more often than do older women—a difference that may be attributable in part to bacterial STI. Although the average age at which women first bear children is increasing, the average age at which women first initiate sexual activity has decreased, and teenage pregnancy remains common in many parts of the world despite the relative availability of contraception. Among sexually active women, whether pregnant or nonpregnant, the prevalence of many bacterial STI agents, such as *Chlamydia trachomatis* and *Neisseria gonorrhoeae,* is highest among women younger than 25 years. The younger the patient, the greater is the likelihood that any given infection is a primary infection. Although immunity to most bacterial STI agents is not well defined, it is likely that, in general, primary infections cause the greatest morbidity.

The two classic venereal agents, *N. gonorrhoeae* and *Treponema pallidum,* have pronounced effects on pregnancy. Fortunately, measures for the diagnosis and management of these infections in pregnancy are readily available and routinely employed where resources permit. Introduction of such measures still remains a major achievable goal in resource-limited settings and in subpopulations that may not access prenatal care consistently in developed countries. Certain bacterial STI pathogens such as *C. trachomatis* are even more common during pregnancy, are more difficult to diagnose without advanced technology such as polymerase chain reaction (PCR), and currently represent a greater dilemma to the obstetrical care provider in resource-limited settings.

Molecular methods to detect bacteria by PCR have identified microorganisms that are not cultivable using conventional microbiological techniques. These methods promise to greatly increase our understanding of the scope of bacterial STI and possibly also infectious causes of pregnancy complications. On the horizon, novel bacterial STI agents such as *Mycoplasma genitalium, Leptotrichia,* and other uncultivable organisms may prove to be important infections in pregnancy. However, the prevalence of these agents in pregnancy and their effect of pregnancy outcome is as yet largely undefined.

Infections of the placenta, chorioamnion membranes, fetus, uterus, and fallopian tubes make the effects of bacterial STI on pregnancy particularly important(Chapter 79). Infection prior to pregnancy can influence the process of implantation, causing infertility and ectopic pregnancy. Infection during pregnancy can produce spontaneous abortion, chorioamnionitis, amniotic fluid infection, preterm birth, and congenital (fetal) infection. Genital infection present at delivery can cause maternal and neonatal infections.

Pregnancy modifies the manifestations of many bacterial STI and presents unique problems for diagnosis and management. Some agents, such as *Candida albicans,* produce disease more commonly during pregnancy. The susceptibility of the pregnant host to infection may be enhanced, owing either to alterations in host defense mechanisms or to changes in anatomic structure.

ALTERATIONS OF HOST–PARASITE RELATIONSHIPS DURING PREGNANCY

IMMUNOLOGIC CHANGES

Immunologic rejection of the fetus does not normally occur during pregnancy, possibly in part because of suppression of

maternal immunocompetence. Suppressed maternal immune function may in turn affect the natural history of many infectious diseases. For instance, higher attack rates or more severe morbidity has been recorded for pneumococcal pneumonia,[1] candidiasis,[2] and malaria[3] in the pregnant host than in the nonpregnant host. Immunologically mediated diseases caused by infectious agents may lessen in severity during pregnancy; for example, in the pre-antibiotic era it was observed that symptomatic syphilis was ameliorated during pregnancy.[4] Animal studies also support the notion that pregnancy interferes with maternal defense mechanisms through immune suppression.[5,6]

Factors other than immunosuppression also may contribute to the increased maternal susceptibility to certain infections during pregnancy. For example, excessive mortality from bacterial pneumonia during pregnancy has been attributed to altered pulmonary mechanics, and the increased susceptibility to renal infection during pregnancy may be related to changes in ureterovesicular muscular tone induced by high levels of progesterone or to partial ureteral compression by the gravid uterus.

ANATOMIC ALTERATIONS IN PREGNANCY

The anatomy of the genital tract changes dramatically during pregnancy. Figure 80-1 illustrates the relationship of the cervix and mucous plug, chorioamnion, and placental bed as seen in late pregnancy. Vaginal walls become hypertrophic and engorged with blood. The glycogen content of the vaginal epithelium increases, and the intravaginal pH significantly decreases during pregnancy.[7] These changes probably influence vaginal microbial flora. The cervix hypertrophies and a larger area of columnar epithelium on the exocervix is exposed to microorganisms.[8] Similar cervical anatomic changes are evoked among nonpregnant women by oral contraceptives and have been associated with an increased prevalence of infection with *C. trachomatis* and *N. gonorrhoeae*.[9] It is not certain whether the higher prevalence of chlamydial and gonococcal infections in nonpregnant women with cervical ectopy is due to increased susceptibility to infection or enhanced cervical shedding among previously infected women or both. The increased area of cervical ectopy during pregnancy also may predispose the cervix to infection, but this has not been well studied. The cervix secretes highly viscid mucus during pregnancy, forming the so-called mucous plug. This mucus is generally believed to limit the access of microorganisms into the uterus, but little research has been done to study the actual effectiveness of cervical mucus as a physical or antimicrobial barrier.[10] Fetal growth is accommodated by uterine growth and by tremendous enlargement of uterine vessels. The risk of salpingitis decreases during pregnancy, especially after the twelfth week,[11] and the risk of chorioamnionitis and amniotic fluid

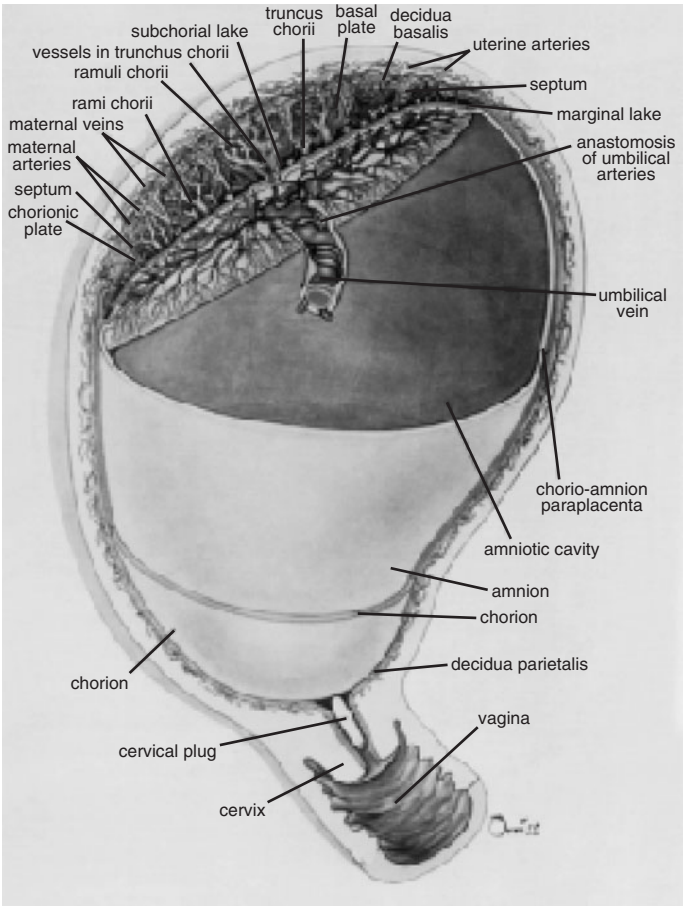

FIGURE 80-1. The relationship within the gravid uterus of the mucus plug, fetal membranes (chorion and amnion), decidua, and placenta. (With permission from JD Boyd and WJ Hamilton, *The Human Placenta*.)

infection increases after the sixteenth week of gestation.[12] After the twelfth gestational week, the uterine cavity becomes obliterated as the chorioamnion becomes juxtaposed with the decidua vera. The risk of infection of the uterine cavity and fallopian tubes is diminished by the elimination of this space. By the sixteenth week, the chorioamnion overlies the cervical os, which may be a factor in the increasing risk of chorioamnionitis during middle and late pregnancy.

The human placenta is of fetal origin and is directly perfused by maternal blood. The trophoblastic placental epithelium projects into the maternal vascular system. This trophoblastic layer regulates fetal uptake of many substances. Anatomically, two layers of trophoblastic epithelium are present, an inner multicellular stratified layer (cytotrophoblast) and an outer unicellular syncytial layer (syncytiotrophoblast). These layers can be seen in (Fig. 80-2). With advancing gestation, Langhan's layer becomes less noticeable but does not regress completely. Lying within the stroma of the mature placenta are placental macrophages that act as a first line of fetal defense to transplacental infection.

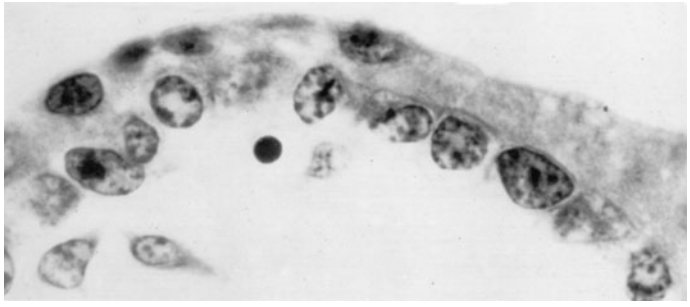

FIGURE 80-2. Photomicrograph of the human triphoblast illustrating the outer (maternal) syncytiotrophoblast on the convex surface; and inner (fetal) cytotrophoblast of Langhan's layer. (With permission from JD Boyd and WJ Hamilton, *The Human Placenta*.)

ALTERATIONS IN CERVICOVAGINAL MICROBIAL FLORA DURING PREGNANCY

The vaginal flora is a heterogeneous ecosystem of anaerobic and facultative bacteria.[13] Several studies have found that during pregnancy, the number of bacterial species present in the vagina decreases, particularly the number of anaerobic species, while the prevalence and the quantity of lactobacilli increase and the rate of carriage of Enterobacteriaceae, group B streptococci (GBS), and other facultative bacteria remains unchanged. The mechanisms that may promote the reported changes in vaginal flora might include changes in the vaginal pH, glycogen content, and vascularity of the lower genital tract, as described above. Following delivery, an increase in rates of isolation of *Escherichia coli* and *Bacteroides* species (which may promote puerperal endomyometrial infections) has been reported, but this observation also requires confirmation.[14]

ECTOPIC PREGNANCY

Infertility and ectopic pregnancy are recognized consequences of salpingitis. Two sexually transmitted organisms, *N. gonorrhoeae* and *C. trachomatis*, produce the majority of cases of primary salpingitis (see Chapter 56). The risk of ectopic pregnancy increases about 10-fold after an initial episode of salpingitis. The incidence of ectopic pregnancy has increased fivefold since 1970 in the United States, and this trend has also been observed in Sweden, Canada, and England.[15] It is likely that this rising incidence of ectopic pregnancy is due in part to an increasing incidence of gonococcal and chlamydial infections and of resulting tubal infections. Ectopic pregnancy and infertility are discussed further in Chapter 79.

POSTABORTAL INFECTIONS

Bacterial STI and other vaginal infections are frequently detected among women presenting for elective termination of pregnancy.[16] *C. trachomatis*, *N. gonorrhoeae*, and bacterial vaginosis (BV) have each been associated with an increased risk of febrile morbidity after surgical abortion. In addition, infection rates after abortion were reduced with routine screening and treatment, if indicated, for both *C. trachomatis* and BV.[17,18] Routine screening for *N. gonorrhoeae*, *C. trachomatis*, and BV is indicated in most populations undergoing surgical abortion. Whether bacterial STIs are a risk factor for pelvic infections after medically induced abortions has not been studied,[19] but screening similar to that done before surgical abortion would seem reasonable, since suction procedures are still required in a small number of women after medical treatment.

INTRAUTERINE INFECTION

Intrauterine infection can result from either hematogenous or ascending microbial spread. Other routes of spread such as extension from infection in areas adjacent to the uterus occur rarely. A hematogenous origin appears to be the major route of spread for organisms present in maternal blood, such as *T. pallidum* or *Listeria monocytogenes*. Hematogenous infection initially involves the placenta, producing the characteristic pathologic lesion of villitis. Placental macrophages likely serve as the initial antimicrobial defense in this situation.

Ascending infection by microorganisms present in the cervix or vagina can occur through intact or compromised fetal membranes, producing the characteristic pathologic lesion of chorioamnionitis and the syndrome of amniotic fluid infection. The integrity of the chorioamnion and the antimicrobial activity of amniotic fluid likely serve as the first line of fetal defense in this situation.

HEMATOGENOUS INFECTION

Only rarely does maternal bacteremia give rise to placental or fetal infection. The nature of the defense mechanisms responsible for protection of the developing placenta and fetus from bacteremic spread is not presently known. It appears that microbial agents inhibited primarily by a cell-mediated immune response are more likely to establish placental infection than are agents inhibited primarily by a humoral immune response, suggesting either that pregnant women are most susceptible to systemic spread of those agents that are inhibited by cellular immunity or that placental defense mechanisms are less effective against such microorganisms.

Microorganisms arrive at the placental bed within lymphocytes, monocytes, or neutrophils, or they may not be cell associated. Fetal defense mechanisms during placental infection include placental macrophages and local production of immune factors such as antibody and cytokines. The immune role of the trophoblast is not well understood, but since this epithelium possesses Fc receptors for

immunoglobulin and unique antigenic determinants and secretory products that regulate lymphocyte reactivity in vitro, an important effect on the maternal immune response seems likely.[20] Placental histopathology following infection with *T. pallidum* serves to illustrate the range of responses detectable in this tissue. *T. pallidum* infected placentas are inappropriately large with focal proliferative villitis and vasculitis with areas of plasma cell infiltration and Langerhans' giant cell formation[21] (Fig. 80-3).

With hematogenous infection, placental infection generally precedes fetal infection, although theoretically it is possible for organisms to traverse the chorionic villi directly by pinocytosis or placental leaks or within maternal leukocytes. The fetal immune response to placental infection may be effective enough to limit infection to this site. Such circumscribed infection has been seen in syphilis.[22] Often, however, spread from infected placental sites to the fetus occurs either by involvement of fetal blood vessels or by extension from placenta to fetal membranes with consequent infection of the amniotic fluid.

The manifestations of fetal infection depend to a great extent on the gestational age at which infection occurs. The infectious agents capable of transplacental infection can produce similar effects. Abortion, stillbirth, preterm birth, growth restriction, congenital disease, and persistent postnatal infection have all been described following infection with *T. pallidum,* the protozoan *Toxoplasmosis gondii,* and with congenital viral infections such as cytomegalovirus and rubella. The similarities in outcome with these disparate infectious agents suggest a common pathway in fetal response to transplacental infection, with severity largely mediated by gestational age at exposure.

ASCENDING INFECTION: CHORIOAMNIONITIS AND AMNIOTIC FLUID INFECTION

Acute inflammation of the fetal membranes (chorioamnionitis) and umbilical cord (funisitis) is seen even more frequently than hematogenous placentitis and often is associated with preterm birth, prolonged rupture of the

FIGURE 80-3. (*Courtesy of G. Altshuler.*)

membranes (PROMs), intrapartum fever, and perinatal sepsis. Chorioamnionitis is defined histologically by the presence of polymorphonuclear leukocytes (PMNs) in the membranes—usually within the chorion[23]; in some cases this acute inflammation is seen only on the fetal side of the discoid placenta. The migration of maternal PMNs from the intervillous spaces or of fetal PMNs through the amnion suggests transcervical infection of amniotic fluid rather than primary hematogenous infection. Figure 80-4 diagrammatically illustrates the patterns and stages of the maternal and fetal inflammatory response to amniotic fluid infection.

The etiology of acute chorioamnionitis is in many cases unknown. Delayed delivery following PROM is an important correlate of acute chorioamnionitis, but most cases of chorioamnionitis are not associated with PROM as an antecedent event.[12] The correlation of chorioamnion or amniotic fluid culture results with histologic chorioamnionitis in several studies is shown in Table 80-1.[23–29] The varied rate of isolation of microorganisms among women with histologic chorioamnionitis can be accounted for by differences in patient populations and specimen handling and sampling, variable use of culture techniques to isolate genital mycoplasmas and fastidious anaerobes, and increasing rates of antibiotic use before delivery in the last decade. Limited microbiologic studies have strongly linked *Ureaplasma urealyticum* to chorioamnion inflammation. The organisms isolated from the chorioamnion are similar to those found in the vagina of women with BV, and in fact, when evaluated, positive chorioamnion and amniotic fluid cultures were associated with BV.[23]

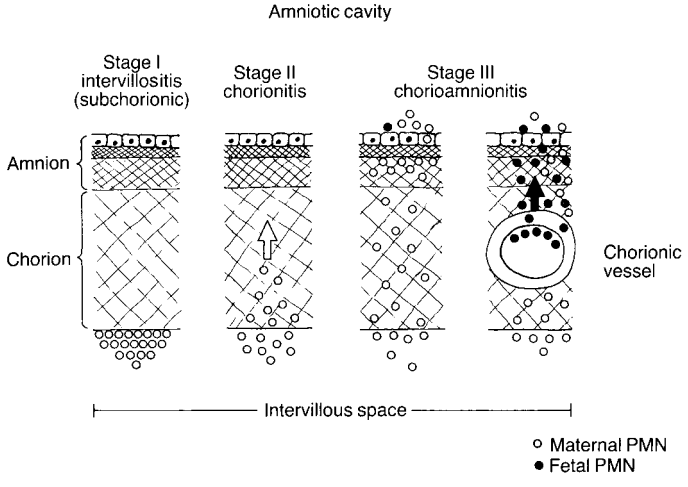

FIGURE 80-4. The stages and patterns of maternal and fetal response to amniotic fluid infection.

Perinatal bacterial infections, especially those occurring within the first 48 hours of life, are commonly acquired by ascending infection *in utero*. Russell[12] found evidence of neonatal sepsis in the first 48 hours of life in almost one-quarter of neonates whose placentas showed chorioamnionitis; neonatal sepsis was rare in the absence of placental inflammation. This and subsequent studies provide compelling data linking chorioamnionitis, amniotic fluid infection, preterm birth, and perinatal sepsis.

Bacteria recovered from amniotic fluid of patients with chorioamnionitis include facultative organisms such as GBS, enteric gram-negative rods, *Haemophilus influenzae,* and strict anaerobic organisms such as peptostreptococci, *Fusobacterium* spp., *Bacteroides* spp., and *Prevotella bivia*.[30–32] These infections are often polymicrobial, resembling the spectrum of organisms found in the upper genital tract of women with salpingitis or postpartum endometritis, and also

CI, confidence interval.

include many of the organisms found in the vagina of women with BV. The relationship of amniotic fluid infection, membrane infection, and histologic chorioamnionitis to preterm birth is discussed in more detail below.

The risk of chorioamnionitis is generally highest among patients of low socioeconomic status who have not received prenatal care.[33,34] These demographic characteristics of patients with chorioamnionitis are similar to those of patients with bacterial STI.

FETAL WASTAGE, PRETERM BIRTH, AND PRETERM RUPTURE OF MEMBRANES

Pregnancy loss and preterm birth comprise a spectrum of adverse pregnancy outcomes. The preterm parturition syndrome is a pathologic process and does not mimic the events of normal term spontaneous labor.[35] Rather there are multiple contributing pathways to preterm parturition, including infectious and inflammatory causes. Spontaneous abortion, stillbirth, and preterm birth may all be caused by infection. However, the proportion of these events attributable to infection is not yet well defined and no doubt varies in different populations. Spontaneous abortion, defined as the delivery of a previable fetus before the twentieth week of gestation and weighing less than 500 g, is a frequent outcome in pregnancy. It is estimated that 50% of fertilized ova fail to implant, and of those which do implant, at least 15–30% subsequently abort.[36] The majority of losses occur in the first trimester; less than 3% of women with normal fetal cardiac activity by ultrasound at 7–12 weeks experience a loss by 20 weeks.[37] This distinction is clinically useful, since first-trimester abortions are frequently associated with phenotypic or chromosomal fetal abnormalities. Second-trimester abortions and stillbirths (weight $\geq$ 500 g, gestation $\geq$ 20 weeks) are more often associated with an otherwise normal fetus. Genital infections may thus be a relatively more important cause of fetal wastage in the second and third trimesters than in the first trimester, although there are some data suggesting BV is associated with implantation failure after in vitro fertilization[38] and first trimester abortion.[39]

Low birth weight, defined as $\leq$ 2500 g, usually results from a preterm birth but can also be caused by intrauterine growth restriction. Both conditions have been associated with infectious agents. The proportion of cases of preterm birth caused by infection versus that caused by noninfectious factors (e.g., diet, smoking, hypertension) remains to be defined. Among preterm births, approximately one-third are obstetrically indicated deliveries for maternal or fetal conditions such as hypertension or fetal distress, one-third are related to progressive preterm labor, and one-third are related to preterm PROM. As discussed in this section, a high proportion of early preterm labor leading to delivery and a majority of cases of preterm PROM appear to be related to infection.

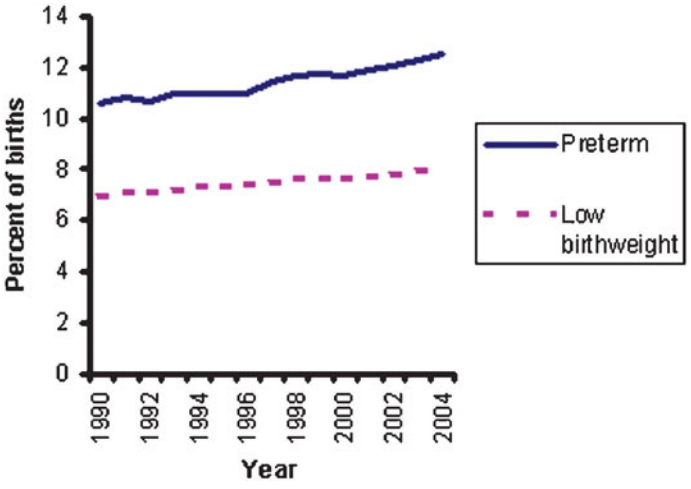

FIGURE 80-5. Steadily rising rates of preterm birth (< 37 weeks' gestation) and low birth weight (< 2500 g), United States, 1990–2004. *Data from National Center for Health Statistics.*[271]

Despite a remarkable decline in the perinatal mortality rate in the United States in the last 40 years, the preterm birth rate has remained essentially unchanged, and has actually increased over the past decade[40] (Fig. 80-5). Between 70% and 80% of all perinatal deaths that are not attributable to congenital malformation occur following preterm birth. Since prematurity and perinatal mortality are so strongly linked, it appears that the decline in perinatal mortality achieved during the last 30 years must be attributable to improvements in perinatal and neonatal care and not to improvements in preterm birth rates. The decline in perinatal mortality has thus been achieved as a result of enormously burgeoning costs of perinatal and neonatal intensive care.[40] The elucidation of preventable causes of preterm birth should ideally lead to interventions that would further reduce both the perinatal mortality and the long-term morbidity rate seen in some infants who survive preterm delivery and substantially decrease health-care costs. Unfortunately, prevention efforts focused on treating infectious causes of prematurity thus far have had little or no impact on preterm birth rates.

In recent years, increasing attention has been brought to racial disparities in health outcomes. In the United States, there is a persistent and troubling disparity in pregnancy outcomes between African American and white women, with the rates of low birth weight, very low birth weight (< 1500 g), and infant mortality among African Americans over twice that seen in whites[41,42] (Fig. 80-6). The increased rates of these adverse outcomes are not readily explained by socioeconomic or other risk factors alone. Environmental factors and other stressors may contribute to the increased rate of preterm birth and infant mortality among African Americans in the United States. One cross-sectional study has shown that microenvironmental factors such as neighborhood stability are associated with BV in pregnancy, among an urban,

predominantly African American population.[43] A secondary analysis of associations between several lower genital tract infections and preterm birth in the vaginal infections and prematurity cohort demonstrated that the proportion of preterm birth associated with infection was considerably higher among African Americans compared to white or Hispanic women[44] (Table 80-2). Clearly, the underlying basis for the racial disparity in preterm birth requires further investigation in order to address this health inequity and improve pregnancy outcomes.

Intriguing data implicating infectious agents in prematurity were serendipitously derived from studies over 40 years ago by Elder et al.[45] In the course of investigating the role of urinary tract infection in prematurity, 279 nonbacteriuric women seen prior to 32 weeks of gestation were alternately allocated to treatment with 6 weeks of oral tetracycline at 1 g per day or with placebo. The patients in both groups were of comparable age, gravidity, race, and marital status. As seen in Table 80-3, even in those without urinary tract infection, the tetracycline-treated group had significantly longer gestations, fewer preterm infants, fewer episodes of postpartum fever, and fewer neonatal complications than the placebo-treated group. Although tetracyclines are now considered contraindicated in pregnancy, these data are intriguing because the salutary effect of long-term broad-spectrum antibiobiotics suggested the presence of unidentified susceptible microorganism(s) that could have contributed to prematurity in the placebo group. *C. trachomatis* and BV-associated organisms are examples of potential lower genital tract pathogens susceptible to tetracycline. In a subsequent treatment trial, Kass et al.[46] randomized 148 women to erythromycin therapy given for 6 weeks in the third trimester or to placebo. Infants in the placebo group weighed less than infants in the treatment group (3187 versus 3331 g, $p = 0.04$). A more recent study in an African population with a high prevalence of bacterial STI showed a modest reduction in low birth weight (4.0% versus 9.2%, $p = 0.08$) and postpartum endometritis (3.8% versus 10.4%, $p = 0.05$) and a higher mean birth weight (3209 versus 3056 g, $p = 0.01$) among 200 women treated at 28 to 32 weeks' gestation with a single 250-mg intramuscular dose of ceftriaxone compared with 200 women randomly assigned to placebo.[47] A large randomized trial of presumptive STI treatment versus iron, folate, and syphilis treatment among pregnant Ugandan women demonstrated significant reductions in preterm birth and neonatal mortality.[48] However, a second multicenter randomized trial of universal treatment of pregnant African women with metronidazole/erythromycin at 24 weeks' gestation and in labor did not prevent histologic chorioamnionitis and preterm birth; the lack of observed treatment effect in this study may be related to the relatively late gestational age at treatment and/or the choice of antibiotic regimen.[49] The effects of universal antibiotic treatment on birth weight, at least in some studies, suggest that prematurity may sometimes result from unrecognized maternal infection, perhaps

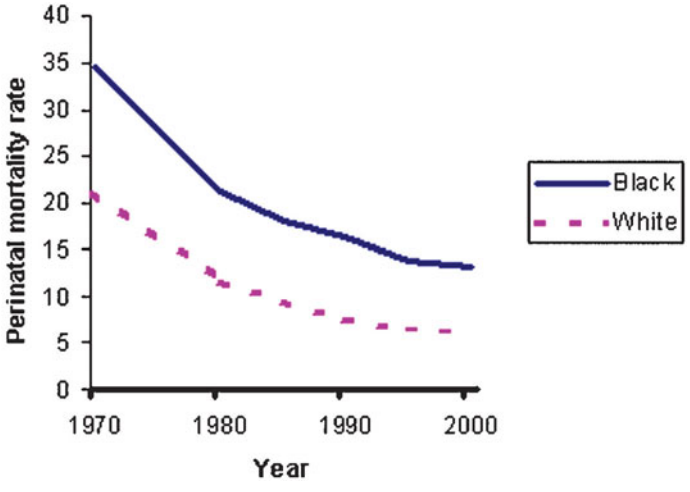

FIGURE 80-6. Trends in perinatal mortality by race. Perinatal mortality is defined as late fetal (≥ 28 weeks) plus neonatal (≤ 28 days age) deaths per 1000 live births plus late fetal deaths. *Data from National Center for Health Statistics.*[271]

bacterial STI involving the lower genital tract. However, both the prevalence of bacterial STI and the rate of infection-associated preterm birth would have to be remarkably high to justify further exploration of a strategy of universal antibiotic treatment for STI to decrease preterm birth. There are other potential disadvantages to universal treatment strategies, not the least of which is the potential to increase antibiotic resistance among bacterial STI and other pathogens.

Many studies have been done comparing the rate of preterm birth and preterm PROM between women with or without specific bacterial lower genital tract infections either early in pregnancy or on admission for delivery. These studies will be discussed in detail below in sections dealing with specific infections. Conclusions from the studies are often limited because only one or a few genital microorganisms could be evaluated in each study. Concomitant risk factors for preterm birth that may be more prevalent among women with genital infections, such as smoking or drug use, often were not considered as potential confounders. Further, if gestational age at enrollment may have been later than the gestation when complications sometimes occur, this could lead to ascertainment bias and underestimation of any association between infection and adverse pregnancy outcome. Despite these limitations, several lower genital tract infections, including *N. gonorrhoeae*, *C. trachomatis*, BV, and *T. vaginalis* have been associated with increased risk of preterm birth. In studies of women with gonorrhea, chlamydial infection, and BV, rates of preterm birth have been reduced among treated compared with untreated women, at least in some populations. Thus, routine screening and treatment of certain genital infections in high-risk populations has the potential to lead to a reduction in the rate of preterm birth.

Increased rates of chorioamnion inflammation and infection and amniotic fluid infection among preterm compared with term deliveries also imply an infectious etiology. The increased rate of neonatal sepsis among preterm infants may be related not only to a less mature immune system but also to frequent exposure to microorganisms in placental and amniotic fluid infection that caused the preterm delivery.

Russell[12] clearly documented the correlation of acute histologic chorioamnionitis with preterm birth. Figure 80-7 illustrates the prevalence of chorioamnionitis by gestational age at delivery. Chorioamnionitis was found in 95% of pregnancies at less than 25 weeks' gestation, 35–40% of pregnancies from 25 to 32 weeks, 11% of pregnancies from 33 to 35 weeks, and only 3–5% of term pregnancies. The mean birth weight of neonates in the chorioamnionitis group was much lower than in a control group without chorioamnionitis (2811 versus 3320 g, $p < 0.001$). The lower birth weight of those with chorioamnionitis was appropriate for gestational age and not attributable to intrauterine growth

restriction. Although chorioamnionitis frequently can be asymptomatic, especially when present near term, two-thirds of the group with chorioamnionitis had intrapartum fever, PROMs, and/or preterm labor.

Many subsequent studies have confirmed the association between histologic chorioamnionitis, chorioamnion infection, and preterm birth.[12,23,24,26,27,29,50–52] These studies are summarized in Table 80-4. As discussed earlier, microorganisms are isolated more frequently from between the chorioamnionic membranes or from biopsy of placentas with histologic inflammation (see Table 80-1). The frequency of histologic chorioamnionitis decreases from over 90% of placentas delivered before 24 weeks' gestation to about 10% at term. Microorganisms isolated most frequently from the placental membranes are *U. urealyticum, Gardnerella vaginalis,* GBS, E*scherichia coli,* anaerobic gram-positive cocci, *Bacteriodes spp., Prevotella bivia,* and *Fusobacterium nucleatum*.

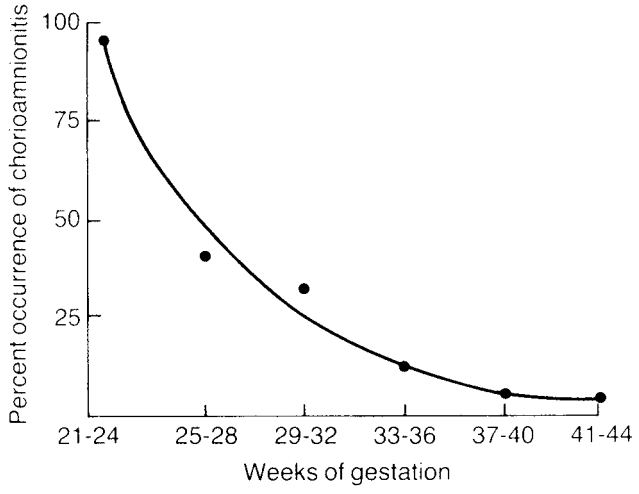

FIGURE 80-7. Rate of chorioamnionitis among deliveries at the stated gestational lengths. The risk of chorioamnionitis is extremely high in preterm deliveries.

Among afebrile women presenting in preterm labor without other obvious cause, bacteria have been isolated from the amniotic fluid obtained by amniocentesis in 131 (10%) of a total of 1275 women in several studies (range, 0–19%).[31,53–68] The range of results can be explained by differences in enrollment criteria, interval from presentation to amniocentesis, gestational age distribution, laboratory methods, and the increasingly common use of antibiotics prior to study enrollment for prevention of neonatal group B streptococcal sepsis. The majority of women with positive amniotic fluid cultures delivered within 2 days (range, 0–4 days) of admission despite tocolytic therapy, while women with negative cultures delivered on average 29 days (range, 25–51 days) after amniocentesis. Women with positive cultures had a lower gestational age at amniocentesis than those with negative cultures. The curve

of the frequency of amniotic fluid culture positivity by gestational age is similar to that of the frequency of histologic chorioamnionitis or positive membrane culture by gestational age, albeit at a lower level. The higher but parallel frequency of membrane infection or inflammation as compared with amniotic fluid infection suggests that infection ascends via the decidua and membranes with secondary infection of the amniotic fluid. Microorganisms most commonly isolated from the amniotic fluid include *F. nucleatum, Bacteroides spp., E. coli, GBS, U. urealyticum, G. vaginalis,* and viridans Streptococcus. Bacteria isolated from the amniotic fluid are similar in distribution to those isolated from the chorioamnion, and in many cases, the same species are found in the vagina with BV.

As the frequency of positive amniotic fluid cultures among women in preterm labor became apparent, investigators began to evaluate the amniotic fluid and vagina for markers of inflammation. Macrophage products including the pro-inflammatory cytokines tumor necrosis factor alpha (TNF-α), interleukin 1 (IL-1), and interleukin 6 (IL-6) in the amniotic fluid have been associated with preterm delivery, positive amniotic fluid culture, and histologic chorioamnionitis.[64,65,67–76] IL-6 is most consistent in predicting rapid delivery among women in preterm labor, even among those with negative amniotic fluid cultures, suggesting either insensitivity of the culture or infection that is limited to the membranes or decidua. Many investigators believe that pregnancy outcomes for women with a negative amniotic fluid culture but high IL-6 concentration are identical to those for women with a positive amniotic fluid culture.[77] Recent studies using PCR to detect bacterial ribosomal DNA have demonstrated the presence of bacteria in amniotic fluid of women with elevated IL-6 concentrations and negative amniotic fluid cultures, suggesting that low bacterial concentrations and/or fastidious organisms may contribute to preterm labor in these cases.[78] *Leptotrichia* species, an uncultivable organism that can be identified only by PCR, has been identified from amniotic fluid in the setting of preterm delivery.[79] This raises the possibility that other as-yet unidentified organisms may be associated with amniotic fluid infection and preterm birth.

Increased concentrations of pro-inflammatory cytokines in amniotic fluid have also been associated with an increased frequency of neonatal complications. Respiratory distress syndrome, intraventricular hemorrhage, and periventricular leukomalacia have all been detected significantly more frequently, even after adjusting for gestational age at delivery, among neonates born to women with, compared with those without, high concentrations of pro-inflammatory cytokines in the amniotic fluid.[80–82] Thus infection-related preterm birth may be doubly damaging, both because of the earlier gestational age of delivery and because of cytokine-mediated complications in the infant.

A monkey model for the study of infection-induced preterm labor has been employed to demonstrate a causal relationship between experimental intraamniotic infection and preterm delivery.[83] Findings from this model are consistent with observations in humans with preterm labor and amniotic fluid infection. Chronically catheterized pregnant rhesus monkeys were inoculated intraamniotically with GBS, and amniotic fluid was sampled serially for levels of GBS, TNF-α, IL-1, IL-6, and prostaglandins E_2 and $F_{2\alpha}$. Intraamniotic cytokine levels rose between 9 and 18 hours after infection, with parallel increases in PGE_2 and $PGF_{2\alpha}$ levels. Increased uterine contractility occurred 10–20 hours after increased cytokine and prostaglandin levels were detected. This delay implies that when women present with preterm labor and amniotic fluid infection, they may have had elevated cytokine levels in the amniotic fluid for several hours or even days. Amniotic fluid and prostaglandin levels in the infected animals were severalfold higher than in control animals in spontaneous labor at term. None of the monkeys with intraamniotic infection developed fever or leukocytosis during labor, consistent with observations in humans presenting in preterm labor with amniotic fluid infection. In a similar design, intraamniotic infusion of IL-1 without bacteria induced preterm labor in all treated animals.[84] This animal model appears to mimic infection-induced preterm labor in humans, allows serial sampling to determine the sequence and timing of cytokine and prostaglandin production, and should provide a valuable tool for evaluation of interventions such as cytokine inhibitors to arrest infection-induced preterm labor.

In addition to the infection-induced production of cytokines and prostaglandins leading to preterm labor and delivery, infection and the resulting inflammatory response may directly damage the fetal membranes leading to rupture. Preterm PROM with resulting delivery accounts for up to one-third of preterm deliveries and frequently is associated with histologic chorioamnionitis. Pathogens commonly found in the genital tract, such as *Bacteroides spp.,* GBS, and *T. vaginalis,* produce proteases that have been shown in vitro to reduce the strength and elasticity of the membranes.[85,86] In vitro addition of *E. coli* or GBS to cultured chorioamnion reduces the bursting pressure of the membranes.[87] Many bacteria produce phospholipases that may directly damage the membranes or lead to prostaglandin production. Thus, exposure of the membranes near the cervical os to lower genital tract bacteria may lead to direct damage and rupture of the membranes or to ascending infection, causing similar resulting damage as well as an inflammatory response leading to cytokine and prostaglandin production and preterm labor.

Since data implicating infection as a cause of preterm labor and preterm PROM are mounting, addition of antibiotics to standard treatments for these conditions might be expected to prolong pregnancy. However, placebo-controlled studies of antibiotics in addition to tocolytics for preterm labor

with intact membranes have not shown prolongation of pregnancy[88–99] (Table 80-5). Since antibiotic levels in the amniotic fluid and the fetus approach or exceed maternal levels and the majority of microorganisms isolated are sensitive to the antibiotics, the infection should be eradicated. However, as shown in the monkey model, contractions are a late finding in the cascade of events leading to preterm birth, and antibiotics at this late stage would not be expected to reverse the cytokine and prostaglandin response. Indeed, lysis of microorganisms during antibiotic treatment actually may increase the inflammatory response. Treatments aimed at blocking the cytokine and prostaglandin response while treating infection must be developed and tested in animal models.

Trials of antibiotic therapy after preterm PROM have yielded more variable results in prolonging pregnancy, probably because the treatments used after preterm PROM have varied considerably[100–108] (Table 80-6). In particular, the Mercer protocol using ampicillin and erythromycin has been demonstrated to prolong gestation after preterm PROM, particularly among the subset of women colonized with GBS.[107] The proportion of infants delivered more than 1 week after membrane rupture has been higher in the antibiotic treatment group than in the placebo group in several studies, although infant hospital stay was not necessarily shortened. The incidences of fever during labor and of postpartum endometritis also were reduced in the antibiotic treatment group in most studies, and infant sepsis and pneumonia were decreased. These findings have led to consensus among experts to provide antibiotic prophylaxis with a macrolide-containing regimen in the context of preterm PROM.[109]

Multiple lines of evidence including epidemiologic studies, data on upper genital tract infection, and animal models implicate lower genital tract infections in the early pathogenesis of a significant proportion of cases of preterm labor and preterm PROM. Since antibiotic treatment of infection-related preterm labor to prolong pregnancy has been largely unsuccessful, and antibiotic adjunctive treatment for preterm PROM is not curative, the best strategy is prevention of these conditions by early detection and treatment of lower genital tract infections before complications occur. Pregnant women should be screened for *C. trachomatis*, *N. gonorrhoeae*,

syphilis, and *T. vaginalis* on the first prenatal visit and treated if positive. Repeat screening later in pregnancy should be done for women in high-risk groups for bacterial STI or with symptoms.

Women of reproductive age should be educated regarding the importance of early prenatal care, safer sexual practices, and STI screening. Pregnant women and their partners should be counseled on symptoms of preterm labor, safer practices, and measures to avoid acquiring new STI during the pregnancy.

MATERNAL PUERPERAL INFECTION

Puerperal endometritis, the most common maternal postpartum infection, can be divided into early infections occurring within the first 48 hours and late infections occurring from 2 days to 6 weeks after delivery.[110] Cesarean delivery greatly increases the risk of early postpartum infection. Without antimicrobial prophylaxis, 36–65% of women who undergo nonelective Cesarean delivery develop infectious morbidity; women delivered by Cesarean are up to 20 times more likely to develop infectious morbidity than are women delivered vaginally. The high infection rate following Cesarean delivery probably results from direct myometrial and peritoneal contamination by organisms present within the amniotic cavity at the time of surgery. Factors that increase microbial contamination of the uterus before delivery such as long duration of labor or rupture of membranes, chorioamnionitis, and number of vaginal examinations also increase the risk of early postpartum endometritis and puerperal sepsis.

Early postpartum endometritis and bacteremia among women following Cesarean delivery usually are due to the anaerobic and facultative bacteria of the cervicovaginal flora, predominantly but not exclusively those associated with BV[111] (Table 80-7). Indeed, the presence of BV diagnosed by Gram stain on admission for delivery was an independent risk factor for postpartum endometritis among women undergoing Cesarean delivery (adjusted odds ratio 5.8, 95% confidence interval [3.0–10.9]).[112] In a separate study assessing reasons for failure of antibiotic prophylaxis with cefoxiten or cefotetan to prevent postpartum endometritis, only the presence of GBS or enterococci in the upper genital tract (amniotic fluid, decidua, chorioamnionic membranes) at delivery was associated with the development of endometritis.[113] Among women without GBS or enterococci in the upper genital tract at delivery who developed endometritis, microorganisms associated with BV were isolated.

In contrast, late postpartum endometritis, occurring 3 days to 6 weeks after delivery, has been correlated with *C. trachomatis* infection.[110] Wager et al.[114] found that approximately 30% of pregnant women with untreated antepartum *C. trachomatis* subsequently developed puerperal infection. One-third of these cases had intrapartum fever attributed to chorioamnionitis and two-thirds had late postpartum endometritis. Clinical manifestations of puerperal chlamydial endometritis, like those of nonpuerperal chlamydial endometritis and salpingitis, are generally mild.

Source: From Watts DH et al. Early postpartum endometritis: The role of bacteria, genital mycoplasmas, and Chlamydia trachomatis. *Obstet Gynecol* 1989; 73: 52–60.

Patients are often afebrile, with mild uterine tenderness and usually with no adnexal tenderness. Such minimally symptomatic postpartum chlamydial infections may contribute to the high rate of Chlamydia antibody among women with secondary infertility because of distal tubal obstruction (see Chapter 79).

The frequency of involvement of the fallopian tubes during postpartum pelvic infection is unknown, since no laparoscopic studies have been reported. The observation that peritoneal infection (as assessed by culdocentesis) commonly accompanies postpartum pelvic infection suggests that fallopian tube infection may not be rare.[115] Similarly, the relationship of postpartum pelvic infection to secondary infertility due to tubal scarring is also unknown. Nevertheless, secondary infertility, usually due to tubal obstruction, is a major problem in Africa,[116] where the prevalence rates of untreated maternal gonococcal and chlamydial infection and the incidence rates of postpartum pelvic infection are very high. However, in the United States, where the majority of postpartum infections occur after Cesarean delivery, no evidence of an increased rate of impaired fertility has been seen after postpartum endometritis.[117]

NEONATAL CONSEQUENCES OF SEXUALLY TRANSMITTED DISEASES

Systemic perinatal bacterial infection is acquired *in utero* or during delivery in 1 to 5 per 1000 live births.[118] Perinatal bacterial infections are two to three times more common than are perinatal viral and protozoal infections. The past 20 years have shown great reductions in major neonatal pathogens, such as early-onset GBS sepsis[119] and ophthalmia neonatorum, as a result of improved screening and treatment protocols. However, as intrapartum prophylaxis for GBS sepsis has become standard of care in the past decade, the dramatic decrease in early-onset GBS sepsis among term infants has unfortunately been accompanied by a concomitant increase in gram-negative sepsis among preterm infants, often with ampicillin-resistant organisms.[120] This undesirable consequence of a well-intentioned and effective strategy to decrease neonatal GBS sepsis illustrates the challenges in devising appropriate interventions for improving perinatal outcomes, and the importance of monitoring results.

CONSEQUENCES, RECOGNITION, AND MANAGEMENT OF SPECIFIC SEXUALLY TRANSMITTED DISEASES DURING PREGNANCY

SYPHILIS

Epidemiology and manifestations

Syphilis remains a common complication of pregnancy in some parts of the world, despite availability of cheap, accurate diagnostic tests, and continued sensitivity of *T. pallidum* to penicillin. Congenital syphilis, discussed in detail in Chapter 82, is entirely preventable with appropriate case detection and treatment programs.[121,122] The provision of adequate prenatal care to all pregnant women remains the foundation for prevention of congenital syphilis. The clinical manifestations of syphilis in adults are well described in Chapter 37 and are not altered by pregnancy. The majority of pregnant women diagnosed with syphilis are asymptomatic, underscoring the need for routine serologic screening of all pregnant women as early as possible in pregnancy. Pregnant women in high-risk groups should have repeat serologic screening for syphilis in the third trimester in addition to their first visit. All patients diagnosed with syphilis should be counseled and tested for HIV infection as well. Women who have fetuses noted to have nonimmune hydrops on ultrasound or who experience stillbirth should always undergo serologic testing for syphilis. Darkfield examination of the amniotic fluid for spirochetes also may be helpful in the evaluation of stillbirth when syphilis is suspected but probably adds little to the evaluation of the patient with syphilis with a live infant.[123]

Pathogenesis

Placental infection with *T. pallidum* occurs during maternal spirochetemia, which is intense until resolution of thesecondary stage. Whether pregnancy promotes recrudescence of spirochetemia, accounting for the congenital infections that occur occasionally in late syphilis, is uncertain.

A detailed clinical description of congenital syphilis is provided in Chapter 82. Untreated primary or secondary syphilis during pregnancy affects virtually 100% of fetuses, with 50% of such pregnancies resulting in preterm delivery or perinatal death.[121] Untreated early latent syphilis during pregnancy results in a 40% rate of prematurity or perinatal death. Ten percent of infants born to mothers with untreated late syphilis show signs of congenital infection, and the perinatal death rate is increased approximately 10-fold. Whereas syphilis is rarely sexually transmissible longer than 2 years after acquisition, women with untreated syphilis apparently may remain infectious for their fetuses for many years, although the proportion of affected fetuses and the severity of fetal disease decrease with longer duration of untreated maternal infection. More recent reports have confirmed the abysmal prognosis with untreated syphilis in pregnancy. In a recent report of 56 cases, only 7 of whom received treatment during pregnancy, 34% were stillborn, and the mean gestational age at delivery was 32.3 weeks.[124] Other studies have shown a 28% incidence of preterm birth even among women with some treatment during pregnancy.[125] Presumptive evidence of congenital syphilis was seen in 15 (26%) of 57 women treated (not always adequately) by 24 weeks' gestation and in 41 (60%) of 70 women treated in the third trimester.[125]

Case detection

Congenital syphilis can be prevented by early prenatal diagnosis and treatment. Nontreponemal serology (rapid plasma reagin, RPR) remains the most useful screening test for syphilis in pregnant women, although there is also a screening treponemal enzyme immunoassay now available.[126] Signs or symptoms are confirmatory but often are not demonstrable; of over 14,000 cases of early syphilis in women, only 11% had a primary lesion, 41% had secondary lesions, and 48% had no manifestations and were detected only by serology.[127]

Infected individuals will develop antibodies to *T. pallidum* by the time of chancre formation or within 2–3 weeks afterward. Virtually all patients with secondary syphilis have a positive serologic test for syphilis, provided steps are taken to avert the prozone phenomenon. This phenomenon occurs when there is an overwhelming excess of antibody in the patient's serum that interferes with the binding to antigen in the flocculation test. If syphilis is strongly suspected

and initial results are negative, the specimen should be diluted before retesting.[128] After lesions of secondary syphilis resolve, latent syphilis is detected serologically.

Despite the low prevalence of maternal syphilis in many developed countries, cost–benefit analysis still favors prenatal first-trimester serologic screening.[129] For instance, in Norway, with a 0.02% maternal prevalence rate, the cost–benefit ratio of the program was still 3.8. Only with an estimated prevalence of maternal syphilis of less than 1 per 20,000 would the costs of the screening program exceed the benefits. This analysis excluded intangible benefits of screening that cannot be measured in economic terms. The US Centers for Disease Control and Prevention recommend serologic testing at the beginning of prenatal care, with repeat testing at the beginning of the third trimester (28 weeks) and at delivery for high-risk women.[130]

The many barriers to detection of syphilis early in pregnancy include those that lead to delayed prenatal care, particularly in developing countries and among poor and minority women in industrialized countries. Approximately one-fourth of pregnant women in the United States receive no first-trimester prenatal care, with a disproportionately higher percentage among Medicaid recipients and uninsured women. Specific practical measures to improve early detection in pregnant women include on-site pregnancy testing in STD clinics and drug-addiction programs of women whose menstrual periods are late, routine RPR testing whenever a positive pregnancy test is obtained in all pregnancy testing programs, and early testing by prenatal programs, before the regularly scheduled prenatal visit when the waiting time for the first scheduled visit is long. In settings with limited resources for testing and early return visit for test results and treatment, rapid clinic-based testing and treatment at the first prenatal visit is essential, even while confirmatory tests are pending.

Treatment

A positive screening RPR test should be further evaluated with a quantitative nontreponemal test (VDRL) and a confirmatory treponemal test such as the fluorescent treponemal antibody-absorption test (FTA-ABS) or microhemagglutination–*T. pallidum* (MHA-TP) test.

Women with a positive treponemal test who do not have clear documentation of previous adequate treatment for syphilis require treatment. Women with an epidemiologic history of recent exposure to an individual with proven syphilis should be treated, regardless of serologic results.

It is not necessary to re-treat women who have had documented adequate treatment for previous syphilis so long as no evidence of serologic or clinical relapse exists. If clinical or serologic relapse or reinfection occurs, therapy should, of course, be reinstituted. If doubt exists about the adequacy of previous therapy, re-treatment should be given promptly.

Treatment of syphilis in the pregnant woman is generally the same as that in the nonpregnant patient and depends on the duration of infection and the presence or absence of central nervous system involvement. Recommended choices and schedules of antimicrobials for the various clinical forms of syphilis are found in Chapters 37 and 82. Pregnant women who develop a Jarisch-Herxheimer reaction after initiation of treatment for early syphilis may have precipitous onset of preterm labor. In one report, 15 (65%) of 23 pregnant women with primary or secondary syphilis compared to none of 10 with latent syphilis experienced the Jarisch-Herxheimer reaction. Symptoms and signs developed within 2–8 hours of therapy, peaked at 6–12 hours, and abated by 16–24 hours after treatment.[131] Uterine contractions and decreased fetal movement or signs of fetal distress on fetal monitoring occurred in 67% of women with the Jarisch-Herxheimer reaction. We recommend hospitalization of women beyond 20 weeks' gestation who have early syphilis for close observation during initiation of therapy to permit fetal monitoring and early tocolytic therapy, if needed. Pregnant women treated for early syphilis should have monthly quantitative serologies throughout pregnancy. Those who do not show a fourfold drop in titer at 3 months or who show a fourfold rise in titer should be re-treated.

Pregnant women who report serious penicillin allergy should be hospitalized for desensitization and penicillin therapy, since there are no other alternatives available that provide adequate treatment to the fetus as well as the mother. Unfortunately, skin antigen testing for penicillin allergy is no longer available. Desensitization can be achieved rapidly by oral administration of increasing doses of penicillin V. One desensitization schedule used in 15 pregnant women who had positive penicillin skin tests involved a starting oral dose of 100 units of penicillin V; the oral dose was doubled every 15 minutes, for a total of 14 doses, each diluted in 30 mL of water, given over a total elapsed time of 3 hours and 45 minutes, with the final dose equal to 640,000 units.[132] Women were desensitized in the hospital, with an intravenous line in place and a physician available at all times. After a further 30-minute observation period, parenteral penicillin was begun. Five patients had evidence of allergic reaction, one requiring epinephrine. After completion of the procedure, full doses of parenteral penicillin therapy can be instituted.

■ GONORRHEA

The recognition that maternal gonococcal infection posed a threat to the newborn's sight motivated Crede's prophylaxis–a major achievement of modern preventive medicine. In the 1880s, ophthalmia neonatorum was a frequent neonatal infection. In Crede's original series, 10% of newborns acquired ophthalmia neonatorum. Rothenberg[133] estimated that the maternal gonococcal infection rate among patients studied by Crede must have approached the astounding figure of 30%.

Epidemiology

The reported prevalence of gonococcal infection among pregnant women shows wide variations, determined by differences in populations studied. Generally, studies of indigent populations in the United States have shown higher prevalence rates than studies from other industrialized countries, and rates in most of the developing world are higher. Risk factors for infection remain the same in pregnancy as in the nonpregnant state. In North America, gonococcal recovery rates are highest in young, nonwhite, unmarried mothers of low socioeconomic status, particularly in large cities. Isolates resistant to penicillin, fluoroquinolones, and other antibiotics have increased in frequency.[134]

Manifestations and pathogenesis

The manifestations and pathogenesis of gonococcal infection in the pregnant host have some unique features.[135] The rate of pharyngeal infection as the sole site of infection may be increased during pregnancy. In some studies, 15–35% of infected pregnant women have had *N. gonorrhoeae* isolated only from the throat and not from the endocervix or anal canal.[136,137] These findings suggest that the frequency of oral sexual activity relative to vaginal intercourse may be increased during pregnancy. Pharyngeal colonization with gonococci may increase the risk of dissemination (see Chapter 35), and some studies have suggested an increased risk of disseminated gonococcal infection among pregnant women.[138]

The frequency of upper genital tract involvement following endocervical gonococcal infection during pregnancy is unknown. Among nonpregnant women, 10–20% with cervical gonorrhea have clinical evidence of pelvic inflammatory disease (PID), and up to 50% of women with recently acquired gonorrhea developed signs suggesting PID in one study.[139] In contrast, acute gonococcal PID appears to be a rare event during pregnancy. Gonococcal infection in pregnancy is occasionally associated with fever and pain, and surgically verified cases of gonococcal salpingitis in pregnancy have been reported between 7 and 12 weeks' gestation (prior to obliteration of the endometrial cavity).[140] However, lower abdominal pain in pregnant women should not be ascribed to PID unless other causes of pain potentially requiring surgical treatment, such as ectopic pregnancy or appendicitis, have been ruled out.

Local cervical factors may decrease the risk for ascending gonococcal infection in pregnancy. Serum progesterone concentrations are greatly increased in pregnancy, and concentrations of progesterone 50–200 times that occurring during pregnancy are known to inhibit the growth of *N. gonorrhoeae* in vitro.[141] The menstrual cycle effects phenotypic changes in gonococci that may alter gonococcal virulence; the effects of pregnancy on phenotypic properties of *N. gonorrhoeae* have not been studied. Cervical mucus becomes impermeable to motile sperm (and perhaps impedes ascent of microorganisms) under the influence of progesterone. Perhaps most important, after the twelfth week of gestation, the chorion attaches to the endometrial decidua with obliteration of the intrauterine cavity, obstructing the route for ascending intraluminal spread of gonococci. All these factors may limit the spread of gonococci from the cervix to the endometrium and fallopian tubes during pregnancy, particularly after the first trimester.

We hypothesize that the chorioamnion itself may become the site of infection by ascending gonococci after the twelfth week of gestation. Among women hospitalized with gonococcal infection during pregnancy, in one study, 35% had septic abortion.[11] This observation has not been addressed subsequently.

In retrospective studies, data have been conflicting regarding the impact of gonococcal infection on preterm birth[142–148] (Table 80-8). Edwards et al.[144] found an increased rate of prematurity among women with positive intrapartum, but not antepartum, gonorrhea cultures. Amstey and Steadman[143] found high preterm birth rates even in women treated for gonorrhea early in pregnancy who remained culture-negative after treatment, while Charles et al.[149] found no difference in outcome between women treated early in pregnancy and those who did not have gonorrhea in pregnancy. Likewise, the association between gonorrhea and increased perinatal mortality, premature PROM, and maternal morbidity has been inconsistent among retrospective studies. Overall, data from these studies suggest that cervical gonorrhea infection in the third trimester may be a risk factor for preterm birth, PROM, and maternal febrile morbidity.

Data from recent prospective studies have been more consistent. In a case-control study of patients with preterm PROM, *N. gonorrhoeae* was isolated from 13% of patients with preterm PROM and no term controls.[150] All patients in the study had been screened and, if positive, treated for gonorrhea early in pregnancy. Two studies from Africa showed a three- to sixfold increased risk of preterm birth and low birth weight among women with untreated gonorrhea, independent of other risk factors.[146,147]

In uncontrolled studies of maternal gonococcal infection, Berstine and Bland[151] reported that 32% of women with antenatal gonococcal infection had puerperal infectious morbidity. A related observation can be found in a matched-pair analysis of 228 cases of endometritis among 4823 women following elective abortion.[152] These investigators found a threefold increased relative risk for endometritis in patients who had untreated gonococcal infection when compared with uninfected control subjects ($p < 0.05$).

In Nairobi, Kenya, Plummer et al.[153] found that postpartum endometritis was significantly correlated with intrapartum gonococcal and/or chlamydial infection. Forty-seven percent

of women with intrapartum gonococcal infection developed postpartum endometritis; approximately 22% of endometritis was attributable to gonococcal infection in this setting, where the prevalence of maternal gonococcal infection was 6%.

These studies collectively provide convincing evidence that maternal gonococcal infection is detrimental to pregnancy. Gonococcal endocervicitis may cause preterm birth, preterm PROM, and chorioamnionitis by infecting the lower pole of the chorioamnion. The effects of gonococcal infection on early pregnancy are less well studied than its effect on late pregnancy, but early infection may cause septic abortion. Acute salpingitis also occurs during the first trimester, but very infrequently. Disseminated gonococcal infection may occur more frequently during pregnancy. The risk of postpartum febrile morbidity is increased among women with cervical gonococcal infection, and neonatal gonococcal ophthalmia represents a frequent and severe complication.

Case detection and treatment

Because of these adverse effects on pregnancy, and because of the risk for neonatal infection, detection of *N. gonorrhoeae* by nucleic acid amplification tests or culture during the initial antenatal visit is justified in most populations.[154] Repeat testing at 36 to 38 weeks' gestation is also indicated among high-risk individuals. Nearly 40% of pregnant women with gonorrhea give a past history of gonorrhea; therefore, past history of gonorrhea is a strong indicator for repeated screening. In patients with preterm PROM, intrapartum fever, or septic abortion, an endocervical swab for *N. gonorrhoeae* testing also should be obtained.

In screening pregnant women for *N. gonorrhoeae*, culture on antibiotic-containing selective medium has long been the preferred method of detection, but is increasingly being replaced by the more sensitive nucleic acid amplification assays for detection of *N. gonorrhoeae* and *C. trachomatis*. Cervical, urine, and vaginal specimens appear to be equally sensitive.[155] Gram stains are not a sensitive test, and enzyme immunoassay methods and fluorescent antibody staining of direct cervical smears lack consistent sensitivity and specificity.[156–158]

Uncomplicated gonorrhea in the pregnant patient can be treated with ceftriaxone, 125 mg in a single intramuscular dose, or cefixime, 400 mg orally in a single dose.[130] In patients who cannot tolerate cephalosporins, spectinomycin, 2 g in a single intramuscular dose, should be used. Tetracycline should not be used because of potential maternal and fetal toxic effects. Azithromycin or amoxicillin, in dosages discussed below, should be added to treat possible coexisting *C. trachomatis* infections. Reinfection after treatment is common. Gonococcal reinfection rates of 11–30% have been reported despite efforts to treat partners. Notification and treatment of sexual partners should be pursued vigorously. If sexual partner therapy is not accomplished, repeat monthly testing is appropriate.

For complicated gonococcal infection in pregnancy (e.g., septic abortion, chorioamnionitis), we recommend treatment for several days with ceftriaxone or cefoxitin plus an antibiotic effective against possible coexisting chlamydial infections, as recommended for PID (see Chapter 56).

Neonatal gonococcal infection: implications for management of gonorrhea in pregnancy

In a recent study in Kenya, 42% of 67 newborns not receiving ocular prophylaxis who were exposed to maternal gonococcal infection acquired gonococcal ophthalmia neonatorum.[159] In addition to this well-recognized neonatal manifestation of exposure to maternal gonorrhea, infection at other body sites also can occur. *N. gonorrhoeae* has been recovered from orogastric aspirate samples from approximately 30% of neonates born of infected mothers.[160] Extraocular sites of neonatal gonococcal infection may be associated with a higher risk of disseminated infection.

The risk of gonococcal amniotic fluid infection syndrome and gonococcal ophthalmia appears to be increased after PROM.[161,162] The failure of silver nitrate ocular prophylaxis to prevent gonococcal ophthalmia may result from *in utero* acquisition of *N. gonorrhoeae* in the setting of PROM.[163]

Gonococcal sepsis occurs in the newborn, although infrequently today. "Natural" bactericidal antibody to gonococci resides in the IgM fraction of serum and is absent from neonatal serum.[164] Whether neonates are at higher risk for gonococcal sepsis than are adults because of this lack of protective antibody is not established. Of importance is the fact that because neonates delivered of mothers with intrapartum gonococcal infection are more likely to be preterm or to suffer prolonged labor, bacterial sepsis due to any etiology occurs more often.

For these various reasons, ophthalmic prophylaxis alone will not prevent all the manifestations and complications of gonorrhea in the neonate. Diagnostic screening and early treatment of infected women during pregnancy represent a more effective means of preventing neonatal gonococcal infection, as well as preventing complications in pregnancy itself.

In addition, in areas where the prevalence of maternal gonococcal infection is greater than 1% or where maternal screening is not undertaken, ophthalmic prophylaxis is useful and should be required.[133] The recommendations made by the Centers for Disease Control and Prevention for the prevention of gonococcal ophthalmia neonatorum (also endorsed by the American Academy of Pediatrics) state that ophthalmic ointment or drops containing 1% tetracycline, 0.5% erythromycin, or 1% silver nitrate are effective and acceptable. One randomized clinical trial of prophylaxis for gonococcal ophthalmia compared the effectiveness of 1% silver nitrate with 1% tetracycline ointment, and one study compared each of those agents to 0.5% erythromycin ointment.[165,166] Both studies found the agents studied to have similar efficacy in reducing the incidence of gonococcal ophthalmia. The prophylactic agents also were highly effective against multidrug resistant *N. gonorrhoeae*. However, the efficacy of topical 1% tetracycline in preventing gonococcal ophthalmia in neonates exposed to gonococci with resistance to tetracycline (25% of US gonococcal isolates in 1995 and a much higher percentage of isolates from other regions) remains uncertain.

Neonates born to mothers with documented untreated antepartum or intrapartum gonococcal infection are at high risk for infection and should receive parenteral antibiotics in standard curative dosage (see Chapter 83) in addition to topical ocular prophylaxis.

C. TRACHOMATIS INFECTIONS

Epidemiology

C. trachomatis infection rates for pregnant women have varied from 2% to 30%. Single marital status and young age, especially adolescence, are the major demographic correlates of chlamydial infections in pregnancy. Adolescents studied routinely have a prevalence of chlamydial infection of over 10%.[167] Although chlamydial infection rates have been highest among nonpregnant women in inner cities, higher rates of chlamydial infection have been reported among pregnant women in rural compared with urban areas in some parts of the country.[168]

Whether pregnancy per se influences shedding of *C. trachomatis* from the cervix is unknown. The rate of isolation of *C. trachomatis* has been reported to be higher during the third trimester than during the first or second trimester.[169,170] However, women who sought prenatal care in the first trimester in these cross-sectional studies may have had a lower risk of bacterial STI than those who did not seek care until the third trimester. Shedding of *Chlamydia* might be influenced by the frequent development of ectopy in pregnancy, which is positively correlated with *C. trachomatis* isolation in nonpregnant women, or by alteration of the immune response to the organism.

Maternal IgG antibody undergoes active transplacental transfer beginning as early as day 38 after conception.[171] The level of transfer remains fairly constant until the seventeenth week of gestation, at which time proportionate increases occur with advancing gestational age. Infants born to seropositive mothers with current or past *C. trachomatis* infection acquire antibody to this organism. Since about two-thirds of exposed neonates become infected (see Chapter 83), it is clear that passively acquired antibody is not completely protective. The influence of maternal antibody on the risk of acquisition of infection or on the severity of disease is unknown. The presence of antibody to *C. trachomatis* in breast milk or colostrum and the role of such

colostral antibody in preventing or modifying neonatal chlamydial infection have not yet been evaluated.

Influence of C. trachomatis on reproduction and pregnancy

In some areas, up to two-thirds of cases of tubal infertility have been attributed to *C. trachomatis* infection.[172] If incomplete blockage of fallopian tubes occurs with infection, there is an increased risk of ectopic pregnancy (see Chapters 56 and 79). In one study, 10 (59%) of 17 of patients with a history of ectopic pregnancy had antibodies to *C. trachomatis*.[173] In another case-control study, more women with ectopic pregnancy not related to intrauterine devices or previous tubal ligation had antibodies to *C. trachomatis* than did women with intrauterine pregnancies [18 of 32 (56%) versus 11 of 49 (22%), $p = 0.0021$].[174] Kosseim et al.[172] estimated that approximately one-third of cases of ectopic pregnancy may be attributable to chlamydial infection. Whether *C. trachomatis* infection can cause abortion is unknown. C. psittaci infection is an important cause of spontaneous abortion in other mammals,[175] and Schachter[176] reported that *Chlamydia* were isolated from 4 of 22 first-trimester spontaneous abortuses in humans. Further work is needed to define the relationship of chlamydial infection to abortion.

The role of genital *C. trachomatis* infection in prematurity and in perinatal mortality has been under active investigation. Examination of birth weights and gestational ages of infants with *C. trachomatis* infection has given conflicting results. Of infants with *C. trachomatis* ophthalmia neonatorum, 15–42% have had birth weights less than 2500 g.[162,177,178] Prospective studies of *C. trachomatis* and pregnancy outcome are summarized in Table 80-9.[179–185] Three separate studies at the University of Washington, each involving a different study design, have all shown a correlation of antenatal chlamydial infections with prematurity, defined by preterm delivery and/or low birth weight.[180,183,186] However, Frommell et al.[187] and Heggie et al.[188] found no association of antenatal *C. trachomatis* infection with prematurity. In a prospective study of 1365 pregnant women, Harrison et al.[179] observed no significant correlation of *C. trachomatis* infection with prematurity but did find a significantly increased risk of low birth weight and of preterm PROM and a shorter gestation among women with serologically defined primary infection with *C. trachomatis* than among other culture-positive women or among culture-negative women. Similarly, Berman et al.[184] and Sweet et al.[182] confirmed the association of preterm birth with IgM seropositivity among *C. trachomatis* culture-positive women. The biologic basis for these serologic correlations among *C. trachomatis* infected women is not defined. Possibilities could include higher bacterial load and/or more extensive chlamydial infection or inflammation in a relatively nonimmune host. In an early study, Martin et al.[180] observed a correlation of antenatal *C. trachomatis* infection not only with preterm birth but also with perinatal mortality. The latter observation has not been confirmed in other studies.

The role of C. trachomatis in maternal puerperal morbidity

Studies of pregnant women in Seattle and in Nairobi, Kenya, have confirmed that antepartum chlamydial infection, if not treated, is correlated with puerperal infection. Wager et al.[114] found that intrapartum fever (clinically ascribed to amnionitis) and late postpartum endometritis were both significantly correlated with untreated antepartum chlamydial infection (Table 80-10). Overall, among women who delivered vaginally, puerperal infectious morbidity occurred in 10 (34%) of 29 women with and in 23 (8%) of 300 women without antenatal *C. trachomatis* infection ($p < 0.001$). Plummer et al.[153] subsequently reported from Nairobi that 24% of 183 women with intrapartum chlamydial infection developed postpartum endometritis, a rate significantly greater than that observed in uninfected women (15%, $p = 0.02$). Chlamydial infection accounted for approximately 22% of endometritis in this setting; this rate may be representative of other African populations in the absence of routine prenatal screening for *C. trachomatis*. These studies collectively suggest that antepartum *C. trachomatis* infection causes amnionitis and late postpartum endometritis, although attempts generally have not been made to isolate *C. trachomatis* at the time these complications have occurred.

Postabortal pelvic inflammatory disease

A syndrome related to postpartum pelvic infection is seen following therapeutic abortion. An excess rate of postabortal PID has been seen among women with chlamydial infection at the time of the procedure.[17,189,190] In settings where gonococcal infection is much less prevalent than chlamydial infection, up to 60% of cases of postabortal PID may be attributable to chlamydial infection. In one study, the risk of postabortal PID among *Chlamydia*-infected women was inversely related to serum antibody titers to *Chlamydia*.[191] We recommend that women undergoing therapeutic abortion should be screened for chlamydial infection to prevent postabortal ascending infection. As noted below, BV also has been associated with postabortal pelvic infection, and it is quite likely that in some populations gonococcal infection also contributes to this condition.

Current recommendations for diagnostic testing for chlamydial infection during pregnancy

The importance of detecting and treating chlamydial infection of the genital tract in pregnant women is certainly no less than in nonpregnant women. In fact, the unquestioned risk of intrapartum transmission to the neonate and the growing evidence that chlamydial infections cause complications of pregnancy and postpartum pelvic infection dictate that a very high priority be given to detecting and treating chlamydial infection in pregnant women. Nucleic acid amplification tests provide a rapid and highly sensitive means to screen for *C. trachomatis* and *N. gonorrhoeae* simultaneously.[155] The ability to test cervical, vaginal, and urine specimens makes these assays relatively easy to perform even in settings where a speculum examination may be less feasible.

As a minimum preventive intervention at present, we advocate selective diagnostic testing of pregnant women who are at high risk for chlamydial infection. A strong argument could be made for screening all pregnant women for *C. trachomatis*, particularly those less than 25 years of age.

Treatment

Tetracyclines, the drugs of choice for *C. trachomatis* infection in nonpregnant adults, cannot be recommended for

Table 80-10. Puerperal Infectious Morbidity in Patients With and Without Antepartum *Chlamydia Trachomatis* Infection, Matched for Demographic Characteristics and Parity

	C. trachomatis Isolated ($N = 32$)		*C. trachomatis* Not Isolated ($N = 350$)		
Complication	Number	Percent	Number	Percent	
Intrapartum fever >38°C	3	9	5	1	<0.025

Total infectious morbidity	11	34	49	14	<0.01

From Wager GP et al. Puerperal infectious morbidity: Relationship to route of delivery and to antepartum Chlamydia trachomatis infection. *Am J Obstet Gynecol* 1980; 138: 1028.

pregnant or breastfeeding women. Azithromycin and amoxicillin are considered the drugs of choice for treating chlamydial infections in pregnant women.[130] A single dose of azithromycin, 1 g, is optimal as this regimen is simple, safe, effective, and well tolerated in pregnancy.[192] Alternatives include erythromycin base or erythromycin ethylsuccinate for 7 days; however, adherence to these regimens may be less than perfect because of gastrointestinal side effects. In pregnancy, a test of cure should be obtained 3 weeks after treatment to assure clearance of infection.

Prevention of neonatal C. trachomatis infections

Hammerschlag et al.[193] reported that erythromycin ocular ointment was significantly more effective than 1% silver nitrate in preventing neonatal chlamydial conjunctivitis. A later study found 0.5% erythromycin ointment to be of similar efficacy to 1% tetracycline ointment or 1% silver nitrate.[166] Others have been unimpressed with the use—effectiveness of topical erythromycin for this purpose in actual practice.[194] Laga et al.[165] compared 1% tetracycline ointment and 1% silver nitrate drops for the prevention of chlamydial ophthalmia. Both agents reduced the incidence of chlamydial conjunctivitis 68–77% in comparison with a historical control group of newborns who had not received ocular prophylaxis. Nonetheless, long-term follow-up of infants exposed to maternal chlamydial infection who received ocular prophylaxis revealed that 23–31% ultimately developed ocular *C. trachomatis* infection.[195] Most of these infections were subclinical. As with gonococcal infection, the detection and treatment of chlamydial infection during pregnancy, together with ocular prophylaxis, would be preferable to neonatal ophthalmic prophylaxis alone.

GENITAL MYCOPLASMAS

Many reproductive disorders have been ascribed to infection with the genital mycoplasmas, *U. urealyticum* and *M. hominis*. However, the ubiquity of these organisms and the high frequency of other coexistent risk factors for adverse pregnancy outcome and coinfection with other bacterial STI agents make it difficult to assess their etiologic roles in such disorders. Isolation of *M. hominis* is strongly associated with the presence of BV, making it difficult to differentiate adverse effects related to *M. hominis* from the other bacteria found at increased levels in BV. *M. hominis* has been linked to preterm birth, endometritis, and postpartum fever, while *U. urealyticum* has been associated with amniotic fluid infection, chorioamnionitis, low birth weight, and preterm birth.

Several studies have compared the rate of detection of genital mycoplasmas among women with spontaneous abortion compared with those with continuing pregnancies. The majority have shown no difference in recovery of either *U. urealyticum* or *M. hominis,*[181,196,197] with one study finding a lower rate of *U. urealyticum* recovery from women with spontaneous abortion.[179] All have been limited by the high frequency of *Mycoplasma* carriage, lack of testing for many other microorganisms, and poor characterization of other risk factors in the population. Harwick et al.[198] detected *M. hominis* bacteremia in 8% of women with febrile abortion versus none of those with afebrile abortion. Serologic evidence of infection with *M. hominis* was found in 50% of septic abortions versus 17% of afebrile abortions. These provocative data require confirmation, with studies of other relevant microbial species together with *M. hominis*. Several studies have found an increased frequency of isolation of genital mycoplasmas from spontaneous abortions than from induced first- and second-trimester abortions,[199,200] but it is unclear whether the infection was present before embryonic or fetal death or occurred as a consequence of nonviability of the pregnancy. In a more recent study, isolation of *U. ureaplasma* from products of conception did not correlate with the presence of histologic inflammation among specimens from spontaneous abortions.[201] Among women with recurrent miscarriage, the rate of isolation of genital *Mycoplasma* from the cervix was similar to the rate among control patients, but *Mycoplasma* were isolated from the endometrium more frequently among women with spontaneous abortion (28%) or infertility (50%) than among controls (7%).[202] Uncontrolled studies have suggested a benefit from treating women with recurrent abortion and genital *Mycoplasma* colonization with doxycycline or erythromycin, but controlled studies are lacking.[202,203] In summary, current data do not support a significant role for *M. hominis* or *U. urealyticum* in spontaneous first- or second-trimester abortion.

U. urealyticum and *M. hominis* must be considered individually when evaluating the potential role of genital mycoplasmas in prematurity. The isolation of *M. hominis* from the lower genital tract is strongly associated with the clinical or Gram stain diagnosis of BV, making it difficult to assess the independent contribution of *M. hominis* to prematurity, if any.[204,205] Isolation of *U. urealyticum* from the lower genital tract during pregnancy is more common with young maternal age, black race, first pregnancies, low income, being unmarried or less educated, having more sexual partners, smoking, and use of marijuana or cocaine, all factors previously associated with an increased risk of preterm delivery.[206] Thus, colonization with *U. urealyticum* may be a marker for other factors contributing to preterm birth, and not necessarily a primary pathogen. Studies of lower genital tract colonization and pregnancy outcome are summarized in Table 80-11.[179,184,196,206–215] Overall, the data do not suggest an increased risk of preterm delivery or low birth weight among women colonized in the lower genital tract with *U. urealyticum,* with prevalences ranging from

Table 80-11. Cohort Studies of *Ureaplasma Urealyticum* in the Lower Genital Tract and Pregnancy Outcome

UU, Ureaplasma urealyticum; BW = birth weight; del, delivery.

44% to 81%. Likewise, treatment studies using erythromycin in colonized women have not shown clear benefit in reducing prematurity. McCormack et al. demonstrated higher birth weights among colonized women treated in the third trimester for at least 6 weeks with erythromycin compared with placebo but did not show benefit with second-trimester therapy.[216] In the large, multicenter NICHD Collaborative Study of vaginal infections in pregnancy among 1181 women with *U. urealyticum,* administration of erythromycin for up to 14 weeks during the third trimester had no effect on birth weight, gestational age at delivery, or neonatal outcome in comparison with women randomized to placebo.[217] The recovery rates of *U. urealyticum* at delivery were similar between the erythromycin- and placebo-treated groups, probably because erythromycin has minimal antimicrobial activity at the lower pH of the vagina. Reports of eradication of *U. ureaplasma* from the amniotic fluid with erythromycin suggest potential activity of erythromycin at that site,[218] although efficacy for treating chorioamnion infection has not been evaluated.

Upper genital tract (amniotic fluid, chorioamnion) infection with several facultative or anaerobic bacteria has been strongly associated with preterm delivery and low birth weight, but isolation of *U. urealyticum* from the amniotic fluid is less clearly associated with preterm birth. In several studies of women in preterm labor with intact membranes, those with other bacteria in the amniotic fluid presented in preterm labor at 27–29 weeks' gestation and delivered within 1 day of admission. Women with negative amniotic fluid cultures presented with preterm labor at 31–32 weeks and delivered an average of 5 weeks after onset of preterm labor. Like those with negative cultures, women with *U. urealyticum* alone in the amniotic fluid also presented at 31–32 weeks' gestation, with an average interval to delivery of 4–5 weeks.[59,66] Chorioamnion infection with *U. urealyticum* has been found more commonly among women delivering preterm than among those delivering at term in case-control studies, but this has not been confirmed in cohort studies of prematurity. In fact, the presence of other bacteria in the chorioamnion was more consistently related to prematurity, as in the studies employing amniotic fluid cultures. However, isolation of *U. urealyticum* from the chorioamnion has been consistently associated with histologic chorioamnionitis in all studies.[25,26,29] These data suggest that *U. urealyticum* may induce a form of chorioamnionitis that is perhaps indolent and does not frequently lead to preterm delivery.

Whether or not *U. urealyticum* in the upper genital tract is a factor causing preterm delivery or a secondary finding,

U. urealyticum has been implicated as a cause of congenital and neonatal pneumonia, especially in preterm infants.[219] In addition, *U. ureaplasma* infection among infants weighing less than 1250 g at birth appears to increase the risk of chronic lung disease by two- to threefold, possibly through an indolent, undiagnosed pneumonia.[219] Thus far, *M. hominis* has not been implicated as a cause of neonatal pneumonia or chronic lung disease.

Data link *M. hominis* to postpartum fever. Platt et al.,[220] in their follow-up study of 535 patients, found that 14 (50%) of 28 postpartum fevers were associated with rises in titers of antibody to *M. hominis*. Positive genital colonization and low predelivery antibody titer to *M. hominis* were predictive of postpartum fever. Harrison et al.[179] also reported a significantly increased risk of postpartum fever among women with antepartum *M. hominis* colonization who were delivered vaginally. However, given the strong association between vaginal *M. hominis* isolation and BV, increased relative risk of PPE with BV,[112] and the almost uniform isolation of other microorganisms with *M. hominis* from the endometrium,[111] it is unclear which microorganisms are most important in the infection. Only a small proportion of colonized women developed this complication.

M. genitalium is a fastidious organism associated with nongonococcal urethritis, cervicitis, and PID.[221–223] This organism cannot be cultured and requires molecular methods such as PCR for detection.[224] Since *M. genitalium* is associated with PID, it is plausible that this organism could invade the upper genital tract in pregnancy and possibly cause adverse pregnancy outcome. To date, the evidence linking *M. genitalium* and preterm birth are conflicting. One case-control study in Lima, Peru, showed a twofold increased risk of preterm birth associated with *M. genitalium*,[225] whereas other studies have not shown an association with preterm birth or other adverse pregnancy outcome.[226] Further study is required to understand whether this is a significant pathogen in pregnancy.

Current recommendations for management of genital Mycoplasma infection during pregnancy

Colonization of the lower genital tract with *M. hominis* or *U. urealyticum* does not appear to increase the risk of spontaneous abortion, preterm delivery, or preterm PROM, and routine screening of pregnant women for these microorganisms is therefore not recommended. The presence of *U. urealyticum* in the upper genital tract is clearly related to histologic chorioamnionitis but not necessarily to preterm birth. Isolation of *U. urealyticum* alone from the amniotic fluid is not an indication for delivery, but treatment with erythromycin could be considered. Further study of the impact of *Ureaplasma*-induced inflammation on preterm birth (chorioamnionitis) and neonatal chronic lung disease (pneumonitis) in preterm infants is required before routine treatment is recommended. Inclusion of antimicrobials with activity against genital mycoplasmas does not appear to be required in the antimicrobicidal treatment of women with postpartum endometritis, but might be considered for women with recalcitrant infections or for those in whom other bacteria cannot be isolated.

BACTERIAL VAGINOSIS

BV is characterized by a nonpurulent, homogeneous, malodorous vaginal discharge, by an increase in vaginal pH, by the presence of characteristic amines and organic acids in vaginal fluid, and by changes in vaginal flora with a decrease in H_2O_2-producing facultative *Lactobacillus* and an increase in frequency and concentration of *Gardnerella vaginalis, M. hominis*, and several anaerobic species[227] (see Chapters 18 and 42).

The prevalence and natural history of BV are similar in pregnant and nonpregnant women.[204,227,228] BV is detected in 12–50% of pregnant women depending on the population studied and the method of diagnosis. Factors associated with an increased risk of BV among pregnant women have included African American race, being unmarried, and not having used antibiotics recently.[228,229]

BV and pregnancy complications

A growing body of evidence links BV with an increased risk for pregnancy complications, including postabortal infections, preterm labor and delivery, preterm PROM, fever during labor, and postpartum endometritis (see Chapter 42). In studies from Sweden, the risk of postabortal infection was found to be elevated among women with clue cells in the vagina,[230] and the elevated risk of infection was reduced among women with BV by treatment with metronidazole before and after the procedure.[18]

Among women with clinically diagnosed amniotic fluid infection during labor, *G. vaginalis, M. hominis*, *P. bivia,* and peptostreptococci were frequent isolates.[231] Women with BV were significantly more likely to develop clinical manifestations of amniotic fluid infection than those with normal vaginal flora on Gram stain.[68,112,231] In addition, detection of BV by Gram stain at delivery has been associated with an odds ratio of 5.8 for the development of post-Cesarean endometritis.[112] Microorganisms associated with BV are isolated in over 60% of women with post-Cesarean endometritis,[111] and these same bacteria have been associated with increased rates of wound infection after Cesarean delivery.[232] BV clearly increases the risk of maternal morbidity during pregnancy.

Of even greater significance is the association of BV with preterm PROM, and preterm birth. Table 80-12 summarizes several studies that established BV as a risk factor for pregnancy complications.[183,186,204,233–239] BV consistently has been identified as a risk factor for preterm delivery, with odds ratios of 1.4–6.9. When preterm PROM was assessed, this also was increased by a factor of 2.1–7.3. The potential role of BV in initiating or continuing preterm labor leading to

delivery is further indicated by the frequent detection of BV-associated bacteria in the amniotic fluid of women with preterm labor and intact membranes,[59,66] by isolation of BV-associated bacteria from the chorioamnionic membranes more commonly from women delivering preterm than from those delivering at term,[23] and by the association of such bacteria with histologic inflammation. Most important, systemic (oral) therapy for BV has decreased the rate of preterm birth in studies of pregnant women at high risk of preterm birth240–242 (Table 80-13). However, the data are conflicting regarding efficacy of BV treatment to prevent preterm birth in subsequent large treatment trials of lower-risk populations. The late timing of therapy and specific antibiotic strategy may have contributed to the lack of protection seen in one large multicenter trial.[243] A more recent randomized trial utilizing oral clindamycin in the early second trimester for treatment of asymptomatic BV among low-risk pregnant women demonstrated a significant reduction in late miscarriage and preterm birth.[244] The inconsistent efficacy of topical clindamycin therapy in preventing BV-associated prematurity[235,245–249] may be related to a lack of effect on established, indolent upper tract infection or to effects related to vaginal overgrowth by *E. coli* and enterococcus.[205] In summary, these data suggest that pregnant women with BV who are at increased risk of preterm birth may benefit from treatment, while treatment for asymptomatic, low-risk pregnant women is probably not justified.

G. vaginalis infrequently has caused neonatal bacteremia, cutaneous abscess, and congenital pneumonia.[250] Anaerobes, however, may be relatively important in neonatal sepsis. Neonatal anaerobic sepsis is often associated with prematurity, amniotic fluid infection, and prolonged ineffective labor. Chow et al.[251] found that 26% of all cases of neonatal bacteremia observed at their institution were associated with anaerobes, with 1.8 episodes of anaerobic bacteremia per 1000 live births. Anaerobic isolates were identified predominantly as species belonging to *Bacteroides, Peptococcus,* and *Peptostreptococcus*. The anaerobic flora associated with BV may provide a large inoculum and thus increased risk of anaerobic sepsis in the neonate.

Case detection and treatment

The sensitivity and specificity of methods available for the diagnosis of BV (see Chapter 42) do not seem to be altered by pregnancy. The two most practical methods for clinical use in pregnancy are the clinical criteria and vaginal Gram stain. BV

[a]In McDonald's study, a subset analysis of women with a prior preterm birth who were randomized to oral metronidazole showed a significant reduction in recurrent preterm birth.[242]

is diagnosed clinically when at least three of the following criteria are present: (1) vaginal pH above 4.5, (2) thin, homogeneous white or gray vaginal discharge, (3) clue cells present on saline preparation of vaginal discharge, and (4) presence of fishy amine odor with addition of 10% potassium hydroxide to vaginal fluid.[252] Diagnosis of BV by vaginal Gram stain is based on an absence or decrease of *Lactobacillus* morphotypes and an increase in small gram-variable or gram-negative rods (*G. vaginalis* and *Bacteroides morphotypes*) with or without the presence of curved gram-variable rods (*Mobiluncus* morphotypes).[253] Gram stain diagnosis may be especially helpful in the presence of bleeding or ruptured amniotic membranes when the pH and other clinical signs may be altered. Pregnant women with symptomatic vaginal discharge should undergo pelvic examination, pH testing, vaginal wet mount or Gram stain examination, and if indicated, testing for other bacterial STI. Current data suggest that pregnant women with a previous preterm delivery after preterm labor or PROM should be screened routinely and offered treatment for BV if it is present. Currently, the potential benefit in reducing preterm birth of screening low-risk pregnant women and treating those with BV remains unproven. In the absence of definitive data, we recommend screening and treatment of BV in pregnancy for all women at high risk for preterm birth, ideally as early in pregnancy as possible. Women should be offered treatment with oral metronidazole, 500 mg twice daily for 7 days, or oral clindamycin, 300 mg twice daily for 7 days. Oral metronidazole appears to be safe and well tolerated in the first trimester.[254,255] Although topical therapy with intravaginal clindamycin or metronidazole has been found effective in eliminating BV,[205,256] systemic therapy is desirable to eradicate any potential colonization of the decidua and amniotic fluid. Pregnant women with symptomatic BV who are not at high risk for preterm birth may also be offered treatment to ameliorate their symptoms, and in this case, either oral or intravaginal metronidazole would be acceptable. Intravaginal clindamycin should be avoided in the second half of pregnancy, as this treatment has been associated with an increased risk of preterm birth.[235,245,257] Routine treatment of male sexual partners has not been shown to

reduce rates of recurrent BV, although there is some evidence that BV may be sexually transmitted between women.[258] Treatment of female sexual partners may be reasonable, although there are no data as yet to show efficacy.

TRICHOMONAS VAGINALIS VAGINITIS

The prevalence of *T. vaginalis* infection in pregnancy has ranged from 3% to 48% depending on the population studied. Among 13,816 pregnant US women studied between 23 and 26 weeks' gestation at six urban centers in the Vaginal Infections and Prematurity Study (VIP Study) during the late 1980s, the culture-positive rate was 12.6%.[259] Factors associated with having *T. vaginalis* in this study were black race, cigarette smoking, single marital status, less education, a history of gonorrhea, greater number of lifetime sexual partners, and lack of barrier or hormonal contraception in the 6 months before pregnancy. Many of these factors have been noted in other studies and are also associated with an increased risk of preterm delivery. Thus, sociodemographic factors and coexisting infections also must be taken into account when assessing a possible role of *T. vaginalis* in preterm birth.

T. vaginalis has been associated with an increased risk of preterm delivery,[236,260–262] preterm PROM,[211,263] and maternal puerperal morbidity.[264] The largest cohort study to evaluate lower genital tract infections and preterm birth, the VIP Study discussed above, has noted a 1.3-fold increased risk of preterm birth with *T. vaginalis* detected by culture at 23–26 weeks of pregnancy, even after adjustment for demographic, behavioral, and other infectious factors associated with preterm birth.[262] The potential role of *T. vaginalis* in preterm birth is further supported by in vitro studies showing that clinical *T. vaginalis* isolates and cell-free filtrates decrease the elasticity, the work to rupture, and the bursting tension of chorioamniotic membranes in an inoculum-dependent fashion.[265] This effect may be due to the organism itself, the proteases produced, the host inflammatory response, or a combination effect.

In 1931, Bland et al.[264] reported postpartum fever in 48% of 92 women with untreated antenatal trichomoniasis, compared with 25% of 110 women without trichomoniasis ($p = 0.001$). The difference was independent of race. Possible confounding by other STI and BV and by several other risk factors was not addressed, and the results were not subsequently confirmed by Trussell et al.,[266] who noted postpartum fever in 8.5% of 223 women with trichomoniasis compared with 8.3% of 657 women without trichomoniasis. It remains uncertain whether *T. vaginalis* might produce intra- or postpartum pelvic infections either on their own or through associated increases in anaerobic vaginal flora.

Neonatal infection with *T. vaginalis* is detected infrequently and causes little morbidity. Because of estrogenic influence during pregnancy, the vaginal mucosa of female neonates is susceptible to infection or colonization with *T. vaginalis*. This is reversed spontaneously within 3–4 weeks after delivery. The risk of neonatal infection with *T. vaginalis* overall is less than 1% and among exposed neonates is approximately 5%. Purulent vaginitis and urinary tract infection have been described as neonatal manifestations of infection.[267] Recently, *T. vaginalis* has been suspected as a cause of some cases of neonatal pneumonia.

Case detection

Whether totally asymptomatic pregnant women should undergo screening for *T. vaginalis* is unsettled. Vaginal culture is more sensitive than direct microscopy of vaginal secretions, but *T. vaginalis* can be detected by microscopy in most women with symptomatic disease.[268,269] Inoculation of vaginal secretions into commercial culture systems will detect the 25–50% of vaginal trichomonal infections that are asymptomatic (see Chapter 43). Vaginal fluid should be examined microscopically at any antenatal visit on all women with symptoms or signs of vaginitis; and in view of the association of *T. vaginalis* infections with preterm birth, screening of all pregnant women who are considered at increased risk for preterm birth or for *T. vaginalis* infection should be considered, using either wet-mount examination, culture, or DNA probe examination. Trichomonal infections suspected on Papanicolaou smears of the cervix should be confirmed by wet-mount examination or culture before treatment during pregnancy.

Treatment

Most clinicians would recommend treatment with oral metronidazole for pregnant women with symptomatic infections. Treatment of asymptomatic *T. vaginalis* in pregnancy is more controversial. Although this organism is clearly associated with preterm birth and puerperal morbidity, one multicenter randomized trial that treated asymptomatic pregnant women in the early third trimester actually demonstrated an increase in preterm birth after metronidazole treatment.[270] It is possible that treatment early in pregnancy would be more effective in preventing preterm birth; this requires further investigation. Metronidazole is safe, effective, and well tolerated in the first trimester.[254,255] Clotrimazole, used intravaginally, has reportedly relieved symptoms in some women with *T. vaginalis* vaginitis and thus represents an alternative treatment, although a topical therapy could not be expected to decrease preterm birth risk. Other alternative treatments are discussed in more detail in Chapter 43.

SUMMARY: APPROACH TO MANAGEMENT OF SEXUALLY TRANSMITTED DISEASES IN PREGNANCY AND THE PERINATAL PERIOD

The most important approach to preventing pregnancy morbidity related to bacterial STI is to prevent infection in women of reproductive age through effective STI prevention programs. Another central prerequisite is ensuring adequate, early prenatal care for all women; the potential for early detection and preventing STI-related morbidity in pregnancy represents one of the strongest arguments for extending prenatal care to all women. As an initial approach to the management of STI in pregnancy, a standard history concerning sexual behavior and past STI should be obtained from all pregnant patients. Information on age, ethnicity, socioeconomic status, marital status, and health care behavior also may help identify those at highest risk of having a bacterial STI. Specific questions, for example, should include (1) prior modes of contraception including intrauterine device use, (2) previous history of gonorrhea, chlamydia, syphilis, HIV infection, vaginitis, genital warts, genital herpes, or PID, (3) current sexual habits, number of current sexual partners (e.g., last 2 months), partner characteristics, and likelihood of having a high-risk partner (4) past sexual experience (e.g., age at first coitus, lifetime number of sexual partners), and (5) intravenous or other drug abuse history that could predispose to transactional sex (cocaine, methamphetamines). Patients should be advised about the risks of acquiring STI during pregnancy and provided with concrete information about how to reduce sexual risk, including safer sexual practices and assessment of the potential risk from their partners.

Pregnant women in most populations should routinely undergo cervical, urine, or vaginal screening tests for gonorrhea and chlamydia and serologic testing for syphilis. Those with a history of past gonococcal infection, who have more than one current sex partner or whose partner has multiple partners should be screened again in late pregnancy. BV or trichomoniasis should be screened for in women at high risk of preterm birth or with vaginal symptoms, as discussed earlier.

During pregnancy, a number of clinical situations occur in which the patient should be evaluated for selected STI. Dysuria, a common complaint in pregnancy, should not be automatically attributed to urinary tract infection without excluding vaginitis, cervicitis, or urethritis as possible causes

Table 80-14. Disorders of Pregnancy and the Puerperium That Have Been Associated with Bacterial STI Agents in One or More Studies

Clinical Event	Associated STD Agents
Ectopic pregnancy	Prior *C. trachomatis* infection; also, 50% of cases have histologic evidence of prior salpingitis
Spontaneous abortion	*N. gonorrhoeae,* bacterial vaginosis
Post therapeutic abortion-pelvic inflammatory disease	*C. trachomatis, N. gonorrhoeae,* bacterial vaginosis
Premature delivery, premature and prolonged rupture of membranes	*C. trachomatis, N. gonorrhoeae,* bacterial vaginosis, *M. hominis, U. urealycticum, T. pallidum, Trichomonas vaginalis*
Amniotic fluid infection	Bacterial vaginosis, *N. gonorrhoeae, Ureaplasma urealyticum*
Congenital abnormalities	*T. pallidum*
Intrauterine growth restriction	*T. pallidum*
Puerperal endomyometritis	
Early (<48 h postdelivery)	Bacterial vaginosis, *Strep. agalactiae, U. urealyticum, M. hominis, T. vaginalis*
Late (>48 h postdelivery)	*C. trachomatis*
Perinatal	
Stillbirth	*T. pallidum, C. trachomatis*
Neonatal death, neonatal infection	*N. gonorrhoeae, C. trachomatis, T. pallidum*

(see Chapter 55). Both gonorrhea and chlamydial infection can cause dysuria. Endocervical, vaginal, or urine assays for *N. gonorrhoeae* and *C. trachomatis* should be obtained from women at any stage of gestation who have signs of mucopurulent cervicitis or a history of exposure to a sex partner with urethritis. Neonatal chlamydial conjunctivitis or pneumonia dictates examination and treatment of mother and father for chlamydial infection. It is to be emphasized that in the setting of neonatal STI, both parents must be interviewed, examined, and treated where appropriate. Women with otherwise unexplained complications such as septic abortion, preterm labor, preterm PROM, and intrapartum fever should be evaluated for STI. Treatable infections (e.g., *N. gonorrhoeae* and *C. trachomatis*) should always be excluded in women with these complications. Women with late-onset endometritis also should be evaluated for *C. trachomatis* infection.

Special surveillance of the neonate may be necessary when the mother is at high risk for STI or develops puerperal infection or intrapartum fever. Such neonates may have to be closely monitored in the hospital for clinical evidence of sepsis and out of the hospital for evidence of ocular or respiratory infection. Considerable controversy surrounds the use of neonatal ocular prophylaxis. To permit initial maternal–neonatal bonding, the American Academy of Pediatrics recommendations allow for prophylaxis to be delayed for up to 1 hour following birth. Presently, silver nitrate, erythromycin, and tetracycline ointment have all been recommended for the prevention of gonococcal ophthalmia neonatorum. An additional benefit of ocular prophylaxis may be the prevention of chlamydial conjunctivitis; the 1-hour delay in applying prophylaxis may reduce the efficacy of prophylaxis for this purpose.

In summary, as shown in Table 80-14, a spectrum of clinical events occurring during pregnancy is associated with infection by bacterial STI agents. The obstetrical consequences of antepartum bacterial STI largely have been neglected until recently and, in fact, represent one of the most important areas for future research on STI. Many studies have shown a relationship of individual STI agents to specific obstetrical complications, as reflected by the large number of citations in this relatively selective review of bacterial STI in pregnancy. Many studies are sometimes difficult to interpret because coinfection with more than one STI agent is common and infection itself may be associated with other noninfectious risk factors for obstetrical morbidity. Primary or new infection with particular STD agents may carry a higher risk than chronic or recurrent infection with the same agents. It may be that coinfection with multiple bacterial STI agents is synergistic in causing obstetrical morbidity. For example, primary infection with an agent such as *C. trachomatis* or *N. gonorrhoeae* might produce chorioamnionitis and lead to preterm PROM, which in turn might lead to a particularly high risk of amniotic fluid infection syndrome in the presence of BV or *T. vaginalis* because of the increased concentration of anaerobic pathogens and/or pro-inflammatory cytokines in the vagina with these vaginal infections. Thus study of the impact, diagnosis, treatment, and prevention of bacterial STI in pregnancy must remain a high priority.

81 Pregnancy and Viral Sexually Transmitted Infections

D. Heather Watts

Several viral STIs may have a significant effect on pregnant women and their fetuses and infants. While primary viral infections such as rubella during gestation are most often associated with adverse effects in pregnancy, several of the sexually transmitted viral infections may cause significant maternal and infant morbidity even with recurrent infection. The changes during pregnancy that may increase the susceptibility to STIs are discussed in Chapter 80. The impact and management of viral agents with sexual transmission as a major feature including cytomegalovirus (CMV), herpes simplex virus (HSV), human papillomavirus (HPV), and hepatitis B virus (HBV) are summarized here. Management of HIV-1 infection during pregnancy is discussed in Chapter 85.

CYTOMEGALOVIRUS INFECTION

CMV is the most common cause of congenital viral infection of the fetus and is the most common infectious cause of mental retardation. The role of sexual transmission in the epidemiology of CMV is discussed in Chapter 25, and the management of pediatric CMV infections is discussed in Chapter 84.

EPIDEMIOLOGY OF CMV INFECTION DURING PREGNANCY

Several studies have shown increasing rates of isolation of CMV from pregnant women with advancing gestation. Women with the highest prevalence of CMV infection may tend to seek care later in pregnancy. Stagno et al.[1] isolated CMV from nonpregnant women at the same rate as from demographically similar pregnant women studied in the third trimester and suggested that lower rates of recovery in early pregnancy are actually due to suppression of CMV shedding in early pregnancy rather than to increased shedding in late pregnancy. Epidermal growth factor, which interferes with the tissue culture isolation of CMV, is present in urine during early pregnancy and may artificially suppress recovery of CMV early in pregnancy.[2]

Reynolds et al.[3] found that young primiparous women are most likely to be cervical shedders of CMV. In one study, 17% of women 14 years of age or younger were culture-positive for CMV compared with 0% of women 30 years of age or older.[1] Most women from whom CMV is isolated during pregnancy have reactivation or recurrent infection rather than primary infection. Depending on the serologic technique employed and the population studied, up to 90% of pregnant women have had serum antibody to CMV. Stagno et al.[4,5] found that 36% of pregnant women in a middle- to high-income group and 77% of women in a low-income group were seropositive.

Among women who are seronegative at the beginning of pregnancy, primary infection occurs relatively frequently. In three studies, from 0.6% to 4.3% of seronegative women developed primary infection during pregnancy.[6–8] Currently, primary CMV infection is undoubtedly many times more common than primary rubella infection during pregnancy. Women most commonly acquire CMV during pregnancy either from sexual transmission or exposure to young children.

Fetal, neonatal, and infant infections with CMV all occur frequently. Congenital infection, as detected by isolation of CMV within the first week of life, occurred in 0.4–2.0% of live-born infants studied in Western countries.[9,10] Prevalence rates of CMV shedding increase during the first few months of life and peak between 3 and 9 months of age at rates ranging from 5.8% to 56% of all infants. Some areas of the world have high rates despite relatively advanced economic development. Starr[11] studied epidemiologic characteristics of mothers whose neonates developed congenital infection. The mean maternal age of 19.0 ± 4.1 years was significantly younger than that of the general population of pregnant women (22.9 ± 5.9 years, $p < 0.01$), and the frequency of primiparity (62%) was significantly greater than that of the general population (31%, $p < 0.01$). These data are also consistent with the concept that primary CMV infection during pregnancy is more likely to be transmitted to the fetus than recurrent infection. With primary infection, congenital infection will occur in approximately 40% of pregnancies, while

transmission to the fetus occurs in 1.0–3.4% of women with reactivation or reinfection during pregnancy. Stagno et al.[4] found in a prospective study that congenital CMV infections were attributable to primary maternal CMV infection in about half the cases among high-income patients, who were less likely to enter pregnancy with preexisting antibody to CMV, but were usually attributable to recurrent maternal infection among low-income patients. Importantly, primary maternal infections were significantly more likely than recurrent maternal infection to result in clinically apparent congenital CMV infection during the neonatal period when infection occurred within the first half of gestation.

MANIFESTATIONS IN PREGNANT WOMEN AND IN THE NEONATE

In the majority of pregnant women who develop primary CMV infection, no recognized clinical illness is discerned. Starr[10] could find no difference in the frequency or type of antenatal illness between 32 women who gave birth to congenitally infected infants and matched controls. All but 1 of 14 primary CMV infections observed by Griffiths et al.[8] in pregnant women were asymptomatic. Heterophile-negative mononucleosis is occasionally recognized in a mother with a primary infection, and Bell's palsy accompanying primary CMV infection has been described during pregnancy.[12] A fetal ultrasound abnormality such as hydrocephalus,[13] intracerebral or hepatic calcifications,[14,15] or hyperechoic bowel[16] may be the first manifestation of primary CMV infection in the mother and fetus.

Women with recurrent (nonprimary) CMV infections almost always have no recognizable clinical abnormality. Women shedding CMV from the genital tract often have simultaneous shedding in the urine and milk.[1] CMV has been isolated from placental tissue, and infected placentas may show chronic villitis with mononuclear or plasma cell infiltrates. Typical cytoplasmic inclusion bodies are not always seen.[17] Amniotic fluid infection syndrome, histologic chorioamnionitis, and spontaneous abortion have not been recognized as manifestations of primary or recurrent maternal CMV infection, although CMV may be isolated frequently from the amniotic fluid of women with primary infections during pregnancy.[18]

Congenital infection is most often associated with early clinical manifestations among neonates born to nonimmune mothers who developed primary CMV infection during pregnancy. Approximately 40% of women with primary CMV will transmit CMV to the fetus transplacentally and 10–20% of these infants will have signs of infection at birth including microcephaly, hepatosplenomegaly, and petechiae. In the largest study of congenitally infected infants born to mothers of known infection status in pregnancy, 24 (18%) of 125 infected infants born to mothers with primary infection were symptomatic at birth.[19] Ninety percent of infants with symptomatic CMV infection at birth will die or have serious sequelae, including microcephaly, mental retardation, developmental delay, seizures, sensorineural hearing loss, and ocular abnormalities.[19,20]

Congenital infection is less frequent and much less often clinically apparent among neonates born to mothers with preexisting CMV infection. Stagno et al.[21] noted that 7 (3.4%) of 208 seropositive women delivered congenitally infected neonates. None of these neonates had apparent clinical involvement. In a more recent study from the same institution, among a cohort of 47 infants born with symptomatic infection, eight cases among 20 with definitively classifiable infection status were documented to have been born to women with anti-CMV antibody before conception.[22] The severity of clinical abnormalities in the infants did not differ from those seen in symptomatic infants born to women with primary infection. Similar findings have been reported by others.[23] On further study of women with preexisting antibody delivering infants with congenital CMV infection, acquisition of new antibody specificities to CMV glycoprotein H were demonstrated among 10 of 16, suggesting reinfection with a different strain, significantly higher than among CMV antibody positive women whose children were uninfected.[24] Given the high prevalence of seropositivity throughout the world, Stagno et al. suggested that recurrent rather than primary infection during pregnancy may be the leading cause of intrauterine CMV infection.[4] Stern et al.[7,25] concluded that cellular immunity may play a role in preventing intrauterine transmission of CMV. In their small study of women with primary CMV infection, they found that the eight women with positive lymphocyte transformation (LT) responses had unaffected infants in contrast with four congenitally infected infants born to the six women who had negative LT responses.

Intrapartum CMV infection and infection during infancy and childhood occur much more frequently than does congenital infection. By the end of the first year of life, 5–50% of infants have been infected. Intrapartum infection can result from exposure to maternal cervical CMV infection, while postpartum maternal-infant transmission can result from ingestion of infected maternal breast milk.[9] No short- or long-term ill-effects are known to result from intrapartum or early postpartum CMV infection among full-term infants. Several studies have documented a high frequency of reactivation of CMV during breast-feeding with transmission to preterm infants. Approximately 10–20% of preterm infants infected through breast-feeding will be symptomatic with sepsis-like findings or viral hepatitis.[26–28]

CASE DETECTION AND MANAGEMENT

Although the incidence and clinical severity of congenital CMV infection are high following primary CMV infection

during pregnancy in the United States, no recommendations currently exist for early identification of seronegative pregnant women who are at risk for primary infections. Women who develop a mononucleosis like illness during pregnancy should have serologic studies performed to exclude primary CMV, although most primary CMV infections in pregnancy are asymptomatic. Women at highest risk for seroconversion, e.g., women working in day-care centers with children under age 3,[29] may benefit from preconceptional testing, with follow-up testing in pregnancy if seronegative. In addition, women with abnormal findings on fetal ultrasound that may be related to congenital CMV infection (intracerebral or intrahepatic calcifications, hyperechoic bowel, hydrops, hydrocephaly, severe symmetric growth retardation) should have serologic testing. Often serum from serologic testing earlier in pregnancy for rubella, syphilis, or HIV may be available for testing to document seroconversion or preexisting immunity early in pregnancy. If earlier specimens are not available, then maternal primary infection can be documented by the presence of IgM by radioimmunoassay or enzyme-linked immunoassay. IgM antibody may be present for up to 4 months after primary infection and rarely with reactivation.[30] IgG avidity testing is a research test that may be useful in differentiating primary from recurrent CMV infection. The avidity of binding increases with duration of infection with avidity below 25–30% consistent with recent infection.[31,32]

If maternal primary infection is confirmed, amniocentesis or fetal umbilical blood sampling may be helpful in determining the fetal infection status.[18,33–38] Amniotic fluid culture and polymerase chain reaction (PCR) testing appear to have a high specificity and a sensitivity of over 80% for the diagnosis of fetal infection status when performed after 20 weeks' gestation or at least 6 weeks after maternal infection. However, the detection of CMV in amniotic fluid does not predict the severity of infection in the fetus. In the presence of an abnormal ultrasound, detection of CMV in the amniotic fluid suggests severe infection. Among women tested because of seroconversion, fetal umbilical blood sampling to evaluate for abnormal transaminase levels or thrombocytopenia may be helpful to detect severely affected infants but these abnormalities may be transient. The patient needs to understand that normal ultrasound and fetal blood studies in the presence of a positive amniotic fluid culture or PCR do not rule out significant fetal damage. Although the risk of damage to the fetus with recurrent CMV infection in pregnancy appears lower than with primary infection, severe fetal infections may occur and may be more likely among immunosuppressed women, such as those with AIDS or after solid organ transplant.[39–41]

Four antiviral drugs, ganciclovir, valganciclovir, foscarnet, and cidofovir, are currently licensed in the United States for treatment of end organ disease among immunosuppressed individuals.[42] All are associated with significant toxicities, and all but valganciclovir require parenteral administration. In addition, CMV immune globulin is licensed for prophylaxis against CMV in transplant recipients and as adjunctive therapy for CMV pneumonitis in immunosuppressed patients. Several case reports of use of ganciclovir in pregnancy for treatment of maternal disease among liver transplant recipients or HIV-infected women suggest that it is reasonably well tolerated.[42] Ganciclovir crosses the placenta and reaches the amniotic fluid. Case reports of use of ganciclovir either parenterally to the mother or by intra-amniotic injection to attempt to treat fetal infection have been limited and do not allow assessment of potential benefit. Given the potential toxicity and lack of date to suggest benefit for fetal infection, use of ganciclovir in pregnant women should be reserved for treatment of end organ disease in the mother or only in carefully designed clinical trials. Experience with other antiviral drugs for CMV in pregnancy is even more limited. Treatment of the neonate and infant diagnosed with congenital CMV infection is discussed in Chapter 84.

Recently, use of intravenous CMV hyperimmune globulin among women with documented primary CMV infection in pregnancy to try to ameliorate the effects of CMV on the fetus among women with CMV detection in the amniotic fluid or to prevent fetal infection among those with recent infection or those declining amniocentesis was reported.[43] In some cases, intra-amniotic or intraumbilical doses were given. In this nonrandomized study, symptomatic CMV disease at birth with persistent handicap occurred among 1(3%) of infants born to 31 treated women compared to 7(50%) of 14 infants born to untreated women ($p < 0.001$). In the prevention group, congenital infection occurred among 6(16%) of infants born to 37 treated women compared to 19(40%) of 47 women not receiving hyperimmune globulin ($p = 0.02$). While these results are encouraging, efficacy must be confirmed in a randomized trial with standardized dosing and more complete assessment of CMV infection status of the fetus at enrollment before this expensive and logistically difficult therapy can be recommended.[44] In addition, practical and reliable algorithms for identification of women with primary CMV infection must be developed before implementation of treatment programs.

Currently, the best preventive measure against congenital CMV infection appears to be prevention of maternal infection through education.[45] Congenitally or perinatally infected infants often shed large amounts of the virus in saliva, respiratory secretions, and urine. Pregnant women should not be exposed to infants recognized to be shedding CMV. Pregnant women should avoid contact with toddler urine and saliva, because toddlers, especially those in day care, have a high rate of infection and shed high levels of virus. Ultimate prevention of severe congenital CMV infection awaits a safe and effective vaccine. Although several vaccines are in development, their potential for protection against congenital infection has

not been evaluated.[46–48] If pregnant women or fetuses require blood transfusion, CMV-negative blood should be used.

HERPES SIMPLEX VIRUS INFECTION

The primary concern with genital herpes virus (HSV) infection during pregnancy is the risk of transmission to the neonate during labor and delivery, although primary infection during pregnancy may also increase the risk of pregnancy loss and preterm birth. Neonatal HSV is estimated to occur in about 1 in 3200 live births.[49] Approximately 85% of neonatal HSV infections are acquired from exposure to HSV in the birth canal, about 10% are due to exposure to other sources of HSV such as orolabial HSV in caregivers, and about 5% occur after transplacental infection.[50]

EPIDEMIOLOGY

Antibody to HSV-2, which causes about 80% of cases of genital herpes in women, has been measured in the U.S. National Health and Nutrition Examination Survey (NHANES) of a random sample of U.S. adults. The prevalence of antibody to HSV-2 increased by 30% from the period 1976–1980 to the period 1988–1994[51,52] (see Chapter 24). Women were more likely than men to be HSV-2-seropositive, and African American women were more likely than Caucasian women to be HSV-seropositive. Among U.S. pregnant women, HSV-2-seroprevalence has ranged from 16.5% to 32%, with the majority being unaware of their genital herpes infection.[53–55] A significant proportion of genital HSV infections are caused by HSV-1 rather than HSV-2. A recent study found that among women, 21.4% of initial genital HSV infections were culture-positive for HSV-1 rather than HSV-2.[56] Factors associated with new genital HSV-1 infections on multivariate analysis included white race, receiving oral sex, and lack of vaginal intercourse. As discussed below, genital HSV-1 infections may be transmitted to the neonate and acquisition during pregnancy is associated with a high risk of transmission.

NATURAL HISTORY AND MANIFESTATIONS OF GENITAL HSV INFECTION DURING PREGNANCY

Primary genital infection with HSV in women may be characterized by clinical illness averaging about 3 weeks in duration, with high concentrations of virus shed from vulvar and cervical lesions, inguinal adenopathy, and frequent systemic manifestations such as fever suggesting viremia. However, only about 25% of women with HSV-2 antibody are aware that they have had genital herpes, suggesting that most primary episodes must be asymptomatic or only produce mild or unrecognized symptoms. Further difficulty in recognizing primary infection in pregnancy was illustrated by a study of acyclovir for primary HSV in pregnancy. This study was terminated when it was found that of the 23 women enrolled with first clinical episodes of HSV, with symptoms suggestive of primary HSV (bilateral lesions, malaise, myalgia, or headache), only 1(4%) was truly primary (seronegative for antibody to HSV-1 and HSV-2), while 3(12%) had nonprimary first episodes (seropositive for antibody to HSV-1 at presentation) and 19(84%) were recurrent (already seropositive at presentation).[57] Type-specific antibody testing is needed for women with their first clinical episode of genital HSV in pregnancy to identify those with true primary or initial infections. Several assays that detect antibodies to HSV-1 glycoprotein G (gG1) and HSV-2 glycoprotein G (gG2) are now available and should be used in this setting to distinguish primary, first episode nonprimary, and recurrent infection.[58] Among the 70–85% of women who are seronegative to HSV-2 or HSV-1 early in pregnancy, 0.25–1.3% will seroconvert by delivery.[53,55] In the largest study, 94(1.3%) of 8508 women seroconverted to HSV during pregnancy. Among women who were HSV-seronegative, HSV-1-seropositive, or HSV-2-seropositive at the first prenatal visit, adjusted rates of seroconversion to either HSV type were 3.7%, 1.7%, and 0%, respectively. [55] The risk of development of a primary genital HSV infection (HSV-1 or HSV-2) adjusted for the entire length of pregnancy was approximately 2%.

Primary genital HSV infection in pregnancy has more potential for an adverse impact than nonprimary first-episode infection or recurrent infection, underscoring the benefit of serologic confirmation of the status of women with a first symptomatic episode of genital HSV in pregnancy. Transplacental infection with HSV during initial viremia appears to be rare, since congenital infection is diagnosed infrequently. Only 8(4%) of 210 neonates with HSV infection enrolled in an antiviral trial were diagnosed as having congenital rather than neonatal infection.[50] Symptomatic primary genital HSV infection in pregnancy has been associated with a significant increase in spontaneous abortion, preterm labor, and low birth weight. Nahmias et al.[59] reported a spontaneous abortion rate of 54% among women with primary infection before 20 weeks' gestation. In that study, among women with symptomatic primary infection after 20 weeks' gestation, 35% of the infants had a birth weight below 2500 gm and 50% developed neonatal herpes. In another study, among 15 episodes of primary HSV during pregnancy, 6(40%) were associated with severe perinatal morbidity (preterm birth, growth retardation, or neonatal HSV infection).[60] Poor outcomes were observed among 4(80%) of the 5 women with primary infection in the third trimester. Among the 14 women with nonprimary, first-episode disease in pregnancy, no cases of preterm delivery, growth retardation, or neonatal HSV occurred. The lack of increase in preterm birth or fetal growth retardation among women with recurrent genital HSV has been confirmed in a larger study.[61]

Among women with asymptomatic seroconversion in pregnancy, whether with or without preexisting antibody to the heterologous HSV type, the principal risk appears to be for preterm labor and increased risk of neonatal infection among those women without homologous antibody to the genital strain at delivery, e.g., with recent acquisition. Women with recent acquisition of HSV are also more likely to be shedding HSV, are more likely to shed both from the cervix and the vulva, and more likely to shed asymptomatically.[62] Asymptomatic cervical shedding of HSV-2 was detected by culture at 10.6% of visits among women with symptomatic primary genital HSV infection earlier in pregnancy and in 0.5% with nonprimary, first-episode disease earlier during the pregnancy.[60]

Data regarding the effects of pregnancy on recurrences of genital herpes are conflicting. Vontver et al.[63] followed 80 pregnant women with a history of recurrent genital HSV with serial cultures. Fifty-six (70%) had at least one positive culture during pregnancy. The proportion with positive cultures did not change with advancing gestation. A subsequent study of 147 women with a history of recurrent genital herpes detected an increase in the number of recurrences from a mean of 0.97 in the first trimester to a mean of 1.63 in the third trimester.[62] A study using daily home collection of vulvovaginal specimens for cultures and PCR testing among a small group of women in the third trimester of pregnancy with a history of recurrent genital herpes antedating pregnancy did not show a change in the rate of symptomatic recurrences, asymptomatic shedding, or PCR-positivity with advancing gestation.[64] Cultures were positive on 3.4% of days and HSV was detected by PCR on 16.8% of days.

Taken together, the data suggest that women with symptomatic primary genital HSV infection in pregnancy may be at increased risk for spontaneous abortion and preterm labor. The risk of preterm labor also appears to be increased among women with asymptomatic seroconversion late in pregnancy. Both groups have increased risk of transmitting infection to the neonate.

RISK OF NEONATAL TRANSMISSION

The incidence of neonatal HSV infection in the United States is estimated to be 1:1400–1:30,000 deliveries.[65] Most neonatal HSV infection is presumed attributable to intrapartum exposure to HSV in the birth canal. While the majority of cases of neonatal HSV are due to HSV-2, in the largest study reported to date incorporating serology and HSV cultures at delivery, 8(44%) of 18 cases of neonatal HSV were caused by HSV-1.[49] Few neonates are affected at birth and most develop signs of infection in the second week of life. Up to one-half of neonates acquiring HSV infection have been exposed to mothers with primary infection occurring late in pregnancy. Whitley et al.[66] observed that 41% of neonates with HSV infection weighed less than 2500 gm at birth and that 51% lacked antibody to HSV in the initial serum sample. Primary genital infection with HSV is a greater risk factor for neonatal acquisition of HSV for several reasons. The association with prematurity makes delivery during the primary infection likely, at a time when the inoculum of virus present in the birth canal is large, cervical involvement is extensive, maternal viremia may occur, maternal antibody is absent, and the infant may be immunologically immature. Neonates born to mothers with recurrent HSV-2 infection appear to acquire protective immunity from the mother and are at low risk of acquiring HSV infection, particularly invasive disease.[67]

The risk of neonatal HSV infection based on maternal HSV antibody status in early pregnancy is summarized in Fig. 81-1.[49,53–55,59,60,63,68–70] Of note, the risk of neonatal HSV is highest among infants born to women who enter pregnancy without HSV antibody because of the higher risk of HSV shedding with recent infection and lack of antibody transfer to the infant. In five studies of infants born to women with first-episode genital infections at delivery, 19(44%) of the 43 infants developed neonatal infection.[55,59,60,69,70] In the one study in which it was evaluated, transplacentally acquired HSV-1 antibody did not decrease the risk of neonatal HSV-2 infection.[70] Two large studies have found much lower rates of neonatal HSV among infants born to women with positive cultures at delivery related to reactivation. Neonatal HSV occurred among 1(3%) of 34 infants and 0 of 34 infants born to women with recurrent HSV and positive cultures at delivery.[67,70] Positive genital HSV cultures at delivery were detected in 0–2.4% of asymptomatic women with a history of recurrent genital herpes.[54,63,68] The risk of HSV shedding at delivery among women with acquisition of genital HSV during pregnancy varies depending on the timing of acquisition.[55] In some cases, preterm labor may occur coincident with primary infection, leading to high levels of HSV in the genital tract, whereas the risk of shedding among women with acquisition in the first trimester may be more similar to women with infections antedating pregnancy. Given the higher risk of transmission after primary infection during pregnancy, at least half of neonatal HSV infections are related to maternal primary infections, although only 1–2% of women have primary infection during pregnancy compared with up to 30% who have preexisting antibody to HSV-2. Therefore, any strategy directed at preventing neonatal HSV must address both prevention of primary infection in pregnant women and detection or prevention of reactivation of recurrent disease at delivery.

Early studies suggested that the route of delivery and duration of rupture of the membranes correlated with risk of neonatal infection when mothers have primary genital herpes at term. Approximately 50% of neonates exposed to such mothers during vaginal delivery acquired the disease. In contrast, only 1(6%) of 16 neonates delivered by cesarean section

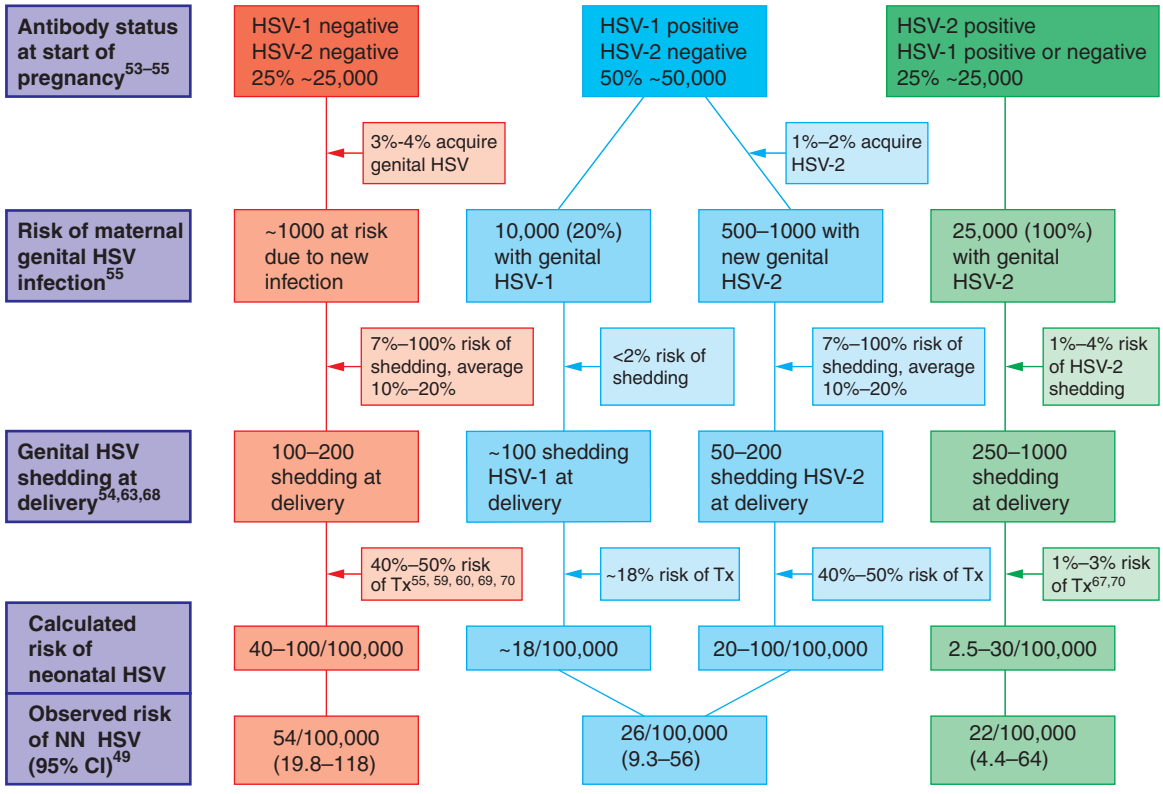

FIGURE 81-1. Calculated and observed risk of neonatal herpes simplex virus (HSV) infection according to maternal HSV antibody status at first prenatal visit among theoretical cohort of 100,000 women.[53–55,59,60,63,68–70]

within 4 hours of rupture of the membranes acquired the disease.[60] In cases where the membranes had been ruptured for more than 4 hours, six of seven exposed neonates acquired the disease irrespective of the route of delivery. A more recent study suggests the value of cesarean delivery even among women with recurrent HSV at delivery.[49] Among over 40,000 women undergoing genital culturing at delivery, positive cultures were detected in 202. The risk of transmission was reduced among all women with HSV detected by culture with cesarean delivery (odds ratio 0.14, 95% CI 0.02–1.08). One case (1.2%) of neonatal HSV occurred among the culture-positive women delivered by cesarean delivery compared to nine cases (7.7%) among 117 women delivering vaginally. However, when adjusted for type of HSV isolated, first episode versus recurrent disease, and isolation from the cervix, mode of delivery was no longer significant. Risk of transmission was increased on multivariate analysis with isolation of HSV-1 (AOR 34.8, 95 CI 3.6–335), first episode disease (AOR 59.3, 95% CI 6.7–525), and viral isolation from the cervix (AOR 15.4, 95% CI 1.8–133) as opposed to the vulva only. Thus, cesarean delivery continues to be recommended for women with active herpes lesions at the onset of labor or among women with acquisition of genital HSV near delivery with a high risk of genital, including cervical, shedding and no homologous maternal antibody.[71] For women with a history of genital HSV but no lesions undergoing labor and vaginal delivery, use of invasive monitoring and instrumental delivery (forceps or vacuum extraction) should be avoided whenever possible, because these procedures may cause breaks in the skin which increase the risk of neonatal infection in the presence of asymptomatic shedding.[49]

Whereas other neonatal viral infections are often subclinical, the majority of neonates with HSV infection have clinical manifestations of disease (see Chapter 84). Infection may be manifest as skin, eye, and mouth disease with involvement limited to the skin and mucous membranes; encephalitis; or disseminated infection with multiorgan involvement. Mortality and long-term morbidity rates remain high with encephalitis or disseminated infection, despite use of antiviral therapy.[72] The unique neonatal propensity to severe HSV infection, which persists for several months following delivery, is presumably related to a poor cellular immune response against HSV during this period.

CASE DETECTION AND MANAGEMENT

Since it is not practical to perform routine screening cultures for HSV on all women at delivery, prevention of neonatal HSV infection currently rests both on preventing primary HSV infection during pregnancy by identifying women at high risk for genital HSV and defining a management strategy for them, as well as on recognizing clinical manifestations of genital herpes

in women near delivery. Whitley et al.[66] analyzed the risk profile of mothers of neonates acquiring HSV and found that 57% had a history of genital herpes, a sex partner with genital lesions suggestive of herpes, or signs or symptoms of genital herpes during pregnancy. Asymptomatic intrapartum shedding of HSV is not predictable from antepartum cultures for HSV among women with a history of genital HSV[69] and these cultures are no longer recommended.

A rapid test for HSV shedding would allow timely detection of asymptomatic shedding and testing of suspicious but atypical genital lesions, thus targeting cesarean delivery for those actually shedding virus; unfortunately, none of the currently licensed rapid tests has adequate sensitivity for this use.[73] PCR testing has enhanced sensitivity to detect asymptomatic shedding, but this method has not been adapted for routine clinical use, and the risk of neonatal infection with low DNA copy numbers detectable by PCR has not been established.[74,75]

Clinicians should solicit and record in the prenatal record the presence or absence of a history of genital herpes in the patient or her partner(s) and should assess her current sexual behavior. Women with a positive history of genital HSV antedating pregnancy should be counseled to report any prodromal symptoms or lesions present at the onset of labor. For women with recent recurrences, the option of prophylactic antiviral therapy to reduce the risk of recurrence and the need for cesarean delivery can be discussed. A recent meta-analysis including five randomized trials of the use of acyclovir from 36 weeks of gestation until delivery found significant reductions in clinical HSV recurrences at delivery, cesarean delivery for HSV, detection of HSV by culture at delivery, and detection of HSV among asymptomatic women at delivery among women receiving acyclovir compared to placebo or no treatment. [76] Overall, use of acyclovir was associated with a 75% reduction in symptomatic recurrences at delivery and a 70% reduction in cesarean delivery for genital HSV. None of 339 acyclovir-treated women had positive genital cultures for HSV at delivery compared to 15(5%) of 293 women not receiving acyclovir (OR 0.61, 95% CI 0.43–0.86). In one study that included PCR testing, HSV was detected by PCR within 2 days of delivery in 1 (2%) of 62 women receiving acyclovir; the subject had lesions at the time.[77] The dosage of acyclovir used in these studies was either 200 mg 4 times daily or 400 mg 3 times daily. One study included only women with first episode genital HSV during pregnancy, two included women with documented recurrent disease, and two did not differentiate between recurrent or primary infections. Based on a previous study attempting to evaluate treatment of new genital HSV acquired during pregnancy, the majority of women with their first symptomatic episode of genital HSV during pregnancy have recurrent disease, which was previously asymptomatic.[57] No cases of neonatal HSV occurred in any of the studies but numbers were inadequate to assess any change in the risk. Based on these studies, acyclovir reduces the risk of HSV recurrences and cesarean delivery for HSV among women with symptomatic episodes during pregnancy. Whether or not acyclovir prophylaxis is beneficial for women with genital HSV is uncertain but no symptomatic recurrences in pregnancy has not been studied.

For women with a first symptomatic episode of HSV infection in pregnancy, attempts should be made to determine whether the episode represents recurrent or true first-episode infection. Several assays are now available that detect antibodies to the HSV-1 glycoprotein G (gG1) and HSV-2 glycoprotein G (gG2), allowing differentiation of the antibody response to the specific HSV types isolated from the genital tract.[58] If reliable testing for type-specific antibody is available, then women with homologous antibody to the HSV strain isolated from the genital tract may be managed as discussed earlier for recurrent disease. Women with primary or first-episode infections, lacking antibody to the genital HSV strain detected in the third trimester of pregnancy should be offered cesarean delivery, ideally before membrane rupture, regardless of symptoms because of the high risk of asymptomatic shedding of high titer HSV in the genital tract and lack of fully developed antibody response.[58]

The most difficult cases to prevent are those related to acquisition during pregnancy. Negative history in the patient (although insensitive for HSV-2-seropositivity), coupled with positive history in the partner (though nonspecific), or risky sexual lifestyle should prompt advice on use of condoms for any intercourse during pregnancy. Women with partners with symptoms or history suggestive of oral HSV infection should avoid oral-genital contact during pregnancy to try to prevent acquisition of genital HSV-1 infection. Women at high risk for primary or recurrent infection should be observed carefully for clinical evidence of genital lesions and, in the absence of herpetic lesions during labor, should be delivered vaginally unless there are other indications for cesarean section. If recurrent herpetic lesions are present in the genital tract at the time of rupture of the membranes or during labor, cesarean section may reduce the risk of neonatal infection and ideally should be performed within 4–6 hours after membrane rupture.

Given the high risk of transmission to the neonate with acquisition of genital HSV during pregnancy, the fact that only about one-quarter to one-third of women with established genital HSV are aware of their infections, and the availability of type specific serologies with reasonable sensitivity and specificity, some experts advocate the use of routine serologic screening for HSV infection in early pregnancy.[58] Identification of women with HSV-2 antibodies but no history of genital HSV allows education regarding signs and symptoms of recurrence that may identify previously unrecognized outbreaks and increase detection of prodrome or

lesions at the onset of labor. In addition, the risks and benefits of antiviral prophylaxis in late pregnancy can be discussed for women with recurrences identified during pregnancy, and the option of suppressive therapy after delivery to prevent partner transmission can be offered. For women who are seronegative for antibodies to HSV-2, the concern regarding acquisition of genital HSV can be discussed and partner testing offered to assess risk of acquisition. It is estimated that about 20% of couples will be at risk for transmission to the woman during pregnancy.[58] If the partner is found to be HSV-2 positive, practices to reduce risk of transmission to the pregnant woman including abstinence, condom use, or partner suppression with antivirals can be discussed. The efficacy of these measures for prevention of acquisition of genital HSV during pregnancy and for prevention of neonatal HSV has not been evaluated. If the partner is HSV-1 seropositive and the pregnant woman is not, then avoidance of oral-genital contact in pregnancy is recommended. In addition, since the male HSV-1 infection may be genital if he is HSV-2 seronegative, avoidance of genital-genital contact is also recommended to prevent genital HSV-1 infection. Again, the acceptability and efficacy of these measures in prevention of neonatal HSV infection have not been assessed. If the partner is not able to be tested, seronegative women can be counseled regarding abstinence and condom use to attempt to decrease the risk of primary infection in pregnancy. In addition, symptoms suggestive of genital HSV infection including genital sores and recurrent irritation can be discussed. Given the expense of routine HSV serology in pregnancy and the unproven benefits of subsequent interventions, routine testing is not recommended currently.[78] However, type-specific maternal serology is indicated for women with first-episode genital HSV in pregnancy and may be useful for women with histories suggestive of genital HSV or with negative histories with a partner with a history suggestive of genital HSV. Further evaluation of HSV serologic testing in pregnancy is needed before routine implementation.

Another key factor in limiting the morbidity and mortality of neonatal HSV infection is early diagnosis and treatment. Despite advances in antiviral therapy, both mortality and long-term morbidity remain high for infants with systemic infection. Parents should be educated about nonspecific signs such as poor feeding or irritability that require notification of the infant's provider, and providers must keep neonatal HSV in the differential diagnosis of infants with illness in the first few weeks of life, regardless of maternal history regarding genital HSV.

Management of pregnant women with HSV lesions and early preterm rupture of the membranes must be individualized. If the pregnancy is at or beyond 34 weeks' gestation, then delivery by cesarean section as soon as possible is indicated. Before this time, risks of prematurity versus risks of in utero or neonatal infection based on gestational age, maternal antibody status, and other clinical factors must be weighed. Consideration should be given to the use of intravenous or oral acyclovir in the mother to shorten the maternal course and possibly decrease the risk of neonatal infection. Over 30 cases of use of this approach without cases of neonatal HSV have been reported but the safety remains to be defined.[79,80]

Although primary genital HSV infection in early pregnancy may cause spontaneous abortion, congenital infection is considered uncommon. For this reason, therapeutic abortion is not recommended for pregnancies complicated by primary infection.

FUTURE DIRECTIONS IN MANAGEMENT OF HERPES DURING PREGNANCY

Strategies aimed at decreasing recurrences among women entering pregnancy with history of genital herpes or HSV-2 seropositivity will only eliminate about half the cases of neonatal HSV. At least 50% are related to acquisition of HSV, especially late in pregnancy.[58] Strategies to decrease exposure and seroconversion in pregnancy would include development of a vaccine to be administered to teenagers before the onset of sexual activity, assessment of ongoing high-risk sexual exposures, and serotesting to identify discordant couples with an HSV-2-seronegative pregnant woman with a seropositive partner, as discussed above. Further evaluation of the use of serotesting and efficacy of interventions is required before routine implementation. A vaccine against HSV-1 and HSV-2 infection could eliminate the risk of primary genital infection during pregnancy but such a vaccine is not currently available. An HSV-2 glycoprotein-D-subunit vaccine showed 74% efficacy in preventing acquisition of genital HSV-2 among women who were both HSV-1 and HSV-2 seronegative at enrollment but no efficacy in women who were seropositive for HSV-1 at enrollment or among men regardless of serostatus.[81] Further trials are underway and vaccine development continues.

HUMAN PAPILLOMAVIRUS INFECTION

From the 1960s through the mid-1980s, the number of initial office visits to physicians in the United States for condylomata acuminata, or genital warts, increased dramatically.[82] Genital HPVs, the causative agents of genital warts and cervical, vaginal, and vulvar intraepithelial neoplasia and cancer, are of concern in pregnancy for three reasons: (1) warts may rapidly enlarge with advancing gestation and mechanically obstruct labor or bleed during delivery, (2) a common form of therapy, podophyllin application, is contraindicated during pregnancy, and (3) perinatal exposure may result in laryngeal papillomas or genital warts in infancy or childhood. The worsening of cervical intraepithelial neoplasia

(CIN) frequently observed during pregnancy may also be due to accelerated HPV replication.

EPIDEMIOLOGY

HPV infection is common during pregnancy. Approximately 1 percent of sexually active adults are estimated to have genital warts, with a range of 0.6–13%, depending on age and sexual risk factors.[83] Rates are highest in those 18–28 years old, peak childbearing years. During pregnancy, genital warts may enlarge, with pronounced vascularity. During the puerperium, regression often follows. The responsible mechanism is unknown but may relate to depression of maternal immunocompetence during pregnancy.

In studies of HPV DNA detection during pregnancy, the prevalence has ranged from 5.2 to 65%, with most studies detecting HPV DNA in 30–40% of pregnant women.[84–95] The majority of studies,[86,89,91,92,95] but not all,[84,90] that have compared the detection of HPV DNA among pregnant to nonpregnant women have found increased detection during pregnancy, even when adjusting for age and sexual exposures. These findings are consistent with animal studies showing up regulation of HPV with pregnancy and with high levels of estrogen and progesterone seen in pregnancy.[96] Thus, genital HPV infection is common during pregnancy.

Infection with genital types of HPV in children may be manifest as genital warts or as laryngeal papillomas. Neonatal exposure to HPV probably occurs most commonly during birth by aspiration of contaminated cervical, vaginal, or vulvar material although some studies have detected HPV in the amniotic fluid without rupture of membranes, and rare cases of genital condylomata present at birth have been reported.[97,98] Studies on the risk of perinatal transmission are summarized below.

Genital warts in young children may be secondary to perinatal transmission of genital HPV, sexual abuse, exposure to nongenital HPV types through autoinoculation or caregiver warts, or fomite transmission.[99] The incubation period for development of warts after perinatal exposure is unknown but is felt to range from 1 month to several years. The evaluation for possible exposure through sexual abuse is discussed in Chapter 87.

Laryngeal papillomatosis, a form of recurrent respiratory papillomatosis (RRP), is the most frequent tumor of the larynx in children. There is a bimodal age distribution, with peaks in children between 2 and 5 years of age and in young adulthood. Twenty-eight percent of childhood cases were detected in infants under 6 months of age.[100] Studies of cellular DNA from genital warts and from laryngeal papillomas have shown that HPV types 6 and 11 account for the majority of genital warts and laryngeal papillomas.[101,102] While malignant transformation of respiratory papillomas is rare, these tumors frequently recur, requiring multiple ablative procedures and potentially leading to hoarseness, respiratory distress, and rarely, death. In one survey, children with RRP underwent an average of 5.1 surgeries annually for treatment of recurrences while in three other studies, the lifetime number of surgeries was 13.7.[103,104] The rate of RRP is low with an annual incidence of 0.4–0.6/100,000 children in Danish studies[105,106] and a range of 0.36–4.5/100,000 in the United States.[107,108] A rate of 4.7/100,000 births was found in a study of Danish births over a 20-year period.[109] In this study, the risk of RRP among infants born to women with genital warts at delivery was estimated to be 6.9/1000 births.

History of condylomata acuminata can be obtained from 37% to over 50% of mothers whose infants develop laryngeal papillomas.[109–112] Subclinical genital HPV infection in the mother is presumably responsible for most of the remainder. Perinatal transmission during vaginal delivery has been the presumed mode of spread, since children born by cesarean section have had a lower risk of acquiring RRP in some studies.[112,113] A more recent study did not find cesarean delivery to be protective for RRP but did find a doubling a risk with labor longer than 10 hours.[109] Other risk factors for RRP in one or more studies were young maternal age and first births, suggestive of primary infection.

RISK OF PERINATAL TRANSMISSION

The reported risk of transmission of HPV from mother to infant has varied considerably in different populations studied by various methods. Detection of HPV DNA from infant oral or genital specimens in the first few days of life has ranged from 3.7% to 72% among infants born to women testing positive for HPV DNA during pregnancy and 0.1–20% among infants born to women without HPV DNA detected during pregnancy.[85,87,88,93,94,97,114–118] Even in studies with high detection rates, the concordance between maternal and infant HPV types is at best about 60%. In a recent large study, the only one to date to use sequencing methods to evaluate concordance between infant and parental HPV types, HPV DNA was detected in 9(1.6%) of 574 infants, including 6(3.7%) of 164 with maternal HPV DNA detection and 3(0.1%) of 410 without genital HPV DNA.[93] Only one mother/infant pair was found to have concordant DNA types. These low rates of HPV DNA detection in the neonatal period in this study are consistent with the larger of the previous studies.[87,115,118] Studies following infants beyond the neonatal period have yielded similar varying rates of HPV DNA detection, with rates varying from 0% to 79% among children born to mothers with genital HPV detected during pregnancy and from 0% to 50% among those without genital HPV detection.[85,93,116–118] In most cases, the HPV detection rate was not related to detection of genital HPV infection in the mother during pregnancy. Thus far, the only clinical manifestations of perinatal HPV transmission appear to be cases of RRP and infant genital warts, both rare occurrences compared to the frequency of genital warts in reproductive age women. No long-term

consequences of perinatal exposure to high-risk HPV types have been documented, although continued evaluation of the role of HPV in oral lesions is needed.

CASE DETECTION AND MANAGEMENT

All pregnant women should have Pap smears to detect CIN, and those with active or past genital warts should be observed to detect recurrence or excessive growth of wart lesions. Pregnant women with visible genital warts should be offered treatment to decrease symptoms, risk of bleeding at delivery, and potentially, risk of transmission, although no studies of treatment to prevent transmission have been reported. The conventional techniques for treating genital warts in pregnancy include bichloracetic or trichloroacetic acid application, electrocoagulation, cryotherapy, laser vaporization, or surgical excision. Since both maternal and fetal deaths have resulted from podophyllin treatment of large vascular warts, this drug, including the patient-applied form, podofilox, should not be used during pregnancy.[119] The safety of imiquimod cream and interferon have not been evaluated in pregnancy, so these agents are not recommended.[120]

Cesarean section is not currently recommended to prevent neonatal exposure to HPV, even among women with visible genital warts.[120,121] While the rate of RRP was lower among infants born by cesarean delivery in some studies, this finding was not consistent.[109,112,113] HPV detection among infants born by cesarean delivery without labor has been reported, and no controlled studies have evaluated the ability of cesarean delivery before labor to prevent RRP. Although cesarean delivery is not routinely recommended for women with genital warts in pregnancy, women with genital warts persisting into the third trimester should be informed of the risk of RRP in the infant estimated at about 7/1000, the lack of data as to whether cesarean delivery decreases this risk, and the risks to her from cesarean versus vaginal delivery. Cesarean delivery may be necessary in rare instances where extensive lesions obstruct the vaginal outlet.

FUTURE DIRECTIONS IN MANAGEMENT OF HPV DURING PREGNANCY

Recent results from trials of multivalent vaccines for HPV suggest that they are effective in decreasing acquisition of vaccine strains of HPV and preventing development of CIN from high-risk HPV types included in the vaccine.[122] A vaccine including antigens from HPV types 6, 11, 16, and 18 is undergoing trials.[123] If protection from HPV types 6 and 11 infection is similar to that seen for types 16 and 18, implementation of preventive HPV vaccines in adolescence before onset of sexual activity could theoretically eliminate the risk of maternal genital warts and transmission of HPV 6 and 11 to infants.

HEPATITIS B

Hepatitis B is a small DNA virus containing three principal antigens: hepatitis B surface antigen (HBsAg), hepatitis B core antigen (HBcAg), and hepatitis Be antigen (HBeAg). Core antigen is present only in hepatocytes. Detection of HBeAg in blood indicates active viral replication and extremely high viral levels and infectiousness.

Acute HBV infection occurs in 1–2 per 1000 pregnancies, and chronic infection is found in 5–15 per 1000 pregnancies in the United States.[124] Risk factors for HBV infection include injection drug use, multiple sexual partners, history of other sexually transmitted diseases, work in a health care or public safety field, work or residence in an institution for the developmentally disabled, and receipt of clotting factor concentrates. Higher risks of infection are found among certain ethnic groups such as Native Alaskans and in immigrants from many developing countries. Despite the increased prevalence of HBV infection in patients with risk factors, screening in pregnancy based on risk factors alone will miss up to 75% of women with HBV infection.[125]

Clinical manifestations and natural history of HBV infection are described in Chapter 29. Symptoms of acute HBV infection, if present, are similar in pregnant and nonpregnant individuals and include malaise, fatigue, anorexia, nausea, and right upper quadrant pain. Signs include jaundice, hepatomegaly, and dark urine. There is no evidence that pregnancy worsens the course of acute viral hepatitis. However, pregnant women with the signs and symptoms listed above, especially women in the third trimester, should be evaluated carefully for indications of preeclampsia (hypertension, proteinuria, edema) or acute fatty liver of pregnancy, since delivery is indicated if either of these is present.[124] Transaminase levels are usually less elevated (200–400 μm(mL range) with preeclampsia or acute fatty liver than with acute HBV (over 1000 μm(mL). The diagnosis of acute HBV can be confirmed by the presence of HBsAg and anti-HBc IgM antibody in the serum (see Chapter 29). In pregnant women with hepatitis, testing acute and convalescent sera for CMV seroconversion is important because of the potential for fetal CMV infection. Pregnant women with acute liver disease should be evaluated for coagulopathy and hypoglycemia. Hospitalization is indicated for encephalopathy, coagulopathy, severe debilitation, or inability to maintain adequate nutrition.

With acute HBV in pregnancy, the risk of perinatal transmission depends on the stage of gestation at time of infection. First-trimester infection is associated with transmission to the fetus in up to 10% of cases; third-trimester acute infection is associated with an 80–90% risk of transmission.[126] Since chronic HBV infection is more common than acute infection during pregnancy, 85–95% of cases of perinatal transmission of HBV are related to intrapartum exposure.

With chronic infection, the risk of perinatal transmission is 10–20% among women who are HBsAg-positive and HBeAg-negative but rises to 50–90% among HBeAg-positive women in the absence of infant immunization.[127–129] Because of the high risk of perinatal transmission of hepatitis B, the 25% risk of death in adulthood from chronic liver disease after infection during infancy, and the 85–95% efficacy of passive plus active immunization of exposed infants, all pregnant women should be screened at the first prenatal visit for HBsAg.[130] Sexual partners and children of HBsAg-positive women should be offered testing and vaccination. Determination of HBeAg status is important for care and follow-up of the mother but does not change the management of the infant. All infants born to HBsAg-positive women should receive hepatitis B immune globulin (HBIG), 0.5 mL IM, and their first dose of hepatitis B vaccine (0.5 mL) at separate sites.[131] Vaccine doses should be repeated at 1 and 6 months of age. Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg at 9–15 months of age to assess infection and immune status.[132] Infants born to HBsAg-negative mothers should receive vaccine on the same schedule or starting within 2 months of birth.

Both passive and active immunization against hepatitis B are safe in pregnancy. If a nonimmune pregnant woman has been exposed to HBV, HBIG should be given in standard doses followed by vaccine. Nonimmune pregnant women in high-risk groups for HBV should also be offered vaccination.

Although the combination of HBIG and vaccination in exposed infants prevents the majority of perinatal transmission, prudence suggests minimizing exposure to maternal blood and secretions during labor, as is currently recommended for HIV-seropositive women. Scalp electrodes or blood sampling and instrument deliveries should be avoided if possible. Artificial rupture of the membranes should be delayed as long as possible. Infants should be washed thoroughly before receiving shots or drawing blood.

The combination of active and passive immunization in neonates fails to prevent infant infection in 5–15% of infants.[128] Failure of prophylaxis is associated with HBeAg positivity and high HBV DNA levels in the pregnant woman but not maternal transaminases levels.[133,134] It is unclear if failure of newborn prophylaxis represents in utero infection or inadequate immune globulin dosing. In an effort to reduce the risk of failure of neonatal prophylaxis, some investigators have advocated use of HBIG in the mother during the third trimester of pregnancy or short-term use of lamivudine in the mother to reduce the level of hepatitis B viremia. A small study ($n = 112$) from China found a decreased rate of markers of HBV infection among newborns of HbsAg-positive women who received monthly injections of HBIG beginning at 28 weeks of gestation compared to those not receiving HBIG, but the infection rate after 9 months was not reported.[135] Lamivudine use has been reported to decrease the risk of failure of neonatal prophylaxis among infants born to women with high HBV DNA levels before therapy compared to historical controls[136,137] but randomized studies are lacking. In addition, the impact of short-term lamivudine on the course of maternal HBV infection has not been evaluated. Further evaluation of these interventions is required before they can be recommended routinely. Interferon, another therapy for HBV, is not recommended for use in pregnancy.[120]

The rate of HBV infection in the infant is not increased with breast-feeding when the infant receives HBIG and HBV vaccine at birth.[138,139] Likewise, mode of delivery does not affect the rate of immunization failure.[140] HBV DNA has not been detected in the amniotic fluid before labor, and the risk of transmission of HBV to the fetus with amniocentesis appears to be low.[141] However, use of amniocentesis in HBsAg-positive women should be minimized by exhausting noninvasive means of testing first. In addition, HBeAg-positive women should be counseled that their risk of transmission may be higher for them.

Ultimately, prevention of HBV infection in pregnancy relies on implementation of immunization recommendations. The rate of HBV infection in pregnancy has been decreasing over time as a result of newborn and adolescent immunization programs.[142] The rate of acute HBV infections among children and adolescents in the United States has decreased by 89% between 1990 and 2002 as a result of immunization.[143] In countries where HBsAg testing and HBIG are not routinely available, implementation of routine newborn immunization still leads to a significant reduction in transmission and reduced population levels.[144]

CONCLUSION

Viral STIs can have a significant impact on pregnant women and newborns, with sequelae of perinatal transmission being lifelong, as in cases of herpes encephalitis or CMV-associated hearing loss. Current management strategies are unable to prevent all perinatal transmission or sequelae but reduce transmission to varying degrees. Ultimately, vaccine development may make all of the viral STIs discussed here rare in pregnancy and virtually eliminate perinatal transmission.

82 Congenital Syphilis

Taraneh Shafii, Justin D. Radolf, Pablo J. Sánchez, Kenneth F. Schulz, and F. Kevin Murphy

HISTORY

EARLY OBSERVATIONS

Congenital syphilis is the oldest recognized congenital infection. The transmission of syphilis to infants has been described in the earliest medical writings on "the French disease" (*morbus gallicus*). Among the first treatises on syphilis was that of Garpar Torella, written in 1497—within 4 years of the first known outbreaks of syphilis in Spain. Torella noted that syphilis was "often seen" in nursing children, first appearing on the face or in the mouth. Although early writers clearly recognized the possibility of congenital transmission,[1–3] they usually presumed that the wet nurse was the source of infection. The first measure advocated for the prevention of congenital syphilis was proscription of the use of wet nurses who had "the French disease," even if apparently cured. Ambroise Paré, the eminent French surgeon, displayed the same prejudice in a chapter on syphilis among his collected works.[4] Paré described a good family of Paris, all of whom allegedly were infected from a syphilitic wet nurse, even the nursing child's two siblings. He concluded by advocating that the nurse be whipped, naked, through the streets of the city.

The German alchemist and physician Paracelsus was the first to state (in 1529) that congenital syphilis is a hereditary illness that passes from father to son.[5] In 1565, Simon de Vallembert described a case of "hereditary syphilis" in the first French text on pediatrics.[6] After apparent recovery from syphilis, a goldsmith of Tours fathered several afflicted children over a 14-year period, although their mother remained unaffected.

In the novel *Moll Flanders*,[7] Daniel Defoe demonstrated that a basic understanding of syphilis transmission from adult to neonate had been achieved by the eighteenth century. Recalling an encounter with a drunken baronet who had paid for her services, Moll imagines the baronet's regret on arriving home to his family:

> How would he be trembling for fear he had got the pox ... how would he, if he had any principles of honour, abhor the thought of giving any ill distemper, if he had it, as for aught he knew he might, to his modest and virtuous wife, and thereby sowing the contagion in the life-blood of his posterity!

In spite of lingering misconceptions about its mechanisms of transmission, several important empirical observations regarding congenital syphilis were made during the nineteenth century, which, in that simpler time, were accorded the status of "laws." Colles's law (1837) stated that syphilitic infants could transmit the disease to previously healthy wet nurses but never to their own mothers.[8] Profeta's law (1865) stated that a healthy infant born to a syphilitic mother is immune to the disease. Kassowitz's law (1876) stated that the toll of the mother's syphilis diminishes with successive pregnancies. Both Paul Diday (1854) and Jonathan Hutchinson (1863) had made this same observation.[9,10] Although neither Colles nor Profeta understood the basis for their observations, their laws illustrated the principle that infection with syphilis confers immunity to reinoculation. The essential character of congenital syphilis finally was clarified in 1906 with Wasserman's development of a serologic test that made it possible to demonstrate that transmission of syphilis to a fetus required an infected, albeit sometimes asymptomatic, mother.[11]

EARLY CLINICAL DESCRIPTIONS

Actual clinical descriptions of congenital syphilis were sparse during the sixteenth through the eighteenth centuries. Lenoir, in 1780, established a lying-in hospital in Paris for syphilitic mothers, the first facility for specialized care of neonates and high-risk pregnancies. Bertin wrote his classic monograph (1810) on congenital syphilis based upon the large accumulated experience at this institution.[12] He recognized several cutaneous lesions; mucous membrane lesions involving eyes, nose, urethra, and anus; adenopathy; and bone lesions, including epiphysitis. Bertin and others recognized the importance of the skeletal examination, although many later authorities, including Trousseau and Diday, considered skeletal lesions rare in congenital syphilis. Diday's major text, originally published in 1854,[9] described most of

the cutaneous and visceral manifestations of congenital syphilis known today and characterized the general appearance of the infant as that of "a little, wrinkled, pot-bellied old man with a cold in his head."[5] Jonathan Hutchinson's writings dominated nineteenth-century British clinical descriptions of congenital syphilis just as Diday's dominated French literature.[5,13,14] His 1857 presentation before the Pathological Society of London of the characteristic dental malformations, the first description of late sequelae of infant syphilis, was received with "expression of incredulity." Hutchinson is best known for this work as well as for his association of the dental deformities of late congenital syphilis with interstitial keratitis and deafness (Hutchinson's triad).[5,13,14]

Working without the benefit of x-rays, Parrot[15] and Wegner[16] provided clear descriptions of the osteochondritis of congenital syphilis; Parrot went so far as to declare that every bone of the infantile syphilitic skeleton is affected. His name is applied to both the cranial nodes ("hot cross bun" skull) and the pseudoparalysis that he described. Unfortunately, Parrot also mistakenly believed that rickets was a later lesion of congenital syphilis, an error subsequently corrected by the American Robert Taylor.[17] Between 1900 and 1907 a succession of bright young radiologists proved that bony lesions were the most sensitive indication of clinical disease and that these lesions could be demonstrated in infants without other clinical manifestations.

The risks of delivering a congenitally infected infant were well described in the landmark Oslo study of untreated syphilis conducted from 1891 to 1910. Boeck observed that 26% of babies born to syphilitic mothers remained free of disease or recovered spontaneously with conversion to seronegativity, 25% were seroreactive but remained clinically unaffected, and 49% displayed manifest disease.[18]

MILESTONES IN PREVENTION

Fournier, a student of Diday, wrote a detailed treatise on the prevention of congenital syphilis[19]; his concepts influenced premarital counseling for almost a century. Before marriage or resumption of intercourse, he required (1) that the syphilitic patient have no active lesions, (2) that the patient wait 3–4 years after onset of disease, (3) that the patient wait at least 18–24 months after the last sign of disease, (4) that the form of syphilis not be grave, and (5) that an "adequate" course of potassium iodide and mercury be completed (3–4 years). After 1906, serological testing for syphilis was added as a further premarital requirement. This practice has since been abandoned by most states in the United States as the detection rate of syphilis through premarital screening has been very low.[20,21]

Several observations made in rapid succession during the early twentieth century became cornerstones of strategies to curtail the spread of congenital syphilis.[5] The experimental transmission of syphilis to apes by Roux and Metchnikoff[5] and the microscopic demonstration of *Treponema pallidum* by Schaudinn and Hoffmann[5] established the microbiologic etiology of venereal syphilis. Wassermann's development of a complement fixation test using syphilitic fetal liver as a source of antigen enabled physicians, for the first time, to identify individuals with asymptomatic syphilitic infection.[5] Within a year Levaditi[5] demonstrated both the presence of spirochetes in syphilitic fetal tissue and the suitability of uninfected liver as an antigen source for the Wassermann test. It was soon recognized that identification of cases of maternal syphilis with the Wassermann test and treatment of the mother with arsenicals could prevent neonatal syphilis. With the introduction of penicillin in 1943 by Mahoney,[5] all of the essential clinical tools for the control of congenital syphilis were available.

EPIDEMIOLOGY

GENERAL TRENDS

The introduction of penicillin as syphilotherapy resulted in a dramatic decline in acquired and congenital syphilis incidence in the United States and Europe. The incidence of syphilis began to rise again in 1959 despite the fact that inexpensive therapy was readily available. It was not until 1978 that the incidence again reached the 1957 low of 3.8 cases per 100,000 live births. From 1986 through the early 1990s, there was a dramatic increase in the number of cases of congenital syphilis, partly reflecting the increases in primary and secondary syphilis among inner-city heterosexual minorities during this same period[22] and partly reflecting a revision of the surveillance definition.[23–25] Interestingly, during this same period, syphilis incidence rates decreased steadily in other industrialized countries.[26,27] Over the past 15 years, however, there has been a decrease in congenital syphilis in the United States and other industrialized countries. However, as with HIV, sub-Saharan Africa continues with an epidemic of congenital syphilis. Globally, congenital syphilis affects over 500,000 infants every year and is the cause of an estimated additional 500,000 miscarriages and stillbirths each year.[28,29] In fact, the true impact of congenital syphilis is unknown because, according to statistics from the World Health Organization (WHO), only 68% of women in developing countries receive prenatal care. Moreover, many of these women seek prenatal care too late in their pregnancy, and only a few countries track syphilis in pregnancy.[28]

INCIDENCE AND PREVALENCE PRIOR TO PENICILLIN

Osler observed in 1917 that syphilis accounted for 20% of all stillbirths and 18–22% of infant deaths in the United States.[30] In Edinburgh, in 1922, Browne found that 35 of 153 neonatal

deaths were syphilitic in origin.[31] The overwhelming importance of perinatal syphilis in that period was a reflection of the prevalence of the disease in adults; 10% of women of the "hospital class" and 4.5% of umbilical cord blood samples in Glasgow's Royal Maternity & Women's Hospital had reactive Wassermann tests.[32] School examinations in 1922 and 1923 in Plymouth, England, indicated an 8% prevalence of manifest congenital syphilis among school-age children. Between 1922 and 1937, the prevalence of syphilis declined steadily, with prenatal seropositivity falling to 1.8% in Glasgow and from 12% to 4% in Kansas City.[33] A 1936 U.S. Public Health Service survey indicated, however, that 2% of U.S. children and 5.6% of U.S. infants were syphilitic, with striking disparities between whites and African Americans (1.7% vs. 12.2%) and between public and private patients (5.3% vs. 1%). Investigations of families of an index case revealed latent or manifest syphilis in about one fourth of family members.[34] A major upsurge in syphilis incidence during World War II in Europe and the United States was associated with a corresponding two- to threefold increase in the number of cases of congenital syphilis.[35] However, this effect was blunted somewhat in areas such as Glasgow where comprehensive prenatal screening programs were well established.[34]

CURRENT INCIDENCE AND DEMOGRAPHICS IN THE UNITED STATES

Syphilis is the only congenital infection with national surveillance data. Infections during the perinatal period comprise the vast majority of new cases of congenital syphilis. Consequently, the incidence of congenital syphilis closely follows that of primary and secondary syphilis among women in the peak childbearing age group (15–29 years) (Fig. 82-1); this is also the peak age group in which early syphilis occurs. From 1970 to 1979, men with male sexual partners accounted for an increasing share of syphilis morbidity, and the ratio of male to female cases of infectious syphilis rose during those same years, peaking at 3.5:1 in 1980 (Fig. 82-2A).[27] Congenital syphilis rates, accordingly, declined steadily during this period (Figs. 82-1 and 82-3). With changing sexual behavior among men who have sex with men (MSM) in response to the threat of human immunodeficiency virus (HIV), the male-to-female ratio of early syphilis cases started decreasing in 1980; by 1993 the ratio had fallen to 1.1:1, reflecting the fact that new cases were occurring predominantly in heterosexuals (Fig. 82-2).

During this same period congenital syphilis rates increased markedly (Figs. 82-1 and 82-3). Two factors are responsible for the dramatic increase in congenital syphilis observed in the United States from 1990 through 1994. The first was the adoption in 1989 of revised reporting guidelines that broadened the surveillance definition for congenital syphilis (Table 82-1).[25,36] Previous criteria for reporting

FIGURE 82-1. A. Annual incidence of infant congenital syphilis compared to that of primary and secondary syphilis, United States, 1940–2005. (*Source*: CDC, STD Surveillance 2005, Table 1.) **B.** Annual incidence of infant congenital syphilis compared to that of women with P&S U.S. 1996–2005. The trend for congenital syphilis follows that of women with P&S. (*Source*: CDC, STD Surveillance 2005, Fig. 37.)

cases of congenital syphilis were based on a clinical case definition; only infants who had clinically apparent disease or laboratory findings suggestive of congenital syphilis were reported.[25] A *confirmed* case represented an infant or stillbirth in whom *T. pallidum* was identified by either darkfield microscopy or specific stains in specimens from lesions. A *probable case* was that of an infant or stillbirth who had a reactive test for syphilis and an abnormal physical examination, abnormal long-bone radiograph, abnormal cerebrospinal fluid (reactive CSF-VDRL and/or elevated CSF cell count or protein without other cause), a nontreponemal serologic test titer fourfold higher than the mother's, a rising nontreponemal test titer during follow up, or a persistently reactive treponemal test beyond 1 year of age. Although relatively specific, two problems with this definition were that it did not include infected live-born infants without evidence of congenital syphilis and it

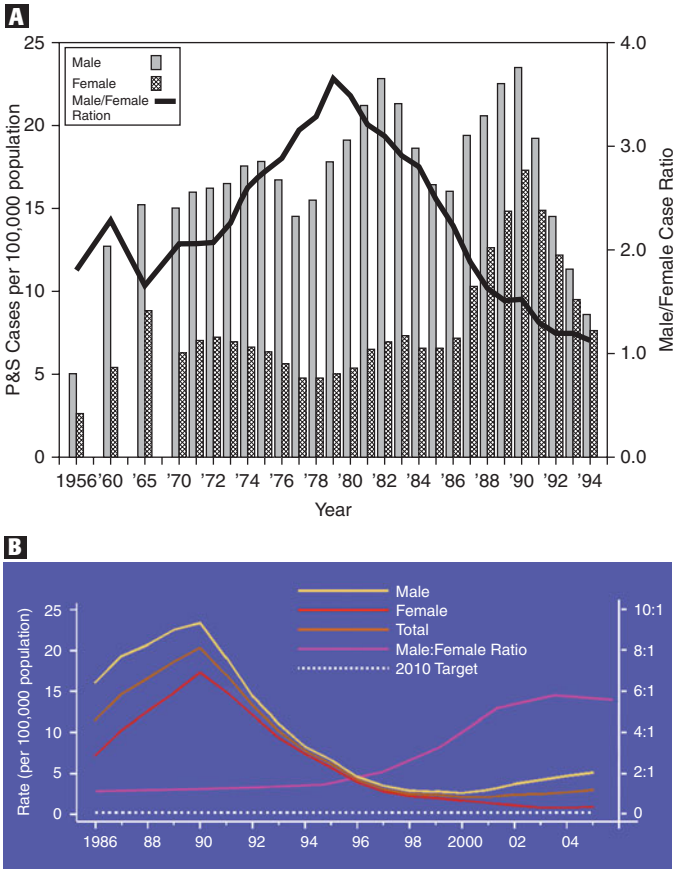

FIGURE 82-2. Incidence rates of early infectious syphilis for men and women, with the male-to-female case ratio, in the United States, **A.,** from 1956 to 1994 *(courtesy of Kathy Dry, Division of STD Prevention, NCHSTP, CDC, Atlanta)* and, **B.,** from 1986 to 2004 (*Source*: Adapted from CDC, STD Surveillance 2005, Figs. 27 and 33).

depended in many cases upon follow-up serologic data to make a diagnosis (Table 82-1). The new surveillance case definition includes all infants with clinical evidence of active syphilis, as well as normal appearing neonates and stillbirths delivered to women with untreated or inadequately treated syphilis (Table 82-1).[23,25] Use of these guidelines increases the sensitivity for reporting cases of congenital syphilis, albeit by including at-risk but truly uninfected cases. Studies have shown that the revised surveillance definition results in a four- to fivefold increase in the number of reported cases.[24,36,37]

The second factor responsible for the upsurge in congenital syphilis cases during that time was the near-epidemic increase in the incidence of primary and secondary syphilis among young females in the United States (Figs. 82-1 and 82-2A), particularly among inner-city minorities in New York, California, Florida, Texas, and Michigan and among rural blacks throughout the Southeast.[23,27,38–40] A major contributor to the increase in urban areas was the use of crack cocaine and the exchange of illegal drugs for sex among multiple sexual partners.[22,41–43] The use of spectinomycin, which is not effective against incubating syphilis,[44,45] for the

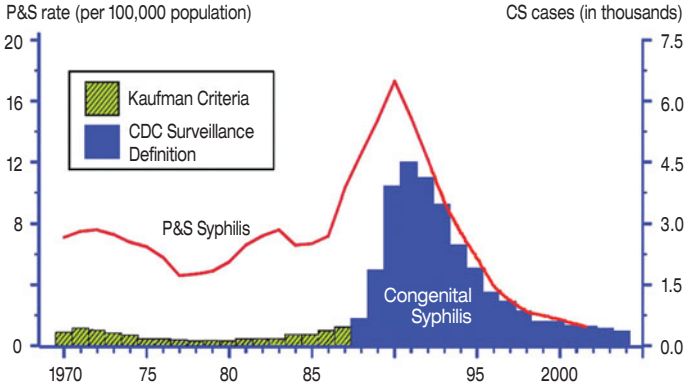

FIGURE 82-3. Reported cases of congenital syphilis in infants younger than 1 year of age and rates of primary and secondary syphilis among women, United States, 1970–2004. Note: The surveillance case definition for congenital syphilis changed in 1988. (*Source*: CDC, STD Surveillance 2005, Fig. 5.)

treatment of penicillinase-producing *Neisseria gonorrhoeae* also may have been contributory.

While rates of primary and secondary syphilis in the United States continued to decline through the 1990s, increasing rates of syphilis were observed once more in males in 2001 with a concomitant rise in the male-to-female rate ratio of syphilis to 5.7:1 in 2005[46] (Fig. 82-2B). The syphilis epidemic among MSMs is attributed in part to waning safer sexual behaviors associated with the widespread use of highly active antiretroviral therapy (HAART) and diminished concern among MSMs about the potential seriousness of HIV infection.

Fortunately, despite the syphilis epidemic in males there have been substantial decreases in the incidence of both infectious syphilis in females and congenital syphilis over the past one and one-half decades (Figs. 82-1 and 82-2).[47] In fact there has been a consistent downward trend in the rates of both primary and secondary syphilis in women and congenital syphilis since 1991.[48] These decreases have been attributed to (1) the implementation in the early 1990s of innovative, community-based outreach methods that facilitate identification and serologic testing of persons at high risk for syphilis by focusing on sex-for-drugs locations rather than on contact tracing of named sexual partners of persons with early syphilis[49,50] and (2) the initiation of the National Syphilis Elimination Plan launched by the Centers for Disease Control and Prevention (CDC) in 1999 with the goal of eliminating primary and secondary syphilis in the United States, thereby decreasing syphilis infection in females and preventing congenital syphilis.[48]

Consistent with the risk factors noted in the early 1990s,[47,51,52] over the last decade women who deliver syphilitic babies are more likely than the general population to be racial/ethnic minorities (black and Hispanic), younger in age (<30 years), unmarried, drug using (specifically cocaine), and living in a high syphilis morbidity areas.[53–56] Of the 329 cases of congenital syphilis in infants less than 1 year of age reported to the CDC in 2005, 46% (151) of mothers

Table 82-1. Summary of the Modified Kaufman and Revised Centers for Disease Control and Prevention (CDC) Criteria for Congenital Syphilis Surveillance

Kaufman Criteria	Revised CDC Criteria[a]
Definite	**Confirmed**
Treponema pallidum by dark-field or histologic examination	A case that is laboratory confirmed
Probable	**Probable**
Rising Venereal Disease Research Laboratory (VDRL) titer over 3 mo or a reactive serologic test for syphilis (STS) that does not revert to nonreactive within 4 mo	A condition affecting an infant whose mother had untreated or inadequately treated[b] syphilis at delivery, regardless of signs[c] in the infant, or an infant or child who has a reactive treponemal test for syphilis and any one of the following:
One major or two minor criteria[d] and either a reactive STS or fluorescent treponema antibody (FTA) test	• Any evidence of congenital syphilis on physical exam
One major and one minor criteria on radiographs of long bones	• Any evidence of congenital syphilis
Possible	• A reactive cerebrospinal fluid (CSF) venereal disease research laboratory (VDRL)
A reactive STS or FTA test without clinical criteria	• An elevated CSF cell count or protein (without other cause)[e]
	• A reactive fluorescent treponemal antibody absorbed-19S-IgM antibody test or IgM enzyme-linked immunosorbent assay
	Syphilitic stillbirth
	A fetal death occurring after 20-wk gestation or weighing ≥500 g, in which the mother had untreated or inadequately treated syphilis at delivery

[a]Revised in 1990 and 1996.

[b]Inadequate therapy defined as nonpenicillin therapy or penicillin given ≤30 days prior to delivery.

[c]Signs in infants and children (<2 years old) are snuffles, hepatosplenomegaly, characteristic skin rash, condylomata lata, anemia, jaundice (nonviral hepatitis, pseudoparalysis, or edema (nephrotic syndrome and/or malnutrition)).

[d]Major criteria: condylomata lata, osteochondritis, periostitis, snuffles, hemorrhagic rhinitis. Minor criteria: fissures of lips, cutaneous lesions, mucous patches, hepatomegaly, splenomegaly, generalized lymphadenopathy, central nervous signs, hemolytic anemia, CSF cell count ≥20, CSF protein ≥100.

[e]CSF cell count ≥5 or CSF protein ≥40.

were black, 37% (122) were Hispanic, 9% (30) were white, 4% (13) were Asian/Pacific Islander, and 4% (13) were other or unknown. The decrease in congenital syphilis cases and racial/ethnic distribution is demonstrated when comparing surveillance date from the last decade. Of the 3209 cases of congenital syphilis reported to the CDC in 1993, 71% (2278) were black, 20% (642) were Hispanic, 5% (160) were white, and 4% (128) were other or unknown.[57] Over the past 50 years a number of studies have identified inadequate prenatal care as the leading predisposing factor.[24,35,52,58,59]

While public health efforts have been successful in increasing syphilis screening in some populations over the last decade, lack of prenatal care continues to be the major risk factor consistently associated with congenital syphilis.[53,54,60,61] In 2002 almost 75% of mothers with reported congenital syphilis cases had no or inadequate treatment for syphilis before or during pregnancy and inadequate prenatal care.[62,63] Of the 451 cases of congenital syphilis reported 64% (288) of mothers received prenatal care; 29% (130) received no prenatal care; and the prenatal care status was unknown for 7% (33). Of the 288 women who reported timing of their first prenatal care visit, approximately one third sought prenatal care in their first trimester (86) and another one third in their second trimester (93). As many as 20% (59) did not receive prenatal care until their third

trimester, and almost one third of these women (18) received care less than 30 days before delivery.[62] For pregnant women overall in the United States health disparities are evident in those who are likely to seek prenatal care and those who are not. In 2001 black and Hispanic women were twice as likely to receive late or no prenatal care when compared to white women.[53,60,64] Similarly, in surveillance data from 2004, of the women who began prenatal care in the first trimester of pregnancy 85% were white, 76% were black, and 77% were Hispanic, whereas of women who began prenatal care late in the third trimester or received no prenatal care at all, 3.2% were white, 5.7% were black, and 5.4% were Hispanic.

GLOBAL BURDEN OF CONGENITAL SYPHILIS

The regions of the world with the highest distribution of syphilis are South America, sub-Saharan Africa, China, and Southeast Asia. Globally syphilis infection is more common among poor populations with fewer resources; lack of access to healthcare; multiple sexual partners; and marginalization from society.[65] In Eastern Europe, Russia, and China, countries experiencing marked economic and social reforms, syphilis and congenital syphilis are on the rise.[65–67] During the Soviet era prenatal care was free and congenital syphilis was rare. This has changed over the past two decades with fewer women accessing adequate prenatal care; the number of cases of congenital syphilis rose 26-fold from 15 in 1991 to 730 in 1999.[67,68] Similarly, under Communist rule in China, the syphilis epidemic of the 1950s was halted in the 1960s and syphilis was virtually eradicated due to government-initiated population screening, free treatment, and ban on prostitution.[69] However, in the era of decreased governmental power, enhanced personal wealth, social freedom and geographic mobility, syphilis and congenital syphilis have reached epidemic proportions.[69] In a case–control study of women attending antenatal clinics in Southern China, infection with syphilis was associated with being unmarried, lower education level, multiple sexual partners, a sexual partner who had traveled within the past12 months, a history of induced abortion, and prior STD.[70] Notably, from national surveillance data, the incidence of congenital syphilis has increased by 72% yearly from 0.01 cases per 100,000 live births in 1991 to 19.7 cases per 100,000 in 2005.[69]

SUB-SAHARAN AFRICA

An estimated 4–15% of women attending antenatal clinics are infected with syphilis in sub-Saharan Africa.[71] Lack of prenatal care, not accessing care until late in pregnancy, and lack of screening despite prenatal care perpetuate the epidemic of congenital syphilis in Africa. Congenital syphilis is estimated to result in 20–30% of all perinatal deaths in sub-Saharan Africa. Yet surveillance in 22 countries found only 38% of women accessing antenatal care were screened for syphilis despite recommendations for universal screening.[72] As congenial syphilis is readily preventable with treatment of maternal syphilis early in pregnancy and as antenatal screening and treatment have proven cost-effective,[71,72] even in settings with low prevalence[73,74] more needs be done to overcome obstacles that prevent pregnant women from receiving care.

Syphilis during pregnancy

With the onset of intensive HIV research activity over the past 20 years, many seroprevalence surveys undertaken included serologic examination for syphilis. In the early 1990s the surveys in sub-Saharan Africa that estimated rates of active syphilis (reactive results for both *T. pallidum* hemagglutination [TPHA] and rapid plasma reagin [RPR] or Venereal Disease Research Laboratory [VDRL] tests) in pregnant women, the median reported prevalence was 6%, with areas in Kenya, Cameroon, Tanzania, Gabon, and Malawi all reporting rates of greater than 10%.[75] More recently over the past decade, in Nairobi, Kenya, the seroprevalence for syphilis was 6.5% in pregnant women at an antenatal screening clinic and 3% in women presenting to hospital for delivery.[76,77] In a syphilis prevalence study of pregnant women in antenatal clinics in Gaborone, Botswana, 11% of the women were TPHA reactive and 5% had active syphilis.[73] In South Africa the antenatal prevalence of syphilis has trended downwards over the past decade from a high of 11.2% in 1997 to a low of 1.6% in 2004 while the prevalence rates between 2001 and 2005 have fluctuated in the range of 1.6–3.2%.[78]

These numbers demonstrate that syphilis during pregnancy is prevalent through out much of Africa. In Nairobi, Kenya, risk factors for syphilis seroreactivity include fewer years of education, history of preterm delivery, three or fewer antenatal visits, maternal HIV infection, more than one sexual partner in the past year, and a history of genital ulcer disease.[79] In a recent study in Mwanza, Tanzania, RPR-reactive women at delivery were more likely than RPR-nonreactive women to have no education or a lower level of education; more likely to have two or more sexual partners in the past year; more likely to be infected with *Trichomonas vaginalis* at recruitment; and more likely to be diagnosed with HIV, placental malaria, and anemia at the time of delivery.[80]

One potential problem with the use of serologic tests when screening for syphilis and when estimating prevalences of syphilis is that these tests cannot distinguish between infection by *Treponema pallidum* and endemic treponematoses, which are not sexually transmitted. For example, yaws, caused by a subspecies of *T. pallidum*, (subsp. *pertenue*), is a nonvenereal infection occurring mainly in poor communities with overcrowding and poor sanitation in tropical areas of Africa.[81,82]

Syphilis and pregnancy outcomes

Over two decades ago the most common outcome of syphilis during pregnancy was spontaneous abortion/stillbirth during

the second and early third trimester; the precise magnitude of this problem is difficult to measure because many African women did not receive prenatal care until the third trimester.[83] Furthermore, compliance with syphilis treatment was poor; only 10% of women completed their prescribed treatment at a teaching hospital.[84] During the same time period, an estimated 5% of all pregnancies were lost each year as a result of syphilis-induced abortions (75,000 pregnancy losses) in Ethiopia.[85] In an even earlier study from Ethiopia, pregnant women who were seroreactive for syphilis were five times more likely to have a spontaneous abortion or stillbirth than women who were sero-nonreactive.[86] In Zambia, 19% of miscarriages were attributed to syphilis.[83] The spontaneous abortion rate among pregnant African women with syphilis in the 1980s was estimated to be as high as 50%.[87] A case–control study from Zambia demonstrated a 28-fold increased risk in stillbirths among women with high-titer RPR card test seroreactivity.[88] In the University Teaching Hospital in Lusaka, Zambia, 42% of stillbirths were attributed to syphilis during pregnancy.[83] In Zambia, congenital syphilis was implicated in 20–30% of total perinatal infant deaths (50 per 1000 births).[89] In 1977, syphilis was the fourth most common cause of perinatal death in Ethiopia, accounting for 10% of the approximately 70 perinatal deaths per 1000 births; syphilis also caused nearly 5% of all post-neonatal infant deaths.[90] In absolute numbers, during this period, each year 15,000 fetal and infant deaths in Ethiopia were directly attributable to syphilis.[85]

Over the past decade, syphilis has continued to be responsible for a significant proportion of adverse pregnancy outcomes. In 1997 Nairobi, Kenya, women untreated with syphilis were four times as likely to have an adverse outcome (e.g., low birth weight <2500 g or stillbirth) than mothers who had nonreactive serologies at delivery. Treatment for syphilis prior to delivery decreased the rate of adverse outcomes from 26% to less than 15%.[76,79] In an analysis of four studies of maternal syphilis in Tanzania, women with high titer RPR tests (>1:8) were 18 times more likely to have a stillbirth, three times more likely to have an infant with low birth weight, and 6 times more likely to have preterm birth when compared to women who were serologically nonreactive.[80,91] More recently (2000–2004), in a study of HIV-positive pregnant women in Blantyre, Malawi, 8%(92) were positive for syphilis. Maternal syphilis was associated with increased in utero, intrapartum and postpartum mother-to-child transmission (MTCT) of HIV.[92]

Incidence of congenital syphilis

Compared with data from Africa on acquired syphilis during pregnancy in the 1980s and earlier, much less information was available on congenital syphilis. A study in Zambia established that nearly 1% of the babies delivered at the University Teaching Hospital in Lusaka had signs of congenital infection at birth, and as many as 6.5% were seroreactive at birth and thus considered at risk.[93] In another study from Zambia, seroreactivity among infants under 6 months of age was 2.9%.[89] Half the seroreactive infants had two or more clinical features suggestive of early congenital syphilis and, of these, 60% required hospitalization. Further confirmation of the incidence and morbidity associated with early congenital syphilis in Zambia comes from two treatment studies. Early congenital syphilis was diagnosed in 9% of admissions to one nursery ward and in 8% of admissions to the intensive care unit.[94]

Syphilis remains the leading cause of perinatal mortality in sub-Saharan Africa, resulting in 21% of all perinatal deaths.[28,87] Estimating the incidence of congenital syphilis in sub-Saharan Africa over the past decade continues to be challenging as few countries track the number of affected infants. Many women in African countries do not have access to prenatal care or receive care too late to prevent congenital syphilis, and many syphilitic pregnancies result in spontaneous abortion or stillbirth prior to the mothers being screened for syphilis.[29] In 1995, it was estimated that worldwide there were more than 1 million cases of syphilis in pregnancy. However, as of 2001, in sub-Saharan Africa alone, it was estimated that 2,300,000 women were infected with active syphilis during pregnancy and of these 1,640,000 were estimated to be undetected and, therefore, untreated and infectious. Using these estimates 328,000 (20%) pregnancies would result in spontaneous abortion; 246,000 (15%) in perinatal death; 328,000 (20%) in low birth weight and 328,000 (20%) in congenital infection totaling 1,230,000 pregnancies affected by congenital syphilis. The overall impact of syphilis in pregnancy rivals, and may even exceed, that of HIV infection in Africa, which is estimated at 720,000 pregnancies.[28,71,87]

Estimates of the incidence of congenital syphilis in South Africa have been possible, however, since 1991 when congenital syphilis became a reportable disease. From 1991 to 2001 there were a total of 5662 cases and 115 deaths of congenital syphilis in that country. This number peaked in 1993 at 903 cases and then steadily declined thereafter to a low of 139 cases in 2001.[78] From 2001 to 2005, the number of congenital syphilis cases continued to decline with only one reported case in 2005. This success may be attributable to public health interventions in the syndromic management of sexually transmitted infections and increased antenatal visits with screening and management of syphilis in pregnancy.[78]

PATHOGENESIS AND PATHOLOGY

■ TRANSMISSION OF SYPHILIS DURING PREGNANCY

Although a mother can transmit syphilis to her infant at the time of delivery,[95,96] the vast majority of cases are believed to arise from in utero infection. In fact, no form of syphilis better exemplifies the remarkable invasiveness of *T. pallidum*

Table 82-2. Prospective Observations of Obstetric Events in Syphilitic Women

Event	150 Syphilitic Women	150 Controls
Pregnancies	1001	826
Miscarriages	9.2%	7.4%
Stillbirths	8.0%	2.1%
Infant deaths	22.9%	11.4%
Infant syphilis	21.0%	0.0%
Healthy child	38.9%	79.1%

than congenital syphilis. Also noteworthy is that *T. pallidum* subsp. *pallidum* is the only pathogenic treponemal subspecies with the capacity to regularly traverse the placenta[65]; this fact is even more extraordinary given the remarkably similar genomes of the pathogenic treponemes.[97–99] Studies with cultured human umbilical vein endothelial cells have documented that *T. pallidum*, but not nonpathogenic treponemes, efficiently penetrates endothelial cells via intercellular junctions,[100,101] and it is likely that a similar, if not identical, process underlies the traversal of maternal and fetal tissues in utero.[100,101] The finding of spirochetes in the placenta and umbilical cord in association with typical histopathologic changes supports transplacental invasion during maternal spirochetemia as the major route of transmission.[102–106] Alternatively, but less likely, *T. pallidum* may gain access to the fetal circulation by first traversing the fetal membranes and infecting the amniotic fluid.[107–110]

The risk of congenital syphilis is directly related to the stage of maternal syphilis during pregnancy and the duration of exposure of the infant in utero. It is extremely high during the first 4 years after acquisition, when spirochetemia is common, and then decreases during late syphilis, when spirochetemia becomes a rare event. Harman (in 1917) followed obstetric events in 150 syphilitic women and 150 healthy women of similar social status (Table 82-2).[111] Sixty-one percent of the pregnancies of the syphilitic women resulted in adverse outcomes or the birth of an infected child, compared to a complication rate of 20.4% in healthy women. In 1951, Ingraham reported that following untreated maternal early syphilis of 4 years or less duration, 41% of infants were live born with congenital syphilis, 25% were stillborn, 14% died in the neonatal period, 2% were premature but without evidence of congenital syphilis, and only 18% were normal full-term living infants.[112] In contrast, only 2% of infants born to mothers with untreated late syphilis of over 4 years duration had congenital syphilis.[112] Subsequently, in 1952, Fiumara and colleagues reported that among infants born to mothers with primary or secondary syphilis, approximately half of the infants were premature, stillborn, or died in the neonatal period; the other 50% developed congenital syphilis (Table 82-3).[58] With early latent syphilis, the transmission rate decreased to approximately 40%, while 20% were premature, 4% died in the neonatal period, and 10% were stillborn; 20% of infants were normal and full term (Table 82-3). With late latent syphilis, approximately 10% of infants had congenital syphilis and another 10% were stillborn, but there was no increase in premature births or neonatal deaths beyond the expected rate among women without syphilis (Table 82-3).[58] Sánchez et al.[113] documented similar rates in a small cohort of 19 infants. In that series, two of two infants born to mothers with primary syphilis had laboratory evidence of infection (reactive serum IgM immunoblot, positive serum/CSF polymerase chain reaction, or positive rabbit infectivity testing) as did six of six infants born to mothers with secondary syphilis. In contrast, only 6 of 11 (55%) infants born to mothers with early latent infection had evidence of infection. In accordance with the above data, experts have more recently pointed out that there are actually two general scenarios that need to be considered when assessing fetal risk for congenital syphilis.[114,115] One occurs when an infected woman becomes pregnant, the other when a pregnant woman becomes infected. The latter tends to be associated with overall worse outcomes for the infant as it always involves the early, spirochetemic stages of disease in which the likelihood of transmission to the fetus is high. Hollier et al.[116] proposed a continuum of fetal involvement that begins with hepatic dysfunction and placental involvement in maternal primary syphilis and progresses to infection of the amniotic fluid, hematologic abnormalities, and, finally, severe multiorgan disease and marked fetal abnormalities in mothers with secondary and early latent disease.

In the past, it was a commonly held obstetric principle that infection of the fetus does not occur before 18 weeks.

In 1938, Beck and Dailey proposed that the prominence of the Langhans' cell layer of the cytotrophoblast prior to mid-gestation explained the rarity of early transplacental infection, and its regression thereafter left the fetus vulnerable to spirochetal invasion.[117] This belief was supported by Dippel's series and his review of more than 200 fetal autopsies culled from the literature.[118] He found no cases of infected abortuses prior to 18 weeks, and the proportion of abortuses that were infected rose steadily with advancing gestation to a peak at 8 months. Dippel also noted that only 19% of syphilitic abortuses showed delayed regression of the Langhans' layer, whereas 50% of uninfected abortuses had an intact Langhans' layer.[118] This theory, however, was disproved by electron microscopic demonstration of the persistence of the Langhans' cell layer throughout pregnancy and by the detection of spirochetes by silver staining and immunofluorescent techniques in fetal tissue from spontaneous abortions at 9 and 10 weeks of gestation.[102,119] Nathan and coworkers demonstrated spirochetes in amniotic fluid as early as 17 weeks of pregnancy, further proving that *T. pallidum* can gain access to the fetal compartment early in gestation.[107] It is now believed that congenital syphilis can occur following maternal infection at any time in gestation, with the risk of fetal infection increasing as the stage of pregnancy advances. Failure to appreciate syphilis as a cause of first-trimester stillbirth is due to the fetus's inability to mount a characteristic histopathologic response within the first 18–20 weeks of gestation.[120]

HISTOPATHOLOGY

General features

Congenital syphilis can involve almost any and every fetal organ, with liver, kidneys, bone, pancreas, spleen, lungs, heart, and brain being the most frequently affected.[121] As with acquired syphilitic infection, the fundamental histologic lesion of congenital syphilis is an obliterative endarteritis typically consisting of mononuclear and plasma cell infiltrates surrounding blood vessels with intimal hyperplasia (of larger vessels) and swollen, hyperplastic endothelial cells.[122–124] Based upon our current understanding of endothelial cell biology[125] as well as immunohistochemical analyses of cutaneous biopsies from patients with secondary syphilis,[126] it is reasonable to presume that the endothelial cells in these lesions are activated and expressing adhesion receptors, cytokines, and other molecules that initiate and sustain the inflammatory response.[125] Moreover, studies have shown that both motile *T. pallidum* and *T. pallidum* lipoproteins can activate vascular endothelium.[100]

Fibrosis and gummas are also frequently observed in congenitally infected tissues. Fibrosis may be relatively fine in character, consisting primarily of collagen deposition about affected blood vessels, or it may substantially distort and replace the parenchyma in affected organs, such as the liver, pancreas, bone, and lung.[121] Microscopic gummas are common, especially in skin, mucous membranes, bone, and liver. They typically consist of a thin peripheral rim of mononuclear cell infiltration, central coagulation ("gummy" necrosis), and fibrosis, but any of these three features may predominate. Unlike the staged histopathology of acquired syphilis, a distinctive feature of congenital syphilis is that these tissue reaction patterns may be present, to various extents, as part of a single syndrome.

Placenta and umbilical cord

Inflammatory changes in the placenta are often more striking than those of the fetus. Grossly, the infected placenta is large, thick, and pale, weighing up to one third of fetal weight.[102,127,128] Microscopic changes include (1) focal proliferative villitis with necrosis and focal infiltrations of maternal lymphocytes and plasma cells, (2) endothelial and adventitial proliferation of villous vessels leading to obliteration, (3) villi which are immature, large, clubbed, and crowded, (4) extensive stromal hyperplasia and deposition of granulation tissue, and (5) occasionally, multiple small ("miliary") gumma (Fig. 82-4).[102,106,128–130] Although there are no absolute pathologic placental findings associated with congenital syphilis, enlarged hypercellular villi, proliferative vascular changes, and acute or chronic villitis have long been considered as the "syphilis triad", findings which, together, are strongly suggestive of congenital syphilis.[102,106,128–131] Spirochetes can often be visualized by silver stain or with more specific immunohistochemical methods (Fig. 82-4). The umbilical cord also may be involved. A deeply seated inflammatory process within the matrix of the umbilical cord, termed *necrotizing funisitis*, has been described,[104] although there is disagreement as to whether this lesion is specific for syphilis.[105] Macroscopically, the umbilical cord resembles a "barber pole"; the edematous portions have a spiral-striped zone of red and pale blue discoloration interspersed with streaks of chalky white (Fig. 82-5). On cross-section, abscess-like foci of necrosis located within Wharton's jelly are centered around the umbilical vessels (Fig. 82-5).

Skeletal system

Characteristic bony lesions are present in 97% of autopsied infants by 6 months of age.[124] Membranous bones are less involved than endochondral (long) bones, in which the pathological process is concentrated at the metaphyseal-epiphyseal junction. Grossly, an irregular yellow line is found at the zone of provisional calcification.[132] When membranous bone is involved, it is generally a periostitis, which leads to localized exostosis and osteoporosis. A perivascular inflammatory infiltrate, found in both types of bone, erodes the

Wendel.)* (Right) Detection of *T. pallidum* by indirect immunofluorescence with rabbit anti-*T. pallidum* antiserum. *(Courtesy of S. Norris.)*

trabeculae and eventually gives way to fibrosis.[133,134] A debate persists regarding the relative importance of inflammatory and trophic influences ("syphilitic dystrophy") on the production of these lesions.[135,136] Caffey attributes the transverse striping of the metaphyses to nutrition and argues that any severe disease of the fetal and neonatal period may produce it.[135] Others have made careful pathoradiologic correlations, describing the sequential development of an "osteochondritis."[137,138] When fully developed, the epiphyseal plate is destroyed, the end of the diaphysis is destroyed, and fragments of bone and cartilage separate to produce a "pseudo-Charcot's joint." The diaphysis acquires a worm-eaten appearance resembling fibrocystic disease. Marrow is trapped between thick layers of periosteum, and islands of cartilage are trapped within metaphyseal bone. Epiphyseal ossification centers are usually spared.

In surviving infants, healing occurs over the first 6 months, usually without residual lesions, and seems little influenced by penicillin.[139,140] This suggests that much of the pathogenesis of these lesions may be trophic rather than directly infectious and that the severely ill infant who comes to autopsy may not be representative of the survivors whom radiologists and clinicians most commonly encounter. Marked inflammation and exuberant fibrosis may be hallmarks of more profoundly affected infants.

Liver, spleen, pancreas, intestines, and lungs

Liver involvement typically takes the form of inflammation confined to the portal triads with rings of collagen deposited about portal ducts and blood vessels. In some cases, focal inflammation and scarring irregularly replace hepatic parenchyma. In the most severe cases, the inflammatory infiltrates produce a diffuse hepatitis with separation of liver plates and, eventually, extensive scarring. Though not specific for syphilis, excessive extramedullary hematopoiesis within hepatic sinusoids and portal triads often accompanies these changes. Diffuse gumma also may be seen. Silver stains of hepatic tissue often show heavy infiltration with treponemes even in the absence of pronounced histologic abnormalities. Splenic sinusoids are widened and crammed with masses of blood-forming cells, explaining the characteristic splenomegaly. Deposition of granulation tissue about splenic blood vessels can be severe enough to cause "onion

skinning." Pancreatitis, which may be intense, consists of isolation and obliteration of ductules as well as acini by inflammatory infiltrates and perivascular deposition of rings of collagen.[121] In the gastrointestinal tract, mucosal and submucosal infiltration with mononuclear and plasma cells is associated with a striking fibrotic response and increase in the width of the submucosa. Though now rare,[121] the classical "pneumonia alba" of congenital syphilis is characterized by grossly enlarged, firm, yellowish-white lungs; these changes are due to an intense obliterative fibrosis in the interalveolar septae.[124]

Nervous system

Meningeal involvement is grossly apparent as a discoloration and thickening of the basilar meninges, especially around the brainstem and optic chiasm.[124] The microscopic[124] changes consist of endarteritis with various degrees of infarction and neuronal damage. Fibrosis during healing may result in obstructive hydrocephalus and/or entrapment of cranial nerves. Parenchymatous forms of late congenital neurosyphilis (e.g., general paresis, tabes dorsalis), now extremely rare, are pathologically indistinguishable from those of acquired syphilis in adults.[141]

Kidneys

An epimembranous glomerulopathy is associated with two different forms of immune complex injury. One involves deposition of IgA, IgG, and IgM with complement and the other involves immune complex deposition without complement along the glomerular basement membrane.[142] Elution studies have demonstrated that the complexes consist of treponemal antigens and antitreponemal antibodies.[143] Interstitial perivascular infiltrates consisting of mononuclear and plasma cells also are present.

Teeth

The late dental consequences of neonatal syphilis are abnormalities of form, structure, and size. There is apical notching, the amelodentinal junction is irregular, enamelization is defective, and the affected teeth are small. The pathogenesis of dental stigmata has been a long-standing controversy. Although Hutchinson himself at first regarded the changes as a part of the syndrome of mercurial stomatitis, he subsequently attributed them to trophic changes.[13,14,127] Early difficulty in confirming the presence of spirochetes in developing dental tissue contributed to the notion that hypoplasia and malformation were due to the general nutritional state of syphilitic infants, to local impairment of nutrition due to endarteritis, or even to rickets.[144] Indeed, as Hutchinson emphasized, it is the first (6 year) molars and central incisors of the permanent set that are specifically affected. These begin to calcify just before and just after birth, respectively. Therefore, perinatal injury would be expected to produce malformation of these teeth, particularly

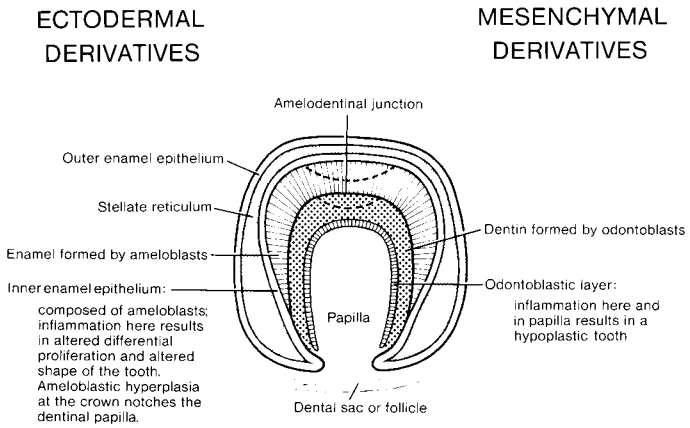

FIGURE 82-6. Development of the permanent incisor, illustrating the effect of treponemal infection or morphogenesis.

if a disturbed process of calcification is the major mechanism of pathogenesis. From 1932 to 1953, however, a series of observations suggested that direct treponemal invasion of the developing permanent tooth and the resulting inflammation are the cause of dental stigmata.[145]

The tooth is formed by mesenchymal protrusion into an ectodermal tooth bud, which invaginates to receive it (Fig. 82-6). A dental papilla of mesenchymal origin gives rise to an outer layer of odontoblasts that ultimately produce dentin abutting the ectodermal enamel organ. An enamel epithelium on the inner aspect of the enamel organ consists of ameloblasts that ultimately produce a layer of enamel rods, lining the outer aspect of the dentin. Interactions between ameloblasts and the underlying mesenchymal odontoblasts initiate the apposition of enamel and dentin. This is followed by calcification of both enamel and dentin and finally by eruption. When the jaws of newborn infants dying of congenital syphilis are examined, the tooth germs of the permanent teeth are inflamed and spirochetes can be found throughout the enamel organ and dental papilla. There is endarteritis and perivascular inflammation in the dental papilla, and spirochetes are found in vessel walls. This results in a complex pathological process culminating in a failure to lay down enamel at the center of the notch and an irregular amelodentinal junction in the mature tooth. Radiographs of syphilitic incisors suggest that the irregular amelodentinal junction is the internal counterpart to the external deformity. The impaired growth of the dentinal papilla, on the other hand, is the precursor of the small size of the incisors and first molars.

CLINICAL MANIFESTATIONS

PREMATURITY AND INTRAUTERINE GROWTH RETARDATION

Intrauterine growth retardation, a commonly cited feature of congenital syphilis, is thought to reflect inadequate nutrition of the fetus as a result of syphilitic placentitis.[146–148] Previously, there were no clear criteria for distinguishing between premature infants and those who are small for gestational age. Furthermore, Naeye's study of 36 syphilitic perinatal deaths seemed to show that, in contrast to rubella and cytomegalovirus infection, syphilis did not affect fetal growth.[90] The difficulty in sorting out the contribution of syphilis to fetal-growth retardation is compounded by the fact that gestational syphilis disproportionately affects the same population in which other causes of fetal-growth retardation, such as maternal use of intravenous drugs and poor nutritional status, are prevalent. Controlled studies, however, strongly support the association between intrauterine infection with *T. pallidum* and prematurity, low birth weight, and small size for gestational age.[149,150]

EARLY CONGENITAL SYPHILIS

Similar to acquired syphilis in adults,[151,152] congenital syphilis traditionally is divided into early and late disease. Those features that typically appear within the first 2 years of life comprise early congenital syphilis, while those that occur after 2 years of age, most often near puberty, comprise late congenital syphilis. In current practice, the vast majority of cases present within the perinatal period.

The clinical manifestations of early congenital infections are a consequence of active infection with *T. pallidum* and the resultant inflammatory response induced in various organs and tissues. The severity of these manifestations is extremely variable, ranging from life-threatening involvement of multiple organs and body systems, as is seen in fetal hydrops, to radiologic or laboratory abnormalities in an otherwise normal-appearing newborn.[147] Indeed, most infected infants are entirely asymptomatic at birth.[34,153–156] In a study from Detroit, only 16 (22%) of 72 infants born to mothers with untreated syphilis had clinical, laboratory, or radiologic evidence of congenital syphilis.[149] When syphilis is not identified in normal appearing infants, the diagnosis is delayed until the patient presents weeks later with such nonspecific complaints as rhinitis, pneumonia, or failure to thrive.[37,95,157,158] In two thirds of untreated cases, the clinical signs of early congenital syphilis begin to appear in the third to the eighth week of life; in nearly all cases, the signs appear within 3 months.[158,159]

Neonates born with manifest syphilis are often severely affected and carry a worse prognosis. Among these are the infants who display the classic picture of marasmic syphilis: the "wizened, pot-bellied, hoarse old man with withered brown skin and runny fissured nose ... senescent decrepitude in miniature."[34] In an earlier era, a number of signs were very suggestive of syphilis, especially when seen together (e.g., snuffles, certain skin eruptions, pseudoparalysis, and epitrochlear lymphadenopathy).[155] Marfan (as cited by Stokes) considered snuffles, palmar and plantar bullae, splenomegaly, pseudoparalysis, and cutaneous syphilids to

form a diagnostic pentad[158]; Bueno suggested that the first three of these signs comprise a triad.[160] None can be considered entirely pathognomonic, however.

Mucocutaneous lesions

Among those infants who have clinical evidence of congenital syphilis, 15–60% will manifest mucocutaneous lesions consisting of rash and/or rhinitis (Table 82-4). Nasal discharge is the earliest sign of congenital syphilis, occurring 1–2 weeks before the rash (Fig. 82-7). It was reported in 68–86% of older series,[140,144,159] but has become much less common over time (Table 82-4).[161,162] The discharge, which contains spirochetes in high concentration, is initially watery and indistinguishable from that of viral or allergic rhinitis, but then it becomes progressively thicker and purulent and then hemorrhagic. Resulting nasal obstruction interferes with feeding. Ulceration leads to deeper involvement, including chondritis with necrosis, and eventually to the septal perforation or saddle-nose deformity of late congenital syphilis. Extension into the throat produces laryngitis and either a hoarse or an aphonic cry.

As with secondary syphilis in adults, there are myriad cutaneous lesions in congenital syphilis. The most common lesion is a large round pink macule that fades to a dusky or coppery hue, lasts 1–3 months without treatment, and leaves a residual pigmentation.[34,158] These lesions are typically distributed over the back, perineum, extremities, palms, and soles, sparing the anterior trunk; they develop slowly over a period of weeks. They may be covered with a fine, silvery scale and may mingle with indurated plaques of similar size and color. The corymbiform lesion consists of a grouped papule around a large central plaque, like a "hen and chicks"; annular lesions occur but are less common than in acquired secondary syphilis.[33] The vesiculobullous eruption, known as *pemphigus syphiliticus*, is highly distinctive when present.[158] Intraepidermal edema leads to spongiotic midepidermal blisters that are most prominent on the palms and soles; the blister fluid teems with spirochetes.[124] When the bullae rupture, they leave a macerated, dusky red surface that readily dries and crusts (Fig. 82-8). Even in the absence of frank bulla formation, desquamation is common and may be generalized or confined to the periungual areas of fingers and toes. Palmar and plantar desquamation is preceded by subcutaneous edema underlying a shiny erythema and sometimes accompanied by shedding of the nails.[1,34] Paronychia also leads to narrow, atrophic nails, producing a claw-nail deformity, particularly of the fourth and fifth digits. Hair may be brittle and sparse; infantile alopecia, especially affecting the eyebrows, is considered very suggestive of syphilis.[34]

The face, perineum, and intertriginous sites are particular targets of syphilitic lesions that may be eczematoid, impetiginous, or even gangrenous (Fig. 82-9 A,C).[1,34,158] The facial eruption preferentially affects the middle third of the face, from the medial portions of the supraorbital ridges to the chin[163] (Fig. 82-9B). At the nares, lips, and anus, the initial lesions may be indistinguishable from the mucous patches of secondary syphilis but then become deeply fissured and hemorrhagic, leading to Parrot's radial scars of late congenital syphilis, known as rhagades.[34] Mucous patches are also found on the tongue and palate.

Condylomata lata affect the same mucocutaneous and intertriginous areas and are raised, flat, moist verrucae that are seen in recurrences of untreated congenital syphilis.[34] They are seen typically toward the end of the first year of life,[1] and, together with the furuncle of Barlow, may be regarded as an intermediate manifestation between early and late congenital syphilis. The syphilitic furuncle is a deep violaceous

nodule, usually on the upper outer thigh, that occurs after 9 months and before 3 years of age.[34] Furthering the analogy between congenital and secondary syphilis is a recent report of diffuse alopecia in an infected neonate.[164]

Reticuloendothelial system

Syphilis was once the most common cause of hepatosplenomegaly in infancy.[165] The majority of infants with clinical evidence of early congenital syphilis will manifest hepatosplenomegaly (Table 82-4).[121,136,154,161,166–168] Hepatomegaly may occur as an isolated manifestation,[161] but splenomegaly without hepatic enlargement occurs rarely, if ever. Both hepatic and splenic enlargement are caused by subacute inflammation and by compensatory extramedullary hematopoiesis.[121,169] Hypersplenism also may contribute to spleen size.[158,170] Up to one third of infants with hepatic involvement will manifest both direct and indirect hyperbilirubinemia as well as elevated transaminase, γ-glutamyltransferase, and alkaline phosphatase levels.[116,171] For unknown reasons, the liver dysfunction may actually worsen with the initiation of penicillin therapy, before gradually improving weeks to months later.[171] On occasion, the liver abnormalities may require as long as a year to resolve; permanent hepatic sequelae (e.g., cirrhosis) are rare, however. Generalized lymphadenopathy is found in 20–50% of cases.[140,162,168,172] The nodes are firm, rubbery, and nontender. Epitrochlear adenopathy, found in 20% of those with adenopathy, is considered especially characteristic of congenital syphilis.[147,158,162,173]

Skeletal involvement

Among syphilitic infants under 1 year of age studied by Nabarro,[34] more than 30% had physical evidence and more than 80% had radiographic evidence of osteochondritis. In an unpublished series from Texas, 70% of infants with probable or definite congenital syphilis had osteochondritis,[174] a figure similar to those in other reports (Table 82-4). The majority of affected infants do not have any symptomatology from skeletal involvement; on occasion, however, the bony lesions may be painful or have superimposed fracture resulting in pseudoparalysis of the affected limb, termed *pseudoparalysis of Parrot*.[147] The physical signs of skeletal syphilis in infants are limited to the signs of epiphysitis. Epiphyses of the radius, femur, humerus, and fibula, in descending order of frequency, are involved. There may be periarticular swelling, and the end of the bone is tender on passive motion of the adjacent joint. When the proximal humerus is affected, the arm hangs in flaccid immobility, internally rotated with the forearm in pronation. Pain elicited by passive motion of the shoulder, however, and development of the condition after birth distinguishes this pseudoparalysis from intrapartum brachial plexus injury. When the femur is involved, the leg is held in rigid flexion. Dactylitis (tender, fusiform swelling of the fingers) was observed in 2–6% of older series,[144] but is now uncommon, probably because it was typically seen in recurrences of untreated congenital syphilis.[30] Osteitis of the skull, particularly of the central margins of the occipital and parietal bones, produces softening (craniotabes) that indents or yields on pressure "like stiff parchment."[34,158] Parrot's nodes are focal, bilateral, frontoparietal swellings, typically separated by a cruciform furrow.

Roentgenographic methods have been used diagnostically in congenital syphilis for more than 80 years. Because the radiographic changes are relatively specific, x-ray formerly rivaled serology in importance for diagnosis and is still highly useful in distinguishing active infection from transplacental transfer of maternal antibodies.[155] The proliferative and destructive changes in bone tissue produce a "celery stick" appearance of increased density alternating with rarefaction on x-ray.[138,175] Radiographic changes are most readily observed in the areas of rapid bone growth, such as in the provisional zone of calcification and in the periosteum (Fig. 82-10). Syphilitic osteochondritis requires approximately 5 weeks to become roentgenographically demonstrable, while periostitis, multiple layers of new periosteal bone formation in response to diaphyseal inflammation, requires 16 weeks. This corresponds to the clinical observation that osteochondritis is usually manifest perinatally, whereas periostitis sometimes is not seen until 4–5 months later.[155] When both lesions are present perinatally, it suggests that the infant was infected during the second trimester[176]; the combination of these lesions makes a diagnosis of syphilis very likely. When periostitis is present by itself, it usually means that an earlier osteochondritis has already healed. Although single bone lesions can occur,[177] such a finding should suggest another diagnosis.

A skeletal survey is required to evaluate infants for congenital syphilis. Widespread lesions involve multiple, symmetrical sites of the long bones and occasionally involve the cranium, spine, and ribs. The tibia and ulna are most commonly followed by fibula, radius, humerus, and femur. Lower extremities are more commonly affected than upper extremities; the femur is more often affected distally, the tibia and humerus proximally.[34] The earliest changes occur in the metaphysis, consisting of a transverse sawtooth radiodense band below the epiphyseal plate; this widened and enhanced zone of provisional calcification is accompanied by an underlying zone of osteoporosis, evident as a radiolucent band. A series of alternating dense and lucent bands may extend into the diaphysis.[133] This process may be followed by radiolucent mottling and finally by fragmentation of the metaphysis itself. Focal defects with cortical destruction may be seen on the lateral aspect of the metaphysis; in the tibia, such lesions occur on the medial aspect of the proximal metaphysis and are usually bilateral, giving rise to the distinctive "cat bite" or Wimberger's sign in 21% of cases of infant syphilis.[178] Erosion of the sigmoid notch of the ulna may be of similar significance.[139] Though also seen in hyperparathyroidism, infantile generalized fibromatosis, and bacterial osteomyelitis, the "cat bite" sign is most suggestive of syphilitic osteitis. Later, longitudinal lines of rarefaction may also

FIGURE 82-10. A. extend into the diaphysis; in serial array, these linear lucencies resemble a "celery stick," a sign also seen in rubella and cytomegalovirus infection.[133] Irregular, patchy focal lucencies may appear in the diaphysis, sometimes containing sequestra that invite confusion with suppurative osteomyelitis.[179] The epiphysis is relatively spared of radiographic changes, except that it may separate as a result of minor trauma.

Fractures through the degenerating metaphysis occur readily, followed by exuberant callus formation, resulting in a cap over the metaphysis called the "bucket handle" sign.[178] Periostitis is found in 71% of cases of infant syphilis and consists of multiple layers of periosteal new bone formation ("onion peel periosteum") in response to diaphyseal inflammation[178]; when exuberant, this process leads to hypertrophic "periosteal cloaking" of the bone, with layers of marrow trapped between layers of subperiosteal bone, thus encasing the entire shaft and producing a radiographic "sarcophagus sign" (Fig. 82-10).

Hematologic manifestations

The major hematologic features of early congenital syphilis are anemia, leukocytosis or leukopenia, and thrombocytopenia. Whitaker et al. found anemia to be the most common laboratory finding in 24 out of 25 cases (96%).[170] The anemia of congenital syphilis is Coombs' test-negative, normochromic, and normocytic or macrocytic with polychromasia, and often striking reticulocytosis and erythroblastosis.[34] Severe anemia may be associated with replacement of marrow by granulation tissue in syphilitic osteitis or with maturation arrest in the erythroblastoid line.[34,180] Autoimmune hemolysis, however, is a more common mechanism,[170,181] and it may be associated with cryoglobulinemia, macroglobulinemia, or circulating immune complexes.[142,143,182,183] Hemolysis may persist for some time following treatment and can be sufficient, if prolonged or complicated by bleeding, to lead to iron-deficiency anemia.

Neutrophilic leukocytosis occurs in over 70% of cases, and congenital syphilis is one of the classic causes of leukemoid reactions in infancy.[184] Leukopenia and monocytosis also have been described.[185] Thirty percent of babies with syphilis develop significant thrombocytopenia.[166,170] Bleeding complications occur in 60% of those who are thrombocytopenic. Thrombocytopenia is believed to be due to diminished platelet survival mediated by immune complexes or hypersplenism.[166,170]

Nephropathy

Syphilitic nephrotic syndrome in infancy is an uncommon complication that has, nevertheless, been recognized since the end of the nineteenth century.[163] Nephrosis was found in 5% of cases of infant syphilis at the Hospital for Sick Children, in London, between 1917 and 1939,[34] which is similar to more recent series[133,181]; glomerulonephritis, with hematuria and cylindruria, is less common.[186] Evidence of nephrotic syndrome appears at 2–3 months of age with the onset of edema, ascites, hypoproteinemia, and proteinuria.

Central nervous system involvement

Neurologic involvement in congenital syphilis ranges from asymptomatic central nervous system (CNS) invasion by *T. pallidum* to acute syphilitic leptomeningitis. Traditionally, asymptomatic involvement of the CNS is inferred from abnormal CSF indices (e.g., pleocytosis, elevated protein content, or reactive CSF-VDRL test). In 1949, Platou reported a 60% incidence of congenital neurosyphilis based upon diagnostic criteria consisting of >5 wbc/mm^3, a protein content >45 mg/dL, and a reactive CSF-VDRL test.[140] These criteria are relatively insensitive and nonspecific, however; in neonates, as many as 25–32 wbc/mm^3 and a protein content as high as 170 mg/dL in CSF can be within the normal range.[187,188] Furthermore, the significance of a reactive CSF-VDRL test in the absence of other diagnostic evidence of congenital syphilis is suspect, inasmuch as nontreponemal IgG antibodies can pass from the serum to the CSF.[189,190] Investigators have analyzed neonatal CSF utilizing immunoblotting for *T. pallidum*-specific IgM antibodies and rabbit infectivity testing (RIT)[191] to arrive at a more precise estimate of the frequency of asymptomatic CNS involvement. Both of these modalities indicated that the likelihood of CNS involvement correlates with the degree of clinical severity. Among infants with clinical and laboratory evidence of congenital syphilis, CNS involvement by IgM immunoblotting ranged from 44% (11 of 25) to 82% (14 of 17).[113,189,192,193] In contrast, only 10–20% of normal-appearing infants with congenital infection had detectable IgM antibodies in CSF.[193] By RIT, the prevalence of CNS invasion by *T. pallidum* was 86% (6 of 7) in infants with symptomatic congenital syphilis, but only 8% (1 of 12) among infants with normal physical examination and laboratory evaluation.[113] More recently, researchers have studied the use of PCR to detect CNS involvement in infants. In a comparison of the diagnostic accuracy of IgM immunoblotting and PCR assay of serum and CSF with the CSF RIT, PCR and IgM immunoblotting of serum and blood best predicted CNS infection with sensitivities of 94% (16 of 17) and 100% (17 of 17), respectively.[194,195]

The neurosyphilitic syndromes described in early congenital syphilis essentially represent diverse clinical expressions of a single pathogenic process—basilar meningitis and meningovascular syphilis. Acute syphilitic leptomeningitis, with meningismus, bulging fontanelles, and intractable vomiting, carries a grave prognosis.[147] Patients who survive this syndrome untreated or inadequately treated are usually left with obstructive hydrocephalus, seizure disorders, and impaired intellectual development. Cerebrovascular accidents occur in the neonatal period, probably as a combined consequence of cerebral arteritis and thrombocytopenia.[166] Untreated neurosyphilis can lead to a chronic meningovascular

process which results in hydrocephalus, cranial nerve palsies, and cerebral infarction late in the first year. Hypopituitarism manifested by persistent neonatal hypoglycemia has been observed among some infants with congenital syphilis.[196] Autopsy specimens have demonstrated interstitial inflammation, fibrosis, and occasionally focal necrosis of the anterior lobe.[121,196] The neurohypophysis is usually normal. Magnetic resonance imaging (MRI) of the pituitary, combined with evaluation of pituitary function, has aided in its diagnosis.

Ocular involvement

Three ocular lesions are associated with early congenital syphilis: chorioretinitis, glaucoma, and uveitis. Syphilitic chorioretinitis typically produces a "salt and pepper" pattern of pigmentary patches at the periphery of a granular fundus.[197] Proptosis, blepharospasm, corneal clouding and edema, and excessive tearing should suggest the possibility of glaucoma. Uveitis usually occurs as an extension of choroiditis. Interstitial keratitis and optic neuritis have been described in infantile syphilis,[34] but they are generally regarded as lesions of late congenital syphilis.

Other manifestations

Syphilitic pneumonitis (pneumonia alba) is uncommon. Radiographically it produces bilateral, streaky infiltrates that can progress to widespread consolidation and may be confused with respiratory distress syndrome (Fig. 82-11).[34,198] Diarrhea in early congenital syphilis may be due to either pancreatitis with malabsorption or direct involvement of the intestinal mucosa. Rectal bleeding and obstruction due to severe ileitis also have been reported.[199] Approximately 10% of infants dying of syphilis have myocarditis.[200] The clinical importance of myocardial involvement in living infants is unknown; there is no convincing evidence of myocardial sequelae in surviving adolescents and adults with congenital syphilis.

■ LATE CONGENITAL SYPHILIS

The malformations or stigmata of late congenital syphilis represent the delayed consequences of the localized inflammatory processes established at sites of treponemal infection during the early stage of disease.[148,201,202] Thus, late congenital syphilis can be prevented simply by appropriate treatment of early infection. Late congenital syphilis in the child or adolescent corresponds to tertiary syphilis in the adult, and, as with tertiary syphilis, late congenital syphilis is not infectious. Although the cardiovascular system is usually spared in the child, other target organs (e.g., bone and soft tissue, eyes, ears, and the CNS) are similar in late adult and congenital syphilis. Moreover, in both instances, gummatous (i.e., granulomatous) lesions tend to supplant the mononuclear and plasmacytic perivascular infiltrates of early syphilis.

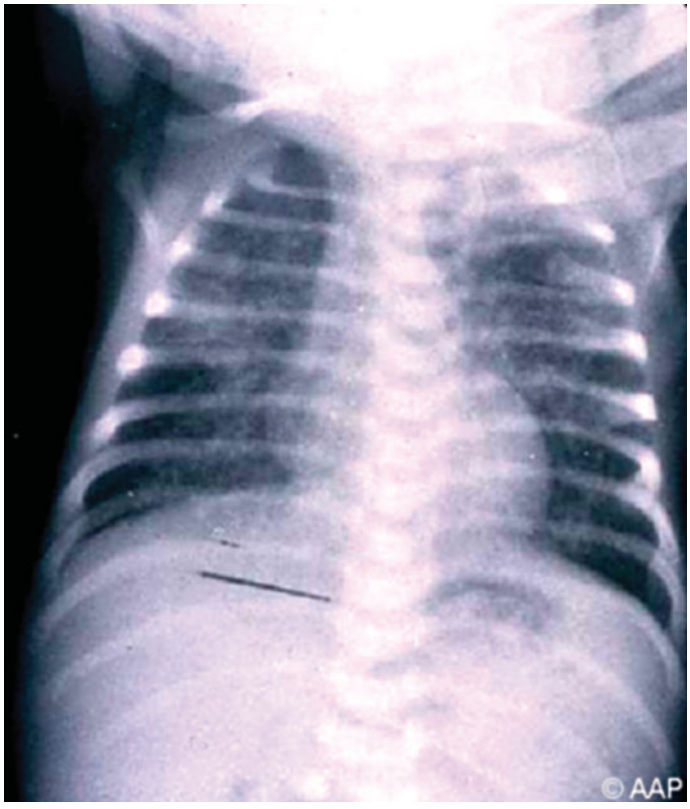

FIGURE 82-11. Congenital syphilis with pneumonia alba. The infant survived with penicillin. (Used with permission of the American Academy of Pediatrics. Red Book Online Visual Library, 2006. Image 128-05. Available at http://aapredbook.aappublications.org/visual; accessed on June 15, 2007.)

Malformations (stigmata)

Chondritis and focal osteitis in infancy may lead to the craniofacial malformations that classic writers on congenital syphilis found so fascinating. The most common is frontal bossing, which occurs in some form in 30–87% of symptomatic cases.[144,158,202,203] Involvement of the parietal bone produces squaring of the cranium or occasionally a "hot cross bun" deformity. Other variations of this malformation include supraorbital thickening (olympian or beetled brow), a high cranium or "tower skull," and, with parietal bossing alone, a sloping skull.[33] Robinson attributed the absence of bossing among his own cases to the disappearance of rickets.[204] By ascribing cranial bossing to associated, unrecognized rickets, he revived the nineteenth century confusion between rickets and congenital syphilis. Since bossing was common in the only other modern series of cases,[202] the controversy may outlive the disease.

Deep necrotizing nasal chondritis in infancy produces a collapsed saddle-nose deformity in 10–30% of patients with late congenital syphilis.[158,162] Involvement of adjacent structures may also lead to a short maxilla and a high palatal arch. The resulting facies has a flat, "dished out" look, with a relatively prominent mandible. Circumoral radiating furrows (rhagades) complete the syphilitic facies in 5–10%. Laryngeal scarring may leave the child hoarse.[34]

Sequelae of periostitis of long bones affect primarily the tibia, clavicle, and scapula, in that order. Anterior bowing of the tibia (saber shin) occurred in 30–40% of older series but is now uncommon (Fig. 82-12).[202,204] Particularly in these children, recurrent acute periostitis of the tibia, ulna, fibula, or femur sometimes followed trauma or febrile illness, and it might be heralded by local tender nodules resembling erythema nodosum.[34] Thickening of the clavicle in its medial third is called Higouménaki's sign and occurs preferentially on the side of the patient's handedness.[158] Robinson doubted its authenticity as a sign of syphilis.[204] Affected scapulae assume a scaphoid shape, concave medially.

Teeth. Syphilis affects morphodifferentiation and apposition, rather than the later stage of calcification as in rickets. There are no consistent abnormalities in deciduous teeth, but when affected they are misshapen and hypoplastic. The permanent teeth that develop later than the central incisors and first molars are much less commonly affected. If the mesenchymal progenitor cells have been destroyed in the newborn period, later developing permanent teeth may be missing. Hutchinson described small canines and incisors that were widely spaced and peg- or screwdriver-shaped.[13] They were tapered from the gingival bases toward a notched biting edge and were rough, dull, and dirty gray in color due to insufficient enamel (Fig. 82-13A). These changes most often affect the upper central incisors but they may also affect the upper, lower, and lateral incisors. They are changes of the permanent, not the deciduous, teeth, although the latter are believed to be more prone to caries than normal in late congenital syphilis. In the first year of life, the diagnosis can be made by x-ray of the unerupted central incisors.[205] Variations of the classic Hutchinson tooth also occur. The lower incisors may have parallel sides and lack a notch but are otherwise small, round, and spaced, resembling little tombstones or top hats projecting from the gum.[34] The upper incisors are sometimes pointed (cannibal teeth) rather than notched.[1] Henry Moon described more completely the molars whose peculiar "tubercular projections" Hutchinson had mentioned; the characteristic 6-year (first lower) molars are dome-shaped with diminutive cusps arrayed in a tight circle at the top of the dome (Fig. 82-13B).[206] Moon's molars have been variously likened to a mulberry, *a bouton de fleur*, a cow's udder, or a string purse. Poorly enamelized, they are highly prone to decay and are rarely present beyond puberty; they are strongly indicative of congenital syphilis when found.

Inflammatory lesions

Inflammatory lesions produce a variety of clinical manifestations, as described below.

Interstitial keratitis. Interstitial keratitis, when accompanied by neural deafness and typical dental abnormalities, forms Hutchinson's triad. Taken alone, keratitis is the most common late manifestation (20–50%) and is bilateral either simultaneously or sequentially in more than 75% of individuals.[158,204,207] The onset, between 5 and 16 years of age, is heralded by unilateral photophobia, pain, excess tearing, and blurred vision. Neovascularization may be so marked as to give the cornea a "salmon patch" appearance. The second eye is involved within 2 months in 80–90% of patients. Keratitis occurs more commonly in females than males and pursues a self-limited, sometimes relapsing, course that ends in corneal clouding (syphilitic nebulae) (Fig. 82-14) or secondary glaucoma. Chorioretinitis and iritis may be found, but less commonly than in congenital syphilis of infancy. Deafness is the least common of Hutchinson's

FIGURE 82-12. Tibial thickening (saber shin) due to periostitis in late congenital syphilis; one of Hutchinson's cases. (From Hutchinson J. *Syphilis*. London: Cassell, 1909.)

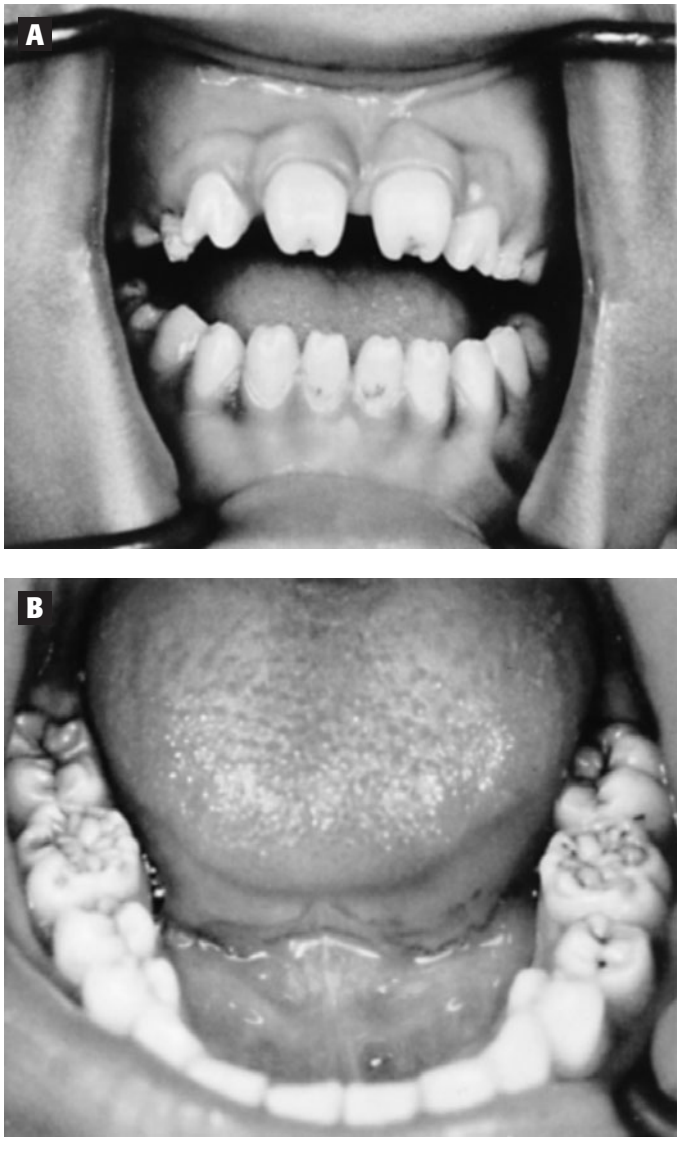

FIGURE 82-13. A. Hutchinson's teeth: The upper and lower incisors are conical, tapered toward the apex, and notched; the canine teeth are hypoplastic and poorly enamelized. **B.** Mulberry molars: the 6-year molars are dome-shaped with a circle of small nob-shaped cusps at the apices. (From Robinson HBG and Miller AS, *Color Atlas of Oral Pathology*. Philadelphia: Lippincott, 1990.)

triad. The primary lesion is osteochondritis affecting the otic capsule and leading to cochlear degeneration. The ossicles occasionally may be affected, so that an associated conduction defect does not exclude syphilis as a cause of sensorineural hearing loss. Karmody and Schuknecht distinguished between the abrupt onset of bilateral deafness without vertigo in childhood and a more gradual asymmetric pattern in adults associated with tinnitus and vertigo.[208] Congenital leutic involvement of the otic capsule leads to fibrous adhesion between the medial surface of the stapedial foot plate and the membranous labyrinth (vestibulofibrosis). The result is Hennebert's positive "fistula sign without a fistula"; this consists of nystagmus and vertigo, despite an intact tympanic membrane, when

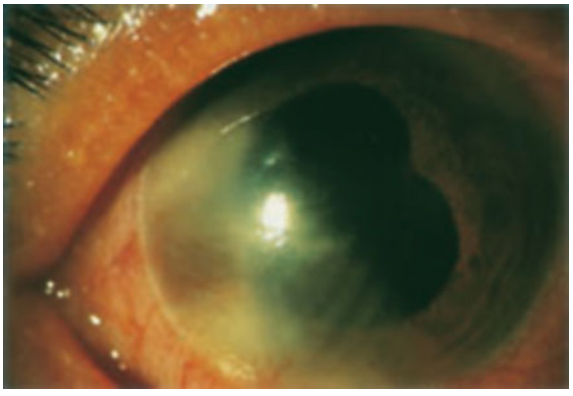

FIGURE 82-14. Congenital interstitial keratitis causing blindness. (*Source*: EyeNet, American Academy of Ophthalmology, January 2004, R. Trubo [BCSC, section 9]. Available at www.aao.org/aao/news/eyenet/comprehensive/comprehensive_jan_2004.htm)

positive and negative pressures are alternately applied to the external canal. Once considered a classic sign of syphilis, Hennebert's sign also occurs in Ménière's disease and vestibular Schwannoma.[209] Hearing loss begins at high frequencies and often progresses to complete bilateral loss of cochlear and vestibular function.

Clutton's joints. Between the ages of 8 and 15, 1–3% of children with congenital syphilis develop symmetrical, painless swelling of the knees (occasionally elbows), with preservation of mobility, often following trauma.[210,211] Adjacent bone erosion (von Gie joint) is rarely seen. Synoviocentesis reveals 10,000–30,000 leukocytes, predominantly lymphocytes. This hydrarthrosis is believed to be due to perisynovitis and resolves spontaneously over several months.

Palatal deformations. Gummata of the palate, throat, and nasal septum begin in late childhood or even adulthood as a gray, sharply defined "raucous patch." These lead painlessly to perforation of the septum and of the soft palate, usually in the midline. Deep ulcers of the throat and tongue occur in a similar fashion.

Neurosyphilis. As many as one fourth to one third of patients over the age of 2 years have asymptomatic neurosyphilis.[162] Symptomatic neurosyphilis, on the other hand, is quite rare, is usually delayed until adolescence, and fits the adult patterns of tabes dorsalis, syphilitic encephalitis (general paresis), and local gummata.[141] Juvenile paresis is the most common of these, occurring in 1–5% of congenital syphilitics, and is generally more severe than the acquired variety.[34,162,204] It typically begins around puberty with deteriorating school performance, bizarre behavior, emotional inappropriateness, and inattention. Over the ensuing 6–12 months, the child develops ataxis, tremor, and dysarthria; half of these patients have seizure disorder, and nearly all have pupillary findings.[212,213] Sequelae of untreated neurosyphilis in infancy, including hydrocephalus, convulsive disorders, and cranial neuropathies, were once common.

Paroxysmal cold hemoglobinuria. Late congenital and acquired syphilis were once the leading cause of paroxysmal cold hemoglobinuria.[214] Only half of these syphilitic patients had other manifestations of disease. About 8 hours following immersion of hands or feet into ice water (Rosenbach test) or other cold exposure, the patient experiences a myalgic, shaking chill and voids dark red or black urine. Many of the syphilitic cases have associated Raynaud's phenomenon.[34] The Coombs' test, Donath–Landsteiner (cold hemolysin) test, and VDRL are all positive. In the syphilitic cases, the attacks cease following penicillin therapy.

DIAGNOSIS

ANTEPARTUM DIAGNOSIS AND STILLBIRTHS

Ultrasonography can be used to diagnose fetal syphilis. The sonographic findings of nonimmune fetal hydrops due to syphilis include skin thickening, placental thickening, serous cavity effusions, hepatosplenomegaly, and hydramnios.[107,215–218] At Parkland Memorial Hospital, hepatomegaly was found to be a reliable sonographic sign of fetal infection and correlated with detection of treponemes in amniotic fluid by RIT.[219] Hill and Maloney also reported noncontinuous gastrointestinal tract obstruction in association with hepatosplenomegaly and placentomegaly in a syphilitic fetus.[217]

As noted earlier, stillbirth is a common outcome of gestational syphilis. According to CDC criteria, a syphilitic stillbirth is defined as a death of a fetus weighing >500 g or having a gestational age >20 weeks in which the mother had untreated or inadequately treated syphilis (Table 82-1).[26,220,221] Whenever possible, this diagnosis should be supported by long-bone radiography or xeroradiography or confirmed by detection of spirochetes in fetal tissues at autopsy.[25,222]

DIAGNOSIS IN THE LIVEBORN INFANT

As noted above, in 1990 and 1996 the CDC issued revised criteria for congenital syphilis surveillance (Table 82-1).[201,220,221] Although intended primarily to help assess the public-health impact of congenital syphilis, these same guidelines also are used by practicing clinicians to determine which infants need further evaluation and treatment. The strength of these criteria lies in their recognition that the diagnosis of congenital syphilis is problematic for three reasons: (1) *T. pallidum* is noncultivatable and often difficult to demonstrate in clinical specimens, (2) serologic analysis of the infant is complicated by the presence of transplacentally acquired maternal antibodies (i.e., absence of a serologic "gold standard"), and (3) a majority of live-born, infected infants have no evidence of infection.[25,222]

CONFIRMED CONGENITAL SYPHILIS

A confirmed diagnosis of congenital syphilis requires laboratory demonstration of *T. pallidum* (Table 82-1). In current practice, this involves detection of live treponemes in body fluids by dark-field microscopy or visualization in body fluids and tissue specimens by silver staining, immunofluorescence, or immunocytochemistry. Dark-field microscopy or immunofluorescence should be performed whenever nasal discharge, mucous patches, vesiculobullous lesions, or condylomata are present. Treponemes abound in such lesions, so definitive diagnosis can be achieved in most cases that exhibit these signs. Unfortunately, conventional methods for detection of *T. pallidum* in clinical specimens are insensitive and/or inapplicable because they require an invasive procedure. For this reason, a confirmed diagnosis is achieved only in the small proportion of infants with florid infection. As is now well recognized, PCR technology has the potential to dramatically improve the ability of clinicians to detect *T. pallidum* DNA in clinical specimens.[194,223] Researchers have demonstrated the usefulness of the PCR testing of amniotic fluid, placental tissue, skin lesions, serum, blood, and CSF in confirming the clinical diagnosis of suspected and asymptomatic congenital syphilis.[194,195,224]

Histopathologic examination of the products of conception

Since the earliest descriptions of syphilitic placentitis, pathologic examination of placentas and umbilical cords has been recognized as a readily available and yet underutilized tool for diagnosing congenital syphilis in at-risk infants.[225,226] Placentas from infants with clinical and/or laboratory evidence of congenital syphilis have very high incidence of histopathological abnormalities, including presence of spirochetes by silver staining.[149,150] Immuno-histochemical methods can facilitate detection of *T. pallidum* in placental tissues.[131,226] Positive PCR testing of placental tissue for *T. pallidum* was significantly associated with placental histological features of congenital syphilis and suggested as useful in identifying cases in the absence of placental changes[227]; these same authors concluded that PCR testing also can be useful when distinctive histopathologic changes are absent in placentae. Stoll and coworkers emphasized the importance of a multidisciplinary approach involving close cooperation among obstetricians, neonatologists, and pathologists to assure that placentas are obtained for routine pathologic evaluation.[150]

Presumptive diagnosis

Congenital syphilis is diagnosed presumptively in the absence of direct demonstration of *T. pallidum* in clinical specimens. The descriptor "presumptive" encompasses a wide spectrum ranging from the floridly symptomatic infant, in whom the diagnosis is essentially certain, to normal-appearing infants without clinical or laboratory evidence of infection.

When a child is born to a woman with reactive syphilis serologies, physical examination should be performed and

the infant's nontreponemal test titer should be compared to the mother's. (Treponemal tests generally are not performed on the neonate because they are not titered and infant reactivity merely reflects the transplacental passage of maternal antitreponemal antibodies.) The CDC no longer recommends obtaining umbilical cord blood because of the potential for contamination with maternal blood. Moreover, there also has been concern that RPR testing of umbilical cord blood is prone to false-positives due to contamination with Wharton's jelly.[147] A guide for the interpretation of maternal and infant syphilis serologies and an algorithm for the evaluation of infants born to mothers with reactive syphilis serologies are presented in Table 82-5 and Fig. 82-15, respectively.[57,228] A diagnosis of congenital syphilis can be made with confidence if the mother has reactive nontreponemal and treponemal serologies and the infant manifests classic signs of disease. Congenital syphilis also is highly likely when the infant's nontreponemal antibody titer is fourfold or greater than the mother's serum, even in the absence of physical findings. In both of the above instances, infants should undergo further evaluation consisting of lumbar puncture with CSF analysis and complete blood cell count to determine the extent of disease and establish a baseline for follow-up. Other tests such as long bone radiographs, liver function tests, and audiologic and ophthalmologic examination should be performed as clinically indicated. Most commonly, the maternal and infant serologic titers are similar or the infant's titer is lower than the mother's.[57,149] Further evaluation is dependent on the maternal stage of disease and treatment status and the infant's physical findings. The following are the most frequently encountered scenarios (Fig. 82-15):

1. The mother was treated *before* pregnancy and her nontreponemal test titer is decreasing appropriately or she is known to be serofast. No further evaluation is required if the infant is asymptomatic.
2. The mother was treated for early syphilis *during* pregnancy more than 4 weeks prior to delivery and her nontreponemal titer decreased fourfold or more prior to delivery. No further evaluation is necessary if the infant is asymptomatic, particularly if follow-up can be assured.
3. The mother was treated appropriately for early syphilis *during* pregnancy more than 4 weeks prior to delivery but her titer did not decrease at least fourfold. Full diagnostic evaluation of the infant (CSF analysis, complete blood

Table 82-5. Guide for Interpretation of Syphilis Serologic Test Results of Mothers and Their Infants

Nontreponemal Test Result (eg, VDRL, RPR, ART)		Treponemal Test Result (eg, TP-PA, FTA-ABS)		
Mother	Infant	Mother	Infant	Interpretation[1]
−	−	−	−	No syphilis or incubating syphilis in the mother or infant or prozone phenomenon
+	+	−	−	No syphilis in mother or infant (false-positive result of nontreponemal test with passive transfer to infant)
+	+ or −	+	+	Maternal syphilis with possible infant infection; mother treated for syphilis during pregnancy; or mother with latent syphilis and possible infant infection[2]
+	+	+	+	Recent or previous syphilis in the mother; possible infant infection
−	−	+	+	Mother successfully treated for syphilis before or early in pregnancy; or mother with Lyme disease (ie, false-positive serologic test result); infant syphilis unlikely

VDRL, indicates **V**enereal **D**isease **R**esearch **L**aboratory; **RPR**, rapid plasma reagin; **ART**, automated reagin test; **TP-PA**, *Treponema pallidum* particle agglutination test, **FTA-ABS**, fluorescent treponemal antibody absorption; +, reactive; −, nonreactive.

[1]Table presents a guide and not a definitive interpretation of serologic test results for syphilis in mothers and their newborn infants. Maternal history is the most important aspect for interpretation of test results; Factors that should be considered include timing of maternal infection, nature and timing of maternal treatment, quantitative maternal and infant titers, and serial determination of nontreponemal test titers in both mother and infant.

[2]Mothers with latent syphilis may have nonreactive nontreponemal test results.

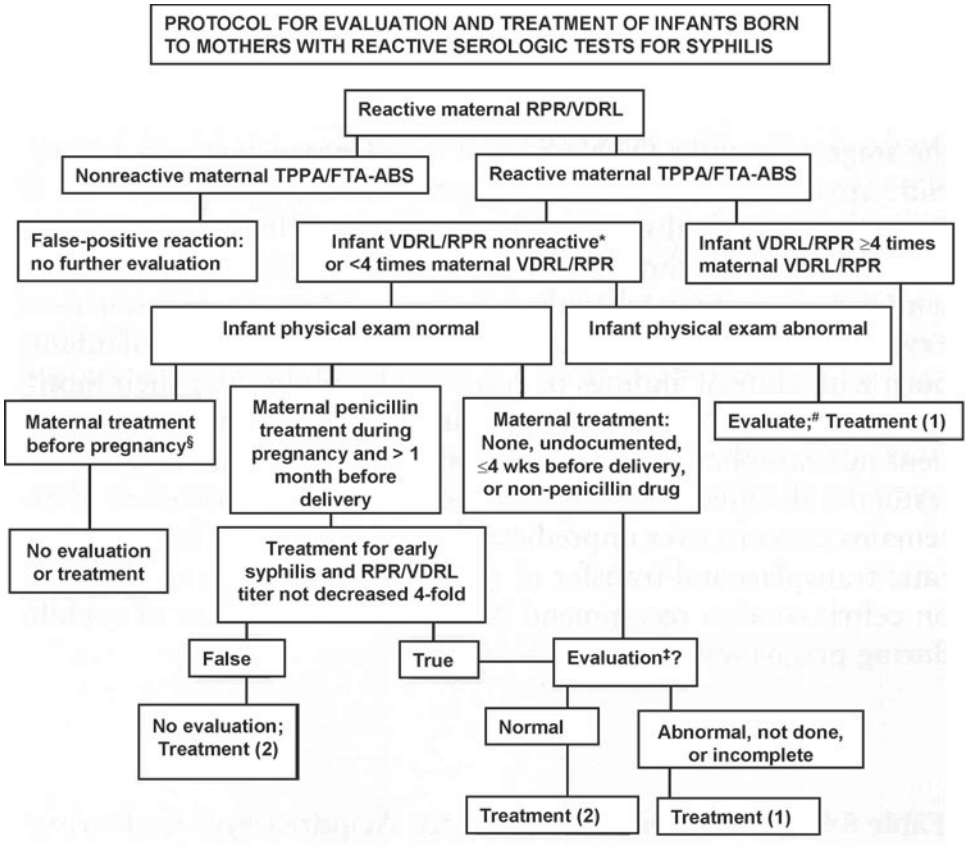

FIGURE 82-15. Approach for evaluation of infants born to mothers with reactive serologic tests for syphilis. Infants of HIV-Ab mothers do not require different evaluation or treatment. *Infant's VDRL may be nonreactive due to low maternal VDRL titer or recent maternal infection. If the mother has untreated or inadequately treated syphilis and infant's physical exam is normal, some experts would not perform diagnostic evaluation but would treat infant with a single IM injection of benzathine penicillin (50,000 U/kg). #Evaluation consists of CBC, platelet count; CSF examination for cell count, protein, and quantitative VDRL; and other tests as clinically indicated (eye exam, long-bone films, chest x-ray, liver function tests, cranial ultrasound, auditory brainstem response). §Women who maintain a VDRL titer ≤1:2 beyond 1 year following successful treatment are considered serofast. ‡CBC, platelet count; CSF examination for cell count, protein, and quantitative VDRL; long bone films. Treatment: (1) Aqueous penicillin G 50,000 U/kg IV q12h (≤1 week of age), q8h (>1 week) for a total of 10 days, or procaine penicillin G 50,000 U/kg IM single daily dose × 10 days. (2) Benzathine penicillin G 50,000 U/kg IM ×1 dose.

count, and other tests as indicated: long-bone radiographs, chest radiograph, liver function tests, cranial ultrasound, ophthalmologic exam, and auditory brain stem response) should be performed to determine appropriate therapy.

4. The mother was untreated, treated during pregnancy with an antimicrobial other than penicillin, or treated appropriately less than 4 weeks prior to delivery. These all constitute inadequate therapy for the fetus, and the infant should be fully evaluated as in scenario 3 above.
5. The mother was treated *during* pregnancy for late latent syphilis and maintained a low, stable titer through delivery. The infant does not require further evaluation if asymptomatic.

Evaluation for *T. pallidum*-specific IgM antibodies. Serodiagnosis of congenital syphilis poses a difficult problem because of the presence of transplacentally acquired maternal IgG in newborn sera. IgM, on the other hand, does not cross the placenta and is actively synthesized by the third-trimester fetus in response to infection. An early approach to the diagnosis of congenital syphilis was the measurement of serum IgM levels at or shortly after birth. In addition to lacking sensitivity,[229] however, elevated total IgM levels are nonspecific and may result from intrauterine infection with other common pathogens including cytomegalovirus, *Toxoplasma gondii*, and rubella.[25] In 1968, Scotti and Logan described an indirect immunofluorescence test for the detection of IgM antibody against *T. pallidum* (fluorescent treponemal antibody– absorption [FTA-ABS] IgM test) as a means of distinguishing infant from maternal antibody.[230] Unfortunately, despite some early successes,[156,231] the FTA-ABS IgM test has been shown to lack both sensitivity and specificity and has fallen into disuse.[232] Chromatographic separation of IgM in neonatal sera to remove maternal blocking antibodies and rheumatoid factor has been used to improve the performance of the FTA-ABS test; this improved version of the FTA-ABS IgM test has been designated the FTA-ABS-19S-IgM test.[233] Though more sensitive than the original FTA-ABS IgM test,[150,169] the FTA-ABS-19S-IgM test is technically demanding and available at only a handful of centers and, therefore, is no longer recommended. Stoll et al.[150,169] evaluated a commercial IgM capture enzyme-linked immunosorbent assay (ELISA) for *T. pallidum*-specific antibodies but found a sensitivity of only 88% among infants with clinical and laboratory findings consistent with congenital syphilis. Both the FTA-ABS-19S-IgM test and the IgM capture ELISA appear to have poor sensitivity for detecting infection in at-risk infants with normal clinical and laboratory findings.[150,169] Currently, no commercially available IgM test is recommended for evaluation of infants for congenital syphilis.[234]

Novel molecularly based diagnostic tests for asymptomatic neonates

The major dilemma in the diagnosis of early congenital syphilis is to differentiate normal-appearing, infected infants

from uninfected at-risk infants with reactive serologies due to transplacentally acquired maternal antibodies. Unfortunately, none of the currently available serologic tests can do this with high degrees of sensitivity and specificity in asymptomatic neonates. To address this critical issue, several investigators have utilized immunoblotting techniques to detect and characterize the neonatal IgM response to *T. pallidum*.[113,192,235–239] IgM antibodies directed against *T. pallidum* antigens with apparent molecular masses ranging from 93- to 15-kDa have been detected in sera from infants with clinical and laboratory evidence of congenital syphilis. IgM immunoblot analysis of asymptomatic infants born to mothers with untreated syphilis has documented that as many as 20–42% of at-risk infants possess IgM antitreponemal antibodies and can be considered actively infected. Fractionation of neonatal sera into IgM and IgG components by high-performance liquid chromatography has confirmed that IgM reactivities obtained with whole sera are not due to rheumatoid factor and are not diminished by maternal IgG antibodies.[238] Dobson and colleagues showed that the serum IgM reactivity disappears 1–3 months after appropriate penicillin treatment of neonates, further supporting the validity of IgM antibody detection as a marker for active infection.[235] Sánchez and coworkers found that immunoblot analysis with recombinant forms of two highly immunogenic *T. pallidum* lipoproteins (47-kDa and 17-kDa lipoproteins) appeared to be even more sensitive than immunoblotting with native *T. pallidum* lysates.[240] Most recently, Rawstrom and coworkers[241] reported that IgM immunoblot using *T. pallidum* lysates was a more accurate predictor of neonatal infection than using a maternal RPR titer >1:16.

Detection of *T. pallidum* is the most definitive means of proving that an asymptomatic child has active infection. Given the cost and difficulties inherent in RIT, PCR has emerged as a highly attractive alternative. Grimprel et al.[194] and Sánchez et al.[113,195] have shown that PCR results for neonatal sera and CSF correlate quite closely with those obtained by RIT. In our experience, virtually all symptomatic at-risk infants have positive PCR and IgM serum studies.[113] In preliminary findings, only 2 of 12 asymptomatic at-risk infants had positive PCR results on serum, while 5 of 12 had *T. pallidum*-specific IgM serum antibodies detectable by immunoblotting.[113] The PCR results presumably reflect low spirochetal burdens and spirochetemia rates in asymptomatic infected infants. Interestingly, one asymptomatic at-risk infant with a negative immunoblot had a positive serum PCR. In a subsequent study conventional (e.g., physical exam findings; radiological evidence; CSF with reactive VDRL, elevated protein or WBCs) and experimental (e.g., IgM immunoblotting and PCR assay) tests were compared with RIT of CSF to diagnose CNS infection in a subset of 76 infants born to mothers with syphilis. Any abnormality of conventional CSF tests resulted in a sensitivity of 82% (14 of 17) and specificity of 65% (33 of 51). IgM immunoblotting of serum yielded 100% (17 of 17) sensitivity and 66% (39 of 59) specificity, but these findings were not replicated when testing the CSF. PCR assay of serum and blood proved the most useful test with a sensitivity of 94% (16/17) and specificity of 90% (53 of 90). PCR testing of CSF had high specificity, but low sensitivity.[195] These data suggest that a comprehensive strategy involving physical exam, laboratory and radiologic findings, IgM immunoblotting, and PCR of serum will be needed for maximal sensitivity to distinguish infected from uninfected asymptomatic neonates.

DIAGNOSIS OF LATE CONGENITAL SYPHILIS

Diagnosis of late congenital syphilis is almost always presumptive and based on the typical clinical findings in association with reactive serologic tests. In the absence of a maternal history of syphilis, serologic testing of the mother can be helpful for distinguishing between acquired and congenital infection.

TREATMENT

A serum concentration of 0.018 mcg/mL is required to ensure adequate killing of the organism and must be maintained for 7 days in early cases and up to 3 weeks in late disease.[242] These basic requirements for achieving treponemicidal levels of penicillin have provided the therapeutic rationale for the use of long acting but relatively low dose penicillin formulations, most notably benzathine penicillin G (BPG), for the treatment of early syphilis in all patients, pregnant or not. Indeed, penicillin remains the drug of choice for the treatment of both acquired and congenital syphilis,[151,234,243] although it is well recognized that there is a modicum of prospective clinical data to support the specific BPG dosing regimens recommended by the CDC.[114,244,245] In the largest prospective cohort, involving 340 women treated antepartum with 2.4 MU benzathine penicillin G, Alexander et al.[246] found that treatment of maternal syphilis prevented congenital transmission in 98% of patients representing all stages of syphilis; congenital transmission was prevented in 95% and 98% of women with secondary and early latent syphilis, respectively. These results, in concert with extensive clinical experience over decades, indicate that BPG regimens, which achieve at best modest serum levels of antibiotic, not only prevent transplacental transmission of *T. pallidum* but also treat infection once it has occurred. In contrast to erythromycin[247] and, more recently, azithromycin,[248] penicillin resistance has not been confirmed among any *T. pallidum* isolates.

TREATMENT DURING PREGNANCY

Pregnant women with reactive serologic tests for syphilis should be counseled concerning the risks of HIV

infection, tested for HIV antibody, and treated with the penicillin regimen appropriate for the stage of syphilis (Table 82-6).[234,243] Tetracycline and doxycycline are contraindicated in pregnancy because both can result in staining of decidual teeth and impairment of long-bone growth. Moreover, tetracycline use during pregnancy has been associated with hepatic toxicity when there is concomitant renal dysfunction. There has been longstanding caution about the use of erythromycin because of reports of treatment failures in infants whose mothers received erythromycin treatment during pregnancy.[249–251] Patient noncompliance with erythromycin therapy due to gastrointestinal side effects also is a major problem. Moreover, there remains concern over unpredictable maternal serum levels and erratic transplacental transfer of the drug.[252] Insufficient data exist on ceftriaxone or azithromycin to recommend its use in the treatment of syphilis during pregnancy.[234] Indeed, the widespread prevalence of azithromycin-resistant strains of *T. pallidum*,[248] combined with recent reports of treatment failures[253] argue that azithromycin also should not be considered as an alternative to penicillin for antepartum treatment of pregnant women with syphilis.

Approximately 5–10% of pregnant women with syphilis report a history of penicillin allergy. Wendel and colleagues have shown that those individuals who are at risk for acute allergic reactions to penicillin can be identified by skin testing; if the skin test is positive, they can undergo oral penicillin desensitization, which makes them temporarily tolerant to a course of parenteral penicillin.[254] No serious adverse reactions were observed, and this regimen is currently recommended so that all pregnant women with syphilis can receive penicillin therapy (Table 82-7).

The Jarisch–Herxheimer reaction commonly occurs after treatment of acquired early syphilis in adults.[151] It consists of fever, chills, myalgias, headache, hypotension, tachycardia, and transient accentuation of the cutaneous lesions; it typically begins within several hours of treatment and resolves within 24–36 hours. The etiology is not fully known; however, since *T. pallidum* lacks lipopolysaccharide,[255,256] the release of treponemal lipoproteins that possess proinflammatory activities from dead or dying organisms has been implicated as the likely inducer of this clinical phenomenon.[243,257–259] Klein and coworkers have shown that another manifestation of the Jarisch–Herxheimer reaction in pregnant women is uterine contractions, possibly mediated secondarily by prostaglandins.[260] By fetal monitoring during the episode, they demonstrated evidence of fetal stress with tachycardia and decelerations, along with a marked decrease in fetal

Table 82-6. Treatment Guidelines for Acquired Syphilis During Pregnancy

Stage of Infection	Regimen
Primary	Benzathine penicillin G, 2.4 mU IM × 1
Secondary	
Early Latent (≤1 yr)	
Late Latent (>1 yr) unknown duration	Benzathine penicillin G, 2.4 mU IM q wk × 3
Neurosyphilis	Aqueous crystalline penicillin G 3-4 mU IV q4h × 10–14 d* or Procaine penicillin G 2.4 mU IM q day and probenicid 500 mg PO qid × 10–14 d*

*Some authorities recommend following this regimen with benzathine penicillin 2.4 mU IM q wk × 3.

From Sullivan TJ. Drug allergy. In: Middleton E, Reed C, Ellis E, et al, eds. *Allergy: Principles and Practice*, 4th ed. St. Louis: CV Mosby; 1993: 1523–1534.

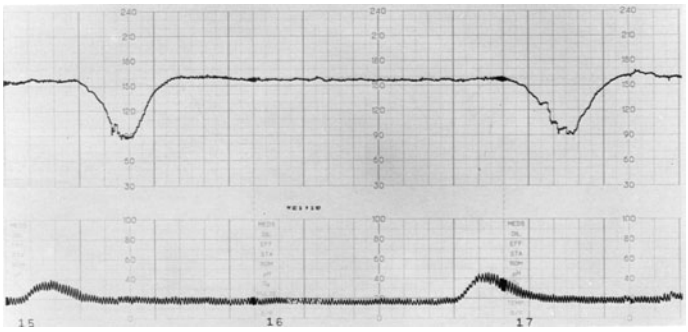

FIGURE 82-16. Fetal heart rate pattern, uterine contractions, and late decelerations occurring during a maternal Jarisch–Herxheimer reaction. Maternal blood pressure was 110/72 mm Hg, temperature 37.2 °C, and pulse 84 beats per minute. (*From* Klein VR, Cox SM, Mitchell MD, Wendel GD, Jr. The Jarisch-Herxheimer reaction complicating syphilotherapy in pregnancy. *Obstet Gynecol* 1990; 75(3 Pt 1): 375–380.)

activity (Fig. 82-16). For this reason, we sonographically evaluate the fetuses of all third-trimester early syphilis patients prior to initiating therapy. If hepatomegaly or other signs of hydrops are detected, the patient is hospitalized for fetal monitoring during the first 24 hours following the administration of penicillin therapy. If there is evidence of fetal compromise prior to the initiation of therapy, the infant is first delivered by caesarian section and then mother and infant are treated.[259]

Concern also exists that presumably adequate maternal treatment for syphilis in the final 4 weeks of pregnancy may be inadequate fetal therapy.[261] A possible explanation is that altered penicillin pharmacokinetics leading to lower serum and CSF levels of penicillin in both the mother and fetus may occur due to increases in renal clearance and plasma volume that are normal adaptations as pregnancy progresses.[219] Moreover, maternal treatment in the final weeks of pregnancy may not allow sufficient time for the fetus to be adequately treated, thus necessitating penicillin therapy for the newborn infant.[262] Because currently available methodologies for diagnosis of congenital syphilis do not accurately identify infants with active infection, the majority of these so-called "treatment failures" probably reflect resolving abnormalities from treated fetal infection. It is well known that the clinical and laboratory abnormalities seen in infants infected with *T. pallidum* may require months for complete resolution, even after prolonged intravenous penicillin therapy. Nonetheless, some treatment failures do occur, as evidenced by autopsy findings of stillborn infants and well documented clinical treatment failures,[55,263] suggesting that currently recommended regimens may be inadequate when fetal treponemal burdens are large.

TREATMENT OF THE INFANT

Given the current absence of a diagnostic "gold standard" and the fact that untreated congenital syphilis is potentially devastating, CDC guidelines recommend treatment of all infants who fit the surveillance-case definition to avoid undertaking the difficult task of determining which at-risk asymptomatic infants are truly infected.[234] Treatment, therefore, is required for infants with proven or highly probable disease: (1) an abnormal physical exam which is consistent with congenital syphilis; (2) a quantitative nontreponemal serologic test that is fourfold higher than the mother's titer; or (3) a positive darkfield or fluorescent antibody test of body fluids. Treatment is also recommended for infants with a normal physical exam and a quantitative nontreponemal serologic titer that is less than fourfold the mother's if (1) the mother was inadequately treated or is lacking documentation of treatment; (2) the mother was treated with erythromycin or another medicine other than penicillin; or (3) the mother received treatment less than 4 weeks prior to delivery. Furthermore, treatment should be considered for low-risk infants when follow-up is uncertain. Treatment should not be delayed until a definitive clinical or serologic diagnosis is made.

Infants 4 weeks of age or less who have confirmed or presumptive disease should be treated for 10–14 days with either (1) aqueous crystalline penicillin G, 50,000 U/kg administered intravenously every 12 hours for the first 7 days of life and every 8 hours beyond 1 week of age for a total of 10 days or (2) aqueous procaine penicillin G, 50,000 U/kg administered intramuscularly once daily (Table 82-8) for 10 days.[234] In our experience, 10 days of either form of penicillin is sufficient. All patients who received aqueous crystalline penicillin G, but only 82% of those who received procaine, had treponemicidal levels in the CSF at the time of testing.[264] Although the significance of this finding is uncertain given that both regimens are curative,[113] some authorities believe that the aqueous crystalline penicillin G regimen is the preferred therapy, particularly in extremely ill infants or infants with neurosyphilis.[57]

An infant with normal physical examination, CSF, radiographic, and laboratory studies and whose nontreponemal test titer is the same or less than the maternal titer can be treated with a single intramuscular injection of benzathine penicillin G (50,000 U/kg) under the following circumstances (Table 82-8)[234,265]: (1) the mother received erythromycin during pregnancy; (2) the mother was treated with the appropriate regimen 30 days or less prior to delivery; (3) the mother received the recommended penicillin therapy for the stage of infection during the pregnancy, but the nontreponemal titer has not yet decreased fourfold; and (4) the mother has untreated syphilis or her treatment status is undocumented.

After the neonatal period, older infants (>4 weeks of age) and children diagnosed with syphilis should have a CSF examination to exclude neurosyphilis and maternal medical records should be reviewed to assess whether the child has congenital or

Table 82-8. Treatment of Congenital Syphilis

Effective prevention and detection of congenital syphilis depends on the identification of syphilis in pregnant women and, therefore, on the routine serologic screening of pregnant women during the first prenatal visit. In communities and populations in which the risk for congenital syphilis is high, serologic testing and a sexual history should also be obtained at 28-week gestation and at delivery.

Scenario 1. Infants with proven or highly probable disease and

1. an abnormal physical examination that is consistent with congenital syphilis,
2. a serum quantitative nontreponemal serologic titer that is fourfold higher than the mother's titer,[a] or
3. a positive darkfield or fluorescent antibody test of body fluid(s).

Recommended evaluation

- CSF analysis for VDRL, cell count, and protein.[b]
- Complete blood count (CBC) and differential and platelet count.
- Other tests as clinically indicated (e.g., long-bone radiographs, chest radiograph, liver-function tests, cranial ultrasound, ophthalmologic examination, and auditory brainstem response).

Recommended regimens

Aqueous crystalline penicillin G 100,000–150,000 units/kg/d, administered as 50,000 units/kg/dose IV every 12 hours during the first 7 days of life and every 8 hours thereafter for a total of 10 days

OR

Procaine penicillin G 50,000 units/kg/dose IM in a single daily dose for 10 d

If >1 day of therapy is missed, the entire course should be restarted. Data are insufficient regarding the use of other antimicrobial agents (e.g., ampicillin). When possible, a full 10-day course of penicillin is preferred, even if ampicillin was initially provided for possible sepsis. The use of agents other than penicillin requires close serologic follow-up to assess adequacy of therapy. In all other situations, the maternal history of infection with *T. pallidum* and treatment for syphilis must be considered when evaluating and treating the infant.

Scenario 2. Infants who have a normal physical examination and a serum quantitive nontreponemal serologic titer the same or less than fourfold the maternal titer and the

1. mother was not treated, inadequately treated, or has no documentation of having received treatment;
2. mother was treated with erythromycin or other nonpenicillin regimen,[c] or
3. mother received treatment <4 week before delivery.

Recommended evaluation

- CSF analysis for VDRL, cell count, and protein.
- CBC and differential and platelet count.
- Long-bone radiographs.

A complete evaluation is not necessary if 10 days of parenteral therapy is administered. However, such evaluations might be useful; a lumbar puncture might document CSF abnormalities that would prompt close follow-up. Other tests (e.g., CBC, platelet count, and bone radiographs) may be performed to further support a diagnosis of congenital syphilis. If a single dose of benzathine penicillin G is used, then the infant must be fully evaluated (i.e., through CSF examination, long-bone radiographs, and CBC with platelets), the full evaluation must be normal, and follow-up must be certain. If any part of the infant's evaluation is abnormal or not performed or if the CSF analysis is rendered uninterpretable because of contamination with blood, then a 10-day course of penicillin is required.[d]

Recommended regimens

Aqueous crystalline penicillin G 100,000–150,000 units/kg/d, administered as 50,000 units/kg/dose IV every 12 hours during the first 7 days of life and every 8 hours thereafte for a total of 10 days

(*Continued*)

Table 82-8. *(Continued)*

	OR Procaine penicillin G 50,000 units/kg/dose IM in a single daily dose for 10 days **OR** Benzathine penicillin G 50,000 units/kg/dose IM in a single dose
Some specialists prefer the 10 days of parenteral therapy if the mother has untreated early syphilis at delivery.	
	Scenario 3. Infants who have a normal physical examination and a serum quantitative nontreponemal serologic titer the same or less than fourfold the maternal titer and the 1. mother was treated during pregnancy, treatment was appropriate for the stage of infection, and treatment was administered >4 week before delivery and 2. mother has no evidence of reinfection or relapse. ***Recommended evaluation*** No evaluation is required. ***Recommended regimen*** Benzathine penicillin G 50,000 units/kg/dose IM in a single dose[e]
	Scenario 4. Infants who have a normal physical examination and a serum quantitative nontreponemal serologic titer the same or less than fourfold the maternal titer and the 1. mother's treatment was adequate before pregnancy, and 2 mother's nontreponemal serologic titer remained low and stable before and during pregnancy and at delivery (VDRL <1: 2; RPR <1: 4). ***Recommended evaluation*** No evaluation is required. ***Recommended regimen*** No treatment is required; however, some specialists would treat with benzathine penicillin G 50,000 units/kg as a single IM injection, particularly if follow-up is uncertain.

[a]The absence of a fourfold or greater titer for an infant does not exclude congenital syphilis.

[b]CSF test results obtained during the neonatal period can be difficult to interpret; normal values differ by gestational age and are higher in preterm infants. Values as high as 25 white blood cells (WBCs)/mm^3 and/or protein of 150 mg/dL might occur among normal neonates; some specialists, however, recommend that lower values (i.e., 5 WBCs/mm^3 and protein of 40 mg/dL) be considered the upper limits of normal. Other causes of elevated values should be considered when an infant is being evaluated for congenital syphilis.

[c]A woman treated with a regimen other than those recommended in these guidelines for treatment should be considered untreated.

[d]If the infant's nontreponemal test is nonreactive and the likelihood of the infant being infected is low, certain specialists recommend no evaluation but treatment of the infant with a single IM dose of benzathine penicillin G 50,000 units/kg for possible incubating syphilis, after which the infant should receive close serologic follow-up.

[e]Some specialists would not treat the infant but would provide close serologic follow-up in those whose mother's nontreponemal titers decreased fourfold after appropriate therapy for early syphilis or remained stable or low for late syphilis.

Source: CDC. *Sexually Transmitted Diseases Treatment Guidelines, 2006.*

acquired syphilis. Any child thought to have congenital syphilis (or having neurologic involvement) should receive aqueous crystalline penicillin G administered as 50,000 U/kg IV every 4–6 hours for 10 days. Some specialists recommend giving one dose of benzathine penicillin G 50,000 units/kg IM after the 10-day course of IV treatment.[234] Procaine penicillin for this age group has not been fully evaluated and, therefore, is not recommended. Children with acquired syphilis who have a normal CSF examination can receive IM benzathine penicillin G 50,000 U/kg per dose as dictated by the stage of infection; the amount of penicillin should not exceed that recommended for adults.[234] The CDC 2006 STD guidelines for evaluation and treatment of older infants and children for syphilis are similar but different in evaluation (e.g., long-bone radiographs, chest radiograph, liver function tests, etc.), dosage, and duration (see Table 82-9).[216]

Table 82-9. Evaluation and Treatment of Older Infants and Children for Syphilis

Children who are identified as having reactive serologic tests for syphilis after the neonatal period (i.e., aged >1 mo) should have maternal serology and records reviewed to assess whether the child has congenital or acquired syphilis.

Recommended evaluation

- CSF analysis for VDRL, cell count, and protein.
- CBC, differential, and platelet count.
- Other tests as clinically indicated (e.g., long-bone radiographs, chest radiograph, liver function tests, abdominal ultrasound, ophthalmologic examination, and auditory brain stem response).

Recommended regimen

Aqueous crystalline penicillin G 200,000–300,000 units/kg/d IV, administered as 50,000 units/kg every 4–6 h for 10 d

If the child has no clinical manifestations of disease, the CSF examination is normal, and the CSF VDRL test result is negative, some specialists would treat with up to 3 weekly doses of benzathine penicillin G, 50,000 U/kg IM.

Infants born to women coinfected with syphilis and HIV may be at higher risk of acquiring infection with both syphilis and HIV.[266,267] It is not known whether infants coinfected with syphilis and HIV respond to treatment for congenital syphilis differently from those infants not infected with HIV. Nonetheless, there are no data to support more aggressive or prolonged penicillin therapy beyond the regimens recommended for infants not exposed to maternal HIV infection. The necessity of serologic follow-up of these high-risk infants cannot be over emphasized.[234]

Less than 1% of infants who are treated for presumed congenital syphilis develop, within several hours of initiation of penicillin therapy, a Jarisch–Herxheimer reaction, consisting of fever, tachypnea, tachycardia, hypotension, accentuation of the cutaneous lesions, and/or death due to cardiovascular collapse.[147] Other than supportive care, there is no specific treatment or prophylaxis.

■ FOLLOW-UP MANAGEMENT

Infants who have reactive serologic tests for syphilis should have serial quantitative nontreponemal tests performed until nonreactivity is documented or the titer has decreased fourfold.[147,234,262] Follow-up for these infants can be incorporated into routine pediatric well-child care at 2, 4, 6, 12, and 15 months.[228] Among infants with congenital syphilis, nontreponemal serologic tests become nonreactive within 6–12 months after appropriate treatment.[265] If the nontreponemal serologic titers remain stable or increase after 6–12 months the child should be reevaluated for syphilis, including CSF examination and treated with parenteral penicillin G for 10 days.[234] Uninfected infants usually become sero-nonreactive by 6 months of age. A reactive *treponemal* test beyond 18 months of age, when all passively transferred maternal antibody has been cleared, confirms the diagnosis of congenital syphilis.[265]

Infants with initial abnormal CSF findings should have a repeat CSF analysis performed every 6 months after therapy until normal.[228,234] A reactive CSF VDRL test, unexplained persistent pleocytosis, or abnormal protein at retesting is an indication for retreatment.[234]

PREVENTION AND CONTROL

■ DETECTION OF SYPHILIS DURING PREGNANCY

The mainstay of prevention of congenital syphilis involves identifying and treating infected pregnant women; penicillin therapy during pregnancy is 98-percent effective in preventing congenital infection.[140,268] Maternal treatment regimens and follow-up are discussed in detail in the 2006 CDC STD Treatment Guidelines. The obstetrician must be alert to the signs and symptoms of syphilis in the pregnant woman. In addition to looking for evidence of active syphilis during prenatal visits, syphilis serologic testing should be performed at the mother's first prenatal visit and repeated in high-risk populations, at 28 weeks gestation and at delivery.[269,270] Repeat testing of high-risk populations is essential to identify women with incubating syphilis as well as women infected later in pregnancy. False-negative nontreponemal tests also may result from the prozone phenomenon that occurs when an excess of nontreponemal antibodies prevents the flocculation reaction required for a reactive test. Experienced laboratories routinely dilute serum specimens to identify prozones. Screening tests at delivery should be performed on maternal blood specimens

rather than on umbilical cord blood; nontreponemal test titers in umbilical cord blood are usually lower than the mother's and may even be nonreactive in the face of a low maternal titer.[149]

Pregnancy occasionally produces a false-positive nontreponemal test (e.g., a reactive nontreponemal test with a nonreactive treponemal test).[271] A cautionary note must be sounded here, however, because an isolated low nontreponemal test titer may be seen with very early syphilitic infection and have disastrous consequences for the fetus if untreated.[149] A detailed sexual history, careful physical examination (looking for evidence of primary syphilis), and serologic follow-up of the mother are required to distinguish false-positive reactivity from early infection. Treatment is warranted if follow-up serologic testing cannot be assured. Women who have previously received standard therapy for syphilis may remain seroreactive with a low nontreponemal test titer; these women are designated "serofast." Because it can be difficult to distinguish the serofast state from reinfection, our practice is to re-treat asymptomatic women whose nontreponemal test titers are greater than 1:2 at the first screening. Women considered to be serofast are followed with serial serologic testing and re-treated if the titer increases fourfold or more.

PUBLIC-HEALTH STRATEGIES FOR PREVENTION

While the cause of congenital syphilis, strictly speaking, is *Treponema pallidum*, the network of social and economic factors that fosters the transmission of syphilis during pregnancy and then allows it to go undetected and untreated also must be considered as part of its etiology. The lines of public-health defense against congenital syphilis can be seen as a series of demographic circles around the fetal population at risk (Fig. 82-17). The first line of defense is the treatment of cases of primary and secondary syphilis and case detection through contact investigations. As noted earlier, this activity is now being supplemented, in many instances, by location-based epidemiologic case finding and treatment. The fewer the total number of cases of primary and secondary syphilis, the fewer the number of cases that joins the pool of early and late latent syphilis, and therefore the fewer the number of latent syphilitics among women in the childbearing age group. The second line of defense is follow-up of reactive serologic tests reported to the health department by clinical laboratories, supplemented by routine screening of high-risk populations. By assuring adequate therapy of cases so detected, this strategy is designed to reduce the pool of women who begin gestation with untreated syphilis. Routine prenatal screening is the last major line of defense against congenital syphilis.

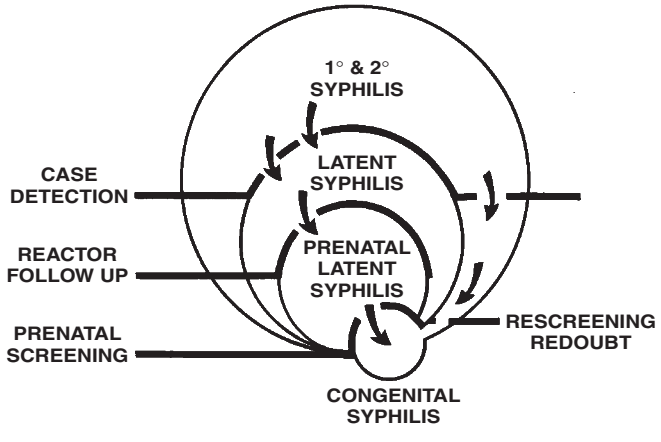

FIGURE 82-17. Sequential lines of defense against congenital syphilis consist of (i) case detection to decrease the population of transmitters of early syphilis, (ii) reactor follow-up to decrease the residual pool of latent syphilis, and (iii) the last line of defense, prenatal screening. In addition, a redoubt is needed to protect the flank (i.e., rescreening to detect acquisition of syphilis during pregnancy).

ANTENATAL SCREENING AND DECENTRALIZATION OF SCREENING PROGRAMS

Syphilis screening should be performed at the antenatal care site, and women found to be seroreactive should be treated immediately at the same visit.[270] On-site testing is recommended by the WHO and may avoid the major difficulties that materialize with laboratory-based testing.

The RPR card test was initially used for on-site testing. In 1990, a syphilis-intervention study in Zambia used this treatment approach in three intervention centers and compared the outcomes to three control centers.[272] With on-site testing the adverse outcomes attributable to syphilis were reduced to 28%, an almost two-thirds reduction when compared to 72% in control centers.[272] In Maputo, Mozambique, an intervention study of antenatal clinics trained nurse midwives to perform the RPR tests and seroreactive cases were treated on-site and partners were encouraged to receive treatment; the intervention was repeated at 30 weeks gestation. At delivery the perinatal mortality (1.3%) was significantly lower in the intervention group as compared to the control group (3.4%).[273]

Screening pregnant women for syphilis has proven cost-effective in the prevention of congenital syphilis.[74] WHO found that at seroprevalences of 15%, 10%, and 1%, respective expenditures of only $9.30, $12, and $70 would avert one adverse outcome.[270] In Nairobi, Kenya, a decentralized clinic-based syphilis control program was implemented in 1992 where pregnant women were screened with the RPR card test by antenatal clinic nurses and treated on-site if RPR-reactive. There was a 6.5% (860) prevalence of RPR-reactivity of which over 87% (751) of these women were treated at their first visit and almost 50% (428) of their partners were treated as well. An estimated 413 cases of congenital syphilis would have been prevented with this program at a cost of U.S.$50 per case.[77]

Decentralization of screening programs has found to be successful in other countries as well. In rural Haiti, prior to

1996 and decentralization of antenatal screening for maternal syphilis, testing was done at a community hospital, followed by sending specimens to an off-site laboratory for testing and requiring women to return for their results and treatment at a follow-up visit. During this time 41% (14/34) of seropositive women did not receive treatment. After decentralization with laboratory installation and personnel training in 12 local dispensaries, 100% (50/50) of seropositive women were treated. The rate of congenital syphilis dropped by 75% (from 550 to 137 cases per 100,000 live births) within 3 years of the intervention.[274]

More recently, the syphilis immunochromatographic strip (ICS) test has been studied in the field as an on-site screening test for syphilis. Studies find that the ICS test outperforms the RPR test and is also cost-effective.[275–279] In Bolivia public health personnel were trained and ICS tests were introduced into antenatal clinics in urban maternity hospitals and rural clinics resulting in over 11,500 women tested of which 5% were seropositive and over 93% were treated.280 In 1992 the Mozambique National Health System prioritized antenatal syphilis screening when only 5% of women in two targeted provinces were screened. Due to their efforts over the past decade annual antenatal screening has increased to 60–95%.

The successful scaling up of antenatal screening programs in one of the world's poorest countries is attributable to (1) the widespread utilization of the rapid ICS test to allow screening in areas without laboratories and where women were previously left unscreened; (2) across the broad strengthening of the health-care delivery system; and (3) continuous monitoring to assess the implementation of changes in health-care delivery.[281]

NEXT STEPS

An estimated 1.5 million cases of congenital syphilis occur annually worldwide which significantly overshadows the estimated 530,000 children infected with HIV each year.[282,283] In fact, "on-site antenatal syphilis screening and treatment is just as cost-effective as prevention of maternal-to-child HIV transmission."[74,284]

From the public health viewpoint, congenital syphilis can be regarded as a "sentinel health event" whose occurrence reflects a failure of delivery systems for prenatal care as well as syphilis control programs.[57] The tragedy of congenital syphilis is that it is a completely preventable disease. In 2004 WHO proposed a strategy for the prevention and ultimately the elimination of congenital syphilis worldwide. Specifically, the goal is to prevent mother-to-child transmission with early antenatal care for all women; the treatment of all sexual partners of infected women and the treatment of all newborns born to seropositive women.[283] As outlined by Schmid et al.,[283] the four pillars of the WHO Strategy are (1) to ensure sustained political commitment and advocacy for the elimination of congenital syphilis; (2) to increase access and quality of health services for pregnant women and newborns; (3) to screen and treat all pregnant women; and (4) to establish surveillance, monitoring and evaluation systems. In an analysis of 14 countries representing low, middle, and high prevalences of congenital syphilis and with existing maternal or congenital syphilis control policies, most did not meet all of the elements of the WHO elimination strategy and there was varying discrepancy between outlined objectives, actual implementation, and effectiveness of the programs.[284,285]

There is a preponderance of evidence that with the appropriate commitment of resources to high-risk populations, the prevention of the morbidity and mortality caused by syphilis in pregnancy is within the grasp of the international health community and that the devastating effects of congenital syphilis can be eliminated.

83 Gonococcal and Chlamydial Infections in Infants and Children

Stephan A Kohlhoff and Margaret R. Hammerschlag

INFECTIONS DUE TO *NEISSERIA GONORRHOEAE* IN INFANTS AND CHILDREN

HISTORY

Gonococcal ophthalmia neonatorum was recognized as a distinct infectious disease related to a maternal genital infection in 1881 when Credé published his report of the effectiveness of eye prophylaxis in the form of a single drop of 2% silver nitrate. Following the introduction of this prophylaxis to all babies the rates of ophthalmia fell from 14 of 187 births (7%) to 1 of 200 births (0.5%).[1] One year later Königstein claimed to have recovered identical bacteria from infected eyes and the mother's genitals.[2] Gonococcal ophthalmia neonatorum used to be a major cause of blindness. The decrease in the rates of blind children with a history of ophthalmia neonatorum demonstrated the efficacy of ocular prophylaxis most impressively.[3] During the second half of the twentieth century the link between gonococcal infections in prepubertal children beyond the neonatal age period and sexual abuse became increasingly recognized.

EPIDEMIOLOGY

Epidemiology of genital infection due to N. gonorrhoeae in children and adolescents

CDC surveillance data from the 50 states in 1998 found that the highest incidence of gonococcal disease was reported in adolescent females, ages 15–19 years, with 761.4 cases per 100,000 population (up from 683.2 in 1997).[4] A similar increase in the number of infections in males also occurred during the teens and early adult years with a peak rate of 564.0 cases per 100,000 population among men aged 20–24 years.[4] Rates have been much higher in some states and populations. The overall rate in African American females, ages 15–19 years in 1995 was 4433 per 100,000 population.[4] Some special risk populations demonstrate an extremely high prevalence such as sexually active female adolescents seen at an inner city clinic in the United States (6%), adolescents entering shelters in Korea (15.4%), adolescents in 14 U.S. juvenile detention centers (5.1% in females and 1.3% in males), or patients visiting a sexually transmitted disease clinic in Amsterdam, The Netherlands (male 10.5%, female 5.9%).[5–8] Van Duynhoven et al. found that being a teenager carried the highest risk of having a positive *N. gonorrhoeae* culture compared to all other age groups.[8] Coinfections with other sexually transmitted organisms, especially *Chlamydia trachomatis*, are also frequent.[7]

Data on the prevalence of symptomatic gonococcal infection in preadolescent children and early adolescent youths are limited to a few studies and case reports. Incidence rates as high as 11 per 100,000 for the age group 1 month through 9 years per year have been reported from *N. gonorrhoeae* infection surveillance data in Florida, which is derived from mandatory reports of laboratory-confirmed episodes.[9] In that study 854 episodes were reported in 849 children aged 1 month through 12 years all of which were assumed to be acquired by sexual abuse. Since there are no screening studies in these age groups and diagnosis and reporting mostly rely on tests performed in symptomatic children, the true incidence of gonococcal infection remains unknown. Presenting complaints of symptomatic children who are subsequently established to have *N. gonorrhoeae* infection are primarily vaginal or urethral discharge, but symptoms resolve spontaneously and may also be absent. Some infected children present for evaluation of sexual abuse or assault, and a number of children have a variety of complaints not related to the genitalia. Despite occasional reports of nonsexual transmission most of which fail to appropriately address the possibility of sexual abuse, it has been recognized that close sexual contact with an infected individual is the main risk factor for transmitting *N. gonorrhoeae* in children.[10–13] The recognition of gonococcal infection in children after the newborn period and before the onset of puberty is particularly important because it is considered an indicator of sexual abuse.[14] Consequently, cultures for *N. gonorrhoeae* should be obtained if child abuse is seriously suspected.

The most recent prevalence rates of gonococcal infections in an American and a British cohort of sexually abused children were 1.2% and 1.9%, respectively.[15,16] The highest number of infections in one study was reported in the 3-year-old age group, and the occurrence of multiple sites of infection is common.[17] In a cohort of 567 prepubertal girls from Rwanda referred for sexual abuse or vulvovaginitis, the most common cause of vaginal discharge was *N. gonorrhoeae* (35.9%).[18] In a prospective patient series of children between 1 and 12 years presenting to the emergency department with symptoms of vaginitis, 9% were culture-positive for *N. gonorrhoeae*.[19] On the other hand, about 20% of children with positive genital cultures have been reported to be asymptomatic in one study.[20] Recently Ingram et al. have proposed a risk assessment algorithm that may help limit unnecessary testing in abused children while correctly identifying all children with *N. gonorrhoeae* infections.[15,21] Identification of infection in children should also lead to a search for contacts within the child's epidemiologic unit.[22] When such contact investigations are performed, the results frequently include identification of significant numbers of adults, often family members, and other children who are also infected.[23] Since sexual abuse of children is usually a chronic and recurring condition, as opposed to rape by a stranger, children may present with recurrent gonococcal infections if they remain unprotected. The special considerations involved in the management of sexually abused children are discussed in detail in the separate chapter on sexual abuse (see Chapter 87).

Epidemiology of conjunctival infections due to *N. gonorrhoeae*

The main population at risk for gonococcal conjunctivitis is neonates born to mothers with genital infection. The transmission rate in unprophylaxed neonates born to infected mothers may be as high as 42%.[24] Signs of infection usually appear from 2 to 5 days after birth, but infection in utero may also occur usually in the context of premature rupture of membranes.[25] Ocular prophylaxis and the availability of antibiotic therapy for ophthalmia neonatorum have led to a decrease in the proportion of new entrants to schools for the blind attributable to ophthalmia neonatorum to 1% by 1950 and to less than 0.1% by 1959.[3] Since then, periods of regional and national resurgences of gonorrheal infections in adults in the United States were reflected in increases of gonorrheal ophthalmia neonatorum.[26,27] Public health programs in the United States and many other industrial countries were established, encouraging the routine screening of sexually active women for gonorrhea at the time of the first antenatal visit and again in the third trimester for those women still at risk.[28] While these efforts have led to overall falling rates of maternal gonorrhea and gonococcal ophthalmia neonatorum in the developed countries, data from developing countries (mostly from Africa) have demonstrated that *N. gonorrhoeae* remains a significant pathogen in the absence of a public health approach toward prevention of ophthalmia neonatorum.[24,29,30] Recognition of gonorrhea early in pregnancy identifies a population at risk that should be followed sequentially throughout pregnancy, since reinfection rates may be high.[31,32] Even in the presence of active prenatal screening programs, poor prenatal care and maternal substance abuse can be risk factors for higher infection rates in pregnant women and neonates.[32,33] Hammerschlag et al. reported that seven of eight infants with *N. gonorrhoeae* conjunctivitis seen in an inner-city hospital over a 2-year period were born to women with no prenatal care, five of whom were "crack" cocaine abusers.[32] None of the infants who were born to women diagnosed with and treated for *N. gonorrhoeae* infection during their prenatal care (248 of 9128) developed gonococcal ophthalmia. Active screening and treatment of pregnant women have reduced the incidence of gonococcal ophthalmia in the United States to the point where any additional effect from prophylaxis is hard to discern. The most recent data concerning the relative frequency of microbiologic etiologies of conjunctivitis in early infancy in the United States were presented in a study published from Seattle in 1992.[34] This case-control study identified, in order of prevalence, *Haemophilus influenzae, Streptococcus pneumoniae, Neisseria cinerea, Klebsiella pneumoniae*, and *C. trachomatis* but not *N. gonorrhoeae*. It should be noted that this population had extremely low rates of maternal *N. gonorrhoeae* and *C. trachomatis* infections. In developed countries *N. gonorrhoeae* is among the least common causes of neonatal conjunctivitis.

All current studies of gonococcal ophthalmia have been performed outside the United States. A case-control study from Nigeria found only one of 122 neonates with ophthalmia neonatorum to be positive for *N. gonorrhoeae*.[35] Unfortunately, it was not stated whether mothers were tested and treated for gonorrhea during pregnancy, and transport of swabs from clinic sites to the microbiology laboratory may have decreased the sensitivity of culture. In a study from Argentina, *N. gonorrhoeae* infection was not detected in 332 consecutive cases of neonatal conjunctivitis; the rates of maternal infection and treatment were not stated.[36]

Neonatal gonococcal ophthalmia may cause primary disease at other mucous membrane sites or cause systemic disease. The ocular disease serves as a signal that the infant has been infected. While gonococcal conjunctivitis is primarily a neonatal infection it can also occur in older infants and children mainly in the context of sexual abuse, but eye to eye spread in the household and community outbreaks has also been reported.[37,38]

Epidemiology of gonococcal infections at other sites

Pharyngeal infections can occur in the perinatal period through ingestion of infected amniotic fluid.[39] Pharyngeal and anal infections in children beyond the neonatal age period occur mainly in the context of sexual abuse and are frequently coinfections of vaginal or urethral infections.[17,40]

Disseminated gonococcal infection has been associated with certain host risk factors such as a deficiency in the terminal complement system, which is also associated with recurrent gonococcal and meningococcal infections.[41] While osteomyelitis is very rare and usually occurs only in patients who have had septic arthritis and an adjacent focus, septic arthritis has been the most commonly recognized manifestation of disseminated gonococcal infection in the neonatal period.[42] In 1905, Holt reported 26 cases of gonococcal arthritis in children, including two infants who developed arthritis within the first month of life.[43] One of these children also had ophthalmia neonatorum, most had no recognized focus, and rectal cultures were not taken. Ophthalmia neonatorum has also often been absent in subsequent reported cases of neonatal gonococcal arthritis. The primary focus of infection in most of the 53 infants with gonococcal arthritis reported by Cooperman in 1927 was uncertain; only one had ophthalmia neonatorum.[44] All of the females were said to have had vulvovaginitis, while several infants had proctitis. Bacteremia in some other cases has been attributed to infection of the mouth, nares, and umbilicus, while the source of bacteremia has been inapparent in many cases reported in the English language since the 1940s.[45,46] Gonococcal meningitis is a rare occurrence in neonates or children, but a high index of suspicion is warranted in patients with meningitis who present with clinical symptomatology or past history of gonococcal infection (including that of source cases).[47] As an iatrogenic cause of infection gonococcal scalp abscesses have been attributed to intrauterine fetal monitoring.[48]

CLINICAL MANIFESTATIONS

Gonococcal infections in children may produce a variety of syndromes that are age related. Investigation of adult gonococcal disease syndromes has demonstrated that there is a very extensive interaction and accommodation between gonococcal surface structures and the host milieu.[49] In contrast, there have been no studies of gonococcal infections of infants or prepubertal children to investigate host-microbe interactions and consequently nothing is known.

Perinatal N. gonorrhoeae infection

Gonococcal infections present several unique problems during pregnancy, most of which are covered in a separate chapter (Chapter 80). A demonstration of ascending infection of the fetus prior to delivery is found in a report of an infected stillborn infant who was found at autopsy to have multiple submucosal foci of the esophagus and upper respiratory tracts containing gram-negative diplococci.[50] The location of the lesions indicated that infection had been contracted in utero during swallowing and respiration. Chorioamnionitis of the placenta was an accompanying finding. Six studies have reviewed the effects of untreated gonococcal disease of the mother on the health of the fetus and infant (Table 83-1). Rates of premature delivery, perinatal distress, and perinatal deaths were higher in infants born to mothers with untreated gonococcal infections at the time of delivery compared to mothers without infection and mothers with infections treated during pregnancy.[51,53,55,56]

Neonatal gonococcal ophthalmia

Conjunctival infection caused by *N. gonorrhoeae* in the newborn usually produces an acute purulent conjunctivitis that appears from 2 to 5 days after birth. The initial course is occasionally indolent, however, and onset can occur later than 5 days after birth, perhaps because of partial suppression of infection by ophthalmic prophylaxis, small inoculum size, or strain-to-strain variations in gonococcal virulence.[57,58] Ocular gonococcal infection without signs of inflammation has been described in a neonate whose conjunctiva and nasopharynx were cultured at 2 and 3 weeks of age as part of

Table 83-1. Outcome of Pregnancy in Mothers Who Were Infected with *N. gonorrhoeae* at Delivery

Outcome	Charles[51] (*n* = 14)	Sarrell[52] (*n* = 37)	Israel[53] (*n* = 39)	Amstey[54] (*n* = 222)	Edwards[55] (*n* = 19)	Handsfield[39] (*n* = 12)
Normal or term infant	–	13 (35%)	30 (77%)	142 (64%)	7 (37%)	–
Aborted	–	13 (35%)	1 (2%)	24 (11%)	–	–
Perinatal death	–	3 (8%)	1 (2%)	15 (8%)	2 (11%)	–
Premature	–	6 (17%)	5 (13%)	49 (22%)	8 (42%)	8 (67%)
Perinatal distress	–	–	2 (5%)	–	2 (10%)	–
Premature rupture of membranes	6 (28%)	8 (21%)	–	52 (26%)	12 (63%)	9 (75%)

the follow-up for a maternal infection at the time of delivery.[59] Permanent corneal damage following gonococcal ophthalmia neonatorum was usual in the preantibiotic era. The infant typically develops tense edema of both lids, followed by chemosis and a progressively purulent and profuse conjunctival exudate, which literally pours or squirts out of the lids when they are separated. If treatment is delayed, the infection extends beyond the superficial epithelial layers, reaching the subconjunctival connective tissue of the palpebral conjunctivae and, more significantly, the cornea. Corneal complications include ulcerations that may leave permanent nebulae or may cause perforation and lead to anterior synechiae, panophthalmitis (rarely), and loss of the eye. While 1% silver nitrate is no longer manufactured or used in the United States, it is still used in many parts of the world and associated with a mild chemical conjunctivitis, which can be easily distinguished from gonococcal conjunctivitis. Evidence of epithelial desquamation and polymorphonuclear leukocytic exudate appears usually within 6–8 hours and disappears usually within 24–48 hours.

Other manifestations of neonatal gonococcal infection

Besides ophthalmia neonatorum and the systemic complications of gonococcemia such as arthritis, other localized forms of neonatal gonococcal infection such as vaginitis, rhinitis, anorectal infection, funisitis, and urethritis have been reported.[60–63] *N. gonorrhoeae* may be an indirect or a direct cause of early neonatal sepsis in the absence of gonococcal arthritis. As noted, intrapartum gonococcal infection has been associated with premature delivery and premature rupture of membranes, which may lead to amniotic fluid infection with a variety of vaginal organisms capable of causing neonatal sepsis. *N. gonorrhoeae* has been isolated from blood of newborn infants with clinical sepsis without arthritis.[64] A small number of gonococcal infections become disseminated, with arthritis being the most common manifestation. The onset of clinical evidence of gonococcal arthritis in the newborn usually occurs from 1 to 4 weeks after delivery. One cannot distinguish between perinatal and postnatal acquisition of infection in most cases. The pustular and necrotic skin lesions that characteristically appear during gonococcemia in the adult have not yet been described in the newborn. The natural history of gonococcal arthritis in the infant is uncertain. Of the 53 cases in newborns that were presumably infected by a single epidemic strain of *N. gonorrhoeae*, described by Cooperman, none had a fatal outcome and permanent impairment of function was uncommon, even without antibiotic therapy.[44] In contrast, 14 of 26 cases that occurred in a series of outbreaks described by Holt were fatal.[43]

Infants with neonatal gonococcal arthritis share several important characteristics with neonates whose arthritis is of other etiologies. Polyarticular involvement is the norm.[44] The primary presentation is refusal to move the involved limb, leading to the appearance of paralysis. Infants with bacterial infections of the hips have a high incidence of subsequent development of aseptic necrosis of the head of the femur, and the physician must examine the child with particular care for this condition. If the infant with gonococcal disease fails to show normal spontaneous movement of a leg, a full workup, often including arthrocentesis, is indicated.

Genital infections in children

Gonococcal vaginitis is the most common form of gonorrhea in children beyond the neonatal period. In contrast to adults, in prepubertal girls the nonestrogenized alkaline vaginal mucosa may be colonized and infected with *N. gonorrhoeae*. Gonococcal vaginitis is often a mild disease, perhaps because it is restricted to the superficial mucosa. The majority of symptomatic children have minor crusting discharge that may discolor the underwear and vaginal pruritus; other signs may be minimal to absent, or they may point to systemic infection.[10,18] Dysuria and polymorphonuclear leukocytes in the urine may accompany this infection. While pelvic inflammatory disease (PID) and salpingitis in women and teenagers are discussed in a separate chapter, it is important to recognize that vaginal infection of females who are adolescent or younger may also progress to involve the fallopian tubes or may disseminate to the pelvis, leading to perihepatitis and PID. Less than 10% of girls with gonorrhea have signs compatible with peritonitis, including fever, diffuse abdominal pain, leukocytosis, and decreased bowel sounds—findings that are similar to those of appendicitis. For these reasons, a perineal examination for vaginal irritation, discharge, or both is important prior to abdominal surgery in young girls. During the examination of patients, it should be kept in mind that gonococcal infections in sexually abused children can occur in other sites, including the pharynx and rectum.[17,40] Gonococcal urethritis in prepubertal males is much less common than is vaginitis in girls. When recognized, the disease is usually symptomatic and resembles gonococcal urethritis in the adult male. As with vaginitis, asymptomatic pyuria is a presentation with which the pediatrician should be familiar.[65] In children with gonococcal infection of the genitourinary tract, concomitant anorectal and tonsillopharyngeal colonization is common. This colonization is usually asymptomatic, as in adults, but it may also cause symptoms.[40,66]

Other forms of gonococcal disease in children

Gonococcal arthritis in older children resembles that of adults and may be accompanied by cutaneous lesions.[67] Multiple septic involvement of joints is not as common as in the newborn period, although a migratory polyarthritis may be part of the prodrome.[68] More typically a single, severely affected joint and myositis, and tenosynovitis predominate.[67]

Each patient must be evaluated for the need for drainage of an involved joint. Since complete response to medical therapy may not occur for several days, most physicians attempt to avoid an open drainage procedure and manage the pyarthrosis with needle aspirations if possible. An exception is purulent arthritis of the hips in which early drainage may be necessary to prevent necrosis of the femoral head. Other complications of gonorrhea are rarely, if ever, reported in the pediatric literature. Gonococcal sepsis, meningitis, Waterhouse-Friderichsen syndrome, endocarditis, myocarditis, and hepatitis may occur in children and may be fatal.[46,47,69–71] However, the pediatric experience with these conditions is limited to case reports and too minimal for comment.

DIAGNOSIS OF *N. GONORRHOEAE* INFECTION IN INFANTS AND CHILDREN

The microbiologic diagnosis of gonococcal infection and disease in infants and children must be made using techniques that are highly specific.[28] This is because the societal response to such infections, in addition to the medical implications, also often includes considerations of abuse and neglect. Child abuse and evaluations for sexually transmitted diseases are discussed in detail in Chapter 87. Because of the medical/legal issues involved, as well as special aspects of the diseases in the young, the following principles and approaches should be observed.

Only standard culture systems for the isolation of *N. gonorrhoeae* should be used for testing for *N. gonorrhoeae* in infants and children.[28] Nucleic acid amplification tests (NAATs) routinely used in sexually active adults, have not been adequately evaluated in children and are not approved for diagnosis. The performance of *N. gonorrhoeae* NAATs in low-prevalence adult populations has not been good with a significant number of false-positive test results.[72] False-positive results from commensal *Neisseria* spp. have been reported, which may be the result of horizontal genetic exchange between members of the genus *Neisseria*.[73] In addition, polymerase chain reaction (PCR) targeting the *cppB* gene may miss isolates lacking that gene.[74] These performance issues with NAATs in adults should lead to caution in applying molecular detection tests in children.

Culture remains the gold standard. However, in order to achieve satisfactory results from cultures, specimens for culture from children may require particularly meticulous handling. First, specimens should immediately be placed into prewarmed media. Second, in many pediatric gonococcal infections the *N. gonorrhoeae* organisms are sparse or are a minority of the flora. It appears to improve isolation rates when two separate chocolate agar plates (one with inhibitory antibiotics, one without) are used rather than a biplate. The larger surface area provided by full-sized plates appears to enable technicians to recognize colonies more completely. Third, plates must be promptly introduced into a 36°C incubator with enhanced CO_2 environment, such as a candle jar. This implies that the clinician must arrange for the appropriate triage of specimens, often to distant laboratories and through inclement weather. The difficulty involved with such processing in remote areas without a laboratory capable of performing *N. gonorrhoeae* is pointed out in a report by Lindsay and coworkers.[75] It highlights the need for continued availability of capabilities for cultural diagnosis in regional laboratories. The clinician should have a policy regarding the identification of specimens and establish a chain of custody so that results can be supported in court procedures when/if issues of the child's safety are being considered. The identification of *N. gonorrhoeae* from a pediatric specimen should be confirmed with at least two tests that employ different principles. Currently used identification models are biochemical, serologic, and enzyme substrate. The standard biochemical tests demonstrate utilization of glucose, but not maltose, sucrose, or lactose and a positive oxidase test. There have been reports of the misidentification of related organisms as *N. gonorrhoeae*.[76–78] Because of the societal responses, such occurrences bring the child into risk of loss of home and into social chaos. Preservation of isolates will enable additional or repeated testing. Finally, the diagnosis of gonococcal infection or disease in a child requires an evaluation for the source of infection and of other children who may also have been exposed to the perpetrator.

A clinician who is examining a prepubertal child for a possible sexually transmitted disease (STD) should be aware that contrary to adults, it is not necessary to obtain a specimen from the cervical canal in order to provide culture material from a prepubertal child for gonorrhea. A specimen from the vaginal canal suffices.

Conjunctival exudate can be directly examined by Gram stain for the presence of gram-negative intracellular bean-shaped diplococci suggestive (but not definitive) of *N. gonorrhoeae*, for gram-negative coccobacilli typical of *Hemophilus* spp. or for gram-positive cocci suggestive of infection with gram-positive pathogens. The presence of one or more polymorphonuclear leukocytes per oil-immersion field in a conjunctival smear supports the diagnosis of conjunctivitis. Detection of typical gram-negative diplococci by Gram stain warrants the presumptive diagnosis of gonococcal conjunctivitis, although other *Neisseria* spp. have also been associated with purulent ophthalmia neonatorum.[79] If infection with *N. gonorrhoeae* is suspected because of maternal risk factors, the diagnosis should be confirmed by culture and tests for antibiotic susceptibility should be performed. A definitive diagnosis is important because of the public health and social consequences of a diagnosis of gonorrhea. Cultures for *N. gonorrhoeae* should also be obtained from the oropharynx and anal canal, since concomitant infection of these sites has been demonstrated in association with gonococcal ophthalmia neonatorum.

Detection of gonococcal infection in neonates who have sepsis, arthritis, meningitis, or scalp abscesses requires cultures of blood, CSF, and joint aspirate. Specimens obtained from the conjunctiva, vagina, oropharynx, and rectum that are cultured on gonococcal selective medium are useful for identifying the primary site(s) of infection, especially if inflammation is present. Positive Gram-stained smears of exudate, CSF, or joint aspirate provide a presumptive basis for initiating treatment for *N. gonorrhoeae* but should be confirmed with definitive tests on culture isolates.

A new development is the typing of *N. gonorrhoeae* isolates using molecular methods such as pulsed-field gel electrophoresis (PFGE), or lip gene sequencing. A recent report by Di Matteo and coworkers illustrates the use of molecular typing in a case of sexual abuse showing different patterns of the isolates from the child victim and the supposed perpetrator.[80] However, this forensic application will need to be evaluated in adult and pediatric populations before its use can be recommended.

TREATMENT

General

Recommendations for therapy of childhood gonorrhea are based on guidelines from the 2006 STD treatment guidelines from the Centers for Disease Control.[28] Treatment recommendations are summarized in Table 83-2. Pediatric patients encompass children from birth to adolescence. When a child is postpubertal or weighs more than 45 kg (100 lb.), he or she should be treated with dosage regimens recommended for adults (see Chapter 35). Ceftriaxone remains the preferred drug for treatment of gonococcal infection in children. Clinician should be aware of the emergence and continuing spread of quinolone-resistant *N. gonorrhoeae* (QRNG) in some areas in the United States (20% in Hawaii 2001).[81] The Gonococcal Isolate Surveillance Project (GISP), the nationwide program for monitoring trends in resistance, performs and releases regular reports on susceptibility testing on clinical isolates.[82]

Management of asymptomatic infants born to a mother with untreated gonococcal infection

The asymptomatic infant born to a mother with untreated gonorrhea should have orogastric and rectal cultures taken routinely. It is recommended that the child receive ceftriaxone, 25–50 mg/kg (up to 125 mg) IV or IM as a single dose.[28] Both mother and infant should be tested for chlamydial infection.

Gonococcal ophthalmia

The patient should be hospitalized until the infection has been controlled. Single dose ceftriaxone was found to be effective treatment even in the presence of penicillinase-producing *N. gonorrhoeae*.[40,83] The currently recommended therapy by both the CDC and WHO is ceftriaxone, 25–50 mg/kg IV or IM in a single dose, not to exceed 125 mg. Topical antimicrobial therapy is not beneficial in the presence of systemic treatment.[83] Recently, Hoosen et al. reported 100% cure rates in 21 neonates in South Africa with culture-proven *N. gonorrhoeae* conjunctivitis using a single "low dose" of 62.5 mg ceftriaxone.[84] Alternatives for the treatment of gonococcal conjunctivitis when ceftriaxone is not available are cefotaxime 25 mg/kg IM in a single dose or kanamycin 25 mg/kg (maximum 75 mg) IM in a single dose (Table 83-2).[28,85–89] There is also some experience with spectinomycin, which is recommended as another alternative at a single IM dose of 25 mg/kg (maximum of 75 mg) by the WHO, but it does not achieve adequate cure rates for pharyngeal infections.[85,90]

Table 83-2. Recommendations for Treatment of Gonococcal Infections in Children Who Weigh <45 kg

Neonatal Infection (Ophthalmia Neonatorum)
Ceftriaxone 25–50 mg/kg (maximum 125 mg) IV or IM in a single dose
Neonatal infection (Disseminated and gonococcal scalp abscesses)
Ceftriaxone 25–50 mg/kg/d (maximum 125 mg) IV or IM in a single daily dose for 7 d, 10–14 d for meningitis
OR
Cefotaxime 25 mg/kg/dose IV or IM every 12 h for 7 d, 10–14 d for meningitis
Prophylactic treatment of neonates whose mothers have gonococcal infection
Ceftriaxone 25–50 mg/kg (maximum 125 mg) IV or IM in a single dose
Children with uncomplicated vulvovaginitis, cervicitis, urethritis, pharyngitis, proctitis
Ceftriaxone 125 mg IM in a single dose
Complicated infection in children (bacteremia, arthritis, meningitis, peritonitis)
Ceftriaxone 50 mg/kg (maximum 1 g) IM or IV in a single dose daily for 7 d (for meningitis increase maximum dose to 2 g, duration of treatment to 10–14 d)

Adapted from Centers for Disease Control and Prevention. 2006 STD Treatment Guidelines. *MMWR,* in press.

Complicated infection in newborns

Arthritis, abscess, meningitis, and septicemia should be treated by hospitalization and administration of ceftriaxone, 25–50 mg/kg/day IV or IM in a single daily dose for at least 7 days.[28] Meningitis should be treated for at least

10–14 days.[28] Cefotaxime can also be used at a dose of 25 mg/kg IV or IM every 12 hours for 7 days, for 10–14 days, if meningitis is documented.[28]

Childhood disease beyond infancy

Children who weigh less than 45 kg and have uncomplicated localized gonococcal disease (vulvovaginitis, urethritis, pharyngitis, proctitis, conjunctivitis) may receive ceftriaxone, 125 mg IM in a single dose, or spectinomycin, 40 mg/kg (maximum 2 g) IM in a single dose.[28,91] Because spectinomycin is unreliable in eradicating pharyngitis, eradication of infection needs to be documented if ceftriaxone cannot be used.[92] A high index of suspicion is key to the management disseminated gonococcal disease. Children who weigh less than 45 kg and have disseminated gonococcal disease (bacteremia, arthritis, meningitis, perihepatitis) may receive ceftriaxone, 50 mg/kg IM or IV in a single daily dose for 7–14 days.[28] Note that only parenteral cephalosporins are recommended for therapy in children; cefixime has been used to treat gonococcal infections in children, but there is no published data in regards to safety and efficacy in children (cefixime is no longer manufactured in the United States at the time of preparation of this chapter, Lupin Pharmaceuticals has received FDA approval for a generic version including a suspension). Quinolones are not approved for this indication in children, and concerns about increases in prevalence of QRNG may limit their usefulness in parts of the United States and other countries. Ceftriaxone is the treatment of choice for genital infections in pediatric patients (Table 83-2). It should be kept in mind that coinfection with *C. trachomatis* is common in children as well as adolescents or adults and the microbiologic evaluation needs to reflect this. Optimal therapy for known or possible coinfection with both pathogens has not been explored in children. See the separate chapter on PID (see Chapter 56) for considerations in the treatment of gonococcal cervicitis and salpingitis in adolescents.

■ PREVENTION OF NEONATAL GONOCOCCAL DISEASE

Prevention of ophthalmia neonatorum is a principal goal of medical care of the newborn and remains an important focus in the fight against childhood blindness in low-income countries.[93] The most effective method is the prevention and treatment of the disease in the mother so that exposure of the newborn does not occur. All pregnant women at risk should have endocervical culture examinations for gonococci as an integral part of prenatal care at the first prenatal visit followed by appropriate antibiotic therapy. A second culture late in pregnancy (third trimester) should be obtained from women who are at high risk of gonococcal infection. This approach, while effective, is also costly and may not be feasible in resource-poor countries where eye prophylaxis is the most common intervention to prevent ophthalmia neonatorum. Credé's topical use of silver nitrate was one of the most successful strategies in preventive medicine resulting in reports of low rates of ophthalmia neonatorum in the presence of prophylaxis. A review of 24 studies conducted from 1930 to 1979 showed an overall risk estimate of 0.06%.[94] Because of reports of failure and the high incidence of chemical conjunctivitis with silver nitrate and the importance of eye contact in mother—infant bonding, interest developed in the use of other agents.[95,96] Alternatives were studied in several prospective trials. Alternating regimens of silver nitrate and erythromycin ophthalmic ointment at hospitals in St. Louis and Chicago showed no gonococcal isolates during the use of either regimen but a higher number of side effects with silver nitrate.[95,96] A randomized prospective trial of silver nitrate versus erythromycin for prophylaxis of ophthalmia neonatorum in Seattle, WA, found no gonococcal infections in either group.[97] Lund et al. compared the incidence of gonococcal ophthalmia neonatorum before and after introduction of prophylactic agents in South Africa and reported decreased incidences of similar magnitude in hospitals using silver nitrate or erythromycin ophthalmic ointment.[98] Tetracycline ophthalmic ointment reduced the incidence of gonococcal ophthalmia among exposed infants in Kenya compared to historic controls by similar or slightly greater amounts than silver nitrate.[99] This effect was seen despite a high percentage of tetracycline resistant gonococci in the study indicating that the high local concentration may be sufficient to eradicate the low inoculum received during birth.[99] The frequency of gonococcal ophthalmia was similar with each of the three prophylactic regimens used in a study by Hammerschlag et al., in Brooklyn, NY, comparing silver nitrate drops, erythromycin ophthalmic ointment, and tetracycline ophthalmic ointment.[33] However, only 3% (11 of 389) of the enrolled mothers had positive cultures for *N. gonorrhoeae* at some point during pregnancy and were treated.[97] A study of 2.5% povidone-iodine solution as prophylaxis against ophthalmia neonatorum in Kenya found that it reduced the overall incidence of conjunctivitis, but the true effectiveness in preventing gonococcal ophthalmia could not be estimated as the rate of gonococcal infections in the mothers, and thus the number of exposed neonates was unknown.[100] Povidone-iodine is not currently recommended as an alternative to the established prophylactic agents.[28] Bacitracin ointment (not effective) and penicillin drops (sensitizing) should not be used. Chemical prophylaxis of the newborn conjunctivae provides excellent but not perfect protection and does not provide effective therapy for an established infection. The main reasons cited for failure of prophylaxis are prematurity, prolonged rupture of the membranes, and infection before birth.[101,102] Prophylaxis with ophthalmic ointments containing antimicrobial agents is not completely without adverse effects, for example the potential selection of resistant bacteria.[103]

Most state health departments in the United States require ocular prophylaxis of some form. Silver nitrate 1% aqueous solution is no longer available in the United States. The remaining recommended agents are 1% tetracycline ophthalmic ointment in a single application, or 0.5% erythromycin ophthalmic ointment in a single application.[28] Prophylaxis should be administered as soon as possible after birth as delay has been associated with increased risk of gonococcal ophthalmia (four- to fivefold with delay ≥4 hours).[104] It should be noted that in countries with a very low prevalence of gonococcal infections in pregnant women and/or a prenatal screening program, the effect of universal eye prophylaxis may not be discernible and the approach may not be cost-effective.[94,105] Therefore, some such countries have adopted a strategy of diagnosing and treating ophthalmia neonatorum in those infants who develop symptoms instead of universal prophylaxis. However, ocular prophylaxis remains an inexpensive preventive tool, which is safe, easy to administer, and effectively prevents most cases of gonococcal ophthalmia.

CHLAMYDIA TRACHOMATIS INFECTIONS IN INFANTS AND CHILDREN

HISTORY

At the turn of the twentieth century, there was no screening of expectant mothers for STDs, no instillation of prophylactic eye drops, and no antibiotic treatment for established infections. In this period, the term *ophthalmia neonatorum* was for all practical purposes synonymous with gonococcal conjunctivitis. As neonatal conjunctivitis came under control with silver nitrate prophylaxis, the importance of another form of ophthalmia neonatorum, termed *inclusion blennorrhea*, was noted. The relationship between maternal genital infection and conjunctivitis of the newborn associated with inclusion bodies within epithelial cells was established by Lindner, Halberstader, Von Prowazek, and others.[106] In 1967, Schachter and colleagues further emphasized the relationship of sexual transmission of the infection in the parents of infants with inclusion conjunctivitis.[107] Respiratory infection in infants due to *C. trachomatis* was probably first reported in 1941 by Botsztejn, who described an entity he called *pertussoid eosinophilic pneumonia*.[108] The syndrome of infantile chlamydial pneumonia was further characterized by Beem and Saxon in 1977.[109]

EPIDEMIOLOGY

C. trachomatis infection is acquired by the infant from his or her mother during parturition.[110,111] This is based on a number of well-controlled prospective studies of maternal-infant infection conducted in the 1970s and 1980s, where infection occurred only in those infants born to infected mothers. There is no convincing evidence of horizontal transmission from mother-to-infant, other family members-to-infant, or from infant-to-infant after delivery. Infection after cesarean delivery or through intact membranes is rare but may occur.[112] In the former, there has usually been early rupture of the amnionic membranes. The overall risk of acquiring infection in an infant born to a mother with active chlamydial infection at any anatomical site has been approximately 50–75% in various studies.[110,111] Infants are often infected at more than one site, including the conjunctiva, nasopharynx, rectum, and vagina. The most frequent clinical manifestation of neonatal chlamydial infection, inclusion conjunctivitis, has been reported to occur in 15–37% of infants born to mothers with untreated cervical chlamydial infection.[110–112] The most frequent site of infection, however, is the nasopharynx, with 78% of infected infants having positive nasopharyngeal cultures in one study.[112] Approximately one-half of infants with inclusion conjunctivitis will also be infected in the nasopharynx. Only a minority of infants with nasopharyngeal infection actually go on to develop chlamydial pneumonia; Hammerschlag et al. found that only 4 of 12 (33%) infants with isolated nasopharyngeal infection subsequently developed pneumonia.[112] The overall risk of developing pneumonia among infants born to chlamydia-positive mothers has been reported to range from 1% to 22%.[110,111]

Data on the risk of acquiring rectal or vaginal infection are more limited. Bell and colleagues demonstrated that perinatally acquired *C. trachomatis* infection may persist for months to years.[113] Twenty-two infants born to women with culture-documented chlamydial infection were followed, and positive cultures from the nasopharynx and oropharynx in the infants were detected as late as 28.5 months after birth. Rectal and vaginal infection persisted for at least 1 year. This can become an important confounding variable when young children are tested for the presence of *C. trachomatis* during evaluation for suspected sexual abuse.

CONJUNCTIVITIS

Before the introduction of systematic screening and treatment of *C. trachomatis* infection in pregnant women in the 1990s, *C. trachomatis* was the most frequent identifiable infectious cause of neonatal conjunctivitis and the major clinical manifestation of neonatal chlamydial infection in the United States.[110,111] Screening and treatment have resulted in a dramatic decrease in perinatal chlamydial infections. However, in countries where pregnant women are not routinely screened, including the Netherlands and many developing countries, *C. trachomatis* remains the most frequent cause of neonatal conjunctivitis.[114–116] The incubation period of *C. trachomatis* conjunctivitis is 5–14 days

after delivery, or earlier if there has been premature rupture of membranes. At least 50% of infants with chlamydial conjunctivitis will also have nasopharyngeal infection. The presentation is extremely variable, ranging from mild conjunctivitis with scant mucoid discharge to severe conjunctivitis with copious purulent discharge, chemosis, and pseudomembrane formation. The conjunctiva can be very friable and may bleed when stroked with a swab. Eyelid erythema and edema are frequently present. A Gram-stained conjunctival smear may initially reveal a predominance of polymorphonuclear leucocytes (PMNs). Chlamydial conjunctivitis needs to be differentiated from gonococcal ophthalmia in some infants, especially those born to mothers who did not receive any prenatal care, had gonorrhea during pregnancy, and/or abused drugs. There can be overlap in both incubation periods and presentation. Bilateral infections are present in two-thirds of cases. A follicular reaction is not seen because infants less than 3 months of age do not have the requisite lymphoid tissue present in the conjunctiva. Although uncommon, chlamydial neonatal conjunctivitis has been noted to induce the long-term sequelae of corneal neovascularization and scarring. However, Hammerschlag and colleagues did not detect micropannus at 1 year of age in seven infants who had culture-documented neonatal *C. trachomatis* conjunctivitis.[117]

PNEUMONIA

Approximately 70% of infected infants will have positive nasopharyngeal cultures. The majority of nasopharyngeal infections are asymptomatic and may persist for 3 years or more.[113] Chlamydial pneumonia develops in only about 30% of infants with nasopharyngeal infection.[117] In those infants who develop pneumonia, the presentation and clinical findings are very characteristic.[118,119] The children usually present between 4 and 12 weeks of age. A few cases have been reported presenting as early as 2 weeks of age but no cases have been seen beyond 4 months. The infants frequently have a history of cough and congestion with an absence of fever. On physical examination, the infant is tachypneic and rales are heard on auscultation of the chest; wheezing is distinctly uncommon. There are no specific radiographic findings except hyperinflation (Fig. 83-1). Significant laboratory findings include peripheral eosinophilia (>300 cells/cm^3) and elevated serum immunoglobulins. If cultured, infants with *C. trachomatis* pneumonia may remain symptomatic and shed the organism from the nasopharynx for protracted periods.[117–119] Generally, infantile pneumonia due to *C. trachomatis* appears to be self-limited. Most infants can be managed as outpatients although there are a few reports of severe disease requiring hospitalization and assisted ventilation. *C. trachomatis* pneumonia in infants also appears to be associated with few sequelae, although data are limited.

OTHER INFECTIONS

Otitis media

Isolation of *C. trachomatis* from middle-ear fluid was first reported by Tipple et al.[119] The organism was isolated from the middle-ear aspirates of 3 of 11 infants with chlamydia pneumonia. These infants were all under 3 months of age and had the typical infantile chlamydial pneumonia and what was described as "serous" otitis media. This may not imply a

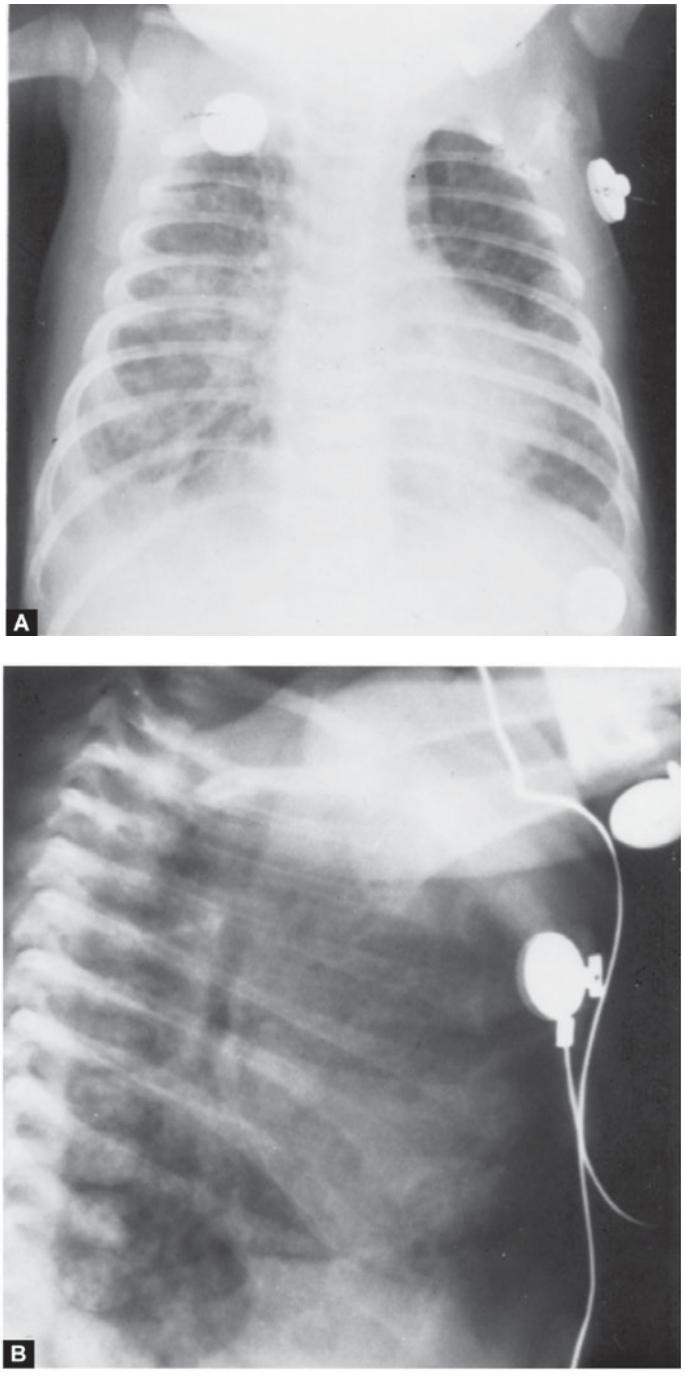

FIGURE 83-1 A. Anteroposterior and, **B.,** lateral chest radiographs of a severely ill 1-month-old male infant with chlamydial pneumonitis. Diffuse interstitial infiltrates and hyperaeration with flattened diaphragms are prominent.

causal relationship, as the middle ear is contiguous with the nasopharynx and the organism is present in the mucosa of the nasopharynx. Infants with chlamydial pneumonia have a significant degree of nasal congestion, which can lead to eustachian-tube dysfunction, and thus the presence of serous otitis media may not be directly attributable to the presence of *C. trachomatis* in middle-ear fluid. However, subsequent studies that have examined middle-ear fluids from older infants and children with acute and chronic otitis media have not found convincing evidence of *C. trachomatis* as an etiologic agent of otitis. Four studies examined middle-ear fluids from a total of 337 children ranging in age from 5 months through 12 years.[120–123] *C. trachomatis* was isolated from ear fluids from five of these children enrolled in two of the studies.[120,121] Chang et al. isolated *C. trachomatis* from ear aspirates of 3 of 26 (11.5%) children but the age of only 1 of these children, a 10-month-old, was given.[120] The culture method used was iododeoxyuridine (IUDR)-treated McCoy cells with iodine staining, which should be specific for *C. trachomatis*. In the other study, Dawson and colleagues isolated presumptive *C. trachomatis* from two ear aspirates from 217 Australian aboriginal children.[121] The positive children were 4 and 8 years of age. The researchers used McCoy cells but confirmed the isolates with a fluorescein conjugated genus-specific monoclonal antibody, and thus it is possible that both isolates may have actually been *C. pneumoniae*. Considering that perinatally acquired nasopharyngeal *C. trachomatis* infections may persist for at least 2 years, it is possible that the organism may be isolated from middle-ear fluids beyond early infancy but a causal relationship has not been established. *C. pneumoniae* is a more likely candidate as a cause of otitis media in older children and was isolated from middle-ear fluids of 8% of children presenting with acute otitis media in one study.[124]

Rectogenital infection in older children

C. trachomatis has not been associated with any specific clinical syndrome in older infants and children. Most attention to *C. trachomatis* infection in these children has concentrated on the relationship to child sexual abuse. Isolation of *C. trachomatis* from rectal or genital sites in children without prior sexual activity may be a marker of sexual abuse.[110,111,125] Although evidence for other modes of spread, such as through fomites, is lacking for this organism, perinatal maternal-infant transmission resulting in vaginal and/or rectal infection has been documented with prolonged infection for periods up to 3 years.[113] This could be an important confounding variable.

Studies have identified rectogenital chlamydial infection in 2–3% of sexually abused children when these children were routinely cultured for the organism.[125] The majority of those with chlamydial infection were asymptomatic. The association of *C. trachomatis* infection and sexual abuse is covered in detail in Chapter 87. *C. pneumoniae* can be confused with *C. trachomatis* in pharyngeal cultures if genus specific monoclonal antibodies are used for culture confirmation.[126] Asymptomatic nasopharyngeal infection with *C. pneumoniae* occurs in 2–5% of children.[110,111]

DIAGNOSIS

It is difficult to make an etiologic diagnosis of neonatal conjunctivitis on clinical grounds alone. There can be significant overlap in both incubation period and clinical findings with infections due to other organisms, especially *N. gonorrhoeae*. In a high-risk population, gonococcal ophthalmia must be seriously considered. The incubation period for gonococcal conjunctivitis is usually 3–5 days but it can be longer. The incubation period for chlamydial conjunctivitis is approximately 5–14 days. Most cases will present by 2 weeks of age, which is after the infant leaves the hospital. Epidemiologic clues can help the physician decide whether gonococcal ophthalmia needs to be considered. Hammerschlag and colleagues noted that seven of the eight infants who presented with gonococcal conjunctivitis were born to mothers who had not received any prenatal care.[33] Five of these women were abusers of crack cocaine. Another epidemiologic clue is a history of gonorrhea or other STD during pregnancy.

The clinical presentation of *C. trachomatis* pneumonitis in infants is fairly characteristic, and one may be able to make a clinical diagnosis with a degree of certainty.

Laboratory diagnosis of C. trachomatis infections in infants and children

The "gold standard" for diagnosis of *C. trachomatis* infections in infants and children remains isolation by culture of *C. trachomatis* from the conjunctiva, nasopharynx, vagina, or rectum. *C. trachomatis* culture has been defined further by the CDC as isolation of the organism in tissue culture and confirmation by microscopic identification of the characteristic inclusions, preferably by staining with a fluorescein-conjugated species-specific monoclonal antibody.[28] Enzyme immunoassays (EIAs) have been used by some commercial laboratories as a "screen" for culture confirmation; however, use of EIAs for culture confirmation has been associated with significant numbers of false-positive results, especially with rectal and vaginal specimens.[127] The CDC has strongly stated that use of EIAs for this indication is not acceptable.[28,127] Several nonculture tests are approved for diagnosis of chlamydial conjunctivitis in infants, specifically EIAs, and direct fluorescent antibody tests (DFAs). The only EIA and DFA assays still available in the United States are Pathfinder, Chlamydia DFA and EIA Microplate (Bio-Rad Laboratories). These tests appear to perform well with conjunctival specimens with sensitivities greater than or equal to 90% and specificities greater than or equal to 95% compared with culture.[128,129] Unfortunately, the performance with nasopharyngeal specimens has not been as

good, with sensitivities ranging from 33% to more than 90%. The DNA probe, Pace II (GenProbe, San Diego, CA), which is still used in many laboratories, does not have approval for any site in children, including the conjunctiva.

There are currently three FDA approved, commercially-available NAATs for diagnosis of *C. trachomatis* infection: polymerase chain reaction (PCR), Amplicor (Roche Molecular Diagnostics, Nutley, NJ), strand displacement amplification (SDA) (ProbeTec, Becton Dickson, Sparks, MD), and transcription mediated amplification (TMA) (GenProbe, SanDiego, CA). These assays all have FDA approval for cervical swabs from women, urethral swabs from men, and urine from men and women. These tests also perform very well in adolescents who have very high rates of genital *C. trachomatis* infection. The use of noninvasive specimens such as urine is especially useful in high prevalence populations such as sexually active adolescents. However, data on use of NAATs in infants and children are limited. Preliminary data suggest that PCR is equivalent to culture for detection of *C. trachomatis* in the conjunctiva and nasopharynx of infants with conjunctivitis.[130] Roblin et al. evaluated Amplicor for the detection of *C. trachomatis* in ocular and nasopharyngeal specimens from 75 infants with suspected chlamydial conjunctivitis.[130] Amplicor was equivalent to culture for eye specimens with sensitivity and specificity of 92.3% and 100%, respectively. The sensitivity and specificity for nasopharyngeal specimens were 100% and 97.2%. PCR also detected *C. trachomatis* in the urine of 12 of 12 mothers of culture-positive infants.

Use of these EIAs and DFAs for vaginal and rectal specimens in the evaluation of children suspected of being sexually abused has been associated with false-positive tests.[127,131] Fecal material can give false-positive reactions with any EIA. Common bowel organisms, including *Escherichia coli*, Group B streptococcus, and even some respiratory flora such as Group A Streptococcus can also give false-positive reactions with EIAs. Another potential problem can occur with use of an EIA for respiratory specimens. As the only currently available EIA, Pathfinder®, Chlamydia EIA Microplate (Bio-Rad Laboratories) uses a genus-specific antibody; if used for respiratory specimens, this test will also detect *C. pneumoniae*.[126] Even though culture is considered the gold standard, culture of *C. trachomatis* is not regulated in any way and sensitivity may vary from laboratory to laboratory. The methods used for culture confirmation became an issue when several large commercial laboratories started using an EIA instead of FA staining and visual identification of inclusions for culture confirmation. This has resulted in at least one "outbreak" of *C. trachomatis* infection in the evaluation of suspected sexual abuse among residents and staff of an institution for the mentally retarded in Ohio in 1990.[127] All the "positive" cultures, mostly rectal specimens, were subsequently determined to be false-positives resulting from carryover of fecal material and bacteria in the culture specimens. The major advantage of culture is that it is 100% specific. When cultures are obtained for *C. trachomatis* in the evaluation of suspected sexual abuse, one should pay careful attention to the laboratory used. Unlike Canada, the United States does not have a system of designated reference laboratories to be utilized for evaluation of sexual abuse or assault.

NAATs are currently not approved for detection of *C. trachomatis* in rectogenital sites from prepubertal children and rectal specimens in adults. The major problem with rectal specimens is the presence of inhibitors of DNA polymerase, which can lead to false-negative results. Data on use of NAATs for vaginal specimens or urine from children are very limited and insufficient at this time to allow making a recommendation on their use. There have been three studies published since 1999 evaluating the performance of NAATs and use of urine for detection of *C. trachomatis* and *N. gonorrhoeae* in children being evaluated for suspected sexual abuse.[132–134] Unfortunately, all are seriously flawed. The major deficiency is the failure to analyze the results by site tested, age, and sex. The majority of the girls in all three studies were postpubertal; some gave histories of consensual sex, which is a major confounding variable. The number of males enrolled (only two of the studies) was small and the data on males were not analyzed separately. Two of the studies used ligase chain reaction (LCx, Abbott Diagnostics), which was withdrawn from the market in 2002.[134] The CDC currently recommends that NAATs may be used as an alternative to *C. trachomatis* culture only if confirmation is available, which means using second FDA-approved NAAT that targets a different gene sequence from the initial test.[28] It is also recommended that all isolates and specimens be preserved for confirmatory testing.

Treatment of chlamydial conjunctivitis and pneumonia in infants

Oral erythromycin suspension (ethylsuccinate or stearate) (50 mg/kg/day for 14 days) is the therapy of choice for the treatment of chlamydial conjunctivitis and pneumonia in infants. It provides better and faster resolution of conjunctivitis as well as treats any concurrent nasopharyngeal infection, which prevents the development of pneumonia. Additional topical therapy is not needed. The efficacy of this regimen has been reported to range from 80–90%; as many as 20% of infants may require another course of therapy.[110,111,117] Erythromycin at the same dose for 2 weeks is the treatment of choice for pneumonia and does result in clinical improvement as well as elimination of the organism from the respiratory tract.

Treatment with oral erythromycin has been associated with infantile hypertrophic pyloric stenosis in infants less than 6 weeks of age who were given the drug for prophylaxis after nursery exposure to pertussis.[135,136] Erythromycin is a

motilin receptor agonist. Data on use of other macrolides, including azithromycin or clarithromycin, for the treatment of neonatal chlamydia infection are limited. There are no published studies of clarithromycin, and only one small study that evaluated azithromycin which found that a short course of azithromycin suspension, 20 mg/kg/day orally, one dose daily for 3 days, was as effective as 2 weeks of erythromycin in eradication of *C. trachomatis* from the conjunctivae and nasopharynx of infants with conjunctivitis.[137]

Chlamydial infections in older children may be treated with oral erythromycin (50 mg/kg/day 4 times a day orally to a maximum of 2 g a day for 7–14 days). Children older than 8 years of age may be treated with tetracycline (25–50 mg/kg/day 4 times a day orally for 7 days). Azithromycin, 1 g orally, as a single dose may also be used in children who weigh ≥45 kg and/or are ≥8 years of age. The first-line treatment for uncomplicated *C. trachomatis* infections in adults and adolescents is azithromycin, 1 g given as a single dose or doxycycline, 100 mg bid, orally for 7 days. Alternative regimens include erythromycin base, 500 mg or erythromycin ethylsuccinate, 800 mg, both orally, qid for 7 days or ofloxacin 300 mg, orally bid for 7 days or levofloxacin, 500 mg orally, once a day for 7 days.

Prevention and control strategies

Since *C. trachomatis* infections are transmitted vertically from mother to infant during delivery, there are several possible options for intervention. One of the first to be considered was neonatal ocular prophylaxis. The results of several prospective studies of mother-to-infant transmission of *C. trachomatis* demonstrated that neonatal ocular prophylaxis with silver nitrate does not prevent the development of chlamydial conjunctivitis.[110,111] These studies had found that the risk of conjunctivitis among infants born to infected women ranged from 18% to 50%. As erythromycin and tetracycline ophthalmic ointments were also approved and used for ocular prophylaxis, it was suggested that they might also be effective for prevention of chlamydial conjunctivitis. The first such study conducted in 1980 found that not one of 24 infants in Seattle born to *C. trachomatis*-positive women and who received topical erythromycin developed chlamydial conjunctivitis, compared to 33% (12 of 36) of those who received silver nitrate drops.[97] There was no effect on the incidence of nasopharyngeal infection or on the subsequent development of chlamydial pneumonia. In a subsequent study, Laga et al. in a subsequent study from Nairobi, Kenya, compared tetracycline ointment with silver nitrate drops,[99] chlamydial ophthalmia developed in 10.1% of the infants born to women with cultures positive for *C. trachomatis* who received silver nitrate drops as prophylaxis compared to 7.2% who received tetracycline ointment. The authors initially concluded that both preparations were efficacious when compared with a historical cohort in which the disease developed in 31.3% of the infants who were not treated prophylactically and who were born to infected women. Most of the infants in this study were followed only for the first 4 weeks of life, however, and the follow-up rate was less than 50%. When these authors examined a smaller group of infants who were followed for at least 6 months, 23% and 31% of those who received silver nitrate and tetracycline, respectively, ultimately acquired an ocular infection with *C. trachomatis*. What is especially interesting about these results is that many of these ocular infections were detected when the infants were more than 2 months of age and were asymptomatic. This is very different from the experience in the United States, where asymptomatic ocular infection has been uncommon.

In 1989, Hammerschlag et al. compared silver nitrate, erythromycin, and tetracycline as neonatal ocular prophylaxis in a large urban hospital in Brooklyn, New York.[33] The prophylaxis preparations were given within 30 minutes of birth. Chlamydial conjunctivitis developed in 20% (15 of 76) of infants born to infected mothers who received silver nitrate drops, 14% (13 of 92) of those who received erythromycin, and 11% (7 of 62) of those who received tetracycline. There was no effect on the incidence of nasopharyngeal infection and pneumonia. A subsequent study from Taiwan compared silver nitrate, the two antibiotics, and no prophylaxis.[138] This study, in contrast to previous studies, did not specifically follow infants born to women with culture-documented chlamydial infection but instead followed all infants delivered during the period of the study—for 4 weeks or until they developed conjunctivitis. Again, there was no difference in the incidence of neonatal chlamydial conjunctivitis among the four groups. The incidences of chlamydial conjunctivitis in the tetracycline, erythromycin, silver nitrate, and no prophylaxis group were 1.3, 1.5, 1.7, and 1.6%, respectively. Diagnosis of *C. trachomatis* was by DFA rather than culture. No data were given as to the prevalence of maternal infection with *C. trachomatis* or *N. gonorrhoeae*. Differences in the prevalence of maternal infection among the four groups could lead to different rates of *C. trachomatis* conjunctivitis in the infants that were unrelated to prophylaxis. Respiratory infection was not assessed. A similar study from a clinic in Kenya was reported by Isenberg et al. comparing povidone-iodine, erythromycin ophthalmic ointment, and silver nitrate drops as neonatal ocular prophylaxis.[100] povidone-iodine was selected because, in vitro, it has a broad antibacterial spectrum; it is also antiviral and is very inexpensive compared to the other prophylaxis agents. As with the study from Taiwan, the pregnant women were not screened for *C. trachomatis* prenatally, and chlamydial conjunctivitis in the infants was diagnosed by DFA. Mothers were told to bring their infants back if conjunctivitis developed. Use of povidone-iodine appeared to result in a 50% reduction in *C. trachomatis* conjunctivitis compared to silver nitrate (5.5% vs. 10.5% of infants) and an approximately 30% reduction

compared to erythromycin (7.4%). There was no difference in the proportions of infants who developed gonococcal ophthalmia. Because of the structure of the study, one cannot be sure if every infant who developed conjunctivitis returned to the clinic. As the prevalence of chlamydial infection among the pregnant women in the population was unknown, the investigators did not know how many cases of chlamydial ophthalmia to expect. The CDC does not recommend the use of providone-iodine,[28] and silver nitrate drops are no longer manufactured in the United States. Another approach that has been considered is oral prophylaxis of infants born to mothers with untreated *C. trachomatis* infection with erythromycin or azithromycin.[139] However, several analyses have found this approach to be very expensive compared to watching and treating the infant when they become symptomatic. In addition, there is the issue of compliance and there are no data on the efficacy of either oral erythromycin or azithromycin for prophylaxis.

The most effective method of control of perinatal *C. trachomatis* infection is screening and treatment of pregnant women. This approach has been validated by a dramatic decrease in perinatal chlamydial infection seen in the United States and the persistence of these infections in countries where screening and treatment of pregnant women is not standard practice, such as the Netherlands, India, and China.[114–116] Rours and colleagues reported that during the period from 1996 to 2001, *C. trachomatis* was responsible for 61–64% of the cases of neonatal conjunctivitis seen in a large university affiliated hospital in Rotterdam.[114] Even though the rate of *C. trachomatis* infection among pregnant women in Rotterdam exceeded 5%, prenatal screening and treatment is not a part of routine prenatal care in the Netherlands.

Reasons for failure of maternal treatment to prevent infantile chlamydial infection include poor compliance and reinfection from untreated or new sexual partners. Even with effective screening, some infected women will be missed, depending on the methods used. There are also women who do not seek prenatal care.

84 Herpesvirus Infections in Neonates and Children: Cytomegalovirus and Herpes Simplex Virus

Russell D. Bradford, Richard J. Whitley, and Sergio Stagno

CONGENITAL AND PERINATAL CYTOMEGALOVIRUS INFECTIONS

Cytomegaloviruses (CMVs) are members of the herpesvirus family known for their ubiquitous distribution in humans and in numerous other mammals. These viruses share a number of biologic attributes in common with herpes simplex virus (HSV) and other members of the herpesvirus family. Both in vivo and in vitro, infection is highly species-specific.[1] The first description of cells containing intranuclear and cytoplasmic inclusions dates from 1881 when Ribbert described them in the kidneys of a stillborn infant with congenital syphilis.[2] In 1954, Smith succeeded in propagating murine CMV in explant cultures of mouse embryonic fibroblasts.[3] Utilization of similar techniques led to the independent isolation of human CMV shortly thereafter by Smith, Rowe et al. and Weller et al.[4–6] The term CMV was proposed in 1960 by Weller, Hanshaw, and Scott to replace the names cytomegalic inclusion disease (CID) and salivary gland virus, which were misleading, since the virus usually involved other organs and the term salivary gland virus had been used to designate unrelated agents obtained from bats.[7]

The propagation of CMV in vitro led to the rapid development of serologic methods and the ability to isolate the virus from clinical specimens. It quickly became apparent that CMV is a significant human pathogen.[8] The natural history of human CMV infection is complex. Following primary infection, viral excretion (occasionally from several sites) persists for weeks, months, or years before becoming latent. Asymptomatic episodes of recurrent infection with renewed viral shedding are common, even years after primary infection. Most maternal CMV infections are subclinical. However, although infection may be without consequences for the mother, it can have serious repercussions for the fetus.[9]

EPIDEMIOLOGY

General

Humans are the only reservoir for CMV. The infection is endemic and without seasonal variation.[1–8] Climate does not affect the prevalence of infection, and there are no known vectors in the natural transmission cycle. Seroepidemiologic surveys have found CMV infection in every human population that has been tested. The prevalence of antibody to CMV increases with age, but the patterns of acquisition of infection vary widely among populations according to geographic, ethnic, and socioeconomic backgrounds. In general, the prevalence of CMV infection is higher in developing countries and among the lower socioeconomic strata of developed nations. These differences are particularly striking during childhood.

The level of immunity among women of child-bearing age also varies widely in different populations. In the United States and eastern Europe, seropositivity rates in young women range from less than 50% to 85%.[9] In contrast, in the Ivory Coast, Japan, and Chile the rate of seropositivity is greater than 90% by the end of the second decade of life.[10–12] Prospective studies of pregnant women in the United States indicate that the rate of CMV acquisition for childbearing age women of middle to higher socioeconomic background is approximately 2% per year, whereas it is 6% among women of lower socioeconomic status.[13]

The modes of transmission from person to person are incompletely understood.[8] The following features of CMV infection make it difficult to study the modes of acquisition. In the majority of individuals, CMV infections are subclinical, including those acquired in utero and during the perinatal period. Virus excretion persists for years following congenital, perinatal, and early postnatal infections. Prolonged viral shedding is also a feature of primary infection in older children and adults. These infected persons continue to expose other susceptible people. Since non-primary infections (reactivated infection or reinfection) are fairly common, intermittent excretion of virus can be anticipated in a significant proportion of seropositive adults. Clearly, a large reservoir of CMV exists in the population at all times. Transmission occurs by direct or indirect person-to-person contact. Sources of virus include urine, oropharyngeal secretions, cervical and vaginal secretions, semen, milk, tears, blood, and transplanted organs.[14,15]

The spread of infection requires close or intimate contact with infected secretions or infected blood and organs. Sexual contact contributes the most to the spread of CMV. Higher rates of seropositivity have been observed among males and females with multiple sex partners and histories of sexually transmitted diseases.[14,16–21]

Certain child-rearing practices influence the spread of CMV among children. Because seropositive women often excrete CMV in breast milk, the incidence of perinatal CMV infection is high where breast feeding is a common practice.[15] In 1971, Weller suggested that the high rate of seropositivity among Swedish children was probably due to the frequent use of day care centers.[1] Swedish children had a rate of infection that was three to four times higher than that observed in London or Rochester, New York. High rates of CMV infection among children attending day care centers were later confirmed in the United States.[22–24] Pass et al. reported that in a group of 70 children of middle- to upper-income background whose ages ranged from 3 to 65 months, the rate of CMV excretion in urine and saliva was 50%.[24] The lowest rate of excretion (9%) occurred in infants less than 1 year of age, and the highest rate (88%) among toddlers in their second year of life. Infants younger than 12 months in group day care who excrete CMV are more likely to have acquired CMV congenitally or perinatally from contact with maternal cervical secretions or breast milk. Twelve children whose mothers were seronegative excreted CMV, which indicated that their infection was not perinatally acquired. These findings have been confirmed by other investigators.[22,23,25,26]

The high rate of CMV infection among children in group day care is caused by horizontal transmission from child to child. The route of transmission that appears most likely is the transfer of virus that occurs through saliva on hands and toys.[27,28] The strongest evidence supporting child-to-child transmission was obtained by Adler who used restriction enzyme digestion patterns of CMV DNA to show the identity of isolates obtained from infected children attending day care.[29] His findings support that CMV is efficiently transmitted from child to child in the day care setting, and that it is not unusual to find excretion rates as high as 20–40% in young toddlers. In many instances, these rates of infection are substantially higher than the seroprevalence rates for the parents of the children and young adults in the cities where the studies were done. No data demonstrate CMV transmission via respiratory droplets.

An important issue is whether children excreting CMV are a source of infection for susceptible child care personnel and parents, particularly women of childbearing age. This mode of transmission has been confirmed by restriction endonuclease mapping of CMV DNA.[30,31] Seroepidemiologic studies suggest that parents often acquire CMV from their children who became infected outside the family.[32–34] Adler and Pass et al. have presented compelling evidence linking the acquisition of CMV by children in day care with subsequent infection of their mothers and caretakers. Pass et al. followed seronegative parents whose children attended a day care center and a similar control population of parents whose children did not attend day care.[26] The groups were followed for a mean of 17 and 21 months, respectively. Fourteen of 67 seronegative parents with children in day care centers acquired CMV as compared with none of 31 susceptible parents whose children did not attend day care. More significantly, all 14 parents of the day care group who seroconverted had a child who shed CMV in saliva or urine. In fact, seroconversion occurred in 14–48 parents of children who shed CMV, compared with none of 21 whose children did not excrete CMV. The highest risk of seroconversion (45%) was for parents with a child shedding CMV who was younger than 18 months at enrollment. In 2 of the 14 cases, DNA analysis indicated the child as the source of CMV infection. In a subsequent study, this group of investigators also demonstrated by means of restriction enzyme analysis that infections acquired by a mother from a child can be transmitted to her fetus.[26] Similarly, Adler observed that of 18 seronegative mothers whose children shed CMV strains associated with day care, 6 seroconverted and excreted CMV strains identical to the strains shed by their children.[35] On an average, these mothers became infected within 4.2 months (range, 3–7 months) after the child's infection.

In assessing the risk to caretakers working with young children in day care centers, Adler reported an annual seroconversion rate of 11% among 202 seronegative women employed at 33 day care centers in Richmond, Virginia.[36] This rate was significantly higher than the 2% annual rate of 229 female hospital employees matched for age, race, and marital status. Restriction endonuclease DNA patterns of 17 of 31 isolates of CMV obtained from day care workers were compared with the patterns of isolates shed by the children cared for by these women. Nine of the 17 isolates were identical to the isolates shed by one or more children. These observations provide evidence that susceptible women who work with children in day care have an occupational risk of acquiring CMV.

From the data generated from these studies, approximately 50% of susceptible children between the ages of 1 and 3 years who attend group day care will acquire CMV from their playmates and become an important potential source of infection for susceptible parents and caretakers. Of particular concern is the risk to seronegative mothers who have children in group day care and who become pregnant.

Fomites may also play some role in transmission because CMV has been both shown to retain infectivity for hours on plastic surfaces and isolated from randomly selected toys and surfaces in a day care center.[27,28]

Maternal infection and vertical transmission

Maternal CMV infection is the origin of congenital infections and of most perinatal infections. As used here, vertical transmission implies mother-to-infant transmission.

Congenital infection

Congenital infection is the result of transplacental transmission. In the United States, congenital CMV infection occurs in between 0.2% and 2.2% (average 1%) of all newborn infants. The natural history of CMV infection during pregnancy is particularly complex and has not been fully explained. With infections such as rubella and toxoplasmosis, transmission in utero occurs only as a result of a primary infection acquired during pregnancy, whereas the in utero transmission of CMV can occur as a consequence of either primary or non-primary infections.[37] Far from being a rare event, congenital infection resulting from non-primary CMV infection has been shown to be quite common, especially in highly immune populations. The initial clue was provided by three independent reports of congenital CMV infections that occurred in consecutive pregnancies.[38–40] In all three instances, the first infant was severely affected or died and the second born in each case was subclinically infected. More convincing evidence came from a prospective study of women known to be seroimmune before conception.[37] The rate of congenital CMV infection was 1.9% among 541 infants born to these seropositive women. These infants were not infected as a result of primary maternal CMV infection since all of the mothers were known to have been infected with CMV from one to several years before the onset of pregnancy. This unique characteristic (intrauterine transmission in immune women) accounts for the high incidence of congenital CMV infection in populations with the highest rate of seroposivity.[41]

The phenomenon of intrauterine transmission occurring in the presence of humoral immunity had been attributed to reactivation of endogenous virus. However, in 2001, Boppana et al. utilized serologic studies of immune mothers to prove that maternal reinfection accounted for a significant number of babies with congenital infection.[42]

Although it seems likely that the route of and risk factors for reinfection are the same as those for primary infection, this has not been established. Additionally, the sites from which CMV reactivates to produce congenital infection are not known. Although CMV excretion is a relatively common event during and after pregnancy, simple isolation of virus from the cervix or urine or both is a poor indicator of the risk of intrauterine infection.[43,44]

Virus can be shed at variable rates from single or multiple sites following primary or non-primary infections in both pregnant and nonpregnant women. Pregnancy per se has no discernible effect on the overall prevalence of viral shedding. However, gestational age influences the rate of CMV excretion, being significantly lower in the first trimester.[45]

The rates of CMV excretion in the genital and urinary tracts of women are inversely related to age after puberty.[46]

Perinatal infection

In contrast to the poor correlation between CMV excretion during pregnancy and congenital infection, a good correlation exists between maternal shedding in the genital tract and/or breast milk and perinatal acquisition. In one study, the two most efficient sources of transmission in the perinatal period were infected breast milk (which resulted in a 63% rate of perinatal infection) and the infected genital tract, particularly in late gestation, which was associated with transmission in 57% of the cases (natal infection).[15] Viral shedding from the pharynx and urinary tract of the mother late in gestation and during the first months postpartum has not been associated with perinatal transmission.

There is considerable variability in perinatal transmission of CMV throughout the world. The age of the mother and her prior experience with CMV, which in turn influence the frequency of viral excretion into the genital tract and breast milk, certainly are important factors. Younger seropositive women who breast feed are at a greater risk for transmitting virus in early infancy, especially in lower socioeconomic groups. In Japan, Guatemala, Finland, and Thailand, the rates of CMV excretion during the first year of life are extremely high (39–56%), and the practice of breast feeding is almost universal. The majority of these women of childbearing age is seroimmune for CMV.

Sexual transmission

In general, in developing areas of the world, 90–100% of the population is infected during childhood, even as early as 5 years of age. Sexual transmission in these populations plays a minor role as a source of primary CMV infection, and its importance in reinfection is unclear. In developed countries, infection is acquired at a lower rate and in some population groups an increase in prevalence of infection occurs only after puberty.

Several lines of evidence indicate that sexual transmission of CMV is at least partly responsible for this increase in seroprevalence. CMV is frequently recovered from semen and cervical secretions.[14,16–21] Increased seroprevalence of CMV and excretion of virus has been found in women attending sexually transmitted disease clinics and in young male homosexuals. Chretien et al. reported a cluster of cases with CMV mononucleosis that occurred in sex partners, but not in persons who shared living quarters but did not engage in sexual contact.[47] Handsfield et al. showed that, in two pairs of sex partners with CMV infections attending a sexually transmitted disease clinic, strains of virus were identical by restriction endonuclease analyses of DNA.[46] Evidence has also been provided for sexual transmission in less promiscuous populations.[16,18] Among the many variables investigated, a significant correlation was found between seropositivity to CMV and greater numbers of lifetime sexual partners and past or present

infection with *Chlamydia trachomatis*. Although the evidence for sexual transmission of CMV is compelling, the fact that CMV is frequently shed in saliva indicates that oral contact may also be an important route of transmission.

Transmission via transfusion of blood and blood products

CMV infection is an important hazard of blood transfusion and organ transplant. In compromised hosts, such as small premature newborns and stem cell transplant recipients, transfusion-acquired CMV has been associated with serious morbidity and even fatal infection. The association between the acquisition of CMV infection and blood transfusion was first suggested in 1960 by Kreel et al., who described a syndrome characterized by fever and leukocytosis occurring 3–8 weeks after open heart surgery.[48] Reports that followed expanded the syndrome to include fever, atypical lymphocytosis, splenomegaly, rash, and lymphadenopathy.[49–56] The term *postperfusion mononucleosis* was then proposed. Prospective studies incriminated blood transfusion as the major risk factor and demonstrated that while the clinical syndrome occurred in approximately 3% of the patients receiving transfusion, inapparent acquisition of CMV infection occurred in 9–58%. It has been estimated that blood donors capable of transmitting CMV range from 2.5% to 12%. In a study of seronegative children receiving blood for cardiac surgery, the risk of acquiring CMV was calculated to be 2.7% per unit of blood.[50] Notably, the risk of acquisition of CMV by seronegative patients increases significantly and directly with total volume of blood transfused.[57] Seronegative immunocompromised patients who receive prophylactic white blood cell transfusions from multiple donors (of whom 50% are expected to be seropositive) are also at increased risk of acquiring CMV.[57]

The observation that two newborn infants who received large volumes of fresh blood subsequently developed symptomatic CMV infections led McCracken et al. to suggest an association between blood transfusion and clinically apparent postnatal CMV infection.[58] Subsequent reports indicated an association between postnatal CMV infection and exchange transfusions.[59] With exchange transfusions, the probability of a seropositive infant receiving seropositive blood becoming infected is 20%, whereas for a seronegative infant receiving seropositive blood, the probability increases to 50%. This remarkably high incidence after exchange transfusions is most likely owing to the fact that infants who receive the transfusions usually receive large volumes (150–200 mL/kg) of fresh whole blood from a single donor. Intrauterine transfusions were implicated by King-Lewis and Gardner as the source of CMV in two pregnant women who subsequently seroconverted and whose infants developed viruria between 2 and 8 weeks of life.[60]

Two prospective studies have proven that seropositive blood is the source of acquired CMV in neonates undergoing multiple transfusions. In the study of Yeager et al., 10 of 74 infants of seronegative mothers who were exposed to one or more seropositive blood donors acquired CMV.[61,62] The risk of infection increased to 24% for patients who received more than 50 mL of packed red cells from at least one seropositive donor. The use of solely seronegative blood completely eliminated the acquisition of CMV by infants. A subsequent study by Adler confirmed these findings and proved further that significant risk factors for transmission of CMV and subsequent disease included transfusions from multiple seropositive donors, lack of passively acquired maternal antibody to CMV, and low birth weight (<1250 g).[49,63]

Transmission to hospital workers

Because hospital workers are often women of childbearing age, there has been concern about occupational risk through contact with patients shedding CMV. Yeager reported a higher seroconversion rate for neonatal (4.1%/year) and pediatric nurses (7.7%/year) than for non-nurse hospital employees (0%), but these differences were not statistically significant.[64] Friedman et al. noted higher seroconversion rates in a pediatric hospital among workers with patient contact compared with those without such contact.[65] Although the difference in rates was not statistically significant, when "high-risk" employees (intensive care nurses and an IV team) were compared with others, a significantly higher rate of CMV infection was found in the former. Dworsky studied nurses in newborn nurseries and other health-care workers and found no difference when the seroconversion rate in these women was compared with that of a large group of pregnant women in the community.[32] Balfour and Balfour measured incidence of CMV infection among transplant/dialysis nurses, neonatal intensive care nurses, student nurses, and a control group; neither the initial rate of seropositivity nor the annual seroconversion rate differed significantly among any of the groups.[66] Their annualized seroconversion rate of 1.84% was very close to rates determined for middle-income pregnant women in Birmingham, Alabama.[13]

The risk for hospital personnel is a function of the prevalence of CMV excretion among patients, the prevalence of seronegative health-care workers, and the degree of their exposure to infected patients. In general, among hospitalized infants and children, viruria occurs in approximately 1% of newborn infants, 13% of premature infants hospitalized for 1 month or longer, and 5–10% of older infants and toddlers. The rate of viral excretion in premature infants depends on the rates of perinatal transmission from mother to infant, breast feeding practices, and blood transfusion policies. In toddlers and older children, viral excretion depends on factors like crowding, socioeconomic status, and childrearing practices (breast feeding, attendance at day care centers). On the other hand, age, race, and, to some extent, sex influence the prevalence of seronegative hospital personnel.

Working with hospitalized children inevitably leads to contact with a child shedding CMV. However, workers who develop primary infection should not assume that occupational exposure or contact with a specific patient was the source of infection.[67–69] Two case reports illustrate this point well. Yow et al. and Wilfert et al. described health-care workers who acquired CMV while pregnant and after attending a patient known to be excreting CMV.[70,71] In each of these reports, restriction endonuclease analysis of DNA from CMV isolates indicated that the source of CMV for the worker and her aborted fetus was not the patient under suspicion. Adler et al. used restriction enzyme methods to study CMV strains from 35 newborns and a nurse who seroconverted.[67] All 35 strains were different, supporting the conclusion that nosocomial spread of CMV to workers or among newborns had not occurred. Although hospital workers, particularly those who attend children or immunocompromised patients, will likely have occupational exposure to CMV, there is no convincing evidence that their risk of infection is increased. There is little information about the risk of CMV acquisition by house officers and medical students. In one study, the annual rate of seroconversion for 25 seronegative pediatric residents was 2.7%, which differed little from nursery nurses (3.3%) but was higher than the risk (0.6%) for 89 serosusceptible students completing their clinical rotations.[66]

PATHOGENESIS

Of the women who acquire CMV infection during pregnancy, 30–40% transmit the virus to their fetuses.[13] The risk for those mothers with non-primary infection (reactivation or reinfection) is unknown. Acute and/or long-term morbidity occurs in a small number (5–15%) of infected offspring.

Although not clearly established, intrauterine infection is assumed to result from maternal viremia with subsequent placental infection and hematogenous dissemination to the fetus. Since intrauterine transmission occurs in only 30–40% of pregnant women with primary CMV infection, a mechanism(s) that is not understood, but is generally referred to as the placental barrier, must operate to prevent fetal infection.

Boppana and Britt examined CMV-specific antibody responses after primary maternal infection to determine if specific deficits in antibody response were associated with in vitro uterine transmission.[72] They reported that anti-glycoprotein B IgG antibodies were significantly higher at delivery in women who transmitted the infection compared to the nontransmitters. This observation suggests that the amount of antiviral antibody was not reflective of protection from transmission. They also examined the qualitative antibody response and found lower neutralizing antibody titers in transmitters, suggesting an association between neutralizing activity and in utero transmission. They also found that a higher antibody avidity index ($\geq$2.0) occurred in the majority of nontransmitters but in less than 20% of transmitters. Antibody avidity correlated with neutralizing titers, suggesting that antibody affinity maturation is critical for production of high levels of neutralizing antibodies during primary CMV infection. This defect in affinity maturation may indicate that subtle abnormalities in cellular immune mechanisms were present in this group. Previous studies of pregnant women suggested that abnormalities in CMV-specific T-lymphocyte responses occurred in some women. Gehrz showed a transient reduction of the blastogenic response during the second and third trimesters.[73] The defect was not generalized, moreover none of the women with the defect excreted CMV, nor did they transmit the infection in utero. Stern showed that women with recently acquired infection who had depressed blastogenic responses had a greater risk of delivering a congenitally infected infant.[74]

In immune pregnant women with non-primary infection, it is difficult to postulate that congenital infection results from cell-free virus in plasma causing placental infection with subsequent spread to the fetus.[75] In this circumstance, the virus could evade the immune system within leukocytes, or local reactivation of infection within the endometrium, myome-trium, or cervical canal could occur.

Once intrauterine infection has occurred, the incidence of harmful effects is higher than at any other time in life, with the exception of severely immunocompromised patients. The clinical manifestations of congenital CMV infection are very different from the signs and symptoms associated with infection acquired at delivery or soon after, even in immature infants, suggesting the importance of the intrauterine environment.

Why some infants are severely affected and others remain free of symptoms is not clear. The most obvious, but not necessarily the most important, pathogenic mechanism is continuous viral replication in affected organs. Longitudinal studies of infants with congenital and perinatal infections have demonstrated that excretion of CMV into urine and saliva persists for years. Likely, chronic viral replication occurs at other sites that are less accessible to virologic examination. Many cells are susceptible to the direct cytocidal effect of CMV, but differences in the intrinsic susceptibility of various tissues to CMV-mediated injury may determine the frequency with which different organs are involved during the course of CMV infection. Another possible factor is vasculitis, which may occur in utero or after birth. Infants with symptomatic congenital CMV infection and who die soon after birth usually have disseminated intravascular coagulopathy.[76] Proliferating endothelial cells within inflamed tissue are susceptible to CMV infection. Injury mediated by immunologic factors also has been studied. The humoral immune system of infected infants is generally felt to be intact and respond normally to antigenic stimulation.[41,77] Hayashi et al. have reported, however, that compared to

healthy perinatally infected infants and infected adults, congenitally infected infants had a much less vigorous CMV-specific $CD4^+$ and $CD8^+$ T-cell response.[78]

Perinatal infection results mainly from non-primary (mostly reactivated) infection in immune women. However, transplacental maternal antibody protects only 50% of exposed infants from becoming infected.[79] The ensuing infection, although chronic, remains subclinical in the vast majority of infants, indicating that the passive transfer of maternal antibody is more protective for virulence than for transmission. Studies show transfusion-acquired infection is more virulent in seronegative than in seropositive infants irrespective of underlying diseases or gestational age.

Congenitally and perinatally infected infants have also been noted to have impaired specific cell-mediated immunity as assessed by the lymphocyte transformation response (LTR) to CMV antigen.[80–83] This test measures only the recognition, not the effector function, of T lymphocytes and does not require other techniques like the use of syngeneic target cells. Another defect consistently observed is the inability of the lymphocytes of these infants to induce interferon production in vitro when challenged with CMV antigens. The impairments are not a reflection of a generalized disturbance, since it is restricted to a blastogenic response to CMV and is highly virus specific. CMV-infected patients who have antibodies to HSV, for example, have a normal blastogenic response to this virus. Infants with impaired LTRs respond normally to both killed and live vaccines. The impairment has no relation to the clinical presentation and outcome, but it is more intense and longer lasting in patients with symptomatic CMV infection. As patients grow older, the impairment disappears together with viral replication. Subtle alterations of host defense mechanisms could contribute to disease, in conjunction with persistent viral replication.

Nature of maternal infection

The impact of the type of the maternal infection on the pathogenesis of congenital CMV infection is in question. Fowler et al. demonstrated that primary infections are more likely to be transmitted to the fetus and are likely to cause more fetal injury than non-primary infections.[84] Intrauterine transmission following primary infection occurs in approximately 30–40% of cases. Current information suggests that gestational age has no apparent influence on the risk of transmission of CMV in utero. However, several studies suggest that infection at an earlier gestational age produces the worst outcome.

Congenital infection also results from non-primary infection, representing either reactivation of infection or reinfection with the same or a different strain of CMV during pregnancy. The risk of congenital CMV infection resulting from a non-primary infection during pregnancy ranges from a high of 1.5% for an American population of low socioeconomic background to 0.19% for women of middle or upper socioeconomic extraction in the United States or from Britain and Sweden.[13,70,85] On the basis of early studies, it was widely thought that though congenital infection occurs in the setting of non-primary maternal infection, symptomatic infection is rare.[84,86] However, in 1999, Boppana et al. challenged that dogma with a study that demonstrated that 8 of 47 infants with symptomatic congenital CMV infection (8 of 20 in whom preconceptual status could be confirmed) were born to mothers with preexisting immunity.[87]

In non-primary infection, preexisting immunity partially inhibits the occurrence of viremia. Maternal IgG antibodies are transmitted to the fetus but their precise role has not been elucidated. Conceivably, cellular immunity may be more important than humoral immunity.

Level of viremia at birth

Recent studies conducted by the Collaborative Anti-Viral Study Group and by Boppana et al. suggest that the level of viremia at or near birth in congenitally infected infants may predict hearing loss, in both symptomatic and asymptomatic infections.[88,89] As this relationship is understood further by future study, it may help identify those patients in whom closer follow-up is warranted and those in whom the benefits of antiviral therapy are most likely to outweigh the risks.

Perinatal infection

Naturally acquired perinatal CMV infections result from exposure to infected maternal genital secretions at birth or to breast milk during the first months of postnatal life. The presence of CMV at these sites may result from either primary or non-primary maternal infection. Iatrogenic CMV infections are acquired predominantly from transfusions of blood or blood products and breast milk from CMV-infected donors. Exposure to CMV in the maternal genital tract has resulted in a 30–50% rate of perinatal infection. During delivery the infant is exposed to genital secretions that may contain high titers of CMV. The transmission from mother to infant via breast milk occurs in 30–70% if nursing lasts for over 1 month. Following ingestion, CMV infection is presumably established at a mucosal surface (buccal, pharyngeal, or esophageal mucosa) or in the salivary glands for which CMV has a special tropism.

Transmission of CMV by blood transfusion is more likely to occur when larger quantities of blood are transfused. The failure to isolate CMV from the blood or blood elements of seropositive healthy blood donors suggests that the virus exists in a latent state, presumably within leukocytes. Presumably, following transfusion, when infected cells encounter the allogeneic stimulus, CMV becomes reactivated.

CLINICAL MANIFESTATIONS

CONGENITAL INFECTION

Symptomatic infection

Acute Manifestations. CID is characterized by involvement of multiple organs, in particular, the reticuloendothelial and central nervous systems (CNS), with or without ocular and auditory damage. Weller and Hanshaw defined the abnormalities found most frequently in infants with symptomatic congenital infection as hepatomegaly, splenomegaly, microcephaly, jaundice, and petechiae.[90] As illustrated in Table 84-1, a combination of petechiae, hepatosplenomegaly, and jaundice is the most frequently noted presentation. In addition, the magnitude of the prenatal insult is reflected in the occurrence of microcephaly with or without cerebral calcifications, intrauterine growth retardation, and prematurity.[91] Inguinal hernia in males and chorioretinitis with or without optic atrophy are less common. Occasionally clinical findings include hydrocephalus, hemolytic anemia, and pneumonitis. Among the most severely affected infants, mortality may be as high as 30%. Most deaths occur in the neonatal period. Neonatal mortality is usually secondary to multiorgan disease with severe hepatic dysfunction, disseminated intravascular coagulation, and secondary bacterial infections. When death occurs after the first month but during the first year, it is usually due to progressive

Table 84-1. Clinical and Laboratory Findings in 106 Infants with Symptomatic Congenital CMV Infection in the Newborn Period

Abnormality	Positive/Total Examined (%)
Prematurity (< 38 wk)	36/106 (34)
Small for gestational use	53/106 (50)
Petechiae	80/106 (76)
Jaundice	69/103 (67)
Hepatosplenomegaly	63/105 (60)
Purpura	14/105 (13)
Neurologic findings One or more of the following:	72/106 (68)
Microcephaly	54/102 (53)
Lethargy/hypotonia	28/104 (27)
Poor suck	20/103 (19)
Seizures	7/105 (7)
Elevated alanine aminotransferase (> 80 U/L)	46/58 (83)
Thrombocytopenia	
$< 100 \times 10^3/mm^3$	62/81 (77)
$< 50 \times 10^3/mm^3$	43/81 (53)
Conjugated hyperbilirubinemia	
Direct serum bilirubin > 4 mg/dL	47/68 (69)
Hemolysis	37/72 (51)
Increased cerebrospinal fluid protein (> 120 mg/dL)[a]	24/52 (46)

[a]Determinations in the first week of life.

liver disease with severe failure to thrive. Death after the first year is usually restricted to the severely neurologically handicapped children and is the consequence of malnutrition, aspiration pneumonia, and overwhelming infections.

Hepatomegaly. This sign, along with that of splenomegaly, is probably the most common abnormality found in the newborn period in infants born with symptomatic congenital CMV infection. Liver function tests are often abnormal but usually not markedly so. The persistence of hepatomegaly is variable. In some infants, liver enlargement disappears by the age of 2 months. In others, significant enlargement persists throughout the first year of life. However, massive hepatomegaly extending beyond the first 12 months of life is uncharacteristic of CID.

Splenomegaly. Enlargement of the spleen is especially frequent in congenital CMV infections and may be the only abnormality present at birth. In some instances, splenomegaly and a petechial rash coexist as the only manifestations of the disease. Occasionally, the enlargement is such that the spleen may be felt 10–15 cm below the costal margin. Splenomegaly usually persists longer than hepatomegaly.

Jaundice. Jaundice is a common manifestation of CID. The pattern of hyperbilirubinema may take several forms, ranging from high levels on the first day to undetectable jaundice on the first day with gradual elevation of the bilirubin level to clinically apparent jaundice. In some instances, jaundice is a transient phenomenon, beginning on the first day and disappearing by the end of the first week. More often, however, it tends to persist beyond the time of physiologic jaundice. Occasionally, transient jaundice may occur in early infancy with pronounced elevation of bilirubin levels during the third month. Bilirubin levels are high in both the direct and indirect components. Characteristically, the direct component increases after the first few days of life and may constitute as much as 50% of the total bilirubin level. Rarely, the indirect bilirubin rises high enough to require exchange transfusion.

Petechiae and Purpura. There is evidence that CMV has a direct effect on the megakaryocytes of the bone marrow that results in a depression of the platelets and a localized or generalized petechial rash. In some patients, the rash is purpuric in character, not unlike that observed in the expanded rubella syndrome. Unlike the latter infection, however, pinpoint petechiae are a more common manifestation of congenital CMV infection. The rash usually appears within a few hours of birth; it may be transient, disappearing within 48 hours. The petechiae may be the only clinical manifestation of CMV infection. More often, however, enlargement of the liver and spleen is coassociated. The petechiae may persist for weeks after birth. Crying, coughing, the application of a tourniquet, a lumbar puncture, or restraints of any kind may result in the appearance of petechiae even months after birth. Platelet counts in the first week of life range from <10,000 to 125,000, with a majority in the 20,000–60,000 range. Some infants with petechial rashes do not have associated thrombocytopenia.

Microcephaly. Microcephaly, usually defined as a head circumference of less than the fifth percentile occurs in approximately 50% of patients with symptomatic congenital infection. Not all infants remain microcephalic. This is especially true if the head measurement is close to the fifth percentile in an infant of low birth weight. If intracranial calcifications are present, brain growth is invariably impaired.

Ocular Defects. The principal abnormality related to the eye in CMV infection is chorioretinitis, with strabismus and optic atrophy being uncommon. Microphthalmia, cataracts, retinal necrosis and calcification, blindness, anterior chamber and optic disk malformations, and pupillary membrane vestige have also been described in association with generalized congenital CID. Chorioretinitis occurs in approximately 14% of infants born with symptomatic congenital infection. CMV chorioretinitis cannot be differentiated from the lesions produced by toxoplasmosis on the basis of location or appearance. Both *Toxoplasma gondii* and CMV can induce central retinal lesions. Chorioretinitis caused by CMV differs from that caused by toxoplasmosis in that it rarely progresses postnatally, becoming inactive in early infancy.

Pneumonitis. Pneumonitis, a common clinical manifestation of CMV infection following bone marrow and renal transplantion in adults, is not usually a part of the clinical presentation of congenital CMV infection in newborn infants. Diffuse interstitial pneumonitis occurs in <1% of congenitally infected infants, even when the most severely affected cases are considered. CMV-associated pneumonitis is more likely to develop in infants with perinatally acquired CMV infections.

Deafness. Sensorineural deafness is the most common handicap caused by congenital CMV infection. Medearis first directed attention to the presence of deafness in symptomatic congenitally infected infants.[92] Subsequent reports confirmed this association and provided evidence that CMV can also cause sensorineural hearing loss in children with subclinical infection.[93]

Because hearing is not commonly assessed within the first month of life, it is difficult to say how many congenitally infected infants, whether symptomatic or not, are born with hearing impairments. This handicap, however, becomes significant in infancy and early childhood. In general, the frequency and severity of the hearing impairment is worse in patients with symptomatic infection.[91] Of

104 surviving patients with symptomatic CMV infection we have prospectively followed over the past 20 years, 100 have had adequate audiometric evaluations and 58 of them (58%) suffer from some degree of hearing impairment.[91] Among the 330 patients with subclinical infection, 299 have received at least one adequate audiometric evaluation and 22 (7.4%) manifest some degree of hearing loss. The sensorineural hearing loss is bilateral in over half the cases and of significant magnitude (50–100 dB) to produce serious difficulties with verbal communication and learning.

Long-Term Outcome. The long-term clinical manifestations of symptomatic congenital CMV infection are highly variable. It is clear that the infection is usually not recognized in infants, especially when it is marked by minor signs such as failure to thrive, mild splenomegaly, and neonatal jaundice. In some cases, psychomotor retardation, neurologic dysfunction, hearing loss, and other delayed complications may take years to identify. The medical significance of congenital CMV derives primarily from the adverse effects that this infection has on the developmental potential of children. The likelihood of survival with normal intellect and hearing following symptomatic congenital CMV infection is small. The most common long-term complications are hearing loss, mental retardation, microcephaly, chorioretinitis, optic atrophy, seizures, paraparesis, diplegia, language delay, and learning disabilities (Table 84-2).[94]

Asymptomatic infection. As indicated in the previous section, nearly 90% of infants with congenital CMV infections have no early clinical manifestations and their long-term outcome is much better. Nevertheless, anywhere from 5% to perhaps as many as 15% are at risk for developing a multitude of developmental abnormalities, such as sensorineural hearing loss, microcephaly, motor defects such as spastic diplegia or quadriplegia, mental retardation, chorioretinitis, and dental defects. These abnormalities usually become apparent within the first 2 years of life. Table 84-2 summarizes our prospective longitudinal study of 330 patients with asymptomatic congenital infection and followed by using serial clinical, psychometric, audiometric, and visual assessments.[95] Follow-up studies of patients with inapparent congenital CMV infection have also been done by Kumar et al., Saigal et al., Melish and Hanshaw, and Pearl et al.[96–99] In general their findings resemble the data in Table 84-2.

In summary, these observations underscore the need for longitudinal follow-up of patients with congenital CMV infection regardless of its clinical presentation at the outset. Careful assessments of perceptual functions (hearing, visual acuity), psychomotor development, and learning abilities must be made in order to recognize the full impact of CMV. With early identification of a problem, corrective measures can be instituted to reduce psychosocial and learning problems.

Table 84-2. Sequelae in Children After Congenital CMV Infection

Sequelae	Percent Symptomatic (No.)	Percent Asymptomatic (No.)
Sensorineural hearing loss	58.0 (58/100)	7.4 (22/299)
Bilateral hearing loss	37.0 (37/100)	2.7 (8/299)
Speech threshold moderate to profound (60–90 dB)[a]	27.0 (27/100)	1.7 (5/299)
Chorioretinitis	20.4 (19/93)	2.5 (7/281)
1Q < 70	55.0 (33/60)	3.7 (6/159)
Microcephaly, seizures, or paralysis	51.9 (54/104)	2.7 (9/330)
Microcephaly	37.5 (39/104)	1.8 (6/330)
Seizures	23.1 (24/104)	0.9 (3/330)
Paresis/paralysis	12.5 (13/104)	0.0 (0/330)
Death[b]	5.8 (6/104)	0.3 (1/330)

Perinatal infection

In order to establish the diagnosis of perinatal CMV infection, one must first exclude congenital infection by showing absence of viral excretion during the first 2 weeks of life. The incubation period of perinatal CMV infection ranges between 4 and 12 weeks. Although the quantity of virus excreted by infants with perinatal infection is less than with intrauterine acquisition, the infection is also of a chronic nature, with viral excretion persisting for years. The vast majority of otherwise healthy infants with naturally acquired perinatal infections remain asymptomatic and the infection does not appear to have an adverse effect on growth, perceptual functions, or motor or psychosocial development.

CMV has been incriminated as a cause of pneumonitis in infants younger than 4 months.[92,100,101] CMV-associated pneumonitis is clinically and radiographically indistinguishable from other causes of afebrile pneumonia in this age group.

In premature and sick term infants, naturally acquired CMV infection may pose a greater risk. Yeager et al. found that premature infants weighing less than 1500 g at birth who acquired CMV from a maternal source often developed hepatosplenomegaly, neutropenia, lymphocytosis, and thrombocytopenia coinciding with the onset of virus excretion.[102] Frequently, these patients required longer treatment with oxygen. In a later prospective study, Paryani et al. suggested that there may be a propensity for an increased incidence of neuromuscular impairments, particularly in premature infants with onset of CMV excretion during the first 2 months of life.[103] However, sensorineural hearing loss, chorioretinitis, and microcephaly occurred with similar frequency in both groups.

Transfusion-acquired perinatal CMV infection can cause significant morbidity and mortality, particularly in premature infants with a birth weight of less than 1500 g born to CMV seronegative mothers.[59–63] The syndrome of posttransfusion CMV infection in premature newborn infants has been characterized by Ballard and coworkers and consists of deterioration of respiratory function, hepatosplenomegaly, unusual gray pallor with disturbing septic appearance, both an atypical and absolute lymphocytosis, thrombocytopenia, and hemolytic anemia.[104] The syndrome was more severe in low-birth-weight infants and occurred approximately 4–12 weeks posttransfusion, at a time when the infants were progressing satisfactorily. Although the course of the disease was generally self-limited (lasting 2–3 weeks), death occurred in 20% of the sick infants. Subsequent work by Yeager and Adler has confirmed these observations.[49,62] Yeager demonstrated that the risk of infection is related to the serologic status of the donor and that these infections could be prevented by transfusing seronegative newborns with blood from seronegative donors.

TREATMENT AND PREVENTION

Antiviral therapy

Recently, Kimberlin and the National Institutes of Health Collaborative Antiviral Study Group (CASG) reported the results of a Phase III study evaluating the use of ganciclovir at 6 mg/kg per dose every 12 hours for 6 weeks versus no treatment in infants with symptomatic congenital CMV infection.[105] Primary endpoints included maintenance of normal hearing or improvement of hearing as measured by brainstem evoked response testing between the baseline and 6-month follow-up visit. Forty-two subjects were fully evaluable for the primary endpoint, 25 of whom received the study drug and 17 of whom received no treatment. The investigators reported analysis of hearing data in both a functional "best ear" approach, where patient's hearing was judged based on the hearing in the best ear, as well as a more biological analysis, or "total ear" approach, where hearing data from each ear was included in the analysis. By best ear analysis, 84% of ganciclovir recipients had improvement of hearing or maintained normal hearing between the baseline and 6-month follow-up visit versus 59% of the no-treatment group ($P = 0.086$). By total ear analysis, 69% of ganciclovir recipients had improvement of hearing or maintained normal hearing between the baseline and 6-month follow-up visit versus 39% of the no-treatment group ($P = 0.011$).

The primary toxicity observed in the study was neutropenia, observed 63% of the time in patients receiving study drug versus 21% of patients in the control group. Half of the ganciclovir-receiving patients who developed neutropenia required dosage adjustment, and only 4 required discontinuation of the study drug.

Despite the results of this study, it is difficult to recommend a global approach to antiviral treatment with ganciclovir in congenital CMV infection. The study subjects all had symptomatic disease with CNS manifestations, which may or may not be the group most likely to benefit from antiviral therapy. The data suggest that antiviral therapy affords some benefit in hearing protection, but the requirement for 6 weeks of intravenous access and the administration of a potentially toxic drug make the issue problematic. Consultation with a pediatric infectious diseases specialist familiar with the issues is recommended prior to initiating treatment with ganciclovir in the setting of symptomatic congenital CMV.

Additional studies are ongoing by the CASG to evaluate the use of valganciclovir (the valine-ester prodrug of ganciclovir), which can be administered orally, in patients with symptomatic congenital CMV. Factors that confound the evaluation of clinical efficacy of antiviral therapy include the wide spectrum of disease resulting from symptomatic congenital CMV infection, the unpredictable natural course of

the disease, and the fact that many patients incur irreversible damage before birth.

Vaccines

In 1999, the Institute of Medicine assigned the highest priority to the development of a vaccine effective against CMV. A number of candidate vaccines have been evaluated clinically are currently undergoing testing or are in the preclinical phase. Several live attenuated vaccines have undergone clinical testing, the AD169 vaccine (no longer in clinical trials), the Towne vaccine, and a series of four vaccines based on Towne strain and Toledo strain chimeras.[106–111]

The only candidate to undergo efficacy trials in humans has been the Towne vaccine. Immunization of susceptible kidney transplant recipients with Towne strain CMV vaccine significantly reduced the morbidity of primary CMV infection, although it did not prevent acquisition of infection. No evidence of reactivation of vaccine virus was found when the patients were immunosuppressed.[112] Healthy CMV-negative adult males who were vaccinated with Towne strain vaccine were protected against low-dose challenge with Toledo strain CMV (a nonattenuated, wild-type clinical isolate), but not against high-dose challenge.[110] In healthy CMV-seronegative women with children in day care (where women are at high risk of exposure via their children) Towne vaccination failed to protect women from CMV infection.[113]

Despite the evidence that the Towne vaccine is safe and immunogenic, and may provide some protection against CMV disease in some situations, it does not appear to provide sufficient protection. One explanation is that it may be overattenuated. Four genetic recombinant viruses have been constructed as chimeras of the Towne and Toledo strains and appear to be well-tolerated, but have not been tested in seronegative individuals.[111,114]

An important objective for the development of a CMV vaccine is to prevent the serious consequences of congenital infection. A candidate vaccine should be able to prevent primary infection in pregnant women without inducing latent infection. Although the AD169 and the Towne strain vaccines have not been shown to reactivate, the possibility that reactivations might occur during pregnancy with transmission to the fetus raises concern about the use of live, attenuated viruses, even in vaccine trials.

A more attractive approach is to use a subunit vaccine that contains surface glycoproteins or other structural or regulatory proteins. The best-studied candidate is glycoprotein gB, the most abundant protein complex of the viral envelope, which is exposed on the surface of infected cells and contains the majority of viral neutralizing epitopes. Immunogenicity and safety of gB when administered with a novel adjuvant (MF59) appears promising, when administered to seronegative adults or to toddlers.[115,116] A Phase III efficacy study evaluating a gB/MF59 vaccine in young, CMV-negative, postpartum women is ongoing.[117,118] The results of this trial may help identify the potential for vaccination to be effective in preventing congenital CMV infection.

Other vaccine constructs in early clinical or preclinical evaluation include other purified subunit vaccines, vectored subunit vaccines (primarily a canarypox vector known as ALVAC and an attenuated alphavirus vector based on the Venezuelan equine encephalitis virus), DNA vaccines, peptide vaccines, and dense-body (enveloped, replication-defective particles formed during CMV replication in cell culture) vaccines.[114]

Prevention of congenital infection

CMV is not very contagious and its horizontal transmission requires close direct contact with infected material, namely, secretions that contain the virus and, less likely, fomites. With the exception of a few small studies that were designed to prevent infection via blood and blood products and transplanted organs, no broad-based strategies for preventing the transmission of this virus have been tested. Although there are still no effective means of preventing congenital CMV infection, or most perinatally acquired CMV infections, a few common sense recommendations can be made.

An average of 2% of susceptible pregnant women acquire CMV infection during pregnancy in the United States; the majority have no symptoms and only 40% of the episodes result in fetal infection. With no proven effective antiviral therapy and a low risk of fetal morbidity, serologic screening of pregnant women searching for primary CMV infections during pregnancy is of limited value. Nigro et al. recently reported the results of a trial of hyperimmune globulin in 68 pregnant women with either known CMV DNA in their amniotic fluid or known recent primary CMV infection which suggests the possibility that hyperimmune globulin may be efficacious in the treatment and prevention of congenital CMV infection in this setting.[119] The nature of this study and the way it was conducted make it difficult to generalize. We do not advocate the use of hyperimmune globulin at this time. Additional studies will be needed to validate the results of the Nigro study.

Primary CMV infection should be suspected in pregnant women with symptoms compatible with a heterophil-negative mononucleosis-like syndrome. At present the sensitivity of intrauterine diagnosis before the twenty-second week of gestation is only 50%.[120–124] Thus, there is inadequate information to serve as a basis for recommendations regarding termination of pregnancy after a primary CMV infection. Similarly, there is no information regarding how long conception should be delayed after primary infection.

The data on which to base recommendations for prevention of congenital CMV infection after non-primary maternal

infection are even more inadequate.[74,125–128] At present, there are no techniques for identifying women with reactivation of CMV that result in intrauterine transmission. Since the risk of transmission is very low and the risk of fetal disease even lower, women known to be seropositive before conception do not need to be virologically or serologically tested, nor do they need to be unduly worried about the very low risk of transmitting the virus to the fetus.

The principal sources of CMV infection among women of childbearing age are exposure to children excreting CMV and sexual contacts. Sexual transmission of CMV can probably be prevented by barrier methods (condoms, spermicides) that reduce the transmission of more common sexually transmitted infections, although no data have been published to specifically assess the effectiveness of such methods for CMV. Concerning the risk from exposure to children, those at greatest risk are susceptible pregnant mothers of CMV-infected children who attend day care centers. Hand washing and simple hygienic measures that are routine for hospital care can be recommended, but it is unrealistic to expect many mothers to comply.

Although hospital workers do not appear to be at increased risk for CMV infection, personnel who work in day care centers certainly are. In hospitals, vigorous adherence to routine infection control procedures such as hand washing and gloving should make nonparenteral acquisition of CMV less likely than in the community. Since the majority of patients who shed CMV are asymptomatic and unrecognized, universal precautions should be emphasized to prevent transmission from unrecognized infected patients as well as from known CMV-excreting patients. In the day care setting, where hygiene is difficult at best, preventive measures may be more difficult to implement. Although there is still debate about the need for routine screening of female hospital personnel and day care workers, we believe it should be recommended for potentially childbearing women whose occupation exposes them to CMV. Those found seropositive can be strongly reassured. Those found to be serosusceptible should be provided with information and reassured that common sense measures, such as hand washing and avoiding contact with secretions, should reduce the risk of acquisition of CMV. Attempts to identify all CMV-excreting patients or children in the workplace so that seronegative workers can avoid contact with them is totally unreasonable.

NEONATAL HSV INFECTIONS

HISTORY

Infections caused by HSVs have been recognized since the era of the ancient Greeks. Greek scholars defined the word *herpes* to mean to creep or crawl in reference to the visualized skin lesions. The Greek historian Herodotus associated mouth ulcers and lip vesicles with fever and called this event *herpes febriles.*[129] Genital herpetic infections were first described by a physician to the eighteenth century French court, Astruc.[130] Over the ensuing two centuries, the infectious nature of HSV was delineated. The transmissibility of these viruses was unequivocally established by passage of virus from lip and genital lesions of humans to either the cornea or the scarified skin of the rabbit.[131]

Only 50 years ago, the first written descriptions of neonatal HSV infections were attributed nearly simultaneously to Hass, when he described the histopathologic findings of a fatal case, and to Batignani, who described a newborn child with HSV keratitis.[132,133] Subsequently, histopathologic descriptions of the disease demonstrated a broad spectrum of involvement in newborns.

In the mid-1960s, Nahmias and Dowdle demonstrated two antigenic types of HSV.[134] The differentiation of HSV into two types resulted in the development of viral typing methods, which were critical in clarifying the epidemiology of these infections. HSV infections "above the belt," primarily of the lip and oropharynx, were found in most cases to be caused by HSV-1. Those infections "below the belt," particularly genital infections, were usually caused by HSV-2. However, this distinction more recently has become less clear. With the finding that both genital herpes infections and neonatal HSV infections were most often caused by HSV-2, a natural cause-and-effect relationship developed between these two disease entities. This causal relationship was strengthened by the finding of viral excretion in the maternal genital tract at the time of delivery, suggesting that acquisition of the virus by the infant occurs by contact with infected genital secretions during birth.

Over the past 20 years, our knowledge of the epidemiology, natural history, and pathogenesis of neonatal HSV infections has expanded greatly (see Chapter 24). The development of antiviral therapy represents a significant advance in the management of infected children, providing the opportunity to decrease mortality and improve the morbidity associated with these infections. Of all the herpesvirus infections, neonatal HSV infection represents the one that should be most amenable to prevention and treatment because it is acquired most often at birth rather than early in gestation. As our knowledge of the epidemiology of HSV infections has increased, it has become apparent that there are modes of infection other than contact with infected maternal genital secretions during delivery. Postnatal acquisition of HSV-1 has been documented from nonmaternal sources. The changing presentation of neonatal HSV infection, particularly the increasing difficulty of diagnosing infection, and the success of antiviral therapy, will be stressed.

EPIDEMIOLOGY OF NEONATAL HSV INFECTION

Nature of infection

Transmission of HSV most often occurs in association with intimate, personal contact.[135] Virus must come in contact with mucosal surfaces or the abraded skin of a susceptible individual for infection to be initiated. After viral replication at the site of infection, either an intact virion or the nucleocapsid is transported by neurons to the ganglia where latency is established. Infection with HSV-1, generally limited to the oropharynx, can be transmitted by respiratory droplets or through direct contact of a susceptible individual with infected secretions (such as virus-containing labial vesicular fluid). Acquisition often occurs during childhood.

Primary HSV-1 infection in the young child is usually asymptomatic. If present, clinical illness is manifested by gingivostomatitis. Primary infection in young adults has been associated with pharyngitis and with a mononucleosis-like syndrome. Like other herpesvirus infections, seroprevalence studies have demonstrated that acquisition of HSV-1 infection is related to socioeconomic factors. Antibodies, indicative of past infection, are found early in life among individuals of lower socioeconomic groups and are presumed to be the consequence of crowded living conditions that provide a greater opportunity for direct contact with infected individuals.

As many as 75–90% of individuals from lower socioeconomic populations develop antibodies by the end of the first decade of life. In comparison, in middle and upper socioeconomic groups only 30–40% are seropositive by the middle of the second decade of life.[136–139] A declining seroprevalence of HSV-1 may account, in part, for the increased clinical awareness of HSV-2 infections, since HSV-1 antibodies may be partially protective against type 2 infection.[140,141]

Because infections with HSV type 2 are usually acquired through sexual contact, antibodies to this virus are rarely found until adolescence. Thereafter, progressive increase in seroprevalence of HSV type 2 develops in all populations.[142] The risk of acquisition of infection with HSV-2 appears related to both socioeconomic factors and the number of sexual partners. Utilizing nonspecific serologic assays, as many as 50–60% of lower socioeconomic populations have antibodies to HSV-2. In contrast, 10–20% of individuals in higher socioeconomic groups are seropositive.[143,144] Utilizing a type-specific assay for HSV-2 (glycoprotein (g) G-2), antibodies were detected in 35% of middle-class women receiving care through an Atlanta health maintenance organization.[145] Similarly, there are differences in seroprevalence between blacks and Caucasians of childbearing age, 65% versus 35% overall, respectively.[146]

Maternal infection

The epidemiology and clinical nature of genital HSV infection do not appear to be greatly influenced by pregnancy. Infection during gestation can manifest in a variety of ways. The most serious but fortunately uncommon problem encountered with HSV infections during pregnancy is that of widely disseminated disease. Infection has been documented to involve multiple visceral sites, in addition to cutaneous dissemination.[147–152] In a limited number of cases, dissemination after primary oropharyngeal or genital infection has led to such severe manifestations of disease as necrotizing hepatitis with or without thrombocytopenia, leukopenia, disseminated intravascular coagulopathy, and encephalitis. Although only a small number of patients have suffered from disseminated infection, the mortality among these pregnant women is reported to be greater than 50%. Fetal deaths have also occurred in more than 50% of cases, although mortality did not necessarily correlate with the death of the mother. Surviving fetuses were delivered by cesarean section either during the acute illness or at term and none had evidence of neonatal HSV infection.

Localized genital infection is the most common form of HSV infection during pregnancy. Overall, prospective investigations utilizing cytologic and virologic screening indicate that genital herpes occurs with a frequency of about 1% at any time during gestation.[153] Most of these infections are recurrent, although a few are primary. Those factors that influence the frequency of both primary and recurrent infection in pregnancy are not well defined.

Maternal primary infection prior to 20 weeks' gestation has been associated with spontaneous abortion.[154,155] Although the original estimate of spontaneous abortion following a symptomatic primary infection during gestation was thought to be as high as 25%, it is likely that this calculation is erroneously high because of the very small number of women followed. Unfortunately, precise data, indicating the true risk of spontaneous abortion following primary infection during gestation, are not available. Infection that develops later in gestation was not associated with the termination of pregnancy.[155–157] The frequency of HSV recurrences during gestation should be of concern for women with a known history of infection. Transmission of infection to the fetus is most frequently related to the actual shedding of virus at the time of delivery. Since HSV infection of the fetus is usually the consequence of contact with infected maternal genital secretions at the time of delivery, the determination of viral excretion at this time is of utmost importance. The actual incidence of viral excretion at delivery ranges from 0.39% to 1.0%.[135,153,158–162] Utilizing polymerase chain reaction (PCR) detection of viral DNA, the prevalence of viral shedding is even higher—as much as four- to fivefold.[163] Several

prospective studies have evaluated the frequency and nature of viral shedding in pregnant women with a known history of genital herpes. In a predominantly white, middle-class population, documented recurrent infection occurred in 84% of pregnant women.[162] Moreover, asymptomatic viral shedding occurred in at least 12% of the recurrent episodes. Viral shedding from the cervix occurred in 0.56% of symptomatic and 0.66% of asymptomatic infections, data similar to the nonpregnant state.[158,160] The incidence of cervical shedding in asymptomatic pregnant women has been reported to be as high as 3%.[157] However, the observed rate of shedding among asymptomatic pregnant women has varied more than that among nonpregnant women (0.2–7.4%), depending on the study population and trial design.[157,158,160,164–167] Overall, these data indicate that the frequency of cervical shedding is low, rendering the risk of transmission of virus to the infant similarly low when the infection is recurrent in nature.[153] The frequency of shedding does not appear to vary by trimester during gestation.[157,168] Overall, no increased incidence of premature onset of labor is apparent in these prospective studies. Regardless, given the high seroprevalence of infection, a significant degree of protection for the fetus must exist or else the incidence of neonatal disease should be significantly higher. Importantly, most infants who develop neonatal disease are born to women who are completely asymptomatic at the time of delivery and have neither a past history of genital herpes nor a sexual partner reporting a genital vesicular rash.[153,167–169] These women account for 60–80% of all women whose infected children develop infection.

Only 27% of women delivering children who developed neonatal HSV infection have had either a history of or evidence of recurrent lesions indicative of HSV infection during the current pregnancy.[169] Furthermore, only half of these women reported genital HSV infection in their sexual partners. The majority of women were without signs or symptoms of genital herpetic infection.

Factors that influence transmission of infection to the fetus

The type of maternal genital infection at the time of delivery influences the incidence of neonatal herpes.[159,170] The duration and quantity of viral excretion and the time to total healing vary with primary, initial (first episode at the nonprimary site), and recurrent (HSV-1 and -2) maternal genital infection (see Chapter 21).[171,172] Primary infection is associated with larger quantities of virus replicating in the genital tract ($>10^6$ viral particles/0.2 mL of inoculum) and a period of viral excretion which may persist for an average of 3 weeks. In contrast, virus is shed for an average of only 2–5 days and at lower concentrations (approximately 10^2–10^3/0.2 mL of inoculum) in women with recurrent genital infection. The difference in the natural history of primary and recurrent disease is likely a major factor that influences the frequency of transmission and, perhaps, the severity of neonatal disease. In 2003, Brown and colleagues reported the results of their study of over 58,000 pregnancies in the Seattle, Washington, area over 17 years, in which they performed cultures for HSV within 48 hours of delivery on nearly 40,000 women without evidence of genital HSV.[170] Of these, 202 women were asymptomatically shedding HSV and 121 of them had HSV serology available, allowing their infection to be classified as first episode primary, first episode nonprimary, or recurrent HSV infection. Fifty-seven percent of babies delivered to mothers with first episode primary infection developed neonatal HSV disease. In comparison, 25% of babies delivered to mothers with first episode nonprimary infection and 2% of babies delivered to mothers with recurrent HSV infection developed neonatal HSV disease.[170]

Paralleling the type of maternal infection, the mother's antibody status to HSV at delivery appears to be an additional factor that also influences the severity of infection as well as the likelihood of transmission. Transplacental maternal neutralizing antibodies appear to have a protective, or at least an ameliorative, effect on acquisition of infection for babies inadvertently exposed to virus.[161,170,173,174] Maternal primary infection late in gestation may not result in significant passage of maternal antibodies across the placenta to the fetus. The distinction between symptomatic and asymptomatic disease whether primary, initial, or recurrent remains poorly defined at present in relation to the risks of transmission of infection to the infant.

The duration of ruptured membranes is also a risk factor for acquisition of neonatal infection. Observations by Nahmias and colleagues indicate that prolonged rupture of membranes (>6 hours) increases the risk of acquisition of virus, probably the consequence of ascending infection from the cervix.[153,155]

On the basis of this observation, it has been recommended for more than three decades that women with active genital lesions be delivered by cesarean section. In the 2003 Seattle study, cesarean delivery was finally proven to reduce transmission of HSV to the neonate.[170] Of 202 deliveries where HSV was isolated, neonatal HSV occurred in 1 infant of 85 delivered by cesarean section (1.2%) versus 9 infants with neonatal HSV of 117 delivered vaginally (7.7%). Importantly, however, neonatal infection still occurs in cases managed according to these recommendations.[169,170,175]

Fetal scalp monitors are a site of inoculation of virus and may increase the risk of neonatal HSV infection.[176,177] Such devices are contraindicated in women with a history of recurrent genital HSV infections.

Incidence of newborn infection

The estimated incidence of neonatal HSV infection is approximately 1 in 2000 to 1 in 5000 deliveries per year.[153,170] Neonatal HSV infection occurs far less frequently than

genital HSV infections in the adult childbearing population. Several countries do not appear to recognize a significant number of cases of neonatal HSV infection in spite of the high prevalence of antibodies to HSV-2. Serologic studies in central Africa indicate that women have a high frequency of antibodies to HSV-2, but the first case of neonatal herpes was reported only relatively recently.[178,179] The United Kingdom presents a similar dilemma. Genital herpetic infection is relatively common in the United Kingdom, but very few cases of neonatal HSV infection are recognized in that country. This may reflect a low number of primary HSV infections in pregnant women. Overall, the United States has approximately 4 million deliveries a year and an estimated 1500 cases of neonatal infection, though the local incidence within the United States varies considerably.[180,181]

Time of transmission of infection

HSV infection of the newborn can be acquired at one of three times: in utero, intrapartum, or postnatally. The mother is the source of infection for the first two routes of transmission. For postnatal acquisition of HSV infection, the mother may be the source of infection from a genital or nongenital site, or other environmental or patient sources of virus can lead to infection of the child. Nevertheless, a maternal source should be suspected when herpetic lesions are discovered promptly after the birth or when the baby's illness is caused by HSV-2. Although intrapartum transmission accounts for 80–90% of cases, the other two routes must be recognized and identified in a child with suspect disease for both public health and prognostic purposes.

Although it was originally presumed that intrauterine infection resulted in either a totally normal baby or premature termination of gestation, intrauterine acquisition of infection can lead to the clinical evidence of congenital infection.[155,158,182–184] Utilizing stringent diagnostic criteria (namely, identification of infected babies within the first 48 hours of life who have virologic confirmation of infection) and excluding other pathogens with similar clinical findings such as congenital CMV infection, rubella, syphilis, or toxoplasmosis, over 100 babies have been identified in the world's literature to date with symptomatic congenital disease.[182] The manifestations of disease in this group of children range from significant neurologic abnormalities to simply the presence of skin vesicles at the time of delivery.

Intrauterine infection can occur as a consequence of either transplacental or ascending infection. Examination of the placenta in cases of neonatal herpes thought to be the consequence of in utero transmission has helped to clarify the route of transmission. A placenta showing evidence of necrosis and inclusions in the trophoblasts suggests a transplacental route of infection and can result in a baby with hydranencephaly at birth or may be associated with spontaneous abortion following intrauterine herpes simplex viremia.[185–187] Virus has been isolated from the products of conception in such circumstances.[186] Histopathologic evidence of chorioamnionitis, suggestive of ascending infection, has been identified as an alternative route for in utero infection as compared with transplacental spread.

Risk factors associated with intrauterine transmission are not known. However, both primary and recurrent maternal infection can result in infection of the fetus in utero. Although it might be convenient to assume that only primary maternal infection is associated with transmission of virus in utero, it has been documented that women with recurrent genital infection can transmit HSV to the fetus as well, leading to disease.

The second, and most common, route of infection is that of intrapartum contact of the fetus with infected maternal genital secretions. Approximately 80–90% of infected babies acquire HSV infection by this route. Those factors that favor intrapartum transmission of infection have been described in the preceding text.

The third route of transmission is postnatal acquisition. Even though HSV-1 has increasingly been associated with genital lesions, postnatal transmission of HSV has been suggested because 15–20% of neonatal HSV infections are caused by this virus type.[153]

In fact, more recent data from the National Institutes of Allergy and Infectious Diseases (NIAID), Collaborative Antiviral Study Group, indicate that the proportion of babies with neonatal herpes simplex infections owing to HSV-1 has increased to nearly 30%.[169] This observation, in light of the recognition that genital HSV-1 infections appear to account for only approximately 5–15% of all genital HSV infections, creates greater concern for postnatal acquisition of infection. However, data recently suggest an increasing number of genital herpes cases caused by HSV-1 in the United States, as occurs in Japan.

Relatives and hospital personnel with orolabial herpes may be a reservoir of virus for transmission to the newborn. The documentation of postnatal transmission of HSV has focused attention on such sources of virus for neonatal infection.[188–195] Postnatal transmission from mother to child has been documented. Maternal–infant postpartum transmission has been reported as a consequence of nursing on an infected breast.[189,191,194] Furthermore, father-to-baby transmission has been documented.[188,195]

Many individuals asymptomatically excrete HSV from the oropharynx and, therefore, represent a potential source of infection for the newborn. The occurrence of fever blisters in various groups of adults has ranged from 16% to 46%.[196,197] Population studies in two hospitals indicated that 15–34% of hospital personnel had a past history of nongenital herpetic lesions.[198–200] In both hospitals surveyed, at least 1 in 100 individuals had a recurrent cold sore each week. No cases of neonatal HSV infection were documented

in these nurseries.[199,201] However, the demonstration in other studies of identical viruses (utilizing restriction endonuclease analyses of viral DNA) in babies with different mothers leaves little doubt of the possibility of spread of virus in a high-risk nursery.[190,193] The sources of virus and vectors for transmission have been inadequately studied. The potential legal implications for HSV infections acquired in a nursery are obvious. There is significant variation in the United States regarding both the concern for nosocomial transmission of infection in the hospital as well as infection control policies for its prevention.

Various individuals and committees have recommended that personnel with cold sores not work in the nursery. If such a policy were followed, the estimated medical costs would be nearly 20 million dollars annually in the United States if calculated just on the basis of estimates of lost work days.[198] Likely, vigorous hand washing procedures and continuing education of personnel in newborn nurseries has helped contribute to the low frequency of transmission in this environment. The existence of a herpetic whitlow in staff providing patient care should preclude direct patient contact, irrespective of nursing unit.

IMMUNOLOGIC RESPONSE TO HSV INFECTION

The host response to HSV in newborns must be distinguished from that of older individuals. Impairment of host defense mechanisms has been implicated as a cause of the increased severity of some infectious agents in the fetus and the newborn. Factors that must be considered in defining host response include the mode of transmission of the agent (viremia versus mucocutaneous infection), time of acquisition of infection, and the potential of increased virulence of certain strains, although this last point remains purely speculative. Two broad issues are of relevance: Protection of the fetus by transplacental antibodies and definition of host response of the newborn.

Host responses to HSV infection influence the likelihood of disease, severity of infection, and the development, maintenance, and reactivation of HSV.[202–204] Clearly, humoral immune responses do not prevent either recurrences or exogenous reinfection. Thus, not surprisingly, transplacentally acquired antibodies from the mother are not totally protective against newborn infection. The key issue, then, is to what extent these antibodies protect and whether specific antibody classes confirm greater protection than others. Transplacentally acquired neutralizing antibodies seem to either prevent or ameliorate infection in exposed newborns.[173,174] Nevertheless, the presence of antibodies at the time of clinical presentation with disease does not appear to influence the subsequent outcome.[167,169,205]

Infected newborns produce IgM antibodies, as detected by immunofluorescence, specific for HSV within the first 3 weeks of infection. These antibodies increase rapidly in titer during the first 2–3 months of life and persist for as long as 1 year. The most reactive immunodeterminants include the viral surface glycoproteins, particularly gD and gB. Humoral antibody responses have been studied using immunoblot technology.[205,206] These studies indicate that the severity of infection correlates directly with the number of antibody bands to defined polypeptides. Children with more limited infection, namely, infection of the skin, eye, and/or mouth, have fewer antibody bands as compared with those children who have disseminated disease. The quantity of neutralizing antibodies in babies with disseminated infection is lower.[206]

Cellular immune responses have been considered important in the resolution of primary herpetic infections. Newborns with HSV infections have a delayed T-lymphocyte proliferative response compared with older individuals.[206] Most infants studied in a recent evaluation had no detectable T-lymphocyte responses to HSV 2–4 weeks after the onset of clinical symptoms, as noted previously by other investigators.[80,206,207] The delayed response to T-lymphocyte antigens in children who have disease localized to the skin, eye, or mouth at the onset of disease may be an important determinant of the frequency of disease progression.[206,208]

Infected newborns have decreased production of alpha interferon in response to HSV antigen when compared to adults with primary HSV infection.[206] The importance of alpha interferon in the maturation of host responses, particularly the elicitation of natural killer cell responses, remains to be defined. Infected babies have decreased gamma interferon production during the first month of life.[206,209,210] Taken together, the data indicate that the newborn has a delayed cell-mediated immune response and lymphokine generation.

Antibodies plus complement and antibodies with killer lymphocytes, monocytes, macrophages, or polymorphonuclear leukocytes will lyse HSV-infected cells in vitro.[211] Antibody-dependent cell-mediated cytotoxicity is an important component of the development of host immunity to infection.[212] However, the total population of killer lymphocytes in the newborn is lower than that in older individuals. Thus, certain cell-mediated immune factors do appear relevant in neonatal disease. Both the type and quantity of antibodies present as well as the immaturity of monocyte and macrophages of human neonates are of greater importance than in adults.[211,213–219] These findings are supported by animal model data.[211,213,214]

NEONATAL HSV INFECTION

Pathogenesis

Following direct exposure, the newborn will either limit viral replication to the portal of entry (namely, the skin, eye, or

mouth) or viral replication will progress and cause more serious disease, including involvement of the brain (causing encephalitis) or multiple other organs. Host mechanisms responsible for control of progression of viral replication at the site of entry are unknown. For CNS disease, intraneuronal transmission of viral particles provides a privileged site that may be immune to circulating humoral and cell-mediated defense mechanisms. Thus, transplacental maternal antibodies may be of less value under such circumstances. In contrast, disseminated infection may be the consequence of viremia or secondary to extensive cell-to-cell spread as occurs with pneumonitis following aspiration of infected secretions.

Clinical presentation

The clinical presentation of babies with neonatal HSV infection is a direct reflection of the site and extent of viral replication. Neonatal HSV infection is almost invariably symptomatic and frequently lethal. Although reported cases of asymptomatic infection in the newborn exist, they are most uncommon, and long-term follow-up of these children to document absence of subtle disease or sequelae has not been carefully performed. Classification of newborns with HSV infection is mandatory for prognostic and therapeutic considerations. Babies with congenital infection should be identified within the 48–72 hours following birth. Babies who are infected intrapartum or postnatally can be divided into three categories: (1) disease localized to the skin, eye, or mouth; (2) encephalitis with or without skin, eye, and/or mouth involvement; and (3) disseminated infection which involves multiple organs, including CNS, lung, liver, adrenals, skin, eye, and/or mouth. Prospectively acquired data obtained through the NIAID Collaborative Antiviral Study Group will be reported here.[220,221]

Intrauterine infection

In the most severely afflicted group of babies, intrauterine infection is apparent at birth and is characterized by a triad of findings, including skin vesicles or skin scarring, eye disease, and the far more severe manifestations of microcephaly or hydranencephaly. Often chorioretinitis alone or in combination with other eye findings, such as keratoconjunctivitis, is a component of the clinical presentation. Serial ultrasound examination of the mothers of those babies infected in utero has demonstrated the presence of hydranencephaly. Chorioretinitis alone can be a presenting sign and should alert the pediatrician to the possibility of this diagnosis, albeit HSV infection is a less common cause than other congenital infections. Severe disease can follow acquisition of infection virtually at any time in gestation. The frequency of occurrence of these manifestations has been estimated to be between 1 in 100,000 and 1 in 200,000 deliveries.[182]

A small group of children will have skin or eye lesions that are present at the time of delivery. These children are frequently born to women who have had prolonged rupture of membranes, sometimes for as long as 2 weeks prior to delivery. The babies have no other findings of invasive multiorgan involvement, including chorioretinitis, encephalitis, or evidence of other diseased organs. The prognosis for successful antiviral therapy in this group of babies is far better than in the children who are born with hydranencephaly.

Disseminated infection

Table 84-3 summarizes the disease classification of 186 babies with neonatal HSV treated with acyclovir from two studies by the NIAID Collaborative Antiviral Study Group.[220] Babies with disseminated infection have the worst prognosis in terms of both mortality and morbidity. Children with disseminated infection usually present to tertiary care centers for therapy between 9 and 11 days of life. However, signs of infection are usually present on an average for 4 to 5 days earlier. Prior to antiviral therapy, this group of babies accounted for approximately one-half to two-thirds of all children with neonatal HSV infection. The principal organs involved following disseminated infection are the liver and adrenals. However, infection can involve multiple other organs including the larynx, trachea, lungs, esophagus, stomach, lower gastrointestinal tract, spleen, kidneys, pancreas, and heart. Encephalitis appears to be a common component of this form of infection, occurring in about 60–75% of children. Constitutional signs and symptoms include irritability, seizures, respiratory distress, jaundice, bleeding diatheses, shock, and frequently the characteristic vesicular exanthem that is often considered pathognomonic for infection. The vesicular rash, as described in the following, is particularly important in the diagnosis of HSV infection. However, 20–40% of children having disseminated infection never develop skin vesicles during the course of illness.[169,220] In the absence of skin vesicles, the diagnosis becomes exceedingly difficult, since other clinical signs are often vague and nonspecific, mimicking those of neonatal sepsis. Mortality in the absence of therapy exceeds 80%; all but a few survivors are impaired. The most common cause of death in babies with disseminated disease is either HSV pneumonitis or disseminated intravascular coagulopathy.

Evaluation of the extent of disease is imperative, as with all cases of neonatal HSV infection. The clinical laboratory should be utilized to define hepatic enzyme elevation (SGOT and GGT), direct hyperbilirubinemia, neutropenia, thrombocytopenia, and bleeding diatheses among others. Cerebrospinal fluid (CSF) examination and use of noninvasive neurodiagnostic tests, as defined in the following, will help assess the extent of brain disease. In addition, chest roentgenograms, abdominal x-rays, electroencephalography, and computed tomography of the head all can be judiciously and serially employed to determine the extent of disease. The radiographic picture of HSV

lung disease is characterized by a diffuse, interstitial pattern that progresses to a hemorrhagic pneumonitis. Not infrequently, pneumatosis intestinalis can be detected when gastrointestinal disease is present.

Encephalitis

Infection of the CNS occurs alone or in combination with disseminated disease and presents with the findings indicative of encephalitis in the newborn. Overall, nearly 90% of babies with dissemination or encephalitis have evidence of acute brain infection. Brain infection can occur either as a component of multiorgan disseminated infection or as encephalitis with or without skin, eye, and mouth involvement. One-third of all babies with neonatal HSV infection have only encephalitis. The pathogenesis of these two forms of brain infection is likely different. Babies with disseminated infection probably seed the brain by a blood-borne route, resulting in multiple areas of cortical hemorrhagic necrosis. In contrast, babies who present with encephalitis alone are likely to develop brain disease as a consequence of retrograde axonal transmission of

virus to the CNS. Two pieces of data support this contention. First, babies with disseminated disease have documented viremia and are hospitalized earlier in life (at 9–10 days vs. 16–17 days) than those with encephalitis. Second, babies with encephalitis are more likely to receive transplacental neutralizing antibodies from their mothers, which may not prevent intraneuronal transmission of virus to the brain.

The clinical manifestations of encephalitis include seizures (both focal and generalized), lethargy, irritability, tremors, poor feeding, temperature instability, bulging fontanelle, and pyramidal tract signs. Although babies with encephalitis alone can have skin vesicles in association with brain infection, 30–40% do not develop skin vesicles at any time in the disease course.[169,220,222–224] Cultures of CSF yield HSV in 25–40% of all cases. Anticipated findings on CSF examination include pleocytosis and proteinosis (as high as 500–1000 mg/dL). Although a few babies with CNS infection proven by brain biopsy have been reported to have no abnormalities of their CSF, this occurs very rarely. Serial CSF examination is useful diagnostically as the infected child with brain disease will demonstrate progressive increases in the CSF protein content. The importance of CSF examinations in all infants is underscored by the finding that even subtle changes have been associated with significant developmental abnormalities. Furthermore, as discussed in diagnosis, CSF provides an essential biologic specimen for diagnostic evaluation by PCR.[225,226]

Electroencephalography and computed tomography can be very useful in defining the presence of CNS abnormalities.[220,227] Death occurs in 50% of babies with localized CNS disease who are not treated and is usually related to brain-stem involvement. With rare exceptions, survivors are left with severe neurologic impairment.[222,224]

The long-term prognosis, following either disseminated infection or encephalitis, is poor. As many as 50% of surviving children have some degree of psychomotor retardation, often in association with microcephaly, hydranencephaly, porencephalic cysts, spasticity, blindness, chorioretinitis, or learning disabilities. It is thought that visceral or CNS damage can be progressive after initial clearance of the viral infection, a possibility suggested by long-term assessment of children with skin, eye, or mouth disease and more recently, in a group of babies with more severe disease.[153,169,228,229]

Despite the presumed difference in pathogenesis, the clinical manifestations of encephalitis alone are virtually identical to those that occur with brain infection in disseminated cases. Only two of three babies with encephalitis will develop a vesicular rash characteristic of HSV infection. Thus, a newborn with pleocytosis and proteinosis of the CSF but without a rash can easily be misdiagnosed as having a bacterial or other viral infection unless HSV infection is carefully considered. In such circumstances, a history of genital lesions in the mother or her sexual partner may be very important in suggesting HSV as a cause of illness.

Skin, eye, and/or mouth infection

Infection localized to the skin, eye, and/or mouth is associated with lower mortality, but it is not without significant morbidity. When infection is localized to the skin, the presence of discrete vesicles remains the hallmark of disease. Clusters of vesicles often appear initially on the presenting part of the body that was in direct contact with the virus during birth. With time, the rash can progress to involve other areas of the body as well. Vesicles occur in 90% of children with skin, eye, and/or mouth infection. Children with disease localized to the skin, eye, or mouth generally present at about 10–11 days of life. Those babies with skin lesions invariably will suffer from recurrences over the first 6 months (and longer) of life, regardless of whether therapy was administered or not. Although death is not associated with disease localized to the skin, eye, and/or mouth, up to 30% of these children eventually develop evidence of neurologic impairment.[156,169,227]

Vesicles usually erupt from an erythematous base and are usually 1–2 mm in diameter. They can progress to larger bullous lesions greater than 1 cm in diameter. Although discrete vesicles on various parts of the body are usually encountered, crops and clusters of vesicles have also been described. For most babies with neonatal HSV infection localized to the skin, eye, and/or mouth, the vesicular skin rash involves multiple and often distant cutaneous sites. However, a limited number of babies have had infection of the skin limited to one or two vesicles and no further evidence of cutaneous disease. This group of babies warrants careful evaluation because many have developed encephalitic involvement when antiviral therapy was not administered. Other manifestations of skin lesions have included a zosteriform eruption.

Infections involving the eye may manifest as keratoconjunctivitis or, later, chorioretinitis. The eye can be the only site of HSV involvement in the newborn.[202] These children present with keratoconjunctivitis or, surprisingly, evidence of microphthalmia and retinal dysplasia. In the presence of persistent disease and no therapy, chorioretinitis can result, caused by either HSV-1 or -2.[230–232] Keratoconjunctivitis, even in the presence of therapy, can progress to chorioretinitis, cataracts, and retinal detachment. Cataracts have been detected on long-term follow-up in three infants with proved perinatally acquired HSV infections.[233]

Localized infection of the oropharyngeal cavity is found in approximately 10% of neonates with HSV infection. Long-term neurologic impairment including spastic quadriplegia, microcephaly, and blindness has been encountered in children whose disease appeared localized to the skin, eye, and/or mouth. Important questions regarding the pathogenesis of delayed-onset neurologic debility are raised by such clinical observations. Despite normal clinical examinations, neurologic impairment develops between 6 months and 1 year of life. The clinical presentation occurs in a manner similar to

that associated with congenitally acquired toxoplasmosis or syphilis. As noted in the following, two factors appear to predict neurologic outcome in babies with disease localized to the skin, eye, or mouth. These are (1) frequency of recurrent skin lesions over the first 3 months of life and (2) detection of HSV DNA by PCR in the CSF at the end of therapy.

Subclinical infection

Although it has been suggested that two newborns had evidence of HSV infection proved by culture isolation of virus but without evidence of symptoms, it has been difficult to document such cases through the serial evaluation in over 1000 infants evaluated in multiple centers around the United States. Because of the propensity of the newborn to develop disease, any evidence of infection should be considered potentially serious and an indication for antiviral therapy.

DIAGNOSIS

Clinical evaluation

The clinical diagnosis of neonatal HSV infection has become increasingly difficult because of the apparent decrease in the incidence of skin vesicles as an initial component of disease presentation. A variety of other disease conditions of the newborn can masquerade as neonatal HSV infections, including hyaline membrane disease, intraventricular hemorrhage, necrotizing enterocolitis, and various ocular or cutaneous disorders. Bacterial infections of newborns can mimic neonatal HSV infection. It is not uncommon for some babies infected by HSV to also experience a concomitant bacterial infection, particularly those caused by the group B streptococcus, *Staphylococcus aureus*, *Listeria monocytogenes*, and gram-negative bacterial infections.

As with other vesicular rashes, alternative causes of such exanthems should be excluded. Such diseases include varicella-zoster virus infection, enteroviral disease, and disseminated CMV infection. With the aforementioned clinical findings in a child presenting to the hospital during the first 3 weeks of life, consideration of neonatal HSV infection is necessary. The presence of skin vesicles provides a natural site for attempted isolation of virus in order to rapidly determine if the etiology of the vesicular rash is HSV as opposed to varicella-zoster virus. Simultaneously, serologic specimens and other virologic cultures should be obtained to exclude other common causes of perinatal infection, including toxoplasmosis, CMV infection, rubella, and syphilis. Such cutaneous disorders as erythema toxicum, neonatal melanosis, or acrodermitis enteropathica often confuse physicians who suspect neonatal HSV infections. Lesions associated with these diseases can be rapidly distinguished from those caused by HSV by the presence of eosinophils on a Wright stain of a tissue scraping and by appropriate viral cultures.

The most difficult clinical diagnosis to make is that of HSV encephalitis, as nearly 40% of children with CNS infection will not have a vesicular rash at the time of clinical presentation. HSV infection of the CNS should be suspected in the child who has evidence of acute neurologic deterioration with the onset of seizures and in the absence of intraventricular hemorrhage and metabolic causes. Serial increases in CSF fluid cell counts and protein concentrations, negative bacterial cultures of the CSF, and negative CSF antigen studies help suggest the diagnosis of HSV infection of the CNS. A maternal genital culture or history of genital herpes in either the mother or a sexual partner reinforces the suspicion of neonatal HSV infection. As noted previously, noninvasive neurodiagnostic studies can be used to define the sites of involvement.

Laboratory assessment

Every effort should be made to confirm infection by viral isolation, the definitive diagnostic method. If skin lesions are present, a scraping of skin vesicles should be transferred in appropriate virus transport media to a diagnostic virology laboratory. Clinical specimens should be shipped on ice for inoculation into appropriate cell culture systems. Shipping of specimens and their processing should be expedited. In addition to skin vesicles, other sites from which virus may be isolated include the CSF, stool, urine, throat, nasopharynx, and conjunctivae. It may also be useful in infants with evidence of hepatitis or other gastrointestinal abnormalities to obtain duodenal aspirates for HSV isolation. The virologic results of the cultures from these sites along with clinical findings should be used in conjunction with clinical findings to establish a disease classification. Typing of an HSV isolate may be done by one of several techniques.

Over the past several years, PCR detection of HSV-DNA in CSF has become the diagnostic method of choice for CNS disease, replacing brain biopsy. It has proved both sensitive and specific when properly performed.[226,234–237]

The serologic diagnosis of HSV infection is not of great clinical value. Therapeutic decisions cannot await the results of serologic studies. Further, the inability of the commonly available serologic assays to distinguish between antibodies to HSV-1 or HSV-2 as well as to denote the presence of transplacentally acquired maternal IgG, as opposed to endogenously produced antibodies, makes the assessment of the neonate's antibody status difficult during acute infection. Serial antibody assessment may be useful if a mother without a prior history of HSV infection has a primary infection late in gestation and transfers very little or no antibody to the fetus.

TREATMENT OF NEONATAL HSV INFECTIONS

Background

Since most babies acquire HSV infection at the time of delivery or shortly thereafter, successful antiviral therapy should

decrease mortality and improve long-term outcome. Inherent in this presumption is the recognition that diagnosis shortly after the onset of clinical illness is essential, as is the case with other perinatally acquired infections. Children presenting with disease localized to the skin, eye, and/or mouth progress to either involvement of the CNS or disseminated infection in approximately 70% of cases when no therapy is administered.[167] When such occurs, the likelihood of an adequate outcome, even with established drugs, is not optimal as many of these children will either die or be left with significant neurologic impairment. Such factors must be considered in the development of any treatment strategy.

Antiviral therapy

Vidarabine was the first drug proven effective for treatment of infants with disseminated or localized CNS disease, being associated with a decline in mortality rate from 75% to 40%.[229] However, vidarabine has been replaced by acyclovir as the treatment of choice for neonatal HSV infection. When outcome was examined according to each of the three disease classifications, the best therapeutic result was achieved in babies with either encephalitis or skin, eye, and/or mouth infection.

Acyclovir is the treatment of choice for neonatal HSV infections of the CNS. It is a selective inhibitor of HSV replication, representing one of the most important advances in antiviral therapy. Acyclovir is a synthetic acyclic purine nucleoside analog which selectively inhibits HSV-1 and HSV-2.[238,239] Acyclovir is converted to its monophosphate derivative by virus-encoded thymidine kinase, an event that does not occur to any significant extent in uninfected cells. Subsequent di- and triphosphorylation is catalyzed by cellular enzymes and results in acyclovir triphosphate concentrations 40- to 100-fold higher in HSV-infected cells than in uninfected cells. Acyclovir triphosphate inhibits viral DNA synthesis by competing with deoxyguanosine triphosphate as a substrate for viral DNA polymerase.[240,241] DNA synthesis is then terminated because acyclovir triphosphate lacks the 3′ hydroxyl required for DNA chain elongation. The viral polymerase has greater affinity for acyclovir triphosphate than cellular DNA polymerase, resulting in little incorporation of acyclovir into cellular DNA. In vitro, acyclovir is active against HSV-1 (average ED_{50} = 0.04 μg/mL), HSV-2 (0.10 μg/mL), and varicella-zoster virus (0.50 μg/mL).

Acyclovir has been established as efficacious for the treatment of primary genital HSV when administered by intravenous, oral, and topical routes.[242–245] Furthermore, the oral and intravenous administration of acyclovir to the immunocompromised host decreases both the frequency of reactivation following immunosuppression and disease duration.[246,247] Acyclovir is superior to vidarabine for the treatment of HSV encephalitis.[248] Because this compound is a selective inhibitor of viral replication, it has a low frequency of side effects. Acyclovir has become a preferred treatment for all serious HSV infections.

In the treatment of neonatal HSV infections, intravenous acyclovir at standard dosing of 30 mg/kg/day for 10–14 days was been shown to be as effective as vidarabine treatment; but not superior.[249] A subsequent study performed by the NIAID CASG evaluating the use of higher-dose acyclovir (60 mg/kg/day) for 21 days demonstrated clear superiority and has become the standard of care.[250] The mortality rate of infants with encephalitis or disseminated infection in this study was 6% and 31%, respectively. This represents a decrease from 20% to 61% for patients receiving standard dosing of acyclovir in the earlier CASG trial, respectively. However, despite the clear benefit in mortality, particularly among those infants with disseminated disease, high-dose acyclovir did not show a statistically significant improvement in morbidity at 12 months of life.[250] There was, however, a borderline significant trend toward improved morbidity when potentially confounding factors were controlled for in a logistic regression model. The most important toxicity of high-dose acyclovir is neutropenia. It is recommended to monitor neutrophil counts twice weekly during high-dose acyclovir therapy. It is prudent to monitor renal function as well, though our experience indicates very low rates of immediate renal toxicity during therapy with acyclovir in this population.

To improve outcome, more active drugs that have greater activity in the CNS must be developed. Importantly, therapy must prevent progression of infection to the CNS or disseminated disease. Ideally, prevention of neonatal HSV infection, including CNS involvement, by either immunization of the mother at risk or immunoprophylaxis and therapy of the newborn delivered to the mother with asymptomatic primary or initial infection would be far more desirable.

Recognizing that disease is often present in these babies for 4 or 5 days prior to diagnosis, a window for administration of therapy earlier in life does exist. This point must be reiterated as earlier therapeutic intervention for any microbial infection will lead to improved outcome, particularly when a vital organ such as the brain is involved. Furthermore, when therapy is instituted early, fewer children will progress from localized skin involvement to more serious forms of infection. Therapy decreases the frequency of progression.

Infants with ocular involvement caused by HSV should receive topical antiviral medication in addition to parenteral therapy. At the present time, few safety and tolerance data are available for topical ophthalmic antiviral drugs. In older patients, viroptic (trifluorothymidine) has the greatest antiviral activity and is the treatment of choice for HSV infection of the eyes. Vidarabine ophthalmic and Stoxil (idoxuridine) have been utilized for a longer period of time. There is more experience regarding their safety in both adults and children, but they are less active.

During the course of therapy, careful monitoring is important in order to assess therapeutic response. Even in the absence of clinical evidence of encephalitis, the CNS should be examined serially for prognostic purposes. Evaluation of certain hepatic (increased SGPT or SGOT) and bone marrow parameters (decreased platelets) may indicate viral involvement of these organs or drug toxicity.

As for all drugs, a consideration of the therapeutic index or a ratio of efficacy to toxicity is important. Experience with acyclovir has indicated little toxicity when used appropriately. However, the possibility of both acute and long-term toxicity should be considered in any child receiving parenteral antiviral therapy and assessed by serially evaluating bone marrow, renal, and hepatic function. The potential for long-term harm from acyclovir appears low. Since these compounds act at the level of DNA replication, physicians responsible for follow-up of these children should be aware of the possibility of mutagenic or even teratogenic effects that may not appear until decades later. A recent topic of debate is the possibility of the development of viral resistance to a drug; the clinical significance remains to be defined, although it has occurred in the newborn.[251]

Continuing discussion surrounds the administration of oral acyclovir following intravenous therapy. Oral therapy appears to decrease the frequency of cutaneous recurrences but has been associated with absolute neutropenia. Since the child with neonatal HSV infection, particularly with skin vesicles, will excrete virus in large quantities, isolation of the newborn is important in order to decrease the potential for nosocomial transmission of infection.

Factors predictive of neurologic outcome

Table 84-4 summarizes the risk factors for mortality and morbidity even with therapy of neonatal HSV infection.[252] Mortality is best predicted by disease classification, level of consciousness, and disseminated intravascular coagulopathy for the entire study population. As it relates to morbidity, disease classification, virus type (HSV-2), and the presence of seizures predict a poor neurologic outcome.

Notably, for babies with disease localized to the skin, eye, or mouth, risk of neurologic impairment increases with the frequency of recurrent cutaneous lesions within 3 months of the completion of therapy. Additionally, infection caused by HSV-2 appears more likely to cause neurologic impairment.

Other therapeutic approaches

At present, there is no indication that administration of immune globulin or hyperimmune globulin is of value in therapy of neonatal HSV infection. Although a series of studies have suggested that high levels of transplacental neutralizing antibodies will ameliorate neonatal HSV infections at the time of presentation with clinical disease, the presence or absence of antibodies does not influence the subsequent

Table 84-4. Prognostic Factors Identified by Multivariate Analyses for Neonates and HSV Infection[a]

	Relative Risk	
	Mortality	Morbidity
Total group ($n = 202$)		
Extent of disease		
Skin, eyes, or mouth	1.0	1.0
CNS	5.8[b]	4.4[b]
Disseminated	33[b]	2.1[b]
Level of consciousness		
Alert or lethargic	1.0	NS
Semicomatose or comatose	5.2[b]	NS
Disseminated intravascular coagulopathy	3.8[b]	NS
Prematurity	3.7[b]	NS
Virus type		
HSV-1	2.3[c]	1.0
HSV-2	1.0	4.9[b]
Seizures	NS	3.0[b]
Infants with disseminated disease ($n = 46$)		
Disseminated intravascular coagulopathy	3.5[b]	NS
Level of consciousness		
Alert or lethargic	1.0	1.0
Semicomatose or comatose	3.9[b]	4.0[b]
Pneumonia	3.6[b]	NS
Infants with CNS involvement ($n = 71$)		
Level of consciousness		
Alert or lethargic	1.0	NS
Semicomatose or comatose	6.1[b]	NS
Prematurity	5.2[b]	NS
Seizures	NS	3.4[b]
Infants with infection of the skin, eyes, or mouth ($n = 85$)		
No. of skin vesicle recurrences		
< 3	NA	1.0
$\geqslant 3$	NA	21[b]
Virus type		
HSV-1	NA	1.0
HSV-2	NA	14[b, d]

[a]CNS denotes central nervous system, NS not statistically significant ($p > 0.05$), and NA not applicable. (No baby with disease confined to the skin, eyes, or mouth died).

[b]$p < 0.01$.

[c]$p < 0.05$.

[d]Because of the correlation between virus type and skin–vesicle recurrence, virus type was not significant in the multivariate model; however, it was significant as a single factor. (Adapted, with permission, from Whitley RJ et al. Predictors of morbidity and mortality in neonates with herpes simplex virus infections. *N Engl J Med* 1991; 324: 450–454.).

course of infection.[169,173,174] Moreover, at present no other form of therapy is useful for treating neonatal HSV infection. Various experimental modalities including BCG, interferon, immune modulators, and immunization have been used, but none have produced demonstrable effects.

LONG-TERM MANAGEMENT OF HSV-INFECTED BABIES

With the advent of antiviral therapy, an increasing number of newborns who suffer from HSV infection survive and require careful long-term follow-up. Three areas of follow-up warrant attention from a medical standpoint. First, it is not infrequent that parents of children with neonatal HSV infection have significant guilt feelings. A once stable marriage can suffer and require interventive support from psychologists, psychiatrists, or marriage counselors. The family physician or pediatrician in this situation can provide support to the family. Second, the most common complications of neonatal HSV infection include neurologic and ocular sequelae which are detected only on long-term follow-up. Therefore, these children should receive serial long-term evaluations from qualified pediatric specialists in these areas, including neurodevelopmental, ophthalmologic, and hearing assessments. Third, skin vesicles will recur with time. These vesicles provide a potential reservoir for transmission of infection to other children who have direct contact with these infants. The increasing use of day care for children in this country, including children surviving neonatal HSV infections, has stimulated many questions concerning how these children should receive care. Certainly, there is some risk that children with recurrent HSV skin lesions will transmit the virus to other children in this environment. The most reasonable recommendation in this situation appears to be simply to cover the lesions to prevent direct contact with them. More likely, HSV-1 is present in the day care environment in the children with symptomatic or asymptomatic gingivostomatitis. In both cases, virus is present in the mouth and pharynx, so that the frequent exchange of saliva and other respiratory droplets that occurs among children in this setting makes this route of transmission much more likely. Education of day care workers and the general public concerning herpesvirus infections, their implications, and the frequency with which they occur would do much to calm fears and correct common misconceptions concerning infections with this virus.

PREVENTION OF NEONATAL HSV INFECTION

Background

In spite of the progress that has been made over the last 25 years in the development of antiviral therapy for treatment of neonatal HSV infection, the best approach is that of prevention. It is not surprising that because of the attention of the lay press to the devastating outcome of neonatal herpes, many women with known genital herpetic infection elect to be delivered by cesarean section rather than undergo the potential risks of exposure of the fetus to the virus at the time of vaginal delivery. As a consequence, an unnecessarily high frequency of cesarean infections is believed to occur in these individuals. All individuals involved in the care of pregnant women and their offspring should individualize the care of mother and child to optimize patient management. Cultures obtained for HSV earlier in gestation prior to delivery do not predict neonatal infection and, therefore, are not indicators.[253–255]

For women with known shedding of HSV at delivery (i.e., genital lesions), cesarean section has been shown to be efficacious in the prevention of neonatal HSV infections. For women with a past history of genital HSV infection, a careful vaginal examination at presentation to the delivery suite is of paramount importance. Although visualization of the cervix is often difficult, speculum examination for documentation of recurrent lesions is extremely important and should be attempted in these women. A culture for HSV obtained at the time of delivery may be of great importance in establishing whether transmission of infection to the fetus is likely.

The fact that predelivery cultures not only fail to predict the woman who excretes virus at delivery but are also an unnecessarily large health care cost burden places their value in further question. Thus, alternative management approaches will have to be developed.[254]

Clearly, identifying the woman who excretes HSV at delivery and then optimizing either prophylactic protocols with safe and acceptable antivirals or delivery by cesarean section is the optimal way to manage genital infection at the time of delivery. Unfortunately, at present isolation of virus in tissue culture or standard HSV PCR are the only commonly available tests capable of documenting the excretion of virus. Alternative, rapid non-culture-based diagnostic approaches are not currently available, though there are ongoing efforts to develop them, in order to expedite identification of women at risk for delivering an infected baby.[256]

An alternative strategy is evolving for women with a history of recurrent genital herpes. The administration of acyclovir during the last 4 to 6 weeks of gestation has resulted in a lower frequency of cesarean sections and viral shedding.[257] However, a recent study demonstrated similar rates of viral shedding and lesions in a cohort of women receiving valacyclovir in the last 4 weeks of pregnancy as compared to those receiving placebo.[258] In a registry of neonates exposed to acyclovir in utero, no significant teratogenic effects to the newborn were seen.[259] However, the study was not powered to detect rare defects, or those presenting after the perinatal period.

For infections that occur in the first half of gestation, no specific recommendations regarding the termination of pregnancy can be made at this time. It appears that the frequency of infection acquired in utero is approximately 1 in 200,000 deliveries

and can occur as a consequence of either maternal primary or recurrent infection. Nevertheless, detailed prospective studies to document this occurrence have yet to be performed. Thus, no specific recommendation regarding termination of pregnancy with such findings can be made.

Serious forms of neonatal HSV infections will continue to be associated with significant mortality and morbidity, even with acyclovir therapy. As a consequence, some investigators have suggested that acyclovir may be useful in preventing the occurrence of neonatal HSV infections in infants who are delivered unknowingly through an infected birth canal. Since the incidence of neonatal HSV infection following maternal recurrent disease is low, the risks and costs will likely outweigh the benefits. However, with a suspected maternal primary infection and a vaginal delivery intravenous acyclovir therapy may be indicated. However, it must be recognized that the women who are at greatest risk for delivering babies who develop neonatal HSV infection are those least likely to have a history of recurrent genital HSV infection or to have a recognized primary case.

Management of high-risk women and their offspring

Infants delivered either vaginally or by cesarean section when membranes are intact to mothers who have no evidence of active genital herpetic infection are at low risk for acquiring neonatal HSV infection. These children need no special evaluation in the nursery other than initial isolation until results of maternal genital cultures are available. With negative maternal genital cultures, these children can be discharged at the time the mother leaves the hospital.

Infants delivered vaginally to mothers with active genital herpes should be evaluated with viral cultures obtained between 24 and 48 hours after delivery. Sites from which virus should be sought include eye, oronasopharynx, and suspect lesions. These recommendations should serve only as guidelines until formal data are available. If any site is positive, a thorough virologic and clinical examination must be performed and therapy instituted. Other sites to be considered for viral isolation include the CSF, urine, and buffy coat of the blood. In addition, neurodiagnostic evaluation by electroencephalogram and a computed tomographic scan, if indicated, is essential.

Postnatal infection

Isolation of mother from baby. An issue of frequent concern is whether the mother with active genital HSV infection at delivery should be isolated from her child after delivery. Women with recurrent orolabial HSV infection as well as cutaneous herpes simplex infections at other sites (breast lesions) are at similar risk for transmission of virus to their newborn. The risks presented to the newborn by other family members, medical personnel, and friends remain unknown but are low and do not justify removal of personnel from the nursery at this time. Since transmission occurs by direct contact with the virus, appropriate precautions by the mother, including careful hand washing before touching the infant, should prevent the necessity of separation of mother and child. Similarly, breastfeeding is contraindicated only if the mother has vesicular lesions involving the breast. We do not isolate babies born to infected women unless they themselves become infected. Hospitalization is not prolonged in the uninfected child.

Parental education

At the time of discharge, it is essential to educate parents with known recurrent herpetic infection regarding the possibility that their child may become infected. The parental stigma of a diagnosis of genital herpes and the monitoring procedures associated with evaluating the newborn can create excessive fear and anxiety in the family. The parents and responsible family members must be educated in order to relieve anxiety and provide prompt access to the health-care delivery system should evidence of infection appear. Information regarding infection should include an overview of HSV infection, the risks associated with transmission of infection to the newborn, the necessity for monitoring, the anticipated consequences of positive and negative viral cultures, planned approaches to treatment, and the potential for postnatal acquisition of infection at home.

Hospital staff

At many institutions, a policy that requires transfer or provision of medical leave for nursing or other personnel in nurseries with a labial HSV infection is impractical and causes an excessive burden in those attempting to provide adequate care. Temporary removal of personnel with cold sores has been advocated on some clinical services. As noted previously, individuals with herpetic whitlows carry a high risk of viral shedding. These individuals should be removed from care of newborns at risk for acquiring neonatal HSV infection since even gloves may not prevent transmission of infection. Education regarding the risk of transmission of virus and the importance of hand washing when lesions are present should be repeatedly emphasized to health-care workers. In addition, hospital personnel should wear masks when active lesions are present.

SUMMARY

Neonatal HSV infection remains a life-threatening infection for the newborn in the United States today. With an increasing incidence of genital herpes and an increase in the incidence of neonatal HSV infections, it is important that pediatricians, neonatologists, obstetricians, and family practitioners continue to maintain a high index of suspicion in infants whose symptoms may be compatible with HSV infections so that

early identification leads to prompt treatment. We hope that over the next decade, the development of safe and efficacious vaccines as well as a better understanding of factors associated with transmission of virus from mother to baby will allow ultimate prevention of neonatal HSV infection.

ACKNOWLEDGMENTS

The section describing CMV was supported in part by grants from the National Institutes of Health, NICHD (HD10699), and General Clinical Research Center (MOI RROO32). Dr. Whitley is indebted to the members of the National Institute of Allergy and Infectious Diseases Collaborative Antiviral Study Group for their support and assistance in developing the database that provided the basis for this report, in particular Dr. C.A. Alford, Jr., and Dr. A.J. Nahmias. In addition, he is exceedingly grateful for the assistance of Arlene Abrams and Rhonda Morrow-Clements.

Studies performed by Dr. Whitley and reported in this chapter were supported in part by research grant RR-032 from the Division of Research Resources, National Institutes of Health, grant CA-13148 from the National Cancer Institute, a contract, NOIA1-62554, from the Development and Applications Branch from the National Institute of Allergy and Infectious Diseases, and a grant from the state of Alabama.

Dr. Bradford is supported through fellowship grants from the Dixon Foundation and the Pediatric Infectious Diseases Society.

85 Pregnancy and Perinatal Transmission of HIV Infection

Lynne M. Mofenson

INTRODUCTION

An estimated 39.5 million people are living with HIV infection; in 2006 alone, there were 4.3 million new infections and 2.9 millions deaths due to HIV. The HIV epidemic is increasingly affecting women and girls; globally, just under half of all people living with HIV are female.[1] In sub-Saharan Africa, women make up 59% of all persons infected with HIV and 76% of youth aged 15–24 years.[1] The predominant mode of HIV acquisition in women is heterosexual contact, and the majority of women are of childbearing age. Thus, the combination of pregnancy and HIV infection is increasingly common.

An estimated 2.3 million children are infected with HIV, predominantly through mother-to-child transmission (MTCT). In 2006, an estimated 530,000 children were newly infected with HIV; about 90% of such infections occurred in sub-Saharan Africa.[1] Prior to the development of effective interventions to reduce MTCT, the estimated rates of transmission ranged from 15% to 25% in nonbreastfeeding women in the United States and other resource-rich countries and 25–40% in breastfeeding women in resource-limited countries. In the last decade, there has been impressive success in the United States and other resource-rich countries in reducing incident pediatric HIV-1 infections and a concomitant dramatic decrease in the incidence of new cases of pediatric AIDS. In 1994, Pediatric AIDS Clinical Trials Group (PACTG) protocol 076 showed that administration of zidovudine (ZDV) to the HIV-infected woman during pregnancy and labor and to her newborn decreased the risk of perinatal HIV transmission.[2] With the implementation of recommendations for universal prenatal HIV counseling and testing, antiretroviral prophylaxis, elective cesarean delivery, and avoidance of breastfeeding, perinatal HIV infection has dramatically diminished to less then 2%.[3]

Clinical trials have also identified effective, simple, and less expensive antiretroviral prophylaxis regimens more relevant to resource-limited countries. However, implementation of these regimens has been slow, and postnatal transmission of HIV through breastfeeding remains a significant problem in such settings, where it is estimated that 1750 infants with HIV infection continue to be born every day.

The obstetrician has a key role in educating women to prevent HIV acquisition, providing state-of-the-art care to HIV-infected women who become pregnant to optimize their health, and in prevention of MTCT. This chapter will discuss HIV testing in pregnancy: the potential impact of pregnancy on HIV infection and maternal health, the potential impact interaction between HIV and pregnancy, MTCT and prevention of MTCT, and the general approach to care and treatment of the HIV-infected woman during pregnancy, including antiretroviral therapy for treatment of the mother and prevention of MTCT. This chapter will focus on management of the HIV-infected pregnant women in the United States and other resource-rich countries but will also briefly discuss management in resource-limited settings.

HIV TESTING IN PREGNANCY

Identification of HIV infection during pregnancy is important both from the maternal health perspective and for prevention of MTCT. Ideally, all women should be screened prior to pregnancy to allow informed decisions regarding pregnancy and optimize maternal health status prior to pregnancy for those women who wish to become pregnant. If not screened prior to pregnancy, all women should be screened for HIV during an initial prenatal visit, as antiretroviral therapy to prevent MTCT is most effective when it is initiated early in pregnancy. The Centers for Disease Control and Prevention (CDC), the American College of Obstetricians and Gynecologists (ACOG), and the American Academy of Pediatrics (AAP) recommend universal and routine offering of HIV testing with patient notification ("opt out") to all pregnant women in the United States.[4–6] Universal antenatal HIV screening has been shown to be cost effective even in settings with very low HIV seroprevalence in pregnant women.[7] Data indicate that use of "opt-out" testing policies can improve uptake rates of testing and is recommended.[5,8,9] "Opt-out" testing with patient notification means that the

HIV test is part of the routine battery of standard antenatal tests, and women are informed that the HIV test is being done and that they may refuse the test. Universal incorporation of HIV testing as part of routine prenatal testing avoids stigmatization based on perceived risk behavior or ethnic group, reduces the cost of testing, and deals with potential geographic shifts in epidemiology.

The use of enzyme immunoassay followed by confirmatory western blot or immunofluorescent assay remains the standard method for diagnosis of HIV infection in pregnant and nonpregnant women, with sensitivity and specificity above 99%.[10] The diagnostic accuracy of standard HIV testing is similar for pregnant and nonpregnant persons, although indeterminate Western blots may occur slightly more frequently in pregnancy.[11]

Repeat HIV testing is recommended in the third trimester for women with initially negative HIV antibody tests who are at high risk of HIV infection (e.g., history of sexually transmitted infection, illicit drug use or exchange of sex for money or drugs, multiple sex partners during pregnancy or a sex partner known to be HIV positive or at high risk, or signs/symptoms suggestive of acute HIV infection), who are in health-care facilities where the seroprevalence of HIV in childbearing-aged women is high (>0.5%), or who have declined testing earlier in pregnancy.[5,12] There are data suggesting that the risk of HIV acquisition may be significantly higher during pregnancy than in the postpartum period. The Rakai Community Cohort Study in Uganda found that the HIV incidence rates were 2.3 per 100 person years during pregnancy, 1.3 per 100 person years during breastfeeding, and 1.1 per 100 person years in the nonpregnant, nonlactating women.[13]

Women who present in labor without prenatal care are at increased risk of HIV infection. The CDC has reported that 15% of HIV-infected women had no prenatal care, with women who used illicit drugs being at greatest risk of lacking care.[14] Data from several studies indicate that 40–85% of infants infected with HIV in recent years were born to women whose HIV infection status was unknown prior to delivery.[5] Starting antiretroviral therapy during labor and delivery or even providing it to the newborn within hours after birth can significantly reduce MTCT.[15–17] To maximize this benefit, routine offering of rapid HIV testing to women whose HIV status is unknown during labor and delivery has been shown to yield accurate and timely results; be feasible, acceptable to women,[18] and cost effective[19]; and is recommended by the CDC, ACOG, and AAP.[4–6,20] Rapid HIV antibody tests that can provide results in 5–20 minutes are now commercially available. While a positive rapid test needs to be confirmed by a supplemental test such as Western blot, because of the importance of rapid initiation of antiretroviral prophylaxis to prevent MTCT, if a rapid test is positive, antiretroviral prophylaxis can be initiated in the mother and the infant while the results of the confirmatory test are pending.[5,20] If the confirmatory test turns out to be negative, then treatment of the infant can be discontinued.

EFFECT OF PREGNANCY ON HIV DISEASE

Data on the impact of pregnancy on progression of HIV disease are mixed, with results differing in resource-rich and resource-limited countries. CD4 lymphocyte count tends to drop during pregnancy in both HIV-infected and HIV-uninfected pregnant women, although the absolute number is significantly lower in HIV-infected pregnant women[21–25]; CD4 lymphocyte percentage tends to be more stable. Theoretically, the drop in CD4 count could allow enhanced viral replication and disease progression, and antigenic stimulation by fetal tissues during pregnancy could lead to T-cell activation and viral replication.

Reports from resource-limited countries suggest a possible increased progression in HIV disease and HIV-related mortality during pregnancy.[26,27] However, it is difficult to interpret these reports because sample sizes are small and subject to selection bias related to the indications for testing.[28,29] However, larger studies from Europe and United States do not show clearly that pregnant women have more rapid progression to an AIDS-defining illness or death than nonpregnant women.[30–32] Thus, at least in resource-rich countries, pregnancy does not appear to accelerate HIV progression or maternal mortality when appropriate care and access to medication are ensured. Additionally, no clear benefit from pregnancy termination on maternal health of HIV-infected women has been shown.[32]

A small, nonsignificant decline in HIV RNA levels during pregnancy with a modest but significant increase in HIV RNA levels (approximately 0.2–0.5 log copies/mL) in the first 3 months postpartum has been reported in infected women, both in those receiving no therapy and also in those receiving and continuing therapy postpartum.[33–35] These data suggest that this increase may be related to physiologic changes during pregnancy that reverse postpartum. However, the clinical significance of this finding is unclear.

EFFECT OF HIV ON FERTILITY AND PREGNANCY OUTCOME

A reduction in fertility has been noted in HIV-infected compared to HIV-uninfected women in the United States, although specific rates of miscarriage, abortion, ectopic pregnancy, and stillbirth among HIV-infected women do not appear to be significantly different from those in HIV-uninfected women.[36] Similar reductions in fertility have been reported in studies from Africa, with the greatest decrease in fertility being observed in women with more advanced HIV disease.[37–40] However, higher pregnancy rates have been reported in women in the highly active antiretroviral therapy

(HAART) era than the pre-HAART era, as rates of immune suppression and disease progression decrease and survival lengthens secondary to therapy, and more women may be choosing to become pregnant.[41]

The data on the effect of HIV (and HIV-related therapies) on pregnancy outcome, such as prematurity, low birth weight, and stillbirth, are mixed. Controlled studies in resource-rich countries prior to routine antiretroviral use have generally not shown an increase in the frequency of prematurity, low birth weight, or intrauterine growth restriction associated with HIV infection.[32] However, the rates of these adverse outcomes in both the HIV-infected and the control groups in these studies were relatively high, possibly due to high rates of coexisting conditions that have traditionally been shown to be independently associated with such outcomes in both groups. Studies that have evaluated risk factors for preterm birth and low birth weight in HIV-infected pregnant women have found that they are similar to those identified among uninfected women, including previous adverse outcomes, hypertension, minority race/ethnicity, smoking, cocaine or opiod use, multiple gestation, bleeding during pregnancy, and *Trichomonas vaginalis* infection.[42,43]

In contrast, controlled studies in resource-limited countries, where the rates of adverse outcomes even in the absence of HIV infection are high, have generally shown higher frequencies of adverse outcomes in HIV-infected women compared to those without HIV infection.[29,44] HIV-infected women with more advanced disease and/or immunosuppression generally had higher rates of adverse outcomes.

The data concerning the effect of antiretroviral therapy, and particularly combination antiretroviral therapy, on pregnancy outcome are also mixed and appear to differ between Europe and the United States.[45–47] It is important to note that the contribution of maternal HIV disease stage and other covariates that might be associated with risk for adverse pregnancy outcome in many of these studies is unclear; as discussed earlier, studies have shown elevated preterm birth rates in HIV-infected women who have not received any antiretroviral therapy.[29,44,48] This is discussed further in the section on antiretroviral therapy in this chapter.

No studies have indicated that there is an increase in the frequency of birth defects related to HIV infection itself.[32] Issues related to antiretroviral therapy and congenital birth defects are discussed in the section on antiretroviral therapy in this chapter.

MOTHER-TO-CHILD HIV TRANSMISSION

MTCT of HIV is the most common mode of acquisition of HIV infection in children worldwide. The risk of MTCT varies geographically, with rates in the absence of intervention ranging between 15–25% in resource-rich and 25–40% in resource-limited countries. Although there may be variation in various risk factors for MTCT in different geographic areas, breastfeeding practices likely account for the majority of differences in MTCT rates between resource-rich and resource-limited countries. In countries like the United States, where formula feeding is accessible, affordable, safe, and sustainable, complete avoidance of breastfeeding by HIV-infected women is recommended, thereby preventing postnatal infection. However, in resource-limited settings, clean water and a sustainable source of formula may not be available or affordable, formula feeding may not be a socially acceptable practice (or would identify a woman as HIV infected), and early infant mortality due to infectious diseases may be high and hence the early protective effect of breastfeeding against diarrheal and respiratory infections during the early months of life is important.[49] In such settings, breastfeeding is nearly universal, and interventions to make breastfeeding safer in terms of HIV transmission are critically needed.

RISK FACTORS FOR HIV MTCT

HIV can be transmitted throughout pregnancy, during labor and delivery, and postpartum through breast milk. Different risk factors may influence HIV-1 transmission during each of these time periods, and different approaches may be required for prevention of transmission during each period. However, maternal plasma HIV-1 viral load has consistently been a strong independent predictor of transmission risk regardless of timing of transmission or antiretroviral use.[3,50,51] Therefore, it would be expected that interventions that reduce viral load might reduce the risk of transmission during each of these periods. Table 85-1 lists key factors during pregnancy, labor and delivery, and breastfeeding that increase risk of HIV MTCT, which are discussed in more detail below.

In utero and intrapartum transmission

In the absence of breastfeeding and antiretroviral prophylaxis, the majority of MTCT of HIV occurs during the intrapartum period; in utero transmission proportionally accounts for 25–30% and intrapartum transmission for 65–70% of transmission.[52]

While HIV transmission can occur at any time during pregnancy, the majority of in utero transmission is thought to occur late in pregnancy.[53,54] During pregnancy, the placenta provides an important physical and immune barrier between maternal and fetal circulations, and also apparently against in utero HIV-1 infection, as the absolute rate of in utero transmission is only 5–10%.[52] The exact mechanisms of in utero transmission are not known, but factors that disrupt placental integrity, such as chorioamnionitis, might be expected to play a role.[55,56] Viral characteristics, such as viral subtype or cellular tropism, and host genetic factors, such as HLA or chemokine receptor genotype, have been reported in some studies to influence in utero transmission.[57–62]

Table 85-1. Key Risk Factors Influencing the Risk of Mother-to-Child HIV Transmission

Risk factors during pregnancy
- High maternal viral load in plasma
- Low maternal CD4 count
- Advanced maternal HIV disease (e.g., AIDS and wasting)
- Placental infection (e.g., sexually transmitted diseases and malaria)
- Viral characteristics (e.g., tropism, chemokine receptor usage, and viral subtype)
- Host genetic factors (maternal/infant HLA)?

Risk factors during labor and delivery
- High maternal viral load in genital secretions
- Vaginal delivery
- Prolonged duration of membrane rupture
- Chorioamnionitis
- Invasive delivery procedures (e.g., fetal scalp electrodes)
- Prematurity and low birth weight

Risk factors during breastfeeding
- High maternal viral load in plasma and/or breast milk
- Low maternal CD4 count
- Advanced maternal HIV disease (e.g., AIDS or wasting)
- Duration of breastfeeding
- Clinical or subclinical mastitis or breast abscess
- Cracked or bleeding nipples
- Infant oral disease (e.g., thrush or mouth sores)
- Mixed infant feeding (i.e., breast milk plus other liquids, nonhuman milk or foods)

There are several mechanisms by which intrapartum transmission can occur: by direct access of cell-free or cell-associated virus to the infant systemic circulation through maternal–fetal transfusions that occur during uterine contractions in labor or by the infant swallowing HIV in genital tract fluids during delivery, with viral passage through the infant's gastrointestinal mucosa to underlying lymphoid cells, followed by systemic dissemination. Consistent with the importance of intrapartum viral exposure, genital tract cell-associated and cell-free virus has been shown to be risk factors for MTCT, independent of plasma viral load.[51,63–65] The proven efficacy of interventions restricted to the intrapartum period to reduce MTCT, such as intrapartum/neonatal antiretroviral prophylaxis or elective cesarean delivery performed prior to labor and rupture of membranes, illustrates the importance of the intrapartum period in transmission.[15,16,66,67]

The Women and Infants Transmission Study has evaluated risk factors for in utero and intrapartum transmission in 1709 infants with known infection status, born between 1990 and 2000.[50] Both in utero and intrapartum transmission were associated with maternal antenatal viral load and use of antiretroviral therapy. After controlling for maternal viral load and antiretroviral therapy, low birth weight was significantly associated with in utero transmission, while maternal age, antenatal $CD4^+$ count, year of birth, preterm delivery, birth weight, and duration of membrane rupture were associated with intrapartum transmission.

Postnatal transmission

Breastfeeding substantially increases the risk of HIV transmission; postnatal infection can account for 30–50% of all MTCT in breastfed infants.[52,68] Antiretroviral regimens that have proven efficacy for prevention of in utero and intrapartum transmission show a significant diminution of efficacy over time in breastfeeding infants.[16,69,70] Thus, to achieve optimal prevention of MTCT in a breastfeeding setting, additional interventions will be needed to reduce postnatal transmission.

Transmission of HIV through breast milk can occur at any point during lactation. Determining the timing of breast milk transmission has been complicated by the difficulty in distinguishing between intrapartum and early breast milk transmission. Data from several studies that compared transmission among breast- and formula-fed infants suggest that the first 6–8 weeks of life may be a particularly high-risk period.[71] In a randomized trial of breast versus formula feeding in Kenya, the SAINT perinatal study of intrapartum–postpartum regimens

for prevention of MTCT, and an observational study in Uganda, the differences in infection rates between breast- and formula-fed infants by age 6–8 weeks were 6.0%, 5.6%, and 9.5%, respectively, with much lower postnatal transmission rates after this time.[72–74]

Most studies have focused on postnatal transmission occurring after age 1 month. The largest study was the Breastfeeding and HIV International Transmission Study, an individual patient meta-analysis of data from over 4000 children in nine clinical trials in breastfeeding populations.[75] Of 539 HIV-infected children with known timing of infection, 225 (42%) had late postnatal transmission (occurring after age 1 month). The overall risk of late postnatal transmission was 8.9 infections per 100 child years of breastfeeding, with the risk being generally constant throughout the breastfeeding period. The cumulative probability of late postnatal infection at age 18 months was 9.3%.

In addition to duration of infant breastfeeding, risk factors for breast milk transmission include high maternal viral load, both in plasma and in breast milk; low CD4 lymphocyte count; breast milk immunologic factors; breast pathology such as clinical and subclinical mastitis, nipple bleeding, cracked nipples, or breast abscess; and infant pathology that may disrupt mucosal integrity, such as thrush.[68,71] More controversial is the role of infant feeding pattern. Several studies have suggested that exclusive breastfeeding during the first few months of life is associated with lower risk of postnatal transmission than mixed feeding of breast milk combined with nonhuman milk, fluids, or other foods.[76,77] The largest study, conducted in Zimbabwe, included 2060 HIV-exposed infants who were HIV uninfected at age 6 weeks; the rate of late postnatal transmission was 1.3% at age 6 months and 6.9% at age 18 months in exclusively breastfed infants compared to 4.4% and 13.9%, respectively, in infants with mixed feeding.[77] It is hypothesized that mixed feeding may result in disruption and damage to the neonatal gut epithelium, thereby making HIV transmission more likely. While this remains controversial, in areas where safe substitutes to breast milk cannot be ensured, exclusive breastfeeding is recommended among HIV-infected women due to its general health benefits in terms of optimally reducing infant morbidity and mortality not related to HIV.[49]

PREVENTION OF MOTHER-TO-CHILD HIV TRANSMISSION

The most effective way to prevent HIV MTCT is through primary prevention of HIV infection among women. Additionally, among women who are HIV infected, prevention of unintended pregnancy through provision of family planning and contraception services is important.

For the woman who is HIV infected and pregnant, the most successful intervention to reduce MTCT is the use of antiretroviral drugs. Additionally, elective cesarean delivery has proven to be effective in reducing intrapartum MTCT in areas where safe operative delivery is possible. A number of additional nonantiretroviral interventions have also been studied but not yet proven to be effective, such as nutritional supplementation, vaginal virucidal cleansing, and empiric antibiotics to prevent chorioamnionitis. The next two sections of this chapter will review studies of the efficacy of these antiretroviral and nonantiretroviral interventions.

ANTIRETROVIRAL INTERVENTIONS TO REDUCE MOTHER-TO-CHILD HIV TRANSMISSION

One of the seminal achievements in HIV research was the demonstration by PACTG 076 that administration of AZT to the pregnant woman and her infant could reduce the risk of MTCT by nearly 70%.[2] In PACTG 076, AZT was started at 14–34 weeks' gestation, given intravenously to the mother during labor and administered for 6 weeks to the infant.

Following the results of PACTG 076, in the United States and other countries with higher-level resources, implementation of the AZT regimen coupled with increased antenatal HIV counseling and testing rapidly resulted in significant declines in transmission in these countries.[3,78,79] Subsequent clinical trials and observational studies demonstrated that combination antiretroviral prophylaxis (initially dual and then triple combination therapy) given to the mother antenatally was associated with further declines in transmission to under 2%.[3,80,81] It is currently estimated that fewer than 400 infected infants are currently born each year in the United States.[78] However, while new perinatal HIV infections are becoming rare in resource-rich countries, infections continue to occur, and the birth of an infected infant is a sentinel event, representing missed opportunities and barriers to prevention.[82,83] Important barriers to eradication of MTCT in the United States include the continued increase of HIV infection among women of childbearing age; delayed or lack of prenatal care, particularly in women using illicit drugs; and lack of full implementation of routine, universal prenatal HIV counseling and testing.[83]

The complexity and cost of the three-part PACTG 076 regimen significantly limit its applicability and implementation within resource-constrained settings. Thus, researchers began to explore the development of shorter, less expensive prophylactic regimens more applicable to resource-constrained settings. Clinical trials initially focused on shortened AZT-alone prophylaxis regimens and moved to evaluating whether combination antiretroviral regimens, such as short-course AZT combined with lamivudine 3TC, might have improved efficacy over AZT alone. Studies also evaluated whether even simpler, less expensive, single-drug regimens, such as single-dose intrapartum/neonatal nevirapine (NVP), would be

effective and whether combining such regimens with other short-course regimens might result in improved efficacy.

MECHANISMS OF ACTION OF ANTIRETROVIRAL PROPHYLAXIS IN REDUCING MTCT

There are a number of mechanisms through which AZT or other antiretroviral drugs can reduce MTCT. An important mechanism is by decreasing maternal viral load in the blood and genital secretions through antenatal drug administration to the mother[84]; it is likely that lowering maternal viral load by antenatal antiretroviral therapy is a critical component of protection, particularly in women with high viral loads. However, antiretroviral drugs have been shown to reduce the risk of transmission even among women with HIV-1 RNA levels <1000 copies/mL.[85] Additionally, the level of HIV-1 RNA at delivery and receipt of antenatal antiretroviral therapy are each independently associated with the risk of transmission, suggesting that antiretroviral prophylaxis does not work solely through reduction in viral load.[3]

An additional mechanism of protection is "preexposure" infant prophylaxis provided by administration of antiretroviral drugs that cross the placenta of the mother during labor, resulting in systemic drug levels in the infant at a time of intensive exposure to maternal genital tract virus during passage through the birth canal. Postexposure infant prophylaxis is provided through administration of drug to the infant after birth; this would protect against cell-free or cell-associated virus that might have obtained access to the fetal/infant systemic circulation through maternal–fetal transfusion during uterine contractions occurring in labor, or through systemic dissemination of virus swallowed by the infant during passage through the birth canal.

It is likely that efficacy of antiretroviral drugs in reducing MTCT is multifactorial, and each of these mechanisms is contributory. The efficacy of antiretroviral regimens administered only during labor and to the newborn or only to the newborn in reducing MTCT, as discussed below, demonstrates the importance of the pre- and postexposure components of prophylaxis in reducing MTCT.[15–17,73,86–88]

CLINICAL TRIALS OF SHORT-COURSE REGIMENS FOR PREVENTION OF HIV MTCT

Table 85-2 summarizes the results of the major clinical trials of antiretroviral interventions for the prevention of MTCT, which have built sequentially on each other. A number of simple regimens have been identified that are effective in reducing MTCT. Because the studies involved different patient populations residing in different geographic locations, infected with different viral subtypes and having different infant feeding practices, making direct comparison of results between trials difficult. However, some general conclusions can be drawn from the study results.

Short-term efficacy has been demonstrated for a number of short-course antiretroviral regimens, including those with AZT alone, AZT plus 3TC, single-dose NVP, and, more recently, combining single-dose NVP with either short-course AZT or AZT/3TC.[15,16,69,70,73,89–92] In general, combination regimens are more effective than single-drug regimens in reducing MTCT, and when it is feasible and affordable, a longer three-part regimen given antenatally, intrapartum, and postpartum is superior in preventing MTCT than a shorter two-part antepartum/intrapartum or intrapartum/postpartum regimen.[16,92]

Almost all trials have included an oral intrapartum prophylaxis component, with varying durations of maternal antenatal and/or infant (and sometimes maternal) postpartum prophylaxis. MTCT is reduced by regimens with antenatal components starting as late as 36 weeks of gestation and lacking an infant prophylaxis component.[69,89] However, longer duration of antenatal therapy (starting at 28 weeks' gestation) is more effective than shorter (starting at 36 weeks' gestation), suggesting that a significant proportion of in utero transmission occurs between 28 and 36 weeks of gestation.[90] More prolonged postexposure prophylaxis of the infant does not appear to substitute for longer duration of maternal therapy.[90]

Because some women may lack antenatal care and first present to the health-care system during labor, regimens that do not include maternal therapy during pregnancy have been evaluated; in many resource-limited settings, this may constitute the majority of pregnant women. Regimens that include only intrapartum and postpartum drug administration have also been shown to be effective in reducing MTCT.[15,16,73] However, intrapartum "preexposure" prophylaxis alone, without continued postexposure prophylaxis of the infant, is not effective.[16] The SAINT trial demonstrated that the two proven effective intrapartum/postpartum regimens (AZT/3TC or NVP) are similar in efficacy and safety.[73]

In some situations, maternal intrapartum therapy may not be possible, and only infant prophylaxis can be provided. Based on epidemiologic data,[17] in resource-rich countries, the standard prophylaxis regimen in the absence of maternal therapy is 6 weeks of infant AZT. To define the optimal infant prophylaxis regimen in these settings, an ongoing study in infants born to women who have not received antenatal therapy is comparing the standard 6-week infant AZT regimen to 6 weeks of AZT combined with either three NVP doses during the first week of life or 2 weeks of nelfinavir (NFV) and 3TC. In resource-limited settings, administration of even 6 weeks of infant AZT may be difficult to achieve, and single-dose NVP is widely used. In a study in South Africa, administration of a single-dose infant NVP given within 24 hours of delivery was compared with 6 weeks of infant AZT therapy in infants born to mothers who did not receive antenatal or intrapartum therapy; overall MTCT rates were not significantly different.[88] A trial in Malawi

Table 85-2. Clinical Trials of Antiretroviral Drugs for Prevention of Mother-to-Child HIV-1 Transmission

Study/Reference/ Location/Infant Feeding	Regimen	Antenatal/Intrapartum	Postpartum	Efficacy
PACTG 076[2] United States, France Formula feeding	AZT vs. placebo	Long (from 14 wk) Intravenous intrapartum	Long (6 wk) (Infant only)	MTCT at 18 mo, 7.6% AZT vs. 22.6% placebo (68% efficacy).
Bangkok Short-Course AZT Trial[89] Thailand Formula feeding	AZT vs. placebo	Short (from 36 wk) Oral intrapartum	None	MTCT at 6 mo, 9.4% AZT vs. 18.9% placebo (50.1% efficacy).
Thai Perinatal HIV Prevention Trial (PHPT-1)[90] Thailand Formula feeding	AZT different length AP and infant PP regimens, no placebo	Long (from 28 wk) Short (from 36 wk) Oral intrapartum	Long (for 6 wk) Short (for 3 d) (Infant only)	Short–short stopped early due to significantly higher MTCT (10.5%). MTCT at 6 mo, 6.5% long–long vs. 4.7% long–short vs. 8.6% short–long (statistical equivalence). However, in utero transmission significantly lower with long vs. short maternal antenatal AZT (1.6% vs. 5.1%).
Ivory Coast Short-Course AZT Trial[69,70] Ivory Coast Breastfeeding	AZT vs. placebo	Short (from 36 wk) Oral intrapartum	None	MTCT at 3 mo, 15.7% AZT vs. 24.9% placebo (37% efficacy).
DITRAME/ANRS 049a[70] Ivory Coast/Burkina Faso Breastfeeding	AZT vs. placebo	Short (from 36 wk) Oral intrapartum	Short (1 wk) (Mother only)	MTCT at 6 mo, 18.0% AZT vs. 27.5% placebo (38% efficacy); MTCT at 15 mo, 21.5% vs. 30.6% (30% efficacy). MTCT at 24 mo (pooled analysis with other Ivory Coast trial) 22.5% vs. 30.2% (26% efficacy).
PETRA[16] South Africa, Tanzania and Uganda Breastfeeding (74%) and formula feeding	AZT + 3TC in three regimens (three-part ante/intra/postpartum; two-part intra/ postpartum; intrapartum) vs. placebo	Short (from 36 wk) Oral intrapartum	Short (7 d) (Mother and infant)	MTCT at 6 wk, 5.7% three-part (63% efficacy) vs. 8.9% two-part (42% efficacy) vs. 14.2% intrapartum vs. 15.3% placebo. MTCT at 18 mo, 14.9% three-part vs. 18.1% two-part vs. 20% intrapartum vs. 22.2% placebo.
HIVNET 012[15] Uganda Breastfeeding	Intrapartum/postpartum NVP vs. AZT	No antenatal ARV Oral intrapartum: single oral dose NVP 200 mg vs. AZT	Single-dose NVP 2 mg/kg within 72 h of birth vs. short AZT (7 d) (Infant only)	MTCT 15.7% in NVP arm vs. 5.8% in AZT arm (41% efficacy) at 18 mo.
PACTG 316[81] (United States, Europe, Brazil, Bahamas) Formula feeding	Intrapartum/postpartum NVP vs. placebo in women already receiving AZT or AZT plus other ARV (77% on combination therapy)	Nonstudy antepartum ARV. Intrapartum: single-dose NVP 200 mg + intravenous AZT	Single NVP dose 2 mg/kg within 72 hof birth + 6 wk AZT (Infant only)	Trial stopped early due to very low MTCT in both arms. MTCT at 6 mo, 1.4% NVP vs. 1.6% placebo.

Table 85-2. *(Continued)*

Study/Reference/ Location/Infant Feeding	Regimen	Antenatal/Intrapartum	Postpartum	Efficacy
SAINT[73] South Africa Breastfeeding (42%) and formula feeding	Intrapartum/ postpartum NVP vs. AZT + 3TC	No antenatal ARV Oral intrapartum: single-dose NVP 200 mg vs. AZT + 3TC	Single NVP dose within 48 h of birth vs. short AZT + 3TC (7 d) (mother and infant)	MTCT at 8 wk, 12.3% NVP vs. 9.3% AZT + 3TC
Thai Perinatal HIV Prevention Trial-2 (PHPT-2)[91] Thailand Formula feeding	AZT vs. AZT + maternal/ infant single-dose NVP vs. AZT + maternal single-dose NVP only	Long (AZT from 28 wk) Oral intrapartum: AZT + single-dose NVP or placebo	1 wk AZT alone vs. 1 wk AZT + single-dose NVP (infant only)	AZT alone arm stopped early due to significantly higher MTCT: MTCT at 6 mo, 6.3% AZT alone vs. 1.1% with AZT plus maternal/ infant NVP vs. 2.1% with AZT plus maternal NVP alone. Final analysis, MTCT at 6 mo, 2.8% with AZT plus maternal NVP only vs. 1.9% with AZT plus maternal/infant NVP.
DITRAME PLUS/ANRS 1201.0[92] Abidjan, Cote d'Ivoire Breastfeeding (54%) and formula feeding	Open label, AZT boosted by intrapartum/ postpartum NVP	Short (from 36 wk) Oral intrapartum: single-dose NVP 200 mg + AZT	Single-dose NVP, + 1 wk AZT (Infant only)	MTCT at 6 wk, 6.5% (95% CI, 3.9–9.1%). Compared to MTCT in historical control AZT alone (1995–2000) 12.8% (in AZT alone group, breastfeeding rate was 97.6%).
DITRAME PLUS/ANRS 1201.192 Abidjan, Cote d'Ivoire Breastfeeding (66%) and formula feeding	Open label, AZT + 3TC boosted by intrapartum/ postpartum NVP	Short (from 32 wk). Oral intrapartum: single-dose NVP 200 mg + AZT + 3TC	AZT + 3TC for 3 d (Mother only) Single-dose NVP + 1-wk AZT (Infant only)	MTCT at 6 wk, 4.7% (95% CI, 2.4–7.0%). MTCT not significantly different than observed with DITRAME 1201.0 regimen AZT + single-dose NVP ($p = 0.34$).
SIMBA[96] Rwanda, Uganda Breastfeeding (median duration 3.3–3.5 mo, upper range 4.9–5.3 mo)	NVP vs. 3TC for 6 mo postnatally in breastfeeding neonates exposed antenatally to AZT + ddI	Short (AZT + ddI from 36 wk). Intrapartum: oral AZT + ddI	AZT + ddI for 1 wk postpartum (Mother only) NVP once then twice daily vs. 3TC twice daily while breastfeeding (Infant only)	MTCT at 6 mo, 7.8%, no difference between the two infant arms. MTCT by age (note median duration of breastfeeding 3.3–3.5 mo): MTCT birth (to 3 d), 5.3%; MTCT 4.28 d, 1.6%; MTCT 1–6 mo, 0.9% Overall, postpartum to 6 mo, 2.4%
NVAZ-1[86] Malawi Breastfeeding	Neonatal single-dose NVP only vs. NVP + AZT	No ARV antepartum or intrapartum (late presenters)	Single-dose NVP immediately after birth + AZT twice daily for 1 wk (Infant only)	Overall MTCT at 6–8 wk, 15.3% NVP + AZT vs. 20.9% NVP only. MTCT at 6–8 wk in babies who were uninfected at birth, 7.7% NVP + AZT vs. 12.1% NVP only (36% efficacy).
NVAZ-2[87] Malawi Breast feeding	Neonatal single-dose NVP only vs. NVP + AZT	No ARV antepartum Intrapartum: single-dose NVP to mother	Single-dose NVP immediately after birth + AZT twice	Overall MTCT at 6–8 wk, 16.3% NVP + AZT vs. 14.1% NVP only. MTCT at 6–8 wk in

Table 85-2. *(Continued)*

Study/Reference/ Location/Infant Feeding	Regimen	Antenatal/Intrapartum	Postpartum	Efficacy
			daily for 1 wk (Infant only)	babies who were uninfected at birth, 6.9% NVP + AZT vs. 6.5% NVP only.
MASHI[93] Botswana Breastfeeding and formula feeding (randomized)	Factorial design, randomized to mode of infant feeding and maternal/infant single-dose NVP vs. placebo Infant placebo discontinued 08/02 (after PHPT-2 results), study modified to maternal NVP vs. placebo, with all infants receiving single-dose NVP	Short (AZT from 34 wk) Oral intrapartum: AZT + single-dose NVP or placebo	Single-dose NVP + 1 mo AZT if formula feeding Single-dose NVP + 6 mo AZT if breastfeeding (infant only)	*Original study* (maternal/infant NVP vs. placebo): Added efficacy from NVP in formula but not breastfed infants. MTCT at 1 mo, formula-fed infants, 2.4% NVP/NVP vs. 8.3% PL/PL; breastfed infants, 8.4% NVP/NVP vs. 4.1% PL/PL. *Revised study* (maternal NVP vs.placebo, all infant NVP): No added efficacy from maternal NVP regardless infant feeding mode. MTCT at 1 mo, 4.3% NVP/NVP vs. 3.7% PL/NVP. *Infant feeding:* Breastfeeding + AZT higher MTCT than formula. MTCT at 7 mo, 9.1% breastfeeding + AZT vs. 5.6% formula.However, higher infant mortality with formula at 7 mo, 9.3% formula vs 4.9% breastfeeding + AZT 18-mo. HIV-free survival did not differ by arm: MTCT/death at 18 mo, 14.2% formula (33 infected, 46. deaths) vs 15.6% breastfeed + AZT (54 infected, 34 deaths).
South Africa[88] Breastfeeding (15%) and formula feeding	Neonatal single-dose NVP vs. neonatal AZT	None	Single-dose NVP within 24 h of birth vs. AZT twice daily for 6 wk (infant only)	Overall MTCT at 6 wk, 11.9% NVP vs. 13.6% with AZT; at 12 wk, 14.3% NVP vs. 18.1% AZT; no significant differences. MTCT at 6 wk in babies who were uninfected at birth, 5.3% NVP vs. 8.2% AZT; at 12 wk 7.9% NVP and 13.1% AZT. Stratified by mode of infant feeding, NVP appeared superior to AZT in breastfed infants ($p = 0.03$) but not formula-fed infants ($p = 0.3$).

MTCT, mother to child HIV-1 transmission; AZT, zidovudine; 3TC, lamivudine; NVP, nevirapine; PL, placebo.

compared single-dose infant NVP to combination of single-dose NVP with a week of AZT therapy when no antenatal maternal therapy was received. The addition of 1 week of AZT therapy to infant single-dose NVP reduced the risk of transmission by 36%, compared to infant single-dose NVP alone.[86] However, when maternal intrapartum NVP was received, thereby providing "preexposure" prophylaxis in addition to postexposure prophylaxis, the infant single-dose NVP alone was as effective as the combined NVP/AZT infant postexposure prophylaxis regimen.[87]

In an attempt to improve the efficacy of short-course regimens but retain a regimen that remains appropriate to the cost limitations existing in resource-limited countries, more recently researchers have evaluated whether the addition of a potent intrapartum intervention—the single-dose NVP regimen—to short-course regimens might increase efficacy. In the setting of short-course antenatal AZT alone or AZT/3TC, the Perinatal HIV Prevention Trial (PHPT)-2 study in nonbreastfeeding women in Thailand, the DITRAME studies in a partially breastfeeding population in the Ivory Coast, and the Mashi study in Botswana (in the formula-fed, but not the breastfed, strata) demonstrated that the addition of single-dose NVP did significantly increase efficacy.[91–93] However, a clinical trial conducted in nonbreastfeeding women in resource-rich countries, PACTG 316, demonstrated that the addition of single-dose NVP did not appear to offer significant benefit in the setting of potent combination antiretroviral therapy throughout pregnancy and very low viral load at the time of delivery.[81] The relative importance of the maternal and infant components of single-dose NVP in the context of short-course AZT regimens remains unclear; the Thailand PHPT-2 study suggests that the infant NVP dose at day 2 of life may not add significant efficacy to the maternal NVP dose alone; however, the Botswana Mashi study suggests that maternal NVP may not be necessary when infant single-dose NVP is provided at birth.[91,93]

Although the short-course regimens identified as effective in nonbreastfeeding populations are also effective in breastfeeding populations, efficacy is diminished over time. The reduction in efficacy is greatest with AZT or AZT/3TC short-course regimens and less with single-dose NVP.[15,16,70] This is likely due to the prolonged half-life of NVP in pregnant women in labor and in neonates, with detectable drug levels that can persist for 2 weeks or longer following a single dose,[94] thereby providing a much longer period of prophylaxis than do nucleoside analogue reverse transcriptase inhibitors (NRTIs) like AZT, which have much shorter half-lives. Consistent with this hypothesis, a study in breastfeeding mother/infant pairs in Kenya found that single-dose maternal/infant NVP was significantly more likely than antepartum/intrapartum AZT to decrease HIV RNA in breast milk during the first through the third week postpartum and was associated with lower transmission at 6 weeks than the AZT regimen.[95]

In breastfeeding populations, several ongoing and planned trials will assess the effect of antiretroviral prophylaxis provided to the breastfeeding infant and/or the mother during lactation, combined with early weaning. Preliminary results from the SIMBA trial suggest that infant prophylaxis may provide some protection against transmission.[96] This study compared 6 months of infant prophylaxis with NVP compared to 3TC in the context of maternal antepartum, intrapartum, and 1-week postpartum combination of AZT and didanosine (ddI). However, the study lacked a control group, had high rates of exclusive breastfeeding (85%) that itself may lower postnatal transmission,[76,77] and a median duration of breastfeeding of only 3.5 months, making interpretation of the results difficult. Several other trials of infant prophylaxis are currently ongoing.

A number of trials will evaluate the effect on the risk of postnatal MTCT of using HAART in breastfeeding women who do not require therapy for their own health; in this case, treatment would be provided solely for reducing breast milk transmission and stopped after weaning.[97] At the present time, there are no data to address the safety and efficacy of this approach. In a study in Botswana, receipt of HAART by lactating women was associated with suppression of cell-free virus (HIV RNA) in breast milk, but not cell-associated virus (HIV DNA).[98] The relative importance of cell-free versus cell-associated virus in breast milk with risk of transmission is not known. Additionally, there is very limited information about penetration of antiretroviral drugs into breast milk. If there were differential penetration, some drugs may have low or undetectable levels while other drugs may have high levels, leading to the potential for developing drug-resistant virus in breast milk as well as the potential for toxicity in the infant. In a study in Botswana in lactating women who received AZT, 3TC, and NVP for treatment of advanced HIV infection, the median breast milk concentration of NVP was only 67% compared to that in plasma, while the levels of 3TC in breast milk were three times higher than those in plasma.[99] Additionally, despite no postnatal infant NVP or 3TC administration, levels of these drugs were unexpectedly high in the infants, nearing levels that might be achieved with therapeutic dosing.[99] In another study in Zimbabwe that evaluated NVP resistance in plasma and breast milk of women who received single-dose NVP, resistance was more common in breast milk than in plasma.[100] Additionally, the resistance mutations were divergent between breast milk and plasma. These data suggest that the breast milk and plasma are separate compartments and that subtherapeutic NVP levels may persist for different periods in milk and plasma, resulting in different patterns of resistance mutations in the virus in each compartment. Therefore, results from clinical trials are needed before recommendations can be made about the efficacy and safety of HAART to reduce breastfeeding transmission in women who do not require it for their own health.

Recommendations for prevention of MTCT in resource-limited countries are based on the results of these studies[101] and are shown in Table 85-3.

SHORT-COURSE ANTIRETROVIRAL PROPHYLAXIS AND ANTIRETROVIRAL DRUG RESISTANCE

Because the short-course antiretroviral drug regimens used for prevention of MTCT do not fully suppress viral replication, there are concerns about the potential for development of antiretroviral drug resistance. This is of most concern for prophylaxis regimens using antiretroviral drugs for which a single-point mutation can confer drug resistance, such as NVP or 3TC. Resistance mutations conferring resistance to NVP can confer cross resistance with other drugs in the nonnucleoside reverse transcriptase inhibitor (NNRTI) class, such as efavirenz (EFV).

In the Ugandan HIVNET 012 study of single-dose intrapartum/newborn NVP for prevention of MTCT, 25% of 279 women receiving single-dose NVP developed detectable NVP resistance mutations by 6 weeks postpartum, most commonly the K103N mutation, and 46% of 24 infants who became infected despite prophylaxis had NVP resistance, most commonly the Y181C mutation.[102,103] In follow-up samples from 12 to 18 months postpartum, resistance mutations were no longer detectable and wild-type virus again predominated in both the mothers and the infants.[102,103] However, using more sensitive assays, resistance may be detected more frequently than detected with standard resistance assays, and very low levels of resistant virus may persist for a prolonged period.[104,105] Factors associated with development of NVP resistance following single-dose exposure include delivery maternal viral load and $CD4^+$ cell count, viral subtype (rates are higher with subtypes D and C than A), time of sampling following exposure (rates are higher closer to time of exposure), number of maternal doses, and possibly body compartment (rates may be higher in breast milk than plasma).[100,102,103,106]

Rapid development of genotypic resistance to 3TC has also been observed when 3TC has been given as part of a nonsuppressive dual NRTI regimen with AZT in pregnant women for prevention of MTCT. In a study in France, where 3TC was added to AZT after 32 weeks of gestation, 39% of 132 women had detectable high-level resistance to 3TC (the M184V mutation) at 6 weeks postpartum and 40% of five infants infected despite prophylaxis had 3TC resistance.[80] Maternal 3TC resistance was only detected in women who had received 3TC for 4 weeks or longer during pregnancy. 3TC resistance was also detected at 1 week postpartum in 12% of women receiving 4 weeks of AZT/3TC for prevention of MTCT in the PETRA study.[107] However, no AZT or 3TC resistance was observed with intrapartum/1-week maternal postpartum AZT/3TC.[107,108] The transient presence of detectable resistance did not have any deleterious short-term clinical effect on infected women or their infants, and despite the high prevalence of 3TC resistance in the French study, the overall MTCT rate in this group was only 1.6%.[80]

However, whether the presence of transient drug resistance may be associated with diminished viral response to subsequent 3TC or NNRTI-based therapy is unknown. In a study in Thailand, response to NVP-based HAART was assessed in immunocompromised women with and without prior single-dose NVP exposure.[109] In those women with prior NVP exposure, the median time following receipt of single-dose NVP to initiation of therapy was only 6 months. Rates of maximal viral suppression (HIV RNA levels <50 copies/mL) after 6 months of NVP-based HAART were lower in women with recent prior single-dose NVP exposure (HIV RNA was <50 copies/mL in 49% of women with and 68% without prior single-dose NVP exposure); however, clinical and immunologic responses were not different.[109] However, in a study from Botswana, exposure to single-dose NVP was associated with higher rates of viral failure only among women who started therapy within 6 months of single-dose NVP exposure, but not among women starting therapy 6 months or more after exposure.[110] Further research is ongoing to more definitively address this issue.

Research is also ongoing to develop interventions to prevent development of resistance following single-dose NVP exposure. Data from a South African study suggest that combining single-dose NVP with AZT/3TC given intrapartum and for 4 or 7 days postpartum significantly reduced (although it did not eliminate) the risk of resistance.[111] NVP resistance was detected at 2 and/or 6 weeks postpartum in 60% of 68 women receiving single-dose NVP without postpartum AZT/3TC, 12% of 67 women who received 4 days of AZT/3TC, and 10% of 68 women who received 7 days of AZT/3TC. Resistance can also occur when NVP-based HAART is discontinued, due to the prolonged half-life of NVP; whether this is decreased by staggered discontinuation of drugs is not clear. Several studies have found that NVP resistance occurs in about 15% of women who stop NVP-based HAART postpartum even if AZT/3TC is continued for 5 days following discontinuation of NVP.[112,113] Given the persistence of NVP levels for up to 21 days after a single dose,[94] the optimal duration of time following single-dose NVP and the optimal regimen for prevention of resistance require further study. Since 3TC resistance can also be conferred by a single mutation, prolonged duration of a dual NRTI regimen containing 3TC also runs the risk of development of 3TC resistance in addition to NVP resistance.

NONANTIRETROVIRAL INTERVENTIONS TO REDUCE MOTHER-TO-CHILD HIV TRANSMISSION

A number of interventions that do not involve antiretroviral drugs have been evaluated for prevention of MTCT. These include elective cesarean delivery, studied in Europe and the

Table 85-3. World Health Organization Recommendations for Antiretroviral Drug Use in HIV-Infected Pregnant Women in Resource-Limited Settings

Clinical Situation	Recommendation
HIV-infected women of childbearing potential and indications for starting therapy	• Antiretroviral regimen choice should follow WHO recommendations. First line regimen for childbearing-age women: AZT + 3TC + NVP. • Avoid drugs with teratogenic potential in women of child-bearing age (EFV) unless adequate contraception can be ensured. Exclude pregnancy before starting treatment with EFV.
HIV-infected women on antiretroviral therapy who become pregnant	***Woman:*** • Continue current regimen except discontinue drugs with teratogenic potential (EFV) or with known adverse potential for the pregnant mother (combination d4T/ddI). • Discontinuation of antiretroviral drugs during the first trimester is not recommended. • Continue antiretroviral regimen during intrapartum period and postpartum. ***Infant:*** • AZT for 1 wk (4 wk of AZT recommended if mother receives <4 wk of antepartum antiretrovirals).
Women first diagnosed with HIV infection during pregnancy with clinical indications for antiretroviral therapy	***Woman:*** • Follow guidelines for non-pregnant women except exclude drugs with teratogenic potential (EFV) or with known adverse potential for the pregnant mother (combination of d4T/ddI). First line regimen: AZT + 3TC + NVP. • For severely ill woman, benefit of therapy exceeds theoretical risk of teratogenicity and therapy can be started in the 1st trimester if needed. • Continue antiretroviral regimen during intrapartum period and postpartum. ***Infant:*** • AZT for 1 wk (4 wk of AZT recommended if mother receives <4 wk of antepartum antiretrovirals).
Pregnant HIV-infected women without indication for antiretroviral therapy	• Initiate antiretroviral prophylaxis to reduce the risk of peripartum mother to child transmission: ***Recommended:*** Short course AZT + single-dose NVP ***Woman:*** AZT starting at 28 wk gestation or as soon as feasible after that; continue with oral AZT during labor plus single-dose NVP at the onset of labor. When possible, intrapartum 3TC plus 1 wk of AZT/3TC should be given to the mother to reduce the risk of NVP resistance. If delivery is imminent, do not give the maternal intrapartum dose but give infant single-dose NVP at birth.

Table 85-3. *(Continued)*

Clinical Situation	Recommendation
	Infant: Single dose NVP plus AZT for 1 wk (4 wk of AZT if mother receives <4 wk antepartum AZT). *Minimum if lack resources for recommended regimen:* Single-dose NVP ***Woman:*** Single-dose NVP at onset of labor. ***Infant:*** Single-dose NVP.
Pregnant women of unknown HIV infection status at time of labor or HIV-infected pregnant women who have not received antepartum antiretroviral drugs	• If there is time, counsel and offer HIV rapid test; if positive, initiate intrapartum prophylaxis. If insufficient time to obtain HIV test result while in labor, offer HIV test as soon as possible after delivery, and follow the recommendations in next scenario. ***Recommended:*** Single-dose NVP ***Woman:*** Single dose NVP. When possible, intrapartum AZT/3TC plus 1 wk of AZT/3TC should be given to the mother to reduce the risk of NVP resistance. If delivery is imminent, do not give the maternal intrapartum dose but give infant single-dose NVP at birth. ***Infant:*** Single-dose NVP. When possible, also give 4 wk of AZT. *Alternative:* PETRA AZT + 3TC ***Woman:*** AZT + 3TC during labor and for 1 wk postpartum ***Infant:*** AZT + 3TC for 1 wk.
Infants born to HIV-infected women who have not received antepartum and intrapartum antiretroviral drugs	• Single dose NVP as soon as possible after birth, plus AZT for 4 wk. If 4 wk of AZT cannot be given, at least 1 wk of AZT recommended. • If regimen is started more than 2 days after birth, unlikely to be effective
HIV-infected women who are breastfeeding	• If indications for therapy, initiate or continue HAART as per non-pregnant scenario. • If there are not indications for therapy, there are insufficient data regarding the safety and efficacy of use of antiretroviral drugs in lactating women solely to prevent breast milk HIV transmission to recommend use outside of clinical trial setting.

HAART: Highly active antiretroviral therapy; WHO: World Health Organization; D4T: Stavudine; AZT: Zidovudine; 3TC: Lamivudine; NVP: Nevirapine; ARV: Antiretroviral; NNRTI: Non-nucleoside reverse transcriptase inhibitor; NRTI: Nucleoside analogue reverse transcriptase inhibitor; NFV: Nelfinavir; SQV: Saquinavir; RTV: Ritonavir.

Data from World Health Organization. *Antiretroviral Drugs for Treating Pregnant Women and Preventing HIV Infection in Infants in Resource-limited Settings: Towards Universal Access.* Geneva, Switzerland: World Health Organization, 2006.

United States, and a number of interventions more applicable to, and studied in, resource-limited settings, including nutritional supplementation, vaginal virucidal cleansing, treatment and prophylaxis of sexually transmitted diseases and chorioamnionitis, and passive and/or active immunoprophylaxis. In general, other than elective cesarean delivery, the nonantiretroviral interventions studied to date have not proven effective in reducing MTCT.

ELECTIVE CESAREAN DELIVERY

Given that most MTCT occurs during the intrapartum period, it was hypothesized that interventions that prevent infant exposure to infectious maternal blood and secretions in the birth canal during delivery could provide some protection against transmission during this time period. Additionally, cesarean delivery performed prior to onset of labor would also prevent maternal–fetal microtransfusions that occur during uterine contractions.[114,115]

Several studies, conducted in an era of either no antiretroviral therapy or AZT monotherapy, demonstrate a protective effect of elective cesarean delivery (performed prior to labor and rupture of membranes) in reducing MTCT.[66,67,116] The largest study was an individual patient data meta-analysis including 8533 nonbreastfeeding mother–child pairs from 15 prospective U.S. and international cohort studies.[66] After adjusting for the receipt of antiretroviral therapy, maternal disease stage, and infant birth weight, elective cesarean section decreased the likelihood of transmission by approximately 50% (adjusted odds ratio [OR] = 0.43, 95% confidence interval [CI] 0.33–0.56). The combination of elective cesarean section and receipt of AZT during the antepartum, intrapartum, and neonatal periods reduced transmission by about 85% compared to other modes of delivery and no antiretroviral therapy (adjusted OR, 0.13, 95% CI 0.09–0.19). Similarly, in a cohort study from France, elective cesarean delivery combined with ZDV prophylaxis was associated with a fivefold lower rate of transmission than vaginal delivery or emergent cesarean section.[116] A protective effect for elective cesarean section was found in a randomized trial of elective cesarean versus vaginal delivery conducted in Europe (MTCT 1.8% in 170 women delivered by elective cesarean section compared to 10.5% in 200 delivered vaginally).[67]

Fewer studies have evaluated the effect of elective cesarean delivery in the HAART era.[117,118] The European Collaborative Study, involving 29 centers in 10 European countries, examined risk factors for MTCT in the HAART era in 1982 patients who were enrolled from January 1997 through May 2004.[117] During this period, receipt of antenatal antiretroviral therapy increased from 5% at the start of the HAART era to 92% during 2001–2003, with concomitant decrease in the rates of MTCT from 5% (1997 to 1998) to <1% (2001 to 2003). In a multivariate analysis including 885 mother–child pairs, MTCT risk was associated with high maternal viral load (adjusted OR 12.1, $p = 0.003$) and elective cesarean section (adjusted OR 0.33, $p = 0.04$). Among the subset of 560 women with undetectable HIV RNA levels, on univariate analysis, elective cesarean delivery was associated with a significant reduction in transmission risk compared with vaginal delivery or emergency cesarean section (OR 0.07, 95% CI 0.02–0.31). However, after adjustment for antiretroviral therapy (none vs. any), this effect was no longer statistically significant in this subgroup (adjusted OR 0.52, 95% CI 0.14–2.03, p = 0.36).

The risks of operative delivery also need to be considered. HIV-infected pregnant women may be at increased risk of developing postpartum complications regardless of the mode of delivery.[119] It is known that maternal morbidity and mortality are higher after cesarean than vaginal delivery in women who are not HIV infected. Complications are more frequent when the cesarean section is performed after the onset of labor or membrane rupture, as opposed to elective cesarean delivery. There have been several studies that have suggested that complications from cesarean delivery are higher in HIV-infected than HIV-uninfected women, particularly in women undergoing emergency cesarean delivery. In the European randomized mode of delivery clinical trial, while the overall frequency of postpartum complications was low, postpartum fever was significantly more common in women with operative rather than vaginal delivery.[67] Similarly, an increased rate of postpartum fever following cesarean compared to vaginal delivery was observed in an analysis of 1200 HIV-infected pregnant women enrolled in the observational Women and Infants Transmission Study and an analysis from another study of HIV-infected women undergoing cesarean delivery solely for prevention of transmission.[120,121] The difference in postpartum complications was greatest among women with more advanced HIV disease and low CD4 cell counts. In an examination of postpartum morbidity among 497 women enrolled in perinatal trial PACTG 185, endometritis, wound infection, and pneumonia were increased among HIV-infected women delivered by scheduled or urgent cesarean section, compared with HIV-infected women undergoing vaginal delivery, but complication rates were within the range previously reported for similar general obstetric populations.[122] Thus, overall data indicate that elective cesarean delivery may be associated with a slightly greater risk of complications among HIV-infected than HIV-uninfected women, with the greatest difference being observed among women with immunologic suppression. Whether these differences would be mitigated by routine use of prophylactic antibiotics in women undergoing cesarean delivery to reduce infectious morbidity is unknown; the published studies did not delineate whether prophylactic antibiotics were administered.

Thus, despite the potential benefits of elective cesarean delivery for prevention of MTCT, the risks need to be addressed for each individual patient. In some cases (e.g., when risk of transmission is very low, such as a woman on HAART with undetectable viral load), the risk of operative delivery to the mother may outweigh the potential benefit in reducing HIV transmission to her infant.[118]

Furthermore, the benefit of cesarean delivery in terms of prevention of MTCT is lost if the procedure is performed after the onset of labor or rupture of membranes.[66,67,116]

NUTRITIONAL SUPPLEMENTATION

The efficacy of nutritional supplementation for prevention of MTCT has been evaluated for vitamin A, micronutrients, and multivitamins. Observational studies evaluating the relationship between maternal vitamin A concentrations and the risk of perinatal HIV transmission have produced conflicting results, with some studies suggesting that low serum retinol concentrations are associated with an increased risk of perinatal transmission, while other reports have shown no such relationship.[123–126]

Several randomized, placebo-controlled perinatal trials have been conducted to determine whether administration of vitamin A and/or other micronutrients to HIV-infected pregnant women would lower perinatal HIV transmission. Maternal antenatal vitamin A supplementation did not reduce in utero, intrapartum, or early breast milk transmission of HIV, nor did it affect maternal morbidity.[77,127–131] In one trial, vitamin A supplementation, started at approximately 20 weeks' gestation and continued throughout lactation, actually increased HIV transmission during lactation (relative risk 1.38), while multivitamins had no overall effect but reduced breastfeeding transmission among mothers with low baseline CD4 counts in a post hoc subgroup analysis.[129] However, this increase in postnatal transmission with vitamin A supplementation has not been observed in other studies.[77,127]

The effect of vitamin supplementation on fetal health and maternal lymphocyte counts was addressed in a randomized controlled trial of 1075 pregnant women in Tanzania who, at 12–27 weeks of gestation, were assigned to placebo, vitamin A alone, multivitamins excluding vitamin A, or multivitamins including vitamin A; one-third were vitamin A deficient at baseline. Multivitamin supplementation, but not vitamin A supplementation alone, was associated with significant improvement in non-HIV-related pregnancy outcomes including fetal death (5.9% vs. 9.6% in the multivitamin vs. placebo groups, respectively), low birth weight (8.8% vs. 15.8%), severe preterm birth at <34 weeks (6.2% vs. 10.2%), and small for gestational-age infants (10.0% vs. 17.6%).[132] Additionally, maternal multivitamin supplementation (but not vitamin A supplementation) was reported to improve postnatal growth and decrease morbidity in their infants.[133,134] Multivitamin but not vitamin A supplementation resulted in significant elevations in maternal CD4, CD8, and CD3 counts during pregnancy and immediately postpartum.[132] Additionally, multivitamin supplementation modestly decreased longer-term risk of HIV disease progression in the mothers.[135]

These data suggest that while micronutrient and vitamin supplementation do not reduce MTCT, they may provide some benefit in terms of improving pregnancy outcome and decreasing maternal morbidity in HIV-infected women and infants residing in resource-limited countries where nutrient deficiencies are common. However, in the United States and other resource-rich countries, where prenatal vitamin supplementation is routinely provided and vitamin deficiency is uncommon, additional supplementation is not recommended and could be harmful. As an example, large doses of vitamin A (>10,000 international units per day) in pregnancy can be teratogenic.[136]

VAGINAL VIRUCIDAL CLEANSING

Use of a microbicide, 0.25% chlorhexidine, to cleanse the birth canal before vaginal delivery has been shown to reduce the risk of neonatal group B streptococcal sepsis and be safe for the mother and infant[137]; this intervention has also been studied for prevention of MTCT of HIV. A perinatal clinical trial in Malawi evaluated vaginal swabbing with 0.25% chlorhexidine every 4 hours during labor, combined with infant cleansing immediately after birth. The treatment was well tolerated, but no overall reduction in HIV transmission was observed (27% vs. 28% transmission in the treatment and control arms, respectively).[138] Similarly, in a study of vaginal lavage with 0.2% chlorhexidine (increased to 0.4% later in the study) during labor in Kenya, there was no evidence of a difference in intrapartum HIV transmission between lavage and nonlavage groups (15.9% vs. 17.2%, respectively).[139] In a West African study of vaginal disinfection with 1% benzalkonium chloride vaginal suppositories, women self-administered a daily vaginal suppository or placebo from week 36 of pregnancy and a single intrapartum dose, and the neonatal was bathed in 1% benzalkonium chloride solution. As in the other studies, no difference in perinatal transmission was observed between treatment and placebo groups (21.2% vs. 21.6%, respectively).[140]

In the Malawi study, non-HIV-related maternal and infant outcomes were significantly improved in the chlorhexidine group. In the neonates, hospital admissions due to sepsis were reduced by 57% and mortality from sepsis by 67%; in the mothers, hospitalizations due to sepsis were reduced by 63%.[141] The duration of hospitalization was also decreased in the treatment group. Thus, while use of vaginal microbicides does not appear to reduce MTCT, it is inexpensive, easily administered, does not require HIV testing for implementation, and could have potential overall benefit to HIV-infected and HIV-uninfected women and infants in resource-limited settings where perinatal maternal and infant morbidity and mortality are high.

TREATMENT AND PROPHYLAXIS OF SEXUALLY TRANSMITTED DISEASES AND/OR CHORIOAMNIONITIS

Some studies have suggested that sexually transmitted diseases may facilitate both heterosexual and MTCT HIV

transmission.[142,143] As a result, it has been hypothesized that treatment of sexually transmitted infections might provide an effective intervention to decrease both sexual transmission and MTCT. A randomized, controlled, community-based trial of mass sexually transmitted disease treatment was conducted in Rakai, Uganda, to address this hypothesis.[144,145] In this study, all adults, including pregnant women, in communities randomized to the treatment regimen received single doses of azithromycin, ciprofloxacin or cefixime (in pregnant women), metronidazole, and benzathine penicillin G, to provide protection against gonorrhea, chlamydia, chancroid, syphilis, and trichomoniasis and short-term control of bacterial vaginosis. Although antibiotic therapy was associated with substantial reduction in overall maternal and infant morbidity and in the rate of sexually transmitted diseases compared to the control communities, there were no decreases documented for sexually or MTCT HIV infection.[145]

Studies have also suggested that clinical and/or histologic chorioamnionitis is associated with MTCT.[56] Chorioamnionitis is associated with significant inflammation and activation of immune cells in the placenta, which could lead to breaks in the placental barrier, allowing passage of virus or infected lymphocytes from the mother to the fetus. Thus, prevention of chorioamnionitis has also been proposed as an intervention to reduce MTCT. However, data from a controlled clinical trial in Malawi and Zambia, in which empiric therapy for chorioamnionitis with a short course of antibiotics was given to HIV-infected pregnant women at 20–24 weeks' gestation and again during delivery, found that such therapy did not reduce HIV MTCT or affect infant morbidity and mortality.[146]

PASSIVE/ACTIVE IMMUNOPROPHYLAXIS

The success of passive and active immunization to prevent perinatal hepatitis B transmission has stimulated evaluation of a similar approach for prevention of MTCT of HIV.[147] A clinical trial conducted in the United States, PACTG 185, examined whether administration of intravenous HIV hyperimmune globulin (HIVIG) combined with AZT prophylaxis would reduce in utero and intrapartum transmission in HIV-infected women who did not breastfeed, compared to intravenous immune globulin without HIV antibody (IVIG). There was no measurable difference in transmission between treatment and control groups overall (MTCT was 4% with HIVIG vs. 6% with standard IVIG); however, there was a suggestion that HIVIG may have had an effect in reducing in utero transmission, as none of the nine infected infants in the HIVIG group had positive HIV cultures at birth compared to five of the 13 (38%) infected infants in the IVIG group.[148]

A clinical trial of HIVIG in breastfeeding women and infants in Uganda for prevention of breast milk transmission is ongoing. A phase I study of HIVIG in Uganda demonstrated that HIVIG was safe but did not have an effect on maternal viral or immune parameters, similar to previous data from PACTG 185.[149,150] A phase III trial of HIVIG to prevent intrapartum and breast milk transmission is ongoing in Uganda. Ideally, a monoclonal antibody product that did not require manufacture from inactivated plasma from HIV-infected individuals, that was targeted against specific conserved HIV epitopes with cross-clade neutralization capacity, and that could be administered intramuscularly would be desirable. Additional studies are planned to evaluate the safety and pharmacokinetics of monoclonal anti-HIV antibody preparations in pregnant women and newborns.

The safety and immunogenicity of HIV vaccine candidates are also being evaluated in newborns of HIV-infected women.[151–153] A study of a fowlpox HIV vaccine (ALVAC) in neonates is about to begin in Uganda. Once a promising candidate vaccine is identified, a phase III trial that would potentially combine anti-HIV monoclonal antibodies with HIV vaccine in neonates to prevent breast milk transmission is planned.

MANAGEMENT OF HIV IN PREGNANCY

Care of the HIV-1-infected pregnant woman should involve an ongoing collaboration between the HIV specialist caring for the woman when she is not pregnant, her obstetrician, and the woman herself. Table 85-4 lists the important HIV-related components of antenatal, intrapartum, and postnatal care for HIV-infected women. Important components of an initial evaluation of an HIV-infected pregnant woman include assessment of the status of her HIV disease, recommendations about beginning or altering antiretroviral treatment, and discussion of interventions to reduce the risk of perinatal HIV transmission. Decisions regarding the use of antiretroviral drugs during pregnancy should be made by the woman, following discussion with her health-care provider of the known and unknown benefits and risks of therapy.[154]

Initial assessment should include evaluation of the degree of existing immunodeficiency, as determined by CD4 cell count and percent, and an assessment of the need for prophylaxis against *Pneumocystis jiroveci* pneumonia (PCP) or *Mycobacterium avium* complex (MAC), or for treatment of any current HIV-related illnesses. The criteria for initiation of PCP or MAC prophylaxis are the same as in nonpregnant individuals.[155] Trimethoprim–sulfamethoxazole (TMP/SMX) is the recommended PCP prophylactic regimen. Because of theoretical concerns regarding potential for teratogenicity during the first trimester, aerosolized pentamidine may be considered as an alternative to TMP/SMX during this period due to its lack of systemic absorption. The drug of choice for MAC prophylaxis in pregnant HIV-infected women is azithromycin, due to safety in animal studies and anecdotal safety in humans. Experience with rifabutin in pregnancy is limited. Clarithromycin has been

Table 85-4. Important Components of Care in the United States for the HIV-Infected Pregnant Woman in Addition to Routine Obstetrical Care

Antepartum

History
- History of HIV-related symptoms, hospitalizations
- Antiretroviral drug past or current use, use of other concomitant drugs, use of alternative medicines (e.g., herbal preparations); assess potential drug interactions with current or planned antiretroviral treatment/prophylaxis

Physical examination
- Ophthalmic examination if CD4 cell count $<50/mm^3$

HIV-related laboratory
- HIV RNA testing at baseline and a minimum of every 3 mo
- CD4 cell count at baseline and every 3 mo
- Antiretroviral drug resistance testing in women on antiretroviral therapy but without virologic suppression, acute infection, or high likelihood of resistant virus (e.g., partner with resistant virus); consideration of antiretroviral drug resistance testing in all women with detectable RNA levels (see text)

Other laboratory
- Tuberculin skin test
- Antibody status for hepatitis B and C, cytomegalovirus, and *Toxoplasma gondii*, if unknown
- Screening for sexually transmitted infections
- Complete blood cell count and renal- and liver-function testing at baseline (and to monitor for antiretroviral drug toxicity; choice of tests, and frequency dependent on antiretroviral drug choice)

Counseling
- Antiretroviral drugs for treatment and/or for prevention of mother to child HIV transmission, adherence counseling, and potential drug side effects
- Discuss risk factors for mother-to-child HIV transmission, need for avoidance of substance abuse, smoking, multiple sexual partners, condom use to avoid sexually transmitted infections, and HIV superinfection
- Discuss mode of delivery
- Discuss recommendation to not breastfeed

Treatment
- Antiretroviral therapy or prophylaxis
- Prophylaxis of opportunistic infections, if needed
- Immunizations (influenza, pneumococcal, hepatitis B, and others if needed)—ideally given immunizations after antiretroviral therapy improves immune function and suppresses virus

Psychosocial support
- General support, mental health and substance abuse treatment if needed; support for adherence to antiretroviral drug regimen

Fetal monitoring
- For women receiving combination antiretroviral therapy, consideration of assessment of fetal anatomy with level II ultrasound and continued assessment of fetal growth and well-being during third trimester

Intrapartum

Antiretroviral therapy
- Continuation of antiretroviral therapy
- Administration of AZT by intravenous continuous infusion

Mode of delivery
- Evaluation of antiretroviral drugs for any interaction with drugs given during labor (e.g., avoid ergot preparations, monitor closely after midazolam use in women on protease inhibitors or EFV)
- Elective cesarean delivery at 38 wk gestation if maternal RNA >1000 copies/mL at 34–36 wk gestation
- If vaginal delivery, avoid artificial rupture of membranes, minimize interval between rupture of membranes and delivery, and avoid use of instruments for delivery
- Avoid invasive monitoring (e.g., fetal scalp electrodes and fetal scalp blood sampling)

Postpartum

Woman
- Decisions about continuation or discontinuation of antiretroviral treatment; adherence counseling if continuing antiretroviral drugs
- Counsel not to breastfeed
- Family planning and contraception services
- Psychosocial support services
- Referral for HIV-related primary care

Infant (see chapter on care of the infant)
- Pediatric referral of HIV-exposed infants to pediatrician with HIV expertise
- Oral AZT for 6 wk
- Initiation of prophylaxis for *Pneumocystis jiroveci* at 4–6 wk of age
- HIV virologic diagnostic testing

demonstrated to be a teratogen in animals and thus should be used with caution in pregnancy. Treatment of serious infections should not be withheld because of pregnancy; regimens should be chosen in consultation between the obstetrician and a specialist in infectious diseases.

Risk of disease progression should be assessed by determination of plasma HIV RNA copy number. While determination of HIV RNA copy number is important for decisions related to maternal treatment, it should not be the determining factor in the decision to begin antiretroviral prophylaxis to reduce MTCT, because antiretroviral drugs reduce transmission regardless of maternal RNA level and transmission may occur when RNA is undetectable.[3,85]

Decisions regarding initiation of antiretroviral therapy in women not currently receiving therapy or to continue or alter treatment in women currently receiving therapy should be based on the same criteria as for nonpregnant individuals, with the additional consideration of the potential impact of such therapy on the fetus and infant.[154] In nonpregnant HIV-infected individuals, initiation of treatment is recommended for all individuals with CD4 cell count <200/mm^3 or an AIDS-defining illness, and to be considered for individuals with CD4 cell count <350/mm^3 or HIV RNA levels >100,000 copies/mL.[156] Standard treatment is three drugs, generally two NRTIs plus an NNRTI or a protease inhibitor (PI),[156] as discussed in more detail in Chapter 73 ("Antiviral Therapy of Human Immunodeficiency Virus Infection"). Recommendations for antiretroviral treatment and prevention of MTCT of women in the United States in different clinical scenarios are shown in Table 85-5 and found in the U.S. Public Health Service guidelines, which can be accessed on the web at http://AIDSInfo.nih.gov.[154] Considerations related to specific antiretroviral drug choice in pregnancy are discussed in the next section in this chapter.

For HIV-infected pregnant women who do not require therapy for their own health, antiretroviral drugs are recommended for prevention of MTCT. In the United States and other resource-rich countries, combination therapy with HAART is recommended for all women with HIV RNA levels >1000 copies/mL, along with consideration of elective cesarean delivery if HIV RNA remains >1000 copies/mL at 34–36 weeks' gestation.[154] For women with HIV RNA levels <1000 copies/mL, the three-part PACTG 076 AZT prophylaxis regimen[2] can be used alone or in combination with other antiretroviral drugs although many experts would use a 3-drug regimen in such women as well. Long-term follow-up (mean 4.1 years) of women who participated in PACTG 076 found no differences in HIV disease progression, time to AIDS or death, CD4 lymphocyte count, HIV RNA levels, or genotypic AZT resistance in women from the AZT group compared to those in the placebo group.[157]

Depending on individual circumstances, provision of support services, mental health services, and drug abuse treatment may be required; such services may be especially important in promoting adherence to prescribed antiretroviral regimens. Adherence to antiretroviral therapy during pregnancy is particularly important for ensuring viral suppression, important for maternal health as well as prevention of MTCT, and prevention of drug resistance. Adolescent women or women who use alcohol or are substance abusers may be at particularly high risk of adherence problems during pregnancy.[158,159] These services need to be coordinated with prenatal care, primary care, and HIV specialty care providers. Discussion of long-term permanency planning for care of the child in the event of maternal illness should be initiated. A long-term treatment plan should be developed with the patient and the importance of adherence to prescribed antiretroviral regimens discussed.

General counseling related to prevention of perinatal transmission should include information about what is known about risk factors for transmission, particularly those potentially modifiable by the patient. Cigarette smoking, hard drug use (heroin, cocaine, and/or injection drug use), and/or unprotected sexual intercourse with multiple partners during pregnancy have been associated with an increased risk of perinatal HIV transmission.[160–164] In addition to improving maternal health, discontinuing cigarette smoking and drug use, and use of condoms with sexual intercourse during pregnancy may independently reduce risk of MTCT.

Plasma viral load and CD4 count should be monitored at least every 3 months during pregnancy and at approximately 34–36 weeks to inform decisions on mode of delivery.[154] Monitoring for potential complications of antiretroviral therapy should be based upon the known side effects of the drugs the woman is receiving. For example, monitoring for hematologic toxicity will be needed in women receiving AZT; women receiving NVP should have frequent monitoring of liver transaminase levels, particularly during the first 18 weeks of therapy, and women receiving PIs may require more frequent monitoring for development of hyperglycemia. Because of the limited data of the effect of combination antiretroviral therapy on the fetus, more intensive fetal monitoring should be considered for women receiving combination therapy during pregnancy, including assessment of fetal anatomy with a level II ultrasound and continued assessment of fetal growth and well-being during the third trimester.

CHOICE OF ANTIRETROVIRAL DRUGS IN PREGNANCY

Antiretroviral therapy in pregnancy involves two separate but related goals: treatment of maternal HIV disease and reduction of MTCT. The special circumstances of pregnancy raise additional issues of toxicity to mother and fetus, which affect choice of antiretroviral drug, and of the need for antiretroviral prophylaxis for prevention of MTCT, but these concerns should be dealt with in the context of assuring optimal

Table 85-5. Recommendations for Antiretroviral Drug Use by Pregnant HIV-1-Infected Women and Prevention of Mother-to-Child Transmission in the United States

Clinical Situation	Recommendation
HIV-1-infected woman of childbearing potential but not pregnant and who has indications for initiating antiretroviral therapy	• HAART as per U.S. treatment guidelines. • Avoid drugs with teratogenic potential (EFV) in women of childbearing age unless adequate contraception ensured. Exclude pregnancy before starting treatment with EFV.
HIV-1-infected woman with indications for antiretroviral therapy, who is receiving HAART and becomes pregnant	***Woman:*** • Continue current HAART regimen except discontinuing drugs with teratogenic potential (EFV) or with known adverse potential for the pregnant mother (combination d4T/ddI). • Discontinuation of antiretroviral drugs during the first trimester is not recommended. • Continue HAART regimen during intrapartum period (AZT given as continuous infusion[a] during labor) and postpartum. • Elective cesarean delivery if plasma HIV-1 RNA remains >1000 1000 copies/mL at 34–36 wk gestation. ***Infant:*** • AZT for 6 wk.
HIV-1-infected pregnant woman with antenatal plasma HIV-1 RNA ≥1000 copies/mL who is not currently receiving antiretroviral therapy	***Woman:*** • HAART (ideally containing AZT after the first trimester). • Due to risk of severe hepatic toxicity with NVP in women with CD4 >250/mm^3, use NVP in this situation only if benefit clearly outweighs risk and alternatives not available. • Continue HAART regimen during intrapartum period (AZT given as continuous infusion[a] during labor). • Evaluate need for continued therapy postpartum; discontinue HAART unless has indications for continued therapy (if regimen includes drug with long half-life like NNRTI, consider stopping NRTIs 3–7 d after stopping NNRTI although limited data). • Elective cesarean delivery if plasma HIV-1 RNA remains >1000 copies/mL at 34–36 wk gestation. ***Infant:*** • AZT for 6 wk.
HIV-1-infected pregnant woman with antenatal maternal plasma HIV-1 RNA <1000 copies/mL who is not currently receiving antiretroviral therapy	***Woman:*** • HAART (ideally containing AZT after the first trimester), plus AZT given as continuous infusion[a] intrapartum. Discontinue HAART postpartum (if regimen includes drug with long half-life like NNRTI, consider stopping NRTIs 3–7 d after stopping NNRTI although limited data). *OR* • AZT given antepartum after the first trimester and as continuous infusion[a] during labor.

(*Continued*)

Table 85-5. *(Continued)*

Clinical Situation	Recommendation
	Infant:
	• AZT for 6 wk.
HIV-1 infected woman who has received no antiretroviral therapy prior to labor	• Several effective regimens are available to choose from for women who have had no prior therapy:
	1. *AZT*
	Woman: AZT given as continuous infusion[a] during labor.
	Infant: AZT for 6 wk.
	OR
	2. *Combination* AZT ± NVP
	Woman: AZT given as continuous infusion[a] during labor, plus single-dose NVP at onset labor. Intrapartum 3TC plus 1 wk postpartum AZT/3TC should be considered to reduce the risk of NVP resistance.
	Infant: Single-dose NVP (2 mg/kg) plus AZT for 6 wk.
	3. *PETRA AZT ± 3TC*
	Woman: AZT + 3TC every 12 h during labor.
	Infant: AZT + 3TC twice daily for 1 wk.
	OR
	4. *Single-dose NVP*
	Woman: Single-dose NVP (200 mg). Intrapartum and 1 wk postpartum AZT/3TC should be considered to reduce the risk of NVP resistance.
	Note: If delivery is imminent (<1 h), do not give the maternal intrapartum NVP as insufficient time to reach adequate level in infant.
	Infant: Single-dose NVP (2 mg/kg) at 48–72 h of age. *Note: If mother did not receive intrapartum NVP, then could give infant NVP at birth and 48–72 h.*
	OR
Infant born to HIV-1-infected woman who has received no antiretroviral therapy prior to or during labor	• AZT given for 6 wk to the infant, started within 6–12 h of birth)
	OR
	• Some clinicians may choose to use AZT in combination with additional drugs, but appropriate dosing for neonates is incompletely defined and the additional efficacy of this approach in reducing transmission is not known.

[a]AZT continuous infusion: 2 mg/kg AZT intravenously over 1 hour, followed by continuous infusion of 1 mg/kg/h until delivery.

HAART, highly active antiretroviral therapy; AZT, zidovudine; 3TC, lamivudine; NVP, nevirapine; EFV, efavirenz.

Adapted from Public Health Service Task Force recommendations for use of antiretroviral drugs in pregnant HIV-1-infected women for maternal health and interventions to reduce perinatal HIV-1 transmission in the United States. For most recent guidelines see http://AIDSInfo.nih.gov. Accessed on October 17, 2005.

treatment to preserve the mother's health; pregnancy should not be a reason to defer standard therapy when it is needed. Table 85-6 delineates recommendations for use of antiretroviral drugs in pregnancy, including Food and Drug Administration (FDA) pregnancy classification and pharmacokinetic and pregnancy-related toxicity data for individual drugs.

Decisions related to choice of antiretroviral drugs during pregnancy involve weighing competing factors influencing risk and benefit. Maternal risk for disease progression and the gestational age of the pregnancy should be considered in determining the risks and benefits of delaying initiation of antiretroviral drugs until after the first trimester. The proven efficacy of antiretroviral therapy to reduce MTCT regardless of maternal HIV RNA levels means that all HIV-infected pregnant women should be receiving some kind of antiretroviral therapy during pregnancy, whether it is HAART or consideration of AZT alone for the rare antiretroviral-naïve woman who has HIV RNA levels <1000 copies/mL. The choice of antiretroviral drugs includes consideration of preclinical, animal, and human studies related to the short- and long-term safety of the particular drug in pregnancy for the woman and her infant. Choice of drug also involves consideration of potential drug interactions between antiretroviral drugs themselves or with other medications the woman is receiving.

The period when the fetus is most susceptible to potential teratogenic effects of the drugs is during the first 10 weeks of gestation, and women who are in the first trimester of pregnancy may wish to consider delaying initiation of therapy until after 10–12 weeks of gestation; discussion should include assessment of the woman's health status and the benefits and risks of delaying initiation of therapy for several weeks. If the clinical or immune status of a woman in the first trimester of pregnancy suggests that she is severely ill, the benefits of early treatment outweigh the potential risk to the fetus. However, use of drugs that are potentially teratogenic, such as EFV (discussed below), should be avoided during the first trimester.

For women who require therapy for their own health and are already receiving treatment when they become pregnant, continuation of treatment is generally recommended as the benefit of therapy to maternal health for women who require therapy outweighs theoretical risk to the fetus. However, if the woman is receiving EFV and her pregnancy is recognized in the first trimester, EFV should be discontinued and another drug substituted due to teratogenicity issues, as discussed below.

Antiretroviral drugs and congenital abnormalities

Data on the risk of congenital abnormalities in infants born to women receiving antiretroviral drugs during pregnancy has been assessed by observational studies and through the Antiretroviral Pregnancy Registry, an international registry of pregnancies exposed to antiretroviral agents prospectively reported by health-care providers.[165–167] In the Antiretroviral Pregnancy Register, the prevalence of birth defects in infants with in utero antiretroviral exposure (during the first trimester or anytime during pregnancy) is not significantly different from the rates in the general population. Among infants with first trimester exposure to any antiretroviral, the birth defect rate was 2.9% (95% CI 2.2–3.8%) and for any exposure during pregnancy was 2.4% (95% CI 2.0–2.9%).[167] In CDC population-based birth defects surveillance, the total prevalence of birth defects identified among live births in the United States was 3.1% (95% CI 3.1–3.2%). Similar data have been reported by the Europeans.[165] There are sufficient numbers of cases of exposure in the Registry to AZT, abacavir (ABC), 3TC, stavudine (d4T), ddI, NVP, and NFV in the prospective cases to exclude a twofold or greater increase in birth defects among pregnant women exposed to these drugs in the first trimester compared to the general population.[167] There are insufficient data for meaningful analyses of other individual agents.

In retrospective case reports, significant central nervous system congenital abnormalities have been with first trimester exposure to EFV.[167] In primates, significant central nervous system malformations were observed in three of 20 infant monkeys with in utero EFV exposure at drug levels similar to those seen with human exposure at standard therapeutic doses; the malformations included anencephaly, anophthalmia and microophthalmia, and cleft palate. Central nervous system abnormalities (including myelomeningocele and Dandy–Walker malformation) have been reported in four human infants with first trimester exposure to EFV-containing regimens.[167–170] Based on these data, EFV has been classified as U.S. FDA Pregnancy Category D (positive evidence of human fetal risk). Pregnancy should be avoided in women receiving EFV-based therapy, and EFV should be used during the first trimester or pregnancy only if the potential benefit justifies the potential risk to the fetus, such as in pregnant women without any other therapeutic options.

Combination antiretroviral therapy and pregnancy outcome

Data are conflicting about the association of combination antiretroviral therapy, particularly therapy containing PIs, and prematurity. Data from European cohorts suggest that use of antenatal antiretroviral therapy including a PI was associated with a 2.5-fold increased risk of premature delivery compared to no treatment, after adjustment for maternal CD4 count and use of illicit drugs, and that risk of preterm delivery was greatest for those women who started PI-based therapy before pregnancy or during the first

Table 85-6. Antiretroviral Drugs in Pregnancy: FDA Pregnancy Class, Pharmacokinetic and Toxicity Data, and Recommendations for Use in Pregnancy

Antiretroviral Drug	FDA Pregnancy Class[a]	Pharmacokinetics in Pregnancy	Concerns in Pregnancy	Rationale for Recommended Use in Pregnancy
NRTIs/NtRTIs			Potential maternal and infant mitochondrial toxicity (see text)	NRTIs are recommended for use as part of combination regimens, usually including two NRTIs and an NNRTI or PI. Use of one or two NRTIs alone is not recommended for treatment (AZT alone may be considered for prevention of MTCT in pregnant women with HIV RNA <1000 copies/mL).
Recommended agents				
Zidovudine (AZT)	C	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated.	No evidence of human teratogenicity Well-tolerated, short-term safety demonstrated for mother and infant.	Preferred NRTI for use in combination antiretroviral regimens in pregnancy based on efficacy studies and extensive experience; should be included in regimen unless significant toxicity or d4T use.
Lamivudine (3TC)	C	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated.	No evidence of human teratogenicity. Well-tolerated, short-term safety demonstrated for mother and infant.	Because of extensive experience with 3TC in pregnancy in combination with AZT, 3TC plus AZT is the recommended dual NRTI backbone for pregnant women.
Alternate agents				
Didanosine (ddI)	B	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated.	Cases of lactic acidosis some fatal, have been reported in pregnant women receiving ddI and d4T together.	Alternate NRTI for dual nucleoside backbone of combination regimens. ddI should be used with d4T only if no other alternatives are available
Emtricitabine (FTC)	B	Study in progress.	No studies in human pregnancy.	Alternate NRTI for dual nucleoside backbone combination regimens.
Stavudine (d4T)	C	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated.	No evidence of human teratogenicity. Cases of lactic acidosis, some fatal, have been reported in pregnant women receiving ddI and d4T together.	Alternate NRTI for dual nucleoside backbone of combination regimens. d4T should be used with ddI only if no other alternatives are available. Do not use d4T with AZT due to potential for antagonism.
Abacavir (ABC)	C	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated.	No evidence of human teratogenicity. Hypersensitivity reactions occur in 5–8% of nonpregnant persons; rate in pregnancy unknown.	Alternate NRTI for dual nucleoside bacbone of combination regimens. Patient with hypersensitivity reaction should not be rechallenged, can be fatal. Patient should be educated regarding symptoms of hypersensitivity reaction.

Table 85-6. (*Continued*)

Antiretroviral Drug	FDA Pregnancy Class[a]	Pharmacokinetics in Pregnancy	Concerns in Pregnancy	Rationale for Recommended Use in Pregnancy
Insufficient data to recommend use				
Tenofovir (TFV)	B	No studies in human pregnancy. Phase I study of single dose in late pregnancy in progress.	Primate studies show decreased fetal growth, reduced fetal bone porosity with in utero exposure; bone demineralization seen with TFV therapy in children; clinical significance unknown.	Because of lack of data on use in human pregnancy and concern regarding potential fetal bone effects, TFV should be used as a component of a maternal combination regimen only after careful consideration of alternatives.
Not recommended				
Zalcitabine (ddC)	C	No studies in human pregnancy.	Rodent studies indicate potential for teratogenicity and developmental toxicity.	Given lack of data and concerns regarding teratogenicity in animals, not recommended for use in human pregnancy unless alternatives are not available.
NNRTIs				
Recommended agents				
Nevirapine (NVP)	C	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated.	No evidence of human teratogenicity. Increased risk of symptomatic, often rash-associated, potentially fatal liver first initiating therapy; unclear if pregnancy increases risk.	NVP should be initiated in pregnant women with CD4+ counts >250 cells/mm3 only if benefit clearly outweighs risk, due to the increased risk of potentially life-threatening s NVP regimens and are tolerating them well may continue therapy, regardless of CD4 count.
Not recommended				
Efavirenz (EFV)	D	No studies in human pregnancy.	Anencephaly, anophthalmia, cleft palate in three of 20 infant monkeys born to mothers receiving EFV in the first trimester at levels similar to human exposure. There are	Use of EFV should be avoided in the first trimester, and women of childbearing potential must be counseled regarding risks and avoidance of pregnancy. Use after the second trimester can be considered if other alternatives are not available and if adequate contraception can be assured postpartum.

(*Continued*)

Table 85-6. *(Continued)*

Antiretroviral Drug	FDA Pregnancy Class[a]	Pharmacokinetics in Pregnancy	Concerns in Pregnancy	Rationale for Recommended Use in Pregnancy
			four reports of central nervous system defects in humans after first trimester exposure; relative risk unclear.	
Delavirdine (DLV)	C	No studies in human pregnancy.	Rodent studies indicate potential for carcinogenicity and teratogenicity.	Given lack of data and concerns regarding teratogenicity in animals, not recommended for use in human pregnancy unless alternatives are not available.
Protease inhibitors		For all PIs studied, lower levels observed in pregnancy than postpartum. With exception of NFV, PIs likely need low-dose RTV "boosting."	Hyperglycemia, new onset or exacerbation of diabetes mellitus, and diabetic ketoacidosis reported with PI use; unclear if pregnancy increases risk. Conflicting data regarding preterm delivery in women receiving PIs (see text).	
Recommended agents				
Nelfinavir (NFV)	B	Adequate drug levels are achieved in most pregnant women with NFV 1250 mg, given twice daily.	No evidence of human teratogenicity. Well-tolerated, short-term safety in mother and infant. NFV dosing at 750 mg three times daily produced variable and generally low levels in pregnant women.	Given pharmacokinetic data and extensive experience with use in pregnancy compared to other PIs, preferred PI for combination regimens in pregnant women, particularly if HAART is being given solely for perinatal prophylaxis. In clinical trials of initial therapy in nonpregnant adults, NFV-based regimens had a lower rate of viral response compared to LPV/RTV- or EFV-based regimens but similar viral response compared with ATV- or NVP-based regimens.
Lopinavir/ ritonavir (LPV/RTV)	C	Preliminary studies of capsule formulation suggest low levels in later pregnancy, may need increased dose (533 mg LPV/133 mg RTV) in third and possibly second trimester; however, by	No evidence teratogenicity well tolerated, short term safety in mother & infant	Specific dosing recommendations for the tablet formulation not established. If used during pregnancy, monitor response to therapy closely. If expected virologic result is not observed, consult with a specialist with expertise in HIV in pregnancy.

Table 85-6. *(Continued)*

Antiretroviral Drug	FDA Pregnancy Class[a]	Pharmacokinetics in Pregnancy	Concerns in Pregnancy	Rationale for Recommended Use in Pregnancy
		2 wk postpartum, standard dose should be used. Pharmacokinetic data on current tablet formulation not yet available.		
Alternate agents				
Indinavir (IDV)	C	Studies show pregnant women receiving IDV 800 mg three times daily have markedly lower levels during pregnancy compared to postpartum, although HIV RNA generally suppressed.	Theoretical concern: increased indirect bilirubin levels, which may exacerbate physiologic hyperbilirubinemia in the neonate, but minimal placental IDV passage. Use of unboosted IDV during pregnancy is not recommended.	Alternate PI to consider if unable to use NFV or SQV-SGC/rtrv, but would need to give IDV as low-dose RTV-boosted regimen. Optimal dosing for the combination of IDV/RTV in pregnancy is unknown.
Saquinavir-hard gel capsule (HGC) (Invirase)/low-dose ritonavir (SQV/rtv)	B	Adequate drug levels are achieved in pregnant women with SQV-SGC 800 mg boosted with RTV 100 mg, twice daily; SQV-SGC no longer available Limited pharmacokinetic data on SQV-hard gel capsule [HGC]/ rtv in pregnancy, suggest 1000 mg SQV-HGC/ 100 mg rtv given twice daily will achieve adequate levels in pregnancy.	Well-tolerated, short-term safety in mother and infant.	Given pharmacokinetic data and moderate experience with use in pregnancy, RTV-boosted SQV-HGC can be considered an alternative for combination regimens in pregnancy.
Ritonavir (RTV)	B	Lower levels during pregnancy compared to postpartum.	Limited experience in human pregnancy.	Given low levels in pregnant women when used alone, recommended for use in combination with second PI as low-dose rtv "boost" to increase levels of second PI.
Insufficient data to recommend use				
Amprenavir (APV)	C	Limited studies in human pregnancy.	Oral solution contraindicated in pregnant women due to	Safety and pharmacokinetics in pregnancy data are insufficient to recommend use of capsules in pregnancy.

(*Continued*)

Table 85-6. *(Continued)*

Antiretroviral Drug	FDA Pregnancy Class[a]	Pharmacokinetics in Pregnancy	Concerns in Pregnancy	Rationale for Recommended Use in Pregnancy
			high levels of propylene glycol, which is not be adequately metabolized during pregnancy.	
Fosamprenavir (fos-APV)	C	Limited studies in human pregnancy.	Limited experience in human pregnancy.	Safety and pharmacokinetics in pregnancy data are insufficient to recommend use in pregnancy.
Atazanavir (ATV)	B	Limited studies in human pregnancy.	Theoretical concern: increased indirect bilirubin levels, which may exacerbate physiologic hyperbilirubinemia in the neonate, although transplacental PI passage has been low.	Safety and pharmacokinetics in pregnancy data are insufficient to recommend use in pregnancy.
Darunavir	B	No studies in pregnancy.	No experience in pregnancy.	Safety and pharmacokinetics in pregnancy data are insufficient to recommend in pregnancy.
Tipranavir (TPV)	C	No studies in human pregnancy.	No experience in human pregnancy.	Safety and pharmacokinetics in pregnancy data are insufficient to recommend use in pregnancy.
Fusion inhibitors				
Insufficient data to recommend use				
Enfuvirtide (T-20)	B	No studies in human pregnancy	No experience in human pregnancy.	Safety and pharmacokinetics in pregnancy data are insufficient to recommend use in pregnancy.

A: Adequate and well-controlled studies of pregnant women fail to demonstrate a risk to the fetus during the first trimester of pregnancy (and there is no evidence of risk during later trimesters).

B: Animal reproduction studies fail to demonstrate a risk to the fetus, and adequate and well-controlled studies of pregnant women have not been conducted.

C: Safety in human pregnancy has not been determined, animal studies are either positive for fetal risk or have not been conducted, and the drug should not be used unless the potential benefit outweighs the potential risk to the fetus.

D: Positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experiences, but the potential benefits from the use of the drug in pregnant women may be acceptable despite its potential risks.

X: Studies with animals or reports of adverse reactions have indicated that the risk associated with the use of the drug for pregnant women clearly outweighs any possible benefit.

[a]Food and Drug Administration pregnancy categories.

NRTI, nucleoside reverse transcriptase inhibitor; NtRTI, nucleotide reverse transcriptase inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor; PI, protease inhibitor; SGC, soft gel capsule; HGC, hard gel capsule.

Modified from Public Health Service Task Force recommendations for the use of antiretroviral drugs in pregnant women infected with HIV-1 for maternal health and for reducing perinatal HIV-1 transmission in the United States. Centers for Disease Control and Prevention. MMWR. For most recent guidelines see http://AIDSInfo.nih.gov. Accessed on October 17, 2005.

trimester.[45,46,171] However, data from U.S. cohorts have not indicated an association of preterm delivery with PI-based HAART use, regardless of time of initiation.[47,172–174]

An association was also suggested between HAART use and pre-eclampsia in cohorts from the UK and Spain[175,176] but was not observed in U.S. cohorts.[172–174] It is hypothesized that there may be an immunologic mechanism for an association of HAART with preterm delivery and pre-eclampsia.[177] Normal immune modulation in pregnancy is associated with an increase in type 2 and decrease in type 1 cytokines, and adverse pregnancy outcome has been associated with poor type 2 cytokine production. HIV disease is accompanied by a shift from a type 1 to type 2 cytokine environment; however, with immune restoration from HAART, there is a resultant increase in type 1 cytokine production, which, it is hypothesized, might induce pregnancy complications such as preterm delivery or pre-eclampsia.[177]

Because the available data are conflicting, no definitive conclusions can be drawn about an association of antiretroviral therapy and adverse pregnancy outcome; further evaluation is needed. HIV-infected women receiving antiretroviral therapy should have careful, regular monitoring for pregnancy complications and for potential toxicities.

Antiretroviral drug resistance testing

Antiretroviral drug resistance develops when viral replication continues under the selective pressure of drug exposure, as can occur with suboptimal, nonsuppressive therapy or if plasma drug concentrations are below inhibitory levels, either due to dosing or pharmacokinetic problems or poor/intermittent adherence to therapy. Drug resistance (along with lack of adherence) is a major reason for therapy failure and lack of viral suppression, which both can affect maternal health and the risk of MTCT. Genotypic and phenotypic assays are available to detect antiretroviral resistance. Transmission of drug-resistant virus has been reported, including through MTCT.[178,179]

Recommendations for antiretroviral drug resistance testing in pregnant women are the same as those for nonpregnant persons: viral failure with persistently detectable HIV RNA levels while receiving therapy or suboptimal viral suppression after initiation of therapy; individuals with a high likelihood of having resistant virus based on community prevalence or resistance, known drug resistance in the woman's partner, or other source of infection; or acute infection.[154,156] In the case of viral failure, resistance testing should be performed while the patient is receiving the failing drug regimen to maximize the detection of drug resistance, as mutations may fade when drugs are discontinued and selective pressure is no longer being exerted, although they may remain archived in cellular virus and re-emerge when the drug or a cross-resistant drug is administered.[156]

Recommendations related to drug resistance testing in antiretroviral-naïve pregnant women with chronic HIV infection has been more controversial. The prevalence of antiretroviral drug resistance in newly infected, therapy-naïve individuals has varied by geographic region; recent studies in the United States and Europe indicate a prevalence of drug resistance among antiretroviral-naïve patients of 8–10%.[180,181] The prevalence of resistance in pregnant women also varies depending on the characteristics of the population studied and does not necessarily correlate with failure of antiretroviral drug prophylaxis of MTCT.[182–184] The International AIDS Society recommends that all HIV-infected pregnant women undergo resistance testing when first seen to guide treatment.[185] A recent analysis by the CDC suggests that resistance testing in treatment-naïve, chronically infected nonpregnant individuals may be cost effective and improve clinical outcome if the prevalence of drug resistance is $\geqslant$1%.[186]

Nucleoside/nucleotide analogue reverse transcriptase inhibitor drugs

The nucleotide analogue reverse transcriptase inhibitor (NRTI) drugs are generally well tolerated in pregnancy (Table 85-6). All the NRTI drugs have been shown to cross the placenta in humans (AZT, ddI, and 3TC) or animals (ABC, d4T, emtricitabine [FTC], tenofovir [TFV], and zalcitabine [ddC]), although with different cord blood:maternal drug ratios (ranging from 0.5 for ddI to 0.85 for AZT).[177,187] Pharmacokinetic studies on the NRTI drugs studied to date in pregnant women (which include ABC, AZT, ddI, d4T, and 3TC) have not demonstrated a need for dose modification of the drugs during pregnancy.[187]

The efficacy of AZT to reduce MTCT was demonstrated in PACTG 076[2]; AZT should be included as a component of antiretroviral therapy or prophylaxis whenever possible, given its proven efficacy in reducing MTCT. In addition to antenatal treatment, the PACTG 076 regimen includes intravenous AZT during labor and administration of 6 weeks of AZT to the infant. The NRTI drugs with the greatest clinical experience with use in pregnant women are AZT and 3TC, which are the preferred NRTIs for use in pregnant women (Table 85-6). Alternative NRTI drugs for use in pregnancy include ABC, d4T, ddI, and FTC. There are not yet data on use of FTC in pregnancy, although data on the other NRTI drugs suggest that standard dosing would be appropriate and it has been classified as FDA Pregnancy Category B (no animal safety concerns but no human data).

There are also no data on use of TFV during pregnancy. Studies in infant monkeys with in utero TFV exposure have not demonstrated gross congenital abnormalities but have shown decreased fetal growth and a reduction in fetal bone porosity within 2 months of starting maternal therapy[188]; additionally, bone demineralization has been observed in some infected

children receiving chronic TFV-based therapy.[189] The clinical significance of these findings for children with in utero TFV exposure is unknown. Because of the lack of data on use in human pregnancy and concern regarding potential fetal bone effects, TFV should be used as a component of therapy in pregnant women only if there are no other alternatives.

NRTI drugs can bind to mitochondrial DNA polymerase gamma, which can cause mitochondrial dysfunction.[154,177,190] Manifestations of mitochondrial dysfunction can include lactic acidosis, hepatic steatosis, myopathy, cardiomyopathy, or neuropathy. Whether such toxicities are enhanced in pregnant women is unknown. However, fatal cases of lactic acidosis and hepatic failure have been reported in pregnant women who received the combination of d4T/ddI throughout pregnancy.[177,190] Use of the dual NRTI combination of d4T/ddI should be avoided in pregnancy and only used when no other alternatives exist. Although this complication has been reported most commonly with long-term use of d4T/ddI, the potential exists with all the NRTI drugs (binding affinity to mitochondrial polymerase gamma is greatest for ddC, followed by ddI, d4T, AZT, 3TC, ABC, and TFV).[191] Therefore, clinicians should be alert for symptoms of liver dysfunction and lactic acidosis, which can be nonspecific, in women receiving NRTI drugs. Routine monitoring of blood lactate is not recommended, because an elevated lactate alone is not predictive of the development of lactic acidosis; however, measurement of serum lactate, along with liver enzymes, would be useful in pregnant women receiving NRTI drugs if suggestive symptoms are present.

It has been suggested that mitochondrial dysfunction might develop in infants with in utero exposure to NRTI drugs. Data from a French cohort of over 4300 uninfected, HIV-exposed children found an 18-month incidence of clinical symptoms of mitochondrial dysfunction of 0.26%, and mortality of 0.07%[192]; these findings were only seen in children with perinatal antiretroviral exposure. The children presented with neurologic symptoms, often with abnormal magnetic resonance imaging and/or episode of significant hyperlactatemia, with deficits in mitochondrial respiratory chain complex enzyme function on biopsy of muscle. The same group has also reported an increased risk of simple febrile seizures in the first 18 months of life and persistently lower (but clinically insignificant) neutrophil, lymphocyte, and platelet counts in infants with in utero NRTI exposure.[193,194] Although the clinical abnormalities and mortality findings have not been duplicated in other cohorts from the United States and Europe to date,[195,196] the European Collaborative Study has reported similar persistent, although clinically asymptomatic, hematologic abnormalities in uninfected infants with in utero exposure.[197,198] Further studies to evaluate mitochondrial DNA content and clinical findings in infants with in utero antiretroviral drug exposure are ongoing. Thus, data are conflicting regarding whether mitochondrial dysfunction is associated with in utero antiretroviral exposure. If the association is confirmed, the risk of severe or fatal mitochondrial disease appears to be extremely rare and must be compared against the clear benefit of antiretroviral prophylaxis in reducing transmission of a fatal infection by 70% or more.[32,154] Mitochondrial dysfunction should be considered in HIV-exposed, uninfected children with perinatal antiretroviral exposure who present with severe clinical findings, particularly neurologic findings, of unknown etiology. Additionally, all children with in utero exposure to antiretroviral drugs should have long-term follow-up into adulthood for potential toxicities of such exposure.[154]

NNRTI drugs

Of the NNRTI drugs, only NVP has been studied in pregnant women; NVP pharmacokinetics during chronic administration in pregnant women are similar to those in nonpregnant women.[187] NVP crosses the placenta, with a cord blood:maternal ratio of approximately 1.0. Data from the Antiretroviral Pregnancy Registry indicate that the prevalence of birth defects with first trimester NVP exposure was 2.1%, similar to the 3.1% total prevalence of birth defects in the U.S. population.[167] NVP is the NNRTI drug of choice in pregnancy, due to extensive clinical experience with this drug in pregnant women (Table 85-6).

However, symptomatic NVP-associated hepatic or serious rash toxicity (Stevens Johnson Syndrome/Toxic Epidermal Necrolysis), while uncommon, can be life threatening, is more frequent in women than in men, and is more likely to be seen in antiretroviral-naïve women with higher CD4 cell count (>250 cells/mm^3).[199–201] It is not known if pregnancy further predisposes women to such toxicities, but cases have been reported in pregnant women.[202,203] Thus, NVP should not be used as a component of an antiretroviral regimen when antiretroviral therapy is being initiated in women with CD4 cell counts >250 cells/mm^3 (e.g., when used solely for prevention of MTCT in women who do not require therapy for their own health) unless there are no other available alternatives.[154] Health-care providers caring for women receiving NVP during pregnancy should be aware of this potential complication and conduct frequent and careful monitoring of hepatic transaminases and clinical symptoms, particularly during the first 18 weeks of therapy. Additionally, transaminase levels should be checked in all women who develop a rash while receiving NVP. Patients who experience clinical hepatotoxicity or severe rash while receiving NVP should have NVP discontinued and should not receive NVP therapy in the future.

The other FDA-approved NNTRI drugs, delavirdine (DLV) and EFV, have not been studied in pregnant women and are teratogenic in laboratory animals. Administration of DLV to pregnant rats at doses producing systemic levels

similar or lower than typical human exposures was associated with ventricular septal defects and increased infant mortality in the offspring.[187] EFV has been discussed previously. As noted previously, if a woman receiving EFV-containing therapy becomes pregnant and this is recognized during the first trimester, EFV should be discontinued and replaced by another drug. If the patient is already in the second or third trimester when pregnancy is recognized, the high-risk exposure has already occurred and some clinicians might opt to continue EFV and evaluate the fetus by ultrasound for defects.[204] The exposure and risk should be discussed with the patient, and adequate contraception should be ensured when the woman is postpartum.

PI drugs

The PI drugs that have been studied in human pregnancy (NFV, saquinavir [SQV], indinavir [IDV], ritonavir [RTV], and lopinavir/ritonavir [LPV/r]) have generally been well tolerated (Table 85-6).[172,187] Gastrointestinal symptoms are the most common side effects of the PI drugs (e.g., nausea, vomiting, and diarrhea). There is minimal transplacental passage of PIs in humans and most infants born to mothers receiving PIs have undetectable PI concentration in cord blood.[205,206] While the limited transplacental transfer may protect the fetus from potential toxicities from in utero exposure to drug, it also suggests that PI therapy during labor will not provide postexposure prophylaxis to the newborn at the time of birth, in contrast to the NRTI drugs or NVP. No specific teratogenic effects have been noted in animals or observed in the Antiretroviral Pregnancy Registry to date, although with the exception of NFV, the numbers of reported pregnancies remain small.[167]

Optimal dosing of PIs in pregnancy remains to be determined; lower serum concentrations have been observed in pregnant compared to nonpregnant women, although in most cases HIV RNA levels in the pregnant women have remained suppressed.[32,187] There are conflicting data regarding NFV levels in pregnant women; however, data suggest that although levels are variable, standard 1250 mg twice daily dosing should maintain adequate levels in most women.[207–210] Other than NFV, use of nonboosted PIs in pregnancy is not recommended. Given the safety experience and documentation of appropriate dosage, NFV given twice daily or LPV/r are reasonable choices for PI drugs in pregnant women (Table 85-6). Some data suggest that drug levels of LPV/r when given on the no longer available capsule formulation may be lower in pregnant women during the third trimester than postpartum[211]; there are not yet data on the currently available tablet formulation of LPV/r. Viral response to treatment should be carefully monitored. There are very limited to no data on the pharmacokinetics of amprenavir (APV), fos-APV, atazanavir (ATV), darunavir (DRV) or tipranavir (TPV) in pregnant women.

Hyperglycemia, new-onset diabetes mellitus, exacerbation of existing diabetes mellitus, and diabetic ketoacidosis have been reported with administration of PI drugs in HIV-infected patients.[177,212] In addition, pregnancy is itself a risk factor for hyperglycemia; it is unknown if the use of PIs will exacerbate the risk for pregnancy-associated hyperglycemia. Some data suggest that pregnant women receiving a PI have a slightly higher risk of developing gestational hyperglycemia or diabetes than HIV-uninfected or HIV-infected women receiving either no therapy or NRTIs only.[173,213,214] In one study, infants born to women with an abnormal glucose tolerance test had lower mean birth weight than those born to women with normal tests.[214] Clinicians caring for HIV-infected pregnant women receiving PIs should be aware of this complication and closely monitor glucose levels. Patients should be educated to recognize the early symptoms of hyperglycemia and to promptly seek health care if such symptoms develop.

PI drugs are metabolized by the hepatic CYP 450 enzyme system and can induce, inhibit, or both induce and inhibit drug metabolism enzymes, leading to the potential for complex interactions of PI drugs with other each other, NNRTI drugs, or other drugs metabolized by these enzymes.[187] Therefore, diligent monitoring of concomitant medications is needed.[215]

MANAGEMENT OF LABOR

The management of the HIV-infected woman during delivery of her infant aims to minimize the risk of MTCT, while not increasing maternal and neonatal morbidity and mortality (Table 85-4). A thorough review of maternal therapies should be done prior to administration of any drugs during labor to avoid any potentially adverse drug interactions. For example, ergot preparations should be avoided and women receiving midazolam should be monitored closely in women receiving PIs or the NNRTIs EFV or DLV because their metabolism may be delayed by such antiretroviral drugs.[32]

The potential mode of delivery should be discussed with the woman throughout pregnancy and final decisions should be based on the HIV RNA level at 34–36 weeks of gestation and the wishes of the mother.[154] ACOG recommends that elective cesarean delivery should be discussed and recommended for all HIV-infected pregnant women with viral loads above 1000 copies/mL[216] (Table 85-5). If the decision is made to perform an elective cesarean delivery, ACOG recommends that it be done at 38 weeks' gestation, due to the potential risk for labor and membrane rupture before the woman would reach 39 weeks' gestation, the standard recommended time for operative deliveries in women without HIV infection. Because of the potential for increased postoperative maternal morbidity in HIV-infected women undergoing operative delivery, clinicians may opt for administering perioperative antibiotic prophylaxisn.[212,217] In the developing world, operative delivery would not be an intervention that could be

routinely implemented safely or easily, due to its expense, invasive nature, and attendant risk of maternal morbidity and mortality.[218,219]

In women at very low risk of transmission, such as those with low or undetectable viral load, the additional benefit provided by elective cesarean section may be marginal. The Public Health Service has developed four clinical scenarios to assist in the decision about whether or not to perform an elective cesarean delivery to reduce perinatal HIV transmission.[154]

Intrapartum management of HIV-infected women should, whenever possible, minimize invasive procedures that might increase MTCT, such as fetal blood sampling and invasive fetal monitoring with procedures that may cause a break in the infant skin, such as scalp electrodes, instrumental delivery, and artificial rupture of membranes. Because duration of membrane rupture is associated with risk of MTCT,[220] in women not undergoing elective cesarean delivery, the interval between rupture of membranes and delivery should be minimized through augmenting labor as needed after spontaneous rupture has occurred.

Intrapartum AZT prophylaxis should be provided regardless of the mode of delivery, as the available data indicate that AZT provides an additional protective effect in women undergoing elective operative delivery.[66,67,116] Intravenous AZT should begin 3 hours prior to a scheduled cesarean delivery. Other antiretroviral drugs should be continued on schedule during labor or preoperatively to provide maximal virologic effects and to minimize the risk of developing drug resistance. However, d4T may antagonize the effects of AZT and therefore for women on a d4T-containing regimen, d4T should be either given orally without AZT or discontinued before intravenous AZT is administered.

Avoidance of episiotomy may decrease exposure of the infant to maternal blood; the infant should be washed before any blood is drawn, injections given, or other invasive procedures performed. Care of the HIV-exposed infant is discussed further in Chapter 86 ("Pediatric HIV Infection: Managing HIV-Exposed and HIV-Infected Children").

POSTPARTUM CARE

Because of the risk of transmission of HIV through breastfeeding, in areas where there are safe alternatives to breastfeeding, such as the United States and other resource-rich countries, HIV-infected women should be advised not to breastfeed.[154,212] This recommendation also applies to women receiving antiretroviral therapy. Passage of antiretroviral drugs into breast milk in humans has been evaluated for only a few antiretroviral drugs. AZT, 3TC, and NVP have been detected in breast milk of women receiving the drugs[99]; while the passage of other antiretroviral drugs into breast milk has not been studied in humans, studies in lactating rodents have demonstrated passage of most other antiretroviral drugs into breast milk. However, while HAART has been found to decrease HIV RNA levels in milk, it does not appear to decrease cell-associated virus.[98] As discussed previously, the efficacy of antiretroviral therapy for prevention of postnatal transmission of HIV through breast milk and the toxicity of chronic antiretroviral exposure of the infant via breast milk are unknown.

Maternal medical services during the postpartum period need to be coordinated between obstetric and HIV-specialist health-care providers. When combination therapy during pregnancy is required for treatment of the woman's HIV disease, assurance of continuity of antiretroviral therapy postpartum is critical. Additional support and measures to enhance adherence to treatment may be needed because the physical changes of the postpartum period coupled with the stress and demands of caring for a newborn infant may make adherence more difficult during this period.[221]

For women receiving antiretroviral drugs solely for prevention of MTCT, an evaluation should be made to determine the need for antiretroviral therapy during the postpartum period. If therapy is not required, antiretroviral drugs can be discontinued. In general, all drugs should be discontinued simultaneously. However, due to the long half-life of the NNRTI drugs[94] and the potential for single mutation to induce resistance to this class of drugs, some clinicians may continue the dual NRTI component of therapy for a period of time (e.g., 7 days) after discontinuation of the NNRTI in an attempt to reduce the risk of developing resistance. The optimal duration of time is not known; NVP resistance was seen in 15% of women receiving NVP-based HAART who had staggered discontinuation of therapy, with 5 days of dual NRTI therapy continued after stopping NVP.[112,113]

HIV-infected women should receive comprehensive care and support services in the period following delivery, including HIV-related medical care, psychosocial support, and assistance with family planning and contraception (Table 85-4). Options for contraceptive methods should be discussed. Barrier methods of contraception are recommended to prevent HIV transmission and potential acquisition of HIV superinfection or other sexually transmitted diseases. If hormonal contraception is being considered, potential interaction with antiretroviral and opportunistic infection prophylaxis drugs should be assessed.[154] Several PI and NNRTI drugs as well as rifampin and rifabutin may lower hormonal levels and decrease contraceptive efficacy of oral hormonal contraceptives (see Chapter 78 "Contraceptive Choices and STD/HIV"). Interactions of antiretroviral drugs with injection hormonal contraceptives, such as depot medroxyprogesterone, are under study.

SUMMARY

The care of the HIV-infected pregnant women is challenging for the obstetrician-gynecologist, who has the dual responsibility of assuring the health of the woman and of her child.

While primary prevention of HIV infection in women is the ultimate goal, half of individuals newly infected with HIV are women, and many will become pregnant. The obstetrician must be able to offer state-of-the-art care to maximize the health of the mother and her fetus and infant and to minimize MTCT. Standards of care for the treatment of HIV infection change rapidly, and up-to-date recommendations from the U.S. Public Heath Service regarding treatment of HIV infection in pregnancy and prevention of MTCT are available at http://AIDSInfo.nih.gov.

86 Pediatric HIV Infection: Epidemiology, Treatment, and Complications in the United States and Internationally

Mary Glenn Fowler, Edward Handelsman and Mark F. Cotton

This chapter presents an overview of the epidemiology, spectrum of disease, and current treatment of HIV-1 infection among infants, children, and adolescents—internationally and in the United States.

BACKGROUND: EPIDEMIOLOGY OF PEDIATRIC HIV-1 IN THE UNITED STATES AND WORLDWIDE

The HIV-1 pandemic has had a profound impact on the health and survival of children worldwide. As of December 2004, UNAIDS estimates that 2.2 million children less than 15 years of age were living with HIV.[1] Of these children, the vast majority (1.9 million) reside in sub-Saharan Africa. In addition, in 2004, approximately 640,000 children under 15 years of age were newly infected with HIV, primarily through mother-to-child transmission—either prenatally, at the time of delivery, or through breast-feeding. Unless there is an unexpected abatement in the global spread of HIV, the numbers of HIV-infected and affected infants, children, and adolescents will continue to escalate with increasing numbers of pediatric HIV infections being seen in the Far East as well as Africa.

The health gains in child survival that were hard won in the 1980s and early 1990s based on widespread implementation of interventions including early childhood immunization programs, promotion of breast-feeding, and use of oral rehydration therapy have in many countries been reversed due to HIV disease among both children and their caretakers. In countries such as Botswana, Zimbabwe, and Swaziland, under 5 mortality rates have doubled in recent years. In 2004, WHO/UNAIDS estimated that 510,000 children worldwide died from AIDS related causes.[1] This is occurring in the background of malnutrition, endemic diarrheal and lower respiratory infectious diseases, and malaria as well as high maternal HIV prevalence which place infants and children at increased risk for both HIV-related and other mortality.[2]

EVOLVING U.S. PEDIATRIC HIV EPIDEMIC

In the United States, there has been major progress in the prevention of perinatal HIV transmission since 1994 when the landmark trial, PACTG 076,[3] demonstrated that an intensive regimen of zidovudine given to the mother prenatally and intrapartum and followed by 6 weeks of zidovudine to the newborn, could reduce mother-to-child HIV transmission by two-thirds. Today with routine prenatal testing leading to identification of HIV-infected women during pregnancy, use of potent combination antiretroviral (ARV) and obstetrical interventions, avoidance of breast-feeding, mother-to-child transmission rates of 2% or less are being achieved.[4,5] In 2003, fewer than 200 HIV-infected infants were estimated to have been born in the United States. Elimination of any new perinatal HIV cases in the United States remains a major public health goal.

By the end of 2003, CDC estimated that there were 9419 cumulative AIDS cases reported among children <13 years since the beginning of the epidemic in the United States, the vast majority of whom were children infected through mother-to-child HIV transmission.[6] Also, by the end of 2003, there were 3927 children <13 years of age living with AIDS. In recent years, the numbers of newly reported perinatal AIDS cases have declined steadily both due to sharp reductions in perinatal HIV transmission since 1994 and potent combination treatment which has slowed the pace of progression to AIDS among HIV-infected children (Fig. 86-1).

With respect to the HIV epidemic among adolescents, at the end of 2003, the estimated number of 13–15-year olds living with AIDS in the United States was 1145 (554 males and 591 females) of whom 989 (86%) were perinatally infected, and the estimated number of 16–19-year olds living with AIDS was 1422 (715 males and 707 females) of whom 672 (47%) were perinatally infected.

The bulk of the pediatric and adolescent HIV epidemic in the United States is represented by an aging population of perinatally infected children with increasing long-term survival due to potent combination ARV treatment, as well as recently

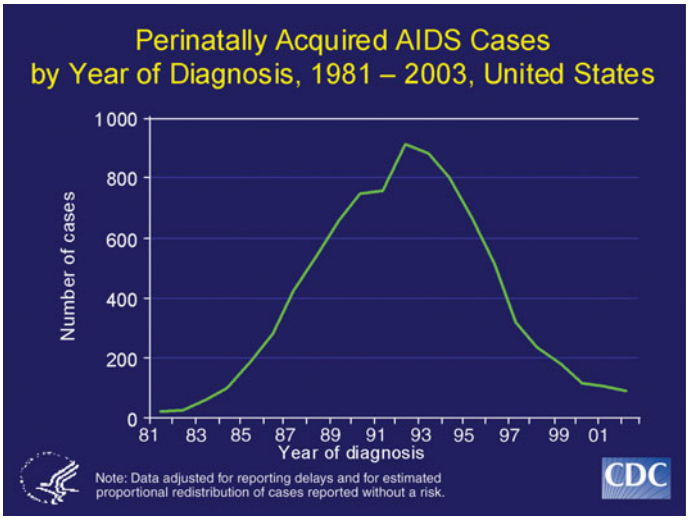

FIGURE 86-1. CDC HIV perinatal AIDS surveillance.

infected adolescents who acquired their HIV from sexual contact and/or illicit drug-related behaviors.

DEMOGRAPHICS OF THE PEDIATRIC/ADOLESCENT HIV EPIDEMIC IN THE UNITED STATES

The majority of children <13 years of age in the United States living with AIDS were perinatally infected and are of black non-Hispanic or Hispanic race/ethnicity.[6] These demographics mirror the HIV epidemic among women in the United States. Equivalent numbers of perinatally infected male and female children <13 years of age are living with AIDS, as are adolescents. Most children with perinatal AIDS live in high prevalence states where the burden of HIV among women is highest.

Emerging adolescent HIV epidemic

The southern region of the United States is seeing an increasing burden of HIV infection among youth. For adolescents aged 13–19 years, 157 of 314 or 50% of the estimated new AIDS cases diagnosed in 2003 were reported in the South. AIDS rates among youth were highest among non-Hispanic blacks followed by Hispanics. About equal numbers of new AIDS diagnoses were seen among male and female teens. AIDS represents one of the top 10 causes of death among blacks aged 10–19 years.[6]

The numbers of behaviorally HIV-infected adolescents living in the United States are likely underestimated due to a number of factors: name-based HIV (non-AIDS) reporting is not done in all states; HIV testing is not usually done as part of routine health care in adolescence; and the majority of recently infected adolescents are asymptomatic. Thus, many behaviorally infected adolescents do not become identified as HIV infected until they become symptomatic from their disease, which often does not occur until their twenties. Available CDC 2003 surveillance data[6] from 33 HIV-reporting states indicates that three-quarters of new HIV infections occurred among black and Hispanic youth, and that in 13–19 year olds, new cases of HIV infection among females and males were equal. Among females, heterosexual transmission was the major mode of transmission. Among males, transmission related to male-to-male sexual exposure accounted for three-quarters of all newly reported HIV (non-AIDS) infections. Rosenberg et al.[7] have estimated that 25% of the 40,000 estimated incident adolescent/ adult HIV infections occurring each year in the United States were among adolescents and youth <22 years of age.

International trends

The major impact of HIV among children worldwide has been experienced in resource-constrained settings. As HIV is a relatively new infection, considerable infrastructure needs to be in place to diagnose and treat HIV infection, both among adolescents as well as HIV-exposed infants. Adolescents in international settings are especially vulnerable to HIV due to initiation of sexual behaviors during puberty in a background of high HIV seroprevalence. In most developing international settings, including middeveloped countries such as South Africa, the majority of adolescents do not use condoms despite broad awareness of HIV.[8] In the 2004 antenatal seroprevalence study in South Africa, the seroprevalence among women less than age 20 years was 16.1%, increasing from 2% in 1992.[9] As access to ARVs increases, increasing numbers of vertically infected infants will also likely reach adolescence. Currently there are few health-care programs or facilities in resource-constrained settings focusing on unique issues associated with adolescents and HIV.

Despite high antenatal HIV seroprevalence in many resource-limited settings in Africa, the introduction of mother-to-child HIV prevention programs has been slow until recently. However, with the infusion of substantive donor funding, infrastructure has improved and more is being accomplished. Perinatal HIV prevention programs are a key entry point for women and their partners into HIV prevention and identification programs. The scale is immense. For example, in South Africa this translates into HIV screening accompanied by pre- and posttest counseling for a million pregnancies per year and perinatal HIV transmission prophylaxis for 270,000 women and their infants.[9] National prevention of mother-to-child transmission programs (PMTCT) in resource-limited settings often rely on single dose nevirapine prophylaxis because of the simplicity of the regimen coupled with moderate efficacy (12% transmission rate; 42% relative efficacy at 6 weeks[10] and 18 months[11]). Relatively more complex programs such as maternal zidovudine from 28 weeks gestation plus single dose nevirapine to mothers and their newborns have been shown to reduce transmission to 2% in a Thailand trial[12] among non-breastfeeding women and to about 5% in a West African breastfeeding setting.[13]

Trials are currently underway to assess the relative efficacy and toxicity of maternal HAART given prenatally and during 6 months of breast-feeding when compared to short course zidovudine plus single dose NVP, as well as trials assessing the efficacy of extended infant prophylaxis during breast-feeding.[14] As trial results emerge and infrastructure to deliver ARV treatment improves, use of maternal HAART for perinatal HIV prevention as well as extended infant exposure to ARVs may become more widespread in resource-limited settings. Follow-up monitoring for potential late sequelae of ARV exposure as well as improvements in child survival will be important.

Early diagnosis of HIV infection among HIV-exposed infants is crucial in order to intervene against the high risk of early mortality. In a meta-analysis of nine perinatal HIV transmission prevention studies undertaken in Africa, 52% of HIV-infected children died by 2 years of age, reflecting more than sixfold higher mortality than in exposed uninfected infants.[15] Infant mortality is affected by many factors, including maternal health, nutrition, and availability of medication to treat and prevent opportunistic and intercurrent infections.

Programs to reduce mother-to-child HIV transmission will not only have considerable benefit for individual children but will enable health-care workers to focus more resources on early infant HIV diagnosis, delivery of ARVs, and careful follow-up management of infected infants and children.

DIAGNOSIS AND DEFINITIONS OF PEDIATRIC HIV INFECTION

INFANT HIV DIAGNOSTIC TECHNOLOGIES

In the United States, capability for early detection of HIV infection among infants advanced rapidly in the 1990s with widespread use of virologic assays. Polymerase chain reaction (PCR) assays are used most commonly and are widely available for infant diagnosis. Other diagnostic technologies used less frequently include HIV culture and immune complex dissociated p24 antigen assays. The majority of HIV-infected infants in the United States are followed at tertiary care centers and can reasonably be diagnosed as infected within the first weeks to months of life given the lack of breast-feeding. In one study by Dunn et al.,[16] about 40% of HIV-infected infants had positive DNA PCRs on samples within the first 48 hours of life, 93% were positive by 14 days of life, and by one month of age 96% of later confirmed infant infections were detected with a specificity of 99%.

RNA PCR is used less frequently for infant diagnosis but several studies suggest that it is as sensitive as DNA PCR for infant diagnosis and may be somewhat more sensitive than DNA PCR in the first few weeks of life.[17,18] At some U.S. pediatric treatment centers, quantitative RNA is used as the confirmatory test after an initial positive DNA test. This approach also has the advantage of providing a baseline viral load assessment prior to initiation of ARV treatment. PCR testing of HIV-exposed infants is usually performed with the first 48 hours of life and then repeated several times during the first several months of life in order to definitively define infant HIV status. The use of PCR kits that are more sensitive in detecting non-B subtypes should be undertaken in U.S. settings if infection with non-B subtypes is a possibility.

In resource-limited international settings, early diagnosis of HIV infection is critical due to the high mortality rate approaching 40–50% for HIV-infected infants by 18–24 months of age.[11,15] However, there are a number of barriers to early infant diagnosis. First, PCR assays are often not widely available to confirm pediatric HIV status particularly in resource-limited settings. Under these circumstances, HIV infection is generally not definitively ascertained until serological testing in the second year of life. Second, even where PCR technology is available, it is often not possible to perform more than one HIV-specific nucleic acid test per patient because of cost and infrastructure limitations.

Given ongoing breast-feeding, the optimum timing of PCR testing has not been determined. A number of perinatal HIV studies in resource-limited settings have documented ongoing infection in breast-feeding populations with a low but continual risk of transmission of about 0.6–0.9% per month after the first 6 weeks of life with an additional absolute risk of about 8–12% for infants who are breastfed through 18–24 months.[19,20] In the PETRA study,[21] transmission increased from 5.7% at 6 weeks to 15.7% at 18 months in the most intensive prenatal, intrapartum, and postpartum intervention arm of the trial. Likewise, in South Africa, the Good Start Study evaluated the operational effectiveness of the South Africa National PMTCT Program in three diverse sites (in Paarl, Western Cape, East Cape, and KwaZulu Natal) and found late transmission varied substantially by site resources. In Paarl, Western Cape, 8% of HIV-exposed infants negative at 3 weeks of age became infected by 36 weeks compared to 12% in KwaZulu Natal and 19% in the East Cape.[22] Currently, South Africa ARV treatment guidelines, as well as Ministry of Health guidance in a number of other African countries, recommend infant HIV testing be done on a single DNA PCR at 6 weeks of age. However, some settings such as the Western Cape of South Africa have opted for PCR testing at 4 months because of increased ease of venipuncture by clinic nurses and ability to identify additional infants who may have been infected during early breast-feeding.

There is also increasing interest in the use of rapid tests for the detection of HIV antibodies in HIV-exposed infants in resource-limited settings due to cost-effectiveness and ease of use in primary care settings.[23] Efficacy is extrapolated from adult data. The test is considered accurate in children above 18 months of age, provided it is correctly performed and that a positive test is confirmed by a rapid test from a different manufacturer and from a separate blood draw. Use of oral fluids for diagnosis could prove extremely useful and avoid the need for blood draws for infant diagnosis.

PEDIATRIC HIV CASE DEFINITIONS–CDC AND WHO CRITERIA

The 1994 CDC definition[24] of definitive pediatric HIV infection requires at least two positive HIV viral assays (generally DNA PCR) on separate specimens. Definitive exclusion of HIV infection among HIV-exposed infants is based on two or more negative virologic tests on separate specimens, one of which is performed after 1 month of age and one after 4 months, and given that the mother is not breast-feeding. Follow-up serology at 15–18 months of age is routinely performed to confirm loss of antibody in an infant with negative PCRs. A positive serology at >18 months can also be used to identify older infants if they did not receive earlier PCR testing. The current CDC Pediatric Clinical and Immune Classification system for HIV-infected children is summarized in Table 86-1. Children with either a Clinical Category C diagnosis (see Table 86–1B) and/or whose CD4 percentage falls in Immune Category 3 are defined as having AIDS.

In international resource-limited settings where many HIV-infected women breast feed, diagnosis of infant infection is considerably more challenging both due to a low but ongoing risk of HIV infection throughout lactation as well as limited availability of early infant virologic diagnosis. Based on studies in Kenya[25] and Uganda,[11] the mortality for HIV-infected infants without treatment is in the range of 40–50% by age 18–24 months. With the expanding availability of ARV treatment, development and implementation of innovative strategies to support early HIV diagnosis and identify infected infants is crucial in order to provide timely ARV and prophylaxis interventions to reduce the high risk of HIV-related mortality. Testing strategies being examined for widespread implementation include collection of infant dried blood spots (DBS) from HIV-exposed infants at 6 weeks of life under a variety of field settings, which can then be transported to regional centers where real-time PCR for infant diagnosis is available at relatively low cost.[26] Another approach is the use of heat dissociated p24 antigen assays, [27] which has the advantage of being a test that can be performed at local rural sites with limited laboratory facilities. However, the test is less sensitive than PCR in the first months of life.

There will continue to be some infants born to HIV-infected women in resource-limited international settings for whom early diagnosis, based on virologic tests, is not available. In this situation, the WHO supports use of total lymphocyte count (TLC) and clinical diagnosis to help identify HIV-exposed infants who are likely to be HIV infected and would benefit from ARV interventions even without a definitive virologic diagnosis.[28]

THE CURRENT WHO CASE DEFINITION[28] OF INFANT HIV INFECTION

Definition of HIV infection in many international settings depends on the resources available for testing. Confirmed laboratory evidence of HIV infection includes the presence of HIV antibody when the child is >18 months and virological PCR or P24 Ag testing for those aged <18 months when these tests are available. Most important is the situation of clinically advanced disease in the absence of virological confirmation, where highly active ARV treatment is indicated.

WHO STAGING

One of the most important issues when initiating a new program is how to effectively deploy scarce resources. Because of late initiation of ARV treatment programs, many children already have advanced disease. The CDC pediatric HIV classification system[24] was devised for North America and Europe and has much predictive value. Although useful in Africa, it does not accurately describe the clinical spectrum of disease. In a study from Malawi,[29] the majority of HIV-infected children had died prior to having any clinical or immunologic CDC staging done. Malnutrition is inadequately dealt with in the CDC classification since in order to be classified in category C, an infant must also have either chronic diarrhea or persistent fever. Malnutrition is a major predictor for death in African children.[30] Only disseminated TB is considered in the CDC pediatric HIV classification although other forms of TB, especially pulmonary, occur commonly in resource-poor settings.[31] The current WHO criteria for clinical and immunologic staging are listed in Table 86-2.

WHO has proposed the following definitions of AIDS for surveillance among children under 15 years: all Clinical Stage 3 or Stage 4 disease or where CD4 is available, any clinical stage with

- CD4% <25% in infants under 12 months;
- CD4% <20% in children 12 months or over;
- CD4 absolute count <350/mm^3 in children 6 years and above.

PEDIATRIC HIV DISEASE PROGRESSION

There are a number of factors that appear to affect the rate of pediatric HIV disease progression. These include both host immunogenetics, viral characteristics, availability and adherence to ARV regimens, completeness of viral suppression, and emergence of drug resistance. Among perinatally infected children, prior to availability of highly active ARV therapy, increased maternal illness severity based on clinical symptoms and CD4 count was noted to be associated with infant disease progression.[32–34] Likewise, in the absence of HAART, high viral load in infants (>1,000,000 copies/mL) and CD4 percent <15 were associated with more rapid progression to AIDS and increased early mortality.[35]

Before effective therapy, the average time till progression to AIDS was 9 years among perinatally infected children.[36] Since the availability of HAART, several studies have confirmed that the rate of pediatric HIV disease progression to AIDS has been slowed and survival length has increased substantively. Reports from several U.S. cohorts confirm that survival rates

Table 86-1. A. CDC 1994 Revised Human Immunodeficiency Virus Pediatric Classification System: Clinical and Immune Categories

Clinical Category N: Asymptomatic

Children who have no signs or symptoms considered to be the result of HIV infection or who have only one of the conditions listed in Category A.

Clinical Category A: Mildly symptomatic

Children with two or more of the conditions listed below but none of the conditions in Categories B and/or C.

- Lymphadenopathy (≥0.5cm at more than two sites; bilateral = one site)
- Hepatomegaly
- Splenomegaly
- Dermatitis
- Parotitis
- Recurrent or persistent upper respiratory infection, sinusitis, or otitis media

Clinical Category B: Moderately symptomatic

Children who have symptomatic conditions other than those listed for Category A or C that are attributed to HIV infection. Examples of conditions in clinical Category B include but are not limited to

- Anemia (<8 gm/dL) neutropenia (<1000 cells/mm^3), or thrombocytopenia (<100,000/mm^3) persisting ≥30 d
- Bacterial meningitis, pneumonia, or sepsis (single episode)
- Candidiasis, oropharyngeal thrush, persisting >2mo in children >6 mo of age
- Cardiomyopathy
- Cytomegalovirus infection, with onset before 1 mo of age
- Diarrhea, recurrent of chronic
- Hepatitis
- Herpes simplex virus (HSV) stomatitis, recurrent (more than two episodes in 1 y)
- HSV bronchitis, pneumonitis, or esophagitis with onset before 1 mo of age
- Herpes zoster (shingles) involving at least two distinct episodes or more than one dermatomes
- Leiomyosarcoma
- Lymphoid interstitial pneumonia (LIP) or pulmonary lymphoid hyperplasia complex
- Nephropathy
- Nocardiosis
- Persistant fever lasting >1 mo
- Toxoplasmosis, onset before 1 mo of age
- Varicella, disseminated (complicated chickenpox)

Clinical Category C: Severely symptomatic

Children who have any condition listed in the 1987 surveillance case definition for AIDS with the exception of LIP. (see Table 86-1B)

Table 86-1. B. CDC Pediatric Clinical Category C Conditions

- Serious bacterial infections, multiple or recurrent (i.e., any combination of at least two culture-confirmed infections with a 2-year period) of the following types: septicemia, pneumonia, meningitis, bone or joint infection, or abscess of an internal organ or body cavity (excluding otitis media, superficial skin or mucosal abscesses, and indwelling cather-related infections)
- Candidiasis, esophageal or pulmonary (bronchi, trachea, lungs), Coccidiodomycosis, disseminated (at site other than or in addition to lungs, cervical, or hilar lymph nodes)

(*Continued*)

Table 86-1. B. (*Continued*)

- Cryptococcosis, extrapulmonary
- Cryptosporidiosis or isosporiasis with diarrhea persisting >1 mo
- Cytomegalovirus disease with onset of symptoms at age >1 mo (at a site other than liver, spleen, or lymph nodes)
- Encephalopathy (at least one of the following progressive findings present for at least 2 mo in the absence of a concurrent illness other than HIV infection that could explain the findings: (a) failure to attain or loss of developmental milestones or loss of intellectual ability verified by standard developmental scales or neuropsychological tests; (b) impaired brain growth or acquired microcephaly demonstrated by head circumference measurements or brain atrophy demonstrated by computerized tomography or magnetic resonance imaging (serial imaging is required for children <2 years of age; (c) acquired symmetric motor deficit manifested by two or more of the following: paresis, pathologic reflexes, ataxia, or gait disturbance
- Herpes simplex virus infection causing a mucocutaneous ulcer persisting for >1 mo; or bronchitis, pneumonitis, or esophagitis for any duration affecting a child >1 mo of age
- Histoplasmosis, disseminated at a site other than or in addition to lungs or cervical or hilar lymph nodes
- Kaposi's sarcoma
- Lymphoma, primary, in brain
- Lymphoma, small, noncleaved cell (Burkitt's) or immunoblastic or large cell lymphoma or B-cell or unknown immunologic phenotype
- *Mycobacterium tuberculosis*, disseminated, or extrapulmonary
- *Mycobacterium*, other species or unidentified species, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes)
- *Mycobacterium avium* complex or *M. kansaii*, disseminated (at site other than or in addition to lungs, skin, or cervical or hilar lymph nodes)
- *Pneumoncytis jiroveci* (formerly carinii) pneumonia
- Progressive multifocal leukoencephalopathy
- Salmonella (nontyphoid) septicemia, recurrent
- Toxoplasmosis of the brain with onset at 1 mo of age
- Wasting syndrome in the absence of a concurrent illness other than HIV that could explain the following findings: (a) persistent weight loss >10% of baseline OR (b) downward crossing of at least two of the following percentiles lines on the weight-for-age chart (e.g. 95th, 75th, 50th, 25th, 5th) in a child ≥1 y of age OR (c) <5th percentile on weight for height charts on two consecutive measurements, 30 d apart PLUS either chronic diarrhea (i.e., at least two loose stools per day for ≥30 d OR documented fever for ≥30 d, intermittent or constant)

Table 86-1. C. Immune Categories Based on Age-Specific CD4 T Cell Count and Percentage[a]

	Age up to 12 Mo	Age 1–5 Y	Age 6–12 Y
Immune category	Absolute CD4 (%) cells/mm	Absolute CD4 (%) cells/mm	Absolute CD4 (%) cells/mm
Category 1: No suppression	≥ 1500 (≥25%)	≥1000 (≥25%)	≥500 (≥25%)
Category 2: Moderate suppression	750–1499 (15–24%)	500–999 (15–24%)	500–999 (15–24%)
Category 3: Severe suppression	<750 (<15%)	<500 (<15%)	<200 (<15%)

[a]Modified from CDC 1994 revised classification system for Human Immunodeficiency Virus infection in children less than 13 years of age.[24]

for perinatally HIV-infected children born after 1996 during the time period when pediatric HAART became increasingly available in the United States were significantly better than for infected children born prior to 1997.[33,37,38] In Europe, de Martino et al.[39] reported similar trends with reduction in mortality for those born between 1996 and 1998.

Average survival of HIV-infected children in resource-limited countries has been much shorter[11,15,25,29] than in the

Table 86-2. A Revised WHO Clinical Staging of HIV for Infants and Children (Interim Africa Region Version)

STAGE 1

- Asymptomatic
- Persistent generalized lymphadenopathy (PGL)

STAGE 2

- Hepatosplenomegaly
- Recurrent or chronic upper respiratory tract infections (otitis media, otorrhea, sinusitis)
- Papular pruritic eruptions
- Seborrheic dermatitis
- Extensive Human papilloma virus infection
- Extensive Molluscum infection
- Herpes zoster
- Fungal nail infections
- Recurrent oral ulcerations
- Lineal Gingival Erythema (LGE)
- Angular cheilitis
- Parotid enlargement

STAGE 3

Conditions where a presumptive diagnosis can be made using clinical signs or simple investigations:

- Unexplained moderate malnutrition[b] not adequately responding to standard therapy
- Unexplained persistent diarrhoea (14 d or more)
- Unexplained persistent fever (intermittent or constant, for longer than 1mo)
- Oral candidiasis (outside neonatal period)
- Oral hairy leukoplakia
- Acute necrotizing ulcerative gingivitis/periodontitis
- Pulmonary tuberculosis[c]
- Severe recurrent presumed bacterial pneumonia
- Conditions where confirmatory diagnostic testing is necessary
- Lymphoid interstitial pneumonitis (LIP)[d]
- Unexplained anemia (<8 gm/dL), neutropenia (<1000/mm^3) or thrombocytopenia (<50,000/ mm^3) for more than 1 mo
- Chronic HIV-associated lung disease including bronchiectasis

STAGE 4[e]

Conditions where a presumptive diagnosis can be made using clinical signs or simple investigations:

- Unexplained severe wasting or severe malnutrition[f] not adequately responding to standard therapy
- Pneumocystis pneumonia
- Recurrent severe presumed bacterial infections (e.g., empyema, pyomyositis, bone or joint infection, meningitis but excluding pneumonia)
- Chronic herpes simplex infection; (orolabial or cutaneous of more 1 mo duration, visceral of any duration)
- Extrapulmonary tuberculosis
- Kaposi's sarcoma
- Oesophageal Candidias
- CNS toxoplasmosis (outside the neonatal period)
- HIV encephalopathy

Conditions where confirmatory diagnostic testing is necessary:

- CMV infection (CMV retinitis or infection of organ other than liver, spleen, or lymph nodes onset at age 1 mo or more)
- Cryptococcal meningitis (or other extrapulmonary disease)
- Any disseminated endemic mycosis (e.g., extrapulmonary histoplasmosis, coccidiomycosis, penicilliosis)
- Cryptosporidiosis
- Isosporiasis
- Disseminated nontuberculous mycobacteria infection
- Candida of trachea, bronchi, or lungs
- Acquired HIV-related rectal fistula
- Cerebral or B-cell non-Hodgkin's lymphoma
- Progressive multifocal leukoencephalopathy (PML)
- HIV-related cardiomyopathy or HIV-related nephropathy

[a]For use in those under 15 years with confirmed laboratory evidence of HIV infection; HIV antibody where age >18 months, virological or P24 Ag testing for those age <18 months.

[b]Moderate malnutrition: Defined as very low weight for age - http://www.who.int/child-adolescent-health/publications/CHILD_HEALTH/ WHO_FCH_CAH_00.1.htm or page4 http://www.who.int/nut/documents/manage_severe_malnutrition_eng.pdf

[c]As for footnote 2.TB is particularly difficult to diagnose in infants and young children

[d]Lymphoid Interstitial Pneumonitis (LIP) : Definitions available in accompanying notes

[e]A presumptive Stage 4 diagnosis in seropositive children less than 18 months old may be made when virological confirmation of infection is not available if an HIV-seropositive infant less than 18 months is symptomatic with two or more of following; oral thrush, ± severe pneumonia,± severe wasting/malnutrition, ± severe sepsis, severe immunosuppression should be suspected and ARV treatment is indicated

CD4 values where available may be used to guide decision making, CD4% below 25 requires ARV treatment

other factors that support diagnosis of clinical stage 4 HIV infection in an HIV-seropositive infant are recent maternal death and advanced HIV disease in mother.

confirmation of the diagnosis of HIV infection should be sought as soon as is possible

[f]Severe Malnutrition: Defined as very low weight or visible severe wasting or edema of both feet Ref: http://www.who.int/child-adolescent-health/publications/CHILD_HEALTH/WHO_FCH_CAH_00.1.htm

(*Continued*)

Table 86-2 B. World Health Organization Immunological Categories for Paediatric HIV Infection[a] (*Continued*)

Immune Status	Age up to 12 Mo	Age 13 Mo or Over	6 y or Over
Not considered to have significant immunosuppression	>35%	>25%	>500 mm^3
Evidence of mild immunosuppression	25–34%	20–24%	350%–499/mm^3
Evidence of advanced immunosuppression	20–24%	15–19%	200%–349/mm^3
Evidence of severe immunosuppression	<20%	<15%	<200/mm^3

[a]CD4 values and their relation to immunological status are provided in the table below to assist clinical decision making and link with monitoring and surveillance.

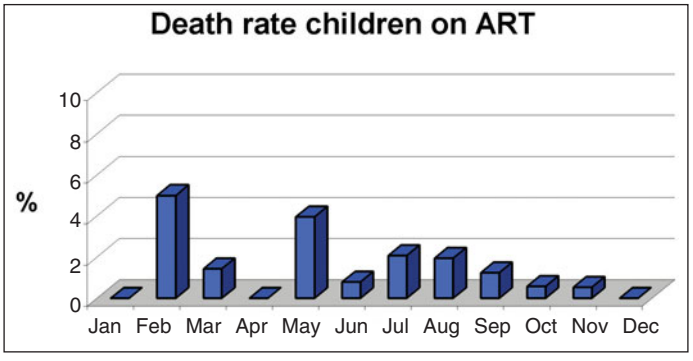

FIGURE 86-2. Death rate over first 12 months of antiretroviral roll-out at Tygerberg Children's Hospital, South Africa 2004 (data from Andre du Preez, Tygerberg Pharmaceutical Service).

United States and Europe. However, with the recent expansion of HAART availability in many international settings, it is anticipated that similar improvements in survival among HIV-infected children will be seen. Because of the scale of the pandemic, despite the high mortality in the first 2 years of life, substantial numbers of HIV-infected children survive infancy, even in the absence of ARV therapy. For example, in the recently completed CHAP trial carried out in Zambia, of 534 children, 21% of subjects were between 6 and 9 years of age and 15% over 10 years of age.[40] In a study from Cape Town, 16% of 143 children followed for more than 6 months were over 5 years of age at first visit to a family clinic for HIV.[41] By this stage, the majority of children have moderate to severe morbidity due to end-organ damage such as chronic lung disease. Early experience with HAART in international settings such as Cape Town, South Africa has confirmed the survival benefit of HAART, with most mortality seen in children where treatment was initiated in the presence of advanced disease (see Fig. 86-2). Likewise, Médecins Sans Frontières (MSF) reviewed data on 1840 HIV-infected children from 13 resource-poor countries and documented a probability of survival of 91% after 24 months (www.msf.org).[42]

TREATMENT RECOMMENDATIONS FOR CHILDREN AND ADOLESCENTS WITH HIV

CURRENT U.S. TREATMENT PRACTICES

Treatment of children and adolescents with HIV includes ARV therapy, prophylaxis and treatment of opportunistic and other infections, treatment of growth and neurodevelopmental problems, and psychosocial support. HAART has been largely successful in preventing many of the complications of HIV in children and adolescents. This therapy must be accompanied by the treatment of comorbid medical and psychosocial conditions.

While the principles of using HAART are similar in children and adolescents to those in adults, a few substantial differences exist. The ongoing somatic growth and nervous system development of children affect both the pharmacokinetic parameters and potential toxicities of specific ARV agents. The fact that HIV infection detected in infants is a newly acquired acute infection increases the urgency and possibly the efficacy of ARV therapy. The limitations in available or palatable formulations of ARVs for use in infants and background of sociocultural risk factors may adversely affect adherence and thus reduce treatment efficacy in children and adolescents.

The timing of initiation of HAART in adolescents and children identified beyond the first year of life is based on the same factors as in adults. Viral load and CD4 percentage are independently correlated with a higher risk to progression to AIDS or death.[35] Thus, clinical disease, immune suppression, and viral load are all indications for initiating therapy. The decision to initiate therapy, as in adults, is made by the patient and provider together and should include any parent or guardian involved in the patient's care. They must take into account the likelihood of achieving the extraordinary level of adherence on which viral suppression is dependent.

Almost all infants identified as HIV-infected in the first year of life should be treated with HAART as early as possible after birth.[43] Newborns infected with HIV have a very high viral load in the first few months of life and have higher viral

set points in the first years of life than do HIV-infected adults.[44] Early treatment with HAART, as in acute HIV infection, may drive down the viral set point and mitigate the effects of HIV.[45] In addition, the risk of neurologic deficits in infants is increased and is not always predictable by viral or immunologic parameters, thus necessitating HAART treatment for most infected infants. The only infants for whom HAART is not automatically recommended[46] are children with no clinical symptoms and no immune deficiency based on the standard CDC classification (Table 86-1).[24]

Initial ARV therapy for children and adolescents consists of two nucleoside analogs and either a protease inhibitor or a nonnucleoside reverse transcriptase inhibitor. The choice of specific HAART regimens is limited by the lack of pediatric indications or pediatric pharmacokinetic data for many of the medications. Pharmacokinetic parameters of several ARVs change considerably with age; thus, extrapolation of dosages from adult data is risky. Furthermore, as of 2007, only 11 of the 23 approved oral ARVs have pediatric formulations (Table 86-3) and none of the multiagent combination forms has a liquid equivalent. Initial regimens for adolescents mirror those in adults, but the recommended U.S. Working Group[46] initial regimens for HIV-infected children (Table 86-4) differ somewhat as infants and young children cannot swallow the simplified combination pills available for adults, adolescents, and older children. Over the last several years, providers have been striving to use once-daily regimens (Table 86-4) especially in adolescents to promote improved adherence. Most of these include efavirenz, which if used in women of childbearing age must be used with effective contraception because of the potential teratogenicity of efavirenz.

Many children and adolescents infected during the 1980s have undergone successive regimens without complete viral suppression, thus inducing resistance to many ARVs. Decisions about switching regimens are made using the same criteria as in adults, taking into account past ARV history, resistance testing, and the likelihood of complete viral suppression. The greatly reduced numbers of newly infected children in the United States and the hesitancy to perform clinical trials in highly ARV-experienced children make pediatric phase I trials rare in the United States. Most recently approved ARV agents have been approved without a pediatric indication. These agents must, by necessity, be used in salvage therapy for pediatric and adolescent patients by HIV specialists extrapolating adult efficacy data and using the limited pharmacokinetic and safety data that has been generated in children.[47] This dilemma underscores the need for continued clinical trials for children with HIV both in the United States and internationally.

The follow-up and monitoring of children and adolescents on ARV therapy in the United States differs little from that of adults. At many tertiary care centers, follow-up phone calls are made within a week or two of initiating or changing therapy to make sure that the patient is correctly following medication instructions and to answer questions and relieve concerns related to possible medication intolerance or side effects. Viral loads are monitored within a month to assess for the expected one log initial viral load decrease. Viral load and CD4 count and percentage are then monitored every 3–4 months thereafter. Assessment for possible side effects varies depending on the regimen but always includes frequent blood counts and chemistries for the first few months to assess for hepatic, renal, or bone marrow toxicity. In general, most clinicians monitor blood counts and chemistries, including pancreatic enzymes, at

Table 86-3. Pediatric Indications and Formulations Approved or Available in the United States in 2005

Medication	Approval Age	Pediatric Formulation
NRTIs		
Zidovudine (ZDV, AZT)	All	Yes
Didanosine (ddI)	All	Yes
Zalcitabine (ddC)	13 y and up	No formulation
Stavudine (d4T)	All	Yes
Lamivudine (3TC)	All	Yes
Abacavir	3 mo and up	Yes
Tenofovir	No pediatric indication	No formulation
Emtricitabine	3 mo and up	Yes
NNRTs		
Nevirapine	All	Yes
Efavirenz	Dosing data for 3 y and up	No formulation
Delavirdine	No pediatric indication	No formulation
Protease Inhibitors		
Saquinavir	No pediatric indication	No formulation
Indinavir	No pediatric indication	No formulation
Ritonavir	All	Yes
Nelfinavir	2 y and up	Yes
Amprenavir	4 y and up	Yes
Lopinavir/r	6 mo and up	Yes
Atazanavir	No pediatric indication	No formulation
Fosamprenavir	No pediatric	No formulation
Tipranavir	No pediatric indication	No formulation
Fusion Inhibitor		
Pentafuside (T-20)	6 y and up	NA (not oral)

Table 86-4. Common First Regimens for HIV Infected Children in United States

2 Nucleoside Backbone		NNRTI or PI
Zidovudine (ZDV) + either Lamivudine (3TC) or Didanosine (ddI) or Emtricitabine (FTC) or ddI + either Lamivudine (3TC) or Emtricitabine (FTC)	+	Efavirenz (Nevirapine for children under 3 years old) or Preferred PI, Lopinavir/r
ONCE DAILY REGIMENS 2 Nucleoside Backbone		**NNRTI or PI**
Choose 2 from: (ddI or Tenofovir) + (3TC or FTC)	+	Efavirenz or Atazanivir/r

least every 3–4 months, and lipid profiles, yearly. Side effects of ARV medications in children are similar to those in adults though the frequency of some, such as lipodystrophy, appears to be related to age and pubertal development.[48]

The improving health and longer life expectancy for HIV-infected children and adolescents have prompted concerns about both long-term adherence and possible late sequelae related to lifelong ARV therapy. Pediatricians have limited experience in the treatment of chronic hypercholesterolemia, and many of the cholesterol-lowering agents have not been approved or even tested in children. Another concern is the development of resistance should the child's adherence falters at any point such as during adolescence. Studies are currently underway to evaluate multifaceted interventions aimed at improving adherence among adolescents. Treatment decisions utilize $CD4^+$ cell count and the child's clinical status, history of prior ARVs used, and resistance testing when needed. Currently available ARVs and their FDA approval status for use in HIV-infected children <13 years of age are summarized in Table 86-3.

PEDIATRIC HIV TREATMENT STRATEGIES IN RESOURCE-LIMITED INTERNATIONAL SETTINGS

International perspectives on antiretrovirals

Although in better-resourced international settings treatment approximates that in North America and Europe, adaptations need to be made to local circumstances. Often, the variety of medications available is less than in resource-rich settings. For example, protease inhibitors are not readily accessible in many African countries. Nevirapine is often the only option as a third component, along with two nucleosides, of antiretroviral therapy (ART). This may be complicated by the use of single dose nevirapine either alone or in combination to prevent mother-to-child HIV transmission and resulting in resistance mutations among infected infants.

Because of cost constraints, many countries rely on generics rather than "brand" drugs. Some countries, notably Brazil and Thailand have shown much vision in providing state assistance for generic drug manufacturing, thus ensuring high standards and reliability of life-saving medications at reasonable cost. India and South Africa have also made progress in manufacturing generics. However, although all classes of ARV generics are available, very few are suitable for children. Only zidovudine and lamivudine are available as suspensions. No generic protease inhibitors are available in liquid formulation. There is an urgent need for more pediatric-friendly formulations. These include fixed drug combinations that are chewable, scored for ease of cutting, and containing appropriate amounts of drug to permit flexibility. Currently, an adult formulation of stavudine, lamivudine, and nevirapine is available as a fixed drug combination for adults in many African countries. Many practitioners adapt these formulations by cutting tablets into two, three or four pieces. The effectiveness of this approach has been confirmed by Puthankit and colleagues in Thailand.[49]

Another important factor is the need for refrigeration of some medications such as stavudine and didanosine suspensions, as well as most protease inhibitors. In resource-limited settings, refrigerators are often not available, even in urban centers. Many formulations, such as lopinavir/ritonavir suspension require storage at room temperature defined as <25°C. Ambient temperature may often exceed this and families need to be advised how to use simple inexpensive measures to insulate containers to keep them cool.

In addition, many of the pediatric HIV liquid medications are administered with an oral syringe. Caregivers need to be carefully trained to use syringes, including how to accurately draw up the correct dose into the syringe and how to expel excess air when drawing up the medication. Decreased visual acuity of some elderly caretakers such as grandparents requires that the exact volume amounts to be drawn up need to be clearly marked on the syringes so that dosing errors can be minimized.

The optimal time to initiate ART therapy for HIV infected children in resource limited settings is not completely resolved, but recent data from a S. African trial suggest that early antiretroviral therapy for HIV infected infants before 12 weeks of age reduces early mortality [personal communication, Prof. Mark Cotton].[49a] The benefits of this approach are that rapid disease progression can be arrested and neurodevelopmental impairment should be prevented.[50]

The WHO currently recommends initiating therapy in children with stage 3 and 4 disease or in those where CD4 counts can be measured when threshold values have been reached (Table 86-5).[28]

Adherence is a major focus in pediatric ARV treatment programs in resource-limited settings in order to ensure that the first-line regimens are likely to succeed as long as possible. An important component is well-trained lay counselors, who assess and counsel caregivers before and during therapy. Counseling sessions to ensure ART preparedness precede therapy. Disease progression may be rapid in young infants, and clinical judgment should be used to fast-track therapy in young, highly symptomatic infants. The counselor discusses how the medication works, the importance of adherence, and introduces the caregiver to the various preparations. Most important is to designate a single caregiver to take responsibility for the medication. Disclosure of status to someone in the household is encouraged. The doctor and the counselor stress adherence at every visit. Once medication is initiated, a follow-up visit is usually arranged within a week to check adherence. Diary cards and pillboxes are useful to focus discussions. If resources permit, color-coding of medication with the child putting a small label with the same color on the diary card is useful. Dosage must be adjusted for weight at each visit as successful therapy implies normal or even accelerated "catch-up" growth. Visits are usually monthly with triage into doctor or nurse-based visits. As therapy stabilizes, more of the visits are nurse-based.

There are a number of barriers that can affect the implementation of HIV treatment for infected children living in resource-limited settings. Although some caregivers elect to travel to tertiary centers to avoid stigmatization in communities, transport is often a major challenge and expense for caregivers who live away from available pediatric HIV treatment centers. For example, in the Western Cape Province of South Africa, pediatric ARV treatment began mainly in tertiary centers, requiring infected children and their caretakers to travel. To ease this burden, community outreach programs that can provide pediatric HIV treatment in facilities closer to the child's home are now being introduced. Another barrier may be that community doctors and nurses are often less trained in HIV treatment of children than adults and this can result in delays in pediatric HIV treatment initiation even though the child meets WHO criteria for therapy.

Table 86-5. WHO Clinical Criteria for Initiating Antiretroviral Therapy in Resource-Limited Settings (in Infants and Children Under 15 Years)

Clinical Stage	ART	
Stage 4	Treat	
Presumptive stage 4	Treat	
Stage 3	Consider treatment for all ages. Children less than 2 y usually require ART	
	CD4 if available, and clinical conditions should be used to guide ART treatment decision	
Stage 1 and 2 where CD4 available	≤11 mo	CD4 ≤25% or ≤1 500 cells/mm^3
	12–35 mo	CD4 ≤20% or ≤750 cells/mm^3
	36–59 mo	CD4 ≤15% or ≤350 cells/mm^3
	≥5 y	CD4 ≤15% or ≤200 cells/mm^3
Stage 2 where only total lymphocyte count (TLC) available	≤11 mo	
	12–35 mo	TLC ≤4000 cells/mm^3
	36–59 mo	TLC ≤3000 cells/mm^3
	≥5 y	TLC ≤2500 cells/mm^3
		TLC ≤1500 cells/mm^3

All HIV-exposed children (until HIV infection is excluded) and HIV-infected children with signs or symptoms of HIV should be given cotrimoxazole prophylaxis.
CD4% preferred in children <5 years.

Because of delays in initiating ARV programs, many children have advanced disease when starting therapy and are often on multiple drugs for other conditions, creating the possibility of increased toxicity because of overlapping side effects. For example, antituberculosis medication has overlapping hepatic and cutaneous toxicity.[51] Also, the immune reconstitution inflammatory syndrome (IRIS) occurs commonly in children with advanced disease. These conditions are often best managed in a referral hospital and include Bacille Calmette-Guérin disease (BCG),[52] worsening TB, and chorioretinitis due to cytomegalovirus (CMV).

COMPLICATIONS OF HIV AMONG CHILDREN AND ADOLESCENTS

COMPLICATIONS OF HIV IN CHILDREN AND ADOLESCENTS: UNITED STATES

The manifestations of HIV and its complications among infected children in the United States have changed over the course of the epidemic. In the late 1980s and early 1990s, AIDS-defining opportunistic infections and severe growth and developmental problems were commonly seen as presenting illnesses that identified a child as HIV-infected. Now, with the sharp reductions in mother-to-child transmission in the United States, early identification of HIV-infected children generally in the first few months of life and early initiation of highly effective ARV therapy with resultant preservation of immune function, most of these opportunistic infections have become rare and replaced by milder more chronic conditions.

While some clinical manifestations of HIV occur in all age groups, the incidence of others varies considerably. Behaviorally infected adolescents display manifestations similar to those seen in adults. Perinatally infected children exhibit a different spectrum of disease largely due to the unique growth and neural development occurring in children and to their immature immune systems that have yet to develop humoral immunity to common infections.

As in adults, *Pneumocystis jiroveci (formerly cariini)* pneumonia was a common opportunistic infection in children throughout the early part of the HIV epidemic. Other common opportunistic infections included *Mycobacterium avium* complex (MAC), herpes zoster, and invasive candidal infections. Cytomegalovirus infection was also relatively common in children, although the presentation was more varied and more often involved central nervous system (CNS), GI tract, or respiratory infection than in adults. One key difference in presentation of HIV in children compared to adults is the very high incidence of bacterial infections including sepsis, meningitis, and pneumonia in HIV-infected children.[53]

The developing CNS of children is at particular risk for compromise from HIV. Most of the CNS involvement in children results from direct effect of HIV. This may present as overt HIV encephalopathy with irritability, cognitive and motor deficiencies, or less intensely as global or motor developmental delay. Opportunistic infections invading the CNS such as Cryptococcus and toxoplasmosis are seen much less frequently in children than in adults.[54]

Severe growth delay involving both height and weight was common manifestation of pediatric HIV infection in the United States in the late 1980s and early 1990s but is much less common now for children who began early on highly effective combination ARV therapy. Differences in growth rates between infected and uninfected children were seen within the first few months of life and increased in severity with time.[55] Growth delay in HIV-infected children can be directly caused by HIV but may also result from infections causing vomiting, diarrhea, or food intolerance from medication side effects or from social circumstances. HIV-infected children with growth delay experience an improvement in growth after starting treatment with HAART but deficits can persist.[56] Delayed puberty has also been reported in significant proportions of HIV-infected children.[57]

Many of the more severe manifestations of HIV have become rare because of earlier identification and prompt initiation of highly effective ARV treatment of children with HIV.[37] *Pneunocystitis jiroveci* pneumonia occurs much less frequently and almost exclusively in few children whose mothers have not been tested for HIV and thus whose identification is delayed. MAC, CMV, and cryptosporidium are now quite rare among children on HAART. Lymphoid interstitial pneumonitis (LIP), a chronic pulmonary condition possibly related to Ebstein Barr Virus (EBV) infection was a common AIDS-defining condition for children early in the epidemic but now is almost never seen. However, oral and esophageal candidiasis and bacterial infections remain relatively common in chronically-infected children and adolescents whose immune function remains compromised.[45,58] While gross HIV-related ence-phalopathy is now rare, developmental delays continue. Neuropsychological disease is much more common in perinatally-infected children and teens; psychiatric hospitalizations occurred at a rate more than three times that of the general population.[59] Softer neurobehavioral findings such as attention deficit/hyperactivity disorder have also been reported among HIV-infected children in some prospective perinatal studies but may be related to background environmental factors.[60]

COMMON OPPORTUNISTIC INFECTIONS SEEN AMONG HIV-INFECTED CHILDREN IN INTERNATIONAL SETTINGS

Among the complications of pediatric HIV disease seen in resource-limited settings, chronic lung disease is common in HIV-infected children surviving infancy, often accompanied by pulmonary hypertension and cardiac failure. The extent of developmental delay is beginning to be quantified. HIV causes

many of the same opportunistic and intercurrent infections seen in developed countries prior to highly effective combination ARV therapy. Candidiasis, including oral, laryngeal, and esophageal, is a frequent opportunistic pathogen. *Pneumocystis jiroveci* pneumonia, while originally assumed to be rare in Africa, actually occurs commonly based on more recent laboratory-based findings.[61,62] Malnutrition, bacterial pneumonia, diarrhea, and tuberculosis occur commonly, often simultaneously.[63–65] Studies comparing bacterial infections such as pneumonia and meningitis and also viral infections in children with and without HIV show increased morbidity and mortality among HIV-infected compared to uninfected children.[66–69] Bronchiectasis[70] and recto-vaginal or recto-vesical fistulae[71] occur relatively frequently and are associated with rapid HIV disease progression.

Pulmonary tuberculosis (TB) among HIV-infected children and adults occurs commonly in resource-limited settings. In HIV-infected adults with latent TB, the annual risk of developing active TB is 5–8%, which is 12–20 times that of HIV-uninfected adults.[72,73] Among hospitalized children in Durban, South Africa, *Mycobacterium tuberculosis* was found in 8% of children with acute pneumonia.[74] In Malawi, more than 60% of childhood TB cases are coinfected with HIV.[75]

Initial TB treatment is with isoniazid, rifampin and pyrazinamide, and sometimes with ethambutol or ethionamide is also included. For HIV-infected children who have had TB coinfection in Cape Town, South Africa, TB relapse or reinfection was documented to occur in about 16% of children on follow-up. The optimal length of TB treatment is unclear and the role and length of secondary prophylaxis following treatment for TB among HIV-infected children also needs further study.[76] BCG disease is an emerging problem. This often presents as regional right axillary adenitis and may be disseminated. It is also seen frequently as part of the IRIS. Disseminated BCG is extremely difficult to manage. Children may be coinfected with *M. tuberculosis*. BCG is inherently resistant to pyrazinamide and may have reduced susceptibility to isoniazid as well.[52]

MAC infection is seen increasingly, presenting in older children with severe immunological depletion. The most common presentation is intra-abdominal lymphadenopathy accompanied by pain and occasionally fever. Prophylaxis is usually not given internationally because of expense and low priority.

Cryptococcal disease is also seen in children with advanced disease in resource-limited settings. This includes meningitis with and without cutaneous and pulmonary involvement. It may be extremely refractory to treatment, occasionally relapsing, and often requiring prolonged intravenous amphotericin B beyond the recommended 2 weeks and also fluconazole at high doses (often 15 mg/kg/day). For pediatric prophylaxis against cryptococcal disease, a minimum of 6–10 mg/kg per day of fluconazole is used in Cape Town, South Africa (personal correspondence M Cotton and Helena Rabie).

A summary of CDC, national institute of health (NIH), and Infectious Disease Society of America recommendations regarding treatment for opportunistic infections among HIV-exposed and infected children is available in the 2004 CDC MMWR[58] and at http://www.aidsinfo.nih.gov/guidelines/. Recommendations for the prevention of opportunistic infections in children in the United States and international resource-limited settings are summarized in the USPSH/IDSA Guidelines for the Prevention of Opportunistic Infections among HIV-infected persons,[77] also available at http://www.aidsinfo.nih.gov/guidelines/. (see Table 86-6.)

In the United States, trimethoprim-sulfamethoxazole (cotrimoxazole) is routinely given to all HIV-exposed infants beginning at 6 weeks of age to prevent Pneum- ocystis jiroveci pneumonia and continued until an infant is determined to not be HIV infected, based on PCR testing.[77] Those infants who are infected continue on cotrimoxazole prophylaxis throughout the first year of life and then are either continued or stopped depending on their immune status.

Internationally, cotrimoxazole is likewise an important component of prophylaxis for children infected with HIV. A recent double-blind randomized study comparing active cotrimoxazole drug to placebo among HIV-infected children in Zambia demonstrated the overwhelming benefit of the active drug irrespective of immune category.[40] The authors recommended using cotrimoxazole for prophylaxis for all HIV-infected infants and children regardless of CD4 count. In a growing number of international resource-limited settings, cotrimoxazole is also being offered to all HIV-exposed infants until HIV infection can be excluded by loss of maternal antibody or by demonstrating virus. Cotrimoxazole prophylaxis is usually given at a dosage of 5 mg/kg/day of the trimethoprim component.

While TB exposure among children in the United States is relatively rare, in international settings TB represents a major problem both among HIV-exposed or -infected children and their parents. All HIV-infected or -exposed children whose parents have TB need to have tuberculosis excluded and if not infected then to receive either isoniazid prophylaxis alone for 6 months or with rifampicin for 3 months. The following pediatric TB prophylaxis guidelines are used in Cape Town, South Africa. (Personal communication HS Schaaf, Stellenbosch University)

TB prophylaxis is indicated in an HIV-infected child <5 years of age when

- a Mantoux test is >4 mm or when there is any reaction to a Tine test (after excluding disease); and/or
- the child has had contact with an infectious adult source case (after excluding disease);
- prophylaxis is individualized in older HIV-infected patients with the above-mentioned criteria.

Table 86-6. CDC Pediatric Prophylaxis Guidelines for Some Common Pediatric AIDS-Related Opportunistic Infections

Opportunistic Infection	Criteria for Primary Prophylaxis	Recommended Prophylaxis and Alternatives	Criteria for Secondary Prophylaxis (Secondary Prophylaxis
Pneumocystis jiroveci pneumonia	HIV exposed infants 4–6 wks through 4 mo; Infected children 1–5 y if CD4 <500 cells/mm^3 or <15% Infected children 6–12 y if CD4 <200 cells/mm^3 or <15%	Cotrimoxazole Pentamidine, dapsone	One episode of P. *jiroveci* pneumonia. Continue lifetime prophylaxis. Insufficient safety data regarding stopping after immune reconstitution
Mycobacterium tuberculosis	TB-exposed infants born to HIV-infected women coinfected with TB; or other close TB exposure	Isoniazid prophylaxis for 6–9 mo Alternative in some international settings: Isoniazid + rifampicin for 3 mo	
Mycobacterium avium complex disease	<1 y olds with CD4 count <750; 1–2 y with CD4 <500; 2–6 y olds with CD4 <74; and >6 y olds with CD4 <50.		Lifetime secondary prophylaxis recommended; the safety of discontinuing after immune recovery with HAART has not been well studied in children

Regimens for TB prophylaxis include

- isoniazid daily 5 days/week or 2 times/week for 6–9 months; isoniazid and rifampicin 5 days/week for 3 months, only if it is given as directly observed therapy

Since multidrug resistant TB is increasing world wide, consultation with an expert for prophylaxis and treatment is important.

INNOVATIVE MODELS OF PEDIATRIC AND FAMILY CARE

■ U.S. MODELS OF PEDIATRIC HIV CARE

In the United States, the HIV epidemic has led to significant changes in the way that care for children with chronic diseases is provided. The varied complications of HIV, both physical and psychosocial, have necessitated that pediatric HIV care be delivered in the framework of a multidisciplinary team. While other chronic diseases have employed such models, the extent to which they are used is unique to HIV care in part based on availability of substantial federal HIV-care funding.

The disenfranchised nature of populations particularly affected by HIV necessitated the inclusion of intensive social service support as part of primary care. The lack of effective treatment early in the epidemic and the urgent need for effective medications necessitated that clinical research be a part of the general care for many children with HIV. The stigma associated with HIV demanded that psychological support and patient advocacy become part of the care. The effects of HIV on growth and neurological development similarly necessitated the inclusion of nutritionists, developmental specialists, and physical and speech therapists. The need for close-to-perfect adherence of multiple medications has led to the development of the health educator as another part of the care team.

HIV care for children has been provided in a model of care teams involving several individuals from multiple disciplines. As few new infants are becoming infected and already infected children are becoming adolescents, models of care are changing to meet the needs of the consumers. Pediatric clinics are referring patients to or becoming adolescent clinics or family care centers.

The family care model provides primary care and other services for the entire family in a convenient setting. Previously, parents (usually mothers) with HIV-infected and uninfected children had the difficulty of keeping up with appointments at three separate clinics; one for themselves, one for their infected children, and one for their

uninfected children. Even though these may have been at the same facility, often they were in different areas or at different times. The family care model attempts to focus primary care for all family members, infected and uninfected, together. Ideally, social support services, mental health services, gynecological consultation, nutritional expertise, and all other services are concurrently provided in the same location.

Another model being utilized is that of the adolescent-focused HIV care and treatment centers. As HIV-infected children age into adolescence, they often feel uncomfortable receiving care in a clinic geared toward younger children. Playrooms filled with crayons, finger paints, and books of nursery rhymes deter them from coming for care. Many centers have set up clinics and times specifically for adolescents with HIV. These are often during after-school and evening sessions, and the clinic areas are decorated by the teens themselves and have CD and DVD players creating a teen-friendly environment. Programs include informal "rap" sessions to discuss their concerns, career and school counseling, and sexual responsibility training. Such youth friendly centers are extremely effective in engaging and maintaining these youth in care.

INTERNATIONAL MODELS OF CARE

Most pediatric HIV ARV treatment and care programs have been based in larger better-resourced centers. However, the goal is to establish networks of district and community-based treatment clinics with links to referral centers for problem solving, where necessary. Although it is ideal for doctors to see the patients, under many circumstances, this may not be possible. Nurses or clinical officers, in small clinics, may need to manage patients. Under these circumstances, an excellent and ongoing education program, a referral network, and doctor-based outreach program are especially important.

Before treating any child, the caregiver needs to be counseled to ensure understanding and should be encouraged to disclose his or her status to someone in the household who can assist with giving medication. Such preparation may take 2–3 weeks. In young infants, the lead in time may need to be shortened because of rapid progression of disease. Once treatment has been initiated, visits can be triaged into doctor or nurse-based. Adherence monitors should regularly talk to caregivers and build up rapport.

One model of care is the establishment of a family clinic.[41] In many areas, successful clinics can be established with minimal cost by reorganizing existing infrastructure. Often the same health-care worker can manage multiple family members. Clinic visits may be more convenient if more than one family member is seen on a single visit. Family clinics have created an important opportunity for family practitioners to become central in HIV management.

Comprehensive care and treatment of HIV-infected adolescents requires innovative models of care tailored to the developmental needs surrounding puberty and psychosocial issues faced by HIV-infected teenagers. Not only is adolescence a period of high risk to acquire HIV and other sexually transmitted infections, increasing numbers of perinatally infected children will reach adolescence and require care. Adolescent-friendly clinics need to be urgently established.

A major feature has been the wide range of organizations that have and are facilitating access to ART. The WHO is coordinating the "3 by 5" program seeking to facilitate and mobilize resources to treat 3 million people by the end of 2005. The program commenced in 2003 and reports major progress in access to ARV drugs in resource-limited settings.[78]

FUTURE DIRECTIONS IN PEDIATRIC HIV TREATMENT AND CARE

INTERFACE OF PERINATAL PREVENTION AND PEDIATRIC HIV TREATMENT

In the United States, routine prenatal HIV testing using an opt out approach has helped identify many asymptomatic HIV-infected women during pregnancy who would not otherwise have been aware of their HIV status. This has resulted in a twofold opportunity: (1) to offer combination ARVs and obstetrical interventions that reduce the risk of perinatal transmission to 2% or less; and (2) to offer comprehensive HIV therapy/care to infected adolescent females and women beginning during pregnancy and to HIV-infected infants soon after birth through early virologic diagnosis. Current pediatric HIV treatment strategies in the United States and Europe have resulted in improved quality of life, decreased opportunistic infections, and prolonged survival into adolescence for children currently living with HIV.

The future in resource-rich settings currently suggests that survival gains will continue among children infected with HIV, while the pool of newly infected infants further declines. Issues that this aging pediatric cohort will need to face as they survive into adolescence and young adulthood are the psychosocial impact of dealing with a serious chronic illness, concerns over disclosure to sexual partners, use of effective strategies to ensure secondary HIV prevention, and difficult reproductive choices. Already there are a number of case reports of perinatally infected girls who have become pregnant and delivered infants.[79] Since many children and adolescents with HIV come from disadvantaged environments, a major challenge will be to support HIV-infected youth with future-directed vocational, higher education, and career opportunities. Other challenges will be ensuring availability of new drugs and simplified drug regimens that take into account the likelihood of decreased drug adherence during adolescence and the inevitable emergence of ARV resistance over a lifetime of treatment as well as dealing

with complications of long-term therapy such as diabetes and lipodystrophy.

In resource-limited international settings, the success of future pediatric treatment will be highly dependent on widespread implementation of prenatal HIV testing leading to timely identification of the majority of HIV-infected women during pregnancy, offering of perinatal interventions, and early virologic testing of HIV-exposed infants. Early infant diagnosis is crucial in these settings in order to initiate ARV treatment and prophylaxis since the majority of infected infants will die before their third birthday without treatment.[11,15,29] Operational research addressing innovative approaches to collection of infant DBS at 6–8 weeks in rural African field conditions, solving the logistics of transportation of the DBS to regional centers for PCR testing, and getting results back to the field site in a timely manner are a high priority in order to identify infected infants early enough to intervene with effective treatment. Likewise, the availability of weight charts that provide clinicians with fixed doses for given weight ranges and scored combination tablets that can be accurately cut for pediatric doses will be needed to ensure that HIV-infected children are not left behind as ARV treatment programs roll out.

One pressing research issue is to understand whether exposure to drugs for PMTCT such as NVP with detection of transient resistance will have a negative impact on early treatment for infected infants and on subsequent maternal treatment. Another is the development of intervention strategies for minimizing nevirapine resistance, such as adding a short course of lamivudine and zidovudine, or equally effective drugs, to lower the chance of developing resistance. A further priority will be ensuring widespread ARV treatment availability for HIV-infected mothers and fathers, as HIV-exposed infants whose mothers die have a twofold to fivefold increased risk of death. Fathers are important for family stability and financial security. Innovative ways of providing ARV care need to be developed and monitoring needs to be simplified. The interrelationship between TB and HIV in infants needs to be unraveled. Ways of preventing TB, such as widespread implementation of isoniazid prophylaxis to HIV and TB exposed infants, should be explored.

In the foreseeable future, the major focus of international programs will be to facilitate the urgent access to ART for children and their families. Pragmatic and simple solutions need to be implemented to facilitate this process. Ways of implementing HAART programs and using lymphocyte counts, weight gain, and growth percentile charts for monitoring should be explored.

87 Child Sexual Abuse and STD and HIV Infection

Amanda J. Thomas

DEFINITIONS

Child sexual abuse represents one facet of the far-wider spectrum of *child abuse*. Many definitions of child abuse exist in the legal and scientific literature but there is no consensus on an absolute definition. Issues that arise in the debate include the influence and attitudes of societies, cultural differences in child rearing, politics, and religious beliefs. In addition, there is a need to examine the factors involved in particular episodes, the context in which the episodes occurred, the opinion of the professionals who are describing or judging these episodes, the current knowledge of the long-term outcomes of particular behaviors to children, and the effectiveness of current interventions. Definitions are, however, very important as they provide a general framework for policy setting, statutory and legal interventions, gathering statistical information, and an understanding of current and future research.

The Federal Child Abuse Prevention and Treatment Act[1] (CAPTA) defines a child as a person who has not attained the lesser of

1. the age of 18 or
2. except in the case of sexual abuse, the age specified by the child protection law of the State in which the child resides.

Child abuse and neglect, at a minimum, is defined as any recent act or failure to act on the part of a parent or caretaker, which results in death, serious physical or emotional harm, sexual abuse or exploitation, or an act or failure to act which presents an imminent risk of serious harm.

The acts of abuse may vary in nature, frequency, intensity, or duration, and each state has statutes to help define what is considered injurious to children, and each state may vary on the required response to recognized maltreatment. Clinicians should be aware of the mandates and child protecting agencies in the state in which the child resides. To recognize sexual abuse, clinicians caring for children must recognize presentations of all forms of child maltreatment, since there is very wide overlap between sexual abuse and other forms of maltreatment. Children who have been maltreated in any way should be considered for evaluation of sexual abuse, and vice versa.

Within the wide range of child abuse and neglect, neglect has been reported to occur most frequently and is probably the most life-threatening. Child abuse and neglect frequently occur together with other forms of interfamilial violence, including spouse battering and violence between siblings.[2]

Definitions of child sexual abuse vary among state statutes and medical opinions. CAPTA defines sexual abuse as

1. the employment, use, persuasion, inducement, enticement, or coercion of any child to engage in, or assist any other person to engage in, any sexually explicit conduct or simulation of such conduct for the purpose of producing a visual depiction of such conduct or
2. the rape, and in cases of caretaker or interfamilial relationships, statutory rape, molestation, prostitution, or other form of sexual exploitation of children, or incest with children.

The three primary foci of definitions of sexual abuse include age differences between child and perpetrator, the acts that are perpetrated, and the caretaking relationship between the child and the assailant. Regarding age differences, many states exclude acts between peers who have less than 5 years difference in ages, where the perpetrator is not age 13 or greater and where the victim is not age 13 or less. Regarding the acts performed, attention is often given to circumstances involving force, threat, coercion, fear, and exploitation of authority. Statutes of many states regarding criminal acts with minors include penile penetrative anal, vaginal, or oral contact; digital penetrative acts; involvement of the child in any act for sexual gratification; allowing a child to be a witness of adult sexual activity, either in person or on film; involvement of a child in the production of child pornography; use of a child for child prostitution; and general statutes such as contributing to the moral degeneration of a child, allowing a child to enter an environment that is injurious to the child's welfare, and contributing to the delinquency of a child. Regarding caretaking relationships, it is

usual to categorize a sexual assault on a child by a caretaker as "abuse" and to categorize an assault by a noncaretaker under the legal definitions of "assaults" also pertaining to adult victims. Common statutes include rape, indecent liberties, and assault on a female. In most aspects, the medical issues of abuse and of assault are similar, although the agency responses may differ widely. In this chapter, the term *abuse* is used to include both categories, unless otherwise specified.

PREVALENCE

Information on the prevalence of child sexual abuse is difficult to obtain because it is usually a hidden offense, surrounded by secrecy, criminality, and shame. It was first described by Kempe[3] as a "hidden pediatric problem" and remains so to the present. The available statistics include only the cases disclosed to the child protection agencies or to law enforcement.

The 2003 annual statistics on child maltreatment from state protective services (CPS) agencies in the United States revealed an estimated 906,000 children were determined to be victims of child abuse and neglect with a victimization rate of 12.4 per 1000 children and a child fatality rate of two deaths per 100,000 children. Neglect was the commonest type of maltreatment in 61% of the child victims, physical abuse in 19%, sexual abuse in 10%, and emotional abuse in 5%. Other types of maltreatment were found in 17% (based on specific State Laws and Policies). Approximately 78,000 children were determined to be victims of sexual abuse with a victimization rate of 1.2 per 1000 children.[4]

A 1992 study by the Bureau of Justice Statistics evaluated female rape victims under age 12 years and whose perpetrators were reported under the FBI's Uniform Crime Reporting Program in 1991 and 1992. An estimated 17,000 girls under age 12 were raped, representing 16% of all female rape victims and not including unreported rapes.[5] Studies have suggested that each year approximately 1% of children in North America experience some form of sexual abuse resulting in sexual victimization of 12–25% of girls and 8–10% of boys by 18 years of age.[6] Convicted rape and sexual assault offenders serving time in State prisons report that two-thirds of their victims were under the age of 18, and 58% of those (or nearly 4 in 10 imprisoned violent sex offenders) said their victims were aged 12 or younger. In 90% of the rapes of children less than 12 years of age, the child knew the offender.[7] Studies of convicted rapists and victims indicated that 20% of victims under age 12 had been raped by their fathers and 46% by a family member.[5]

In studies by Finkelhor on adult survivors, 90% of the diagnosed cases of sexual abuse involved male perpetrators, 70–90% of whom were known to the child. Boys are reportedly abused at one-third to one-quarter the rate of girls.[8,9] Forty percent of reported offenders who sexually assaulted children under age 6 were juveniles (under the age of 18).[10]

Although there are profound legal and psychosocial differences between consequences of sexual assault by a noncaretaker and sexual abuse by a caretaker, this chapter incorporates both situations into the term *sexual abuse* unless otherwise specified.

Compared with the general population, children who experience poverty, parental inadequacy, unavailability, conflict, harsh discipline, and emotional deprivation experience elevated risks of abuse.[11–13] Substance-abusing parents, chaotic home environments, spousal abuse, other felonies on the part of household members, and high levels of stress are also commonly noted. All the above-named factors decrease the quality and quantity of supervision and protection, leaving the children more vulnerable, emotionally deprived, and at higher risk.[14] Race appears not to be a risk factor.

CONSEQUENCES

The effects of sexual abuse on the behaviors of a child may vary widely, and there is no "sexual abuse syndrome" that a child develops once sexually abused. How a child internalizes a trauma and then copes with it depends on many factors. Issues that worsen the impact of sexual abuse on the emotional well-being of the child include the extent of familial denial; abuse that is longer in duration; type and frequency of abuse; closer relationships to the perpetrator; the use of violence, threats, force, or penetration; lack of maternal support; and the child's overall functioning before the abuse began. Post-traumatic stress disorder is one of the most commonly cited aftereffects of child sexual abuse.[15–17] Attention deficit hyperactivity disorder (ADHD) and oppositional behaviors also appear more frequently in children who have been sexually abused.[18] One study of preschoolers suggested that overt sexualized behaviors (public masturbation; compulsive sexual curiosity; acting out of adult sexualized themes on toys, other children, or themselves; and exposure of genitals) comprise behaviors that are relatively specific for sexual abuse.[19] However, sexual behavior is also related to a number of variables other than sexual abuse. These include family nudity, the boundaries displayed in the home, stress, exposure to sexual activity, and exposure to both pornography and sexually explicit materials.

Although there are no universal behavioral consequences of sexual abuse, there are commonly seen symptoms.[2,20] Absence of or presence of a given symptom cannot automatically rule in nor rule out sexual abuse. Symptoms in abused males often differ from those in females.[21] The severity of symptoms is influenced by numerous factors, including the protective response of the mother or lack thereof, use of force during the assault, duration of time during which the child experienced repetitive assaults, the relationship of the perpetrator to the child (in which assault by trusted family

Table 87-1. Common Behaviors and Symptoms of Sexually Abused Children

Cruelty to animals
Self mutilation
Indiscriminate sexual behaviors
Fire setting

members is more severe), and penetrative trauma.[22–24] (Table 87-1) lists common behaviors and symptoms.

PERPETRATORS

Perpetrators of sexual assault or abuse of children often appear to be otherwise normally functioning citizens and may be without history of other criminal behaviors. However, higher rates of perpetrators come from populations of persons who have histories of inflicting domestic violence on any family member, have sexually assaulted other children, are alcoholic or use illicit drugs, or have criminal records of felonies. Approximately 90% of perpetrators are males. Women may be perpetrators, but only a small minority of sexual abuse allegations involve women. Caretakers appear to perpetrate more frequently than do biologic parents.[25]

Substantial numbers of offenders are juveniles, and several studies of incarcerated adult offenders have reported accounts of perpetration against children that began while the adult was a juvenile.[26,27] It appears that the prior experience of the adolescent as an abused or nonabused child may influence his or her behaviors as a perpetrator.[28]

REPORTING OF SEXUAL ABUSE

Each State and U.S. Territory designate individuals, typically by professional group, who are mandated by law to report child maltreatment. Any person, however, may report incidents of abuse or neglect.[29]

Individuals typically designated as mandatory reporters have frequent contact with children. Such individuals include

- health care workers
- school personnel
- child care providers
- social workers
- law enforcement officers
- mental health professionals

When a clinician suspects sexual abuse, reporting that suspicion is mandated. Persons making good faith reports are protected from liability. Most state statutes specify that this reporting requirement supersedes all claims of professional-client privilege. Sexual assault of a child is a crime in all 50 states and the District of Columbia. Almost all states have specific criminal penalties for failure of a "mandated reporter" to report a suspected child abuse situation. The laws regarding reporting indicate that any person or institution having cause to suspect that any child is abused, neglected, or has died as the result of maltreatment must report to the child protection agency of the county in which the child resides. The report may be made orally, by telephone, or in writing.

Laws are often vague concerning how much evidence regarding abuse must be available to a clinician in order to require that a report be made. Since abuse of children is highly prevalent in the United States, most pediatricians consider the possibility that abuse may play a role in the condition of many of their patients. Similarly, laws are often silent about the timing of a required report, and the clinician must use his or her best judgment. All clinicians who provide medical care for children should familiarize themselves with the laws and practices of their community regarding resources for evaluating children suspected of being abused. The agency that receives reports of suspected abuse or neglect is usually the county department of social services. Some communities have agencies that are very active in the protection of children, while others require a greater level of evidence before an investigation is initiated. A high level of mutual respect and education between clinicians and agencies is essential for optimal evaluation and protection of endangered children.

Although the rate of reporting has increased, only a minority of cases are actually reported. One reason for failure to report is fear of lack of adequate evidence.[30] Despite reporting mandates for professionals, the largest category of reports

is made primarily by victims (30%), followed by school personnel (16%), legal professionals and social service providers (each at 12%), and medical professionals (11%).[31] In surveying physicians, 24% indicated that they had failed to report a suspected case because they felt that the child protective services were of poor quality or overreacted to reports.[30]

MEDICAL DIAGNOSIS OF SEXUAL ABUSE

A comprehensive medical assessment of suspected victims of child sexual abuse involves careful questioning, evidence-collection procedures, specialized examination techniques, and equipment. Many physicians feel inexperienced or unprepared to conduct these evaluations and referral on to other physicians or health care professionals with expertise in this area is appropriate. Knowledge of the relevant skilled professionals, legal requirements, reporting mechanisms, procedures, and documentation are essential for all physicians.

The basic elements of the medical evaluation of a child for child sexual abuse may include

1. an intake process to coordinate the components of the evaluation;
2. gathering documentation and information about the relevant other services concerned with the child (teachers, physician);
3. interview of primary caretaker for child's medical history and review of systems;
4. investigative interview with child's caretaker(s);
5. separate investigative interview with the child;
6. physical examination of the child (general physical, genital, and anal examinations);
7. documentation of the findings;
8. laboratory tests as indicated by examination and history;
9. review of case with relevant agencies.

Investigative interviews should be conducted by social services and/or law enforcement agencies, but this does not preclude physicians asking relevant questions to obtain a detailed history and a review of systems. Medical history, past incidents of abuse or suspicious injuries, and menstrual and sexual history (for older adolescents) should be documented. The medical history should include information helpful in determining what tests should be done and when, how to interpret medical findings when present, and what medical and mental health services should be provided for the child and family. Most expert interviewers do not interview children younger than 3 years.[6] The American Academy of Child and Adolescent Psychiatry and the American Professional Society on the Abuse of Children (APSAC) have published guidelines for interviewing sexually abused children.[32,33] It is desirable for those conducting interviews to avoid leading and suggestive questions as these may contaminate evidence that may be put before the courts. An interview needs to be done in a neutral manner with no suggestion that the interviewer knows what the child should feel or what has happened. The interviewer should make no personalized comments or react strongly to what the child states, since this may cause the child to withdraw.

Sexually abused children may not always disclose abuse and may present to medical settings with a variety of symptoms and signs. Physicians require a high level of suspicion and a willingness to consider abuse as a possibility. The majority of sexually abused children are abused chronically and do not come to diagnostic attention at the first assault. There are many well-studied reasons why children may not disclose sexual abuse or will disclose sexual abuse initially but subsequently will recant their statements[34] (Table 87-2). As many as one-quarter of the children, who have been confirmed to have been sexually abused, as evidenced by admission of the perpetrator, recant their disclosure at some time in the interviewing procedure. Most often the reason for a child to recant is pressure from the family to protect the alleged perpetrator. Disclosure is a function of the child's safety and developmental level and is a reflection of the child's environment. Disclosure is often a process rather than a one-time event and often occurs in stages rather than as an initially complete account.[35] A child will rarely disclose sexual abuse if he or she is living with the perpetrator. Where possible, the parent or caretaker should not be present during the interview so that influences and distraction can be kept to a minimum.

A number of aids, such as anatomic dolls,[36] can assist the interviewer when asking children about their abuse. These are generally only used by professionals trained in interviewing young children.

Methods of recording the professional interview include videotaping of the interview, transcription of verbatim notes, and audio recording. Methods used vary widely with each state and agency or clinic. Each of the techniques mentioned is supported by APSAC, and each technique has advantages and limitations or disadvantages. When audiotaping or videotaping is used, protocols should be coordinated with the district attorney's office in accordance with state guidelines. Because the issues of credibility and suggestibility of the child are often raised, the use of videotaping or transcription of verbatim notes provides a means of ensuring an accurate and complete record of the interview.

PHYSICAL EXAMINATION

The child should have a thorough pediatric examination performed by a health care provider with appropriate training and experience who is licensed to make medical diagnosis and recommend treatment. The physical examination should not

Table 87-2. The Child Sexual Abuse Accommodation Syndrome

1. ***Secrecy.*** Secrecy is both the source of fear and the promise of safety. "Everything will be OK if you don't tell." Most children never tell.

2. ***Helplessness.*** The adult expectation of child self-protection and immediate disclosure ignores the basic subordination and helplessness of children within authoritarian relationships. The child often has no choice but to submit quietly to the overpowering adult and to keep the secret.

3. ***Entrapment and accommodation.*** Often the only option for the child is to learn to accept the situation and survive. The child is given the power to destroy the family (by telling the secret) and the responsibility to keep it together (by keeping the secret).

4. ***Delayed, conflicted, and unconvincing disclosure.*** Many adults, including parents, teachers, doctors, social workers, and attorneys, cannot believe that a normal adult could be capable of repeated, unchallenged sexual molestation of a child. Disclosure generally is an outgrowth either of overwhelming family conflict, incidental discovery by a third party, or outreach and education by child protective agencies. Disclosure may occur months or even years after the initial abuse. It may contain details and descriptions that seem distorted or fanciful and therefore lack credibility.

5. ***Retraction.*** The child's retraction is often readily accepted by authorities and relatives as the truth, whereas the child's initial disclosure of abuse is considered doubtful. Unless there is consistent support for the child and immediate intervention to force responsibility on the perpetrator, the child will follow the "normal" course and retract his or her complaint.

result in additional physical or emotional trauma to the child. Provided the child agrees, it is advisable to have a supportive adult (not suspected of involvement of abuse) present during the examination. A chaperone and/or nurse support is also recommended. Careful documentation of the child's responses to questions should be made during the examination as in some cases children who have not previously disclosed may do so at this time.

The aims of the medical assessment are to assess the whole child to include

- growth, health, development, and behavior
- identification of injuries that require treatment
- identification of signs of other forms of abuse and neglect
- identification of other conditions that have not received usual medical attention
- screening for, or diagnosis of, sexually transmitted infection (STI) and prevention of infections
- evaluation of the risk of pregnancy and pregnancy prevention
- documentation of findings of potential forensic value
- forensic evidence collection
- recording and documentation of injuries and physical signs with detailed diagrams and preferably by photography

Following the general physical examination, the child receives an examination of the anal and genital areas. See (Table 87-3) for important general policies regarding these examinations. Examinations of children may require more than one appointment to gain the confidence of the child. Gentle and careful coaching with distraction for younger children will allow most children to cooperate with an examination.

EXAMINATION TECHNIQUES

Various examination techniques and positions visualizing the genital and anal structures in children and adolescents have been described.[6,37]

The examination of prepubertal girls is recommended as follows:

- The child is examined in the supine "frog-legged" position (young children can be held on a carer's lap). The knee-chest position can be used to give a better view of the posterior hymen.
- The external genitalia should be inspected; the labia majora should be gently separated to view the hymenal orifice; gentle traction at the posterior edge of the labia majora, between the thumb and index finger, allows clearer visualization of the hymen. Warm sterile water dropped via a syringe or dropper may assist in separation of the edges of the hymen.
- Buttock separation, in the left lateral position, using the palms of both hands to view the anus for 30 seconds.

The examination of a pubertal girl will require additional techniques to view the folded edges of an estrogenized hymen. A cotton tipped swab is useful to gently examine the hymenal rim. Foley catheters are becoming a popular method to spread out the estrogenized hymenal tissue. The hymenal opening should be assessed by gentle digital

Table 87-3. General Policies Regarding the Physical Examination

The genital examination of an awake prepubertal female should not include devices inserted through the hymen such as a speculum, otoscope, or ureteroscope; if the child requires an invasive examination, general anesthesia is often indicated.

A child should not be examined if he or she is unable to fully cooperate. Conscious sedation may be required for very fearful children. Physical restraint should not be used.

The child should have as much decision making as possible during the examination. He or she may be asked by whom he or she wishes to be accompanied, draping, or gowning wishes, etc. Books should be available should the child's caretaker wish to distract the child.

The accompanying caretaker should be instructed to remain at the head of the table, assisting and reassuring the child. Out of respect for the child's privacy, the caretaker should not view the child's anal or genital findings.

When sexual abuse is strongly suspected for any reason, the clinician should attempt to ensure that the child leaves the clinic to go to a safe environment. This may require urgent services from the police or department of social services.

Results of assays or clinical specimens may have legal implications. Specimens must be labeled, delivered to the laboratory, and processed in a manner that allows a chain of custody to be supported.

insertion followed by an appropriate sized speculum examination to assess for vaginal/cervical injuries and carry out sexually transmitted disease (STD) screening, once forensic sampling has been completed.

The examination of boys is recommended as follows:

- Young children can be held on a carer's lap.
- The external genitalia should be inspected; the foreskin, if present, should be gently retracted, where possible, to view the urethral meatus and frenulum; the scrotum should be gently palpated to assess for the presence, and any pathology, of both testes.
- Buttock separation, in the left lateral position, using the palms of both hands to view the anus for 30 seconds.[38,39]

The knee–chest position is also helpful in both genders in obtaining an optimal view of the anal and perianal tissues and in assessing the child for anal dilatation.

Instruments that magnify and illuminate the genital and rectal areas such as colposcopes with photo documentation are commonly used and recommended.[40] Speculum or digital examinations should not be performed on the prepubertal child unless under anesthesia (e.g., for suspected foreign body) and digital exams of the rectum are unnecessary.[6]

During the physical examination, the child's behavior should be noted. Children who have been sexually traumatized may complete the general examination without difficulty and display various trauma symptoms when the genital or anal examination is initiated. Common trauma symptoms include a fearful inability to endure a visual examination, sexualized behaviors during the examination, and dissociative symptoms.

SCHEDULING OF EXAMINATIONS

Examinations should be performed without delay in the following circumstances[38,39]:

- When the alleged sexual abuse has occurred within 72 hours.
- There is a history of acute trauma.
- There is a possibility of pregnancy resulting from the abuse in a postpubertal girl.
- The child is not considered to be in a safe or protected environment.

When more than 72 hours have passed, the child is safe, and no acute injuries are present, the examination can be carried out at the earliest convenient time for the child, the family, the physician, and the investigative team.

Forensic evidence collection is recommended when sexual abuse has occurred within 72 hours.[6] Local policies and procedures for evidence collection should be followed. Body swabs in prepubertal children more than 24 hours after a sexual assault are unlikely to yield forensic evidence, and nearly two-thirds of the forensic evidence may be recovered from clothing and linens.[41]

INTERPRETATION OF GENITAL/ANAL FINDINGS

A clear statement by the child is the single most important factor in making a diagnosis of sexual abuse.[6,39] A diagnosis of sexual abuse should rarely be made on physical signs alone. A substantial proportion of sexually abused children have no abnormal physical signs. The proportion varies with the types of abuse and the time elapsed since the most recent abusive

episode.[39] Many types of abuse leave no physical evidence and mucosal injuries often heal rapidly and completely. Absence of signs does not imply absence of abuse.[39,42–47]

The interpretation of physical findings continues to evolve as evidence based research becomes available.[48] The physical examination may be classified as to the significance of the findings. Findings diagnostic of trauma and/or sexual contact include[39,48]

1. abrasions or bruising to the genitalia;
2. an acute or healed laceration in the hymen that extends to or nearly to the base of the hymen;
3. bruising to the hymen;
4. a markedly decreased amount of hymenal tissue or absent hymenal tissue in the posterior aspect;
5. injury to or scarring of the posterior fourchette, fossa navicularis, or hymen;
6. perianal bruising, lacerations, or scarring;
7. pregnancy;
8. the presence of semen/sperm in specimens taken directly from a child's body;
9. the presence of a positive culture for *Neisseria gonorrhoeae* (GC), *Chlamydia. trachomatis* (CT), or *Trichomonas vaginalis* (TV); or a positive serologic test for syphilis or HIV infection if perinatal or neonatal transmission has been excluded (and in the case of HIV, transmission from blood products has been excluded).

EVALUATION FOR SEXUALLY TRANSMITTED DISEASES

An integral component of the physical examination of a child for suspected sexual abuse is the evaluation of the child for STDs. The results of assessments for STDs are critical for the welfare of the child because the evaluation pertains not only to the physical health of the child and any required therapy but also may provide evidence that the child has been abused and is therefore in need of protection from further assault.

Children can acquire STDs through vertical transmission, by autoinoculation, or by sexual contact. Each of these mechanisms should be given appropriate consideration in the evaluation of a preadolescent child with an STD. Evaluation based solely on suspicion of an STD should not proceed until the diagnosis has been confirmed. Factors to be considered in assessing the likelihood of sexual abuse in a child with an STD include whether the child reports a history of sexual victimization, biologic characteristics of the STD in question, and the age of the child.[49] Two reviews[50,51] concluded that accidental transmission (fomite, close physical contact, or autoinoculation) is an exceptionally uncommon mode of transmission of STDs to children. The identification of sexually transmissible agents in children beyond the neonatal period is suggestive of sexual abuse. The significance of an STD as evidence of possible child sexual abuse varies by pathogen.[52] Vertical transmission is a possibility in a child aged less than 3 years, although sexual abuse can also occur within this age group. In evaluating adolescents, it should be remembered that consensual sexual activity and sexual abuse can coexist. The social significance of each STI and the recommended action regarding reporting of sexual abuse are summarized in (Table 87-4).

THE RISK OF INFECTION

Approximately 5% of sexually abused children acquire an STD as a result of their victimization.[49] The risk of acquiring an STD is dependent on several factors including the following[38,49]:

- The regional prevalence of STDs within the population.
- Maternal STD during pregnancy leading to vertical transmission to the infant.
- The type of sexual activity, e.g., penile, vaginal, or rectal penetration is more likely to lead to infection than other types of sexual activity.
- Injuries of the genital tract. Trauma increases the susceptibility to infection.
- The sexual maturity of the young person. A young person has an increased biological susceptibility to carcinogens and STDs due to physical and immunological immaturity of the genital tract.
- The lack of use of barrier contraception.
- The frequency of physical contact between the perpetrator(s) and the child.
- The number of assailants.
- The infectivity of various microorganisms.
- Whether the child has received intercurrent antimicrobial agent treatment.

SCREENING FOR STDs

Universal screening of postpubertal patients is recommended because the prevalence of preexisting asymptomatic infection in this group is high.[49] The decision to screen prepubertal children must be made on an individual basis. The following situations involve a high risk of STDs and constitute a strong indication for testing[49,52]:

- The child has or has had signs or symptoms of an STD or an infection that can be transmitted sexually, even in the absence of suspicion of sexual abuse.
- A sibling, another child, or an adult in the household or child's immediate environment has an STD.
- A suspected assailant is known to have an STD or to be at high risk of STDs (e.g., has had multiple partners, a history of STDs, and a history of intravenous drug use or same sex partners).

Table 87-4. Implications of Commonly Encountered STDs for the Diagnosis and Reporting of Sexual Abuse of Infants and Prepubertal Children

STD Confirmed	Sexual Abuse	Suggested Action
Gonorrhoeae[a]	Diagnostic[b]	Report[c]
Syphilis[a]	Diagnostic	Report
HIV infections[d]	Diagnostic	Report
C. *trachomatis* infection[a]	Diagnostic[b]	Report
T. vaginalis infection	Highly suspicious	Report
Condyloma acuminata[a] (anogenital warts)	Suspicious	Report
Genital herpes	Suspicious	Report[e]
Bacterial vaginosis	Inconclusive	Medical Follow-up

[a]If not perinatally acquired and rare, nonsexual vertical transmission is excluded.

[b]Although the culture technique is the "gold standard," current studies are investigating the use of nucleic acid-amplification tests as an alternative diagnostic method in children.

[c]To the agency mandated in the community to receive reports of suspected sexual abuse.

[d]If not acquired perinatally or by transfusion.

[e]Unless there is a clear history of autoinoculation.

From Kellogg N and the Committee on Child Abuse and Neglect. American Academy of Pediatrics: The evaluation of sexual abuse in children. Pediatrics 2005; 116: 506–512.

- There were a number of assailants.
- The patient or family requests testing.
- The prevalence of STDs in the community is high.
- Evidence of genital, oral, or anal penetration or ejaculation is present.

SAMPLING TECHNIQUES[38]

The genital organs of female infants, children, adolescents, and adults have important anatomical and physiological differences. These differences influence the microbiological flora of the genital tract and the sampling sites for screening.

- Sampling techniques must be specific for the sexual maturity of the young person.
- Samples should be the least invasive and the minimum necessary. Priority should be to obtain suitable specimens to identify *N. gonorrhoeae* (GC), C. *trachomatis* (CT), *T. vaginalis*, (TV) and, in the presence of genital ulcers, herpes simplex virus (HSV).
- Sterile cotton tip swabs are recommended and these can be moistened with sterile water (or the viral culture medium if performing viral cultures).
- For prepubertal girls, smaller ear, nose and throat (ENT) swabs are useful for transhymenal vaginal sampling. Avoiding contact with the hymen will reduce discomfort and increase cooperation of the young person. ENT swabs are also useful for male urethral sampling, if undertaken.
- Recommended sample sites for prepubertal females include
  - vulva
  - posterior fourchette
  - posterior vaginal wall
  - vulval or vaginal washings are also suitable. Urethral swabs cause discomfort and should be kept to a minimum
- Postpubertal females can be screened according to local protocols for female adults if tolerant of speculum examination. In some pubertal females it may be impossible to pass a speculum. Blind vaginal sampling together with

urethral and/or urine Nucleic Acid Amplification Techniques (NAAT) are advised.

- Screening of male young people will depend on their presenting history and the method of abuse (where suspected). Urethral swabs cause discomfort and their use should be kept to a minimum. Urine NAAT should be considered.

DIAGNOSTIC METHODS[6,38,49,52]

Most screening tests for STDs have been developed and approved only for genital sites in the adult population. In sexually abused children the following should be considered:

- Specimens should be obtained by health care professionals with experience in the evaluation of sexually abused/assaulted children.
- The most sensitive and specific test available for the organism should be used.
- Culture tests are still considered the "gold standard" for diagnosing GC (bacterial culture) and CT (cell culture). New tests such as nucleic acid-amplification tests (NAAT) may be more sensitive but data regarding use in prepubertal children are limited.
- When an organism is isolated, the sample should be preserved for future analysis (in case of medico-legal implications).
- A positive test should be confirmed preferably by a test that involves a different process because the prevalence of STDs in children is low and the positive predictive value of these tests is lower than that of adults.
- The presence of one STD indicates the need to look for others.
- Testing before any prophylactic treatment is preferable to prophylaxis without testing.
- Specimens for laboratory analysis should be labeled carefully and standard hospital procedures for transferring specimens from site to site should be followed to preserve the "chain of evidence."

The STD screening should focus on likely anatomic sites of infection (as determined by the patient's history or by epidemiologic consideration).

- Specimen cultures for GC can be obtained from the pharynx and anus in boys and girls, the vulva(vagina for prepubertal girls, the cervix for pubertal girls tolerant of a speculum, and the urethra in boys (the urethral meatus is an adequate substitute for an intraurethral swab for boys with urethral discharge).
- Specimen cultures for CT can be obtained from the anus in boys and girls, the vulva (vagina for prepubertal girls, the cervix for pubertal girls tolerant of a speculum, and the urethral meatus in boys with urethral discharge. Pharyngeal specimens in children of either sex are not recommended, as the yield is too low. NAAT may be an alternative where confirmation is available or culture systems for CT are unavailable.
- A vaginal swab for culture and wet mount should be taken for TV and bacterial vaginosis (BV).
- Viral culture swabs should be obtained from any ulcerative or vesicular lesions.
- Anogenital warts (AGWs) are clinically diagnosed without testing.
- Serum sampling for HIV, hepatitis B and C, and syphilis should be made on a case-by-case basis, taking into account the patient's and family's wishes, the presence of another STD, the risks from the assailant where there were multiple assailants, and the type of abuse/assault.
- Pregnancy testing and prevention should be considered in all pubertal girls.

SCREENING SCHEDULE FOR STDs[38,52]

The scheduling of examinations should depend on the history of abuse(assault and incubation periods of STDs. They should be determined on an individual basis taking into account the child's (and their parent/carer's) psychological and social needs. A single examination may be sufficient if the child has been abused over an extended period by the same person/people or if the last episode of abuse was at least 3 months back. A general guide for examination timing is

- immediate (if practical) for oral sampling (if available), serology, and initial specimen collection
- 2 weeks after the initial abuse/assault for initial sampling or repeat sampling (if immediate sampling performed), and pregnancy testing in pubertal girls, with a follow up visit for results and counseling at a further 1–2 weeks
- 12 weeks for repeat serology and 6 months in some cases. Serum samples can be taken and stored for testing at a later date

The risk of HIV infection should be discussed, as it is a major concern of abused young people. Counseling of the young persons will need to be tailored to their age and understanding and should also involve the parent/carer. Ideally and where possible, the alleged perpetrator should be tested first.

PROPHYLAXIS[38,49,52]

As the prevalence of most STDs following abuse(assault is low and prepubertal girls appear to be at lower risk for ascending infection than adolescent or adult women, preventive therapy in prepubertal children is not recommended routinely. The potential benefit of treating a sexually abused

child should be weighed against the risk for adverse reactions and the likelihood of compliance. Each case should be dealt with individually taking into account the wishes of the child/family, the type of assault, any risk factors identified in the perpetrator, the number of perpetrators, and the local prevalence of STDs.

The following prophylactic regime can be used as a guideline:

For CT, GC, and BV, a combination of ceftriaxone 125 mg IM in a single dose plus metronidazole 2 g orally in a single dose (15 mg/kg/day orally, in 3 divided doses for 7 days in children <45 kg) plus azithromycin 1 g (20 mg/kg orally in children <45 kg) orally in a single dose (or doxycycline 100 mg orally twice per day for 7 days in children >45 kg). The efficacy of these regimes has not been currently evaluated.

Postexposure prophylaxis for HIV in children should be considered within 72 hours of the sexual abuse or assault and on an individual basis. If antiretroviral postexposure prophylaxis is being considered, a professional specializing in HIV-infected children should be consulted.

Hepatitis B vaccination prophylaxis should be considered at the initial examination if it is within 3 weeks of the sexual abuse/assault and the child has not previously been vaccinated. Follow-up doses should be administered at 1–2 and 4–6 months after the first dose.

SPECIFIC STDs

The following should be read in conjunction with the relevant chapters within this book. Treatment guidelines for each of the conditions can be found in the "Sexually Transmitted Diseases Treatment Guidelines 2002"[52] and in the "2003 Red Book" (American Academy of Pediatrics[49]). Periodic updates of both these sources should be noted by clinicians caring for children with relevant problems.

Chlamydial infection, genital warts, and GC are the most prevalent clinically evident STDs in sexually abused children. HIV infection and syphilis are rare.[37]

N. GONORRHOEAE

The reported prevalence of GC in studies of sexually abused children ranges from 2.9% to 11.2%, with highest rates in adolescents.[53,54] Infection may occur in the conjunctiva, oropharynx, urethra, vagina, endocervix, and rectum. The incubation period is 3–7 days.

The commonest symptom in prepubertal children is vaginal discharge. Asymptomatic infection, pelvic inflammatory disease, and perihepatitis can occur but are uncommon (5% had no vaginal discharge in one study of sexually abused preteenage girls[55]). Rectal and pharyngeal infections are typically asymptomatic and are often unrecognized.

Currently standard culture methods are considered the "gold standard" for screening and testing.

CHLAMYDIA TRACHOMATIS

Chlamydial infections have been identified in 1.2–17% of sexually abused young people when specimens were routinely cultured. Coincident infection with CT has been observed in up to 27% of young people with GC. The higher rates are more common in postpubertal young people.[54,56–58] Prolonged shedding of CT may occur after contamination of the infant in the perinatal process and may last until age 3 years[59]; consequently, genital CT is a confirming STD only in children older than 3 years of age. If a positive CT culture is obtained from a child suspected of being sexually abused, the evidence for abuse is strengthened if asymptomatic maternal infection has been excluded and if urethral infection in the alleged perpetrator can be demonstrated by culture.[39]

Chlamydial infection in children can be symptomatic including vaginitis in prepubertal girls; urethritis, cervicitis, endometritis, salpingitis, and perihepatitis in postpubertal females; epididymitis in males; and Reiter's syndrome (arthritis, urethritis, and bilateral conjunctivitis). It can also be asymptomatic and the infection can persist for months to years. Symptomatic infection of the pharynx is rare. The incubation period of chlamydial infection is variable depending on the type of infection, but is usually 1 week.

Standard cell culture systems should be used but NAAT may be an alternative where confirmation is available or culture systems for CT are unavailable.

HUMAN PAPILLOMAVIRUS DISEASE

Genital human papilloma virus (HPV) disease may be recognized clinically as classic genital warts or, as in adults, as flat mucosal lesions in any body site (mouth, eye, anus, urethra, introitus). As in adults, an exfoliative cytologic examination of mucosal lesions may yield a diagnosis, or a biopsy may be indicated.[60] AGWs may cause soreness, irritation, or bleeding but may also be symptomless. AGWs were found in 1.8% of 1,538 young people aged between 1–12 years being evaluated for possible sexual abuse.[58]

The incubation period for HPV is 1–20 months but latency periods of at least 2 years are suspected. The epidemiology of HPV transmission is complex. Children can acquire HPV infection from vertical transmission, autoinoculation, or sexual abuse(activity. It is the general consensus opinion of experts that vertical perinatal transmission is considered no longer likely as a cause of AGWs appearing after the first 2 years of life.[61] Considerable evidence supports the position that AGWs in young people appearing after 2 years are usually acquired from sexual contact.[62] Limitations in diagnosis of preverbal children have led to uncertainty regarding the means of transmission, especially in this age group.

Children with AGWs should be screened for other STDs. The parents(caretakers and siblings should be examined and screened for HPV infection.

TRICHOMONAS VAGINALIS

The reported prevalence of TV in studies of children evaluated for suspected sexual abuse range from 1% to 2% with higher rates in pubertal girls.[54,63]

Perinatal infection of the vagina may occur for up to 1 year if not treated. Beyond infancy the presence of TV in a vaginal specimen is strongly suggestive of sexual abuse.[64] Vulvovaginitis is the commonest presenting symptom in prepubertal young people. In pubertal girls, infection can be asymptomatic or present with a frothy vaginal discharge, dysuria, and vulvovaginal itching. Infection in males can be asymptomatic or present with urethritis, epididymitis, or prostatitis.

The incubation period averages 1 week but ranges from 4 to 28 days.

Culture tests should be used and are more sensitive than examination of a wet mount.[64]

BACTERIAL VAGINOSIS

The significance of finding BV in children and adolescents is unclear. Sexual transmission has not been clearly documented and it is not regarded as an STD in adults. It is of doubtful significance in the interpretation of abuse but it is commonly found following sexual assault in adults and adolescents.[65] Gardnerella *vaginalis* (*G. vaginalis*) has been cultured from various sites in the newborn but it has not been established that for how long these sites may be colonized. The majority of case reports and studies in children have been based only on the identification of *G. vaginalis*, not on Amsel's criteria (clue cells, a positive amine or "whiff" test, a white homogenous vaginal discharge, and a vaginal fluid pH greater than 4.5). One of the four criteria cannot readily be applied to girls, as during the childhood or prepubertal period the vaginal environment is alkaline. *G. vaginalis,* has been isolated from vaginal cultures of 1–32% normal or control young people, compared to 7–34% in sexually abused or sexually active girls.[64] Hammerschlag, et al. found BV in 13% of sexually abused girls compared with none of the controls.[66] BV may cause a vaginal discharge but may also be asymptomatic. Where there are symptoms, diagnosis and therapy are frequently helpful to the patient.[66]

For pubertal girls, Amsel's criteria should be used on a wet preparation of a vaginal swab. An alternative method of establishing the diagnosis is a Gram stain of vaginal secretions using Nugent's criteria. A smear containing no lactobacilli and heavy Gram-negative and/or Gram-variable rods and curved Gram-positive rods would be diagnostic for BV. This method has not been evaluated in prepubertal children.[64]

HUMAN IMMUNODEFICIENCY VIRUS

The incidence of HIV infection acquired by children through sexual abuse/assault is unknown. One study reported that 14.6% of children with HIV infection had been assaulted sexually, and at least 4% had been infected through abusive sexual contact.[67] A second study found positive HIV tests in 0.7% of children being evaluated for sexual abuse with sexual abuse identified as the most likely source of infection in 0.5%.[68] A further study of HIV-infected children aged less than 13 years found that 0.3% had been sexually abused. Of those 0.15% had no other identified risk factors other than the sexual abuse.[69] Sexual abuse as a mode of transmission is difficult to ascertain as some cases of perinatally acquired HIV infection may not present with an AIDS defining illness until over the age of 10 years.

Where a child is found to have a positive HIV test[38]

- maternal HIV status should be ascertained depending on the age of the young person and their lifestyle/risk factors. Sexual abuse as a cause of HIV infection should not be discarded exclusively on the grounds that the victim's mother is known to be seropositive as both sets of risk factors may occur and coincide within one family setting.[68]

Where maternal testing is negative and a transfusion route is excluded, sexual abuse must be suspected and child protection procedures followed

- the subject should be referred to a pediatrician/center experienced in the care of young people with HIV and AIDS.
- the subject and their parents/carers should receive appropriate counseling and multiagency support.
- sexual contacts should be offered screening and counseling.
- a full STI screen should be performed unless already completed.

Child protection teams are seldom in a position to know with useful certainty the risk factors for HIV that a given assailant may have, whether the assailant acted alone, the HIV status of the assailant(s), or even with certainty the acts that were committed. Because of these limitations of information and concerns, each service must construct its own policies. In some states, children may be tested if medically indicated even if the parent is reluctant to permit it.

In instances in which a perpetrator is reported to the police, it is occasionally possible to obtain serologic assays from that person.

SYPHILIS

The prevalence of syphilis among children suspected to have been sexually abused is approximately 0–1.8%.[64] Prepubertal children with primary or secondary stages of syphilis occurring beyond the neonatal period should be presumed to be victims of sexual abuse.[50]

Most adolescents with syphilis have acquired their disease through consensual sexual activity, although sexual abuse should still be considered as a possibility as studies have

demonstrated that between 10 and 32% of adolescents with syphilis had a history of sexual abuse.[70]

The presentation of acquired syphilis in children is the same as adults. Children can present with primary chancres, secondary syphilis, or latent syphilis with only positive serology as evidence of infection. The incubation period of acquired pri mary syphilis is 3 weeks but ranges from 10 to 90 days. Nontreponemal antibody tests (Venereal Disease Research Laboratory, Rapid Plasma Reagin and Automated Reagin Test) are used for screening and treponemal tests (fluorescent treponemal antibody absorption test and *T. pallidum* particle agglutination tests) are used to establish a presumptive diagnosis.

HEPATITIS B AND C

We recommend that children who are being examined for HIV and/or syphilis should also be considered for testing for hepatitis B and C.

GENITAL HERPES

Herpetic infection is caused by HSV types 1 and 2. The incubation period for HSV occurring beyond the neonatal period ranges from 2 to 20 days. Both types of virus can cause all the clinical syndromes. HSV infection of the genitalia may present with typical multiple vesicles or may present with a more generalized erythema of varying severity. HSV 2 has been attributed to be the cause of most genital herpes, but 10–20% of genital herpes in adults can be due to HSV 1.[64] The virus type found on the genitalia of a child does not, therefore, rule out sexual abuse.

HSV 1 and HSV 2 have been recovered from the genital area in children who appear to have been sexually abused.[71,72] The prevalence of infection following sexual abuse/assault is unknown. Children can also acquire genital infection by autoinoculation if they have a gingivostomatitis. Children presenting with genital herpes should be carefully examined for coexistent gingivostomatitis. Sexual abuse should be considered in those children with no evidence of gingivostomatitis.

Although commercially available serologic tests to distinguish HSV-1 and HSV-2 antibodies are now commercially available, their specificities vary by assay. In addition, since detection of HSV-1 antibody only does not rule out sexual abuse, their forensic value is limited. Currently, viral cell culture methods are considered the "gold standard" for screening and testing.

REPORTING CHILDREN WITH SEXUALLY TRANSMITTED DISEASES FOR SUSPECTED ABUSE

Each state mandates that persons who suspect that a child has been the victim of abuse must make a report to an authority that is constituted to receive and investigate such reports. In many states, these laws specify that persons who are in positions of authority over children must make such reports, and clinicians are usually included as "mandated reporters." For the clinician who has diagnosed a child with an STD, two major decisions must be made. First, he or she must decide the strength of the evidence that the child has been abused, based on the diagnosis of the STD, the details of the history, and the examination findings. Second, he or she must decide if the child should be reported to the agency constituted by that community to receive reports of suspected child abuse. Recommendations on these two issues as they pertain to the major STDs are found in Table 87-4 and represent recommendations formulated by the American Academy of Pediatrics.[6] Acquired STDs that are considered diagnostic of sexual abuse are

- a positive confirmed culture for GC from the genital area, anus, and throat in a child outside the neonatal period;
- confirmed diagnosis of syphilis, if perinatal transmission is ruled out;
- positive culture from genital or anal tissues for CT, if the child is older than 3 years of age at the time of diagnosis, and the specimen was tested by cell culture or comparable method approved by the Centers for Disease Control;
- positive serology for HIV, if neonatal transmission and transmission from blood products have been ruled out.

The diagnosis of TV infection in a child older than 1 year of age, with organisms identified (by an experienced technician or clinician) in vaginal secretions by wet mount and by culture is considered highly suspicious of sexual abuse. The diagnosis of genital warts and genital HSV infection provides the clinician with a "suspicious" diagnosis of sexual abuse. Diagnosis of these conditions should result in a report to the investigative agency and thorough evaluation of the child for safety and for other evidence of possible abuse. The significance of BV and several other organisms, including genital *Molluscum contagiosum*, is uncertain, and their presence usually is not evidence, when seen alone, that requires a report. However, a child with BV should be evaluated for other STDs.

COORDINATION OF FINDINGS

The final diagnosis of sexual abuse may be derived from information from numerous sources. These may include the medical evaluation, school information, home evaluation, police investigation, witnesses, and acknowledgment by a perpetrator. The medical evaluation for abuse should summarize the results of the findings and the medical conclusions. The conclusions should include a statement of the level of certainty of the diagnosis and whether or not the evaluation was completed. For example, the report may state that the diagnosis of sexual abuse was confirmed, suspected, or unknown or that there was

no evidence of abuse. The basis of the conclusion should be clearly stated. The report should state whether or not a report of suspected abuse was made or had already been made. If safety measures are indicated, the report should clarify who is responsible for planning and implementing these services.

If abuse is confirmed or strongly suspected and a perpetrator identified, other siblings or children closely exposed to the perpetrator should receive an evaluation for abuse.[73] If no perpetrator is identified, other children sharing the same environment as the abused child should be evaluated.

Following the examination, most caretakers wish to know the results. The clinician should coordinate with any involved agencies as to whether or not a report should go to the caretakers. If a child has disclosed abuse or neglect by a family member, decisions must be made regarding the distribution of the information to the family. In addition, for most instances of suspected or confirmed sexual abuse, a mental health evaluation of the child should be scheduled. In many abusive/neglectful homes, parental compliance with treatment interventions is poor, and the child may require extensive monitoring in order to ensure safety and recovery. This is especially the case in families of sexually abused children.[74]

The evaluation and management of problems resulting from sexual abuse of a child require the most skilled personnel from numerous intersecting services and agencies. These commonly include physicians, other medical examiners, social workers, police, guardians ad litem, other court personnel, and mental health evaluators and therapists. Sustained multiagency working together with good communication between agencies is essential to safeguard and protect the welfare of abused children. Reabuse is common even when high-quality services have been provided.[75] Clinicians have a role in prompt recognition and treatment, reporting, advocacy, and surveillance of abused and/or perpetrating children.

88 The Role of Primary Care Clinicians in STD, HIV, and Hepatitis Prevention and Care

Gale R. Burstein, Zsakeba Henderson, Nidhi Jain, and Kathleen L. Irwin

INTRODUCTION

Until the 1980s, most sexually transmitted infections (STI) services were provided in public health department STI clinics, community health centers, private physician's offices, hospital emergency departments, and health maintenance organizations (HMO).[1] By the late 1990s, about 70% of STI care was provided by private providers or to privately insured persons[2] and the number and hours of dedicated STI clinics had declined substantially.[3] Meanwhile, enrollment in the commercial and Medicaid managed care health plans has risen dramatically, especially in the South[4] where bacterial STI rates are highest.[5] Another factor that prompted attention to STI care in the private sector was greater awareness of the high burden of viral STIs such as herpes and anogenital warts among Americans of all income levels and health insurance status and the introduction of new diagnostic and treatment modalities for these viral STI.[6] The advent of high quality rapid and point-of-care human immunodeficiency virus (HIV) tests and highly effective antiretroviral therapy has resulted in a dramatic shift of HIV services from specialized HIV counseling and testing sites and dedicated HIV care clinics to primary care practices.[7] Recent initiatives to expand hepatitis risk assessment, serologic screening, and vaccination beyond high-risk persons served by public clinics have motivated more primary care clinicians to offer this service.

Many cases of STI, HIV, and hepatitis occur in adolescents and young adults. Consequently, primary care clinicians, including obstetrician/gynecologists (Ob/Gyn), family practitioners, and pediatricians, who are often affiliated with commercial or Medicaid managed care health plans, now provide much of the STI, HIV and hepatitis services in the United States and will play a greater role in preventing, detecting, and managing these infections in the future.[1,8,9] This chapter addresses the roles of the primary care clinicians in bacterial and viral STI, HIV, and sexually transmitted hepatitis prevention and care in primary care settings outside dedicated STI or HIV care clinics. These roles include risk assessment, physical examination, screening and diagnostic testing, treatment, risk reduction counseling, patient education, vaccination, management of sex partners, case reporting, and collaboration in outbreak control. The chapter addresses why these are important functions, the extent to which these services are delivered in private primary care settings over the last decade, barriers to delivering these services, and interventions that have been used to improve delivery of these services.

RISK ASSESSMENT

The primary care health visit offers an important opportunity to assess risks for STIs, HIV, and viral hepatitis. Risk assessment may reveal the need for (1) risk reduction counseling or patient education to reduce risky sexual behaviors that could lead to infection, (2) screening laboratory tests, (3) vaccines to prevent STIs, HIV, and viral hepatitis, (4) condom distribution, or (5) referral for special services such as drug treatment programs. Several national organizations recommend providers assess sexual and parenteral drug use as part of the periodic health-care visit screening services (Table 88-1).[10–28] The risk assessment should be performed confidentially; for adolescents this means without parents present.[10,13–15,21,25] Table 88-2[13,15,17,21,25,29] lists questions about sexual activity and parenteral exposure risks for STIs, HIV, and hepatitis that providers should ask patients during a routine primary care visit. Focused sexual health risk screening and brief counseling as part of routine preventive health services to adolescent patients can be feasible and acceptable to both providers and patients.[30]

Although preventive health-care visits offer an ideal opportunity for sexual and parenteral drug use behavior risk assessment, many adolescents and adults, especially boys and young men, do not have coverage for or do not access any preventive care services or may choose to seek services from sources other than their usual provider to protect confidentiality.[31–35] In an acute care or problem oriented visit, a sexual and parenteral drug use behavior risk assessment that is not related to the reason for the visit is rarely performed. Even among individuals who receive preventive health-care services, sexual and parenteral drug use behavior risk assessment is often

Table 88-1. National Recommendations by Organizations for Periodic Sexual and Parenteral Drug Use Risk Assessment and Counseling

Organization	Recommendations	Reference
American Academy of Pediatrics	• Integrate sexuality education and sexual risk reduction counseling into clinical practice • Obtain a comprehensive sexual history from all adolescent patients	11–13
American College of Obstetricians and Gynecologists	• Ask all adolescents annually about sexual activity • Counsel adolescents about methods to prevent STIs and unintended pregnancy • Provide all pregnant women education and counseling about HIV prevention • Evaluate and counsel all women for high-risk sexual behaviors at periodic examinations	14–17
American Academy of Family Physicians	• Counsel adolescents and adults regarding STI risks and how to prevent them	18
United States Preventive Services Task Force	• Advise all adolescent and adult patients about risk factors for HIV and other STIs, and counsel about effective measures to reduce the risk of infection. • Offer individuals at risk for specific STIs screening for syphilis, NG, HBV, HIV, and CT • Advise injection drug users about measures to reduce their risk and refer them to appropriate treatment facilities. • Assess risk factors for HIV by obtaining a careful sexual history and inquiring about injection drug use in all patients	19, 20
Centers for Disease Control and Prevention	• Educate sexually active patients regarding HIV and other STIs • Assess the patients' risk factors for infection • Offer at-risk patients advice about behavior changes to reduce the risk of infection • Offer HIV counseling with testing in areas where HIV prevalence ≥1% • Provide all pregnant women with information about HIV and HIV testing • Routinely obtain a history that inquires about use of illegal drugs • Provide counseling and education to prevent initiation of drug-injecting practices • Provide prevention messages for persons with high-risk drug practices and for those at risk of percutaneous exposures to blood in health-care and other settings (e.g., tattooing and body piercing)	21–24
American Medical Association	• Provide all adolescents health guidance regarding responsible sexual behaviors • Ask all adolescents about involvement in sexual behaviors that may result in pregnancy, STIs, and HIV • Always include a sexual history as part of their routine history and physical examination • Counsel for CT prevention • Educate patients about STIs, including HIV, and condom use	25–28

STI: sexually transmitted infections; HIV: human immunodeficiency virus; NG: *Neisseria gonorrhoeae*; HBV: hepatitis B virus; CT: *Chlamydia trachomatis.*

overlooked due to competing priorities for other preventive services. In a nationally representative survey of noninstitutionalized individuals aged 18–64 years, among persons who reported having a routine check up in the past year, only 28% reported being asked about STIs compared to 59% being asked about smoking and 49% being asked about alcohol use.[36] A nationally representative telephone survey found that 31% of women of reproductive age (18–44) have talked to their doctor about their sexual history and specific issues, such as STIs (28%) and HIV/AIDS (31%) in the past 3 years.[37]

Nationally representative surveys of high school students have found that only 43% of female and 27% of male

Table 88-2. Questions About Sexual Activity and Parenteral Exposure Risks for STIs, HIV and Hepatitis Recommended to be Addressed During a Routine Primary Care Visit[13,15,17,25,29]

Sexual activity:
Type of sex (oral, vaginal, and anal), age at coitarche, gender(s) of partner(s), number of current partners and number of partners in the past 6 months and in lifetime, substance use with sex
Presence of symptoms suggestive of an STI, acute HIV infection or hepatitis:
Vaginal or urethral discharge, dysuria, abdominal or scrotal pain, throat pain, oral lesions, flu-like symptoms, or jaundice
Concerns about STIs, HIV, or viral hepatitis infection
Prior STI, viral hepatitis, or HIV tests, result, or treatment
Contraception practices:
Barrier contraceptive use: condom use, frequency, and method; diaphragm, cervical cap
Hormonal contraceptive use or spermicide use
Parenteral exposure risks:
Receipt of blood products and hemodialysis
Injecting-drug use, including reusing or "sharing" syringes, needles, water, or drug preparation equipment, cleaning drug preparation equipment with bleach and water, and using sterile syringe, needles, and water from a reliable source (e.g., pharmacies)
Accidental needle stick exposure
Tattooing and body piercing history in a noncommercial site (e.g., jail or gang tattoo)
Prior vaccinations:
Hepatitis A
Hepatitis B
Other STI vaccines

STI: sexually transmitted infection; HIV: human immunodeficiency virus.

students who received a health-care visit in the past year reported having discussed STI, HIV, or pregnancy prevention at those visits[31] and that only 31% who reported having sex without contraception discussed this behavior with their primary care provider.[38] In Washington State Medicaid health plans during 1998, only 15% of male and 45% of female enrollees aged 14–18 years who had received primary care services had Medicaid record evidence of a sexual history being taken.[39] Surveys of Colorado and California primary care providers revealed that about three-fourths reported taking sexual histories from their adolescent patients.[40,41] Although it is difficult to assess the proportion of at-risk patients assessed for HIV risks in primary care settings, data indicate that HIV-risks of infected persons who accessed primary care services were present but were missed until HIV infection, including AIDS, was identified. In a large commercial health plan where access to care was reasonably good, review of medical records up to 5 years before HIV diagnosis found that only a minority of patients ultimately identified as belonging to a classic HIV-risk group had such risk documented ≥1 year before HIV diagnosis.[42]

In some cases, providers may initiate an STI or HIV risk assessment, but the quality of the dialogue may be insufficient to assess risk and to inform appropriate clinical actions. An analysis of videotaped patient–physician discussions about HIV risk found that in 73% of the encounters, physicians did not elicit enough information to characterize patients' HIV risk status.[43] In a survey of primary care physicians in Connecticut, 62% of respondents reported routinely asking all patients about a history of injection drug use, 5% did not routinely elicit injection drug use histories, and 33% reported asking about injection drug use from patients where other risk factors, such as a history of STIs, incarceration, or body tattooing, were already identified.[44]

Provider-, health system-, and patient-level factors may discourage routine STI, HIV, and hepatitis behavioral risk assessment and screening in private sector settings.[9,45] Many adolescents lack continuous health insurance, precluding care for anything but urgent problems.[34] The need to address competing clinical priorities during brief well-care or preventive visits is a major challenge.[46,47] Provider-level barriers include clinician misperception that prevalence of risk behaviors in more affluent, commercially insured persons is low, or is correlated with insurance status or race, and the belief that routine sexual and drug-related risk assessment is not cost-effective.[8,46,48] Lack of provider comfort with discussing sexual activity may also preclude sexual risk assessment. For example, surveys of adolescent and family medicine providers have shown that sexual activity is less frequently assessed than drug use.[40,49] Family physicians cited concerns about their own and their patients' discomfort discussing sexual matters but not drug use.[49]

Several interventions have attempted to promote risk assessment in primary care. They include developing policies to promote routine access to confidential care for patients, such as training providers in asking sensitive questions,[50] routinely excusing parents from adolescent encounters to allow for risk assessment;[51] adopting short, standard self-administered or provider-administered risk assessment tools[52–54] or using patient-administered, computer-based assessment tools to collect a sexual history and then providing computer-based written counseling messages tailored to that patient's risks.[55] Other methods include clinician training on risk assessment methods, using nonphysician staff to collect risk information,

such as by a confidential patient questionnaire,[51,53,54] making risk assessment a covered service,[56] and increasing reimbursement.[57] Few of these primary care risk assessment interventions have been evaluated for their impact on risk assessment practices on a short- or long-term basis. The optimal intervention for a particular setting may vary.

PHYSICAL EXAMINATION

An anogenital examination should be performed as part of a comprehensive physical examination during a health maintenance visit or as part of a focused visit for sexual health related concerns. The genital examination should include inspection of the pubic hair for evidence of lice and vaginal or urethral discharge, and the perineum and anus for lesions such as ulcers or warts. In female patients, if vaginal, urethral, or rectal discharge is noted, a full pelvic examination, including an abdominal examination, should be performed to assess for vaginitis, cervicitis, pelvic inflammatory disease, and proctitis. For male patients, in whom urethral discharge or rectal discharge is noted, a full genital examination should be performed to assess for urethritis, epididymitis, and proctitis. For both male and female patients, physical examination of other organ systems should be included to assess for signs of STIs, HIV, and hepatitis. The oropharynx should be examined for evidence of pharyngeal *N. gonorrhoeae*, oral chancres, or herpetic lesions, especially for men who have sex with men (MSM), adolescents, or other patients who commonly engage in oral sex. Finally, the skin should be examined for dermatologic evidence of STI or hepatitis infections, such as syphilitic rash, scabies, and jaundice.[29]

Anecdotes suggest that many providers may not provide oropharyngeal or anal examinations, thereby missing opportunities for diagnosis of infections acquired through oral or anal sexual contact. Anecdotes also suggest that common barriers to conducting a thorough examination include lack of time, lack of awareness of oral or anal sexual contact, and lack of familiarity with oral and dermatologic manifestations of STI. The mainstay interventions for promoting comprehensive physical examinations skills have been training programs in professional schools, continuing medical education, on-the-job training venues, and clinical alerts (e.g., about oral manifestations of syphilis among MSM) sent to clinicians by health departments.[58,59] However, few of these interventions have been evaluated for their effectiveness in improving actual examination skills.[58,59]

STI, HIV, AND HEPATITIS SCREENING OF ASYMPTOMATIC PATIENTS

STI screening of asymptomatic patients is a basic, effective tool used to identify an unrecognized condition so that treatment can be offered before symptoms or serious sequelae of asymptomatic infection develop.[19] Primary care providers play a key role in STI screening because preventive care and health maintenance are central responsibilities.

Screening and diagnostic testing can be accomplished from invasive tests, such as endocervical and urethral specimen tests for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, blood tests for syphilis, HIV, and viral hepatitis, as well as less invasive tests, such as urine-based or vaginal swab-based *C. trachomatis* and *N. gonorrhoeae* nucleic acid amplification tests (NAAT), oral conventional HIV tests, and rapid HIV tests performed on finger-stick and oral specimens.[60–61] Office-based, rapid screening tests for syphilis and HIV are also available but require confirmation with laboratory-based tests. Home collected tests for HIV are also available.[62] The recent introduction of *C. trachomatis* and *N. gonorrhoeae* combination (NAAT) and DNA probes tests may be cost effective for diagnostic testing of symptomatic persons or screening populations with a high prevalence of both infections. However, when combination *N. gonorrhoeae* and *C. trachomatis* tests are used to screen for *C. trachomatis* in privately insured populations with very low *N. gonorrhoeae* prevalence, they may yield few positive *N. gonorrhoeae* cases, low *N. gonorrhoeae* test predictive value, and poor cost-effectiveness.[61]

Several national organizations recommend screening asymptomatic patients for STIs in specific population groups (Table 88-3).[11,13–18,21,22,25,28,29,61,63–71] Various published STI, viral hepatitis, and HIV screening guidelines are somewhat inconsistent, a fact related to different guideline audiences and different interpretation of the clinical value and cost effectiveness of screening patients of differing age, risk behaviors, geographic location, and health-care settings. Some guidelines recommend general "STI" screening that may lead to over-screening for some pathogens, e.g., *N. gonorrhoeae* screening in commercially insured, married women with very low *N. gonorrhoeae* prevalence, and underscreening for other populations with varying prevalence rates, e.g., lack of *C. trachomatis* screening if the prevalence is misperceived to be low.[66,72–74]

Guidelines recommend primary care providers screen for selected bacterial STIs in their patients who are adolescents or young adults (i.e., <25 years old),[13,29,63–64] are pregnant[14–18] (i.e., as part of prenatal care), or who engage in behaviors which may place them at risk for STI (i.e., injection drug user, prior STIs, >1 sex partner in past 6 months, exchange sex for drugs or money, MSM, or has at-risk sex partner).[25,28,66–71] Several guidelines recommend routine prenatal screening for several pathogens and routine screening of sexually active adolescent and young adult female patients (Table 88-3). Routine screening of asymptomatic patients who lack specific risk factors for other bacterial and viral STIs and hepatitis B virus infection is not recommended due to low yield or low cost-effectiveness.[29,67] However, screening is recommended

Table 88-3. National Recommendations for Periodic STI Screening by Organizations

Organization	CT	NG	Syphilis	HIV	HBV	Nonspecific STIs	Reference
American Academy of Pediatrics	1) Test all sexually active adolescents during gynecologic examination 2) Screen 20–24 year old women if have multiple partners or do not use barrier contraception	Screen all pregnant women at first prenatal visit and additional screening in 3rd trimester for high-risk women	Screen all women early in pregnancy and at 3rd trimester and additional screening at 28 weeks of gestation for high-risk women	Test all those requesting and encourage testing for all those with prior STI, >1 sex partner in past 6 months, IDU, sexual intercourse with partner at-risk, sex for drugs or money, homeless, MSM.	Screen all women early in pregnancy and additional screening later in pregnancy for high risk women	1) Perform dipstick urine for leukocytes annually for all sexually active adolescents 2) Screen all sexually active adolescents (11–21 years) for STIs annually	11, 13, 63–64
American College of Obstetricians and Gynecologists	1) Screen all sexually active adolescent female patients annually 2) Screen all pregnant women if at-risk	1) Screen all sexually active adolescent female patients annually 2) Screen all pregnant women if at-risk	1) Screen all sexually active adolescent female patients for prenatal care, if prior STIs, multiple sex partners, exchange sex for drugs or money, illicit drug use, admitted to detention facility, or lived in endemic area 2) Screen all pregnant women	1) Screen all pregnant women 2) Periodic screening for women ⩾19 years at risk (e.g., multiple or high-risk sex partner(s), prior STIs, attendance at STI clinic) 3) Screen all female patients if pregnant, prior STIs, multiple or high-risk sex partners, exchange sex for drugs or money, IDU, admitted to detention facility, long-term residence or birth in endemic area, blood transfusion before 1985	Screen all pregnant women	Periodic STI screening for women ⩾19 years at risk (e.g., multiple or high-risk sex partner(s), prior STIs, attendance at STI clinic)	14–17, 65

for patients at high risk for hepatitis A or B virus in the context of offering hepatitis vaccine to persons with high likelihood of past infections, such as persons born in areas with high disease endemicity, MSM with large numbers of sex partners, injection drug users, and sexual contacts of persons with chronic viral hepatitis infection (Table 88-3). Hepatitis A and B serologic screening may be a cost effective option to identify noninfected patients who could benefit from hepatitis A and B vaccination.[29] All pregnant women, regardless of risk factors, should be tested for hepatitis B viral infection.[16,29,67] In 2006, the CDC published revised HIV screening guidelines that recommend voluntary HIV screening for all patients aged 13–64 years, at least once, in all health-care settings and include HIV screening in the routine panel of prenatal screening tests for all pregnant women after the patient is notified that testing will be performed unless the patient declines (opt-out screening).[21] CDC also recommends simplifying the screening process by not requiring a separate written consent or prevention counseling for HIV testing to occur.[21] For high-risk patients, i.e., injection-drug users and their sex partners, persons who exchange sex for money or drugs, sex partners of HIV-infected persons, and MSM or heterosexual persons who themselves or whose sex partners have had more than one sex partner since their most recent HIV test, providers should test at least annually. The U.S. Preventive Services Task Force (USPSTF) HIV testing recommendations vary. USPSTF recommends that clinicians incorporate voluntary HIV screening into routine medical care for pregnant women and for individuals who engage in behaviors that may place them at risk for HIV infection, patients who request an HIV test despite reporting no individual risk factors, clinical settings serving populations at increased behavioral or clinical HIV risk (e.g., drug treatment facilities and STI clinics), and in high-prevalence settings.[68,69] Proponents of HIV screening in primary care settings with lower HIV prevalence rates argue that the cost-effectiveness of screening is similar to that of commonly accepted interventions, and HIV infection treatment is readily available and less complex if first offered early after infection.[75–77]

Because of a lack of nationally representative surveys or medical record reviews about screening practices, various sentinel studies best estimate screening practices. Such studies show that the extent of prenatal STI screening varies by STI and clinician specialty. In a national survey of 130 obstetrics and gynecology office-based practices, all practices reported hepatitis B prenatal screening with 95% of women tested.[78] In a 1998 national survey of primary care physicians practicing internal medicine, family practice, emergency medicine, and pediatrics reported routine screening rates of their pregnant patients between 30% and 32% for syphilis, *N. gonorrhoeae, C. trachomatis* and HIV.[79] However, the surveyed obstetricians and gynecologists reported much higher STI screening rates of their pregnant patients; 85% for syphilis, 79% for *N. gonorrhoeae*, 78% for *C. trachomatis*, and 81% for HIV.[79] In a national sample of commercial health plan claims data during 1998–1999, 63% of pregnant women had claims for syphilis tests, but only 33% for HIV screening.[80] A 1998–1999 study of HIV prenatal testing in eight U.S. states found that testing rates ranged from 25% to 85%. Rates were higher in states with mandatory newborn HIV testing and in states where HIV testing was included in a standard panel of prenatal tests.[72]

In contrast, in most primary care settings, *C. trachomatis* screening rates of sexually active female patients outside of prenatal care are low to moderate. Annual *C. trachomatis* screening of sexually active adolescent female patients was reported by over 50% of Medicaid-participating physicians (53%) and midlevel providers (54%) in seven cities,[81] by 32% of primary care physicians surveyed in Pennsylvania,[48] and 54% of primary care providers surveyed in Colorado.[41] In the 1998 national primary care provider survey, only a third of physicians reported routinely screening women for chlamydial infection, although obstetrician/gynecologists reported higher screening rates.[79] Since annual *C. trachomatis* screening of sexually active female health plan enrollees 15–26 years old was introduced as a health plan performance measure, average screening rates have increased slightly in commercial health plans (from 20% in 1999 to 26% in 2001) and Medicaid health plans (from 28% in 1999 to 38% in 2001).[74] Medicaid managed care plans have consistently had higher *C. trachomatis* screening rates than commercial health plans.[82] Most studies in primary care settings demonstrate fairly high yield when screening adolescent female patients—from 3% to 9%.[51,83–85]

Because routine, annual, *N. gonorrhoeae*, syphilis, and HIV screening are currently recommended only for selected groups, population-based screening rates are low. A national survey of internal medicine, family practice, emergency medicine, and pediatric physicians demonstrated that few primary care physicians routinely screened male (19%) and nonpregnant female (20%) patients for syphilis or for *N. gonorrhoeae*; (13% screened male and 30% screened nonpregnant female patients).[79] Although the population of persons at-risk for HIV infection is unknown, nationally representative surveys reveal that approximately 10–12% of Americans aged 18–64 years who reported being tested for HIV in the past 12 months[86] were tested outside their primary care settings, possibly to protect confidentiality. Many HIV-infected individuals are not being detected early in infection through screening in primary care and other health-care settings.[42,73]

Provider knowledge, attitudes and practices can present barriers to widespread STI, HIV, and hepatitis screening in primary care. Misperception that STI prevalence in private sector primary care patient settings is low and the belief that routine *C. trachomatis* or HIV screening is not cost-effective have been substantial barriers to screening in the private

sector.[8,46,48] Perception of STI as a low overall health priority may explain why *C. trachomatis* screening rates are lower for internists, pediatricians, and family physicians than for obstetrician/gynecologists.[47] Lack of awareness and confusion about new laboratory tests using noninvasive urine specimens, approved specimen types, and test performance can lead to low screening rates. For example, 80% of primary care physicians surveyed in Albany, NY were not aware of urine *C. trachomatis* NAAT availability and only 2% had ordered them in their practice.[87] Finally, many providers are unaware that in all 50 states minors may consent for their own sexual health services and disclosure of provision of these services and screening test results to parents is not mandatory.[88–90] Policy-level factors that discourage screening include lack of reimbursement, screening policies and routine protocols, decision support tools, noninvasive urine screening tests, performance feedback, and reminder systems. (Table 88-4).[91,92] Also, providers may not be aware of the full range of general billing codes that can be used to document STI or HIV services without risking confidentiality violations if someone other than the patient sees an itemized medical bill or "explanation of benefits" (Table 88-4).[46–48,74]

Table 88-4. Commonly Cited Barriers to High Quality STI Care in Private Sector Settings[91,92]

Level	Barrier
Patient	• Concerns about confidentiality of medical information, medical records, or billing information that would reveal sexual activity • Discomfort with discussing sexual issues with health-care providers • Stigma of STI • Limited understanding of high prevalence and asymptomatic nature of many STI and serious and long-term consequences of untreated STI
Provider	• Brief patient encounters and competing clinical priorities discourage sensitive, labor intensive tasks such as sexual risk assessment, patient counseling and education, and sex partner management • Discomfort discussing sexual issues with patients and doing pelvic examinations (especially on adolescent patients) • Lack of training in sexual risk assessment and sexual risk reduction counseling and educating, and sex partner management • Difficulty keeping up with revised recommendations on STI screening and treatment • Insufficient and/or nonconfidential reimbursement methods for routine risk assessment, screening, risk reduction counseling, patient education, sex partner management, and case reporting • Lack of awareness of noninvasive STI screening tests
Health system	• Lack of explicit policies/protocols for STI care • Lack of decision-support tools • Lack of provider feedback and reminder systems • Cost-containment pressures that discourage STI prevention services, routine risk assessment, screening, counseling, education, and sex partner management • Limited support staff to assist with risk assessment, counseling, education, sex partner services, and case reporting • Medico-Legal/Liability concerns about potential confidentiality breaches or legal requirements to report evidence of sexual activity of minors (e.g., reporting statutory rape, sexual abuse) • Nonavailability or lack of reimbursement for noninvasive STI screening tests (e.g., urine) • Lack of centralized systems, dedicated staff, or electronic data systems that facilitate case reporting • Limited organizational commitment and "internal champions" due to stigma and perception that STI are low volume, low cost conditions • Limited demand by health-care purchasers and MCO enrollees for STI quality improvement

STI: sexually transmitted infections; MCO: managed care organization. (Reprinted from *Infectious Disease Clinics of North America*, 2005;9(2):491–511, with permission from Elsevier.)

Cost-containment pressures in health plans favor diagnostic testing of a few symptomatic patients over routine screening of large numbers of asymptomatic patients. For example, *C. trachomatis* screening is cost-effective from a societal perspective and is ranked among the top preventive services in terms of disease averted and cost-effectiveness.[93] However, rapid health plan enrollee turnover makes it difficult for health plans to reap benefits of prevention in the short term since many sequelae of undetected, untreated infection occur years later.[81] For patients, especially adolescents, the stigma of STI and concerns about maintaining the confidentiality of sexual activity or infection status information discourages demand for and acceptance of screening.[32,94,95] For example, in a survey of adolescent patients in two North Carolina general pediatric practices, 92% would agree to urine-based STI testing if confidentiality could be assured, but only 35% would agree to such testing if parents would find out.[95]

Several interventions have been introduced to promote STI, HIV, and hepatitis screening. State laws have played a key role in improving prenatal screening rates. Syphilis testing in standard prenatal testing panels, longstanding national screening guidelines, and state regulations mandating syphilis screening have supported high screening rates for decades.[80] A study assessing state laws and regulations regarding United States prenatal syphilis serologic screening in 2001 found that 46 (90%) states and the District of Columbia had laws regarding antenatal syphilis screening and that states with a heavy burden of infectious syphilis in women were likely to require more frequent prenatal syphilis testing.[96] An eight-state HIV prenatal testing surveillance study found that states shifting from an opt-in approach (women typically are provided pre-HIV test counseling and must consent specifically to an HIV-antibody test) to either an opt-out approach (women are notified that an HIV test will be included in a standard panel of prenatal tests and that they may refuse testing) or mandatory newborn testing approach if the mother's HIV status is unknown at delivery (newborns are tested for HIV, with or without the mother's consent), increased their prenatal HIV-testing rates.[72]

Several interventions have been introduced to promote routine *C. trachomatis* screening of sexually active adolescent and young adult female patients. Simple interventions include development, dissemination, and "championing" of print- and web-based practice or health plan-specific screening guidelines and protocols,[51,85] and introducing noninvasive urine tests.[51,97,98] Other methods include using nonspecific primary care billing codes for screening services to protect confidentiality,[99] routinely collecting *C. trachomatis* screening tests with every pelvic examination,[4,85] and Web-based clinician instruction using clinical cases relevant to commercial health plans.[100] Laboratories can cut costs by pooling specimens from numerous patients and retesting individual specimens from positive pools,[61] A multifaceted intervention involving the use of multimedia educational materials and an intensive office-based "academic detailing" approach increased *C. trachomatis* screening rates by 17% for Medicaid and 30% for commercial enrollees.[87] More complex interventions have also increased *C. trachomatis* screening in young female health plan enrollees. Examples include inviting health plan enrollees classified as high risk through administrative data for *C. trachomatis* screening with personalized letters[101] and a system-level practice improvement approach that provided screening performance feedback to providers, introduced routine urine-based *C. trachomatis* testing, and implemented parent "rooming in" policies that gave adolescent patients time alone with their providers.[51,102] In contrast, no appreciable increase in *C. trachomatis* screening was observed in three different health plans that sent young adult enrollees health newsletters that included information about, and how to get access to screening.[103]

Several interventions to increase HIV counseling and testing have increased screening rates in primary care settings (see Chapter 69). For example, several community-based health centers in areas with high HIV prevalence rates have implemented simplified HIV counseling and testing that takes 5–10 minutes to complete.[104]

STI, HIV, HEPATITIS DIAGNOSTIC TESTING OF PATIENTS WITH SYMPTOMS OR SIGNS

CDC recommends *C. trachomatis* and *N. gonorrhoeae* diagnostic testing of patients who present with clinical urethritis and cervicitis (see also Chapters 55 and 59); herpes simplex virus and syphilis diagnostic testing of patients who present with genital ulcers (see Chapter 63); and hepatitis serology testing of patients with signs of clinical hepatitis, such as jaundice or signs of chronic disease, such as cirrhosis or liver cancer (see Chapter 29). CDC also recommends HIV counseling and diagnostic testing for persons with evidence of acute retroviral syndrome, opportunistic infections, and other infectious diseases with high HIV coinfection rates (i.e., syphilis and tuberculosis), and laboratory abnormalities consistent with HIV (see Chapter 69).[21,29,105] Several organizations recommend DNA testing for high-risk types of human papillomavirus (HPV) as one option to manage women with Papanicolaou tests categorized as atypical squamous cells of undetermined significance (ASC-US).[29,65,106–109] Under this option, female patients with positive HPV tests are advised to undergo prompt colposcopy to obtain a biopsy, whereas female patients with negative HPV tests should be followed with subsequent Pap tests. The HPV DNA test is not FDA-approved as a "stand alone" STI screening test for female patients with genital warts or for any reason in male patients (see Chapter 28).

Despite guidelines recommending STI diagnostic testing, many persons with an STI are presumptively diagnosed

without laboratory tests, especially in episodic care settings like emergency departments and urgent care centers. Analysis of National Hospital Ambulatory Medical Care Survey data examining visits by nonpregnant 15–44 year old women seen in primary care clinics between 1997 and 2000 found that STI testing occurred in only 13% of visits by women with genitourinary symptoms.[110] For male patients with signs and symptoms of NGU, specific diagnostic criteria and treatment guidelines exist and so providers may not feel the need to perform further diagnostic testing, especially when invasive urethral specimens are the only testing option.[111]

Additional challenges in STI diagnostic testing in primary care settings include managing patients who may have false positive test results. This is especially a concern when screening in low prevalence populations, e.g., positive *N. gonorrhoeae* test was performed in a patient with a suspected chlamydial infection because a combination *C. trachomatis/N. gonorrhoeae* laboratory test was used (see Chapter 55). Other challenges include interpretation of syphilis antibody titers as a recent versus latent infection because many providers may not have access to a full record of previous syphilis antibody titers, including titers obtained after treatment (see Chapter 37). There is also confusion regarding hepatitis serology results interpretation and distinguishing old versus new infections (see Chapter 29) and counseling and confirmatory testing for reactive rapid HIV tests and for indeterminate HIV western blots (see Chapter 70).

TREATMENT PRACTICES

Treatment of STIs, HIV, and viral hepatitis is critical to reduce patient symptoms, prevent serious sequelae of untreated infection, and prevent risk of transmission to sex partners and the fetus. Many treatment guidelines for STI, HIV, and viral hepatitis are issued by federal agencies, such as CDC, the Health Resources and Services Administration (HRSA) HIV/AIDS Bureau, and the National Institute of Health (NIH), professional medical organizations, such as the American Academy of Pediatrics, and various health plans.[29,63,112,113] Treatment recommendations are also found in clinical texts, such as the Physicians' Desk Reference, the Sanford Guide, and the Johns Hopkins Hospital Guide to Medical Care of Patients with HIV Infection.[114–116] While some treatment is straightforward, other treatment is complex. Providers may refer patients with positive screening syphilis tests to the health department for final diagnosis and management because of unique access to past serologic test and treatment information needed to interpret screening test results. Given the evolving drug resistance, *N. gonorrhoeae* treatment has become challenging.[117,118] Given the evolving drug resistance, *N. gonorrhoeae* treatment has become challenging.[117,118] CDC's Gonococcal Isolate Surveillance Project data demonstrate that fluoroquinolone-resistant gonorrhea is now widespread in the United States.[119] Therefore, fluoroquinolones are no longer recommended for the treatment of gonorrhea in the United States.[119] Some providers treat genital warts in their practice setting; others may refer to surgical subspecialists for more invasive treatments. Because viral hepatitis treatment can be complex, primary care providers may refer hepatitis-infected patients to hepatologists. For HIV-infected patients, some primary care providers manage all care, some manage only primary care issues, some refer HIV-related care to infectious diseases or HIV care specialists, and some refer all care for HIV-infected patients.[29]

Generally, chart review and provider reports demonstrate that uncomplicated lower genital tract chlamydial infection and gonorrhea are appropriately treated in the majority of cases. Among 1078 patients with positive tests for genital chlamydial infection in two large health plans, more than 97% of men and nonpregnant women and more than 98% of pregnant women were prescribed treatment consistent with current CDC guidelines.[29,120] Among the primary care clinicians surveyed at these health plans, 89% reported they would use CDC-recommended treatments for laboratory-confirmed chlamydial infection in pregnant women and 62% reported they would use CDC-recommended single dose azithromycin to treat chlamydial infection diagnosed in injection drug users in whom compliance to longer regimens might be questioned.[121] In a publicly funded Minnesota health plan, CDC-recommended treatment was documented for 91% of enrollees diagnosed with *C. trachomatis* and 75% diagnosed with *N. gonorrhoeae*.[99] In the seven-city Medicaid health plan study, 78% of primary care clinicians reported using single-dose azithromycin for *C. trachomatis* treatment.[81] In a Massachusetts health plan, all men with symptomatic urethritis who had a positive *N. gonorrhoeae* test result, and 88% of those with a positive *C. trachomatis* test were prescribed CDC-recommended treatment at their initial visit.[122] The rest were treated within 5 days. Treatment practices for other STIs associated with more complicated, clinically based diagnosis, polymicrobial etiology, or drug-resistant pathogens tend to be more varied than laboratory-confirmed STI associated with a single pathogen. Regarding treatment of PID, a condition that is usually diagnosed presumptively and is often polymicrobial in etiology, 52% of California physicians (78% of whom practiced in private sector settings) reported that they did not use CDC treatment guidelines.[123]

Barriers to appropriate STI treatment include cost, compliance, drug intolerance, and other side effects. Medication costs, even generic drugs that are typically less expensive than brand names, may present a barrier to treatment for uninsured patients and those who want to pay out-of-pocket to maximize confidentiality. In some cases, single dose medications that promote adherence are more costly than multidose regimens, e.g., single dose azithromycin versus a 7-day course of doxycycline to treat uncomplicated genital chlamydial

infections. Treatment for viral STIs, such as genital herpes (e.g., chronic suppressive treatment), or genital warts (e.g., patient-applied therapy), may be difficult for patients to follow long-term. When disease recurs despite treatment, providers may encourage future adherence by educating patients about the chronic, relapsing nature of these viral diseases. Providers should be aware that medications, especially for viral STIs such as HIV may cause side effects or drug intolerance such that patients must discontinue the treatment.[124,125]

As with any treatment challenge, providers develop creative strategies to maximize treatment success. Strategies to minimize out-of-pocket treatment expenses could include disregarding copayment fees, prescribing generic formulations, and dispensing pharmaceutical samples. Prescribing a simplified, convenient, drug regimen can maximize compliance, such as prescribing FDA-approved single dose treatment for bacterial STIs. To increase compliance, CDC recommends dispensing medication in the office, optimally at the visit where STI is diagnosed, and directly observing the patient taking the first dose.[29] Advising patients of possible medication side effects in advance can decrease the likelihood of unexpected unpleasant side effects and may improve compliance.

RISK-REDUCTION COUNSELING AND PATIENT EDUCATION

The phrase "risk reduction counseling" implies interactive discussion about risk reduction measures, tailored to an individual patient's risks, a strategy recommended by CDC guidelines.[29] The term education implies sharing information about reducing risk of STI acquisition or transmission through clinicians or health educators, verbal instructions, print, audio and web-based materials, or referral to telephone hotlines and support groups. Risk reduction counseling to prevent chronic viral STI, HIV, and hepatitis transmission is more complex than STI counseling because of the risk of lifelong sexual transmission, and, for HIV and hepatitis, parenteral transmission (Chapters 29 and 72). Tailored counseling has been shown to be an effective strategy in changing behaviors, such as increasing condom use and in reducing incidence of bacterial STI in STI clinic patients in one study.[126] This and other studies have shown that such counseling may also reduce HSV acquisition.[127,128]

These studies and expert opinion have provided support to long-standing guidelines that patients at risk for or infected with STI, HIV, or hepatitis should be offered counseling and/or education to reduce risky sexual behaviors to prevent reinfection and transmission to current and future sex partners.[29,129] Patients diagnosed with bacterial or viral STI, HIV, and hepatitis should be advised that abstinence, condom use, and minimizing the number of sex partners can reduce the risk of acquiring future infections or transmitting their current infection to sex partners. Some providers directly dispense condoms at low or no cost. For patients diagnosed with acute bacterial STI, important counseling messages include the need to adhere to the prescribed treatment, especially completing the full course of antibiotics, and abstaining from sex until treatment is complete. Patients should be notified to contact recent sex partners and encourage them to seek evaluation, and patients diagnosed with an STI that is reported to the health department should be notified that health department staff may contact them to offer assistance with notifying partners.

Patients diagnosed with chronic or recurrent viral STI such as HSV, genital warts, or hepatitis B require special counseling tailored to the specific infection. For HSV, this may include counseling patients about circumstances that may promote recurrence of lesions, the benefits of suppressive therapy, the relation between symptoms and viral shedding, and long-term strategies to prevent transmission to sex partners.[128] For patients with genital warts or HPV-related cervical cytologic abnormalities, experts recommend that patients should be advised to limit the number and type of sexual partners, and that consistent condom use might afford some protection in reducing the risk of HPV transmission and associated diseases of anogenital warts and cervical neoplasia (cervical cancer precursors and invasive cancer).[130] For patients with either genital herpes or anogenital warts, patients should be advised that transmission may result from genital skin contact and does not require penetrative penile, anal, or vaginal contact. Patients with hepatitis should be counseled about both sexual and parenteral exposure risks; and if parenteral risks are identified, patients should be referred to resources to reduce risky injection behaviors and to promote use of sterile injection equipment. Special consideration must be given to pregnant patients for risk-reduction counseling and education in the prevention of transmission of HIV/STI to avoid pregnancy complications and perinatal transmission. Pregnant patients should be encouraged to avoid behaviors that put them and the fetus at risk and should be given information about how to prevent perinatally transmitted HIV, hepatitis, *C. trachomatis*, *N. gonorrhoeae*, and HSV[29] (see also Chapters 80, 81, and 85).

Several studies have assessed sexual risk-reduction counseling practices of private providers, but few have described if the focus was STI in general, bacterial STI, or viral STI. For example, in one nationally representative survey in 1998, 78% of physicians reported always telling their patients to avoid sex and 76% reported telling their patients to use condoms during STI-related treatment visits.[131] In another nationally representative sample of clinicians that cared for patients with anogenital warts, most clinicians surveyed (>80%) reported counseling patients about the cause and prevention of warts.[132] A survey of primary care physicians contracted to Medicaid health plans in seven U.S. cities found that 98% of physicians reported they provided prevention

counseling while taking a sexual history despite the fact that only 81% of their affiliated medical groups and 57% of their health plans explicitly recommended this practice.[81]

However, medical record reviews suggest that sexual risk reduction counseling is less commonly performed or documented than clinicians report in surveys. For example, studies show that HIV/STI counseling was documented in the medical records of only 30–35% of all ambulatory care visits in which HIV or bacterial STI tests were done.[99,133] Another study showed that less than 10% of the patients had been counseled regarding risks and prevention of sexually transmitted hepatitis B virus infection, even though sexual transmission accounts for >50% of hepatitis B virus infections.[134] Most studies that have evaluated the extent and quality of HIV risk-reduction counseling have addressed HIV test settings, not private sector primary care settings (see Chapter 69). The 1995 Public Health Service guidelines that recommended that all pregnant women receive in-person pretest counseling about the risks of perinatal HIV and be offered voluntary HIV testing were later revised, making in-person counseling optional due to evidence that such counseling was not commonly delivered or was often incomplete.[22]

Several barriers to sexual risk reduction counseling and patient education in primary care practices have been identified. A 1999 survey of primary care providers in staff and network health plans found that more than 30% reported that having a limited number of staff members to counsel patients or difficulties keeping up-to-date on how to manage patients at risk for STI were STI management challenges.[91] Other challenges include belief that counseling is ineffective in changing behavior, patient or provider discomfort with or lack of training on counseling, competing clinical priorities during brief visits, lack of staff dedicated to counseling and education, lack of decision support tools such as counseling checklists or talking points, and the absence of guidelines, policies, protocols, reminders, feedback, and adequate reimbursement[57,97,135] (Table 88-4). For example, a 1998 Washington State survey found that the indemnity health plans that dominated in the state were less likely to cover STI counseling services (29%) than the less common HMOs (100%).[136] Others have observed that clinicians may forego counseling enrollees of capitated health plans that do not provide added reimbursement for this service.[1,4] In a nationally representative sample of clinicians that cared for patients with genital warts, leading barriers to counseling patients about warts (or addressing HPV with patients diagnosed with warts) included providing definitive answers about when or from whom HPV infection was acquired (86%), dealing with patients' emotional, psychosocial and relationship issues (76%), and reimbursement for time needed for patient counseling or education (73%).[132] A significant challenge to effective implementation of counseling and educational interventions for HSV and HPV is the low level of knowledge among clinicians, patients, and the general public about the high prevalence of these infections, the high prevalence of asymptomatic shedding, and transmission risks.[128,130] Barriers to HIV counseling are detailed in Chapter 69.

Various interventions have attempted to increase STI and HIV counseling and patient education in primary care settings but few have been vigorously evaluated.[137] Interventions to reduce behaviors that increase HIV risk in private primary care settings have been more extensively evaluated (see Chapter 89). Simple approaches include providing clinician training in risk-reduction counseling and communication about sexual issues.[118] A group-model health plan saw sustained improvements in sexual health knowledge and counseling among providers after training was offered, staff roles were clarified, tools and materials were provided, and reminder and feedback systems were implemented.[138] Increases in counseling rates for adolescents by pediatric primary care providers have also been found after targeted training and the integration of screening and charting tools in two HMO outpatient pediatric practices.[53] Successful adolescent STI prevention counseling strategies have included interactive educational opportunities for patients to assess their own risks, developing personalized, realistic plans for self protection, and addressing barriers to change.[139] Since interactive counseling may require more time than a standard office visit, health educators and educational resource supports may be needed for effective counseling in the primary care setting. Patient educational supports include pamphlets, videos, hotlines, websites, or referrals to group counseling or community support groups.[140] One potentially time-saving tool is a patient-administered, computer-assisted program that tailors counseling messages to patient's risk factors,[55] or an interactive, computer-based program to educate patients about STIs.[141] Because inadequate reimbursement may preclude counseling, some Medicaid agencies include counseling and patient education as a covered service in health plan service contracts to encourage delivery of these services.[56] Information on the extent of counseling and patient education for HIV and hepatitis, barriers to delivering these services and interventions to improve service delivery are detailed in Chapter 89. There is little specific data available on successful interventions to improve delivery of HIV and hepatitis counseling and education for adolescents, adults, and pregnant women in private sector primary care. However, interventions that streamline and improve delivery of counseling and education services for other STI in general may be applicable to these specific infections as well.

VACCINATION AGAINST HEPATITIS B AND OTHER STI

Vaccinations are considered one of the most important clinical and public health interventions. Primary care providers have critical roles in offering vaccines to their patients to prevent serious acute infections in individual patients and to prevent

disease transmission in the community. In the United States, vaccines against hepatitis B and hepatitis A are licensed by the FDA and are recommended for use in selected patients by several national organizations[142,143] (Table 88-5). In addition, several vaccines against bacterial and viral STI are in various stages of development, but not yet approved for clinical use.

HEPATITIS B VACCINE

Vaccination against hepatitis B is important to prevent acute liver inflammation and insufficiency and chronic liver disease, cirrhosis, and hepatocellular carcinoma.[144] Since licensure of the vaccine in 1982 and implementation of recommended guidelines by several national organizations, the number of new cases of hepatitis B has declined dramatically (see Chapter 29).[145] Current recommendations include vaccination of all children and adolescents through age 18 years[146] and of adults at high risk for hepatitis B infection, such as persons with multiple sexual partners, intravenous drug users, MSM, patients receiving hemodialysis, and health-care workers. For sexually active adolescents and adults, providers should assess risk for acquiring hepatitis B infection and offer hepatitis B vaccine if the patient is considered high-risk. Serologic testing to determine if the patient is already immune before vaccination is

	immunization records and should complete the vaccine series if they were not previously vaccinated or were incompletely vaccinated	
	Adults: Vaccinate persons at high risk of HBV infection including:	
	Persons with occupational risk	
	Susceptible persons who have chronic liver disease HIV positive persons	
	Clients and staff of institutions for the developmentally disabled.	
	Hemodialysis patients	
	Recipients of certain blood products, i.e., clotting factors	
	Household contacts and sex partners of HBV carriers.	
	Adoptees from countries where HBV infection is endemic	
	International travelers if spending more than 6 months in areas with high endemicity	
	Injecting drug users.	
	Sexually active homosexual and bisexual men	
	Sexually active heterosexual men and women	
	Inmates of long-term correctional facilities	
US Preventive Services Task Force (USPSTF)	Hepatitis A vaccine is recommended for persons at high risk for hepatitis A virus (HAV) infection.	19
	Hepatitis B vaccine is recommended for all young adults not previously immunized and for all persons at high risk for infection.	

only recommended within populations with high prevalence (>20%) of past infection. The hepatitis B vaccine is highly effective; in adolescents and healthy adults aged <40 years, approximately 30–50% develop a protective antibody response (anti-HBs >10 mIU/mL) after the first vaccine dose, 70% after the second, and >90% after the third dose. Consequently, even if providers are concerned that the patients will not complete the series of the three vaccinations, the first dose should be offered to provide partial protection.[29] Providers who care for HIV-infected persons should also be aware that vaccination may be complicated by blunted antibody response to past hepatitis infection, an issue that also complicates interpretation of hepatitis serologic tests that determine eligibility for vaccine.[147]

Despite vaccination recommendations, gaps in vaccination coverage exist among children and adults served by private sector providers. In 2000, approximately 30% of self-identified high-risk men and women reported having received a single dose of hepatitis B vaccine despite having previous visits to a clinic within the past year.[148] In 2002, despite children 19–35 months having vaccination coverage of 90%, adolescents 13–15 years only had coverage of 67%.[146] Barriers to hepatitis B vaccination include the cost of the vaccine and the lack of reimbursement to providers, reluctance to start the vaccine series if it may not be completed, and lack of provider awareness of the high prevalence of patient behaviors that may expose patients to hepatitis B.[146]

Several interventions have increased the vaccination rates of children, adolescents, and adults by primary care providers. Introduction of mandatory hepatitis B vaccination for adolescents entering middle school in several states in the late 1990s has been followed by large increases in vaccination

rates.[149] The Advisory Committee on Immunization Practices (ACIP), the American Academy of Family Physicians (AAFP), the American Academy of Pediatrics (AAP), and the American Medical Association (AMA) recommend a well-child office visit at 11–12 years to evaluate the vaccination status for varicella, MMR, and hepatitis B; this visit provides an opportunity for catch-up vaccination.[150,151] Other methods to increase vaccination coverage include educating patients and parents about vaccine benefits and safety, and implementing practice systems that support adherence to vaccination guidelines such as standing orders and reminder recall systems to avoid missed vaccination opportunities, developing immunization registries to deal with fragmented care and to track multidose vaccinations, and giving fair reimbursement of vaccines to providers.[152] For high risk adults, integration of hepatitis B vaccination into programs that provide services to persons with risk factors for HBV infection (e.g., STD clinics, HIV counseling and testing sites) have increased vaccination rates in high risk adults.[146] Special measures to protect confidential information about sexual behavior and drug use in billing and medical records may also be needed to encourage vaccine acceptance by adults, adolescents, and children and their parents. Streamlining consent procedures for adolescents may promote vaccination in states that require parental consent for adolescent vaccination, e.g., classifying hepatitis B vaccination under "comprehensive STD services" that may not require parental consent. (See http://www.guttmacher.org/statecenter/spibs/spib_OMCL.pdf for further information on state-specific regulations on adolescent consent for such services.)

HEPATITIS A VACCINE

Vaccination against hepatitis A can prevent acute hepatitis A disease and its rare sequelae of liver failure. Hepatitis A is acquired primarily through fecal-oral transmission by person-to-person contact, or ingestion of contaminated food or water. With the recent decline in incidence of hepatitis A among children, adults (especially men ages 30–49 years) are now more likely than children to acquire this disease, in contrast to past decades. Recently, outbreaks related to sexual and parenteral transmission have occurred among MSM and injecting drug users. The proportion of hepatitis A cases among MSM has increased from 1.5% in 1992 to 8.4% in 2002,[153] but a slight decrease in cases among MSM has also occurred most recently in 2004.[154]

Hepatitis A vaccine was first licensed in 1995 and is highly protective. In adults and children, adequate antibody levels develop in 94–100% of recipients 1 month after the first dose and all recipients develop protective levels after the second dose.[142] Vaccine introduction has been associated with substantial declines in disease, especially among children residing in states where vaccination is universally recommended.[155] In 1999, the Advisory Committee on Immunization Practices and several national organizations recommend hepatitis A vaccine for certain individuals, including children and adults living in populations with high rates of disease (e.g., American Indian/Alaska Native [AI/AN], Asian/Pacific Islander, and selected Hispanic and religious communities), travelers to countries with high or intermediate disease endemicity, MSM, injecting-drug users, and persons with chronic liver disease to avoid additional liver damage due to hepatitis A.[142] Routine vaccination is strongly recommended for children residing in 11 states with high disease prevalence (Alaska, Arizona, California, Idaho, Nevada, New Mexico, Oklahoma, Oregon, South Dakota, Utah, and Washington) and is recommended as an option for children in six states with moderate prevalence (Arkansas, Colorado, Missouri, Montana, Texas, and Wyoming).[142] In 2006, recommendations for hepatitis A vaccine were expanded to include routine vaccination of all children aged ≥1 year.[145] Some organizations recommend that primary care providers of children offer vaccine to children at well-care visits[156] and should assess adult risk factors for hepatitis A acquisition (e.g., multiple sexual partners, and travel to endemic areas) and risk factors for hepatitis A transmission (e.g., commercial food handlers) at primary care visits.[142] Several organizations also recommend that HIV-infected persons be routinely assessed for hepatitis A vaccine eligibility and offered vaccine, if eligible.[157]

Barriers to providing hepatitis A vaccine in private sector settings are similar to those related to hepatitis B vaccine, and relate to provider awareness of vaccine recommendations, identification of individuals at risk, and costs and reimbursement of the vaccine. Interventions to increase coverage of hepatitis A vaccine and to reduce disease transmission have included promoting the guidelines of national organizations that recommend routine vaccination of children, who are often a source of infection for adults. Introduction of combination vaccines against both hepatitis A and B have also been shown to be cost-effective in increasing vaccination coverage of high-risk persons.[158]

PROPHYLACTIC VACCINES AGAINST GENITAL HUMAN PAPILLOMAVIRUS (HPV) INFECTION

Genital HPV infection is the most commonly sexually acquired infection, with an estimated 40 million people in the United States infected (see Chapter 28). Although most genital HPV infections are transient, asymptomatic, and clear without medical interventions, some cases of persistent infection may lead to anogenital warts, intraepithelial neoplasia and cancer of the cervix, penis, vulva, vagina, anus, and oral cavity, and infantile respiratory papillomatosis.[159,160] A quadrivalent vaccine against the two most common types of HPV associated

with cervical cancers (16 and 18) and the two most common types associated with anogenital warts (6 and 11) has been approved by the FDA; an application for licensure for a bivalent vaccine against HPV types16 and 18 is under FDA review. In 2007, the ACIP recommended the quadrivalent HPV vaccine for females aged 9–26 years.[161] If HPV vaccine is approved by the FDA, primary care providers may consider its use in patients before the onset of sexual activity.

PROPHYLACTIC VACCINES FOR OTHER STIs

Clinical trials have evaluated vaccines for *N. gonorrhoeae*, *C. trachomatis*, herpes simplex virus type 2, cytomegalovirus (CMV) and HIV.[162] Based on usual research, development, and approval timelines, these vaccines for these STI are not likely to be approved for clinical use within the next 5 years.

MANAGEMENT OF EXPOSED SEX PARTNERS

Prompt evaluation and treatment of sex and needle-sharing partners of patients infected with STI, HIV, and hepatitis is also recommended to prevent reinfection of the index patient and further transmission in the community.[29] Although managing sex partners has inherent value at the level of an individual patient or sexual partnership, there is little evidence that clinician recommendations to infected patients to notify sex partners, and partner notification by health department staff are effective in reducing STI or HIV incidence at the population-level. Providers should encourage their patients to notify sex partners of potential STI risk and urge them to seek evaluation, testing, and treatment.[29] Ideally, cases of notifiable bacterial STI and HIV infection that are reported to public health departments should prompt disease investigation specialists to contact a patient and offer assistance in notifying their partners and referring them for evaluation. However, staff shortages in most public health agencies often limit partner notification services to the small number of patients with HIV and syphilis, two potentially fatal diseases, the latter of which has a limited period of infectiousness most amenable to partner interventions. Syphilis cases may be prioritized over chlamydial and gonorrhea cases because prompt partner management is required to prevent infection during the short period of primary and secondary infectiousness[163] (see also Chapter 54).

In the 1998 national primary care physician survey, 80% of providers reported always asking STI-infected patients to notify their partners, but less than half of physicians indicated they always reported patients' names to health departments to initiate partner services, and less than 5% reported always contacting partners themselves.[131,164] A minority of private providers surveyed in Seattle reported addressing sex partner management.[165] Among physicians affiliated with Medicaid health plans in seven cities, 62% reported testing and treating sex partners even if they were not enrolled in the index patient's health plan, despite the fact that only 61% of their medical groups and 10% of their health plans explicitly recommended this.[81] A minority of patients with STI reported to health departments are provided partner management services by health department staff, even in high-morbidity areas of the U.S.[81,163] The extent of partner notification and referral for patients infected with HIV and Hepatitis is addressed elsewhere (see Chapters 53, 54, and 72).

Primary care clinicians cite several challenges to addressing sex partners of patients diagnosed with STI and HIV. Few clinicians or health plans collect contact information or notify sex partners because of the lack of clear policies about out-of-plan partners, medicolegal liability concerns, cost containment pressures, lack of reimbursement, and time or staffing constraints.[9,166] Other barriers include lack of providers' and patients' comfort discussing partners, and patients' and providers' concern about maintaining confidentiality or adverse consequences to relationships when partners are notified. Primary care providers also face challenges addressing partner services for MSM with numerous anonymous sex partners who may be impossible for patients or health department staff to contact.[167]

These challenges have prompted alternative approaches to partner management, such as expedited partner therapy, in some private sector settings. In a few states, laws or regulations allow clinicians to prescribe treatment for their patients' sex partners, even if the partners are not their patients, or to permit their patients to deliver treatment to partners.[168] Some health plans allowing clinicians to write antibiotic prescriptions for sex partners of patients diagnosed with chlamydial infection or gonorrhea not enrolled in the health plan have introduced methods for third party reimbursement for uninsured partners.[4,9,97,169] A recent trial showed that notifying patients with chlamydial infection and gonorrhea that they could refer their partners to get treatment at commercial pharmacies without visiting a physician was acceptable and increased partner treatment.[170] Some health plans provide brief "after visit summaries" for patients diagnosed with or tested for STI that list actions to take with sex partners and have explored using telephone advice nurses to explain sex partner management services to patients with positive STI tests.[171] Notification and referral practices for partners of HIV-infected and hepatitis-infected patients are detailed elsewhere (see Chapters 53, 54, and 72).

CASE REPORTING AND COLLABORATION IN STI OUTBREAK CONTROL

Public health departments use compilations of case reports of STI, HIV, and hepatitis reported by clinicians or affiliated laboratories to plan, implement, and evaluate prevention and

control efforts, to prompt partner notification services, and to detect outbreaks.[172] Name-based reporting of *N. gonorrhoeae*, *C. trachomatis*, and syphilis cases by laboratories and/or providers is mandatory in every state.[5] HIV, Hepatitis A, B, and C cases are also reportable by name or other unique identifier in every state.[173] Some states accept only reports of laboratory-confirmed cases, while others accept reports of clinically diagnosed cases with or without lab confirmation. Providers should be aware of reporting requirements in their local jurisdiction, and whether the reporting responsibility falls to them, their staff, their health plan, or the laboratories, and whether cases without laboratory confirmation are reportable. They should also notify patients that if a case is reported, the patient may be contacted by the health department to offer them assistance notifying sex partners.[171] Anecdotes suggest that patients may decline STI or HIV testing (or decline testing under their real name) if they do not want their name reported to health authorities, but the extent of this practice is uncertain. There has also been particular concern that high-risk individuals will defer testing due to name-based reporting requirements. Name-based HIV reporting policies have been shown to result in delays in testing in injection drug users, but have not been shown to be associated with avoidance of HIV testing because of worry about reporting.[174,175]

STI reporting appears to be more complete and timely from public STI clinics than from private-sector providers.[31] Most physicians surveyed in various private-sector settings and Medicaid health plans are aware that laboratories report STI cases to health authorities.[47,79,176] Nevertheless, studies suggest that 9–28% of laboratory-confirmed cases of *C. trachomatis* and *N. gonorrhoeae* from such plans are not reported.[177–179] In an evaluation of reporting in commercial health plans in three states, most cases were reported 1–3 weeks after specimen collection, and reporting was faster when laboratories electronically reported cases to health departments.[177]

Factors that may preclude STI case reporting include (1) lack of provider awareness about reporting obligations, (2) confidentiality concerns with billing, medical records, and health department staff, (3) lack of reimbursement for reporting functions, (4) lack of centralized systems to facilitate reporting, and (5) a limited public health perspective of private sector providers who may not appreciate how case reports are used to detect outbreaks, initiate sex partner services, and track disease trends in the community.[177,179]

Several interventions have been designed to increase completeness and timeliness of STI case reporting for primary care settings. These include having dedicated staff members, such as infection control specialists assigned to reporting functions, use of secure methods to electronically transfer positive laboratory test reports directly to health departments, attaching case report cards to positive laboratory results received by clinicians, and regular communication between health plans, clinicians, and health departments about types of cases that might activate sex partner notification by health departments.[177] Some California health plans have developed systems to automatically track and report STI cases to speed reporting and measure enrollee STI burden.[4] Policy-level interventions that may improve reporting include reimbursing clinicians for time spent on reporting and disseminating memoranda of understanding that detail reporting roles of providers, laboratories, and health department staff. Some states have formal contracts that require out-of-state laboratories to report cases to the state where the patient resides, an important issue as large regional laboratories now serve health plans in several states.[4,180]

Over the past decade, several STI outbreaks have occurred among the persons cared for outside public STI clinics, underscoring the growing role of primary care providers in outbreak detection and control.[59] In some instances, primary care providers may note an increase in STI cases in their practice; such suspicions should be reported to the local health department for confidential follow-up. In addition, health departments may alert primary care providers of local outbreaks of STI, HIV, and hepatitis through newsletters, press releases, letters, email alerts, or phone calls.[59] These alerts may recommend increased screening of asymptomatic patients, routine examination for STI signs, or educating patients about STI symptoms or STI prevention.

CONCLUSION

Private sector primary care providers provide critical functions in STI, HIV, and hepatitis prevention and care in the United States and will become more important as more patients at risk for these infections are cared for in private sector settings. Primary care providers will continue to promote and test new tools, such as computer-based assessment and counseling methods that require less provider time, hepatitis and STI vaccines, rapid and/or noninvasive HIV and STI tests, and expedited sex partner management strategies. Evidence suggests that in many primary care settings, the extent and quality of diagnosis and treatment of symptomatic infections is better than the extent and quality of STI prevention services such as risk assessment, screening, counseling and patient education, management of sex and needle-sharing contacts, and hepatitis B vaccination. These gaps point to areas that merit attention for quality improvement efforts in primary care settings. Fortunately, there are many examples of policy-, health system-, provider-, and patient-level interventions that have improved delivery of STI, HIV, and hepatitis services in primary care settings. Health plans, quality improvement

experts in health systems, medical directors of practices, and individual clinicians interested in improving STI, HIV and hepatitis services should consider how these intervention approaches can be tailored to their practice setting, patient population, and clinical priorities.

ACKNOWLEDGMENTS

We thank Jim Newhall, PhD, and Robert Johnson, MD, for valuable advice on STI laboratory testing issues and Cindy Weinbaum, MD, and Joanna Buffington, MD, for valuable advice on hepatitis issues.

Prevention and Control of STI and HIV Infection

This page intentionally left blank

89 Multilevel Approaches to STD Epidemiology and Prevention

Sevgi O. Aral, Lisa E. Manhart, and King K. Holmes

The essence of any public health program is prevention, which is strictly defined as "action intended to obviate or provide against an anticipated danger or mischief" (Oxford English Dictionary, 2005). Broadly speaking, the anticipated danger or mischief in this case is transmission of, acquisition of, or complications associated with sexually transmitted diseases (STDs) or HIV infection. Preventing such events requires a complete understanding of the complexity of influences on risk behaviors, which span across and interact with each other on the individual, group, and population levels.

Hippocrates, arguably among the earliest to conceptualize causes and prevention of illness, emphasized risk factors for disease that have largely population level impacts such as season of the year, local weather conditions, and community behaviors. Today, however, many would argue that more attention is paid to the individual and less to the population. Partly in response to this focus on the individual, Geoffrey Rose introduced the importance of differences between "sick individuals" and "sick populations" and the need for different prevention strategies for the control of individual and population level health problems.[1] This perspective has been reinforced even more recently with the growing interest in social epidemiology and its emphasis on examining the social and economic determinants of health[2] alongside the traditionally evaluated individual-level risk factors. In this chapter, we hope to reinforce this notion and focus on STDs and HIV as multilevel problems.

The foundation of an effective prevention intervention at any level is the epidemiologic data that guide its development. Thus, etiologic research must be appropriately designed or it will fail to identify the points in the causal pathway that will yield the greatest reductions in disease. With this in mind, we discuss separately etiologic research and related methodological considerations before discussing preventive intervention research.

Table 89-1 presents examples of how the individual, the group, and the population can be considered in epidemiologic and prevention intervention research. For epidemiologic research, risk factors can be measured on an individual, group, or population level, and likewise, the disease of interest may be measured in individuals, groups, or across populations. Similarly, in prevention intervention research, the target or beneficiary of the intervention may be an individual, group, or a population and the mechanism, vehicle, or agent of change may also be considered on an individual, group, or population level. For example, peer-led interventions that use individuals to implement change and that target groups of commercial sex workers benefit not only the individual prostitutes but also their clients and the wives and other sex partners of their clients so that ultimately the general population benefits. Indeed, the benefit to the population may exceed the benefit to the individual sex workers. For example, in areas characterized by high occurrence of HIV infection, such as Thailand or Kenya, many individual female sex workers eventually become infected, because of repeated high-risk exposures, despite continuously striving toward consistent condom use, even though incident infection is reduced in the population.[3,4]

ETIOLOGIC RESEARCH AND METHODOLOGICAL CONSIDERATIONS

Preventive interventions target those risk factors identified in etiologic research that influence the probability of acquiring infection for individuals, the possibility of transmission within the population and, given acquisition of infection, the likelihood that complications will result. Table 89-2 provides examples of two possible risk factors for HIV infection, hormonal contraception and infection with herpes simplex virus (HSV), as well as the kinds of research needed at individual and population levels to support development of interventions addressing these risk factors for STDs and HIV. For risk factor research, the difference between individual and population levels may sometimes be one of measurement, because all individual variables may be assessed by summarizing the results across several individuals; for example, an individual's age versus the average age of a population, or an individual's infection status versus the prevalence of infection in a

Table 89-1. Examples of Individual, Group, and Population-Level Approaches in STD/HIV Preventive Interventions

Level of Intervention	Risk Factor	Target of Intervention	Beneficiary of Intervention	Mechanism of Change	Measure of Disease
Individual	Unprotected intercourse with partner(s)	Women attending family planning clinics	Individual woman and her partner(s)	Counsel women to use condoms	Individual infection
Group	Unprotected intercourse with clients	Female sex workers	Clients of sex workers subsequent female partners of these clients	Peer leader mediated condom promotion with female sex worker (FSW)	Prevalence or incidence of infection in group or sub-population
Population	Social status of women	School-aged female children	Women; whole population	Education of school-aged female children	Prevalence or incidence of infection in population

Table 89-2. Individual and Population Perspectives on Objectives of Research on Potential Risk Factors for HIV Infections, with Two Examples

	Individual Perspective	Population Perspective
Objective of research	Assess individual risk factors associated with susceptibility or progression to disease	Consider risk factors measured across groups or populations associated with transmission
Contraception	Study OCP use and other forms of contraception, as risk factors for an individual acquiring HIV	Study oral contraceptive pill (OCP) use and other forms of contraception as risk factors for mucosal shedding and transmission of HIV
Herpes simplex virus infection	Determine association of HSV-infection with increased risk of an individual acquiring HIV	Assess the effect of suppressive acyclovir therapy in persons with HSV infection on population-level HIV incidence

population. Alternatively, factors that affect morbidity in the population may not be reducible to the individual level (e.g., herd immunity subsequent to vaccination).

At the smallest group or partnership level, factors such as the type of partnership, the gender power dynamics in the partnership, and the contextual pressures on the partnership may be important.[5,6] Just as individuals are embedded in sexual partnerships, partnerships are embedded in sexual networks. The structure of the sexual links among individuals who make up the network determines the potential paths through which sexually transmitted pathogens may travel. While sexual networks are difficult to identify, interventions that make use of the structure inherent in social networks are beginning to be tested.[7]

Factors that only apply at the population level include degree of urbanization, political factors such as the amount of governmental funds spent on public health or war, or social factors such as cultural norms. On a population level, higher levels of social inequality in populations have been correlated with higher syphilis rates.[8] Furthermore, poverty,

the ratio of men to women, and racial segregation influence sexual behavior, which in turn influences risk of STDs.[9]

The very nature of infectious diseases has methodological implications as well. For chronic, noncommunicable diseases, the relative risk, risk difference, and attributable risk, together with the distribution of a particular risk factor in the population measure the overall importance of the factors as a cause of the disease. These measures are unconditional, meaning that they are defined as events per person-time, and do not depend on the occurrence of other events. However, communicable diseases in general, and STDs in particular, are transmitted by intimate person-to-person contact, and thus the risk of acquiring an infection depends on the overall prevalence of infection in the population and contacts between infected and susceptible individuals. This essential feature of communicable disease transmission is known as the dependent happenings relation[10] and is illustrated by the fact that a single infected individual with many exposures can cause infection of many others. Because of this, traditional measures of effect such as attributable risk, that are static in nature, may be less straightforward for STDs than for chronic, noncommunicable diseases.[11–13] More complex mathematical models are required to predict the proportion of communicable disease that could be prevented by the elimination of a risk factor.

One additional complication with communicable diseases is that risk factors measured on an individual level can contribute either to increased individual susceptibility or increased infectiousness. For example, infection with an STD may increase both the infectiousness of an HIV-infected individual and the susceptibility of an HIV-uninfected person and thus, such individual level factors may amplify the spread of infection in the population. Therefore, it may be inappropriate to use purely individual level models when assessing risk factors for STD/HIV infection.[13,14] Yet another level of complexity is added when sexual contact patterns and networks are considered. The pattern of sexual mixing, which can only be measured at the population level, may be the most important determinant of disease spread and is increasingly being studied through simulation modeling.[13,15]

Most risk and health-promoting behaviors are not distributed randomly in populations. Such behaviors tend to cluster with one another and are correlated with the positions of individuals in the social structures they inhabit. The structure and dynamics of the social hierarchy and of sexual networks also interact with contextual factors. Demographic, epidemiological, social, and political contexts directly influence the structure and dynamics of social hierarchy and sexual networks and, in turn, are influenced by them. Political conflict, economic and social disruption, and migration predictably lead to the breakdown of existing structures and the formation of new ones.[16]

PREVENTION RESEARCH

The concepts of primary and secondary prevention, although developed by preventive medicine specialists in the context of noncommunicable disease, apply equally to infectious diseases, although with some adaptation. The term "primary prevention" generally refers to prevention of the first occurrence of disease, and "secondary prevention" refers to prevention of complications or reoccurrence of disease among those who are already affected. Interventions for STDs including HIV differ somewhat from those developed for chronic disease because of the dependent happenings relation; infection is regulated by contact between susceptible and infected individuals. Thus, while detection and treatment of existing infections constitute secondary prevention of complications of infection in the individual patient, early detection and treatment of infected individuals can also prevent further transmission to others and thus provide primary prevention of infections at the population level. In fact, for STDs, this strategy may provide the greatest primary prevention impact at the population level as demonstrated by the efficacy of expedited partner therapy for STDs[17,18] and periodic presumptive therapy for sex workers.[19,20] The reductions in viral load subsequent to initiating HAART would, theoretically, be another example of a primary prevention treatment intervention to reduce the transmission probability, yet the impact of this on HIV incidence at the population level has not yet been empirically demonstrated. However, trials examining this are currently underway.

Finally, because of the social stigma attached to diseases transmitted via sexual contact, prevention of STDs also has powerful political, social, and related economic consequences. In communicable diseases, individuals "at risk" for acquiring disease (the uninfected) are often perceived by society as differing markedly from those likely to transmit it (i.e., the former may be perceived as potential victims, the latter as threats or vectors). This same social stigma likely impacts the effectiveness of preventive interventions. Embarrassment over stigmatizing conditions can lead to nondisclosure of disease status, unwillingness to negotiate condom use, or reluctance to seek testing and treatment. Previously, many countries selectively avoided developing prevention efforts specifically designed to prevent transmission by individuals with chronic viral STDs out of fear that targeting prevention efforts to infected individuals would carry the risk of stigmatization and discrimination. However, this has begun to change with the advent of more affordable therapies both for HIV and HSV infection.

The distinction between acquisition and transmission is not trivial. Interventions focused on infected individuals and designed to limit transmission benefit the population. Alternatively, interventions focused on susceptible individuals limit acquisition and more directly benefit the individual.

Thus, emphasis on preventing acquisition of infection among all susceptible individuals in the community versus emphasis on preventing transmission of infection from a relatively small number of infected individuals produces different distributions of costs and benefits across the population.[21] In the United States, by the time the HIV/AIDS epidemic was recognized, a large proportion of men having sex with men and IV drug users had become infected, and prevention emphasized changing the behaviors of all susceptible members of high risk groups and even on changing behaviors of the general population. In contrast, in Sweden, where only a small proportion of individuals in these highest risk groups had become infected by the time the HIV/AIDS epidemic was recognized, a much greater emphasis was placed on identifying and changing the behaviors of the few who had become infected. This emphasis on secondary prevention among HIV-positive individuals, or "prevention for positives" to reduce transmission in the population has come late to the United Statess, and only recently have trials of such preventive interventions been undertaken. Most notably the WiLLOW program demonstrated that HIV-positive women receiving care at health departments or HIV/AIDS clinics who attended group sessions emphasizing sexual risk reduction, gender pride, and enhanced social networks experienced an 81% decrease in incidence of bacterial STDs when compared to controls.[22] This reduced incidence of bacterial STDs demonstrates empirically the effects of safer sex practices, which should translate to less HIV transmission to susceptible new partners.

When the emphasis is on prevention of acquisition for all susceptibles (a universal prevention strategy), the whole population incurs the financial costs of interventions and the intangible costs of undergoing preventive behavior change and they collectively receive the benefits of avoiding acquisition of infection. With emphasis on prevention of transmission by a relatively small proportion of the population, a more targeted approach would be justified. The general population still receives the benefit of avoiding acquisition and associated future health costs and may again incur the financial costs of implementing the intervention. However, these financial costs may be less, and fewer people incur the major burden of behavior change.

In this age of limited resources, cost effectiveness analyses are becoming increasingly important. Using a simulation model to estimate the costs per disability adjusted life year (DALY) averted in 2000 international dollars ($Int) for two of the regions with the highest HIV/AIDS burdens (sub-Saharan Africa and South East Asia), one group has concluded that mass media, education, and treatment of STDs were the most cost-effective interventions, at costs of <$Int150 per DALY averted. Voluntary counseling and testing, in contrast, was over twice as expensive (<$Int350 per DALY averted). Prevention of mother-to-child transmission was extremely cost-effective in sub-Saharan Africa (<$Int50 per DALY averted) but much less so in South East Asia (~$Int850 per DALY averted). School-based education strategies were slightly less cost-effective ($Int430–790 per DALY averted) than first-line antiretroviral therapy (~$Int550 per DALY averted).[23]

PREVENTIVE INTERVENTIONS

Like prevention research, preventive interventions are designed and conducted on several different levels and may be conceptualized in terms of the level of intervention (individual, group, or community); the implicit or explicit primary outcomes (decreased acquisition, transmission, or complications of STDs/HIV); and the intervention modality (behavior change, vaccination, topical microbicide use, treatment [prophylactic, curative, or suppressive], surgical intervention). Figure 89-1 presents a framework, showing points of intervention to prevent acquisition of STDs/HIV by an uninfected individual and those to prevent STD/HIV transmission from and/or complications in infected individuals or sexual dyads.[24]

Clearly a given behavioral, biomedical, or structural intervention may influence multiple outcomes. For example, a successful HPV or HIV vaccine might reduce the risk of acquisition of subsequent transmission or the risk of complications.

In contrast to individual or group-level interventions, community level trials evaluate more complex pathway linkages and indirect and total intervention effects.[25] For example, in community randomized trials of early treatment of STDs,[26–28] a fall in prevalence or incidence of STDs in the general population presumably reflects both decreased duration of infection and resulting decreased STD transmission, whereas the resulting decline in HIV incidence at the

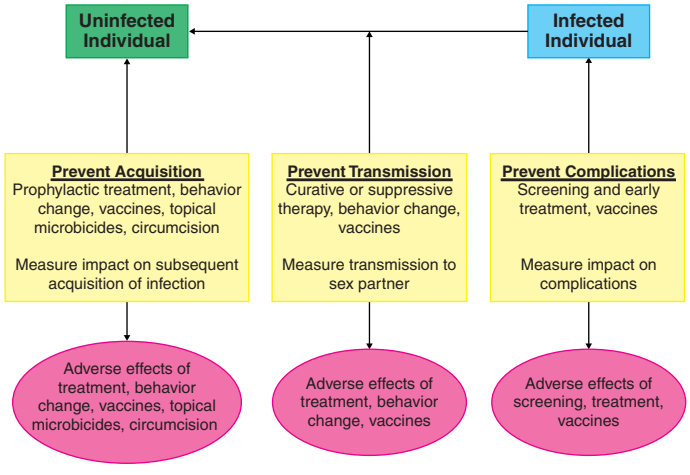

FIGURE 89-1. Framework for outcomes analysis at the individual or sexual dyad level: examples of types of preventive intervention trials, with outcomes potentially measuring sexual acquisition, or transmission, or complications of STDs/HIV.

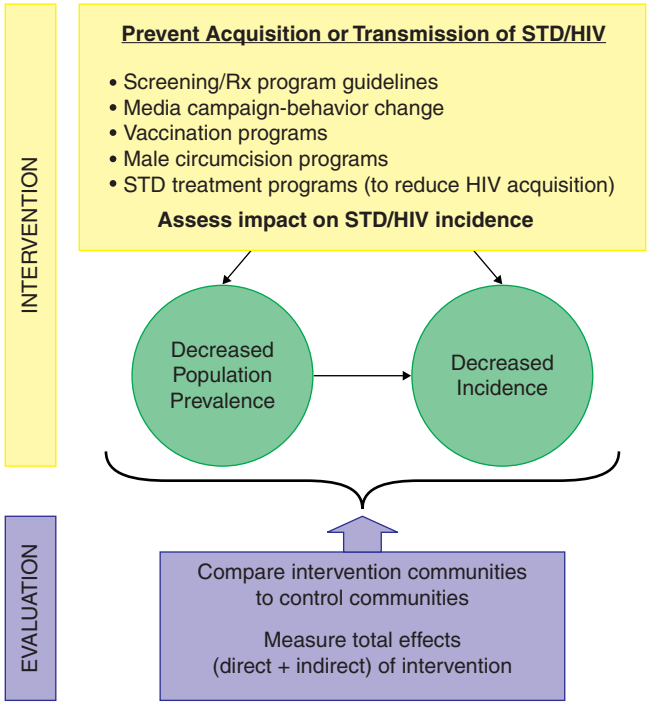

FIGURE 89-2. Framework for outcomes analysis at the population level: examples of causal pathway linkages in community intervention trials to prevent sexual transmission or acquisition of STDs and HIV.

population level could reflect the potential impact of reduced STD morbidity on transmission or acquisition of HIV, or both. Thus, a separate analytic framework applies to community level interventions (Fig. 89-2).[24]

This separation of levels is not always straightforward or distinct. For example, use of screening tests in asymptomatic women in family planning clinics to identify those needing treatment for infection primarily benefits the individual woman but may also contribute to decreasing transmission to future partners. Such screening also defines the prevalence of infection within that group, thereby guiding decisions to implement largescale population-level prevention interventions, such as mass condom promotion. Thus, these various approaches should be viewed as complementary and overlapping, both in implementation and impact. Nevertheless, it is conceptually important to clarify the meanings of the terms "individual," "group," and "population" level interventions.

Table 89-3 provides individual and population perspectives on the objective of STD/HIV preventive interventions, as well as examples of specific behavioral and biomedical interventions, and prevention research. Note that the distinction between biomedical and behavioral prevention research, although commonly made, is misleading because biomedical interventions require supportive behavioral intervention components. In addition, biomedical outcomes are needed in the more definitive behavioral intervention research; and multiple component (biomedical plus behavioral) interventions are of growing interest in prevention research (as in the Masaka, Uganda study that combined behavioral and STD treatment interventions for HIV prevention).[27] The principles here are similar to those that apply to research on etiology of disease. From an individual perspective, interventions may prevent initial acquisition of infection and prevent subsequent development of associated sequelae, whereas the most important principle from the population perspective is to prevent transmission. Depending on whether the focus is on the beneficiary or the target, some of the interventions listed here could be classified either as population- or individual-level interventions. Further, risk factors defined on a population level can influence interventions directed toward individual risks. For example, accepted social norms defined on a population level can constrain and shape behavioral interventions targeted toward individuals.[29]

Although we advocate a multilevel approach to STD/HIV prevention that goes beyond the medical model of providing detection and treatment to individual patients, limited resources may constrain choice. Furthermore, choice of the level on which to target an intervention might also depend on the phase of an epidemic. In general, at the early phases of an epidemic in settings where small core groups of high-risk individuals are the first to acquire disease and account for most transmissions, core group interventions may be most feasible and cost-effective. In later phases of a mature epidemic, when prevalence is more widespread, interventions directed toward core groups may remain highly cost-effective but no longer sufficient to rapidly contain the epidemic.[30]

The next section describes particular interventions in detail and reviews interventions that occur among progressively larger units of analysis: individuals, couples, groups, communities, populations, and the networks that link individuals and groups. Examples of the strengths and weaknesses of approaches at each level are discussed, as are relevant methodological issues.

INDIVIDUAL INTERVENTIONS

Examples of individual approaches to prevention include programs that seek to alter the modifiable individual-level factors. Individual-level risk factors include factors related to host susceptibility in susceptibles or increased infectiousness in the infecteds and include biological factors such as cervical ectopy, vaginal flora, immunological competence, and viral load; behavioral risks including sexual practices; number, temporal spacing, and choice of partners; and preventive behaviors such as use of condoms, vaccines, and microbicides. The mechanism of change involves vaccination, counseling and testing, partner notification and treatment, or case finding (either clinic-based or active outreach screening programs) and subsequent treatment.

Table 89-3. Individual and Population-Level Perspectives on Objectives of STD/HIV Preventive Interventions, with Examples of Preventive Intervention and of Biomedical and Behavioral Prevention Research

	Individual Perspective	Population Perspective
A. Objectives of preventive interventions		
	Prevent acquisition	Prevent transmission
	Relieve symptoms and prevent progression to complications or death	Intervene in those most likely to transmit, to achieve maximum effect with minimum expense
B. Examples of intervention		
Partner notification, treatment	Treat exposed partner	Treat source partner
Screening	Screen individuals and treat those found to be infected	Establish subpopulation specific prevalences and mass treat subgroups depending on prevalence
	Screening based upon risk factors for having infection, or developing a complication; for example, screen all younger females regardless of number of partners	Screening based upon risk factors for spreading infection, for example, screen males with many partners
	Detect, treat infectious and late syphilis	Detect, treat infectious syphilis
Condom promotion	Promote use of condoms by male with spouse	Promote use of condoms by men during sex with sex workers
Improve access to STD/HIV services	Provide STD services in managed care organizations for employed, insured individuals	Provide free access to STD services for uninsured inner city crack cocaine users
	Provide treatment for early chlamydial or gonococcal infection in women to prevent tubal factor infertility	Provide treatment for early chlamydial or gonococcal infection in men to prevent tubal infertility in women
Counseling /education risk reduction	Counsel or educate uninfecteds on decreasing acquisition	Counsel or educate infecteds on decreasing transmission
C. Biomedical prevention research		
Male circumcision	Evaluate effect of male circumcision on acquisition of HIV among circumcised males	Evaluate effect of male circumcision on acquisition of HIV among female partners of circumcised and uncircumcised males
Vaccine programs	Evaluate therapeutic vaccine to reduce progression of HIV	Evaluate preventive HIV vaccine to reduce acquisition or mucosal shedding and thus prevent subsequent transmission
STD treatment to prevent HIV infection	Randomized trial of selective routine treatment of STD in sex workers to lower their risk of acquiring HIV	Community randomization trial of syndromic management of STD (Mwanza trial) or of mass treatment of STD (Rakai trial) to lower community-wide incidence of HIV infection

Table 89-3. (*Continued*)

	Individual Perspective	Population Perspective
HIV antiretroviral treatment	Evaluate impact of antiretroviral therapy on progression of immunodeficiency	Evaluate impact of antiretroviral therapy on mucosal shedding or transmission to partners
Microbicides	Evaluate existing spermicides and new microbicides on prevention of acquisition of HIV and other STDs	Evaluate impact of spermicide and microbicide use on preventing transmission of STD/HIV
Needle exchange/ drug treatment	Evaluate impact of needle exchange program on incidence of HIV in exchange participants	Evaluate impact of needle exchange program on incidence of HIV in the general population of injecting drug use (IDU) who do not use the exchange
	Randomized trial of impact of increased access of uninfected IDU to drug treatment programs on individual risk of acquisition of HIV, HBV, HCV, or HTLV-II	Community randomization trial of the impact of improved access of infected IDU to drug treatment programs on incidence of HIV, HBV, HCV, and HTLV-II among communities cohorts of IDU
Behavioral research	Evaluate individual behaviors associated with risk of acquiring infection	Evaluate individual behaviors associated with transmission of infection
	Randomized trial of impact of individual, small group, or work site information, education, or counseling on rate of acquisition of STD/HIV	Evaluate characteristics of risky sexual networks Community randomization trial of impact of population-wide information education and communication for STD/HIV prevention on incidence of STD/HIV

Using the individual as a target for an intervention allows for tailoring the intervention to the needs of particular individuals. Because of the communicable nature of STDs, an additional benefit to this kind of program may be that prevention or treatment of infection in one individual may break a chain of transmission, preventing further spread. Individual risk profiles may be developed and appropriate interventions can then be selected. Prochaska's stages of change model is an example of this kind of approach where individuals are "staged" according to their readiness to adopt a prevention strategy and then the intervention is tailored to this stage.[31] Another theory that has received increasing attention is motivational interviewing and the related information-motivation-behavioral skills model. Implementation of this model in a clinician-delivered intervention with HIV-positive patients resulted in significant reductions in unprotected sex, thus reducing transmission.[32] One weakness of this kind of individual behavioral approach is that the time and labor involved in individual assessment can make the intervention costly. In addition, it may be difficult to identify those individuals at risk who would benefit most from the intervention.

Male circumcision is an individual-level intervention with population-level implications. The potential efficacy of this intervention was suggested by early ecologic studies showing that HIV prevalence was lower in countries where the majority of the male population practiced circumcision[33,34] and subsequent observational studies supporting this hypothesis.[35,36] In the three randomized controlled trials of male circumcision, the risk of acquiring HIV was reduced by 50–60% among men who had been circumcised, compared to those whose circumcision was deferred.[37–39] While this individual-level intervention works presumably by reducing the circumcised man's susceptibility to HIV, it should also reduce overall transmission of HIV on the population level, provided behavioral disinhibition does not result in offsetting increases in risk behavior.

COUPLE-BASED INTERVENTIONS

Because STDs, by definition, are transmitted between individuals, it may be more appropriate to use couples rather than individuals as the smallest unit of analysis for epidemiologic study. This enables simultaneous examination of factors related to infectiousness and susceptibility, including those individual factors delineated above. The mechanisms of change in couple-based interventions may parallel those identified for individual interventions, such as case finding, counseling, and testing.

Interventions directed toward couples discordant on either their infection status or their risk status provide excellent examples of prevention strategies at this level. In one study, Kamenga et al. followed 149 HIV serodiscordant couples in Zaire.[40] At entry into the study, fewer than 5% of the couples consistently used condoms compared to 77% of couples 18 months later. They detected a seroconversion rate of three new infections per 100 person years of follow-up. In a similar study in Rwanda, Allen et al. counseled and followed 60 serodiscordant couples.[41] Condom use was reported by 3% of couples at baseline and by 57% at 12 months follow-up. They reported an HIV seroconversion rate of 4 per 100 man years of follow-up and 9 per 100 woman years of follow-up. Among participating women, the seroconversion rate was >50% lower than the estimated rate in women whose partners did not undergo HIV counseling and testing. Finally, Padian et al. followed 175 discordant couples in California.[42] Among these couples, 32% reported consistent condom use at entry into the study and 75% reported consistent condom use as many as 9 years later. In this study, which had no control group, no new seroconversions were observed during greater than 3000 couple months of follow-up. Although these studies have focused on behavior change and condom promotion among HIV-discordant couples, discordance on other STDs may merit other approaches. For example, discordant couples have been the subject of studies assessing the effect of HSV treatment and vaccination on reducing transmission.[43,44]

The strengths of the "couples" approach are apparent. Because transmission events are associated with sexual activity between infected and susceptible individuals, targeting interventions toward couples is obviously appropriate. A weakness of this approach is that these interventions are only appropriate for couples who are in relationships that remain stable. In the case of studies or interventions targeting discordant couples, length-biased sampling may be an issue. Many believe that most transmission in a partnership occurs early on and that couples who both remain together and remain discordant are somehow different from couples who do not. Thus, long-standing discordant partnerships are probably not fully representative of all couples. This limitation can be overcome by enrolling people in a study or intervention at partnership formation, but this approach has only rarely been used.[45] Additionally, interventions delivered to couples may be less effective for individual members of the couple following the break-up, and selection of couples likely to remain together throughout the research trial may require very restrictive eligibility criteria, increasing recruitment costs and reducing generalizability. Furthermore, delivering a behavior change intervention to both members of a couple is not always associated with any increased effect.[46,47] Finally, including serostatus as part of eligibility adds complexity because not all individuals know or want to know their serostatus and because these parameters, such as the status of the partnership itself, change over time. The importance of couples-based prevention research and interventions is highlighted by the two ongoing trials of HSV-suppressive therapy currently being conducted among HSV-discordant couples. If efficacious, this intervention may have a greater impact on the population level transmission dynamics than its effect at the level of the sexual dyad.

"CORE" GROUP INTERVENTIONS

Groups may be thought of as clusters of individuals and couples. One such group considered central to STD epidemiology is the "core group," first described by Heathcote and Yorke.[48] Although the definitions of core groups vary somewhat, they are generally characterized by individuals connected to each other through social and sexual networks, who display risk behaviors and high infection rates and who sustain transmission of an STD pathogen within the population. The theory is that population rates of STDs are driven by spread among groups of individuals that are characterized by high rates of exposure to an STD (often related to frequent concurrent exposure), longer duration of infection (often related to poor access to acceptable health care), and highly efficient transmission of infection per exposure (often related to undiagnosed or untreated coinfection with other STDs, young age, risky practices, lack of male circumcision, etc.). These groups act as foci for STD spread so that a pathogen newly introduced into the community soon becomes concentrated in these groups. By virtue of mixing (or "bridging") with individuals outside of the group, they may also be responsible for seeding infection among individuals who are not identified as being part of the core group.[49] Examples of core groups include men and women involved in commercial sex, migrant workers, truckers, STD clinic attendees who have repeat infections, individuals who have many sexual partners over a defined period of time, or persons living in a defined geographic area characterized by high STD/HIV incidence.[50]

One intervention strategy for core groups employs peers as the agents of change, since peer leaders such as opinion leaders, role models, or peer educators may best influence the behavior of the entire group.[51,52] Their objective is to change social norms. Another strategy involves population-based

actions such as changes in laws or health codes as they apply to such groups. These approaches, characterized by removal of barriers to implementation of prevention interventions or creation of barriers that prevent risky behavior, have been called "enabling" approaches because they enable the desired behavior change to occur.[53]

One example of interventions targeted at core groups is the many condom distribution programs aimed at female sex workers. In both Kenya and Zimbabwe, such programs increased rates of condom use and decreased rates of STDs among women as well as in the larger community.[52] The major part of these interventions was delivered by peer educators and counselors who distributed condoms and provided information about safe sex along existing social networks linking at-risk women. In Kenya, 1 year after initiation of this program, sex during menstruation and the number of clients during the prior week decreased, the charge per client increased, and the frequency of condom use with all clients increased from 4.6% to 36.5%. Similar results were reported in Zimbabwe where condom use increased from 18% to 66% within 2 years of the program.

In the condom promotion program among sex workers implemented in Thailand, individuals educated other individuals, but governmental sanctions were added to insure behavior change and STD treatment was expanded through the opening of 508 district STD clinics.[54] Here, the government required condom use at brothels and free condoms were distributed. This was supplemented by mass advertising, interviews of brothel workers to insure that condoms were used, and identification of particular customers when a worker was diagnosed with an STD. Over 2 years, reported condom use in brothels increased from 14% to 94%, and five major STDs (syphilis, gonorrhea, nongonococcal urethritis, lymphogranuloma venereum, and chancroid) decreased in men by 79% over 5 years. Nevertheless, although rates of these STDs were reduced, HIV incidence among young men initially remained high. Eventually, in military conscripts who were also targeted by HIV prevention programs, HIV rates also fell.[3,4]

Another example of a core group intervention is the provision of periodic presumptive therapy to commercial sex workers, with the goal of preventing acquisition of STDs and HIV by them and subsequent transmission to their clients. One study in Kenya, and another in Zimbabwe, have demonstrated efficacy in reducing STDs other than HIV but no reduction in HIV acquisition was observed in one,[19] and rapid reinfection rates were observed in the other, suggesting that frequent dosing would be required to ensure ongoing success.[20]

The benefits of targeting interventions at core groups extend beyond the core to the larger community in which such groups reside.[55,56] In addition, targeting many individuals within the core group simultaneously provides a greater opportunity for concomitant changes in social norms than if such programs are targeted at individuals. Such interventions could also be cost-effective because they do not require assessment of infection status or behavioral risks among individuals. Weaknesses of this kind of program include the potential for stigmatization where core group identification results in labeling. Likewise, because core group membership is ill-defined and individuals may move in and out of such groups, it may be difficult to successfully identify members. Furthermore, the phase of the epidemic must be considered. Mathematical models have shown that core group interventions are most effective during concentrated epidemics with a low reproductive potential. However, in epidemics with a high reproductive potential, although core group interventions are still necessary, they are not sufficient and interventions in the general population are also required.[57]

COMMUNITY-BASED INTERVENTIONS

Groups of individuals who live or work together or who have similar life styles represent another kind of group characterized by more heterogeneous behavioral risks than in the core groups just described. Examples of these kinds of communities include minority, urban teens of low socioeconomic status, gay men of diverse risk status, or geographic or worksite clusters. Here, the strategy for intervention can resemble that described for core groups but often involves intervention on multiple levels.

One example of a community intervention was that conducted among gay men by Kelly et al.[58] The intervention began with selection of peer opinion leaders who then engaged other men who have sex with men (MSM) in bars in conversations about the benefits of safe sex, resulting in so-called "diffusion" of the intervention into the community. The intervention, conducted in a staggered, serial fashion in three cities, resulted in a 15–24% decrease in unprotected anal intercourse, a 14–29% decrease in insertive anal intercourse, and a 26–28% decrease in unprotected receptive anal intercourse. In a follow-up randomized community trial where pairs of small cities in Wisconsin, New York, West Virginia, and Washington were randomized to a similar intervention, men in intervention cities reported a significant decrease in the number of episodes of unprotected anal intercourse and increased uptake of condoms at gay bars, while no change was observed in the control cities.[59]

The Mwanza study of improved syndromic management of STD in rural communities in Tanzania represents another example of a successful community-based intervention.[26] Six intervention villages were paired with six control villages. The intervention included training of clinic staff in syndromic diagnosis and treatment of STDs, provision of necessary antimicrobial drugs, and dose supervision. After a 2-year period, HIV seroconversion rates were 42% lower in the intervention communities compared to the control communities.

Despite these two successful community level interventions, more recent examples have demonstrated mixed success. In a community level intervention in Masaka, Uganda that used mixed intervention modalities (syndromic management of STDs and/or information, education, counseling [IEC]), only the IEC intervention arm experienced a reduction in HSV-2 seroconversion, while participants in the combined intervention only experienced declines in incidence of syphilis and gonorrhea. No decrease in HIV incidence was observed.[28] In the Mema Kwa Vijana study in Mwanza, Tanzania, although knowledge increased and sexual-risk behaviors decreased subsequent to a 4-component intervention consisting of in-school sexual and reproductive health education, enhanced reproductive health services for youth, condom distribution, and community activities, there were no significant reductions in HIV or HSV-2 seroincidence, STDs, or pregnancy outcomes in communities receiving the intervention.[60] Similarly, another multicomponent intervention in Manicaland, Zimbabwe (community based peer education, free condom distribution, income generating projects, clinic-based STD treatment and counseling services) did not reduce population level HIV-1 incidence or STD symptoms, despite reducing HIV-1 incidence in the immediate male target group.[61]

The strengths of these community-level interventions are similar to those that result from targeting core groups of sex workers. It is easier to change social norms when multiple individuals are targeted at once. However, transmission dynamics at the community level are complex and more work remains to be done to design multicomponent community-level interventions that are consistently successful.

POPULATION-BASED INTERVENTIONS

As with group or community-level interventions, changing social norms may also be a goal of interventions targeting entire societies. Programs that operate at this level may include structural mechanisms to restrict risky behaviors and encourage healthy ones. Mechanisms of change employed may include use of mass media for health education, modifications in the environment, institution of laws or regulations, taxation of alcoholic beverages, service delivery (clinical guidelines for HIV or chlamydia screening), or large-scale vaccination programs. Examples have included legalizing needle exchanges, outlawing bath houses or closing brothels, providing routine selective screening and treatment for STDs, mandating 100% condom use in brothels, and providing training and economic opportunities for women. The Thai condom promotion distribution programs described earlier used a structural mechanism of change, but targeted a core group rather than the whole population even though the whole population might benefit from the intervention.[54]

In the HIV-control program in Cuba, government regulations resulted in a ban on all imported blood and blood derivatives; enforced widespread screening of travelers, blood donors, pregnant women with STDs, prisoners, and individuals identified in certain neighborhoods where infection rates were prevalent; imposed quarantine of infected individuals; and recommended abortions among HIV-infected pregnant women.[62] Although this program has not been objectively evaluated by an external group, infection rates remain low, and unlike many of its Caribbean neighbors, Cuba does not seem to have a major HIV epidemic. On the other hand, it has been argued that segregation of high-risk individuals away from the rest of the population could accelerate the spread of infection within the high-risk group so that occasional contact with others outside the group through so-called "bridge populations" could continue to spread infection.[4]

Although vaccination can be considered an individual level intervention because it is given to unique individuals and confers individual-level protection, widespread vaccination also confers substantial protection on a population level in the form of herd immunity. Perhaps one of the most exciting recent advances in STD prevention has been the successful development of a highly efficacious vaccine against HPV.[63–65] These vaccines protect not only against acquisition of HPV but also against progression to precancerous lesions.[66] The vaccines are just now being implemented and hold tremendous promise not only for preventing individual infections but also for reducing transmission overall on a population level.

One strength of population-level programs is that the cost of strategies employing use of mass media may be lower than the cost of individual and group outreach. In addition, the potential for social stigma could be avoided if universal prevention strategies are employed, even though some individuals may be more affected by the strategy than others. For example, outlawing bathhouses applies to everyone, although frequent patrons may be more likely to feel the effects of this change. Although Rose and others have argued that prevention must be universal so that shifts in the distribution of risk can be made for the entire population, many individuals not at risk are targeted.[1] Such programs may curtail individual rights and privileges to benefit the health of the population.

NETWORK ANALYSES

Prevention approaches that seek to identify social and sexual networks to characterize patterns of mixing between individuals combine considerations of individual, group, and population approaches. Both the overall rate and the extent of spread of STDs/HIV depend on the structure of sexual networks.[67] Frequent rates of concurrent sexual interactions among people lead to rapid rates of STD/HIV spread. Greater numbers of sexual linkages among subgroups can lead to extensive dissemination of infection between subgroups and throughout the population. Conversely, if a population is

divided into isolated subpopulations with low rates of sexual interaction within each, STDs entering the population tend to be confined primarily to one subpopulation and to spread slowly in that subpopulation.[68]

The sexual networks that fuel the spread of STDs do not tend to overlap greatly with the social networks that channel the spread of prevention information and preventive behaviors. Sexual networks that spread STD are most frequently located in subpopulations at the lowest levels (tails) of the education, income, power, and prestige distributions, whereas networks responsive to prevention efforts are generally located within subpopulations at the highest levels of these distributions. In addition, although sex partners are usually chosen from among those with whom social linkages already exist, particular types of sexual linkage, for example, commercial or casual sex, take place between individuals less likely to be socially linked to each other.[69] Nevertheless, in a unique approach using social networks to disseminate prevention and risk reduction messages in Bulgaria, social networks of Roma men randomized to the intervention (counseling by a trained network leader) had significantly lower prevalence of unprotected intercourse at follow-up when compared to control networks.[70]

Just as the structure of sexual networks and sexual-mixing patterns determine routes of transmission of STDs, the structure of social networks and social-mixing patterns determine routes of the diffusion of attitudes, beliefs, life styles, and behavior patterns through a society.[71,72] Social networks tend to be more open than sexual networks and are marked by higher rates of interchange within population subgroups, greater numbers of social contacts, and greater numbers of linkages across population subgroups. Thus, attitudes, beliefs, and behavior patterns, including preventive patterns, would spread more rapidly and extensively throughout the population. Moreover, the responsiveness of individuals to prevention information and interventions varies across population subgroups. For example, population subgroups marked by higher levels of education would be more accessible to prevention programs and more responsive to prevention messages. Similarly, population subgroups with lower prevalences of risk behaviors may respond more effectively to prevention efforts owing to their higher levels of education and their health-seeking orientation.[72] In summary, prevention efforts first reach and affect subpopulations that are least likely to contain sexual networks that spread STD. Furthermore, the nature of social networks within subpopulations having high STD rates may hinder diffusion of prevention information and interventions into the sexual networks within these subpopulations.

Although health education and health promotion interventions utilize the social network concept, partner notification, mentioned previously under couple-based interventions (where infected individuals name sexual partners and these partners are then identified, tested, treated, and counseled), is a public health intervention based on the sexual network notion. Attempts have been made to identify more extensive sexual networks that trace partners of partners and so on. The technique known as "cluster contact tracing," in which serologic screening for syphilis was extended to social contacts of persons with infectious syphilis, was an interesting experiment in extending disease control efforts from sexual networks to social networks. However, behavioral and other prevention interventions that target this more complex type of network have been given little attention. Probably the closest approximation is those interventions based on social diffusion where few individuals who are integrally bound into the community initiate and model social change, described in community-based interventions.[51] Such diffusion models are theoretically capable of changing social norms throughout the community while identifying and targeting sexual networks. This is clearly an area that merits additional research.

CONCLUSION

The acknowledgment of differences within the population with respect to infection status, risk behaviors, incurring of intangible and financial costs, as well as receipt of benefits, has led to the formulation of a series of questions related to the political economy of STD epidemiology and prevention and related issues of policy. Who is at risk? Should prevention strategies be targeted or universal? Who should pay for the intervention? In this chapter, we have highlighted only a few examples of successful interventions applied using targets and levels of intervention at various units of analysis. Our goal was to illustrate individual, group, and population perspectives on STD/HIV prevention. Glib references to "individual level" or "population-level" interventions, without distinguishing between the target of the intervention, the beneficiary of the intervention, and the mechanism and agent or vehicle of the intervention, has often led to confusion and poorly conceived design and evaluation of STD/HIV interventions. We do not advocate any one approach over another but suggest that STD/HIV is a multilevel problem. In the same way that risk factors can be defined on multiple levels, interventions must be designed and evaluated appropriately for multiple levels.

90 STD/HIV Prevention Programs in Developed Countries

John M. Douglas, Jr. and Kevin A. Fenton

INTRODUCTION AND DEFINITIONS

STD prevention programs emerged in developed countries in the early twentieth century. Initial efforts were largely focused on "social hygiene," emphasizing the dangers of prostitution and relying on education and structural approaches to discourage it.[1,2] Subsequent strategies, particularly focused on syphilis, emphasized screening, treatment, partner referral, and public education, which were the mainstay of the first national STD program in the United States beginning in 1938.[2,3] The discovery of penicillin and its increased use in the 1940s reenforced an increasingly biomedical approach to STD prevention, which expanded to include screening and treatment for gonorrhea in the 1960–1970s and chlamydia in the 1990s. The advent of HIV/AIDS in the 1980s dramatically altered the balance between secondary prevention (efforts to diagnose and treat infection to prevent complications and ongoing transmission) and primary prevention (behavioral approaches to prevent initial acquisition of infection). The high mortality associated with AIDS, its prominent political profile, and the varying routes of HIV transmission (parenteral as well as sexual) have often led to a separation of STD and HIV prevention program. However, particularly with the advent of highly active antiretroviral therapy (HAART), STD and HIV prevention approaches are becoming more similar, and there is an increasing recognition that coordination of HIV and STD prevention activities can provide important synergies.[4,5]

Historically, STD prevention programs have focused on curable bacterial infections, although there is a growing programmatic interest in the non-HIV viral STDs of genital herpes simplex virus (HSV), genital human papillomavirus (HPV), and hepatitis B virus (HBV) infection, given the large population burden and increasing possibility of specific prevention activities (e.g., diagnostic tests, suppressive therapy, and vaccines).[6–8] HIV prevention programs have also evolved over time, moving from an initial emphasis on preventing acquisition of infection among the uninfected (e.g., blood screening, reduction of risky sexual and needle use behavior, and condom promotion) to a greater focus on prevention of transmission from those already infected (e.g., enhanced case finding, treatment of HIV-infected pregnant women, risk reduction activities, and STD screening promoted as part of HIV care).[9]

This chapter begins with an overview of key concepts that influence the design of STD/HIV prevention programs and then reviews essential program components in the areas of surveillance, prevention interventions, and program support. While there is generally consensus about the broad domains of activity needed for effective STD/HIV prevention programs, the conceptualization of what constitutes essential program components has varied slightly.[5,10,11] This chapter considers essential components of STD/HIV prevention programs in three key domains: surveillance, four essential interventions (clinical, laboratory, partner management, and individual and community behavioral intervention services), and four program support components (program leadership and management, professional training, monitoring and evaluation, and research). Although there are variations in the specifics of STD/HIV programs by country, the background concepts are applicable to all developed countries. Specific examples in this chapter will be drawn largely from the United States and the United Kingdom, with illustrative examples from other developed nations.

OVERVIEW OF KEY CONCEPTS FOR STD/HIV PREVENTION PROGRAMS

INDIVIDUAL VERSUS POPULATION GOALS

STD/HIV prevention programs focus on two levels of prevention outcome: that of the individual and that of the larger population. Individuals benefit from activities that prevent acquisition of infection, alleviate symptoms, and reduce complications, but for the general population, the primary goal of prevention is to reduce ongoing transmission and thus overall population prevalence and health impact.[11,12] Since most activities that prevent acquisition of infection or

lead to detection and treatment of curable infections also prevent subsequent transmission, they provide population as well as individual impact. The relative value of individual versus population benefit will vary by the subpopulation. Specifically, prevention programs targeted at subpopulations more likely to be involved in ongoing transmission, such as "core groups" (discussed below), can be more important for population benefit than those targeted at the general population.[13]

DETERMINANTS OF STD/HIV TRANSMISSION AND THEIR IMPACT

Over the past 20 years, a key concept in understanding STD/HIV epidemiology and possible strategies for prevention at the population level is a transmission dynamics model described by May and Anderson.[14] This model defines the average number of new infections that an infected individual generates, or the reproductive rate in a population (R_0), as a function of three parameters—the average probability of transmission per sexual contact between susceptible and infected individuals (B), the average number of sexual partnerships formed per unit time between susceptible and infected persons (c), and the duration of infectiousness (D)—with $R_0 = BcD$. When R_0 exceeds one in a population, infection spreads and population incidence and prevalence increase. Likewise, if R_0 is maintained below 1, incidence and prevalence decrease. Thus, an increase in any of the three parameters will increase R_0 and population incidence and prevalence, while a decrease in any will reduce both parameters.[15,16]

STD/HIV prevention interventions achieve population impact by reducing one or more of these three transmission determinants, and examples of the impact of different interventions on each are outlined in Table 90-1. Reducing the duration of infectiousness by enhancing detection and treatment of infected persons has been the mainstay of programs for the prevention and control of bacterial STDs. These measures include approaches to enhance access to and utilization of health care, to improve case finding, and to increase likelihood and timeliness of treatment following clinical contact.

The prevention interventions that reduce transmission efficiency (B) and the number of partnerships exposing susceptible to infected partners (c) are important for control of all STDs, but are critical for HIV and other viral STDs for which curative therapy is not available. The primary approaches to reducing transmission efficiency have been behavioral—health promotion efforts to increase the use of condoms and to reduce practices with relatively high STD/HIV transmission risk such as anal sex and needle sharing. In addition, a number of biomedical approaches to reduce transmission efficiency have been or are under evaluation. For example, many STDs serve as cofactors for HIV transmission by an increasing susceptibility and/or infectiousness.[17] There is substantial evidence that control of bacterial STDs can reduce HIV transmission at the population level when STD prevalence is high and HIV prevalence is relatively low,[5,18,19] and suppression of genital HSV-2 infection with antiviral therapy may also reduce HIV transmission.[20] Finally, immunization with effective vaccines can dramatically reduce susceptibility.

Approaches to reduce the rate of exposure of susceptible to infected partners can potentially impact the broadest array of infections. However, they can be difficult to implement effectively. Programs encouraging delayed onset of sexual activity have been widely promoted in the United States during the last 10 years. Although as yet incompletely evaluated, there are indications that promoting abstinence in adolescents without providing education about other prevention strategies such as condom use and STD testing may not reduce STD rates.[21–24] The benefit of reducing sex partner number is supported by observations about the association of most STDs with number of recent and lifetime partners, the impact of concurrent sex partners on amplifyinig the transmission at the population level,[25] and observations from several countries with successful reductions in HIV prevalence.[26] Promoting the concept of avoiding partners who may be infected with an STD is likewise a plausible approach, although one that may not be practical in settings of unequal power, such as those experienced by many women. Finally, for HIV infection, reduction in exposure of susceptible to infected partners may be enhanced through intentional selection of partners of the same HIV serostatus (i.e., serosorting).[27]

CORE GROUPS AND SEXUAL NETWORKS

A related key concept in STD/HIV epidemiology and control is that of the "core group," who are persons in a small subset of the population with multiple partners who maintain endemic foci of STDs.[28–30] Core groups have been defined as those with a high enough rate of sex partner change to maintain $R_0 > 1$. Their characteristics will vary by specific STD based on the efficiency of transmission and duration of infection of the STD in question. When B and D are relatively low, c must be relatively high to maintain disease transmission, resulting in a smaller core group. The latter circumstance occurs when effective STD/HIV prevention programs are in place, although this smaller core group may become increasingly hard to reach as it shrinks.[31] Because of the importance of the core group in sustaining transmission, targeting prevention efforts at them is theoretically more cost-effective than broader programs.[32] However, defining strategies that can practically access core groups is difficult, and for many persons, inclusion in a core group is dynamic, changing over time.[28]

Because of the communicable nature of STDs, including HIV infection, the concept of "population" is important not

Table 90-1. Impact of STD/HIV Prevention Program Activities on Determinants of Transmission[a]

Determinant of Transmission	Examples of STD/HIV Prevention Interventions
Efficiency of transmission between infected and susceptible person (*B*)	Immunization
	Use of physical or chemical barriers with partners at risk of infection (e.g., male or female condoms, possibly topical microbicides)
	Reduction of risky sexual practices (e.g., anal sex) or needle-sharing
	Reduction of cofactors that may enhance susceptibility or infectiousness (e.g., treatment of bacterial STI and possibly suppression of HSV-2 shedding to reduce HIV acquisition or transmission)
	Suppressive therapy of chronic viral infections to reduce viral burden (e.g., for HIV, HSV-2)
	Postexposure prophylaxis after known or likely exposure to STI/HIV (e.g., antimicrobials, antivirals, immunization, immune serum globulin; possibly preexposure antiretroviral prophylaxis)
	Reduction of sexual exposure during times of likely increased infectivity (e.g., outbreaks of genital herpes, acute and advanced HIV infection)
	Male circumcision to reduce susceptibility (e.g., HIV, HSV-2)
Average rate at which new sexual partners are acquired (*c*)	Promotion of abstinence and delay of sexual debut among young people as part of a comprehensive prevention strategy.
	Promotion of monogamy and reduced rates of partner change
	Promotion of messages about potentially safer partners (e.g., those with fewer prior partners, those known to have been recently tested) or avoidance of partners in higher risk settings (e.g., bathhouses, brothels)
	Promotion of selection of partners known to be concordant for chronic viral infections (e.g., HIV)
Duration of infectivity (*D*)	Detection of infection through screening, diagnosis, and partner evaluation
	Accessible, high-quality health services for testing and treatment
	Evaluation and treatment of exposed partners
	Health promotion activities to enhance regular care-seeking for screening and early diagnosis/treatment of symptomatic persons
	Development and availability of simple, effective, inexpensive treatments for cure or suppression of infection
	Strategies to increase likelihood of treatment following clinical or public health contact (e.g., syndromic management, rapid point of care tests, systems to rapidly communicate test results and locate infected but untreated persons, possibly mass treatment of selected populations)
	Laboratory monitoring of antimicrobial resistance

[a]Modified from St. Louis M, Holmes H. Conceptual Framework for STD/HIV Prevention and Control. In: Holmes K, Mardh PA, Sparling P, et al., eds. *Sexually Transmitted Diseases*, 3rd edn. New York: McGraw-Hill, 1999, pp. 1239–1253.

only as a level at which to measure public health impact, but also because it contains structures and networks that influence likelihood of transmission.[13,33,34] Sexual networks are groups of individuals directly or indirectly sexually connected to each other. The location of an individual in such a network can be as or more important than personal sexual behavior because it affects the prevalence of infection in those to whom the person is directly sexually connected.

PHASE-SPECIFIC TOPOLOGY OF STI EPIDEMICS

The phase-specific topology construct provides a useful theoretical framework for understanding the evolution of STD epidemics over time,[35] especially when applied to localized outbreaks of bacterial STDs. The construct describes STD/HIV epidemics as evolving though four main phases characterized by changes in the subpopulations in which STDs/HIV are concentrated (Fig. 90-1), starting with a growth phase followed by hyperendemic, decline, and endemic phases. This progression is affected by sexual behavior, as manifested in the patterns of sexual partnerships and networks, as well as effectiveness of prevention services and related health-seeking behaviors. The construct also includes two types of sexual networks (spread and maintenance) that are important in facilitating population spread of STD/HIV. The spread networks or core groups are generally dense and characterized by high rates of partner change and concurrency (e.g., commercial sex workers [CSW], some MSM core groups). They enhance STD/HIV transmission both within networks as well as between networks due to bridge populations (e.g., bisexual men) or bridging behaviors (e.g., new sex partner acquisition while on holiday). The maintenance networks comprise individuals or partnerships characterized by lower prevalence of risk behaviors and lower interconnectedness. However, given their greater prevalence in the population, the maintenance networks are a key determinant of continued endemic disease propagation.

MULTILEVEL DETERMINANTS AND SOCIAL CONTEXT

Variance in the evolution of STD/HIV epidemics in different populations has increasingly highlighted the complex impact of societal determinants on disease transmission.[36,37] For example, the prevalence of an individual risk behavior (such as unprotected sex) may generate and, in turn, be influenced by social norms (a group-level factor) regarding its acceptability, which also reflects demographic and social trends and the delivery and effectiveness of prevention

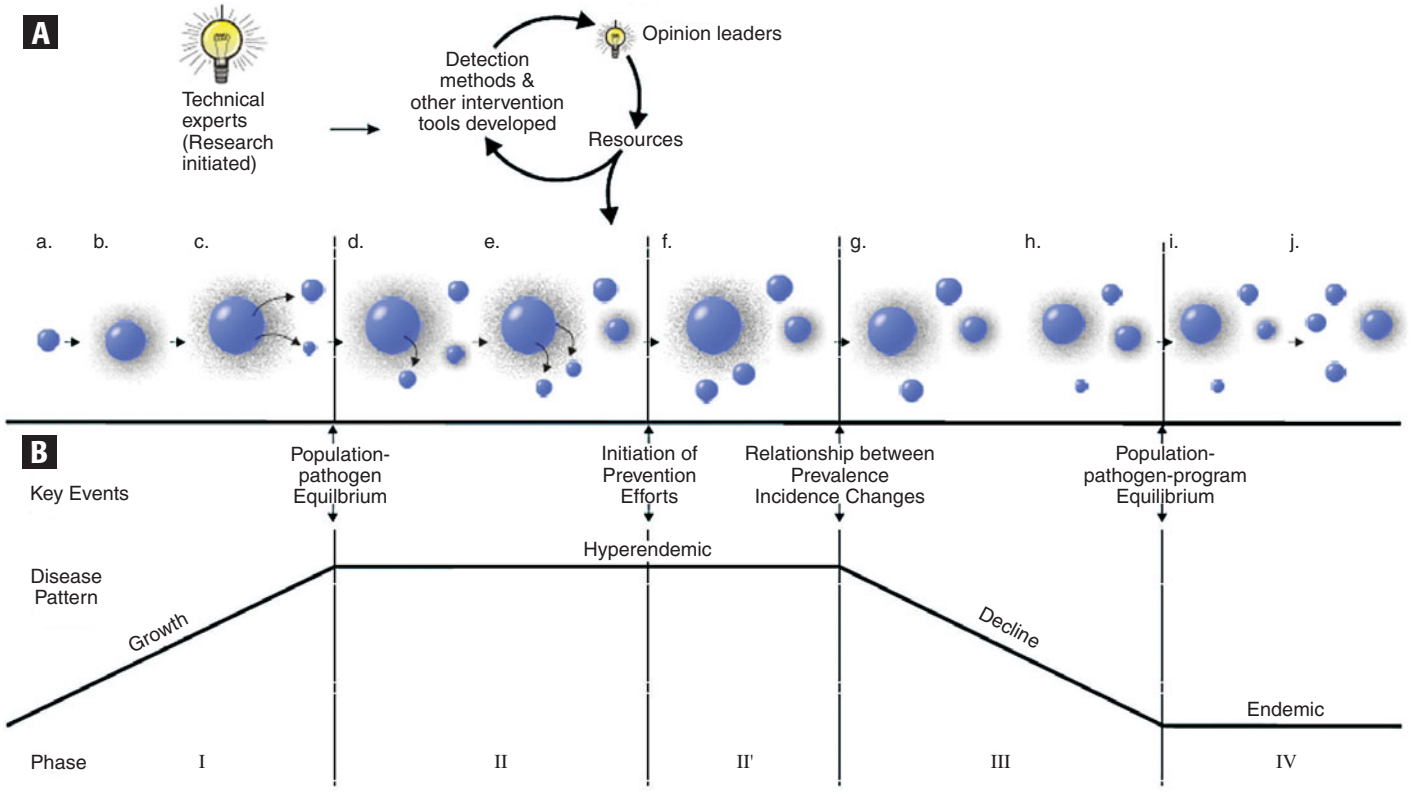

FIGURE 90-1. Dynamic trajectory of phases of STD epidemics, indicating complementary changes over time from perspective of sexual networks and disease patterns. **A.** Trajectory from perspective of subpopulations in which spread and maintenance sexual networks are located, emphasizing importance of different types of sexual networks and of public health interventions. "Dense spheres" indicate subpopulations with spread networks, "mottled halos" represent larger subpopulations containing maintenance networks, and "arrows" represent bridge populations. **B.** Trajectory from perspective of disease patterns, reflecting population-pathogen relationship.

interventions. This complex ecology of disease transmission, in turn, influences prevention by demanding that comprehensive HIV/STD interventions take into account the occurrence and interactions of factors operating at numerous levels within a given society.[33,38] At the *individual level*, many factors affect STD/HIV transmission, including age, presence of other STIs, circumcision status, nutrition, immunogenetic factors, type of exposure, and, most critically, having sex with an infected partner. At the *partnership level*, factors affecting transmission include type of partnership and societal contexts (e.g., social norms and expectations, gender roles). At the *sexual network level*, demographic, epidemiological, social, and political contexts directly influence the network structure and dynamics and, in turn, are influenced by them.[12,39,40] Political conflict and economic and social disruption may all result in the breakdown and formation of novel sexual and social networks.[12]

SELECTING PREVENTION PRIORITIES

Given the large number of STDs and the growing range of prevention options, programs must determine which infections to target and which activities to prioritize. The criteria for selecting priorities include the following: (1) relative importance of specific STDs in terms of population burden and cost; (2) potential effectiveness and cost-effectiveness of interventions in preventing transmission and complications; (3) intervention feasibility and acceptance by providers and target populations; (4) potential for alignment with other prevention programs.[11,16] While some interventions can be effective against a variety of STDs, most are infection-specific, based on biomedical tools such as diagnostic tests treatments, and vaccines. Prevention interventions must be acceptable to both providers and target populations if they are to achieve broad coverage and be sustainable.[16,41] For providers, feasibility can be impeded by clinician discomfort with an intervention, cumbersome logistics or limited resources. For patients, acceptability is affected by quality and cost of services[42] and by misunderstanding of risk or perception of stigma in seeking STD services.[5]

As an example of the situation in many developed nations, Table 90-2 outlines recent estimates of the burden of infection, the phase of the epidemic, and key prevention strategies in the United States. Prevention activities have primarily focused on curable bacterial STDs, HIV, and HBV. The target of the longest-standing prevention programs, syphilis, has been at historically low levels for 10 years and efforts are now focused on elimination. Gonorrhea is also at historically low levels, albeit at an intermediate level of endemicity with wide population variability by race and ethnicity, and prevention efforts are increasingly focused on reducing these disparities.[43] In contrast, after a relatively shorter period of national prevention effort, chlamydia remains hyperendemic and broadly distributed in the population. Twenty-five years into the AIDS epidemic, HIV incidence has fallen from peak levels, but now plateaued, prompting new efforts at intensive case finding and prevention case management among those HIV-infected.[9] HBV has been dramatically reduced as a result of widespread vaccination in children, although rates of infection remain high among at-risk adults for whom there are no systematic immunization programs.[6] Prevention efforts for HPV have largely focused on preventing complications, with impressive reductions in cervical cancer after 50 years of Pap smear screening programs.[8] The advent of an effective HPV vaccine provides an opportunity to prevent other manifestations of infection, such as genital warts and abnormal Pap smears, as well as further reduce cervical cancer.[44,45]

Finally, although prevention strategies are typically assessed as individual interventions,[46] they are usually implemented programmatically as part of a package. As prevention options grow, it is vital to understand how most effectively to implement and evaluate such packages, especially when they operate at multiple levels.[33] Sometimes this involves program trade-offs. For example, resource-constrained programs in the United States responding to outbreaks of syphilis in MSM are attempting to balance the relative value of provider education, health communication to affected communities, outreach testing, and partner services activities.[47,48] Similarly, U.S. HIV prevention programs are balancing prevention approaches (e.g., increased testing and condom promotion) in high-risk populations such as MSM and African Americans, with those focused on persons known to be HIV-infected (e.g., partner services, serostatus disclosure, and STD testing).[9]

INTEGRATION OF PREVENTION SERVICES

As noted above, one of the criteria for prioritizing various STD/HIV prevention activities is the degree of alignment with other public health programs. Such alignment can enhance program synergies by improving cost-effectiveness and feasibility of implementation and can range from selected attempts to integrate services at the patient level (e.g., STD screening in family planning clinics and contraceptive care offered in STD clinics) to full consolidation of public health programs.[4] Probably the most important focus of recent integration efforts is that between STD and HIV prevention programs, which have been largely separate for the past 20 years in the United States. There is increasing attention to potential programmatic synergies in a variety of areas including surveillance, clinical services (e.g., routine HIV testing in STD clinics and STD testing in HIV care settings), partner management, education and health promotion, and community partnerships.[4] An equally important partnership is that between STD prevention and reproductive health,[5] which led to the initiation of a national chlamydia prevention program in the United States in the early 1990s, with an emphasis on screening in both family

Table 90-2. Health and Economic Impact of STDs in the United States

STD	Reported 2005 Incidence	Estimated (2000 Incidence/ Prevalence[a]	Estimated Annual Direct Cost (2000 $ in Millions)[b]	Major Sequelae in the United States	Phase/ Focality	Key Prevention Strategy[c]
Bacterial and Protozoal						
Chancroid	17[d]	NA[e]	N/A	HIV transmission	Low endemic/High	Typical presentation, curative therapy
Syphilis	32,499[d]	50,000–70,000/NA	$16.5	Congenital infection and still-birth, neurosyphilis, HIV transmission	Low endemic/High	Serologic Testing for screening and diagnosis; curative therapy
Gonorrhea	339,593[d]	718,000/NA	$128	Infertility and ectopic pregnancy, congenital infection, HIV transmission	Intermediate endemic/Medium	Testing for screening and diagnosis; curative therapy
Chlamydia	976,445[d]	2.8 million/ 1.9 million	$464	Infertility and ectopic pregnancy, congenital infection and low birth weight, HIV transmission	Hyperendemic/ Low	Testing for screening and diagnosis; curative therapy
Trichomoniasis	NNN[f]	7.4 million/NA	$133	Low birth weight/ prematurity, HIV transmission	Hyperendemic/ Low	Testing for diagnosis, curative therapy
Viral						
HIV	35,537[g]	40,000/560,000	$5,994	Opportunistic infections and malignancies	Low endemic/High	Testing for screening and diagnosis; risk reduction counseling; suppressive antiviral therapy
HBV	5,494[h]	81,000/417,000	$31.5	Chronic hepatitis, cirrhosis, liver cancer	Decline	Immunization
HSV-2	NNN	1.6 million/ 45 million	$732	Congenital infection, HIV transmission	Hyperendemic/ Low	Testing for diagnosis; suppressive antiviral therapy
HPV	NNN	6.2 m/≥20 million	$3,891	Anogenital cancer	Hyperendemic/ Low	Clinical diagnosis and local therapy for genital warts; cervical cancer prevention by Pap and HPV testing, immunization;

planning and STD clinics.[49] In addition, with the growing possibility of vaccines for a variety of STDs, there is increasing recognition of the importance of linking STD and immunization programs, especially as the latter involve adolescents and adults. Correctional health care, including both jails and prisons, is another important setting for STD/HIV prevention activities, with particular focuses on screening for chlamydia[50] and syphilis,[51] and HBV immunization.[6]

Integrating prevention services into existing programs with different health goals can present challenges. Although integrated prevention services enhance convenience and thus coverage for clients, they can require additional resources to implement.[5,6] Other problems may include the potential for diffusion of expertise or overshadowing of programs dealing with less visible priorities (e.g., chlamydia or syphilis prevention) by those focusing on more visible ones (e.g., HIV prevention and care).[52] In spite of these issues, coordination and integration of programmatic activities remains a high priority for STD/HIV prevention.

ESSENTIAL PROGRAM COMPONENTS

Given the issues raised by the concepts outlined above, we next consider the key attributes of each of the essential components of effective STD/HIV prevention programs.

SURVEILLANCE

Accurate surveillance is the cornerstone of effective public health and is critical for optimal performance of other program components. Public health surveillance is defined as the systematic and ongoing collection, analysis, interpretation, and dissemination of health-outcome-specific information for the purpose of planning, implementing, and evaluating public health practice.[53,54] Such data allow public health staff to develop prevention strategies, prioritize resources, and determine health impact of programs. They also allow the recognition of outbreaks of new or reemerging health problems and thus are essential for effective outbreak responses. The legal authority for surveillance activities is based on laws and regulations of the relevant jurisdiction. In the United States, such authority resides at the level of the individual states, although other organizations, such as the CDC, play important roles in developing surveillance approaches and case definitions and in interpreting and disseminating data. Because of the stigmatizing nature of STD/HIV,[53] the confidentiality relevant to all personal health records is especially critical for surveillance of these diseases and is generally required by statute.

In the United States, a variety of surveillance approaches are used to monitor STDs and HIV/AIDS. These include case reporting (disease registries), prevalence monitoring, sentinel surveillance, and population-based surveys. In addition, behavioral and health services surveillance can provide useful supplemental information.[53,55] Each surveillance approach has strengths and limitations which must be considered when interpreting data, and because they are complementary, multiple approaches are often used to better "triangulate" a problem.[55]

Case reporting provides a measure of new cases of disease per unit of time. It is the core surveillance activity for most diseases and can help assess the overall burden of disease, monitor trends over time, and detect the emergence of outbreaks. In the United States, STDs reportable in all states include gonorrhea, chlamydia, chancroid, syphilis, hepatitis B, and AIDS. Other STDs such as genital and neonatal herpes, genital warts, and pelvic inflammatory disease (PID) are reportable in a few states.[55] While reporting of AIDS cases has been a national priority for many years, reporting of HIV infection has been more controversial, and has only recently become routine in all states, limiting national trend data. Case reporting generally relies on voluntary reporting by both providers and laboratories; the latter is of growing importance because of the capacity to rapidly and accurately transfer computerized data. Completeness of reporting affects the value of surveillance data, and it is impacted by both underdetection and underreporting. Underdetection results from both empiric treatment of STD syndromes or sexual partners without diagnostic testing, as well as the asymptomatic nature of many STDs, which never come to clinical attention. For example, the dramatic rise in the rate of reported chlamydia infection in the United States and the threefold higher rate of infection in women than men is largely due to increased screening of asymptomatic persons, especially women.[43] For those infections with confirmed diagnoses, estimates of the completeness of reporting range from 64% to 95% for gonorrhea, 55–98% for chlamydia, and 79% for syphilis.[55–58] Completeness of reporting of AIDS is even higher and is considered to be among the most complete of any notifiable disease.[59]

Prevalence monitoring is used to assess STD/HIV prevalence among defined populations undergoing routine screening. These efforts complement case report data and can provide assessments of disease burden when changes in testing behavior cause spurious increases in reported disease. For example, CDC prevalence monitoring activities for chlamydia among women attending family planning and STD clinics have confirmed that, in contrast to reported cases, prevalence has changed relatively little over the past decade.[43] Monitoring of HIV seroprevalence has also been used in routinely screened persons in the United States, such as those entering the Job Corps or military.[60,61]

Sentinel surveillance refers to the collection of data from small "sentinel" populations, thought to be representative of the larger population, often for outcomes not typically monitored or reported. Sentinel surveillance has been useful in monitoring antimicrobial resistance and in assessing HPV

prevalence in clinic-based populations.[62] Because the chronic nature of HIV infection makes assessment of new infection difficult, sentinel surveillance using "detuned" serologic tests is playing an increasing role in helping define HIV incidence in high-risk populations.[63,64]

Finally, *population-based surveys* extend sentinel surveys by conducting surveillance among samples thought to be representative of the general population. A series of assessments of STD/HIV prevalence have been carried out in the United States as part of the National Health and Nutrition Examination Survey, including studies of HSV-2, HPV, chlamydia and gonorrhea, and syphilis.[62,65–67] While these surveys provide limited behavioral data, they have been essential in determining both disease burden and trends at the population level. Several such surveys have recently documented similar rates of chlamydia in the United States and Europe, with little variation by gender.[62,68,69]

In Western Europe, surveillance for acute bacterial STDs relies primarily on case reporting from clinicians and/or laboratories. Case reporting is mandatory for gonorrhea and syphilis for all providers in most European Union countries, and for GUM clinics in the U.K. In contrast, for chlamydia, clinician reporting is required only in Sweden, Ireland, and the U.K. (from GUM clinics only), with other countries relying upon laboratory or sentinel case reporting.[70] Congenital syphilis is reportable in all countries except France and the Netherlands. Reporting of viral STDs (genital herpes and warts) is required in relatively few EU countries at present, similar to the U.S. Prevalence can be monitored in Denmark, Norway, and Sweden (and in Greece for gonorrhea) where reporting of denominator data is routine.[70]

In addition to assessment of morbidity, supplemental behavioral and health services surveillance can provide valuable programmatic insights. *Behavioral surveillance* data can be useful in monitoring prevention program impact and detecting behavioral trends that may affect transmission patterns. In the United States, national surveys collecting data relevant for STD/HIV prevention include the youth risk behavior survey (YRBS), which assesses health-risk behaviors in high-school students, and the national survey of family growth (NSFG), which includes women and men 15–44 years of age in the U.S. household population. A national sexual attitude and lifestyle survey carried out in 1990 and 2000 in the U.K. also provided general population data and showed increases in sexual risk behaviors, including the proportion of MSM.[71] *Health services surveillance* can use administrative data from clinical encounter, laboratory, and pharmacy records to assess provider compliance with prevention guidelines and the population coverage of prevention interventions. Excellent systems are in place in the United States to monitor childhood immunization coverage.[72] In addition, coverage of annual chlamydia screening in sexually active women younger than 25 years of age has been tracked through the health plan employer data and information set (HEDIS) measure since 1999.[73]

HIV/STD PREVENTION INTERVENTIONS

The actual impact of STD/HIV prevention programs in providing individual and population health benefit results from application of the four intervention components: clinical services, the closely allied component of laboratory services, partner management services, and health promotion and education services.

Clinical services

Clinical services for STD/HIV prevention include a broad array of diagnostic, treatment, and prevention services. Considered by transmission determinants (Table 90-1), virtually all activities designed to reduce the duration of infectivity are delivered through clinical services, as are the biomedical interventions designed to reduce the efficiency of transmission and the individual counseling interventions focused on both transmission efficiency and exposure of susceptible to infectious partners. Although these services are typically offered in settings such as STD, HIV, family planning, and primary care clinics, screening can be conducted in a variety of nonclinical, outreach settings.

Traditionally, the mainstay of clinical service provision for STDs has been through dedicated specialty settings such as STD clinics in the United States and GUM clinics in the U.K. In other western European countries, dedicated STD clinics also play an important role.[74] Patients seeking care in STD and GUM clinics generally have lower incomes and greater risk behaviors than the general population.[75,76] These clinics are often staffed by health-care providers with greater clinical expertise and access to supportive diagnostic and treatment services than other providers and are often publicly funded, offering care that is both confidential and low cost. Both attributes are considered critical in reducing barriers to timely access to care in persons with possible STDs.[77–79,42] The availability of adequate resources to ensure sufficient clinical capacity is a longstanding issue in STD clinics. A 1995 survey indicated that only 61% could see a new patient on the day of initial request,[80] and the recent increase in STDs in the U.K. and Europe has created a similar backlog.[81,82]

In the United States, Program Operation Guidelines published by the CDC in 2001 offer recommendations about core clinical services for STD clinics. They outline clinical management, laboratory support, partner services, and reporting functions expected of such clinics (Table 90-3), as well as a broad array of recommendations regarding clinic accessibility, clinic environment, registration processes, and quality assurance procedures.[83] More detailed STD management recommendations for providers are provided in CDC's regularly updated STD treatment guidelines (see Appendix B).[84]

Table 90-3. Recommended Core STD Clinic Services, CDC Program Operations Guidelines

Range of clinical services

Accurate diagnosis, treatment of bacterial STD

Clinic availability of treatment for other locally prevalent STD

Provision of condoms and risk reduction counseling

Specific protocols for follow-up/referral of other services if offered (e.g., Pap testing, pregnancy testing)

Specific protocols for referral for related services (e.g., family planning, prenatal care, drug counseling/treatment)

Collaboration with immunization programs to provide immunization services for HBV

HIV prevention: Confidential testing, risk reduction counseling, partner services, referral to care

Laboratory support for clinical services

On-site certified laboratory

On-site point-of-care laboratory services

–light microscopy for gram stain for detection of white blood cells, intracellular gram negative diplococci

–saline wet mount examination for T. vaginalis, clue cells

–KOH wet mount for identification of yeast and amine odor (whiff test)

–nontreponemal antibody rapid test

–darkfield microscopy for T. pallidum

–urine pregnancy test

Mechanism for providing non point-of-care testing

–Gonorrhea: culture or nonculture definitive testing

–Chlamydia: nonculture definitive testing

–Syphilis: quantitative nontreponemal and confirmatory treponemal testing

–HIV antibody testing

Partner services

Protocols specifying conditions and patients to receive partner services

On-site or on-call staff for partner services

Procedures to assure regular communication, consistent prevention messages, confidential exchange of information between clinical and partner services staff

Reporting

Staff familiarity with applicable STD/HIV reporting and confidentiality statutes

Procedures for prompt submission of reports of notifiable diseases

If medical or laboratory records computerized, linkage to electronic morbidity reporting

Clinic protocols for reporting, and referral of suspected sexual assault, child sexual abuse, and domestic assault

Similar guidelines have been developed for Europe (European STD Guidelines 2001).

Although STD and GUM clinics are recognized as a critical safety net for clinical services, such services are increasingly provided in other public and private clinic settings in both the United States and Western Europe.[43,74,75] For example, in the United States, sites other than STD clinics now report the majority of cases of primary and secondary syphilis (67%), gonorrhea (65%), and chlamydia (76%).[43] Much of this care is provided through screening programs in other public clinic settings where STD services can be integrated with other prevention programs. In the United States, the national chlamydia control program has effectively focused on both family planning and STD clinics,[85] while screening in correctional facilities has played an important role in syphilis elimination activities.[48] In the U.K., the national chlamydia screening program is centered primarily on non-STD focused health-care facilities.[86] However, primary care and other private sector clinicians also play a large role in both the United States and Europe.[43,74]

Clinical services for HIV prevention include those focused both on persons not known to be infected as well as persons diagnosed with HIV infection. In the United States, publicly-funded HIV counseling and testing sites (CTS) have provided the most visible HIV prevention clinical services infrastructure, although as for STD, most testing occurs in other settings.[87] Despite a high volume of testing nationally in the United States, the substantial proportion of HIV-infected persons who are diagnosed at an advanced stage of infection or who remain undiagnosed altogether[88] has increased support for HIV screening. Routine screening of all sexually active persons in health-care settings is considered to be cost-effective[89,90] and recommendations to enhance screening in a variety of clinical settings have recently been emphasized.[9,91]

The growing number of persons living with HIV as a result of improved treatment has led to increased focus on preventing transmission from those who are HIV-infected.[9,92] While HAART reduces blood and genital viral load and, thus probably the efficiency of transmission, treatment is not recommended for all HIV-infected persons[93] and even those with undetectable plasma viral loads may still be infectious.[92] Thus, HIV care providers are advised to consider a variety of other prevention activities for persons in care, including assessment and behavioral interventions for ongoing risk behavior, screening and treatment of STDs, referral for services such as substance abuse treatment, and facilitation of partner management services.[92,94]

Laboratory services

Laboratory services are a core component of both accurate surveillance and clinical services. Diagnostic tests are critical for early and accurate disease detection and can be used for diagnosis of symptomatic persons, screening of high-risk persons or general populations, and assessment of sexual partners of persons with STDs.[10] Ideally, tests for diagnosis of STD/HIV should be accurate, inexpensive, simple, and rapid. For curable STDs, sensitivity has traditionally been considered a higher priority than specificity, since the risk of failing to diagnose an infection with transmission potential was considered to be greater than the risk of a false positive diagnosis resulting in a short course of unneeded treatment.[10] However, the growing importance of chronic infections, such as HIV and HSV-2, as well as the desire to avoid the distress and stigma of a false-positive diagnosis, underscore the need for high specificity.

Rapid "point-of-care" diagnosis at the time of initial evaluation enhances the ability of early treatment to resolve symptoms and reduce ongoing transmission and also supports prevention counseling and partner management. STD clinics have traditionally emphasized stat labs with both microscopy for rapid detection of gonorrhea and urethritis by gram stain, trichomoniasis by wet mount, and syphilis by darkfield examination, as well as rapid nontreponemal serologic tests[83] (Table 90-3). In settings with poor return for follow-up, rapid tests result in a larger proportion of infected persons treated than more sensitive but slower conventional tests.[95] Rapid HIV antibody tests have recently become available and are increasingly used both to encourage testing and to reduce the problem of patients failing to return for results.[96] These tests are also simple enough to use in outreach settings where they may be performed by nonlaboratorians, and they can enhance testing of hard-to-reach persons.[92] Rapid syphilis tests may have a similar value, although are not currently licensed in the United States.[48,97]

Most laboratory tests for STD/HIV prevention are not point-of-care tests and are performed in conventional laboratory settings. In the United States, public health laboratories have traditionally played an important role in such testing, although as for clinical care, laboratory testing is increasingly provided by the private sector. Recent surveys in the United States of manufacturers of STD diagnostics and public laboratories[98,99] indicate that of approximately 26 million chlamydia tests sold in the United States, only 19% were sold to the public laboratories, in contrast to 41% and 23% in 1994 and 2000, respectively. The surveys also documented the growing proportion of testing using the more sensitive NAATs format (57% for chlamydia and 49% for gonorrhea). Appropriate use and selection of laboratory tests remains an ongoing challenge. For example, the most recent survey indicated that many labs still offer non-type-specific HSV serologic tests, which are less reliable than tests that can differentiate HSV-1 and -2.[99]

In addition to screening and clinical management, laboratory testing is essential for monitoring trends in antimicrobial resistance. Such surveillance has been essential in monitoring trends in gonococcal resistance since the 1970s, documenting the emergence of resistance to penicillins, tetracyclines, and more recently fluoroquinolones.[43] National surveillance systems exist in many developed countries, such as the gonococcal isolate susceptibility project (GISP)[43] in the United States and the European Surveillance of STI (ESSTI) programs in Western Europe.[100] More recently, the recognition of emerging resistance to all classes of antiretrovirals has led to recommendations for susceptibility testing among those failing treatment and consideration of testing at initiation of therapy as well.[93]

Partner management services

Partner management services, also known as contact tracing or partner notification, is a well-established disease control measure that has long been important for STD control and is now playing a growing role in HIV prevention. Its primary focus is informing sex or drug-injection partners of persons diagnosed with STD/HIV of their exposure and facilitating their testing and treatment.[101–103] There are two basic approaches to partner management: provider referral and patient-referral.[101, 103] Provider referral involves an interview of the index patient by a clinician or public health worker to elicit partner names, exposure, and identifying information, followed by confidential notification of partners about their exposure, with referral for examination and treatment. Patient (or self)-referral relies upon the index patient to notify partners, often assisted by written materials from a provider or public health worker. Contract- or conditional-referral is a hybrid approach in which providers notify partners if patient-referral has not been completed within a specified timeframe. For patients with multiple partners, these approaches can be combined. For all approaches, the voluntary participation of the index patient and strict adherence to confidentiality are essential.

The impact of partner management is most commonly measured as the number of new cases of STD diagnosed and treated per index patient interviewed. A recent review of the effectiveness of partner management reported a similar yield for syphilis, gonorrhea, and chlamydia, with approximately 0.22–0.25 infected partners treated for every index case interviewed.[102] Not surprisingly, patient referral has a lower yield than provider referral.[102,104] Assessing the impact of partner services on disease transmission and population prevalence has been challenging, although several studies have reported temporal associations of declining gonorrhea incidence with intensified partner management efforts,[105–107] and modeling studies suggest that for chlamydia, partner treatment can enhance the benefit of screening in reducing prevalence.[108]

In the United States, partner management has been an essential element of syphilis control since the 1940s and has also been recommended and used for the other curable STDs. The STD program in each jurisdiction prioritizes the STDs for which partner management will be provided, with providers encouraged to advise patient referral for other STDs.[101] Questions have been raised in recent years about the population coverage provided by partner management services. A recent national survey of U.S. STD programs indicated that provider referral by public health staff was conducted for 89% of syphilis cases, but only for 17% of gonorrhea cases and for 12% of chlamydia cases.[109] This situation has promoted interest in alternative approaches. One such promising strategy is expedited partner therapy, in which partners are provided treatment without an examination, often via oral medications delivered by the index patient. This strategy can be effective in preventing re-infection with gonorrhea and chlamydia,[84,110–112] and its greater cost-effectiveness[113] could increase population coverage and reduce disease prevalence.[114]

Partner management for HIV infection[84,107,110] has been more controversial because of concerns over confidentiality, heightened by fear of HIV-associated stigma.[102,103,115] Thus, although long-recommended as an important component of HIV prevention,[116] U.S. surveys indicate that provider referral is offered to only 32–52% of newly diagnosed patients.[109,117] The increased focus on prevention for HIV-infected persons has led to a renewed emphasis on partner management for HIV infection[9]. Recent reviews have documented both high yield of provider referral, with 80% of named partners notifiable and 21% of those tested found to be HIV-positive,[118] as well as high client acceptance (59–82%).[115]

In Europe, although partner management has been a component of STD control in some countries since the early 1900s, there is a considerable variability at present.[119] Partner notification is compulsory for notifiable STDs in a few countries such as Norway and Sweden. In others, partner management is voluntary, with variable practices and degrees of emphasis in national guidelines. As in the United States, the primary focus is on the bacterial STDs, although services are offered for genital HSV and HPV in some countries. Most countries use patient-referral but provider referral is used in some settings in Norway, Sweden, Finland, Ireland, and the U.K. Expedited partner therapy is used in many countries, although only in a small proportion of cases.

Individual and community behavioral intervention services

Individual-focused interventions. Individual-focused behavioral interventions aim to change behavior at the individual level by providing knowledge or attempting to alter beliefs, attitudes, norms, motivation, or skills.[120,121] Examples of individual-focused interventions include: outreach and counseling programs for substance-abusing populations; client-centered risk reduction counseling and skills-building programs for women, adolescents, and MSM; and condom distribution programs for CSW and other high risk individuals.[122–125] Individual-focused interventions are most efficiently delivered in settings where high-risk individuals can be easily accessed.[120] For example, in Project Respect, risk reduction counseling of STD clinic patients resulted in fewer new STDs at 6 and 12 months of follow-up compared with controls.[126,127] Interventions targeting adolescents must address the issue that youth often feel relatively invulnerable and thus may choose not to remain sexually abstinent or to use condoms if they do become sexually active.[120,128] Nevertheless, several individual-focused interventions have reported significant impact on adolescent sexual risk behaviors.[125,129,130]

Community-focused interventions. The goal of community-focused interventions is to modify social norms, influence social networking opportunities, and reduce barriers to healthy sexual and healthcare-seeking behaviors.[120,131] They address the behavioral risks of individuals in the context of their personal networks and social environments.[120] These interventions include capacity building of community organizations, community mobilization, peer outreach, mass media campaigns, and community-based health promotion.[132–134] An example of a community-focused intervention that was successful in changing social norms among MSM was the Mpowerment Project, which utilized outreach, small groups, and a media campaign,[135] and which resulted in a reduction in anal intercourse. Another community-focused intervention, the AIDS Community Demonstration Projects, targeted hard-to-reach populations in community settings and resulted in an increased condom use and intention to use bleach kits.[136,137]

Health communication and health marketing. Health communication and health marketing have become increasingly important for both individual and community behavioral change. Health communication involves design and delivery of messages and strategies based on consumer research to promote the health of individuals and communities.[132,138]

Its goal is to help shape perceptions regarding health issues, and it is particularly useful when combined with other prevention approaches.[120] Health marketing is an emerging field that integrates traditional marketing approaches with public health research, theory and practice, and provides a framework for designing health interventions.[139] It involves creating and delivering health information and interventions by using customer-centered and science-based strategies to promote healthy behaviors. At the *individual level*, effective health communication can help raise awareness of health risks and solutions, provide motivation and skills to reduce these risks, help individuals find support, and affect or reinforce attitudes.[120] At the *community level*, health communication influence can help the public agenda, advocate for policies and programs, improve delivery of public health and health-care services, and encourage healthy social norms.

PROGRAM SUPPORT

Program leadership and management

Effective leadership and management are essential to direct, energize, and integrate all of the other program intervention and support components. Leadership and management are closely related, but focus on different levels of activity. While leadership focuses on broad directions, characterized as "doing the right things," management deals with an array of operational issues (planning, budgeting, staffing, etc.) involved with "doing things right."[140] The key aspects of effective leadership and management include partnerships and collaboration, priority setting and planning, and policy development and implementation.

Partnership and collaboration are leadership activities of growing importance. Governmental public health agencies have historically played the primary role in assessing need and assuring delivery of services.[141] However, a sole reliance on government to assure public health is increasingly inadequate for several reasons, including limited resources, recognition of the broad array of sectors that can impact health, and increased understanding of the importance of collaborations among individuals, communities, and institutions to improve health.[142] A more robust approach to public health involves a collaborative response by other sectors of society including the health-care delivery system, academia, communities, businesses, and the media.[126] Participation by community-based organizations in the delivery of prevention services has been a key aspect of HIV prevention in many countries since the mid-1980s, and is also now playing an important role in syphilis elimination efforts in the United States.[48] Another essential partnership has been with professional organizations and the health-care delivery sector in support of the U.S. national chlamydia screening program.[143,144,145] Health system support will be similarly critical in attempts to expand HIV screening and prevention in HIV-infected persons.

An equally important leadership focus for STD/HIV prevention is priority setting and planning. For example, national planning of HIV prevention has been supplemented over the last decade by a community planning process, involving collaboration between public health and community organizations to tailor plans based on local considerations.[146] In addition, re-assessment of HIV prevention activities following the publication of an IOM report on HIV prevention in 2001[147] led to greater prioritization of screening and prevention in HIV-infected persons.[9] Likewise, the shift in syphilis epidemiology in the United States, with resurgence in MSM, has put greater priority on awareness campaigns aimed at the MSM community and at providers serving them[47] and also led to a renewed emphasis on local tailoring of prevention strategies.[48]

Finally, policy development creates an overall architecture for public health programs, and successful policy implementation is the primary driver of long-term public health benefit.[141] It is a critical leadership responsibility at all levels of public health practice. Important examples of national STD/HIV prevention policy efforts in the United States include the Congressionally authorized national Infertility Prevention Program,[85] the National Syphilis Elimination Plan,[48] and the recent Advancing HIV Prevention initiative, focusing on screening and prevention in care.[9] A notably comprehensive national policy effort was the National Strategy for Sexual Health and HIV released by the U.K. Department of Health (DOH) in 2001,[148] which broadly frames an approach intended to reduce STD, HIV, and unintended pregnancy. An increasingly critical component of policy development is an effective communication of prevention needs and opportunities to public and private decision-makers. In the United States, key aspects of such effort include activities by groups such as the National Coalition of STD Directors and the American Social Health Association, as well as proactive efforts to communicate policy issues through mass media.[147]

Professional training

High quality workforce training is vital for implementation of each of the other essential STD/HIV program components. For public health in general, as the spectrum of responsibilities has grown from a largely biomedical approach to one encompassing new areas of expertise such as behavioral science, communications, and informatics, the range of educational and training needs has similarly broadened.[142] The same is clearly true for STD/HIV prevention training. Given the growing role of nonspecialty clinics in providing STD clinical services, STD management training of primary care providers is a particularly high priority.[126]

In the United States, a core element of such training is provided by government-sponsored training networks, the most

important of which are the AIDS Education and Training Centers (AETCs)[149] and the National Network of STD Prevention Training Centers (NNPTCs).[150] These efforts are supplemented by reproductive health training offered by the Regional Training Centers.[151] The AETCs provide training for primary care physicians, reaching over 125,000 participants per year.[150] The NNPTCs offer not only clinical training, but also training in behavioral intervention, partner services, and program management, accessing over 25,000 students per year.[150] The growth of the Internet as a training medium has enhanced possibilities for low cost and easily accessible training. The Internet may be particularly useful in providing "just in time" training and rapid access to guidelines for clinicians who infrequently manage STD/HIV.[152,152,153] Finally, similar to the need to better integrate STD and HIV prevention program activities, there is a need to coordinate training efforts, both to enhance efficiency and to support the practice of integrated prevention approaches.

In the U.K., the DOH works with the Health Development Agency to develop and disseminate information and evidence for professionals' need, including good examples of best practices. The DOH also supports continuing professional development, and has included sexual health information in its practice Development Toolkit available for all health visitors and school nurses.[154] Additional training is provided by professional organizations such as the British Association of Sexual Health and HIV and the Society for Sexual Health Advisors.

Monitoring and evaluation

Monitoring and evaluation (M&E) is a key support component for optimal and accountable performance of all other program activities.[155] Its overall purpose is to measure and assess performance in order to more effectively manage program outputs and outcomes. Monitoring describes a continuing function that provides management and main stakeholders of a prevention program with ongoing indications of progress in the achievement of outputs. Evaluation, in contrast, intermittently assesses progress towards and the achievement of outcomes. The objectives of results-oriented M&E of STD/HIV prevention programs are many, but key among them are to enhance organizational learning, ensure informed decisionmaking, and support accountability and organizational redirection.[155, 156]

At the national level in the United States, STD performance measures have been developed by CDC as part of its commitment to standardized, measurable outcomes of program performance activities.[157] These measures are in alignment with CDC and U.S. Government goals such as those outlined in Healthy People 2010.[158] To ensure quality programs and measure progress, project areas track a set of measures related to specific program components such as timeliness and completeness of case reporting and adequacy of clinical services. Another example of STD M&E activities is the inclusion since 1999 of chlamydia screening as a health plan employer data and information set (HEDIS) measure.[73] HEDIS is a set of standardized measures that provides a "report card" on the performance of managed care organizations. HIV prevention program monitoring is conducted by the project evaluation and monitoring system (PEMS),[159] a system jointly developed by CDC and its partners. It consists of a comprehensive set of standardized variables and integrates multiple data sets into one system. Although the uses of automated performance measuring systems are less developed within Europe, mechanisms are in place to ensure accountability of funds and use of data to improve programs. For example, in the U.K., recent development of systems to monitor waiting times in GUM clinics[160] provides an assessment of local clinic capacity and performance in response to the local health needs.

Research

The final support component is research, the impetus for ever-improving, science-based policy and practice. Virtually all of the major STD/HIV prevention programs and policy advances of the last 10 years have resulted from focused research efforts. Basic research refers to investigation in fundamental areas such as molecular biology, microbiology, immunology, psychology, statistics, economics, etc. In contrast, clinical research focuses on research on human participants. Another approach, operations research, aims to develop a scientific model of a system to predict and compare the outcomes of alternative decisions, strategies, or controls.[161] More recent interest has focused on the role of translational research, defined as the bidirectional transfer of knowledge between the basic work and the whole patient or population.[162] Such efforts can provide better understanding of the mechanisms of disease and maintenance of health as well as lead to new methods of diagnosis, treatment, and prevention.

Research priorities in STD/HIV prevention have been defined for many western industrialized countries. In the U.K., nationally funded priorities are established by the Medical Research Council Sexual Health and HIV Research Strategy Committee.[163] In the United States, a framework for prevention research priorities has been developed by the CDC in its research guide: *Advancing the Nation's Health: A Guide for Public Health Research Needs,* 2006–2015.[164] It documents priority research areas for the next decade for CDC and its partners, including issues related to sexual and reproductive health. The CDC prevention research portfolio is complemented by the much larger investments in research by the National Institutes of Health.

FUTURE DIRECTIONS

The overall challenge for STD/HIV prevention efforts in developed countries is ensuring that comprehensive prevention services are provided through a well-coordinated system

that is seamless at the client level and utilizes a broad array of community resources. The essential components of STD and HIV public sector programs are in place in most developed countries; however, these components must be strengthened and better linked with other prevention programs to maximize public health impact. This section highlights some of the emerging prevention approaches that are likely to impact the nature and form of STD/HIV prevention services over the next decade.

Program collaboration and service integration

Program collaboration and service integration describes a mechanism of organizing and coordinating activities and services so that they are designed, implemented and evaluated to maximize public health impact.[165,166] Examples of collaboration between STD and HIV programs are found across many U.S. and European contexts, although the level of collaboration varies tremendously.[167] There are a number of barriers to better collaboration between categorically funded programs, including lack of local flexibility to shift funds across budget lines, lack of guidance for program integration, and difficulties in merging surveillance and evaluation data.[3,5,168] Program collaboration and service integration has the potential in many settings to enhance prevention effectiveness and efficiency.

Mathematical modeling

Mathematical models can serve many purposes including delineating basic processes underlying disease transmission, defining the most important determinants of an observed pattern, designing and evaluating interventions, and examining the impact of population-level factors on intervention efficacy.[169] Models have been used extensively to explore the processes determining observed patterns of infection in STD epidemiology, the effect of sexual mixing, the intersection between epidemics, and the impact of prevention programs on population levels of infection.[170–172] Of particular importance, models may help to demonstrate how prevention campaigns can benefit targeted populations.[173,174]

Cost-effectiveness analyses

Cost-effectiveness analysis (CEA) is a technique for selecting among competing priorities in the context of finite resources by comparing the relative value of various strategies.[175,176] In its most common form, CEA compares a new strategy with current or established practice. For example, Cohen et al.,[177] estimated the relative cost-effectiveness for 26 HIV prevention interventions and found that the two most important factors were population HIV prevalence and cost per person reached. Consequently, in low-prevalence populations, the most cost-effective interventions were population-level interventions (e.g., mass media and condom distribution), whereas in high-prevalence populations, individually focused behavioral interventions were also relatively cost effective. In the future, wider use of CEA will be essential to prioritize the best mix of interventions.

Structural interventions

Structural interventions refer to public health interventions that promote health by altering the structural context within which health is produced.[178,179] For example, structural interventions may be used to influence the social, political, or economic environments in which people live to effect positive health outcomes.[264] Micro-credit and other programs aimed at improving women's economic status may impact STD/HIV prevention by reducing economic dependency on male partners.[180,181,182] As a component of a multilevel approach to STD/HIV prevention with an especially broad reach, structural interventions are likely to be of increasing importance.[183,184]

Network analysis

Social network analysis provides an essential tool for analyzing social structures, including sexual networks. Work in this area is growing[185] as new studies emphasize the importance of understanding the structure of sexual networks in STD/HIV transmission.[186] Patterns of sexual mixing, concurrency of partnerships, and the existence of sexual bridges help create the socioeconomic, racial, and ethnic disparities seen with STDs/HIV.[172] Practical programmatic use of the concept of networks is still evolving; however, there are promising examples from syphilis control[187,188] and HIV prevention.[189]

The internet

The past decade has seen a dramatic expansion in population access to the Internet, as well as the diversity of sexual activities that may be pursued through this media. Both trends are likely to continue for the foreseeable future. Elevated levels of high-risk sexual behavior among people who meet sexual partners through the Internet are well-documented.[190–192] Although substantial progress has been made using web-based technologies to enhance health communication, partner notification, disclosure of HIV status, and STD/HIV screening, future prevention efforts must increase the focus on the practical uses of this emerging field[193,194] (see Chapter 108).

Biomedical interventions for STD/HIV prevention

In addition to ongoing research on HIV vaccines, there is an enthusiasm regarding novel biomedical approaches for STD/HIV prevention,[195,196] including vaginal microbicides,[197] cervical barrier methods, pre/postexposure prophylaxis,[198] suppression of HSV-2,[20] and male circumcision.[199,200] Combinations of methods must be studied, as no single intervention is likely to be 100% effective. The development, implementation, scale-up, and M&E of these interventions

will require commitment from many sectors, including industry, foundations, research networks, and communities.

CONCLUSIONS

As the STD/HIV prevention programs in developed countries move into the twenty-first century, they face a variety of opportunities and challenges. There has been great progress in the control of curable bacterial infections such as syphilis and gonorrhea, on which prevention programs have been focused for the longest period. Although chlamydia remains hyperendemic, improving diagnostic tools make effective screening programs more feasible than ever, while enhanced partner management offers great potential for preventing ongoing transmission. Immunization programs have been highly effective in reducing the incidence and impact of HBV, and new HPV vaccines offer similar hope. Newer approaches to HIV prevention, such as rapid testing and prevention services for HIV-infected persons, and male circumcision promise to complement the improvements in care over the past decade, and, relevant to all STD and HIV, the growth of evidence-based behavioral interventions offer tremendous opportunities. However, the high population burden posed by STD/HIV, despite concerted prevention efforts, point to obvious challenges, as well. These include gaps in our biomedical approaches (e.g., viral infections for which curative therapy is not available, rising antimicrobial resistance for infections such as gonorrhea and HIV, and absence of vaccines for most STDs), and challenges in behavioral approaches, such as the difficulty of sustaining behavioral change. Challenges also include the varied social and environmental determinants that affect behavior and access to prevention services and are likely to become more complex as broad phenomena such as population increase, growing economic disparity, and global warming continue to unfold and impact sexual networks and social and health structures. Finally, in societies in which so many resources are focused on curative medicine, "marketing" prevention to enhance societal commitment to full population coverage of prevention programs will be critical to achieve the full benefits of STD/HIV prevention.

91 Integration of HIV and STD Services

Matthew R. Golden and Allan Ronald

Although the need to integrate clinical and preventive services for HIV and other sexually transmitted diseases (STDs) is intuitive, in practice, health-care systems globally have often fragmented these services. In most developed nations, STD clinics have long played a central role in public health efforts to identify new cases of HIV[1–3] and have served as sentinel surveillance sites to monitor trends in HIV incidence and sexual risk behavior.[4–10] However, how to best counsel and test persons for HIV has been controversial, and little attention has been paid to the role of STD clinics in the ongoing care of persons with HIV infection. Although HIV prevalence is frequently high among STD clinic patients in developing nations, these clinics have not, to date, been regarded as a central component of most national HIV prevention plans. In both high- and low-income nations, HIV clinics have not consistently provided quality STI services, despite evidence that these infections are common in this setting and important biologic markers of risky behaviors.

Widespread acceptance of the idea that STDs other than HIV enhance HIV transmission,[11] and a new emphasis on directing prevention efforts toward persons already aware of their HIV infection[12,13] have prompted wider consideration of how to integrate STD and HIV services, and how to incorporate prevention into the care of persons with HIV wherever they are seen. In this chapter, we discuss the role of STD clinics in HIV diagnosis, medical care and prevention, and the integration of STD services into the ongoing activities of HIV clinics in both developed and developing nations, emphasizing the many areas in need of further study. The integration of preventive services other than STD care into HIV medical care is covered elsewhere in this text (Chapter 72).

INTEGRATION OF STD AND HIV SERVICES IN HIGH-INCOME NATIONS

■ INTEGRATING HIV CARE INTO STD CLINICS

STD clinics play an important role as centers for HIV testing and counseling in most developed nations. The prevalence of HIV among tested STD clinic attendees in the United States and Europe is typically 1–2% overall[14–16] but varies considerably by HIV risk. In a study of 52,260 STD clinic patients tested in 14 U.S. cities in 1997, 9.1% of men who have sex with men (MSM), 5.1% of injection drug users (IDUs), and 1.4% of non-IDU heterosexuals tested HIV positive.[16] HIV prevalence in European STD clinics is variable but somewhat higher overall. Among 128,602 STD clinic patients tested in 17 European nations between 1990 and 1996, 16.5% of MSM (range 2–53%), 28% of IDUs (range 0–80%), and 0.6% of non-IDU heterosexuals (range 0.01–3.9%) tested HIV positive[17]; HIV prevalence in this study declined over time.

Data on the proportion of all HIV tests and all new cases of HIV diagnosed through STD clinics are fragmentary and, at times, conflicting. A study evaluating the HIV testing experience of a probability sample of Americans found that 24% of tests were performed in public testing sites but that only 0.1% was performed in STD clinics.[18] This is somewhat at odds with CDC data that almost a quarter of all publicly financed testing occurs in STD clinics.[14] Regardless of the percentage of all tests that are performed in such clinics, it is clear that STD clinics diagnose large numbers of cases. In 1998, the last year for which national U.S. statistics are available, 25% of all cases of HIV diagnosed through publicly financed testing were diagnosed in STD clinics.[14] Estimating the percentage of all new cases in the population identified in STD clinics is more difficult. In King County, Washington in the United States, an estimated 35% of all HIV cases are diagnosed through publicly financed testing, and 20% of all newly reported cases are diagnosed in a single STD clinic (unpublished data). In the U.K., the majority of all HIV diagnoses are thought to occur in genitourinary medicine (GUM) clinics.[19] Between 1986 and 1994, 14% of all HIV cases diagnosed in Sweden originally tested HIV positive in an STD clinic.[20] Between 1995 and 2005, 14% of HIV cases diagnosed in British Columbia, Canada were diagnosed in STD clinics (personal communication, Paul Kim and Daphne Spencer).

Two main obstacles have impeded the optimal use of STD clinics as sites for HIV diagnosis: the low percentage of persons tested and large number of tested persons who do not receive

their HIV test results. A 1997 anonymous unlinked serosurvey of over 52,000 patients seen at U.S. STD clinics found that clinics tested a median of 58% of patients, and HIV seroprevalence was higher among persons not tested for HIV, even after excluding persons previously known to be HIV infected as documented in their medical records.[16] (Some persons previously diagnosed with HIV may not have informed evaluating clinicians of their HIV diagnosis.) Similarly, in the U.K., 55% of GUM clinic patients without a prior diagnosis of HIV were tested for HIV in 2003; almost half of HIV infected persons were not tested, and persons who sought evaluation for an acute STD were less likely to be HIV tested.[21] The problem of poor uptake of testing is compounded by the relatively high proportion of persons who test but do not learn their test results. In 1998, only 55% of all HIV-infected persons tested in U.S. STD clinics received their results.[14] Factors significantly associated with a higher risk of not returning for test results include younger age, African American race, seeking evaluation for symptoms of STD, and male gender.[22,23]

Recognition of these problems has prompted U.S. and U.K. public health authorities to advocate making HIV testing more routine. How to do this is uncertain. Explicit informed consent has been identified as a barrier to HIV testing acceptance,[24] and recent attention has focused on adopting more of an "opt out" approach to HIV testing in which patients would be told that testing was routine and no written consent would be required. Rapid HIV tests may also lead to more effective HIV testing. Patients prefer rapid HIV tests[25] that provide preliminary positive results in 20 minutes, and these tests clearly increase the proportion of all tested persons who receive their results.[26,27] A growing body of literature suggests that rapid tests may also increase testing acceptance. One study evaluating rapid tests found that 80% of STD clinic patients agreed to take such a test when offered, a number that is higher than traditional levels of testing acceptance, and a randomized trial that compared rapid tests to standard HIV testing found that rapid tests resulted in more eligible clients accepting testing and receiving HIV test results in gay men's bathhouses (16% vs. 9%, $p < .0001$) and in a needle exchange (7% vs. 3%, $p < .0001$).[28] Recently, investigators at the Denver STD clinic evaluated a new system of opt out testing coupled with routine use of rapid tests for all HIV testing. Compared to a historical control period during which written consent and standard serological testing were performed, the percentage of persons accepting HIV testing increased from 81% to 97% with no change in the percentage of persons testing HIV positive; while the number of new HIV diagnoses in MSM was relatively stable during the standard testing and rapid testing time periods (30 vs. 33 new cases), the number of new diagnoses in non-MSM increased substantially (9 vs. 17).[29]

There are also some potential downsides to rapid tests. The tests are somewhat more costly than standard HIV tests and probably add time to clinic visits, further increasing the cost of testing. In Denver, an effort was made to limit the amount of time added to visits by rapid testing procedures by having nonclinical staff initiate HIV testing on all patients before they were seen by clinicians. By eliminating the need for follow-up clinic visits or telephone calls to receive results, rapid tests may be cost saving in some settings, though insofar as most STD clinic patients have other laboratory tests performed that require follow-up to receive results, rapid tests probably save little in terms of follow-up in most STD clinics. There are also some downsides to rapids tests. Recent evidence suggests that at least some rapid tests may be less sensitive than 3rd generation enzyme immunoassays,[30] and weakly positive tests are sometimes false positives.[31] Rapid test may also involve some loss in counseling efficacy, at least in selected populations. Project Respect II, a randomized trial that compared rapid and standard HIV testing in 3297 STD clinic patients, found no significant difference in sexual risk behavior or in STD incidence between patients tested using rapid and standard tests at 6 and 12 month follow-up. However, among MSM, the group at highest risk for HIV infection, STD rates were higher in the rapid test group (21.8% vs. 11.8%, RR 1.86 95% CI 0.92–3.76). This finding was not statistically significant, was observed in a subgroup analysis of only 172 men, and merits future study. However, it raises concerns that among MSM, two-session client-centered counseling may be more effective than single session testing and counseling. More broadly, it also raises the issue of what counseling should be performed with HIV testing in STD clinics.

Project Respect I, a randomized trial that enrolled 5758 HIV-negative heterosexual STD clinic patients, compared HIV testing with pre- and posttest counseling involving either a didactic message or brief client-centered counseling. Persons in the client centered counseling arm experienced a lower incidence of STD over 6 months follow-up than those in the didactic counseling arm (7.3% vs. 10.4%, $p = .005$).[32] This study substantially defined CDC's HIV testing and counseling guidelines in the 1990s.[33] However, STD clinics were inconsistent in adopting the approach supported by the Project Respect findings, possibly because of the high cost such an approach might involve if applied to all patients.[34] Recent U.S. initiatives have de-emphasized counseling, placing greater weight on the benefits of simply ensuring that infected persons know their status.[12,13] To date, the intensity of HIV counseling in the United States has not varied based on patient risk, though a more flexible approach based on patient risk seems rationale and merits consideration.

Thus, while STD clinics are clearly important sites providing HIV testing, there are unanswered questions regarding how to best HIV test STD clinic patients. These include (1) how can clinics increase the proportion of all patients tested, (2) who should be tested using rapid tests, (3) how can we most efficiently counsel persons being tested for HIV, and (4) how can clinics selectively intensify counseling among those at greatest risk?

CARE OF PERSONS WITH PREVIOUSLY DIAGNOSED HIV IN STD CLINICS

Beginning in the early 1990s, studies began to draw attention to the occurrence of incident STD in HIV-infected persons who were already aware of their HIV serostatus. Initial reports in both the United States and Europe focused primarily on patients seen in STD clinics[35–39] and called for greater attention to the problem of ongoing risk among persons with HIV infection (Table 91-1). Several of these reports examined trends in the occurrence of STD among persons with HIV infection and documented a decline in STD incidence that paralleled the general decline in STD rates seen among MSM in the late 1980s and early 1990s.[41,42,54,63,64] However, since that time, studies from both the United States and Europe have reported rising rates of STDs among MSM, as well as increases in high-risk sexual behavior.[5,6,64–72] Prompted by the increased recognition that STDs can enhance HIV transmission and a community-level randomized trial showing that treating STDs can decrease HIV incidence,[11,73] in the 1990s CDC began to emphasize the control of STD as a means to prevent HIV transmission.[74] In 2001, CDC initiated a new HIV prevention program that explicitly emphasized the importance of individuals knowing their HIV serostatus and developing and instituting HIV prevention interventions among persons who are HIV-infected.[12]

SERVICES FOR HIV-INFECTED PERSONS IN STD CLINICS

Although STD clinics frequently treat persons with previously identified HIV infection, to date, little has been done to modify STD services and prevention counseling for such patients. The impact of STD clinics on HIV positives is uncertain, though public health program data from King County Washington provide some insight into at least one STD clinic's reach into the high-risk HIV-positive population. Clinicians in the Seattle-King County STD clinic evaluated 329 different MSM with previously diagnosed HIV in 2004. Forty-three percent of these men reported having unprotected anal intercourse with partners of unknown or discordant HIV status.[75] There are an estimated 40,000 MSM in King County, of whom 15%, or 6000, are HIV-infected. A 2003 random digit dial study of MSM in King County found that 15% of HIV-infected MSM had engaged in unprotected anal intercourse with a partner of unknown or discordant HIV status in the preceding year, or approximately 900 HIV-infected men.[76] Thus, in a single year, the STD clinic sees approximately 15% of MSM who are aware of their HIV status and potentially transmitting the virus to others. HIV-infected MSM seen in STD clinics have been successfully recruited into small research studies[77] but, to date, have not been actively enrolled into prevention programs. Developing interventions for this population is a high priority, as well as a relatively neglected area of research and public health practice. However, to the extent that King County estimates are accurate and generalizable, they also demonstrate that most high-risk MSM do not attend STD clinics.

STD SERVICES IN HIV CLINICS

Clearly, greater emphasis should be placed on incorporating STD care and prevention into the care of persons with HIV infection. Table 91-1 summarizes studies assessing the incidence and prevalence of STDs among HIV-infected persons. These studies suggest several conclusions that affect how STD services might be provided in HIV clinics. First, the incidence of STDs among some populations of persons with HIV is relatively high. This conclusion is supported by studies employing passive surveillance among HIV-infected STD clinic patients,[35–37,41,42] data from a multicenter surveillance analysis of persons receiving HIV care,[47] and studies in which women were serially tested for STDs.[49–53,56] Prospective studies of STD incidence with scheduled STD testing have not been performed in men. Second, in women, trichomoniasis is overwhelmingly the most common curable STD. Indeed, the incidence of bacterial STDs among women has been quite variable. Third, asymptomatic urethral infections in men are relatively uncommon and are usually present in <2% of men, including MSM. Fourth, the prevalence of asymptomatic cervical infections in women is highly variable, ranging from <2% to ~10%. Fifth, asymptomatic bacterial infections in the rectums of MSM are relatively common and are present in ~5% of men.

Table 91-2 presents a summary of the CDC, Infectious Disease Society of America, and U.S. Health Resources and Services Administration STD screening recommendations for persons with HIV infection.[78] UK guidelines also recommend annual screening for STDs among persons with HIV but are less explicit.[21] Additional recommendations related to STD prevention in HIV-infected persons are discussed in Chapter 71.

Although recommendations to screen HIV-infected persons for other STDs are now well established, the proportion of HIV-infected patients who actually receive recommended STD testing is not known, and how to institute existing recommendations is uncertain. Urine-based testing for genitourinary infections using nucleic acid amplification tests (NAATs) is relatively simply performed, whereas screening for rectal infections in MSM is more difficult. At present, chlamydial culture, the only FDA approved test to identify *Chlamydia trachomatis* in rectal specimens, is not widely available. Some investigators and public health programs have used NAATs on rectal specimens[61,79,80] but the operating characteristics of these tests on such specimens are not well established, and the tests are not FDA approved for use on rectal specimens, creating a substantial barrier to widespread compliance with existing recommendations.

Table 91-1. Studies Evaluating the Prevalence and Incidence of Bacterial STDs in Persons with HIV

Author (Year)	Population	Type of Follow-Up[a]	Study Years	Disease Incidence	Comment
Incidence studies					
Lee (1990)[35]	139 Kansas City STD clinic patients (92% men)	Passive	1988–89	13 (9%) developed gonorrhea and 6 (5%) nongonococcal urethritis	Incidence not calculated Subjects knowledge of HIV positivity uncertain
Zenilman (1992)[36]	615 Baltimore STD clinic patients (77% men)	Passive	1988–89	60 (9.7%) returned with gonorrhea, syphilis, or trichomonas	Incidence higher in men than women
Otten (1993)[37]	897 Miami STD clinic patients (72% men)	Passive	1987–89	Gonorrhea incidence 11/100 py	Excludes persons not seen in STD clinic prior to HIV diagnosis
Fennema (1995)[40]	59 Amsterdam female commercial sex workers	Active	1985–92	Gonorrhea—27/100 py trichomonas 66/100 py Early syphilis 5/100 py Chlamydia 12/100 py	
Osewe (1996)[41]	5615 persons diagnosed with HIV in a Miami STD clinic	Passive	1988–92	16% of persons diagnosed in 1988 and 2.4% of those diagnosed in 1992 returned within 1 y with a new STD or as contacts to an STD	
Golden (1996)[42]	1157 Baltimore STD clinic patients (75% men)	Passive	1988–1989 and 1991–93	77 (7%) were diagnosed with gonorrhea or syphilis during follow-up. Incidence STD 8.6/100 py 1988–89 and 2.3/100 py 1991–93	
Belongia (1997)[43]	2315 persons in Minnesota, USA	Passive	1983–94	30 (1.3%) of persons were reported with a new STD (gonorrhea, chlamydia, or syphilis) in a median of 3	Cases ascertained through matching of STD and HIV case registries Gonorrhea incidence 10 times the state's age adjusted incidence
Sorvillo (1998)[44]	212 women in an HIV clinic in Los Angeles, USA	Passive	1992–95	37 (17%) of women were diagnosed with trichomonas incidence 14/100 py	
Munoz-Perez (1998)[45]	1161 Spanish IDUs receiving HIV care	Active follow-up for symptoms but no routine testing	1993–96	STD diagnoses during follow-up: Syphilis (3.7%), gonorrhea (1.8%), trichomonas (0.3%)	Median or mean length of follow-up not reported
George (1998)[46]	132 STD clinic patients	Passive	1994–95	1 (1%) was seen with gonorrhea, chlamydia, or syphilis during 1 year follow-up

Table 91-2. CDC, IDSA, HRSA Guidelines for Integrating Prevention into the Care of HIV-Infected Patients

Risk Screening

STD symptoms–All visits

Sexual history– perform at initial visit and at least annually thereafter
- Any sex– vaginal, anal, oral
- Number of sex partners
- Partners' HIV status (infected, uninfected, unknown)
- Types of sex– vaginal, anal, oral
- Condom use
- Barriers to abstinence or condom use
- Desire to become pregnant

Injection drug use
- Any injection drug use
- Sharing of needles or other injection equipment
- Number of persons with whom patient has shared needles or other injection equipment
- HIV status of persons with whom patient shared needles or other injection equipment
- Use of new or sterilized injection equipment
- Barriers to ceasing illicit drug use or adopting safer injection practices

STD screening

Initial Screening Women
- All women: Trichomonas, RPR,
- Chlamydia–age ≤25 or "increased risk," consider in patients based on local epidemiology
- Gonorrhea–consider based on local epidemiology

Initial Screening Men
- All: RPR
- If patient reports receptive anal sex: rectal cultures for gonorrhea and chlamydial infection[a]
- If patient reports receptive oral sex: pharyngeal culture for gonorrhea
- Consider screening for urethral gonorrhea or chlamydial infection based on local epidemiology

Screening should be repeated at least annually

More frequent testing indicated in persons with any of the following risks:
1. Multiple or anonymous partners
2. History of STD
3. Identification of behaviors associated with transmission of HIV and other STD
4. Sex or needle sharing partners with any of the above 3 risks
5. Developmental changes in life that may lead to behavioral change with increased risky behaviors (e.g., dissolution of a relationship)
6. High prevalence of STDs in the area or in the patient population

[a]Some clinicians use nucleic acid amplification tests. Requires local laboratory validation.

Existing recommendations on STD screening in persons with HIV do not explicitly recommend testing for herpes simplex virus II (HSV-2). However, detection and treatment of HSV-2 may be particularly important in HIV-infected persons, both because of the high prevalence of coinfection and because of the multiple mechanisms by which HSV-2 facilitates HIV transmission. In most populations, 50% or more of persons with HIV infection are also infected with HSV-2.[81–84] HIV can be detected in herpetic lesions,[85] and the presence of recent genital ulcers has been associated with HIV transmission.[86] In addition to creating portals of exit (and entry) for HIV, HSV-2 appears to augment HIV replication, resulting in increases in plasma viral load by as much as 0.5 log copies/mL,[87,88] suggesting that HSV-2 may increase the transmissibility of HIV infections as well as progression of HIV disease. Chronic suppressive therapy with acyclovir or valacyclovir has been shown to decrease HSV-2 shedding and the occurrence of clinic outbreaks of HSV-2 in persons with HIV[89] and to decrease HSV-2 transmission in HIV-uninfected heterosexuals.[90] These findings suggest that routine screening for HSV-2 and chronic suppressive therapy for HSV-2 infected persons may be an effective means to decrease HIV transmission. Ongoing trials are testing this hypothesis. At present, routine serological screening and treatment is not promoted. However, some experts recommend that HSV type-specific serologies be offered to HIV-infected patients at their initial visit and that chronic suppressive therapy be considered for persons with HIV and HSV-2 coinfections[91] (see Appendix B) particularly in the context of frequent recurrences.

INTEGRATION OF HIV AND STD SERVICES IN RESOURCE CONSTRAINED COUNTRIES

Many of the barriers that limit STD and HIV integration in developed nations also affect developing nations. Health-care systems are fragmented and HIV testing has not been adequately routinized; persons with HIV experience high rates of other STDs that are inadequately addressed, and little has been done to integrate prevention into the ongoing medical care of persons with HIV or those at greatest risk for HIV.

The disease burden of STDs in developing countries is discussed in Chapter 101. Many publicly funded STD services in developing countries are chaotic, overloaded, and poorly supported.[92] The adverse, frequently delayed consequences of STDs are underappreciated and, in most countries, the formal response from government sectors for prevention and care has been inadequate. However, efforts to recognize the epidemiological synergies between other STDs and HIV infection[11,93] and to create shared prevention strategies to reduce sexual risk behaviors and introduce proven interventions are occurring.[94,95]

The specific role of STDs and STD treatment interventions in HIV transmission across HIV epidemic settings remains controversial.[96] In 2000, UNAIDS and WHO published the document *Consultation on STD Interventions for Preventing HIV: What Is the Evidence* as an outcome of a review of strategies for HIV prevention.[97] The consultation concluded that substantial scientific evidence supported the observation that controlling STDs reduces HIV incidence at the population level and recommended that STD management be an essential component of AIDS control programs. Subsequent reviews have explored the specific, significant roles of genital herpes and chancroid in augmenting HIV transmission.[98,99] However, the most recent UNAIDS HIV prevention monograph (2005) *Intensifying HIV Prevention* no longer identifies STD management as a specific intervention.[100] In July 2006, UNAIDS/WHO again convened an expert panel to examine these issues, particularly in the context of generalized epidemics such as those that now exist in much of sub-Saharan Africa. The report emphasized that the contribution of STDs to HIV transmission is likely to remain significant across epidemic phases, but that the relative contribution of specific STDs usually changes because the curable, bacterial STDs that are more common in concentrated epidemics are often replaced by currently incurable, viral STDs such as HSV-2 as HIV epidemics become generalized.[101] The recommendations also highlighted the importance of STD services as an entry point for early identification of HIV-infected and at-risk individuals and the risks of resurgence of STDs if STD services are cut back in settings in which they have successfully controlled these diseases.

INTEGRATING HIV CARE INTO STD CLINICS

STD services and resources in resource-limited societies can be broadly categorized as (a) syndromic management and care programs; (b) screening programs; (c) prevention programs; and (d) laboratory support services. Model programs are described in the literature.[94,102] Unfortunately, in 2006, few have been brought to scale and in most countries, there is little integration with HIV services. Currently, individuals with symptomatic STDs receive care from shopkeepers, pharmacies, the private health sector, and occasionally from public clinics.[79,103–112] The proportion of persons with STDs who receive care through public STD clinics is variable but in most low-income countries it is probably very low.[106–108] For example, a survey conducted in Accra, Ghana in the 1990s found that in 1 year governmental clinics treated 2000 cases of STD, while the city's pharmacies treated an estimated 90,000 cases.[104] The high cost of medical care prompts many patients to seek care outside of the formal health sector, and patients frequently seek care in the formal health-care sector only after treatment with medications obtained through other means are unsuccessful.[110,112–114] In many regions of the

world, the public sector is perceived negatively by at-risk populations for a wide variety of reasons including inferior, often stigmatizing services, inadequate drug supplies, and fear about lack of confidentiality.[103] As a result, few individuals choose these services unless no alternative exists. However, this perception is not consistently accurate. In Kenya, investigators used simulated patients to test the quality of care in several settings and determined STD case management adhered to preset criteria more often in the public setting compared to other venues.[102] Moreover, numerous studies have documented poor adherence with national STD guidelines among private sector clinicians, as well as pharmacy workers.[105,107,111] With the rapid implementation of HIV care programs, a multibillion dollar investment is occurring (2004–2008) throughout much of the resource-constrained world in both public and nongovernmental sectors to enable HIV-infected individuals to access care and other services within their communities. This includes investments in capital projects, human resources, drugs, and prevention strategies. Opportunities to achieve prevention and care synergies with STD services are obvious if these are complementary to HIV prevention and care.

An STD service delivery center, whether in a caregiver's office, a nursing station, or a public health clinic should provide (a) trained personnel with knowledge about STD care and prevention; (b) counseling services, including provision of condoms with clear, client-centered interaction about their use; (c) essential drugs, particularly antiinfectives; and (d) some laboratory services. In addition, the capability to perform a complete physical exam to search for STD clinical signs remote from the genitalia and a facility to perform pelvic exams with visualization of the cervix should be a part of all STD services. Unfortunately, most STD care sites do not currently fulfill several, if not most, of these "minimal" requirements, and integrating HIV care into an inadequately resourced and managed clinic may only make services more ineffective.

Table 91-3 summarizes the prevalence of HIV among persons accessing care in various developing country settings for a variety of reasons, but largely due to perceived STD symptoms or serological surveys.[115–121] The opportunity to counsel, screen for HIV, facilitate entry into HIV/AIDS care programs, and mitigate the societal consequences of HIV are obvious. A huge, often undiagnosed, burden of HIV infection exists in the population of patients seeking care for other STDs in most of the resource constrained world. STD patients should be routinely offered screening for HIV infection with the option to decline. This does not occur in most STD clinics due to policies restricting testing, limited counseling services, lack of laboratory resources, and the reticence of caregivers to create a conducive environment where most clients would choose to be tested for HIV.[103] Limited investigation supports the thesis that a significant majority of individuals offered HIV counseling and testing would accept an HIV test.[125] In some STD clinics in Africa, 50% or more of the patients are HIV-infected. Without testing, they remain unaware of their status and present for HIV care with advanced disease, often just prior to death. Screening, counseling, and support for HIV-infected individuals in STD clinic settings would be cost-effective in reducing expensive, often fatal AIDS-related infections, reduce the probability of transmission of HIV (and perhaps tuberculosis) to regular and casual contacts, and possibly identify individuals during their acute HIV infection, when multiple partners may be common and transmission is particularly frequent.[126] Rapid test technologies could ensure that individuals learn of their HIV test results during the screening clinic visit, make it more "user" friendly, and reduce the requirement for clients to return for follow-up[27]—often a barrier in rural areas in developing countries. Moreover, some individuals in STD clinic settings are aware of their HIV status but have acquired an STD. Counseling in this setting can reinforce the HIV prevention message.

STD clinics can also be useful as sentinel sites for tracking HIV prevalence in high-risk populations, or in identifying "hot spots" for HIV transmission where intensified prevention activities could be provided. Commonly transmitted STI pathogens such as *Neisseria gonorrhoeae, C. trachomatis, Trichomonas vaginalis,* and *Treponema pallidum* can predict where communities and/or individuals are at increased risk of HIV transmission and prevention programs can be scaled up and made more effective at these sites.

While integrating HIV testing into STD clinics is an important goal, because these clinics typically see so few patients, they are likely to play a limited role in voluntary counseling and testing (VCT) programs in most developing nations unless their number and capacity is greatly expanded. Other sources of reproductive health services in most developing countries have traditionally not offered HIV counseling or care services. However, family planning clinics could become efficient vehicles for integrated services for the diagnosis, care, and prevention of STDs, including HIV infection. "One stop" demonstration models are needed for delivery of integrated reproductive health services that attract men to share in the responsibilities of family planning, promote sexual health, facilitate STD screening, and encourage HIV VCT[127] In addition, innovative efforts to integrate VCT, perhaps using self-testing kits, into care within the informal health-care system, such as pharmacies, merit consideration.

Both HIV and other STDs are embedded within a social milieu that fosters the spread of infection. As a result, ideally, prevention efforts would address factors such as gender equity and violence against women, sexual coercion and abuse, poverty and illiteracy, legal rights, and cultural practices. The efficacy of public health campaigns to address these problems is uncertain, and, even if successful, change in many of these areas is likely to require one or more generations. However, some interventions specifically designed to reduce HIV and

Table 91-3. Incidence and/or Prevalence of HIV in STD Settings or of Other STDs Among HIV-Infected Populations in Resource-Constrained Countries

Author (Year)	Population/Site	Study Years	Disease Prevalence/Incidence	Comments
Mehendale (1996)[122]	Two STD clinics in Pune, India 5321 attendees	1993–1995	HIV prevalence in women 32.3%, in men 19.3% Overall HIV incidence 10.2% annually	90% of men were contacts of sex workers
Wilkinson (1998)[123]	360 STD patients at Hlabisa Hospital in rural South Africa	1997	42.5% HIV prevalence	Rural clinics
Fonck (2000)[124]	520 female STD clinic attendees	1998	HIV prevalence 29% *N. gonorrhoeae* 6% *C. trachomatis* 4% syphilis 4%	Most women were at low risk for STDs; only 11% had multiple partners
Eis-Hubinger (2002)[116]	161 in STD clinic in Douala, Cameroon	1998	17.4% HIV-positive	HSV-2 higher in HIV-positive patients (85.2% vs. 64.1%)
Connolly (2002)[117]	77 female sex workers, all HIV-positive	1996–1999	Incidence: *N. gonorrhoeae* 66/100 py *C. trachomatis* 30/100 py *T. vaginalis* 150/100 py	
Msuya (2003)[118]	382 females, 3 PHC's in Moshi, Tanzania	1999	HIV prevalence 11.1%	HSV-2 highest in HIV-positive 61.4% vs. 36.1%
Joesoef (2003)[119]	STD clinics: 15,889 patients in several cities in Kenya	1990–2001	HIV 16% 1990; 41.8% 1997	
Kaul (2004)[120]	466 HIV-negative female sex workers in a Nairobi slum	1998–2002	HIV incidence 3.6/100 py	HSV-2 (prevalence 72.7%) predicted HIV-1 incident infections (RR 6.3)
McClelland (2005)[121]	1215 female sex workers in Mombassa, Kenya	1993–2003	HIV infection increased incidence by a hazard ratio (HR) for *N. gonorrhoeae* 1.6, for genital ulcer disease 2.8, and for vulvovaginal candidiasis 1.5	
Reynolds (2006)[115]	2732 HIV seronegative at 4 clinics in Pune, India	1993–2000	HIV incidence 5.8/100 py Syphilis 5.4/100 py	Adjusted hazard ratio for HIV infection with "incident" syphilis was 4.44

other STDs have been spectacularly effective at the country level. Success has occurred with condom promotion for risky sex in the Thai military, behavioral modification including delay in sexual debut and fewer lifetime partners in Uganda and Zimbabwe, and risk reduction among sex workers in Kenya.[128–132] These prevention activities have markedly reduced several STDs in populations where they have been measured. Synergies among these interventions occur, and together, they may reduce the incidence of STDs, including HIV, within regions and even countries, if applied consistently. In particular, HIV prevention programs should assist sex workers in reducing their incidence of all STDs; obtaining skills and counseling to leave sex work when possible; and, if sex work continues, reducing transmission risks to their partners. Such programs have been shown to reduce the prevalence and incidence of all STDs including HIV.[130,131]

INTEGRATING STI SERVICES IN HIV PREVENTION AND CARE SETTINGS

As in high-income nations, the need to integrate STD services into the care of persons with HIV is justified both by the increased risk of STDs among persons with HIV and the role the STDs may play in enhancing HIV transmission.[121,133,134] While relatively few data are available on the incidence of other STDs in persons with HIV infection in low-income nations, a study conducted in Pune, India found that persons with HIV experienced a much higher incidence of syphilis than HIV-uninfected persons, with an adjusted hazard ratio of 4.44.[115] Studies conducted among men in Malawi have shown that both genital ulcer disease, primarily chancroid and herpes, and urethritis are associated with elevated levels of HIV in semen, suggesting an increased probability of HIV transmission.[135] Preventing, diagnosing, and treating STDs are of particular importance in the setting of HIV care. However, screening programs for STDs do not generally occur in HIV care settings in most resource-poor areas. The consequences were highlighted in a recent study from Haiti, where the failure to screen HIV-infected pregnant mothers for syphilis led to infants dying of congenital syphilis despite adherence to a complex intervention to prevent HIV transmission.[136] Prenatal syphilis screening must be employed alongside HIV screening.[137] Of particular note, oncogenic HPV types are more persistent and invasive in HIV-infected patients, and cervical screening cytology programs should ideally be routine to prevent invasive cervical cancer.[138] Failure to assess sexual risks, screen for and treat STDs, initiate partner notification where necessary, and counsel patients should, perhaps, be viewed as a form of negligence in the HIV clinic setting in both resource-limited countries and industrialized nations.

Monitoring the occurrence of STDs among persons receiving care for HIV may also be useful for program evaluation and surveillance purposes. Common STDs detected during clinical care or through screening can be viewed as biologic surrogates for potential HIV transmission and, though imperfect, can be used to validate behavioral outcomes measured to assess interventions designed to reduce HIV transmission. With behavioral surveys, the veracity of the results is dependent on subjective responses. In particular, with the concern about disinhibition in patients treated with antiretroviral drugs, objective parameters become critical for program evaluation.[139]

Syndromic therapy for symptomatic STDs has been promoted as the "practice standard" by WHO for two decades and adopted in most countries. Essential drug programs include the specific antimicrobial agents needed and public programs have often provided them. Most symptomatic STDS in HIV-infected populations present with similar or more flagrant symptoms and signs compared with those seen in HIV-negative patients, though standard syndromic management is generally effective even in immunocompromised patients. As a result, caregivers can usually treat STDs without reference to their HIV serostatus. Herpes simplex virus 2 (HSV-2) is an exception. The severity, prevalence, and recurrence likelihood together have made this pathogen the major STD challenge in HIV clinics. Acyclovir is not on most countries' essential drug list in 2007, and substantial, often prolonged, distress due to extensive ulceration experienced by a large proportion of HIV-infected patients. The growing evidence that HSV-2 is a major risk factor for HIV transmission, perhaps increasing both infectiousness and susceptibility,[99] coupled with the clinical importance of the infection and evidence suggesting HSV may increase viral load mandates that national STD programs respond rapidly and integrate HSV-2 management into HIV clinics. No studies conducted in the developing world have looked at the health-seeking behaviors of HIV-infected individuals with STD syndromes, and additional research is required to determine what health education and promotion practices would increase the uptake of STD services, if such services were offered at HIV care clinics.

POLICY AND PROGRAM INTEGRATION

Regardless of whether they are implemented by governments, schools, NGOs, or workplace sites, HIV and STD prevention policies and activities should be linked throughout the health care and education systems in both wealthy and resource constrained societies. Evaluation activities should further the goals of program integration. Sexual and reproductive health, due to their inherent importance to all societies, are issues that have an audience in every setting. The desire to prevent HIV that is now evident globally can be further enhanced with individual and societal consensus that STDs are serious and "worth avoiding." Important health issues such as infertility, ectopic pregnancy, the risks of STD

transmission to infants, and the consequences of "sexual ill health" should be combined with the better known adverse consequences of HIV infection. Health promotion activities can be carried out jointly and, when appropriate, combined with family planning, prenatal, postpartum, school, workplace, and other programs to create a continuum of consistent messages that impact on the individual. Increased awareness of these illnesses should allow effective communications to be presented through a variety of media and health promotion outlets. Moreover, cultural practices such as vaginal douching, the absence of male circumcision, early female sexual debut, concurrent partnerships, and sex work increase the incidence not only of HIV infection but also other STDs.[139] Prevention synergies can occur if policies are aligned with effective promotion of sexual and reproductive health. Sustained effective advocacy led by the multinational agencies is essential for this is to occur. Organizational changes may be necessary to ensure that STD programming is integrated bidirectionally with HIV prevention and care. Model programs, disease burden studies, and observational and controlled intervention trials are needed, but societies must proceed with program implementation without waiting for additional scientific evidence of effectiveness. Current scientific evidence must be translated into action plans that will dramatically reduce the burden of all STDs, including HIV.

92 STD-Related Health-Care Seeking and Health Service Delivery

Sevgi O. Aral, Matthew Hogben, and Judith N. Wasserheit

INTRODUCTION

Timely treatment of sexually transmitted diseases (STDs) and HIV infection plays a central role in the prevention of sequelae of STD/HIV and in limiting their spread. Treatment constitutes primary prevention of that STD for other members of the population and secondary prevention of complications for infected individuals. To the extent that the encounter between infected individuals and the health-care system delivers effective primary prevention messages, STD/HIV treatment may also constitute primary prevention of repeat infections with the same organism, or future infections with other sexually transmitted organisms, for the infected individual him/herself.

Three large categories of social and behavioral factors contribute to the timely treatment of STD/HIV. These are health-care seeking behaviors of members of the population, behaviors of STD/HIV health-care providers, and the organization of STD/HIV-related health service delivery. Each of these three components can be conceptualized at both the individual and the population levels, and is influenced by and, in turn, influences factors at both levels.

This chapter summarizes conceptual frameworks applicable to STD/HIV-related health-care seeking, the provision of STD/HIV services, and the behaviors of health-care providers. It proposes an STD/HIV-specific conceptual framework based on integration and adaptation of the general conceptual models, through the consideration of selected additional factors that are specific to STDs or HIV infection. These factors include characteristics of the STDs and the populations affected by them; phase of the particular STD/HIV epidemic; the detection strategies and technologies employed; the therapeutic regimens and sex partner management approaches utilized; characteristics of providers who see STD/HIV patients (e.g., their skill levels); and the health system (e.g., availability, accessibility and acceptability of services, the availability of patient management guidelines, and the extent to which compliance with such guidelines is assured).

Research findings relevant to STD/HIV-related health-care seeking, behaviors of STD/HIV care providers, and organization of STD/HIV services are summarized in separate sections. The conclusion discusses implications of current conceptual frameworks and empirical findings for future directions in STD/HIV research and prevention efforts.

The underlying integrating focus is provided by the health outcome of interest, which is defined as the timely and appropriate treatment of individuals infected with sexually transmitted pathogens to achieve cure of bacterial and parasitic STDs, and suppression of incurable viral STDs, including HIV. Cure of bacterial or parasitic STDs stops symptoms and infectiousness, and prevents complications. Suppression of incurable viral STDs, in general, decreases severity of symptoms and viral shedding (thereby decreasing infectiousness), and may slow disease progression. Both cure of bacterial STDs and suppression of incurable viral STDs decrease duration of infectiousness, which slows the rate of transmission in the population. To the extent that infection with some STDs increases infectiousness of and susceptibility for other STDs, a decrease in the duration of infectiousness with one STD will also decrease the transmissibility (and therefore the rate of spread) of other STDs and sequelae such as PID. Recent data suggest that PID has in fact diminished in conjunction with decreases in chlamydial and gonococcal infections among women.

A final theme in this chapter is interaction among concepts and variables. With respect to STDs/HIV, if suppression is incomplete, as is the case for HAART, treatment interacts with both infectiousness and duration, decreasing the former but potentially *increasing* the latter. Current modeling research suggests duration or infectiousness may predominate, depending on the nature and epidemiology of the disease.

Interaction of variables in the epidemiologic equation is reflected in the potential for interaction among the various levels of health-care seeking and service delivery with one another. During a single episode of disease, the levels function in a given order, with an individual's recognition or suspicion of infection followed by some probability of health-care seeking,

then some probability of service provision, and so forth. But the type of service provision experienced on one occasion may affect the likelihood of health-care seeking on the next.

CONCEPTUAL FRAMEWORK

Several theoretical approaches have dealt with the issues of health service utilization and health-care seeking, in general, at both the population and individual levels of analysis. These are helpful in understanding STD/HIV-related health-care seeking and provision.

POPULATION LEVEL, GENERAL CONCEPTUAL MODELS

At the population level, two general conceptual models that deal with implications of health policy decisions in health service utilization are relevant. McKinlay's Major Approaches to Characterizing Predictors of Health Services Utilization is an inductively constructed model based on integration of research findings.[1] The Behavioral Model of Health Services Utilization is a systems model originally formulated by Ronald Andersen in 1968 and further developed by Aday, Andersen, and other colleagues between 1974 and 1987.[2,3]

According to McKinlay, the six approaches to health service utilization are the demographic; social structural; social psychological; economic; organizational; and systems approaches.[1] The demographic approach focuses on age, sex, marital status, family size, and residence as predictors; the social structural approach emphasizes social class, ethnicity, education, and occupation; the social psychological approach considers health beliefs, values, attitudes, norms, and culture; the economic approach covers family income, insurance coverage, price of services, and provider–population ratios; the organizational approach looks at the organization of physicians practices, referral patterns, and regular source of care. The systems approach adopted by McKinlay includes all or most of the predictors mentioned in the context of a set of relationships. Interactions among the levels are evident in research employing this model; for example, the interaction of physician and patient attributes in diagnosis of depression.[4]

The Behavioral Model of Health Services Utilization[2,3] assumes that health policy decisions, whether they deal with issues of financing or organization, will have an effect on utilization of health services, consumer satisfaction, and the characteristics of both the population at risk and the health delivery systems, which, in turn, affect each other.[5] The characteristics of the population, including demographic, social structural, and belief variables, are predisposing factors that describe the propensity of individuals to use services. The means individuals have available to them to use services, such as income and insurance are enabling factors. Finally, health status, or need for health services is a key determinant of utilization in this model. These factors may be alterable by health policy (mutable), or by biological or social givens, not open to alteration by health policy (immutable).

This model has been applied to evaluate whether services are equitably distributed.[6] To the extent that differences in utilization are explained by need variables and demographic correlates of need such as age or sex, differential distribution of services is considered equitable. If other factors such as income or insurance coverage are the most important predictors of who-gets-care, then the system is considered to be inequitable.

Applications of this model have shown that, of the population characteristics, age is curvilinearly related to health service utilization, with the young and the old having higher utilization than those in the middle.[6] Utilization is also higher among women than men and among those in poor health than in good health. Some inequities exist: utilization is higher among whites than nonwhites (although the gap is narrow to nonexistent for reproductive health care among adolescents by race[7]); among whites and nonwhites than Hispanics; among those living in metropolitan and urban areas than those living outside metropolitan areas and in rural areas.

Education and income are related to health service utilization in more complex ways. People with higher education tend to utilize preventive services more than those with less education, whereas people with less education have higher rates of hospitalization. Prior to Medicare and Medicaid, persons with greater income tended to utilize health services to a greater extent; however, following the enactment of Medicare and Medicaid, lower income persons have started using certain health services at higher rates than persons with high incomes.

Focusing on the characteristics of the health-care delivery system, regular source of medical care consistently emerges as a strong, consistent predictor of health service utilization, particularly the utilization of preventive services. Moreover, the directionality of this association has been explored and availability of regular source of medical care appears to have a direct and causally prior impact on health services utilization.[6]

INDIVIDUAL-LEVEL, GENERAL CONCEPTUAL MODELS

At the individual level, there are at least four conceptual models of patient decision making regarding health-care seeking. One of these is Suchman's sociological five-stage decision-making model that focuses on an illness episode and describes the stages of decision making as experience of symptoms; assumption of the sick role; establishment of contact with medical care; assumption of the dependent patient role; and recovery and rehabilitation.[8] According to Suchman's model, persons with traditional, parochial affiliations, and a popular orientation to medical care would tend to delay assuming the sick role and seeking medical care, and would not comply with therapeutic recommendations.[8–10]

Kosa and Robertson's psychological stage model of patient decision making describes four stages, including assessment of disturbance; anxiety arousal; application of the person's own medical knowledge to address the problem; and an attempt to alleviate anxiety either through rational therapeutic activities or through gratifying activities that facilitate denial.[11] Later, Folkman and Lazarus described problem-focused and emotion-focused stress responses as general coping mechanisms applied to health behaviors.[12]

A third conceptual model of patient decision making was developed by David Mechanic.[13] According to this model, the social and psychological factors that affect perception of need to seek care are symptom recognizability; perceived seriousness of symptoms; the extent to which symptoms disrupt regular activity; the frequency, persistence, and recurrence of symptoms; the tolerance level of persons evaluating the symptoms; the information, knowledge, and cultural assumptions of the evaluator; basic needs that lead to denial; needs that compete with illness responses; competing interpretations for symptoms; and finally the availability of care and financial and psychological costs of taking action, including issues of stigma, social distance, and humiliation.[13]

The fourth conceptual model that has focused on patient decision making regarding health-care seeking is Marshall Becker's health belief model.[14] This model focused on the individual's subjective state of readiness based on perceptions of susceptibility and severity of consequences of illness; the individual's evaluation of the costs and benefits of seeking care; and a cue to action that may be "internal" (e.g., symptoms) or "external" (e.g., coverage of the issue in the mass media). These models are all visible in a summarizing principle posited by Fisher and Fisher; that health-related behavior is a function of both information and motivation.[15]

Such conceptual work focusing on individual level factors that affect health-care seeking behaviors has also viewed health-care seeking along continuous dimensions. These recent approaches focus on delays in seeking care. Such conceptualization represents a departure from earlier models, discussed above, which have constructed health-care seeking as a dichotomous variable measuring a decision either to seek or not seek health care. Recent conceptual work has also concentrated on integrating independently conceived approaches. Predicting health behavior at the individual level relies on three cardinal elements: intentions (reflecting motivations), suitable skills, and lack of environmental constraints.[16] Subsidiary considerations include beliefs about prevailing social norms, net positive outcomes, and one's own abilities.

The logical application of analyzing dimensions rather than categories is to focus on delays in seeking care rather than seeking versus not seeking. One recent model proposes that appraisal of whether an unusual bodily condition is, indeed, a symptom typically accounts for the major portion of the delay in seeking care.[17] Expectations lengthen this period of appraisal in various ways, including the attribution of the cause of the condition to factors in the environmental context; an unrealistic optimism regarding the risk of contracting disease (optimistic bias); denial that a threat exists; and biased monitoring of bodily changes.[18–20] In addition, "lay theories of disease" also contribute to delays in seeking care.[21]

One recent STD-specific conceptualization, recognizing that the process of problem identification differs from the process of resolving barriers to seeking care, used the timing of the decision to seek care to distinguish two intervals: an "appraisal interval" defined as the time between recognition of a problem and the decision to seek clinical care, and a "procrastination interval" defined by the interval between the decision to seek care and actual care.[22] As would be expected, factors that influence the appraisal interval are different from the factors that influence the procrastination interval. That these factors differ illustrates the interactive nature of individual level and system-level approaches. For example, increased skills building at the individual level can be mirrored by system-level interventions that make it easier for to seek health (e.g., increased health-care seeking by HIV-positive patients exposed to active case management versus passive referrals[23]). Health-care seeking and health-care provision are thus two interacting concepts affecting the same health outcomes.

At the health-systems level, how care is organized and financed has a great impact on both health-care seeking behaviors and health-care providers' behaviors. The most immediate operational indicators for the individual patient of how care is organized and financed are whether one has a regular source of care and insurance coverage, and the particular type of care and coverage. Currently, in the United States, these factors remain in flux as they relate to STD care. Persons falling within the age ranges with greatest prevalence of many STD (e.g., 19 to 24-year-olds) are among those least likely to have consistent insurance.[24,25]

PERSON-TIME OF INFECTIOUSNESS (PTI): A BEHAVIORAL MODEL IN A SYSTEM CONTEXT

The conceptual model being proposed here has several important characteristics. First, the outcome being focused on is a health outcome rather than a behavioral outcome. Second, the health outcome of interest here is jointly determined by factors at the individual, population (or societal), and health-system levels, and the interactions among these factors. Third, this health outcome itself is influenced by the behaviors of infected individuals and providers, and properties of the health system.

As mentioned earlier, the health outcome of interest is the timely and appropriate treatment of individuals infected with sexually transmitted pathogens to achieve the cure of bacterial

and parasitic STDs and suppression of incurable viral STDs. This particular health outcome translates into the product of duration of infectiousness (D) and efficiency of transmission (β), two of the three determinants of the reproductive rate in infectious disease transmission dynamics.[26,27] Even if suppression is not total, such that β does not fall to zero and D may actually increase, the health outcome should be such that the product of β and D over a given period of time lowers the reproductive number relative to the product for an untreated STD. In cases with effective antimicrobial therapies, β does fall rapidly to zero, making duration of infectiousness the key parameter to consider in elucidating STD-related health-care seeking and health service delivery.

The timely and appropriate treatment of STDs is a function of four basic detection and treatment components (11 subcomponents) and one additional prevention component. These components may be viewed both in terms of the proportion of the infected population that never successfully complete the component (percent of individuals experiencing delay) *and* the time spent in each component by those who are able to move to the next one (duration of infectiousness) (Fig. 92-1). Although in the final analysis, both types of concepts are reducible to the single measurement of "infectious person days" or "person days of infectiousness" (referred to as person time of infectiousness [PTI]), conceptually differentiating between proportions of the population who never complete a component, and the time it takes to complete the component for those who do, facilitates the identification of individual, population, and system level factors and the behaviors of infected individuals and providers that influence the components and the outcome of interest. The four components of the model follow.

Component I: lost to detection and resolution of infectiousness

This component refers to the proportion of infected individuals (both symptomatic and asymptomatic) who never receive treatment. It translates into PTI terms as the time elapsed from infection to resolution of infectiousness (if applicable) as determined purely by biological dynamics between the pathogen and the host. It includes symptomatic individuals who never seek health care, symptomatic or asymptomatic infected individuals who are not detected through testing, and symptomatic or asymptomatic individuals who are not brought to treatment through partner notification. Individuals may not be brought to treatment because they are never detected or because they are lost to follow up during components III or IV.

Component II: health-care seeking delays

This component focuses on time elapsed from infection to initial contact with the health-care provider who makes the

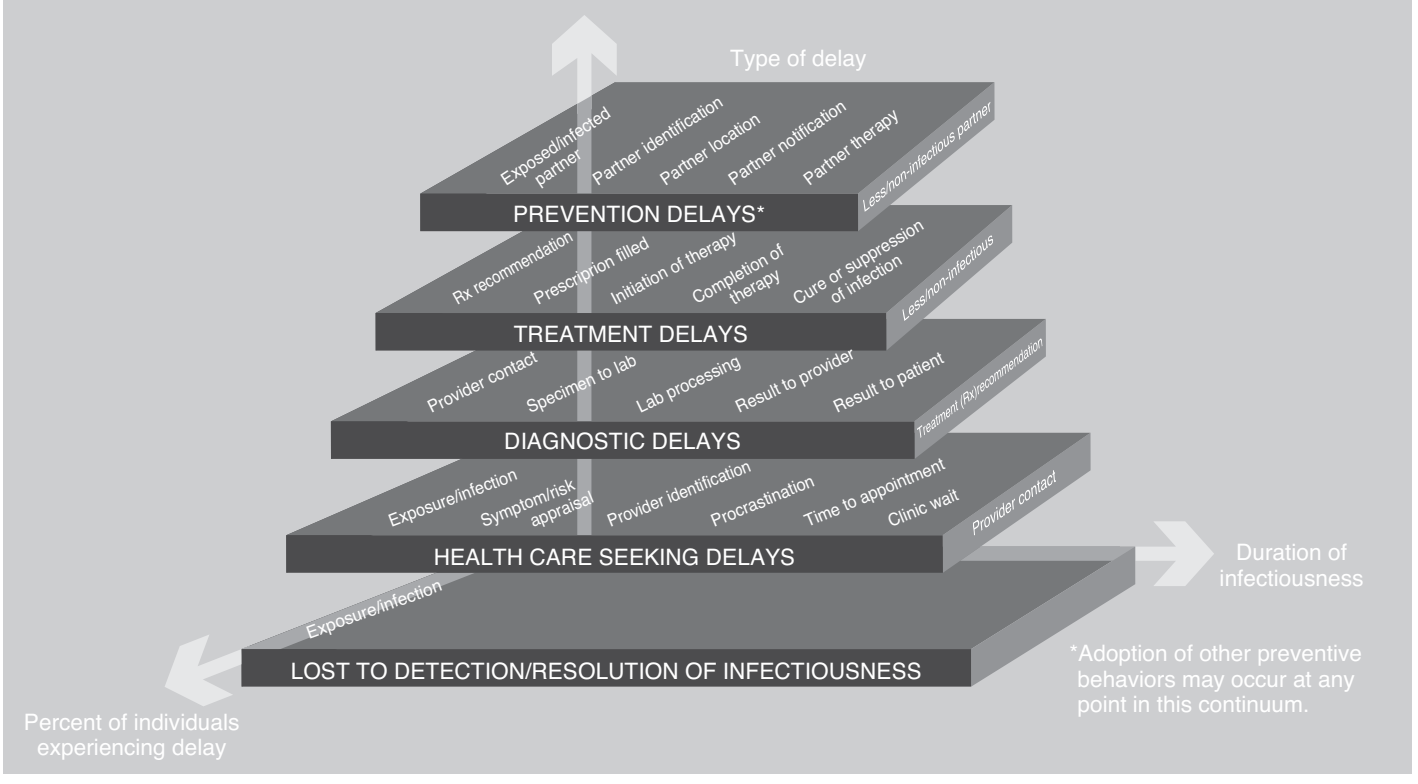

FIGURE 92-1. The person–time of infectious model.

diagnosis and recommends therapy. It is composed of five subcomponents: (1) Time elapsed in symptom or risk appraisal, during which the individual attempts to interpret symptoms, often by gathering additional information regarding the symptoms and their significance. Individuals may wait and see if the symptoms resolve on their own or they may attempt to treat themselves during this period. Asymptomatic individuals who suspect exposure may gather information regarding their potential risk of infection and wait to see if symptoms occur. (2) Time elapsed from decision that symptoms (or risk of exposure) require attention from a health-care provider to decision regarding where to seek care, often involving information gathering regarding types of providers and accessible service sites. (3) Time elapsed from decision to seek care from a specific provider or clinic to making the call or the visit to make the appointment, referred to as the procrastination period. (4) Time elapsed from making the appointment until the time of the appointment, which may range from minutes to days or weeks depending, often, on the health-care provider and system. (5) Time elapsed from arriving at the health-care facility to initial contact with the provider, which generally would not be longer than a few hours.

Component III: diagnostic delays

Time elapsed from initial contact with the health-care provider to communication of a diagnosis to the patient constitutes this component. It is conceptually composed of two subcomponents: time elapsed from initial contact with provider to diagnosis; and time elapsed from diagnosis to the provider's presentation of that diagnosis to the patient. In some circumstances, these subcomponents entail time elapsed to establishment of a laboratory diagnosis, followed by time elapsed from test result to the infected individual's return to the health facility to receive the test result. The first subcomponent includes the time it takes to send the specimen to the laboratory, the laboratory processing of the specimen, and the communication of the test result to the provider.

In other circumstances, providers may rely on clinical diagnosis based on signs and symptoms, reducing time elapsed for each subcomponent substantially. Availability of rapid tests on site can have the same effect. On the other hand presumptive treatment and clinical diagnosis may lead to coinfections being missed or misdiagnosed. Although a laboratory test will only reveal those infections for which tests are run, a negative test provides diagnostic information not available to providers relying on clinical diagnosis alone.

Component IV: treatment delays

This component consists of time elapsed from therapy recommendation to cure of bacterial and parasitic infections and suppression of viral infections. It is composed of four subcomponents: (1) Time elapsed from the infected individual receiving the therapy recommendation to filling the prescription. (2) Time elapsed from the individual filling the prescription to actually starting the medication. (3) Time elapsed from initiation of therapy to completion of therapy. (4) Time elapsed from completion of therapy to actual cure or suppression. In some cases cure or suppression may occur prior to completion of therapy; however, data on the frequency of this occurrence are scarce. Some light is shed through study of incomplete adherence to multidose therapy regimens. One study observed therapeutic effects, even for partial completion of doxycycline regimens for chlamydial infection.[28] As such results may not generalize to other therapies and STD, multidose regimens nevertheless pose problems in that individuals may not complete the recommended course. On the other hand, single dose, directly observed therapy may also pose problems in that individuals may assume they are cured instantaneously and may resume sexual activity while still infectious.

Component V: prevention delays

An additional, post-PTI component in the model, referred to as *prevention delays*, includes time elapsed to the treatment of partners and adoption of preventive behaviors to prevent reinfection and infection with other sexually transmitted pathogens.

FACTORS THAT INFLUENCE PERSON-TIME OF INFECTIOUSNESS

A certain proportion of individuals infected with sexually transmitted pathogens are never identified as cases and are never treated (component I, Fig. 92-1). Properties of the pathogen and host, health seeking behaviors of the infected individuals, behaviors of providers, health system, and societal parameters all contribute to this component (Table 92-1). Some STDs tend to be more frequently asymptomatic compared to others. For example, only one out of ten individuals who had serologic evidence of infection with herpes simplex virus Type 2 reported ever having had genital herpes.[29] The odds of whether or not a particular infection is symptomatic also vary by gender. Many STDs tend to be more frequently asymptomatic among women than men. Persons with asymptomatic infections do not have a reason for seeking STD-specific health care, and some evidence suggests that asymptomatic persons and those with short symptom duration are less likely than others to seek care.[30] However, symptomatic persons are not always more likely than others to seek treatment, even when they suspect they are infected,[22,31] especially if they lack appropriate skills and believe the net outcome of care-seeking will be negative.[16]

Table 92-1. Factors Influencing PTI: Lost to Detection

Properties of the pathogen and host	Proportions symptomatic; proportions with signs
Individual behavior parameters	Gender, risk recognition, symptom recognition, symptom description, extent of routine contact with health care
Provider behavior parameters	Risk assessment practices, screening practices, counseling practices, PN practices, compliance with programmatic and diagnostic guidelines
Health system parameters	Existence and quality of guidelines on risk asssessment, screening, counseling, PN and diagnosis; existence and quality of STD health-education/health promotion programs; extent of reinforcement for provider compliance with existing guidelines; extent and quality of provider training, cost of care
Societal parameters	Level of education, level of overall health, available diagnostic technologies, availability, acceptability, accessibility of health care, cultural factors affecting sexuality, health, and disease, phase of epidemic and stage of program

The STD prevention program may successfully identify asymptomatic persons as being infected if effective screening initiatives are in place. Whether or not wide-scale screening is conducted depends on the stage of the particular prevention program and the phase of the particular epidemic.[32] In addition, if the prevention program has effective health education initiatives for the general population in place and values the quality of the relationship between provider and patient, individuals who have been exposed to infection may recognize their risk and seek screening.

Another element of a prevention program that identifies infected persons (whether they are symptomatic or not) is partner notification. Provider behaviors also contribute to component I. Providers who do effective risk assessment help identify infected individuals even if the person is not seeking STD care. Thus, those STDs that tend to be asymptomatic; those providers who do not conduct effective STD risk assessment; and those prevention programs that do not include effective screening, partner notification, and health education for the general population all contribute to higher proportions of infected individuals who never get treated.

At a more global or societal level, the availability, accessibility, and acceptability of health care may contribute to the proportion of infected individuals who are never identified as cases and treated. Acceptability of available STD/HIV services may be a major issue for members of particular subpopulations. The interactions among levels of the PTI are visible here: for example, quality of physician–patient relationship (component II) affects medication adherence among Latino patients.[33] High levels of overall poor health may be associated with persons not seeking care even for severely symptomatic STDs. For example, observations in South Africa indicate that this may be the case for some parts of the population (Ronald Ballard, personal communication). The quality of existing clinical and laboratory STD diagnoses is another system level factor that may contribute to the proportion of infected individuals who may never be detected and treated, even if they are seen in a clinic setting. For example, in Morocco, some women with vaginal infections are not diagnosed as such.[34,35] Lack of insurance (presumptively a marker for inability to pay) is a third contributor. Parents of children in the United States (up to age 17) with no or inconsistent insurance coverage were over 12 times more likely than those with continuous coverage to delay health-care seeking.[36] Uninsured 19–24-year-old men and women were three to four times more likely to delay or avoid seeking medical care and three to four times more likely to not fill a prescription. In Australia, lack of (private) insurance was correlated with leaving a clinic without seeking care.[37] Thus, among infected individuals who do seek care or get screened, a certain proportion may not be identified as cases. All infected individuals, whether asymptomatic or symptomatic, who are never identified as STD cases are considered to contribute to component I in the model proposed here. That is, component I refers to all infected individuals who are never identified as cases.

For those who are ultimately identified, there may be a variable period of delay before they are identified as infected. Such delays increase the probability of complications following infection and may contribute to further transmission of infection in the population. Properties of the pathogen and host, in combination with the symptom recognition and description behaviors of infected individuals and risk-assessment behaviors of providers contribute to health-care seeking delays (Table 92-2).

Some STDs are easier to detect than others, and some providers are better at detecting disease than others. For the latter, there appear to remain substantial knowledge gaps among primary care providers responsible for reproductive health care.[38] Even more troubling is that knowledge appears associated with putatively irrelevant factors such as physician age and gender (controlling for factors such as specialty). Ease and rapidity of detection may be affected by the diagnostic approach employed, including clinical versus laboratory diagnosis, choice of diagnostic test, and laboratory in

Table 92-2. Factors Influencing PTI: Health-Care Seeking Delays

Explosure/Infection		Contact with Provider		
Symptom/Risk Appraisal	Identification of Provider	Procrastination	Time to Appointment	Clinic Wait
Properties of the pathogen and host	Proportions with symptoms			
Individual behavior parameters	Gender,[a] risk recognition, symptom recognition, symptom description, extent of routine contact with health care, awareness of availability, and properties of STD specific health services			
Provider behavior parameters	Clinical and referral practices, partner notification practices			
Health system parameters	Availability, accessibility, acceptability *and* visibility of services, clinic overload, hours of operation, waiting time to clinic appointment, waiting time in the clinic (after clinic arrival)			
Societal parameters	Organization of STD health services; organization of funding for STD health services; cultural factors influencing STD, STD services, and sexuality stigma			

[a]This demographic parameter is included here because it is so strongly associated with symptom status and health-care behaviors.

Table 92-3. Factors Influencing PTI: Diagnostic Delays

Provider Contact		Treatment Recommendation	
Specimen to Laboratory	Lab Processing	Result to Provider	Result to Patient
Properties of the pathogen and host	Proportions with symptoms; proportions with signs: the extent to which signs and symptoms are differentiating		
Individual behavior parameters	Risk recognition and reporting; symptom recognition and reporting		
Provider behavior parameters	Risk asessment practices; clinical diagnostic practices; laboratory diagnostic choices; specimen collection practices		
Health system parameters	Availability of and choice for diagnostic technologies; availability and quality of diagnostic guidelines and protocols; quality and timeliness of laboratory procedures; extent and quality of training for clinicians and laboratory personnel; sanctions association with compliance with clinical and laboratory guidelines		
Societal parameters	Phase of epidemic; stage of program; technological, societal and economic development stage		

which the testing is performed. Some laboratory tests take longer than others. The prevention program and the health-care system affect these parameters both directly and indirectly through availability of screening guidelines, systems for timely reporting of laboratory results, and specific training for health-care providers and laboratory workers. Thus, factors that affect detection delays include properties of the infection that influence severity and duration of symptoms; symptom recognition and reporting behaviors of infected individuals; risk assessment, clinical diagnosis, and specimen collection behaviors of providers; and their test and laboratory choices (Table 92-3). At the health-system level, diagnostic delays are affected by the availability of diagnostic technologies, availability and quality of screening guidelines, quality and timeliness of laboratory processing and reporting procedures, and the extent and quality of required training for clinicians and laboratory personnel. For example, rapid tests for HIV require training not just in their use and diagnostic parameters, but in counseling changes and possibly in identifying those for whom a test that does not require a blood draw and that gives results during the clinic visit would be most appropriate.

Table 92-4. Factors Influencing PTI: Treatment Delays

Treatment Recommendation		Less/Noninfectious	
Prescription Filled	Initiation of Therapy	Completion of Therapy	Cure of Suppression of Infection
Characteristics of the pathogen and host	Proportions symptomatic, severity of symptoms, responsiveness to medication, existence of resistant strains		
Individual behavior parameters	Adherence with dosage and recommendations; patient nonadherence may be owing to misunderstanding, forgetting, or intention (person may decide the dosage is too much or they are cured and do not need to continue medication)		
Provider behavior parameters	Therapy choices of providers, including number, dosage, timing of medications, and side effects provider compliance with treatment guidelines, consideration of patients' adherence to recommended therapy in therapy choices, communication behaviors in explaining the need for compliance.		
Health system parameters	Availability, accessibility, affordability of medications; availability, quality, extent of dissemination of treatment guidelines; availability of effective surveillance or resistant strains, emerging and reemerging infections; phase of the epidemic and stage of the program.		
Societal parameters	Overall level of education, level of development, level of health, relative importance of health		

At a more global societal level, the levels of economic and technological development and the phases of the program and the STD epidemic influence the choices of diagnostic protocols, the levels of training, the availability of appropriate guidelines, and the extent to which provider compliance with guidelines is assured.

Many factors contribute to treatment delays once a therapy recommendation has been made by the provider (Table 92-4). Properties of the infecting pathogen affect responsiveness or resistance to therapy. Therapy compliance (or adherence) behaviors of the infected individual determine whether the patient takes all of the prescribed medication at the prescribed times. Patients' nonadherence may be due to misunderstanding or forgetting, or may be intentional—the patient may experience a side effect, or decide the drug dosage is too much, or that he or she is already cured. Therapy delays are also influenced by the providers' compliance with treatment guidelines and choice of therapy, including the timing and duration of therapy, the number of medications to be taken, and consideration of whether the patient can adhere to the recommended therapy regimen. The providers' communication behaviors, including counseling the patient on the importance of taking the full course of medication at the recommended times, and assessing the patient's ability and willingness to comply with the recommendations, are also important. Finally, health-system properties including the availability, accessibility, and affordability of medications; quality and dissemination of treatment guidelines; and existence of an effective surveillance system that detects emergence of resistant strains in a timely manner are important in this context. In the United States, provider and health-system adherence to CDC-recommended treatment guidelines is high,[39,40] but the relative costs of single dose versus multidose regimens may still reduce patient adherence.

Factors that influence prevention delays or adoption of preventive behaviors also include those at individual, provider, and health-system levels (Table 92-5). At the individual level, motivation to reduce risk; current behaviors; current social environment; extent of control over social environment; ability and willingness to help with the identification, location, and notification of partners or to offer medication to partners all influence prevention delays. Providers' counseling behaviors, including counseling patients on adoption of preventive behaviors and on partner management issues are important in this context, especially to counter behavioral disinhibition. While HIV-infected patients overall appear to reduce their risk behaviors subsequent to discovering their status,[41] some persons do not. Similarly, a Ugandan study of persons receiving ART revealed overall reductions in risk behavior, but not within marriage.[42] Other Ugandan men exposed to a condom promotion campaign used more condoms, but also increased their numbers of partners.[43] Health-system characteristics, including the availability of continuous and effective health education and health promotion initiatives, maintenance and reinforcement of good relationships that encourage trust between health agencies and the populations they serve, availability of a variety of partner management procedures, effective triaging of patients to the partner notification and management procedures most appropriate to their needs, and well-trained staff to assist with partner notification and management,

Table 92-5. Factors Influencing PTI-Prevention Delays

	Exposed/Infected Partner		Less/Noninfectious Partner		
	Partner Identification	Partner Location	Partner Notification	Partner Therapy	Adoption of Preventive Behaviors
Individual behavior parameters	Level of motivation, current behaviors, social environment, control over social environment; ability and willingness to help with the identification, location and notification of partners or to offer medication to partners; willingness to engage in safer sex behaviors and future health promotion strategies (e.g., condom use, periodic testing).				
Provider behavior parameters	Counseling patients on adoption of preventive behaviors; counseling patients on partner management issues, partner notification practices, partner management behaviors; provision of risk reduction education or counseling to partners (via individual or dyadic intervention); distribution of condoms.				
Health system parameters	Availability of a variety of partner management procedures; effective triaging of patients to the partner management procedures most appropriate to their situation; availability of continuous and effective health education/health promotion; existence of good relationships that encourage trust between health agencies and population; stage of epidemic, stage of program.				
Societal parameters	Overall level of education, level of development, level of health; relative importance of prevention; the extent to which social networks are conducive to diffusion of interventions.				

when appropriate, may be the factors with the greatest impact on prevention delays. For example, King County's public health service permits patients infected with chlamydial or gonococcal infections to take prescriptions or medications to partners if they do not fall into empirically derived high-risk categories such as having many partners, or not expecting to see a given partner again.[44]

The model described in the preceding is influenced by at least two conceptual approaches formulated earlier, namely, the force-of-infectivity concept and the application of Piot's public health model on tuberculosis to STDs, by Fransen.[45,46] However, this particular conceptualization is new. Thus, the existing literature in this area does not lend itself to an organization exclusively by the components of our conceptual model. On the other hand, each component of the model is influenced by factors related to patients, providers, and the health system. In the following, we review the available data on STD/HIV care-seeking behaviors, provision of health services, provider behaviors, and health-care system characteristics.

STD CARE SEEKING BEHAVIORS

WHERE CARE IS SOUGHT

Available data on STD-specific care seeking behaviors are limited. However, interest in empirical investigations in this area has increased drastically within the past decade. Recent data from the United States indicate that the majority of people seek care for bacterial STDs at private physicians' offices (53%) or non-STD public facilities (35%), and only a minority (12%) report seeking care at dedicated STD clinics.[47] The proportions seeking care for viral STDs are even more skewed (80, 15, and 5%, respectively). The proportion of adolescents and women seeking care at STD clinics are still lower.[47] A 1999–2000 national probability sample of U.S. physicians showed that physicians in private settings diagnosed STD widely,[48] with physicians in emergency departments diagnosing more STD per physician than even obstetricians and gynecologists.[49]

Similar patterns are observed in health-care seeking for pelvic inflammatory disease (PID). Women with acute PID often seek care in emergency departments (EDs). According to data from the National Hospital Ambulatory Medical Care Survey (NHAMCS), an average of 258, 235 cases (4.2 per 1000 women between 15 and 44 years) of PID were treated in ERs.[50] High proportions of ER visits for PID occur among adolescents.

A somewhat different picture is gleaned from a focus on STD clinic attendees in a study that sought to characterize the demographic characteristics, STD morbidity, insurance status, reasons for attending the STD clinic, and preferences for where clients would seek STD services under universal access to STD care.[51] Responses of 2490 clients attending five STD clinics for new problem visits indicated that walk-in services, confidentiality, and low cost were the major reasons why clients sought care at STD clinics. Even if they had unlimited choice, two-thirds of clients surveyed would still prefer to be seen at STD clinics in the future.

One study sought to determine how often STD clinic patients use other health-care sources and whether choice of other sources of care differed by gender and STD diagnosis.[52]

Among STD clinic patients who reported treatment for an STD within the past year, 14% of men and 35% of women treated for STDs reported receiving care only in non-STD clinic settings. Women were significantly more likely to have received care in non-STD clinic settings, including doctor's offices (19.9 vs. 6.1%); emergency rooms (10.0 vs. 4.9%), family planning clinics (4.7 vs. 0.5%), and other sites (3.7 vs. 0.7%).

Results of a nationally representative general population survey conducted in the United Kingdom indicate that health-care seeking behaviors of people living in England are, in general, similar to those of people living in the United States.[53] Of the respondents, 8.3 % of men and 5.6% of women had attended an STD clinic in their lifetime, and, 3.4% of men and 2.6% of women had done so within the last 5 years. Behaviors, but not the attitudes, of STD clinic attendees differed markedly from those of nonattendees. As in the United States, clinics appear to attract primarily those with high-risk lifestyles but only a minority of those reporting risk markers for STD transmission attend STD clinics.[53]

DELAYS IN CARE SEEKING

At the individual level, the first delay in receiving treatment for STDs relates to the time elapsed between the perception of STD-related symptoms by the patient and health-care utilization. A common response to illness is to "wait and see" if symptoms subside, persist, or worsen.[8] For example, symptoms of gonococcal and chlamydial cervicitis are often mild, inconspicuous, or completely absent, and syphilitic chancres are not only painless, but resolve spontaneously, which presumably contributes to delayed health-care seeking. Many women interpret their STD symptoms as part of normal variation in their menstrual cycle.[54] Uncertainty regarding genital symptoms ultimately leads to health-care seeking, but only 45% of women motivated to seek care do so immediately.[54] In another study, about 25% of individuals with STD-related symptoms waited longer than 4 weeks before seeking care.[55] Delay in seeking care was particularly long among women living with one "permanent" partner, perhaps reflecting their perception of low STD risk associated with their own monogamous sexual behavior.[55] These data also suggested that the stigma concerning STDs may act as a barrier to prompt care seeking. Moreover, neither higher perception of vulnerability resulting from having sex with more than one partner without using a condom, nor being a recurrent attendee at STD clinics with STD-related symptoms resulted in less delay in seeking health care.[55] In fact, previous delayed health-care seeking may be a predictor of delayed health-care seeking in the present and future.[56] Perceptions about quality of care received may affect health-care seeking: a multicity study of 1201 health facility attendees and 806 persons from the surrounding communities showed that perceptions of quality of care were more closely related to seeking care for gonorrhea than were stigma or inconvenience (even though the latter two factors were more negatively rated by respondents).[57]

Apparently, prior to health seeking, compared to adolescent men, adolescent women spend a longer period of time on symptom appraisal, whereas time spent seeking social support, seeking information, and self-treating are common to both men and women.[22] The average total care seeking interval (the interval from presumed infection to seeking care) was 9.6 days for symptomatic women, 5.8 days for asymptomatic women, 6.3 days for symptomatic men, and 7.3 days for asymptomatic men. Low income and perception of stigma related to STD were associated with longer delays in health-care seeking for adolescent women.[22]

These findings highlight the importance of differentiating between symptomatic and asymptomatic infection with respect to delays in detection. In the case of symptomatic infection, the most important social and behavioral factors contributing to delays in detection are factors related to the client. In the case of asymptomatic infections, factors related to the behaviors of health-care providers and those related to the health system may play a more important role. Asymptomatic women may recognize that they are at risk following a risky sexual encounter, and seek screening. Alternatively, health-care providers may recognize risky behavioral patterns through history taking, or respond to demographic characteristics associated with risk for infection and screen asymptomatic women for a particular STD. Cases of disease may be missed and treatment delays may result through existing deficits in sexual history-taking,[58,59] including comfort doing so.[60] Finally, the health system may provide guidelines that result in routine screening of asymptomatic women on the basis of individual or population level markers that may not be recognized by either the client or provider such as current U.S. recommendations to screen women $\leq$ 25 years annually for chlamydial infection.[61] But these recommendations are not always followed and overall screening of women for STDs is inconsistent.[62]

On the other hand, the difference between symptomatic and asymptomatic infections should not be overemphasized. In some populations, response to STD symptoms may be minimal and may, in fact, be associated with considerable delays in seeking health care. In one investigation of a chancroid outbreak in Mississippi, an assessment of health-care seeking behavior of male patients with ulcers showed long delays in seeking treatment and a substantial amount of unprotected sex with untreated ulcers during this delay.[63] The median time from onset of symptoms to clinic visit was significantly longer for syphilis (14 days) and chancroid patients (10 days) than for HSV patients (4 days); for 65% of all male ulcer patients there was at least a 1-week delay in receiving care.

Similarly, in one multisite study of delay in care seeking, of 1621 patients with genitourinary symptoms, over one-third (35% of men and 37% of women) presented to STD clinics

only after 1 week or more of symptoms.[64] Men with genital warts (73%), with nongonococcal urethritis (23.1%) or symptomatic men who were recent contacts to sex partners with STDs were significantly more likely to delay clinic attendance more than 1 week than men with gonorrhea (6.5%, $p < 0.001$ for each). Overall, 43.8% of women receiving specific clinical diagnoses other than genital warts delayed clinic attendance for more than 1 week. When asked why they delayed clinic attendance respondents were most likely to respond that they hoped their symptoms would "go away" (48.5% of men and 49.4% of women who waited 1 week or more before seeking care).

An additional issue related to health-care seeking among adolescents involves confidentiality. In a recent survey, a majority (58–69%) of adolescents indicated that they had health concerns they wished to keep confidential and that they would not seek health services because of these concerns.[65] An experimental manipulation of confidentiality guarantees (unconditional, conditional, none) found adolescents without an unconditional guarantee would be less likely to seek future health care and to disclose sensitive information during a visit.[66] Moreover, some jurisdictions have stringent requirements for reporting sexual behaviors. For example, providers in Texas are required to report identities of persons under 17 who are sexually active.[67]

Perhaps related to issues of confidentiality, seeking to cure symptoms through self-treatment is one specific reason why people delay health-care seeking after onset of symptoms. In one study, women were almost two times more likely to self-treat than men, and the average incremental delay in health-care seeking associated with self-treatment was 2 days.[68] In another study conducted in Kenya, self-treatment was the most important factor contributing to delayed care seeking.[69]

ADHERENCE TO THERAPY RECOMMENDATIONS

Poor adherence to therapy recommendations on the part of infected individuals is another factor that contributes to delays in cure and some proportions of infected persons not being cured. The literature suggests that among women with PID who seek care, suboptimal adherence to multidose regimens may exceed 65%.[70] Among women with asymptomatic gonococcal or chlamydial infections, on multidose regimens, noncompliance rates may be even higher. As noted earlier, some persons may be cured even with partial adherence to multidose regimens.[28]

PROVISION OF STD SERVICES

SOURCES OF CARE

As is the case in the health-care seeking area, data on STD-related health-care provision are scant. Often, available data are not specific to particular population subgroups or particular STD diagnoses. Nevertheless, in order to minimize time elapsed between infection and treatment for cure of curable bacterial or parasitic STDs and suppression of incurable viral STDs, it is important that information on where to seek care for STD-related symptoms (or suspicion of exposure to STDs) is available to the population; STD services are accessible and acceptable to the target population; communication between providers and patients is effective; and, where necessary, outreach services are available for hard-to-reach populations.

According to the first survey of a nationally representative sample of public health department STD programs ever conducted, in 1994, U.S. public sector STD services are limited in distribution, clinic hours, and outreach capacities and address a limited range of STDs. An estimated 1437 local health departments half of all local health departments in the country, provided STD diagnosis and treatment to clients, through 2 million visits, at 2587 clinic locations.[71] Of those clients who received these services, 16% were under 18 years of age, 19% were 18 to 19, and 30% were 20 to 24; 6 out of 10 clients were women; 45% had incomes below the official poverty level, and 38% were between 100% and 250% of the poverty level; 55% were non-Hispanic whites, 35% were African Americans, and 9% were Hispanic. On average, 43% of these clients did not have any STDs. Among those who had a STD, 40% had chlamydia, 22% had gonorrhea, 5% had early syphilis, and 32% had some other STD. Almost all agencies offer testing and treatment for gonorrhea and syphilis, but only 82% offer testing for chlamydia.

Only 14% of local health departments that offer STD services do so in clinic sessions solely devoted to STDs. These health departments are much more likely to be in large metropolitan areas, and to have large client caseloads; they provide 37% of all STD visits annually, and most of their clients are men. Most local health departments that offer STD services integrate STD and other health services, such as family planning in the same clinic session (37%), or offer both integrated sessions and sessions devoted to STDs (49%). Providers that integrate STD services and other health care in the same clinic sessions tend to serve nonmetropolitan areas, serve smaller number of STD clients, and have women as the majority of their clients.[71]

The findings from the survey also indicate that 40% of the half of the local health departments that do provide STD services cannot see a new patient on the same day that he seeks care and 15% report that new clients have to wait 3 days or longer before being diagnosed and treated. Only 23% of STD clinics are open evenings, and only 5% are open on weekends. These data are consistent with those from a 1993 study of STD clinics in 24 metropolitan areas demonstrating that up to 46% of patients cannot be seen on the same day that they present for care.[72] In terms of prevention delays (component V), two surveys found

health departments interview the vast majority of patients (89%) with syphilis for information pursuant to partner notification, but as few as 32% of HIV patients and less than 20% of patients with gonorrhea or chlamydial infection.[73,74]

In aggregate, these data are remarkable in that they document the overburdening of public health department STD clinics serving clients living in metropolitan areas. An average of 3 days' delay in diagnosis and treatment would significantly add to the duration of infectiousness, and in the ecologic setting of metropolitan areas may greatly accelerate the spread of STDs.

Public health departments provide only one portion of all STD services. Preliminary results from a pilot study conducted in four states in the United States indicate that STD clinics report the greatest numbers of new STD cases diagnosed within the past 2 weeks: 46% report five or more new STD cases; followed by family planning clinics, 36%; colleges, 16%; hospitals, 15%; and abortion clinics, 12% (Abt. associates, personal communication). Of the specialties surveyed, those in emergency medicine and general practice reported the greatest numbers of new STD cases, similar to results found in a national probability sample of physicians in private (88%) and public (12%) settings.[48,49]

STD vaccines have the potential to reduce the overall morbidity of associated diseases and to reduce their burden upon all practice settings where STD are diagnosed (see Chapter 99). In 2006, a safe, highly efficacious human papillomavirus (HPV) vaccine, developed by Merck, was licensed for use in 9–26-year-old women. Both this quadrivalent (HPV 6/11/16/18) vaccine, and a bivalent (HPV 16/18) vaccine developed by Glaxo SmithKline, prevent precancerous cervical and vaginal lesions, and for the Merck vaccine, genital warts persistent infection,[75–77,78] For HSV-2, a 2002 trial estimated 73–74% efficacy for women who were seronegative for HSV-1 as well as HSV-2, but no efficacy for men or for women who were seropositive for HSV-1.[79] Efforts to produce a vaccine continue, as they do for HIV.

Most young women (for whom the HPV vaccines would be most useful), health-care providers, and parents are generally well-disposed toward STD vaccines, including for HPV.[80–82] The effect of any efficacious vaccine eliminates delays attributable to care-seeking, diagnosis, testing or treatment, but only for those STDs for which a vaccine exists. Behavioral research is needed to inform how to ensure vaccination does not result in reduced health-care seeking or provision for other STDs (or for disease related to nonvaccine types of HPV and Pap smear screening for cervical cancer). However, with attention to such negative unintended consequences, the potential savings to health-care systems from virtually eliminating the need to test for vaccine-preventable diseases may be considerable and present opportunities to focus resources on other STDs.

Vaccine uptake is certainly not guaranteed by its mere presence. Vaccination against HBV has been available since 1982, when a national strategy targeting high-risk adults was implemented in the United States. The approach achieved poor coverage and was subsequently revised to the current universal immunization strategy. Primary HBV vaccination now occurs in infancy, and HBV incidence data between 1990 and 2002 (a decline of 90 among children and adolescents, 67% over all ages) reflect increasing success with this route.[83] However, vaccination of adults at risk for this sexually transmissible disease continues to be far less successful in spite of recommendations to vaccinate all previously unvaccinated adults.84 Recent surveys in STD clinics indicate prevalent vaccination rates of roughly 10–20%.[85,86] Although subsequent agreement to be vaccinated across studies runs to around 50–70%,[87–89] adherence to the six-month, three-dose schedule results in many under-vaccinated at-risk adults.[90] Individual-level motivations to protect health and prosaic concerns such as time to protect health are related to refusal rates: some have suggested prevaccination counseling.[85,88,89]

STD HEALTH-CARE PROVIDER BEHAVIORS

Health-care provider behaviors constitute a major contributing factor in determining the proportions of STD-infected individuals who never get detected or who are not treated even if detected. Provider behaviors also contribute to the delay between infection and cure. Provider behaviors that are important in this context include conducting STD risk assessment, arriving at a clinical or laboratory diagnosis, providing a therapy recommendation, providing counseling for preventive behaviors, and providing partner referral counseling and management. Available data on provider behaviors are limited; however, in recent years a few studies of provider behaviors have been conducted both in the United States and in the developing countries.

A recent national survey of U.S. health-care providers indicated that most providers do not actively assess patients' risk for STDs, but rely on patients to mention STD symptoms or concerns,[91] although they do report taking appropriate clinical actions (but minimal partner management) when they suspect STDs.[92] STD risk assessments are rarely a routine part of care by physicians or other office-based health-care staff. Only 16% of physicians and only 27% of other health-care professionals assess STD risk in all new adult patients. Fifty-five percent of physicians and 43% of other health-care providers stated that they conduct a risk assessment only when prompted by patients' symptoms or complaints. As considerable proportions of common STDs are asymptomatic,[93] and patients typically prefer physicians to bring up the topic of sexual behavior,[94] reliance on patients to disclose symptoms can easily lead to missed diagnoses or delayed

treatment. Only 65% of physicians and 63% of other providers collect information on a patient's prior history of STDs. A 1992 national survey of primary care physicians found that although the majority of these providers routinely asked about cigarette, alcohol, and contraceptive use, the percentage of physicians who would "usually" or "always" assess STD risk by asking about condom use, number and type of sex partners, or sexual orientation ranged from 27% to 31% with new adult patients and 27–52% with new adolescent patients.[95]

Other provider behaviors related to STD detection are perhaps more difficult to study and data on these behaviors are not available. However, at a population level, whether providers use clinical diagnostic approaches, based on signs and symptoms, or laboratory diagnostic approaches may have a great effect on the proportion of infected individuals who are appropriately diagnosed, and on the length of time that elapses between the infected individual's initial contact with the provider and the identification of a cause of infection and, ultimately, effective treatment. Indeed, there are trade-offs between the more timely detection and treatment of a larger number of patients using clinical diagnosis and the more accurate detection of a smaller number of patients whose treatment may be delayed. Symptoms and signs for some STDs may not be reliable for diagnostic purposes. Many STDs are asymptomatic, particularly in women; moreover most populations do not receive adequate STD-related health education to provide them with symptom recognition skills. As mentioned earlier, in a nationally representative serologic survey, only one out of ten individuals with serologic evidence of HSV-2 reported having genital herpes.[29] Signs for STDs may also be misleading, particularly in women and particularly for nonulcerative STDs. However, even clinical diagnosis of genital ulcers may be problematic if providers fail to recognize that multiple etiologies are common in their population and do not tailor treatment regimens accordingly. For example, in a recent chancroid outbreak in Mississippi, cases of ulcers that were not clinically diagnosed as being caused by chancroid were found to be caused by *Hemophilis ducreyi* on testing with the polymerase chain reaction (PCR) technique.[63] In South Carolina, a 1993–1994 trial of STD diagnosis using clinical signs and symptoms with only Clinical Laboratory Improvement Act (CLIA) waived laboratory test (vaginal pH and endocervical swab test) instead of "moderately complex" CLIA tests (RPR, dark fields, Gram stains, and wet mounts) resulted in substantial increases in misdiagnosis, particularly for genital ulcers and discharge syndromes in women (Greene and Lindman, personal communication). Moreover, signs may vary across populations, depending on the phase of the particular epidemic and whether infections being diagnosed are predominantly incident infections or longstanding prevalent infections.[32,35]

The choice of a laboratory test may be associated with other issues. The type of specimen that is required for a given test will determine not only patient acceptance of testing, but also ease of specimen collection, storage, and transport by the provider. Ease of specimen collection has increased with the advent of urine-based screening and rapid tests for some STD, including gonorrhea, chlamydial infection and HIV. But reliance on a particular method of specimen collection can inhibit collection of specimens for which, for example, blood draws are still required (e.g., syphilis). Time elapsed between specimen collection and receipt of the test result is another consideration in choosing between alternative diagnostic tests. Delay in receipt of test results contributes to longer durations of infectiousness in infected individuals and, in addition, may result in lower proportions of infected individuals being treated since some persons do not return to get their results and therapy recommendations. In one study that compared a rapid office-based test with standard cell culture for screening of women for chlamydial infections, the median interval between testing and therapy for women with positive screening cultures was 14 days. Nearly 25% of the women with positive screening cultures did not return for therapy.[96]

Another study evaluated treatment outcomes of patients with positive cultures who had not received presumptive treatment at their initial visit, using retrospective chart reviews of computerized medical records. The findings indicated that overall, 20% of patients with positive screening cultures for gonorrhea and chlamydia failed to return to the clinic for treatment within 30 days of screening. Of those who did return, 30% did so only after at least 2 weeks had elapsed.[97]

Although recommendations for detection and treatment are important factors influencing provider behaviors in these areas, some providers do not adhere to such recommendations. A recent study compared PID screening, diagnosis, treatment, and reporting practices among primary care physicians with the CDC guidelines for PID.[98] Fifty-five percent of primary care physicians surveyed had treated at least one case of PID during the preceding 12 months. Of these, 52% were unsure of, or did not follow, the CDC guidelines for PID, and only 44% reported that they consistently followed the CDC guidelines. Among the physicians who reported treating PID during the past year, only 3% answered all of the PID management questions in accordance with the CDC guidelines. Major deviations from the guidelines occurred in the areas of diagnosis (11%), overtreatment (11%) and undertreatment (12%).[98] A more recent study conducted in an emergency department did not address treatment deficits, but noted only 10% of PID as judged by CDC standards was reported within 6 months of diagnosis.[99]

Based on findings from the national survey of providers, counseling behaviors of health-care providers could also be improved. Only 35% of physicians and 38% of other

providers routinely discuss safer sex or condom use with their herpes patients. Only 31% of physicians and 29% of other providers discuss telling sex partners about STDs,[91] and less than half of adolescent males (26%) and females (43%) report discussing sexual health with a provider at their last visit.[100] Clinics with written protocols tend to fare better in regard to asking patients about their sexual practices than those without.[101] Patient and provider expectations of the clinical encounter may vary significantly. Patients expect to be examined in a timely fashion, and excessive waiting times or early clinic closures tend to frustrate and distance patients from the health service delivery system. Lack of privacy and confidentiality in the clinical encounter create further problems. In one study, in St. Louis, Missouri, 55% of women and 44% of men were dissatisfied with the amount of time they had to wait to be seen; and 26% of women and 34% of men stated that their privacy was not preserved in interactions with the clinical staff.[102]

STD HEALTH-CARE SYSTEM CHARACTERISTICS

Several properties of the health system have important effects on the time elapsed between infection and cure of bacterial or parasitic STD or suppression of viral STD. These include education and training of providers, availability and distribution of diagnostic tests, availability and distribution of medications, and program and practice guidelines, organization and funding of basic services necessary for effective STD prevention including laboratory diagnostic services, screening services, and partner management services.

Education and training of health-care providers in STD and HIV/AIDS is often inadequate, although curricula for sexual health care exist.[103,104] In 1991, 102 medical schools of 126 queried in the United States and Puerto Rico reported the extent of clinical training for medical students in the areas of sexually transmitted diseases (STD) and HIV/AIDS. The median number of hours of clinical training in STD, ranged from 1 to 5 hours (internal medicine and obstetrics and gynecology were the highest). The median number of hours of clinical training in HIV ranged from 1 to 4.5 hours (internal medicine). The departments most likely to have STD training as an explicit objective were obstetrics and gynecology (87%) and internal medicine (73%), whereas the least likely were dermatology (26%), urology (26%), and psychiatry (21%). Clinical training in HIV/AIDS was most likely to be an explicit objective in internal medicine (86%) and obstetrics and gynecology (68%), and was least likely in dermatology (23%) and urology (15%). A clinic specifically devoted to STD existed at 42% of institutions, and one devoted to AIDS existed at 73%, but an exclusive elective for medical students in STD or HIV/AIDS existed at only 37% of the institutions. In the 10 years prior to 1991, the amount of clinical training in STD had decreased at 6% of the institutions, remained the same at 17%, and increased at 77%.[105] Particularly in the areas of STD diagnosis, treatment, and prevention, new technologies and knowledge accumulate rapidly. Thus, there is an additional need for continuing education of health-care providers. However, national data on the numbers and proportions of health-care providers who receive continuing education in the STD area are not available. Moreover, a formal assessment of provider education, training, and continuing education needs has not been conducted. Posteducation training that involves physicians carries promise: in one trial, physicians in a managed care organization who participated in ongoing sessions devoted to improving screening conducted more screening and uncovered more disease than other physicians.[106] But these results are minimally applicable to physicians in solo practice or small-group multispecialty settings.

Since many STDs are asymptomatic or have nonspecific symptoms, laboratory diagnosis is required for their detection. Underuse of laboratory testing, owing to lack of availability of reagents or other resources, may limit appropriate detection, reporting, and treatment of STDs. No national data are available to assess the facilities that offer testing for various STDs or estimate training and support needs for the future.[107] A 1996 study analyzed responses to a survey inquiring about the range of tests offered, changes in testing, and reasons for changes.[107] Results indicated that, in recent years, the number of facilities testing for *Chlamydia trachomatis* has increased with increased funding and availability of nonculture tests; the number of facilities testing for chancroid and gonorrhea has decreased; and that the implementation of the Clinical Laboratory Improvement Act (CLIA) may be associated with a decrease in the number of facilities performing tests for STDs. Most of the 405 responding facilities collected specimens for nontreponemal tests for syphilis (86.9%). Since each facility's information was last updated, the number reporting testing for *C. trachomatis* rose from 39.5% to 71.1%, but testing for gonorrhea and chancroid decreased from 90.1% to 81%, and from 44.9% to 7.9%, respectively. Of the 364 responses to a question on changes in tests performed in the last 2 years, 249 (68.4%) reported no change, 81 (22.3%) reported an increase, and 37 (10.2%) reported a decrease. The most frequently added tests were nonculture tests for *C. trachomatis* (34 of 81 [42%]), and the most frequent reason for adding tests was targeted funding (25 of 81 [30.9%]). The most frequently discontinued tests were cultures and Gram stains for gonorrhea (15 of 37 [40.5%]) and other in-house tests (9 of 37 [24.3%]). Most facilities that discontinued testing cited CLIA as the reason. By 2004, 94.7% of 114 labs surveyed reporting conducting over 3.5 million tests for *C. trachomatis*, of which 64.4% were through nucleic acid amplification tests (NAATs).[108]

Gonorrhea testing had rebounded compared with the 1996 results, with the same proportion of responding labs reporting testing for *N. gonorrhoeae* as for *C. trachomatis* (94.7%).[108] Sixty-one percent of tests for *N. gonorrhoeae* in 2004 were NAATs. Of the 114 responding labs, 93.9% reported testing for syphilis, although the proportion using a treponemal test was lower, 75.4% (i.e., some labs presumably had to send RPR-positive samples for confirmation as syphilis elsewhere). The proportion of labs running tests for other STD was much lower: 47.4% tested for HSV; under 5% tested for HPV or trichomoniasis.[108]

More promising, however, is the rise in attention to home-based testing using urine-based tests, which may decrease delays in care-seeking and possibly prevention (if tests can be sent to partners of infected persons). Home testing appears popular with adolescent females relative to clinic vists,[109] although the presence of asymptomatic disease suggests routine health-care seeking should not be compromised.

The advent of new tests for HPV and HSV presents both opportunity and challenges for laboratories. A newly approved DNA test is suitable for detecting high-risk HPV types (although it does not detect *which* high-risk type exists); the specimens are cervical cells as for a Pap test.[110] The DNA test reduces diagnostic delays in that high-risk HPV can be identified from a single test collected during a Pap test. For HSV-1 and HSV-2 testing, "real time" PCR tests have reliably detected HSV among asymptomatic individuals[111] and can even be used for estimating susceptibility of a given infection to treatment (which could reduce treatment delays).[112] The challenge for laboratories lies in the training and equipment needed for a new test.

An additional aspect of laboratory diagnosis that affects the timely and appropriate treatment of STDs relates to the timeliness of laboratory testing and reporting of positive test results. Many health-system level factors may contribute to timeliness of laboratory services, including inadequate resources, overburdening of particular facilities owing to absolute overload or uneven distribution of demand for laboratory services, and characteristics of diagnostic technology. In a study of completeness and timeliness of laboratory surveillance for syphilis, timeliness was found to be a much more serious problem than completeness, especially for laboratories outside public clinics.[113]

Availability of up-to-date program and practice guidelines for the prevention, detection, and treatment of all STDs is an important health-system parameter with great potential impact on timely and appropriate STD management. However, such availability does not assure provider compliance with guidelines. In fact, recent data indicate that compliance levels may be quite low, even in the Unites States, where higher levels of compliance with practice guidelines would be expected in light of malpractice legislation.[98]

Organization and funding of STD services may be the most important health-system parameter influencing timely treatment of STDs. In the Unites States, the evolution toward managed care has accelerated dialogue between public health and private medicine regarding the mutual responsibilities of these sectors. In general, the public health sector is more narrowly defining its responsibilities to encompass population level health services, including health planning, disease surveillance, and primary prevention activities (such as health promotion and education, partner notification, vaccines, and regulatory strategies). It will rely on the private medical sector to accept more of the responsibility for providing individual level detection and treatment services.

For STDs, the private sector can play an important and expanded role in disease prevention. However, those without insurance for private care include many of the economically and socially marginalized persons most likely to acquire and transmit STDs. Furthermore, with the advent of Medicaid managed care, some of the distinctions between private and public sector are beginning to blur. Because early detection and curative treatment represent primary prevention for communicable diseases, the public health sector must ensure that accessible, acceptable services for STD prevention are available to both the uninsured and insured alike.[114]

STD health-system characteristics in the Unites States are probably not as favorable to minimizing time elapsed from infection to cure or suppression of STDs as those in other developed countries. The limited data available from developing countries indicate that health-system characteristics in many of these countries also greatly compromise the timely and appropriate treatment of STDs.

One initiative undertaken by AIDSCAP, called targeted intervention research (TIR), has brought to light many aspects of STD health-system characteristics as well as health seeking and provider behaviors in several developing countries, including Malawi, Senegal, Ethiopia, Zambia, and the Philippines.[115] Findings point to the importance of lack of knowledge regarding STDs, lay theories regarding STD etiology, perceptions of stigma, seeking of health care through inappropriate sources such as pharmacies and traditional healers, inadequate knowledge and training regarding STD diagnosis and treatment among health-care providers, lack of resources for appropriate diagnostic technologies, and inadequate communication between patients and providers as the main factors impeding appropriate and timely diagnosis and treatment of STDs in many developing countries.[114] A survey of STD case management conducted in Malawi in 1994 found that the prevention indicator rate for correct assessment and treatment of STD patients was 11% (81% for history taking, 46% in physical examination, and 13% in current antibiotic treatment according to national guidelines).[115] In the same study, the prevention indicator

rate for overall patient counseling was 29% (65% for partner notification and 40% for condom advice). Only 16% of patients with genital ulcers were treated effectively for chancroid and 56% were treated effectively for syphilis. Female STD patients were treated less comprehensively than male STD patients, and only 20% of STD patients were offered condoms.[115] These findings reflect the net effects of inadequacies in the prevention and control of STDs resulting from a multiplicity of problems in the interface of health seeking behaviors, provider behaviors, and health system-characteristics related to STDs.

IMPLICATIONS FOR FUTURE RESEARCH AND PREVENTION EFFORTS

The AIDS epidemic has resulted in far-reaching advances in our understanding of and ability to change risky sexual behavior. In contrast, empiric work on the prevalence and determinants of timely and effective STD-related health care, and on the development and evaluation of interventions to achieve it remains extremely limited. Future research in this critical area must bridge factors operating at the client, provider, and health-system levels in considering each of the components and subcomponents contributing to "person-time of infectiousness." Research to define and address factors shaping component I (lost to detection) is likely to be particularly important because of the large numbers of infected individuals that fall into this category, especially in subpopulations and communities with the highest STD rates. New STD and HIV detection technologies, including urine and saliva tests, will facilitate the kinds of population-based studies that are needed to answer questions about component I. Research on factors shaping components III and IV (diagnostic delays and treatment delays) is even more limited than that on health-care seeking. Such research is critical to conduct since provider behaviors and health-system variables may prove more responsive to interventions than behaviors of the general population. Advances in STD and HIV detection technologies, prevention technologies (especially vaccines), and the organization of health services in the Unites States also suggest that, in many communities, STD/HIV-related health-care behaviors may be uniquely vulnerable to intervention or in transition already. This makes the need for both descriptive and intervention research in this area particularly urgent and relevant to prevention of all STDs, including HIV infection.

The PTI conceptual framework and the data summarized in this chapter also have profound implications for STD prevention efforts. They highlight the need for interventions that promote early and effective STD-related health-care behaviors to go beyond the traditional focus on partner notification, and, in some settings, clinic-based counseling. STD prevention programs must build on local assessment of the PTI components and subcomponents not only to target improvements in clinical prevention services to those provider and health-system factors responsible for the greatest delays, but also to incorporate into health promotion efforts tailored messages that will reduce loss to detection, health-care seeking delays, and noncompliance with management recommendations in high-risk subpopulations. Partner notification approaches should also be reexamined in light of the concepts discussed here. Finally, available data clearly indicate that the majority of STD care is not sought through public sector categorical clinics. To optimize STD-related health care, STD services must also be offered as part of routine primary health care by both public and private sector providers. This means that, in the future, efforts directed at provider behaviors, such as guideline development, training, and evaluation, must extend to providers in these settings, and stronger linkages must be forged across these health-system components.

93 Condoms and Other Barrier Methods for Prevention of STD/HIV Infection and Pregnancy

Markus J. Steiner, Lee Warner, Katherine M. Stone, and Willard Cates, Jr.

INTRODUCTION

When used consistently and correctly, male latex condoms can reduce the risk of pregnancy and many sexually transmitted infections (STIs), including HIV. Strong evidence, based on biologic plausibility, laboratory studies, and mounting data from clinical studies supports the public health recommendation that condom use reduces the risk of STI for sexually active persons. The general consensus is male condoms must play a central role in any STI/HIV prevention program.[1]

In this chapter we provide an overview of the effectiveness of male latex condoms for prevention both of STI/HIV and pregnancy and describe trends in condom use. The majority of the chapter is dedicated to the latex male condom because this method represents the most commonly used barrier method worldwide. We also provide brief overviews of the effectiveness of other physical barriers, including natural membrane and synthetic male condoms, female condoms, diaphragms, cervical caps, and barriers for oral sex.

MALE CONDOM

Male condoms protect the wearer and his partner from infection by covering the penile glans and shaft, which are the major portals of entry and exit for STI pathogens. To be effective, condoms must be placed on the penis prior to any genital contact and used throughout intercourse, must remain intact, and must be used consistently. About 97% of male condoms available in the United States are manufactured from latex.[2] Other male condoms available are made of either the intestinal caecum of lambs ("natural membrane" condoms) or synthetic materials.

Condoms are regulated as medical devices by the U.S. Food and Drug Administration (FDA), and manufacturing standards have become more stringent in recent years.[3] Every condom is tested electronically for holes and weak spots before it is packaged. Samples of condoms also undergo a series of additional laboratory tests for leakage, strength, dimensional requirements, and package integrity.[4] A recent Consumer Reports Survey showed that all condoms tested met industry standards, and that test performance was not related to condom price, thickness, or country of manufacture.[5]

LATEX CONDOMS, EFFECTIVENESS

Laboratory studies indicate that latex condoms provide an effective physical barrier against passage of even the smallest sexually transmitted pathogen (hepatitis B).[2,6–12] When placed on the penis before any genital contact and used throughout intercourse, the condom prevents direct contact with: (1) semen; (2) genital lesions and subclinical viral shedding on the glans and shaft of the penis; and (3) penile, vaginal, or anal discharges. Condoms reduce the risk of STIs that are transmitted primarily to or from the penile urethra such as HIV, gonorrhea, chlamydia, trichomoniasis, and hepatitis B. Condoms should also reduce the risk of STIs that are transmitted primarily through skin or mucosal surfaces when these areas are covered by the condom, such as genital herpes, syphilis, chancroid, and human papillomavirus (HPV) infection. The protection provided by condoms may be less when these STIs involve areas not covered by the condom.

The levels of protection from condoms are likely to vary for different STI because STIs vary in their routes of transmission, infectivity, and prevalence. Clinical studies have shown inconsistent protective effects for most STIs, with the exception of HIV.[2] Much of this inconsistency in condom use effectiveness estimates can be attributed to limitations in study design. Specifically, limitations in measurement of self-reported condom use and exposure to infected partners complicate the interpretation of condom effectiveness estimates.[2,3,13–32]

HIV

Clinical studies have shown latex condoms to be highly effective against sexually acquired HIV infection,[17,32–34] the most consistently fatal STI. Thus, male latex condoms should be promoted to sexually active clients at risk for STI for this reason alone.[35] Studies of discordant couples (where one partner is infected with HIV and the other is not) consistently

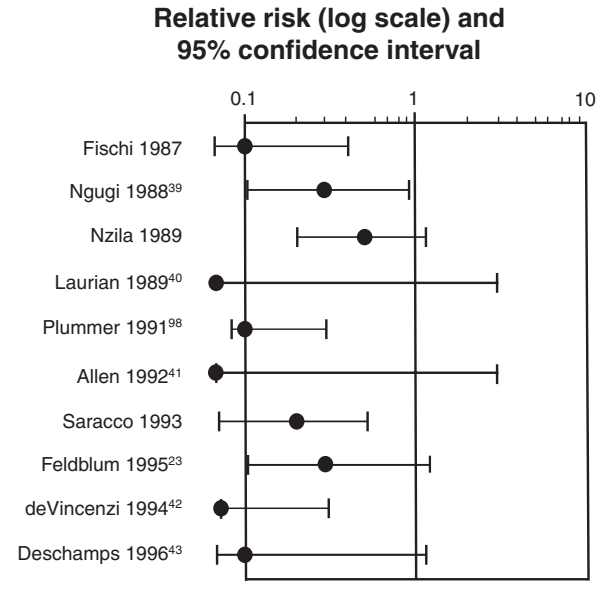

FIGURE 93-1. Risk of HIV infection among heterosexual couples using condoms (selected cohort) studies.

demonstrate that condoms provide effective protection against HIV (Fig. 93-1).[36–44]

Investigators have summarized estimates of the effectiveness of condoms for HIV prevention into a single measure in meta-analyses.[17,33,45,46] Because these meta-analyses are also impacted by biologic and epidemiologic factors (e.g., stage of HIV infection, coinfection with other STIs, validity of self-report) that may vary across studies, these summary estimates of effectiveness should not be considered precise. The two most recent meta-analyses[17,33] place the estimated effectiveness of consistent condom use between approximately 80% and 95%. The most recent meta-analysis[17] of discordant couples also illustrates that transmission of HIV infection among consistent condom users is infrequent. Across the 13 cohort studies reviewed, there were only 11 seroconversions among 587 consistent users, and many individual studies showed no seroconversions.

Other STIs

The overall quality of clinical studies to assess the effectiveness of condoms against acquisition of STIs other than HIV is considerably weaker. Systematic reviews have been conducted for clinical studies for several STIs, including gonorrhea, chlamydia, genital herpes, and HPV.[13,31,32,47,48] A recent systematic literature review of 45 published studies of condom use and gonorrhea and chlamydia concluded that condoms reduce risk in both men and women (Figs. 93-2 and 93-3).[13] Many studies did not measure critical factors such as exposure to infected partners, consistent and correct condom use, or incident infection. Therefore, the observed protective effects are likely to be underestimates of the true protective effect.

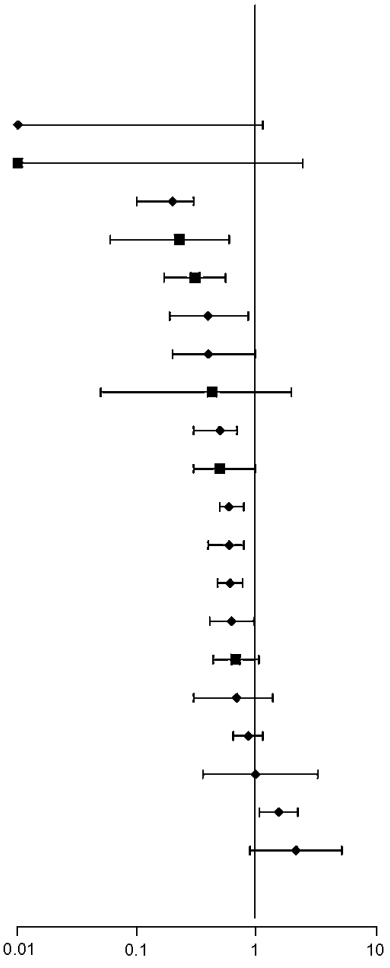

FIGURE 93-2. Studies assessing the association between condom use and risk of gonorrhea (1966–2004). Measure of effect and 95% CI (Females = ◆, Males = ■). (Adapted from Warner L, Stone KM, Macaluso M, Buehler JW, Austin HD. Condom use and risk of gonorrhea and Chlamydia: A systematic review of design and measurement factors assessed in epidemiologic studies. *Sex Transm Dis* 2006; 33: 36–51.)

Adequately controlling for confounding from differences between condom users and nonusers (such as exposure to infected partners) appears to be among the most critical limitations of studies. Two recent studies of gonorrhea and chlamydia restricted to sexually transmitted disease (STD) clinic patients with known exposure to infected partners, for example, reported protective effects for condom use which were two-to-three times stronger than those reported for patients with unknown exposure in the same studies.[18,49] Moreover, other recent analyses[14–16] have clearly documented that condom effectiveness is underestimated in studies because of limitations in study design.

For HPV, a systematic literature review in 2004 concluded that the effectiveness of condoms to prevent HPV infection in women and men is unknown due to difficulties distinguishing new from preexisting infections and the failure of most studies to analyze consistent and correct condom use.[48] Since then, a well-designed prospective study has

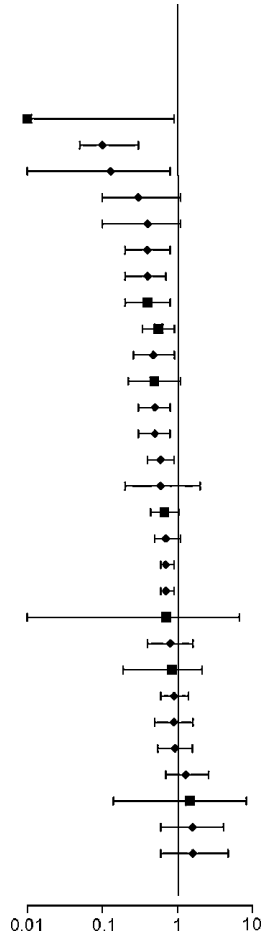

FIGURE 93-3. Studies assessing the association between condom use and risk of chlamydia (1966–2004). Measure of effect and 95% CI (Females = ♦, Males = ■). (Adapted from Warner L, Stone KM, Macaluso M, Buehler JW, Austin HD. Condom use and risk of gonorrhea and Chlamydia: A systematic review of design and measurement factors assessed in epidemiologic studies. *Sex Transm Dis* 2006; 33: 36–51.)

demonstrated that consistent and correct use of condoms can reduce incident cervical HPV infection in young women.[50] In addition, literature reviews have concluded that condom use can reduce the risk of HPV-associated diseases including genital warts in men[2,31,48] and women,[48] cervical intraepithelial neoplasia (CIN), and cervical cancer.[2,31,48] Two recent randomized trials showed condom use was associated with higher rates of regression of HPV-associated penile lesions in men,[51] CIN in women,[52] and higher clearance rates of HPV infection in women.[52]

Systematic literature reviews have concluded that condom use reduces risk of genital herpes simplex virus (HSV) transmission in women[32,47] and men.[32] The single study of discordant couples found that condom use was associated with a significant reduction in risk of acquiring HSV-2 for women but not men.[53] Two recent prospective studies showed that condom use reduced risk of HSV-2 acquisition for both men and women.[54,55]

The body of literature examining condom effectiveness for preventing the remaining STIs is sparse by comparison. Despite limitations that would tend to underestimate the protective effect, several studies have demonstrated that condom use reduces the risk of PID[56–58] and trichomoniasis[59–61] in women[62,63] and syphilis in men and women.[59,62,64–66] One study showed condoms reduced risk of Hepatitis B in women.[67] No studies have specifically addressed condom use and risk of chancroid.

Pregnancy

Three studies meeting modern standards for design, conduct, and analysis[68] provide compelling evidence on the effectiveness of male latex condoms to prevent pregnancy.[69–71] The most recent review of these three trials estimated that during the first 12 months of consistent use of the male latex condom, 2% of women will conceive; the corresponding annual pregnancy rate for typical use (including inconsistent and/or incorrect use) is estimated to be 15%.[68] By contrast, the typical annual pregnancy rate for women not using contraception is 85%.

■ FACTORS REDUCING CONDOM EFFECTIVENESS

Condom effectiveness depends heavily on the skill level and experience of the user.[3] Studies have documented relatively high levels of problems when condoms are used, many of which can be minimized with appropriate counseling and practice.[16,19,72–74]

Common problems with condoms that may place users at risk for STIs and pregnancy include the following:

1. *Failure to use condoms with every act of intercourse.* Nonuse of condoms, rather than poor condom quality or other condom-related problems, is the most common problem.[75] The highest single priority for any STI/HIV program should be to address factors that lead to nonuse of condoms.
2. *Failure to use condoms throughout intercourse.* Recent studies have documented that some men put on condoms after starting intercourse or remove condoms before ejaculation.[16,19,23,76] These behaviors, which represent product misuse, could expose users and their partners to risk of pregnancy or STI. Men and women should be encouraged to use condoms every time from start to finish.
3. *Condom breakage and slippage.* Although users often fear the condom will break or fall off during use,[77,78] these events are rare with proper use and tend to be concentrated among a small proportion of users.[79] The majority of studies show that, during vaginal sex, condoms break approximately 2% of the time during intercourse or withdrawal; a similar proportion slip off completely.[3,69,80–84] However, rates of breakage and slippage vary widely across some studies (0–22% for breakage;[73,80] 0–9% for slippage).[80,85] For studies that have recorded

higher breakage and slippage rates, it is unknown how much of this variability is attributable to incorrect use and how much is due to misreporting of these events.

Reviews of studies evaluating breakage and slippage during anal intercourse indicate the rates may be slightly higher than during vaginal intercourse.[86,87]

4. *Improper lubricant use with latex condoms*. Unlike water-based lubricants (e.g., K-Y Jelly), oil-based lubricants (e.g., petroleum jelly, baby oil, and hand lotions) reduce latex condom integrity[88] and may facilitate breakage. Some individuals use oil-based products as condom lubricants, mistaking them for water-based lubricants because they readily wash off with water. Because vaginal medications (e.g., for yeast infections) often contain oil-based ingredients that can damage latex condoms, clients who will be using these medications should be advised to remain abstinent, use synthetic condoms, or use other protective measures until the medication is fully completed and the infection is cured.

N-9 LUBRICATED CONDOMS

Condoms lubricated with a small amount of the spermicide nonoxynol-9 (N-9) have been available in the United States since 1983. However, their use is not recommended because spermicidal condoms are no more effective than other lubricated condoms despite their higher cost and shorter shelf life.[89] Also, concerns have been raised about N-9 products in general, because high frequency use of vaginal N-9 products may cause genital ulceration and irritation and therefore facilitate transmission of STIs including HIV (see Chapter 94 on Topical Microbicides and Other Chemical Barriers for Prevention of STD/HIV Infection and Pregnancy). Since the amounts of N-9 contained in a spermicidal condom are much lower than those found in vaginal products, they are probably less likely to cause adverse effects; however, spermicidal condom use was associated with increased risk of urinary tract infections in young women in one study.[90]

NATURAL MEMBRANE CONDOMS

Natural membrane condoms ("natural skin," or "lambskin") are made from the intestinal caecum of lambs. No contraceptive or STI prevention effectiveness data are available. Unlike latex condoms, natural membrane condoms contain small pores in the surface that may permit the passage of viruses, including hepatitis B virus, herpes simplex virus, and HIV and thus may not offer the same level of protection as latex condoms.[9,91] Therefore, they should not be recommended for STI/HIV prevention.

SYNTHETIC MALE CONDOMS

Male condoms manufactured from polyurethane or other synthetic materials offer several advantages over natural rubber latex condoms. Synthetic condoms are generally odorless, colorless, nonallergenic, have a longer shelf life, and are compatible with both oil-based and water-based lubricants.[3,92] Three synthetic condoms have been cleared by the U.S. FDA and are currently available in the United States (Avanti, Trojan Supra, and eZ·on). For pregnancy prevention, synthetic male condoms have similar rates to their latex counterparts. However, the effectiveness of synthetic condoms in preventing STI/HIV has not been studied and FDA labeling restricts their recommended use to latex sensitive condom users.

CONDOM PROMOTION

Despite evidence that condom use can effectively reduce the risk of unintended pregnancy and many (STI), including HIV infection, the promotion of condoms remains controversial in many countries, including the United States. According to two recent reviews,[93,94] behavioral interventions featuring condom promotion have been associated with increases in reported condom use[95–101] and, to a lesser extent, decreases in STI incidence.[94–96,102]

The type of condom offered has little influence on measured level of protection. A four-country intervention focused on condom attributes found that providing a choice of condoms led to increased acceptability but had no impact on self-reported use or incident infections.[103]

Latex condoms are among the most inexpensive and cost-effective contraceptives, given the additional protection provided against STI.[3] Condom distribution has also been shown to be cost-effective for STI prevention in high-risk populations.[104,105] Though widespread support exists for targeted interventions to encourage condom use,[1] concerns have been raised about the potential negative consequences of condom promotion.[106] Increased promotion[107] or availability[108] of condoms may not necessarily translate into increased levels of use. Also, some interventions promoting condoms may result in a "disinhibition" effect[106] that facilitates the onset or frequency of high-risk sexual activity, as suggested by some studies.[109,110] However, the most recent meta-analysis of 174 sexual risk reduction intervention studies concluded that condom-related interventions do not "inadvertently undermine sexual risk reduction efforts by increasing the frequency of sexual behavior."[111]

Levels of condom use have increased in recent years; however, current levels of use remain low based on results of national surveys of adolescents[112,113] and adults.[114–117] The low levels are insufficient to have a major public health impact on preventing pregnancy and STI. Not surprising, consistency of condom use is higher in casual than primary partnerships because of the perceived higher risk of infection. However, even among couples discordant for HIV or genital HSV, where a risk for infection is known, fewer than

half of couples regularly use condoms.[17,53] New strategies that emphasize condom use for contraception in addition to disease prevention (dual protection),[118] as well as new condom technologies that can address personal (e.g., device, psychological, and logistical) barriers to use, may help increase overall levels of use.

ROLE OF CONDOMS IN COMPREHENSIVE HIV/STD PREVENTION STRATEGIES

Like any prevention tool (e.g., seat belts, airbags, smoking cessation programs, virginity pledges), condoms are not 100% effective. What then is the appropriate role of an imperfect prevention method, like condoms, among strategies to reduce HIV spread? Those using various approaches to preventing STI/HIV, as well as other health conditions, recognize that incremental, partially effective steps work best to produce collectively effective (but not perfect) prevention programs.[119] Controlling the spread of STIs will require different, mutually reinforcing techniques.

Although these combined prevention strategies can dramatically affect HIV spread,[120] they need to be carefully designed and implemented. Accurate messages about condoms must build on (and not substitute for) a wide range of HIV/STI risk avoidance and risk reduction approaches.[121] These approaches include delayed initiation of sexual intercourse, mutual faithfulness, and selection of low-risk partners.[122] Together with condoms, these reinforcing epidemiologic truisms have been labeled both now and in the past as an "ABC strategy:" abstinence, be faithful to one partner, or—if "A" or "B" cannot be achieved—use condoms.[1] This ABC approach defines an appropriate role for condoms as an essential part of a larger armamentarium for HIV prevention.

CONDOM INSTRUCTIONS

Instructions for condom use are often overcomplicated and may have no scientific basis.[3,123] During a WHO experts meeting (Geneva, June 22–24, 2005) to develop a Global handbook for family planning providers, consensus was reached on five key condom instructions. These five messages, with minor modifications, are as follows:

1. Use a new condom for each act of intercourse if any risk of pregnancy or STI exists.
2. Before any genital contact, place the condom on the tip of the erect penis with the rolled side out.
3. Unroll the condom all the way to the base of the erect penis.
4. Immediately after ejaculation, hold the rim of the condom and withdraw the penis while it is still erect.
5. Throw away the used condom safely.

Additional, more detailed condom instructions are available elsewhere.[3,124]

FEMALE BARRIER METHODS

Though modern vaginal barriers such as caps and diaphragms have been used for pregnancy prevention since the early nineteenth century,[125] recent effort has focused on developing effective female barrier methods that women may use as an alternative to male condoms for prevention of HIV/STI.

FEMALE CONDOMS

The female condom provides a physical barrier that lines the vagina and shields the introitus. The first female condom, originally called Reality, was approved by the FDA in 1993 for over-the-counter sale in the United States. This device is a soft, loose-fitting polyurethane sheath with two flexible polyurethane rings. One ring lies inside, at the closed end of the sheath, and serves as an insertion mechanism and internal anchor. The other ring forms the external, open edge of the device and remains outside the vagina after insertion. This female condom is now called FC1, has been introduced in over 90 countries and is still the only such device cleared by the FDA in the United States.[126] Variations to its basic design have been developed and distributed outside the United States.

FEMALE CONDOM, EFFECTIVENESS

Limited laboratory data suggest that the female condom provides an impermeable barrier to HIV and cytomegalovirus[127] and to much smaller viruses.[128]

A study comparing male and female condoms found that the female condom had significantly lower breakage rates (0.1% vs. 3.1%) but significantly higher slippage rates (5.6% vs. 1.1%)[82] A recent randomized crossover study using prostate specific antigen (PSA) as a marker for semen exposure found significantly more PSA after female condom use compared to male condom use.[129] Self-reported problems were significantly higher with the use of female condoms as well.

No clinical studies have evaluated the female condom's ability to prevent HIV transmission. One small clinical study detected no trichomoniasis reinfection in a group using female condoms consistently but was underpowered to detect differences between consistent female condoms users and two control groups.[130] In two of three randomized trials of behavioral interventions promoting the female condom, groups assigned female condoms had lower STI rates than groups assigned male condoms although the differences were not statistically significant.[131,132] In the third trial the STI rates in the group with access to only male condoms was the same as in the group with access to both male and female condoms.[133] A nonrandomized study provides evidence that adding female condoms to a male condom distribution program targeting sex workers may significantly increase both the proportion of protected acts and significantly reduce STI prevalence.[134]

Because these devices cost substantially more than male condoms, the cost-effectiveness of providing female condoms in public sector programs remains under study.[126,135] One approach to reducing the cost of female condoms is reusing the device. Different protocols for disinfecting female condoms have been evaluated for their effectiveness.[136–138]

For pregnancy prevention, the most rigorous data are from the US-based study submitted to the FDA of 221 couples using the Reality female condom for pregnancy prevention.[139] In this study, the risk of pregnancy during the first twelve months of consistent use of the female condom was 5% (21% during typical use), a figure higher than that associated with consistent use of male condom. Additional published studies in the UK and Japan had somewhat lower rates.[140,141] In conclusion, head-to-head comparisons of male and female condoms using both pregnancy and STI outcomes are still lacking.

CERVICAL BARRIERS

Diaphragms and caps usually combine two contraceptive mechanisms: a physical barrier to shield the cervix and a chemical to kill sperm. Moreover, these devices help to hold spermicide in place against the cervix. In recent years, the choice of cervical barrier methods has expanded from the traditional latex diaphragms and cervical caps to a new generation made of silicone.[142] The N-9 sponge has both physical and chemical properties (see Chapter 94).

CERVICAL BARRIERS, EFFECTIVENESS

The cervix is the primary target for gonorrhea, chlamydia, and possibly for HIV because it contains a high number of specific chemokine receptors known to be HIV coreceptors.[143,144] No published studies have evaluated cervical barriers for HIV prevention, although several are underway. Although no cohort or intervention studies have evaluated cervical barriers for other STIs, a review of the case-control and cross-sectional studies evaluating cervical barriers suggest that diaphragms may reduce the risk of some STI.[144] We have to await results from current prospective trials before drawing more definitive conclusions about cervical barriers' protective effect against STI/HIV.

On the other hand, the contraceptive effectiveness of cervical barriers is well established. Cervical barriers are among the least effective contraceptive methods, with the pregnancy rate for the first year of consistent use ranging between 6% and 26% (pregnancy rates for typical use range between 16–32%).[68]

BARRIERS FOR ORAL SEX

Condoms are recommended for use during fellatio.[3,89] Latex sheets to be used for cunnilingus/anilingus have also been cleared by the FDA for sale over the counter. Household plastic wrap (including the microwaveable variety) is another option for cunnilingus/anilingus, although it has not been manufactured, intended, or cleared by the FDA for this use. No effectiveness data are available.

CONCLUSION

Male latex condoms, if used consistently and correctly, reduce the risk of transmission of HIV (the most serious STI), many other STIs, and unintended pregnancy. The public health endorsement of male latex condoms is based on the barrier properties of condoms, biologic plausibility, and evidence of risk reduction from clinical studies.

For other barrier methods, the evidence for STI/HIV protection, while weaker, is strongest for the female condom based on biologic plausibility and limited laboratory and clinical studies. For the remaining barrier methods, we need to wait for results from well-designed, on-going clinical studies before deciding whether and how these devices should be incorporated into prevention strategies.

For all barrier methods shown to be effective in clinical studies, achieving consistent and correct use remains the largest problem impacting their "real world" effectiveness. To optimize use of male condoms in sexually active populations with a high prevalence of HIV/STIs, public health messages must reinforce and unequivocally communicate the scientific evidence on condom effectiveness.

94 Topical Microbicides and Other Chemical Barriers for the Prevention of STD/HIV Infection

Zeda F. Rosenberg, Michael Gross, Sharon L. Hillier, and Willard Cates, Jr.

HISTORY

Less than 2 years after the earliest reports of what came to be known as AIDS, a case series published in 1983 indicated that the syndrome was beginning to surface among women.[1] Their only identifiable risk was a male sexual partner with AIDS. Less than a decade later, the incidence of HIV infections worldwide among women exceeded that among men, with a large fraction of infections attributable to their sole lifetime male partner.[2] To address the need for women to protect themselves from HIV infection, research on "germicides for HIV and other microbes" emerged as a high priority on the HIV prevention agenda.[2]

That same summer in 1992, results appeared from the first controlled clinical trial of a commercial spermicide-impregnated sponge for preventing vaginal transmission of HIV.[3] Although the active ingredient, nonoxynol-9 (N-9) effectively destroyed HIV in vitro, in this trial, N-9 was associated with a nonsignificant increase in risk for HIV acquisition compared with a non-N-9 product. It was also found to produce elevated rates of vulvitis and genital ulcers.[3] Investigators hypothesized that the dose of N-9 (1000 mg) and frequent exposure to its surfactant activity may have disrupted healthy epithelial tissue to cause the genital lesions and inflammation found among the Kenyan sex workers. Women's health advocates remained hopeful about prospects for N-9, but some scientists urged caution while further data on lower doses and different formulations were being collected.[4]

For the next decade, the unrelenting global spread of HIV continued, with an increasingly disproportionate impact on women, especially young women and adolescent girls.[5] Among women surveyed in southern Africa, 40% were HIV-positive even though 66% reported having only a single lifetime sexual partner and 79% had abstained from sex until at least 17 years of age.[6] For a large fraction of women in many developing countries, the greatest source of risk was their husband.[7] Even with increased access to female condoms,[8] less than 5% of married women of childbearing age worldwide used condoms regularly.[9] Men's extreme resistance to condoms, women's reluctance to risk reprisals by suggesting them, and cultural and familial norms that make childbearing a critical determinant of women's status together rendered condoms ineffectual against the risk of HIV exposure by nonmonogamous husbands.[10–13]

During that same decade, a series of other commercially available N-9 formulations entered clinical trials for efficacy against HIV and other STDs.[14–17] The fact that these products were already approved by U.S. regulatory authorities for use as contraceptives meant that alternative forms of N-9 products could be evaluated in trials rapidly. Additional trials were also motivated by the hope that lowering the dose of N-9 and delivering it in a different formulation such as a film or gel would retain microbicidal potency while avoiding toxicity to healthy tissue. Phase I and II "safety" trials of these N-9 formulations provided evidence to substantiate their safety but Phase III results for HIV prevention showed no evidence of protection. Additional evidence of toxicity to vaginal epithelium was found among high frequency users, even at low doses and despite variations in the delivery system. These findings prompted the abandonment of N-9 as a potential microbicide for HIV prevention[18] and heightened caution about toxic effects of other candidate surfactants.[19]

While the N-9 trials were being conducted, a new class of microbicides, polyanions, was being developed. These products entered efficacy trials in 2004–2005 among women living in sub-Saharan Africa. Newer classes of products, based on HIV antiretroviral therapy were developed and evaluated in preclinical and clinical safety studies. The importance of targeting multiple mechanisms as a principle of HIV antiretroviral therapy that increases efficacy and delays onset of resistance has begun to influence microbicide product concepts. However, all microbicide products evaluated for efficacy in the first wave of trials and most products in advanced preclinical testing represent single agents, some of which may have dual modes of anti-HIV activity.

In addition to vaginal microbicide use, increased attention has been directed at product safety with rectal administration.[20,21] Acceptability of surrogate products for a rectal microbicide is

being investigated.[22] In addition to an unmet need for additional methods for reducing risk of unprotected sex between men, an important incentive for such research came from studies showing that anal intercourse was part of the sexual repertoire among a substantial number of sexually active heterosexuals worldwide.[23,24] Moreover, rectal exposure appears to transmit HIV more efficiently than vaginal intercourse.

Finally, protection against unintended pregnancy is an issue. A product with dual efficacy as both a contraceptive and microbicide would increase its appeal for women who do not wish to become pregnant. However, in many developing countries, a woman's economic survival and social well-being, as well as the durability of her marriage, may depend on her capacity to bear children. Thus, for those women desiring pregnancy, a noncontraceptive method to avoid HIV infection is essential. Using condoms is not an option in this context.

MICROBICIDES: CONCEPTS AND CHARACTERISTICS

Topical microbicides are designed to kill or inactivate HIV and/or other STDs to interrupt mucosal (vaginal and/or rectal) transmission at or near the site of exposure. Various criteria describe a successful microbicide, beginning with safety and efficacy, the sine qua non of a successful product (Table 94-1). Other considerations range from those that influence feasibility, such as heat stability (which is critical in developing countries where refrigerated storage is impractical) through those that may influence speed of dissemination, such as expeditious approval of over-the-counter availability.

HIV TRANSMISSION AND INACTIVATION

Opportunities to prevent HIV infection have emerged with the elucidation of specific cellular and molecular processes involved in the establishment of infection. The critical threshold for protection is successful blocking of the integration of the viral genome into host cell DNA.[25,26] Integration is problematic because resting cells that contain the HIV genome are indistinguishable from uninfected cells, putting HIV out of reach of therapeutic drugs. Eventually, these resting cells are likely to be reactivated, whereupon they begin to translate HIV genes into infectious viral particles capable of disseminating infection to previously uninfected host cells.

More than a decade of research has elucidated specific molecular structures and mechanisms involved in the process through which cell-free or cell-associated HIV from an infected, transmitting partner establishes infection in lymphocytes and other susceptible cells. Each such step that can be interrupted offers a hypothetical point of attack for microbicides designed to prevent the establishment of latent infection (Figure 94-1).

Initially, HIV either crosses a breach in otherwise intact vaginal or cervical epithelial tissue to reach susceptible host lymphocytes beneath or encounters macrophages, lymphocytes, or Langerhans cells, a specialized type of dendritic cell, in the vaginal lumen or the cervix. Among macrophages and lymphocytes, establishment of infection may occur directly after HIV has attached to the membrane of those target cells.

In contrast, Langerhans cells may be exploited as a kind of "Trojan horse" by HIV: normally present within the vaginal mucosa with processes that extend into the vaginal lumen, they adsorb and deliver infectious agents to reservoirs of T cells in regional lymph nodes[26] that are activated to respond to the pathogen that has been adsorbed by the Langerhans cell. When a Langerhans cell that has adsorbed HIV migrates to a regional lymph node, it may recruit additional susceptible cells to the site of infection.

Once attachment occurs, binding, fusion, and entry of HIV continue via an interaction between gp120 molecules on the outer envelope of HIV with CD4 receptors on the surface of host target cells.[27] An additional molecular interaction must occur to effect HIV entry, in which binding sites on the HIV envelope interact with a coreceptor molecule on susceptible target cells,[28] called a "chemokine receptor" because its conventional immunologic role is to respond to the presence of specific chemokines, a family of molecules that normally regulate immune cell activity.

HIV subtypes are characterized by their coreceptor binding specificity. Most sexually transmitted subtypes preferentially bind to CCR5.[28] Consequently, CCR5-blockers are of great interest as potential microbicides. CXCR4 may mediate sexually transmitted HIV infections[29] and has been isolated in early specimens from sexually exposed individuals who lack a pair of functional genes required for expression of CCR5, but it is otherwise much less likely to be implicated in sexual transmission. CXCR4 subtypes emerge among about half of patients with advanced HIV disease—they cause more rapid lymphocyte depletion than CCR5-tropic subtypes.[28] Dendritic cells also express a third coreceptor, DC-SIGN.

Interactions between HIV envelope binding sites and target cell receptors and coreceptors initiate a conformational change that exposes gp41,[30] another molecular constituent of the HIV envelope that participates in the fusion of viral envelope with the target cell membrane. The specific interactions between HIV binding sites and target cell receptors present opportunities for blocking HIV attachment, fusion, and entry into susceptible cells. The first drug approved for treatment that uses this strategy, enfuvirtide or Fuzeon™,[31] is a fusion inhibitor that blocks a region of gp41 that is involved in the fusion of viral envelope with host cell membrane.[30] Other agents that block interactions between gp120 binding sites and either CD4 or the coreceptors CCR5 and CXCR4 are areas of active research for therapeutic drug development.

Once HIV gains entry into a susceptible host cell, its genetic sequences, encoded in a single-stranded RNA molecule, provide a template for the synthesis of a two-stranded DNA

Table 94-1. Fundamental Microbicide Characteristics

Essential	
efficacious	randomized controlled clinical trial(s) demonstrate at least 30% effectiveness, with sufficient power to assure that the lower bound of the confidence interval for the effectiveness point estimate exceeds zero
nontoxic	absence of product-related epithelial lesions detectable with the naked eye or under colposcopic examination
	absence of subclinical inflammatory responses that recruit susceptible target cells to the vaginal mucosa
	absence of interference with natural defenses against infection, e.g., low pH, presence of peroxide-producing *Lactobacillus*
	absence of symptoms or sensations that may discourage use, e.g., itching, burning
acceptable	women's willingness to use product is foremost; men's responses, if any, likely to influence product use.
	acceptability pertains to completeness of coverage for all sex acts not protected by barrier and to adherence with guidelines for product administration (e.g., timing, dose)
Critical	
heat stable	storage and distribution have no cold chain requirement, which would be unfeasible for many resource-poor countries
readily commercialized	no intellectual property issues threaten technology transfer, licensing, etc.
	methods used for pilot amounts of product for large-scale clinical trials can be scaled up readily for large-scale manufacturing
Desirable	
active against other STDs	reduces direct mortality and morbidity, including potential threat to fertility; may reduce susceptibility to HIV infection associated with STD-associated genital lesions or inflammatory responses
noncontraceptive and contraceptive	noncontraceptive product addresses a need for protective method compatible with social/cultural/family incentives or pressures to bear children; dual efficacy against HIV and for pregnancy prevention may facilitate product use among women who seek to prevent pregnancy
minimal adherence barriers	noncoitally dependent expected to improve adherence and facilitate protection against HIV for unplanned sex acts, both elective and coerced
low cost/dose	use by women in resource-poor settings will depend on cost; if access depends on securing price subsidies, availability may be delayed or unevenly distributed
discreet	women can use the product without requiring male acceptance or approval in those situations where male cooperation may be problematic

transcript of the proviral genome. The process of reverse transcription of viral RNA uniquely characterizes the lifecycle of retroviruses. Two strategies for blocking the unique retroviral requirement for reverse transcription have been a focus for development of therapeutic drugs. One technique substitutes a rogue molecule, instead of the normal subunit, into the developing linear sequence of the DNA transcript. This substitute subunit is unable to form a chemical bond with the next subunit, thereby terminating the DNA transcript before it has been completed. This approach was the first component of the HIV lifecycle targeted for therapeutic drug development, which has generated an array of nucleoside reverse transcriptase inhibitors (NRTIs) as therapeutic drugs, as well as one nucleotide compound with similar activity.

Instead of interfering with the DNA transcript, a second strategy for interfering with reverse transcription employs a molecule that has been engineered to bind preferentially to an active site on reverse transcriptase, blocking the enzyme from

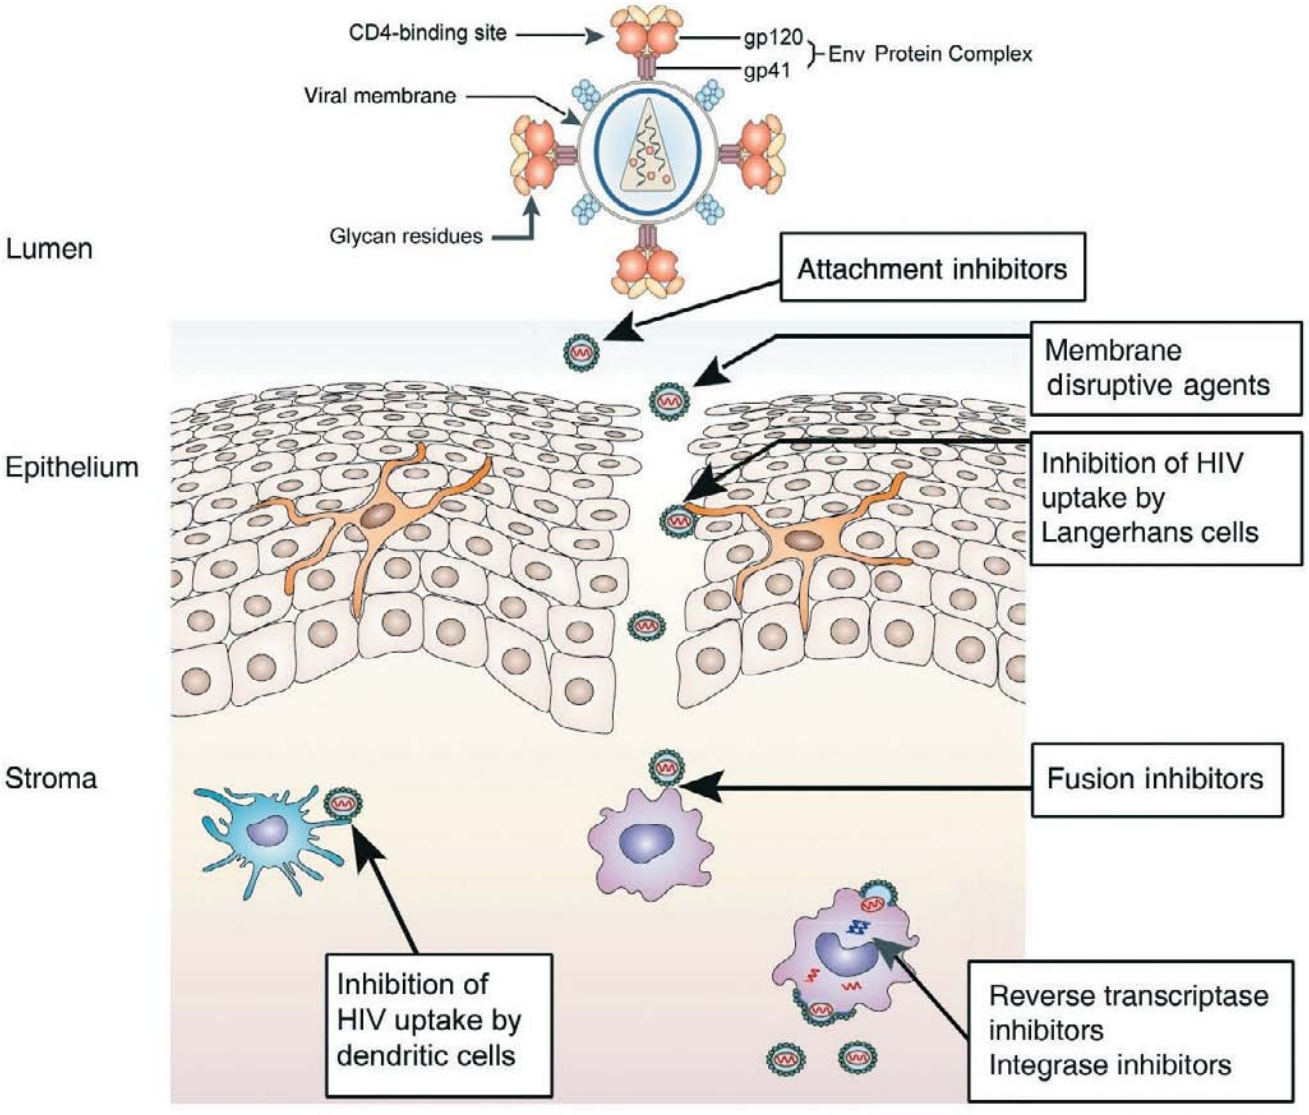

FIGURE 94-1. Potential approaches to prevention of HIV infection by topical microbicides. The lower portion of the figure illustrates potential mechanisms by which a topical microbicide could block HIV-1 infection of sub-epithelial target cells in the vaginal lumen. In the upper portion of the figure, an enlarged schematic of an HIV-1 particle identifies specific molecular structures associated with HIV-1 binding, fusion, or entry into target cells. (Adapted from Shattock RA, Moore JP. Inhibiting HIV-1 Sexual transmission. *Nat Rev Microbiol* 2003; 1: 25–34.)

assembling a DNA transcript of proviral RNA. Non-nucleoside reverse transcriptase inhibitors (NNRTIs) include some of the most potent therapeutic drugs, and development of new agents in this class that have minimal cross-resistance with licensed NNRTIs is a vigorous area of therapeutic antiretroviral research.

Before a completed DNA transcript can be integrated into host cell DNA, another enzyme, integrase, must effect a series of molecular modifications associated with "strand transfer" in which proviral and host cell DNA are prepared by a specific cutting reaction followed by joining together of the processed ends of the two dual-stranded DNA molecules.[32] Integrase inhibition is one of the newest components of the HIV lifecycle to be targeted for therapeutic drug development.

Among strategies to interrupt the postentry HIV lifecycle, reverse transcription and integration are of particular relevance for microbicides designed to disable HIV before proviral DNA sequences are integrated into the genome of host cells. In contrast with the blockade of HIV before proviral DNA is integrated into the host cell genome, protease inhibitors, another class of antiretroviral drugs that have proven highly effective for treatment of chronic infection, interfere with the HIV lifecycle after infection has been established, when the proviral genome has already begun to direct synthesis of new viral particles.

MICROBICIDE MECHANISMS AND CANDIDATES

Microbicides are most often categorized by their mode of action: (1) nonspecific antimicrobial agents,[33] (2) nonspecific and specific attachment/fusion/entry inhibitors,[34]

Table 94-2. Selected Microbicides in Development

Class	Compound	HIV Research & Development Status	Sexually-Transmitted Infections[a]						Preclinical Contraceptive Activity
			CT	HD	NG	TP	HPV	HSV	
Membrane Disruptive Agents									
	Sodium lauryl sulfate[b]	Phase I/II					V	V	V
	Sodium dodecyl sulfate (SDS)	Preclinical							
Acidifying Agents									
	Carbopol (Buffergel)	Phase IIb	V A		V		V A	V A	
	Acid buffering gel (Acidform)	Phase I	V A					V A	V A
Attachment/Fusion/Entry Inhibitors									
Polyanions	Carageenan (polystyrene-4-sulfonate) (Carraguard)	Phase III	V		V A		V A	V A	
	Naphthalene sulfonate polymer (PRO 2000/5)	Phase IIb, III	V		V A		V A	V A	V
Dendrimers	Vivagel (SPL7013)	Phase I					V A	V A	
CCR5 Blockers	L-860,167	Preclinical							
	PSC-RANTES, RANTES analogs	Preclinical							
gp120 Inhibitors	BMS-599793	Preclinical							
Reverse Transcriptase Inhibitors									
Non-nucleoside Reverse Transcriptase Inhibitors	MIV-150[c]	Phase I							
	TMC120 (dapivirine)	Phase I							
	UC781[d]	Phase I							
	S-DABO	Preclinical							
Nucleotide Reverse Transcriptase Inhibitor	PMPA (Tenofovir)	Phase II/IIb							
Uncharacterized Mechanism	Praneem (polyherbal tablet)	Phase II							

[a]CT, *Chlamydia trachomatis*; HD, *Haemophilus ducreyi*; NG, *Neisseria gonorrhoea*; TP, *Treponema pallidum*; HPV, human papilloma virus; HSV, herpes simplex virus; A, animal model; V, in vitro.

[b]Formulated in a thermoreversible gel as "invisible condom" designed to supplement surfactant activity with a physical barrier.

[c]Formulated in Carraguard gel as PC-815.

[d]Formulated in cellulose acetate phthalate.

(3) intracellular replication inhibitors,[35] and (4) unspecified mechanism (see Table 94-2).

NONSPECIFIC ANTIMICROBIAL AGENTS

Although absence of evidence of HIV protection led to the cessation of N-9 and C31G development as active microbicides, other surfactants remain under consideration. For example, there is still some research being conducted on sodium lauryl sulfate and sodium dodecyl sulfate. A critical question for surfactant molecules is whether effective performance against HIV can be achieved without clinically significant toxicities.

Another means of nonspecifically inhibiting HIV seeks to enhance natural vaginal antimicrobial defenses. Two products in clinical development—Acidform and Buffergel—help maintain low vaginal pH even in the presence of semen (which elevates pH). An additional natural vaginal defense mechanism is associated with the normal colonization by *Lactobacillus*

species that secrete hydrogen peroxide, a disinfectant. The hydrogen peroxide produced by some species of *Lactobacillus* can combine with halide (Na+) and myeloperoxidase to create reactive oxygen species, which have potent antimicrobial properties. Suppositories have been developed which contain a large dose of *Lactobacillus* in a preserved state. It is hoped that these exogenous *Lactobacillus* might help restore an optimal vaginal microbiota. In addition to hydrogen peroxide, these bacteria also help maintain low pH by producing lactic acid.

ATTACHMENT/FUSION/ENTRY (A/F/E) INHIBITORS

Nonspecific attachment inhibitors

A group of negatively charged polymers, or polyanions, electrostatically binds to the positively charged HIV envelope, physically blocking attachment of virus to target cells in the vagina. Three of these molecules entered large-scale efficacy trials in 2004–2005. PRO2000/5 may have contraceptive activity; Carraguard is expected to be noncontraceptive. Two phase 3 trials of cellulose sulfate gel, a third polyanion attachment inhibitor, were not completed after an external study monitoring group review found that preliminary data from one trial had exceeded protocol-determined thresholds for stopping.[36] No evidence for effectiveness could be reached. Dendrimers, such as VivaGel, are highly branched macromolecules that also prevent HIV from attaching to the target cells in in vitro studies.[37] VivaGel safety studies were initiated in 2005–2007.

Cellulose acetate phthalate (CAP) another polyanion, is water insoluble at low pH and formulated as micronized beads in an acid-buffering system (Aquateric). Seminal plasma seems to lower the effective dosage of Carraguard, cellulose sulfate, and PRO2000/5 in vitro, but acid buffering preserves anti-HIV activity of Aquateric and Buffergel.[38]

Specific A/F/E inhibitors

Specific molecular structures and interactions are associated with attachment and fusion of HIV with the membrane of target cells. For example, cyanovirin-N and BMS-599793 both bind to gp120 to prevent its interaction with the CD4 docking site on host target cells. Drugs in preclinical development that block CCR5 include analogs of RANTES, a naturally occurring chemokine that binds to the CCR5 receptor and CMPD-167. Suppression of CCR5-tropic virus may permit CXCR4 subtypes to predominate, resulting in accelerated disease progression, a concern that might be addressed by including compounds that block CXCR4 in a combination product.[19]

Another hypothetical risk of blocking coreceptors stems from their role in the regulation of normal immune responses. Effects of long-term blockade of the CCR5 receptor on T cell functionality have yet to be determined. While approximately 1% of Caucasians do not express the CCR5 receptor and yet maintain a normal inflammatory response,[29] their responses may not pertain to immunoregulatory interactions among individuals who do express CCR5.[19]

The dendritic cell coreceptor DC-SIGN[39] is inhibited by compounds such as mannan, but the majority of dendritic cells also express CCR5 and CXCR4 coreceptors, as well as the CD4 surface marker. Compounds like mannan would function most effectively in a microbicide with complementary activity, e.g., molecules that blocked CD4 or the alternate coreceptors CXCR4 or CCR5.[19]

Therapeutic efficacy of Fuzeon in chronic HIV infection demonstrates the potential utility of blocking that component of the viral lifecycle, but the large size and complex 3-dimensional structure of the Fuzeon protein requires a costly manufacturing process, even with economies that derive from large-scale production. Smaller, less costly molecules are being developed that would be more feasible as candidate microbicides.[40,41]

INTRACELLULAR REPLICATION INHIBITORS

Two classes of antiretroviral drug that target postentry mechanisms seem well-adapted to the requirements for a microbicide administered at a mucosal site of potential HIV exposure: reverse transcriptase and integrase inhibitors.

Reverse transcriptase inhibitors

Most NRTIs approved for treating established HIV infection are nucleosides, which require three phosphorylation reactions,[42] a process influenced by cellular factors such as cell type, stage in the cell division cycle, and activation and infection status of the cell in which they occur.[42] In particular, initial phosphorylation by nucleoside kinases is believed to be rate-limiting.[43] One NRTI, tenofovir, is a nucleotide, which does not require the initial, rate-limiting step and which undergoes only two phosphorylation reactions,[43] making it more suitable for microbicide development. Clinical studies are in progress with tenofovir formulated as a microbicide gel,[44] including one efficacy study.

Among molecules that have been designed to block a binding site on reverse transcriptase, a subgroup of NNRTIs bind irreversibly to reverse transcriptase, are highly potent, and have long half-lives. In addition to inhibiting the replication of HIV within the host cell, NNRTIs may also inhibit infection by cell-free virus[45] that may enable a microbicide based on such a compound to inactivate HIV in the vaginal lumen. However, the mechanism of this cell-free inhibition has yet to be determined and its relevance in vivo is unknown.[46] NNRTIs currently in development as microbicides include dapivirine (TMC120), MIV 150, UC 781, and S-DABO.[37,47,48]

Integrase inhibition

The integration of the proviral DNA into host cell DNA involves multiple steps that are catalyzed by the HIV-1

enzyme integrase. Integrase inhibitors are a new class of antiretroviral compounds that prevent this process from occurring, which in turn prevents translation of the HIV genome into enzymes and proteins that would generate new HIV particles. Although designed to block incorporation of the viral genome into host cell DNA, integration occurs after transcription of viral RNA, which is relatively late in the HIV lifecycle. In theory, infection may be established if only one viable copy of the viral genome evades an integrase inhibitor. Therefore, an active agent from this drug class may be effective only if used in combination with drugs that supplement this strategy with other modes of action.

COMBINATION PRODUCTS

If HIV escapes from one blocking or inhibitory mechanism, a product that exploits an additional vulnerability of HIV would be expected to increase overall efficacy. For example, one of the NNRTIs, MIV-150, has been formulated in Carraguard for clinical evaluation.[48] Further advantages observed during in vitro and animal model studies of combination product concepts stem from synergistic effects of some combinations, as observed, for example, in vitro for UC-781 formulated in CAP.[49] Such synergy may permit reduced drug concentrations of the active agents without loss of potency that may reduce the risk of local or systemic toxicities and, possibly, per dose manufacturing cost. On the other hand, preclinical and clinical studies should take into consideration that multiple active ingredients may display unexpected toxicities.[19] Combination products also address two hypothetical concerns about microbicides using antiretroviral drugs that may develop cross-resistance with drugs in use for HIV therapy. The first is the potential for transmission of drug-resistant strains that may overcome a microbicide based on an antiretroviral drug.[46] As with HIV therapy, combinations of active agents may pose a higher barrier against infection by cross-resistant HIV subtypes in circulation. However, because resistance reflects reduced susceptibility of HIV rather than total invulnerability,[50] microbicide resistance will also depend on drug concentration in the vaginal lumen or target tissues.

The second concern about resistance pertains to microbicide use among HIV-positive women who are unaware of their HIV status. If concentrations of an adsorbed antiretroviral were high enough to select for resistance, fewer treatment options may remain available to infected women.[46] Combination products may reduce the likelihood of selecting for cross-resistance to therapeutic drugs, especially in mucosal tissue where active drug is delivered. To reduce the potential for systemic toxicity, microbicides based on antiretroviral drugs are formulated to deliver effective concentrations of active ingredients locally while minimizing systemic concentration, which may also reduce the possibility of selecting for resistance. To gain a better understanding of the relevance of these concerns, resistance studies are planned in conjunction with the development of microbicides based on antiretrovirals. It will also be critical to follow women who acquire HIV infection during evaluation of ART-based microbicides, to assess the impact of microbicide exposure on emergence of resistant virus populations and the long-term impact on response to treatment.

Just as antiretroviral therapy achieves potency and durability by combining drugs that together erect a higher genetic barrier against drug resistance,[51,52] microbicide concepts that anticipate and preempt potential resistance may avoid potential disadvantages associated with sustained use. For example, investigators studying agents that block coreceptor utilization by CCR5-tropic HIV subtypes have suggested including activity against CXCR4 coreceptor binding in order to avoid selecting for the more pathogenic CXCR4 subtype.[19] Combination microbicides may also retain potency longer than single-agent products in the context of rapid mutation or recombination of circulating viral strains. Future microbicide development will include technologies designed to accommodate combinations of active components.[53]

FORMULATION IN MICROBICIDE DEVELOPMENT

One of the important recent advances in microbicide development efforts has been the increased emphasis on formulation science. Composition and physicochemical properties of a formulation can influence a product's efficacy, including its delivery of an active ingredient to target tissue, timing of its release from a vehicle or other delivery system, physical dispersion on mucosal surfaces, systemic absorption, and toxicity. Formulation influences both cost and acceptability to the user. Delivery systems that allow for coital independence and techniques for modifying the sensory properties of a candidate microbicide are especially pertinent to microbicide development. Specialized techniques for measuring delivery of active molecules by topically applied vehicles and for examining intravaginal distribution and retention of vehicle prototypes and candidate products contribute to product optimization.

Formulation expertise also supported development of a placebo that meets stringent requirements for an inert gel against which the performance of a variety of candidate topical products can be compared. To maintain study blinding, an ideal placebo gel would be identical to the gel vehicle in the active arm. However, an identical placebo is not feasible for microbicide vehicles that have bioadhesive, lubricating, and pH buffering properties, all of which might contribute to the protective effect of the active gel.

These considerations suggested the utility of a "universal placebo" for multiple trials, which might be distinguishable

from the investigational microbicide, but still could be masked so that participants and research staff would not know which study gel is placebo and which is the investigational product. Key considerations were absence of clinically significant microbicidal activity, lack of detectable toxicity, and sensory properties sufficiently similar to those of candidate products to minimize differences in frequency of product use, which could otherwise confound the analysis of efficacy or toxicity outcomes. Based on these premises, a universal placebo gel was developed for the control arm of many current efficacy trials of polyanion gels.[54] Ongoing studies, which will evaluate the impact of this placebo gel versus no gel, will provide a critical assessment of whether the placebo gel has any impact on HIV acquisition.

Although topically applied products initially captured attention because they could be applied just before sex and seem more compatible with sexual pleasure than latex or urethane barrier devices, coitally dependent products pose obstacles that may impair the consistency with which they are used.[55] Since adherence problems can reduce the effectiveness of microbicide candidates, coitally independent products that eliminate the need to administer the product just before sex are in development. If the flexibility of daily or less frequent application helps assure fuller coverage of all sexual contacts, especially those which are unanticipated or coerced, overall effectiveness should be improved over coitally-dependent approaches.

Taking this concept one step further, vaginal rings are being studied as a means of delivering a drug or combinations of drugs for periods of 1 month or more.[56] The feasibility of a vaginal ring to deliver the NNRTI, dapivirine, has recently been demonstrated in both animal studies and pilot clinical trials.[57]

Sustained release formulations may be able to control delivery[58] so as to minimize the likelihood of systemic absorption. However, even with good control over systemic absorption, local toxicity or irritation to the vaginal or cervical mucosa remains a concern for all topically applied products. Severe local toxicity could breach the mucosal epithelium, allowing HIV to enter the systemic circulation and reach susceptible target cells.[59] Cell types recruited to the vagina or cervix by more subtle inflammatory responses are also target cells for HIV,[60] suggesting the possibility that subclinical markers of inflammation may predict an elevated risk of HIV infection. As discussed in the context of preclinical and clinical testing, establishment of sensitive, reliable markers of unacceptable toxicities is an extremely high microbicide research and development priority.

Formulation science may help minimize perturbations of vaginal ecology that would compromise this natural barrier to infection, for example, by minimizing interference with hydrogen peroxide producing *Lactobacillus* species. Lactobacillus is also under consideration as a potential drug delivery system that might be another way to achieve coital independence. The concept involves vaginal insertion of *Lactobacillus* modified by genetic engineering to express a gene for an anti-HIV protein or nucleic acid fragment with specific anti-HIV activity. In effect, this is a kind of combination microbicide in which the drug delivery system, modified *Lactobacillus*, delivers an active molecule with specific activity against HIV while offering the nonspecific protective benefits associated with colonization by peroxidase-secreting bacteria.

Regional variations in cultural preferences and sexual practices suggest that no single product-type will be universally acceptable. Microbicide developers are investigating diverse formulations including lotions, films, intravaginal devices, and solid dosage forms such as foaming pills, as well as novel polymers and biologically triggered drug release systems.[53,61]

MICROBICIDES AND PREVENTION OF OTHER STDs AND PREGNANCY

Initial microbicide interest focused on the active ingredient in commercial spermicides, N-9, and examined its effects on the full range of sexually transmitted infections. In vitro assays and animal studies indicated that N-9 was effective against herpes simplex virus (HSV), *Neisseria gonorrhoeae, Treponema pallidum*, and *Trichomonas vaginalis*.[25] Moreover, the widespread commercial availability of N-9 contraceptives permitted epidemiologic studies of both its safety and its efficacy against STDs but findings were inconsistent.[62]

Beginning in 1990, well-conducted randomized controlled trials compared different N-9 formulations—sponge, film, and various gels—and dosages[3,15–18,63] for their efficacy against HIV and other STDs. Taken together, these studies demonstrated little (if any) protection against gonorrhea and chlamydia. Accordingly, N-9 products are not recommended for STD protection.

Newer candidates in large-scale HIV efficacy trials demonstrate activity against other STDs when tested in vitro or through vaginal challenge studies among animals. Several also display some level of contraceptive efficacy (Table 94-2). Dual activity in protecting against HIV and other STDs could enhance a candidate's future because of the potential synergy between direct activity against HIV and control of STDs that otherwise might increase HIV susceptibility. Statistical models of dual activity against HIV, as well as other STD that potentiate HIV acquisition, predict an amplified impact on HIV transmission.[64]

Large-scale efficacy studies of topical microbicides generally include frequent screening for sexually transmitted pathogens such as *N. gonorrhoeae*, *Chlamydia trachomatis*, HSV-2, syphilis, and *T. vaginalis*. It is likely that these studies will provide some evidence about whether microbicides have substantial impact on the acquisition of other STD organisms.

RECTAL MICROBICIDE DEVELOPMENT AND EVALUATION

Epidemiologic data suggest that HIV is more transmissible rectally than vaginally, which is consistent with biological differences between rectal and vaginal mucosa. Columnar epithelium in the rectum poses a less robust barrier to pathogens like HIV than stratified squamous epithelium in the vagina. Even in the absence of infection, the gastrointestinal tract is enriched in susceptible target cells for HIV in comparison with vaginal mucosa.[20] In addition, men who engage in anal sex have indicated a high level of interest in topical products for rectal use to reduce HIV[65] risk when condoms are not used or as a backup against condom failure.

Anal sex, the predominant mode of HIV transmission in the United States and many other industrialized countries, is also a part of the sexual repertoire of heterosexuals in both developing[23] and developed[24] countries. Heterosexuals who engage in anal sex typically report that they are less likely to use condoms for that practice than when they have vaginal intercourse.

Evaluation of the safety of candidate microbicides when administered rectally has become one component of vaginal microbicide research and development. Until recently, most of this activity has involved preclinical systems, but clinical safety trials are increasingly included in product development programs. Rectal safety of candidates currently in large-scale efficacy trials has been assessed by nonclincal studies using tissue explants and mouse or macaque animal models. Markers of toxicity employed in those studies include sloughing of rectal epithelium, cytotoxicity measured in cell viability assays, and rectal challenge studies with HSV-2 as a marker of disruption of rectal epithelium. Phase I studies have been conducted or are planned for the NNRTI candidates UC-781 and TMC-120,[44] as well as VivaGel.

Participants in large-scale trials of vaginal microbicides are advised not to apply products rectally and are asked to refrain from anal intercourse. Caution about rectal administration of candidate products recognizes that preclinical and clinical safety markers still have uncertain predictive value. Avoidance of anal sex helps assure that infections during efficacy trials provide the most accurate measure of protection against vaginal HIV transmission, the indication for which current products are being tested. A higher rate of infections from anal sex would be indistinguishable from vaginally transmitted infections, leading to a deceptively low estimate of protection against vaginal transmission.

Early efforts to develop rectal microbicides recapitulated the beginnings of vaginal microbicide research and development, starting with a Phase I trial of the N-9 spermicide applied rectally.[66] Absence of rectal toxicity in that study may have depended on the time at which observations were made, 12 hours on average after administration. Subsequently, rectal lavage studies demonstrated that within 15 minutes of exposure to N-9, large patches of epithelial tissue slough off rectal walls.[67] Observations such as this quickly ended consideration of N-9 as a potential active ingredient in a product designed for rectal protection. Further studies demonstrated the potential risk of N-9 as an ingredient in various brands of sexual lubricant.[68]

Research has progressed on the biology of rectal HIV transmission in a compartment anatomically, physiologically, and immunologically unlike the vagina and cervix.[20] Efforts to identify sensitive, predictive, clinical, and laboratory markers of rectal toxicity of candidate products continue.[20] Studies have also been undertaken to evaluate completeness of coverage of rectal mucosa by various vehicles that might be used to formulate a rectal product. Acceptability research has progressed from surveys of prospective users' opinions of hypothetical products to studies of acceptability and tolerability of different volumes and types of vehicles and delivery systems potentially useful for rectal products.[22] Critical new research is also being conducted on the applicators to be used for rectal microbicides.

PRECLINICAL TESTING PROCEDURES AND UNCERTAINTIES

Guidelines for specific in vitro and animal safety and efficacy data have been largely standardized (Table 94-3). Most refer to in vitro, ex vivo, and animal model studies of safety and efficacy before any humans are enrolled in clinical trials. Others parallel the transition from the earliest, small-scale safety studies to larger trials that involve greater risks, e.g., reproductive toxicology in animals in conjunction with approval to expose pregnant women to an investigational product. Additional studies that require the longest time to complete, e.g., carcinogenicity testing, may be required only when clinical trials have been completed and the product's sponsor seeks regulatory approval of an application for licensure or registration.

IMPROVING SENSITIVITY AND PREDICTIVE VALUE

Ability to predict the two key outcomes that preclinical tests are designed to evaluate, safety and efficacy, remains elusive in microbicide research and development. The large trials of N-9 have highlighted the inadequacy of standard in vitro and animal models designed to predict toxicity and show plausibility of efficacy. Even Phase I and II clinical trials failed to signal toxicity risks.

Such disconnects are not unique to the field of microbicides, as illustrated by other pharmaceuticals that revealed unanticipated safety problems late in development or postmarketing. Nevertheless, additional efforts at assay development and standardization are a high priority both for assuring minimal toxicity and for screening multiple candidates to select the most promising for advanced clinical evaluation.

Table 94-3. Preclinical Microbicide Assessments[a]

Pre-phase I[b]
- **In vitro**
  - efficacy:
    - multiple HIV subtypes including lab-adapted and primary isolates; CCR5 and CXCR4-tropic; variants representative of circulating strains of HIV
    - activity against STD, especially Chlamydia, gonorrhea
  - safety
    - cytotoxicity (cellular viability): vaginal, cervical, rectal, penile, oral mucosa
    - antiretroviral drug resistance, cross-resistance
    - condom integrity
    - carcinogenicity
    - genotoxicity: bacterial genome alterations + mouse lymphoma thymidine kinase or mammalian cell cytogenicity
  - product characterization
    - mechanism of action
    - chemistry and manufacturing controls (CMC): purity, stability, strength
- **ex vivo tissue explant system**
  - efficacy[c]
  - safety
    - cellular viability, integrity of epithelial cell-cell junctions
    - cytokine and chemokine response to microbicide exposure
- **in vivo**[d]
  - local toxicity: exposure: 2 animal species (one nonrodent, usually daily exposure in 10-day rabbit vaginal irritation model)
    - macroscopic: epithelial lesions detectable by naked eye and colposcopy-assisted
    - microscopic: histological assessment of inflammation (local recruitment of HIV target cells)
    - immunologic: changes in proinflammatory cytokines (interference with, or up- or down-regulation of, HIV binding to cell surface receptors)
  - pK (absorption, disposition, metabolism, and excretion),
  - systemic toxicity[e]
  - reproductive toxicology
  - teratogenicity (2 mammalian species, usually rat and rabbit)
  - hypersensitivity
  - maintenance of low vaginal pH
  - effect on normal vaginal flora (especially hydrogen peroxide-producing lactobacilli)
  - efficacy in animal challenge studies

Prephase II
- **in vivo**
  - chronic toxicity: 6 months rodent, 1 year nonrodent
  - completion of reproductive toxicology, teratogenicity studies

Prephase IIb/III – Pre-NDA
- **in vivo**
  - carcinogenicity: rats, mice (2-year exposure data prior to NDA submission unless otherwise agreed upon)

Recommendations for the nonclinical development of topical microbicides for prevention of HIV transmission: an update. *J Acquir Immune Defic Syndr* 2004;36(1): 541–552.
[b]When feasible assess in vitro and in vivo safety and efficacy in the presence of seminal plasma.
[c]Not required for regulatory purposes but possible correlate of protective efficacy in human trials and potentially useful in clarifying anti-HIV mode of action.
[d]Use formulated product equivalent to the material that will enter clinical trials.
[e]If human absorption exceeds level in animal model, FDA recommends 3-month oral exposure for in vivo evaluation of systemic toxicity.

The importance of candidate selection is crucial given limited research capacity available to support multiple large-scale registrational trials. Clinical trials are the most costly component of pharmaceutical research and development, with the cost of pivotal efficacy trials to support licensure for a single product estimated at up to $100 million.[69–71]

INNOVATION IN PRECLINICAL ASSESSMENT

Increased knowledge of both immunoregulation and the molecular and cellular processes associated with sexual transmission of HIV have helped to refine in vitro, ex vivo, and animal model systems for nonclinical testing. Institutionally, a program has been initiated to facilitate collaboration among microbicide research laboratories to devise improved preclinical safety assays, standardize protocols for critical preclinical methods such as tissue explants, and support quality assurance of assay performance among laboratories volunteering to utilize the program.[72]

Tissue explant systems

The increased use of animal and human tissue explants is among the most important innovations in preclinical methods. Human cervical tissue explants from patients who have undergone hysterectomies have been employed to predict both safety and efficacy in subsequent clinical trials. A particular advantage of such a system is that it includes migratory Langerhans cells, which permit studies of the ability of potential products to block dendritic cell transport of HIV to subepithelial target cells. Rectal tissue explants, using specimens from surgical resection or endoscopic biopsy, are being used to develop analogous methods to predict rectal safety and efficacy,[20] and pilot studies of foreskin explants for evaluation of penile toxicity are also underway.

Inflammatory markers

Intensive studies of the cellular and molecular intricacies of HIV infection after exposure to the virus have generated an appreciation for the complexity of immunologic signaling systems, which may influence both susceptibility and resistance to infection. Cytokines involved in immunologic signaling regulate the intensity and duration of inflammatory responses. Elevated levels of proinflammatory cytokines in vaginal mucosa may recruit target cells susceptible to HIV infection and may also upregulate the density of target cell receptors to which HIV binds. Molecules that resemble naturally occurring cytokines or bind to cytokine receptors also might downregulate some protective immune responses. In addition, some novel peptides or proteins developed for use as fusion or entry inhibitors may be sufficiently immunogenic to elicit antibodies that neutralize their beneficial microbicidal activity.[19]

Clarifying the specific assays that are most useful for predicting toxicities and establishing appropriate thresholds for such markers would be a valuable contribution. They are apt to be more sensitive than visual inspection or histological assessment and they can be more reliably standardized among diverse laboratories. These methods may also provide less invasive approaches for use in clinical trials. Such assays should, ideally, permit more frequent sampling than is feasible for vaginal exams, given considerations of cost, logistics, space, availability of specialized staff, and participant burden.

Animal models of efficacy

Recent progress has occurred in animal models for preclinical testing of microbicides efficacy. New HIV challenge stocks have been developed to investigate the protective utility of NNRTI-based microbicide candidates. One NNRTI-sensitive viral construct that can infect rhesus macaques has recently been developed but results from its use in experimental studies of an NNRTI-based microbicide candidate are not yet available. Another NNRTI-sensitive construct is currently in development.

A new testing algorithm with repeated animal exposures to virus may more accurately model sexual transmission in humans. Another rationale for this low dose, multiple-challenge model was the potential to quantify relative efficacy of different products. Previously, animal challenge studies were designed with high dose challenge stocks standardized to assure that infection would occur with only one exposure to the test virus. Reliable infection after a single exposure of control animals was intended to avoid ambiguity in interpreting absence of infection in microbicide-treated animals.

However, a consequence of this strategy is the requirement for a large number of costly and scarce macaques for comparative tests capable of discriminating quantitatively between candidate products. The typical animal protection study might compare from three to six control animals with an equivalent number of animals that received a candidate microbicide. Statistically, protection of four out of six animals could not be differentiated from protection of six out of six with sufficient certainty to assert a product-related difference in protective efficacy.

Use of a low dose multiple-challenge strategy was designed to introduce a source of variability associated with protective efficacy that might allow quantitative comparisons of the performance of different candidates, which would be measured by continuing the experiment until all control animal(s) and experimental animal(s) given the experimental product became infected. Level of protection would be correlated with the number of exposures required to establish infection.

Comparison of the two model systems with the same microbicide candidate and the same challenge stock has shown that the two models require the same cumulative

animal infectious dose of virus even though the delivery of that dose is spread across multiple exposures in the multiple-challenge system.[19] Ongoing examination of the performance of these models and the question of equivalence would be useful to achieve consensus on methods to compare candidates.[71]

Antiretroviral drug resistance

Microbicide candidates based on antiretroviral compounds elicit concerns about both durability of microbicide efficacy and impact on treatment options for individuals and communities using such a microbicide. Preclinical techniques for assessing the potential of a microbicide to elicit resistance can help evaluate various scenarios, including exposure of uninfected microbicide users to cross-resistant subtypes, or use of a microbicide by a woman who is unaware that she is HIV-infected. One concern is decreased efficacy of therapeutic drugs locally available for infected individuals. A second concern is infection with microbicide resistant subtypes that begin to circulate in a community and gradually undermine the efficacy of a microbicide as selective pressure causes the resistant variants to predominate.[19] To date, these concerns are quite speculative. Different modeling approaches have provided inconsistent conclusions. Moreover, if an antiretroviral microbicide is eventually found to be effective, the relative value of prevention versus treatment must be weighed.

■ DOSE DETERMINATION

Preclinical tests are also used to help establish a target dosage and frequency of drug administration. Ideally, laboratory assays could be performed on human volunteers to achieve precision in dose determination. For drugs used to treat HIV, assays that measure the concentration of HIV particles in peripheral blood provide a sensitive marker of response to treatment and a useful predictor of clinical benefit based on studies correlating viral load with reductions in HIV-related morbidity and mortality. For microbicides, no such validated surrogate marker exists.

Dose levels for Phase III microbicide studies are selected primarily based on in vitro antiviral activity assessments, animal model studies of product safety and efficacy in response to different doses of a candidate, pharmacokinetic data in women, and on the physicochemical characteristics of the product such as its intravaginal coverage, distribution, and retention, as well as the drug release properties of the formulation. Further specification of a dosage for large-scale trials comes from Phase I/II clinical trials that are typically designed to escalate dosage through several levels and to double the frequency of exposure (if applicable) from once to twice daily until a threshold is reached based on clinically significant indicators of toxicity or tolerability concerns that impair a product's acceptability. However, the only definitive measure of whether a microbicide administered at the selected dosage (and frequency, if applicable) will work remains the large-scale efficacy trial.

CLINICAL EVALUATION OF MICROBICIDE PERFORMANCE

A series of unique characteristics of microbicide research has prompted innovative modifications to clinical trial methods, some of them controversial. Other aspects of microbicides pose unresolved dilemmas that have implications for clinical trial designs now and in the future.

Microbicide trials depart from the conventional sequence of Phase I through Phase III (Table 94-4). Phase I trials typically evaluate safety with healthy volunteers, unaffected by the condition being addressed, and determine pharmacokinetic parameters such as bioavailability and half-life. Phase II trials evaluate safety in individuals affected by the condition and demonstrate that the product has the anticipated effect on a surrogate marker that predicts clinical benefit from the investigational product. Phase III trials are specifically designed to support licensure by providing a precise estimate of efficacy in a randomized, placebo-controlled study.

Microbicide clinical trials represent a more fluid continuum of these goals. For example, expanded safety data in higher risk populations may begin with the last cohorts enrolled in Phase I trials. Likewise, the clinically intensive safety goals of Phase I and II trials may be integrated into the study protocol for the first several hundred women enrolled in large efficacy trials, in effect transforming such trials into Phase II/III or Phase II/IIb trials. This strategy enables cohorts that otherwise would have been enrolled in a separate Phase II expanded safety trial to contribute to the sample enrolled in large-scale efficacy trials.

■ SPECIAL CONSIDERATIONS FOR MICROBICIDE CLINICAL TRIALS

Although the issues discussed below are not necessarily unique to microbicide trials, each has had a notable impact on how the field approaches clinical trial design.

Absence of surrogate markers of safety and efficacy

Phase II clinical trials typically provide the first preliminary indication of likely safety and efficacy in the population to be studied in Phase III trials. Without validated surrogates for microbicide safety and efficacy, the latter can be determined only through large-scale efficacy trials.[73] Moreover, the same measure used to determine efficacy, HIV seroconversion, is the most important measure of safety. Experience with N-9

Table 94-4. Clinical Trial Phases

Trial Phase	Objectives	Endpoints	Duration	Population: Cohorts, Sample Sizes, Overall Design
I	safety	cervicovaginal mucosal findings (unaided visual and colposcopic examination) subjective signs and symptoms integrity of vagina l milieu (pH, microbiology for normal Lactobacilli)	2 wk product exposure; total trial=6 mo	*N*=10–50 [10 per exposure cohort] low risk [mutually monogamous, no recent STD history, with option of initial sexually-abstinent cohort]
	pharmacokinetics	local, systemic absorption		May include control comparison group or may use participants at baseline as their own controls
	tolerability	willingness of participants to comply with study-specified use-frequency, dose, and method of application/administration/insertion		
II	expanded safety	cervicovaginal mucosal findings (unaided visual and colposcopic examination) subjective signs and symptoms	2–6 mo, usually with ≥1 mo of exposure per participant	*N*=50–250 women at increasing risk, e.g., recent (past 3 mo) STD
	acceptability	survey, qualitative: product attributes, interest in future product		
IIb/III	effectiveness against HIV and other STD if supported by preclinical data	HIV seroincidence STD incidence	6 mo to 3 y, usually with 1 yr maximum duration of participant enrollment and use of product	randomized, controlled trial [usually blinded design with control by placebo, possibly unblinded with no gel as control]
	expanded safety	cervicovaginal mucosal findings subjective signs and symptoms		*N*=1000–10,000 women at high risk, characteristic of those for whom product would be recommended if licensed
	adherence to product use	vaginal sex with: microbicide, condom, microbicide + condom, neither		
	acceptability	quantitative and qualitative self-reports on product		
I/II	supplementary prephase IIb/III/ licensure safety/ tolerability trials: • penile tolerance • rectal safety	visual lesions (rectal + penile); rectal anoscopy/ flexible sigmoidoscopy subjective signs and symptoms mucosal [penile/rectal] findings (e.g., urethral screen by leucocyte esterase urinary dipstick, rectal swab for cytokine markers, biopsy for histopathology)	3–6 mo each, usually with 1–2 wk of product exposure	*N* = 20–50 each; cohorts (*N* ≥ 10) of HIV- and HIV + circumcised and uncircumcised cohorts for penile study

will hopefully allow laboratory scientists to identify surrogates for microbicide safety.

Relatively low event rate for the primary efficacy outcome

For many pharmaceuticals used to treat diseased populations, clinical testing is expedited by high event rates that permit definitive efficacy trials to enroll relatively small samples, often less than 1000 participants, for relatively brief enrollment periods, e.g., 6–12 months. However, prevention trials are an order of magnitude more challenging than treatment trials. HIV incidence, even among the highest risk cohorts identified for microbicide trials, is typically 5% per year or less, which translates into sample sizes in thousands and follow-up periods of 12–24 months in trials, intended to measure microbicide efficacy.

If HIV incidence in the study population falls below the rate used in trial design calculations, adjustments must be made to accrue sufficient endpoints to measure efficacy reliably. If the departure from an initial estimate is great

enough, it may not be feasible to complete the trial. For example, a Phase III trial of a surfactant product, Savvy, was terminated because the incidence rate, initially estimated at 3.7%, was 2% about 2 years in the study[74] at clinical trial sites in two different countries in West Africa. Prospective cohort studies that emulate trial conditions are a time-consuming and costly prerequisite for determining efficacy trial design parameters such as HIV seroincidence. Other less costly approaches available for estimating event rates once the trial is underway are being evaluated.

Pivotal importance of behavioral factors, especially adherence and acceptability

Microbicides only work if they are used. Consistency of product use is so important a modifier of efficacy outcomes that all phases of clinical research include assessments of product use and factors that increase or decrease its acceptability.

Ethical standards for the conduct of microbicide trials require that participants are provided with, and counseled to use, condoms.[75] This has led to relatively high levels of self-reported condom use, and various studies are using biologic measures to validate these self-reports. A confounding factor is that self-reported microbicide use tends to correlate with condom use. This will attenuate the trial's ability to demonstrate microbicide efficacy.

Low rates of product use may also provide a misleading underestimate of a product's efficacy. For the coitally dependent gels currently in efficacy trials, participants report utilization rates ranging from 40% to 80%.[76] Social desirability influence on such self-reports may generate overestimates of adherence to product use. Therefore, consideration must be given to ways of improving levels, and measures, of adherence in studies.

Selection of suitable control(s)

The universal placebo used in most of the efficacy trials now underway shows no protective efficacy in vitro and in animal models. However, its effect on HIV incidence in humans is unknown. Moreover, although it shows no evidence of toxicity preclinically and, thus far, in clinical use, hypothetical concerns persist about its long-term safety in the clinical trial context.[77] One current trial has included both placebo and no-gel control ("condom only") arms to address these concerns. The no-gel control is also intended to assess the hypothetical risk that use of microbicides could decrease condom use, resulting in a net increase in HIV infection rates.[78]

Critics of this design have suggested that the safety concern could be addressed separately and more efficiently than by requiring two control arms. The use of a no-gel control to assess microbicide-related reductions in condom use seems irrelevant to the situation in resource-poor countries where condom use rates remain low even when promoted. Methodologically, differences in condom use between comparison arms may be neither interpretable nor generalizable.[75,79,80] Since a third arm requires a 50% increase in the size of the study, with consequential increases in time, cost, and strain on the limited capacity of clinical trial sites,[79] hopefully, the data from the current dual control arm trial will obviate a need for no-gel control arms in future efficacy trials.

TRIAL DESIGN DILEMMAS

Cost, constraints on capacity, and a sense of urgency about identifying effective products and delivering them to high-risk populations generate questions about how to design future efficacy trials. Underlying many of these dilemmas is a tension between establishing proof of concept as efficiently as possible versus designing more complex and costly trials that may expedite access to a product, if it is found to be safe and effective.

Efficacy trial precision

Two designs have been used in microbicide efficacy trials: (1) the conventional, definitive Phase III trial establishes targets for sample size and duration of follow-up that can yield a precise estimate of the efficacy of the investigational product; (2) a "screening trial" or "Phase IIb" design has been used as an alternate strategy to obtain a less robust estimate of product efficacy more quickly and with a smaller number of participants. The Phase IIb trial is considered a particularly appropriate design when considerable uncertainty exists about the efficacy of an intervention because it can eliminate ineffective approaches from further consideration. However, unless an intervention is highly effective, an intermediate outcome means that a definitive trial would subsequently need to be conducted to satisfy most regulatory authorities.

Such an intermediate outcome poses a policy dilemma for those who feel that the result is not persuasive enough to proceed with implementing a new and urgently needed means of preventing a potentially lethal infection. It also raises ethical problems because the evidence for efficacy it provides may make it difficult to gain agreement about a subsequent placebo-controlled trial to meet regulatory requirements. Even if a second trial were determined to be ethically acceptable to a host country and community, information provided during informed consent might make it difficult to enroll participants or else difficult to maintain trial integrity (e.g., participants might share some of their supplies of the investigational product so that they all gain access to some samples that are protective).

Enrolling adolescents in efficacy trials

Adolescent girls and young women are important target populations for microbicides. They are among the most severely affected groups and the most vulnerable to pressure not to use condoms. However, enrolling adolescents in efficacy trials triggers special requirements, often including

parental consent for their participation, and can put adolescents at a "social" risk. Moreover, their vulnerability may lead policy officials to discourage sponsors from trying to include adolescents. It will be critical to perform at least some safety studies among adolescents to provide "bridging" data to support labeling of microbicides approved for the prevention of HIV in young women.

Pregnancy during the conduct of clinical trials of reproductive aged women

Women enrolled in Phase III efficacy trials are required to use at least one form of contraception during the study.[75] However, despite this prerequisite, high pregnancy rates of up to 70% have been observed in some of the current efficacy trials,[81,82] while other effectiveness studies have had pregnancy rates in the 15% rate range. Some microbicide protocols require women who become pregnant to discontinue product use and leave the study, while other protocols allow for the continued follow-up of women who become pregnant on the trial. High pregnancy rates complicate data interpretation and result in a study that is underpowered to demonstrate whether a microbicide is effective. Improved access to contraception at the clinical trial sites is one characteristic of clinical trial protocols that have had fewer incident pregnancies. The possibility of maintaining pregnant women on product throughout pregnancy has been proposed, provided the preclinical program has been completed, including the full package of reproductive toxicity studies and carcinogenicity studies.[81] However, completing all of these studies prior to the initiation of efficacy studies would mean substantial delays prior to the initiation of these trials.

Even if favorable efficacy outcomes precede completion of reproductive toxicology and carcinogenicity studies, it may be important to complete these studies before licensure. Licensing a new microbicide that women are told to stop using during pregnancy poses daunting logistical problems related to assuring ongoing, appropriately frequent pregnancy testing among users. Even if such a product were subsequently qualified for use during pregnancy, the initial restriction during product rollout may adversely influence future attitudes about its safety and/or cause confusion among prospective users long after pregnancy-related concerns have been resolved by additional data.

Measuring non-HIV STD endpoints in efficacy trials

In addition to causing serious morbidity themselves, non-HIV STDs may also facilitate HIV transmission. Thus, trials designed to measure efficacy against HIV should include other STDs as endpoints. If the microbicide also has activity against other STDs, approval for STD indications and adoption of a microbicide for that purpose in areas where HIV has not begun to spread may forestall a future HIV epidemic. Expanding the market for a microbicide by also disseminating it for STD prevention may increase overall acceptance. However, designing efficacy trials to include definitive endpoints for STDs is almost certain to increase complexity and cost of such trials.

Optimal duration of enrollment and follow-up

Retention in clinical trials, especially those with follow-up periods beyond 1 year, is particularly challenging to HIV prevention trials.[82] Unlike treatment trials that integrate follow-up care for a medical condition with research procedures, prevention trials enroll populations that are at risk for a condition but not under treatment. Often, the populations at greatest risk and, therefore, most appropriate for evaluation of a new prevention intervention are the most difficult to reach, both for enrollment and especially for retention. Unstable housing and occupational migration may exacerbate the challenges of sustained contact, as well as the ability to complete scheduled follow-up visits. Nonetheless, some of the large-scale efficacy trials of topical microbicides have demonstrated participant retention of 90% or greater after 18 months of follow-up, suggesting that conducting high quality trials among women at high risk of HIV is feasible.

Relatively brief follow-up periods have many potential benefits. These include higher retention, the ability to evaluate intensive interventions such as directly observed product administration (a strategy that should increase adherence in trials of a coitally independent microbicide requiring daily administration), and increased validity of behavioral assessments. However, the longer the period of trial participation, the better the trial will be to identify toxicity or tolerability problems that emerge after relatively longer exposure periods. Such trials will also be more informative about time-dependent reduction in participants' willingness to use the product.

Prevention interventions for trial participants

Populations at greatest risk of HIV infection must have access to the most effective prevention interventions available, if they are to bear the risks of microbicide testing. Currently, this amounts to HIV testing with risk reduction counseling, free supplies of male and female condoms, and periodic diagnosis of and treatment for non-HIV STDs. Ethical considerations pose a dilemma regarding when to offer newly-established HIV prevention interventions to participants in microbicide efficacy trials. New and potential prevention interventions include male circumcision, use of cervical barriers, HSV-2 suppressive drugs to reduce HIV susceptibility and/or infectiousness, use of oral antiretroviral drugs for preexposure prophylaxis, and preventive HIV vaccines. Failure to expedite access by microbicide trial participants and their sexual partners to such new methods, as soon as their effectiveness and safety are established, may be criticized as unethical.

However, each host country for microbicide trials will differ in its pattern and rate of adoption of new HIV prevention

interventions such as male circumcision. In settings where such new methods have not yet been made readily available, expediting access for prospective trial participants (or their partners in the case of male circumcision) may, itself, be unethical if it is perceived as a coercive inducement to join a microbicide trial. The challenge will be striking a balance between an ethical obligation to assure that participants in microbicide trials are offered the best available standard of prevention and an ethical obligation to avoid undue incentives that compromise an individual's decision making during the informed consent process.[75]

PLANNING FOR SUCCESS

Ongoing progress in HIV prevention research has two important implications for microbicide research and development. First, success in demonstrating efficacy of a new method to prevent HIV will affect continuing efforts to optimize existing methods and to evaluate other approaches. Second, proof of microbicide efficacy will shift the focus to implementation: whether and how to mainstream an experimental prototype into an accessible product in the most resource-poor regions of the globe.

RAISING THE BAR FOR EFFICACY TRIALS

Although every advance in preventing HIV is unarguably a welcome outcome, each incremental reduction in HIV incidence increases the difficulty of designing efficient, affordable, feasible efficacy trials of experimental interventions. Establishing partial efficacy of an investigational microbicide—even at levels of protection of 30–50%, which has been considered sufficient to justify licensure in some settings—sets a new basis for comparison for a next generation of investigational microbicides that shows promise of greater efficacy. Once regulatory approval has been secured, comparison of an investigational microbicide with the equivalent of a "no gel" or a placebo would violate ethical principles of research on human subjects. Trials designed to measure superiority would require considerably larger sample sizes than current efficacy trials. Moreover, the dilemmas associated with identifying a suitable control condition only become more complicated if a proven effective product uses a different delivery system (e.g., coitally dependent gel) than the newer investigational product (e.g., once-daily gel). In this case, the evaluation of efficacy may offer little information about biological efficacy if confounded by the impact of coital dependence or independence on adherence.

FROM CANDIDATE TO COMMODITY

Adoption and adherent use of a self-administered protective product requires active and sustained efforts to encourage consistent and correct use, especially for coitally dependent products. Ongoing surveillance for any adverse effects or indicators of declining effectiveness will be important.

If the first approved product is available only by prescription, the gateway role of a health-care provider may challenge the capacity of an already fragile health infrastructure. Optimal availability and broad dissemination would require additional studies to support over-the-counter distribution and regulatory submissions to obtain such approval.

The fastest possible access depends upon availability of suitable manufacturing capacity and effective distribution and dissemination strategies. Advance arrangements to address financial barriers would expedite access by the poorest populations in need of products that otherwise might be financially out of reach.

As daunting as these and derivative challenges will be, success in demonstrating that a microbicide works to prevent HIV infection will represent a profound breakthrough in HIV prevention science and a boon to humanity.

95 Behavioral Interventions for Prevention of STDs and HIV Infection at the Community Level

Jeffrey A. Kelly, Kathleen J. Sikkema, and David R. Holtgrave

Community outreach and education programs have a long history of use in many public health primary prevention, early disease detection, and health care interventions. Within the primary prevention arena, community-level approaches have been widely used, with varying degrees of effectiveness, to address issues such as cigarette smoking cessation, cancer and cardiovascular risk reduction, and alcohol and other drug abuse prevention. Community-level early disease detection methods have been used to encourage care-seeking behaviors related to screening and early diagnosis of breast cancer, hypertension, prostate cancer, and other diseases where early intervention is critical. Community outreach methods have also been widely used in both developing and developed countries to promote other health care-related behaviors such as pre- and postnatal care, child immunizations, and HIV testing among persons at risk for AIDS. These interventions have in common their focus on using community-level interventions to encourage behavior change on the part of population members, particularly those at risk for negative health outcomes. Similar community outreach and prevention methods, targeted toward sexual behavior change, are pertinent to efforts to prevent and control sexually transmitted diseases (STDs).

People contract STDs and HIV in the community, not inside STD clinics, physicians' offices, or other clinical and health care settings. Communities, therefore, are appropriate venues for STD prevention interventions. Although secondary prevention efforts often need to take place within settings that treat people who have already contracted STDs, including HIV, primary prevention efforts to reduce the incidence of STDs or HIV infection may have their greatest potential effect when they are undertaken in communities, not just in clinics. To the extent that it is possible to reduce levels of sexual risk behavior in population segments presently vulnerable to STDs and HIV, it should also be possible to reduce the number of new disease cases arising in those communities.

In this chapter, we will consider how community-level and community outreach interventions can be used in the primary prevention of STDs or HIV infection. We will organize this discussion around four major issues: (1) psychosocial characteristics of community or population members associated with high levels of sexual risk behaviors that, therefore, are characteristics that can serve to define the nature and targets for community interventions; (2) the goals of community intervention; (3) models and examples of successful community-level STD prevention interventions undertaken to date; and (4) important new directions for work in the field of community-level STD/HIV prevention interventions.

PSYCHOSOCIAL CHARACTERISTICS RELATED TO SEXUAL RISK BEHAVIOR IN STD-VULNERABLE POPULATIONS

Community-level STD/HIV prevention interventions and, indeed, behavior change interventions of any kind, are effective only when they are focused on changing psychological and social characteristics that presently "drive" risk-taking behavior. Understanding the determinants of high-risk sexual behavior within populations vulnerable to STDs or HIV infection provides information needed to tailor interventions to change those relevant determinants. Fortunately, behavioral and social science research, guided by several theoretical frameworks concerning behavior and its change, has identified a set of psychosocial factors that predict levels of sexual risk behavior in a variety of STD/HIV-vulnerable populations, including ethnic minority heterosexual adolescents, sexually active college students, heterosexual men and women, and gay and bisexual men.[1–5] The fact that a relatively consistent set of sexual risk-taking behavioral determinants has been identified across multiple and diverse community populations attests to the salience of these psychosocial factors.

There are at least six key elements and objectives of community-level sexual risk behavior change interventions (Table 95-1). Normative perceptions concerning whether peers and sexual partners use condoms and practice safer sex are highly predictive of an individual's own level of risk behavior. To the extent that peers or members of one's social reference group, as well as one's own sexual partners, are

Table 95-1. Key Elements and Objectives of Community-Level Sexual Risk Behavior Change Interventions

Element	Community Change Objective
Sexual behavior normative perceptions	Creation of social reference group norms, especially among peers and sexual partners, that encourage and support behavior changes to reduce or avoid STD/HIV risk
Behavior change intentions	Strengthening population members' intentions and personal commitment to reduce or avoid sexual risk behavior
Attitudes toward condoms	Creating positive attitudes toward condoms including perceived benefits, positive outcome expectancies, and connotation of con dom use with positive attributes (concern, caring, pride, and sponsibility)
Perceived risk reduction self-efficacy	Instilling confidence that individuals can successfully enact personal risk reduction or risk avoidance behavior change strategies
Risk reduction behavioral skills	Providing opportunities to observe, model, and rehearse behavioral skills needed to reduce risk including technical skills (such as condom use) and sexual assertiveness, negotiation, and communication skills
Readiness for change	Tailoring messages that encourage movement along a continuum from behavior change contemplation to preparation to action to maintenance of action in reducing risk

believed to subscribe to the norm that condom use is accepted and expected, individuals are more likely to use condoms themselves.[6–10] Strength of behavior change intentions, a robust predictor of behavior change enactment in many health-related areas, also predicts condom use.[2,8,10–12] Positive attitudes toward condoms, including perceived benefits of condom use and positive outcome expectancies, are associated with greater likelihood of engaging in STD preventive behavior.[13, 14] Individuals high in perceived self-efficacy for enacting risk reduction behavior change—those who are confident in their ability to take risk reduction steps in relevant personal situations—are more likely to exhibit behavior change than persons low in self-efficacy.[15,16] Well-developed sexual communication skills, including assertiveness skills for refusing high-risk sexual coercions and sexual negotiation skills for initiating discussion with potential partners about condom use, have been associated with lower levels of sexual risk behavior.[13,17] Finally, and recognizing that different members of a population are at different stages of contemplating, attempting, making, and maintaining change, an individual's present stage or readiness for change has proven to be a useful heuristic for understanding the type of intervention that may best meet the needs of given populations and population members.[3,18–20]

These are not the only determinants shown in the literature to predict STD/HIV high-risk behavior or success in behavior change efforts. A number of situational factors, including substance use, relationship status and familiarity of sexual partners, positive HIV serostatus knowledge, and presence of competing life stressors, also influence levels of sexual risk behavior in some populations.[21–24] Although AIDS risk knowledge does not frequently appear as a strong determinant of sexual risk behavior, probably because basic factual knowledge about AIDS is now quite high in most populations, there are likely to be more widespread misconceptions about STDs other than HIV, and it is possible that these misconceptions contribute to STD risk-taking behavior. For example, women's use of oral contraceptives protects against pregnancy, but oral contraceptive use not only increases risk of cervical chlamydial infection but also predicts nonuse of barrier methods that protect against STDs.[25] Perhaps this is owing, in part, to misconceptions about the protective effects of birth control pills.

The body of research identifying determinants of sexual risk behavior in populations is critical to the development of community-level and outreach-based STD/HIV prevention interventions because it identifies domains in which those intervention efforts should focus their attention. Based on

research conducted to date and summarized here, important targets for community-level STD/HIV prevention programs include changing population normative perceptions about the social desirability of risk reduction steps; strengthening behavior change intentions, attitudes, and perceived efficacy of change; and increasing population member skills (and motivation to use those skills) to resist coercions to engage in unwanted or unsafe sex and to negotiate safer sex practices.

DEFINING A COMMUNITY FOR INTERVENTION AND IDENTIFYING THE GOALS OF INTERVENTION

It is possible to conduct mass (and usually mass media) sexual behavior change encouragement programs directed toward the entire population of a city, state, or county. "America Responds to AIDS" is an example of a broadly focused media campaign directed, especially in its earlier years, toward the American population as a whole. Evaluations of such untailored educational campaigns indicate that they can increase public awareness of a problem, can increase public knowledge and correct misconceptions, and may influence general attitudes but rarely have been shown to reduce actual sexual risk behavior, especially among hard-to-reach and high-risk population segments.[26,27] This may be owing to what is usually the very general and nontailored nature of mass media campaign messages directed toward the public as a whole, messages likely to be intentionally nonexplicit in a potentially controversial area such as sexual behavior. The preponderance of both theory and research literature indicates that community-level risk reduction behavior change interventions, whether undertaken using mass media or other community and outreach intervention approaches, are most successful when they are directed toward a particular and identifiable segment or subpopulation of a community; when the community intervention is carefully tailored to the culture, attitudes, beliefs, and change readiness that characterize that population segment; when the intervention is sustained and uses multiple channels of delivery; and when the intervention is based on psychological, motivational, and social principles, rather than factual information provision alone.[28–30]

The ultimate public health goal of STD/HIV prevention interventions is to reduce the incidence and prevalence of STDs. However, community-level STD/HIV prevention behavioral intervention trials rarely have been designed to examine change in disease rates in a population as a primary intervention outcome endpoint. Instead, most community interventions tested to date have sought to change population risk behavior characteristics or, even less proximal to the disease change outcome, to change population psychological or motivational characteristics related to risk behavior. Examples of behavior change outcomes relevant to STD/HIV prevention are reducing rates of multiple-partner sexual contacts, reducing sexual network "mixing" between members of presently low-STD/HIV prevalence population segments and members of high-STD/HIV prevalence population segments (such as commercial sex workers), or increasing rates of condom use in sexual encounters that might otherwise confer STD/HIV risk. Less proximal endpoints in community-level interventions are promoting changes in population member risk behavior knowledge, attitudes, or change intentions. Although much less convincing as a sole endpoint than outcomes that demonstrate change in population risk behavior levels or STD/HIV rates, it is possible to make the case that attitudinally "moving" a presently condom-resistant population toward greater acceptance of condom use, for example, is an intervention goal not without merit.

Community-level and outreach-based interventions may also have behavior change goals other than sexual risk behavior change. Examples of such goals might be encouraging greater HIV or STD testing within the population or encouraging population members to access more intensive and personalized risk behavior change assistance resources in their community. The key point here is that community and outreach-based STD/HIV prevention refers to a modality for delivering prevention services to population members in the community; the behavioral objectives of these programs may vary, and the elements to be incorporated in a given program need to be defined by what kind of change—sexual risk behavior change, attitude or motivation change, or other kinds of prevention help-seeking—the intervention is meant to bring about.

Finally, community-level interventions may be critical for promoting not just the initiation of risk reduction behavior change but also its successful maintenance in STD/HIV-vulnerable populations. Traditional one-on-one and clinic-based counseling—even when intensive, culturally-tailored, and guided by sound behavior change principles—is based on the presumption that persons will be able to carry forth successfully their risk reduction efforts in the real world when they "leave" counseling and that they will be able to do this for long periods. However, the real world does not always, and perhaps does not often, reinforce persons' risk avoidance efforts. Resisting coercion to have sex or insisting on condom use are actions that may elicit negative reactions from sexual partners or potential partners, and risk reduction behavior changes are not yet accepted norms within many of the populations segments at greatest risk for STDs, including HIV infection. It is possible to view STD/HIV prevention as the task of attempting to change an individual's attitudes, motivations, and skills and then hoping that the individual will be able to sustain change when confronting unsupportive real-life relationships and risk pressures. Alternatively, it is possible to take a broader social learning perspective in which behavior change maintenance is viewed not only as a function

of an individual's efforts but also of peer group social norms that may either help to reinforce change efforts or contribute to relapse over time.[1] Community and outreach-based interventions that change norms and behavioral expectations within at-risk populations to support risk avoidance efforts can play an important role in creating social environments that promote behavior change maintenance.[31]

EXAMPLES OF COMMUNITY AND OUTREACH-BASED INTERVENTIONS TO REDUCE SEXUAL RISK BEHAVIOR

A number of investigations and program descriptions of community-level risk behavior change interventions have appeared in the literature and have advanced our knowledge concerning how to produce population-level risk reduction. Most of these interventions have been cast primarily as AIDS/HIV prevention efforts. Because many of the same behavior changes that afford protection from HIV also reduce risk for other STDs, we will consider HIV and STD sexual risk reduction interventions together. Three types of community-level intervention have most commonly been reported in the literature. These are (1) approaches that use community opinion leaders to redefine sexual norms and safer sex expectations within the peer groups; (2) outreach-based risk reduction workshops offered in community settings; and (3) multifaceted community mobilization and activation risk reduction programs.

OPINION LEADER COMMUNITY NORM CHANGE INTERVENTIONS

Peers and, in particular, those members of one's own social reference group who are considered popular, influential, and likable are potentially important models of behavior. From a social learning experience, well-liked peers can serve to influence the behavior standards of those who observe their actions.[1] From the perspective of diffusion of innovation theory, popular individuals within a community social network often function as opinion leaders who can set new trends that are observed by others, that are then copied by "early adopters," and that gradually diffuse throughout the social network until the new trends become accepted and normative.[32] From either theoretical framework, the implication for behavior change promotion is that cadres of well-liked, popular opinion leaders or peer models can, through endorsement and modeling processes, influence the social norm perceptions and behavior of the larger population segment or social network in which they are influential.

In a set of community-level trials, Kelly and colleagues evaluated whether interventions based on diffusion of innovation principles can produce population-wide reductions in the level of HIV high-risk sexual behavior among gay men who lived in small cities and patronized gay bars in those cities.[33–35] The project focused on gay men in small cities because prior research had revealed that many small-city gay men, unlike their counterparts in major AIDS epicenters, continue to engage frequently in high-risk sexual behavior and do not perceive safer sex as a socially accepted peer norm.[36] To establish baseline levels of population risk behavior, all men entering all gay bars in each study city were administered anonymous surveys eliciting information on their sexual behavior practices in the past 2 months and on their perceptions concerning the safer sex norms held by friends. Although there was some variability across city populations, about one-third of men reported engaging in unprotected anal intercourse in the past 2 months, usually not with an exclusive partner of known HIV serostatus.

When the intervention was ready to be initiated sequentially in a city, bartenders were trained to observe the crowd of people in a city's clubs and to identify those persons who were most popular, most sought out for conversations by others, and most frequently seen to interact with others. About 15% of the total number of persons in the bars were identified as popular opinion leaders by multiple, independent bartender observers. These key opinion leaders were then contacted and invited to attend a series of four group sessions that taught them how to communicate effective risk reduction behavior change endorsement messages to their friends and acquaintances, provided guidance and problem solving in how to initiate norm change conversations with others, and systematically engaged each opinion leader to seek out opportunities to have peer conversations following each group session. Some opinion leaders self-monitored up to 100 risk reduction endorsement conversations with friends over a 6-week period. The opinion leaders also wore distinctive buttons that visually demonstrated their personal involvement and support of risk reduction efforts.

To determine the effectiveness of the intervention in changing population-wide sexual risk behavior in initial studies,[33,34] all men patronizing bars in each intervention city were surveyed 3 months following the intervention. In each city population, reductions of between 15% and 29% from baseline levels were found in the proportion of population members who reported engaging in any unprotected anal intercourse in the past 2 months. In a subsequent expansion of the trial to eight additional cities, half of which received the same opinion leader intervention and half of which served as comparison cities, a reduction of about 30% in the prevalence and frequency of self-reported high-risk sexual behavior was found at a 1-year follow-up.[35] Taken together, these findings indicate that interventions that

actively engage a sufficient number of key opinion leaders to endorse and recommend behaviors change to their peers can produce reductions in population sexual risk behavior levels.

OUTREACH-BASED RISK REDUCTION WORKSHOPS OFFERED IN COMMUNITY SETTINGS

A number of randomized clinical outcome trials have demonstrated the efficacy of intensive small-group intervention programs based on cognitive-behavioral change principles for producing reductions in HIV risk behavior among gay and bisexual men, at-risk inner-city women, and disadvantaged adolescent males and females.[17,37–43] Although tailored in content to the different risk circumstance confronting each population, these interventions delivered in workshops or in multiple-session programs have all combined such elements as risk education, sexual assertiveness and negotiation skills training, teaching condom use and risk behavior self-management skills, enhancing positive attitudes and motivations toward behavior change, and reinforcing efforts to change risk behavior.[44] All of these intervention trials produced effect sizes indicative of moderate to large reductions in self-reported sexual risk behavior, usually reflected by reductions in rates of unprotected sex and increases in condom use. Behavior change self-reports have often been corroborated by change in other indices of risk reduction such as condom redemption or purchase, improvement in objectively assessed sexual assertiveness skills, and other validation measures.

For the most part, research evaluations of these small-group and workshop interventions have taken place in clinic or institutional settings. However, a number of projects have utilized outreach methods to "market" and recruit participants in AIDS-vulnerable communities to attend the workshops or small-group programs, and, in this sense, the interventions can be viewed as prevention resources available for at-risk community members who are identified through community outreach.[37,40]

Another form of workshop intervention widely used by community-based organizations in the United States and abroad is the "Stop AIDS" program.[45–47] Originating in the gay community but extended more recently to other HIV-vulnerable populations, Stop AIDS consists of workshop programs usually led by trained volunteer facilitators that involve discussion about risk behavior, promotion of positive attitudes toward behavior change, and skills training exercises in areas related to the successful implementation of changes. The 3–4-hour workshops are often conducted in community members' homes and frequently include members of entire social networks and friendship circles who participate together in the same session. Because Stop AIDS originated as a grassroot community-based HIV prevention program to deal with a health emergency, it was implemented directly without planning for scientifically controlled or randomized evaluation methods. Nonetheless, outcome evaluations have shown that participants exhibit change in sexual risk behavior knowledge, attitudes, change intentions, and behavior following attendance at Stop AIDS groups.[46,47]

MULTIFACETED COMMUNITY MOBILIZATION AND ACTIVATION INTERVENTIONS

Several community-level interventions focused on shifting population risk behavior utilizing multiple components have recently been described in the literature. Those interventions differ from those described earlier because they rely on a combination of different programs and levels of effort in order to mobilize or activate population behavior change.

Because young gay men continue to contract HIV and other STDs at high rates and have been less influenced by AIDS prevention efforts than their older counterparts, young men who have sex with men constitute a population of importance in HIV/STD prevention efforts.[48] Kegeles and colleagues evaluated a community intervention in a small California city that combined risk reduction workshops with ongoing community social events that included risk reduction endorsement messages disseminated by opinion leaders identified in the populations of young gay men.[49] The intervention also included distribution of safer sex education materials, t-shirts, and logos among young men in the cities' bars, clubs, and other socializing areas. Cross-sectional population member and cohort follow-up surveys revealed reductions in rates of self-reported risk behavior of about 20% from preintervention levels to follow-up in each city.

Sikkema and colleagues have undertaken a community mobilization intervention focused on women who live in 18 housing developments within inner-city census tracts with high rates of STDs.[50] In nine housing developments that received the HIV prevention intervention, women identified by their neighbors as key opinion leaders were invited to attend workshop programs offered in the developments; the workshops focused on women's health concerns, HIV and STD, risk education, risk reduction skills building, and strategies for "networking" HIV prevention messages to other women in the development. The opinion leader women also recruited successive "waves" of their neighbors to attend the same program, and the key group of women initially identified as opinion leaders formed "Women's Health Councils" in each development to plan ongoing social events organized around AIDS prevention and awareness themes. The program was evaluated by conducting anonymous risk behavior surveys of all women in the nine intervention and nine control condition housing developments before and again

3 months and 9 months after intervention. Findings of the study indicate that condom use among women in the intervention housing developments increased from about 24% of intercourse occasions at baseline to approximately 43% of intercourse occasions at follow-up, with the effects most pronounced among those women who both attended risk reduction workshops and were also exposed to the community-level AIDS awareness events. No significant change was found over time in rates of unprotected sex or condom use among women in the control condition housing developments.

Finally, in a large multisite demonstration project, investigators at the Centers for Disease Control and Prevention (CDC) have evaluated the impact of community-level and population-focused HIV prevention interventions for a variety of AIDS-vulnerable, but hard-to-reach populations, including men who have sex with men, youth in high-risk situations, female partners of IDUs, and female commercial sex workers.[23,51] The interventions tested in these AIDS community demonstration projects include community educational outreach by lay prevention educators, the use of culturally tailored "role model" portrayals used in "small media" campaigns to illustrate how peers have changed risk behavior, and intervention elements intended to increase population member readiness or stage of change for enacting risk reduction steps. Evaluated with street intercept interviews conducted with targeted population members before and following intervention, outcome findings of the project indicate evidence of attitude, change readiness, and risk behavior change in a number of the population. Among community members who reported exposure to the intervention elements, consistent condom use with nonprimary partners significantly improved relative to rates of risk behavior found in comparison neighborhoods. Greater behavior change readiness was also observed in the intervention area populations.[52]

Most of the community-level intervention trials described in this chapter were undertaken in the United States. STD/HIV disease burden is far greater in resource-poor and developing countries. Some culturally tailored community approaches have shown efficacy in international contexts. For example, Roma (Gypsies) are the largest and one of the most disadvantaged ethnic minority populations in Eastern Europe, vulnerable to STDs and other social health problems.[53,54] Living in impoverished insular communities and distrustful of outsiders, Roma rely on members of their personal social networks for trusted advice. A recent randomized trial recruited intact high-risk social networks or friendship groups of Bulgarian Roma men, assessed all participents' reported sexual risk behaviors, tested participants for STDs treating all positive cases, provided risk reduction counseling, and randomized networks to experimental or comparison conditions.[55] The influence leader of each experimental condition network was identified and attended a group intervention that provided ongoing training and guidance for counseling other members of the same network in STD/HIV risk reduction. Follow-up behavioral and STD testing assessments undertaken over the subsequent 12 months revealed declines in the prevelance of unprotected intercourse, especially with casual partners. By 12-month follow-up, 14% of men in the control group had contracted gonorrhea relative to only 8% of members of experimental condition networks. The trial is one of the few community-level interventions conducted in a resource-poor country to demonstrate impact on both behavioral and disease outcomes.[55] A similar social network intervention undertaken with gay or bisexual men in Russia also showed similarly promising outcomes.[56]

GAPS IN OUR KNOWLEDGE ABOUT COMMUNITY-LEVEL INTERVENTIONS

Outcomes from these trials of community-level interventions for sexual risk reduction have shown considerable promise. However, the effects even of successful interventions are not necessarily permanent. There were sharp declines in risk behavior and in the incidence of HIV and other STDs among gay or bisexual men during the decade following the appearance of AIDS and the development of wide-scale community prevention programs.[57–59] However, now there are more frequent reports of STD outbreaks, especially syphilis, and a resurgence of high-risk behavior in some segments of the gay community. This finding underscores the importance of sustaining community-level interventions, ensuring that new generations of young people who become sexually active are also exposed to prevention interventions and targeting community approaches to reach highest-risk social and sexual networks within the community. It is well known that STDs cluster within high-risk networks.[60,61] Behavioral interventions targeted directly toward vulnerable community social networks constitute a level of precision that is promising and worthy of greater attention.[56]

Although the programs described in this chapter have demonstrated the effectiveness of community outreach interventions in promoting sexual behavior change in some populations at risk for HIV infection, there remain important unanswered questions about how best to apply these approaches to other STD-vulnerable groups. Most community-level sexual behavior change interventions have been developed from the perspective of HIV prevention, and the populations targeted by intervention often have been gay men. With the exception of the Sikkema et al. community-level intervention and several reports describing risk reduction small group programs undertaken in community settings with at-risk women, there have still been very few applications of community outreach sexual behavior change interventions tailored expressly for women, even though women are, in many respects, the population most affected

by non-HIV STDs.[17,39,40,50] In addition, community-level behavioral interventions have had AIDS as their primary focus, a disease widely-known, widely-feard, and likely to motivate strong mobilization responses. Non-HIV STDs are less understood and less feared by most people, and different approaches may be needed to motivate population-level protective efforts related to STDs other than HIV.

Related to this, most conceptualizations of factors related to sexual risk behavior change appear to be based on the premise that sexual behavior decisions are volitional and determined primarily by an individual's own wishes, attitudes, intentions, skills, and normative perceptions. However, these models do not adequately take into account the behavior change barriers; social, economic, and cultural factors; and relationship pressures faced by women who are in coercive and power-imbalanced relationships with high-risk men resistant to condom use. Until further advances are made in female-controlled STD and HIV prevention methods, special obstacles will continue to be faced by women in dependent relationships with high-risk men. Because men's attitudes substantially influence whether or not condoms will be used during sex, community-level outreach interventions focused on changing the attitudes, norm perceptions, and behavior practices of high-risk heterosexual men are essential. To date, little intervention attention has been directed to this critical population.

Finally, STD/HIV prevention community-level interventions to date have primarily targeted reductions in sexual risk behaviors. A protective vaccine against human papillomavirus (HPV) is now available, and recent studies have shown that male circumcision considerably reduces the probability of HIV transmission in developing country populations with high HIV disease prevelance.[62–65] Whereas HPV vaccination and male circumcision are medical procedures, the process of getting persons to accept, seek, and obtain these procedures is behavioral. The success of such medical prevention advances will require that individuals perceive acceptance of them as desirable, beneficial, and culturally and socially normative. Further, the protective benefits of procedures such as male circumcision could be lost or diminished if persons then felt overly protected, reduced their condom use, or increased their sexual risk behavior. Community-level behavioral interventions that promote population acceptance and seeking out of new medical protective approaches, while also avoiding risk behavior increase compensation, can play an important role in translating medical prevention advances into public health benefits.

CONCLUSIONS

Community- and outreach-based interventions to encourage reduction in sexual risk activities hold considerable promise for the primary prevention of STDs. Such approaches to intervention have the potential for bringing culturally-tailored prevention services to hard-to-reach population members and for changing the risk awareness, social norm perceptions, attitudes and change readiness, and sexual risk behavior of populations presently vulnerable to STDs and HIV infection. A specific and unique benefit of community interventions for STD/HIV prevention is their potential for creating social norm changes in populations that encourage the maintenance of sexual risk behavior changes. The field of community-level interventions to prevent STDs including HIV infection is still relatively new, and many issues concerning how best to tailor, implement, and evaluate the effectiveness of these programs still require attention and study. Nonetheless, community and outreach programs are important components of comprehensive approaches to STD and HIV primary prevention.

96 Marketing, Communication, and Advocacy for Large-Scale STD/HIV Prevention and Control

William A. Smith and Robert Hornik

This chapter focuses on large-scale behavior change efforts using marketing, communication, and/or advocacy to influence the behavior of individuals at risk of disease. It defers discussion of face-to-face (individual and small group) approaches that have been characteristic of counseling and testing, for example, in favor of a better understanding of mass approaches that mediate direct contact with the target audience through radio, television, billboards, diffusion of new products and services, and/or policy change. In practice, both face-to-face and large-scale approaches often work together (e.g., a mass media program can be used to increase the number of individuals volunteering for counseling and testing). In this chapter, however, we focus on the unique problems and opportunities for behavior change on a large or mass scale.

Large-scale approaches offer significant public health advantages in scale of effect. Large-scale programs are often characterized in three ways: product/service, message, or policy approaches. The basic assumptions underlying this chapter are as follows:

1. The objective quality of products, services, and behaviors promoted by persuasive messages about them, and the reduction of barriers to using them, are important determinants of successful behavior change.
2. People's perceptions of the products/services, messages, and policies vary among individuals and groups and are the means by which people judge the objective characteristics of a product, service, or behavior.
3. Marketing, communication, and advocacy are three approaches, individually or in combination, to successfully promote products/services, messages, and policies to large-scale audiences. They integrate the objective and perceived values of new behaviors to foster effective behavior change. See Fig. 96-1.

PRODUCT/SERVICE APPROACHES

Product/service approaches make it easier for a large number of people to make healthy choices by increasing the access and attractiveness of products/services that make prevention and control more viable (longer operating hours, services closer to home, ensured confidentiality, etc.).

MESSAGE APPROACHES

Message approaches (campaigns, entertainment media, and news reporting) help ensure that people are both aware of and believe in the choices opened to them. These approaches provide basic information and increase the perception that the target behavior is widely acceptable and even popular. Successful message approaches ensure that information is clear, accurate, and persuasive. They use targeted channels of communication to reach an intended audience frequently, appropriately, and with high credibility to the audience.

POLICY APPROACHES

Policy approaches use law, regulation, and enforcement actions to provide disincentives for unhealthy behavior (criminalize sex with minors, criminalize prostitution, close bathhouses, tax pornography, etc.), or provide positive incentives for healthy behavior (lower insurance premiums, tax breaks, antidiscriminatory legislation).

The successful practice of large-scale behavior change is the story of how these three approaches are combined in different ways to meet the needs of specific audiences and conditions. Although different in many important ways, all three program strategies share a common belief that interventions should be designed based on the perceived desires, the real-world barriers, and the objective health needs of the at-risk population. They share a basic logical process model (Fig. 96-2) in which behavior is influenced by people's perceptions, as well as objective reality of the intervention changes.

This logical process model illustrates the steps between problem identification and problem solution. For example: a health problem (rapid rise in HIV/AIDS cases) is detected through surveillance. A behavioral cause—untreated sexually

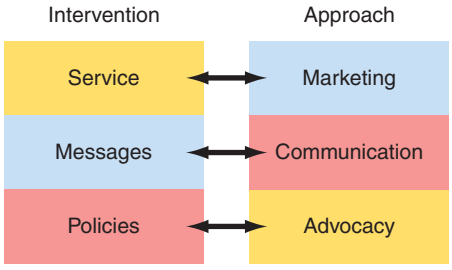

FIGURE 96-1. Associating intervention strategies and approaches to behavior change.

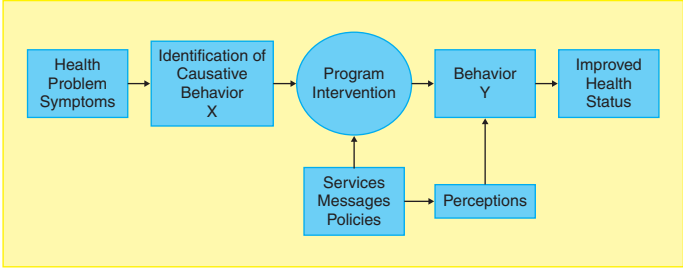

FIGURE 96-2. Logical process model.

transmitted infections (STIs) of that health problem is identified. A program intervention (counseling, testing, and treatment services) is expanded to address the behavioral problem. How people perceive that intervention influences whether people use the new services as much as the objective quality of the service itself.

Objective quality and personal perception are indispensable partners of effective behavior change in this logical process model. Several key perceptions have been identified as targets of opportunity to foster positive change, including (1) perceived benefits (*If I go to be tested and treated for STI, will I get something that I want or th*at is better for me than not knowing); (2) self-efficacy (*I know I should get tested, but I just can't face telling my family if I have the* disease—It's just something I can't do); and (3) social norms (*I'd get tested if I knew my friends expected me to get tested or were getting tested; but I am not going to be the first one to do it*).

PRODUCTS, SERVICES, OR "BEHAVIORS"

A discussion of several recent success stories of HIV prevention illustrates how products, services, and behaviors differ from each other and yet play complementary roles in the success of a large-scale program. Take, for example, two of Uganda's ABC (abstinence, being faithful, condom use) behaviors that have received a great deal of attention: sexual abstinence and being faithful. Both of these behaviors are lifestyle decisions influenced primarily by internal perceptions of what is best, what is possible, and what is popular.

The prevalence of HIV in Uganda peaked in 1991 at 15% in the overall population and 30% among pregnant women in urban areas. By the end of 2003, HIV prevalence had dropped to 4.1% nationally.[1] These declines were accompanied by declines in the number of young men reporting to have ever had sex and increases in the age at which young women reported having had their first sexual encounter. Levels of self-reported monogamy increased and condom use rose among unmarried sexually active men and women. Some analysts have pointed out that other African countries saw similar increases in condom use with little or no decline in HIV prevalence but did not experience similar increases in monogamy or abstinence as reported in Uganda. David Wilson of the University of Zimbabwe concludes, "…condoms may not be the primary intervention for reducing HIV prevalence in generalized high-prevalence epidemics spread largely by heterosexual transmission. They remain essential, however, in interventions targeted to high-risk groups."[2]

Abstaining from sex and sticking to one partner are not behaviors that can be packaged, distributed, put on a shelf, priced in a currency, and sold. Neither are they services that can be identified and used. They are life decisions, sometimes called "lifestyle" decisions which, even though they are not products or services, are susceptible to marketing, communication, and advocacy approaches. Like product and service behaviors, lifestyle behaviors have benefits and barriers as interpreted or perceived by a specific target audience.

To market a lifestyle behavior it is necessary to address these benefits and barriers—tip the balance between perceived costs and benefits so that the perceived benefits outweigh the costs for specific high-risk audiences. Mass media is helpful in shaping the perceptions of a nation as to what acceptable behavior ought to be. Uganda did not just have a policy of ABC, it promoted that policy through multiple communication channels. The President of Uganda became a major spokesperson. Entertainment media, news media, and mass media campaigns, all targeted these lifestyle behaviors over a long period in culturally persuasive ways at the same time that condoms were being made widely available and marketed. The effect was to create a new social norm around sexuality. A young man no longer had to have multiple sexual partners to be a "man" in Uganda. A young woman no longer had to say yes to an older man's sexual advances. At the same time that new perceived benefits were being added to the behaviors, the negative consequences of alternative behaviors (multiple partners) were being made more "costly" by using the fear of AIDS to make the dangers of multiple partners seem real.

Thailand's 100% condom use program, which targeted sex workers and used policing strategies to enforce tough new laws, also received world attention as an alternative approach to Uganda's ABC strategy. Between 1989 and 1993 results of a comprehensive sexually transmitted disease (STD) monitoring program in Thailand showed that condom use in commercial sex workers in Thailand increased from 14% to 94% and in

men the occurrence of the five most common STDs dropped by 79%. New cases of STDs in women declined by 54%.[3]

From a large-scale behavioral perspective it is important to point out two aspects of this success not immediately apparent in this data. First, the Thai program was much more than simply 100% condom use among female sex workers (FSWs).[4] Indeed, a massive multi-intervention national program was initiated by Thailand's new Prime Minister soon after his inauguration in 1991, including the establishment of 508 STD clinics significantly expanding access to treatment. There was a massive education campaign directed by one of the world's foremost and most successful social showmen, Mechai Viravaidya, with anti-AIDS messages broadcast every hour on the 488 state-owned radio stations. A number of repressive policies that required the reporting of the names and addresses of AIDS patients were repealed.[5]

The second aspect of the Thai experience is that it builds on Thai history and culture. Thailand is a predominantly Buddhist culture which is supportive of men and women sharing decision-making power. Thailand also had one of the world's largest and most successful long-term programs of family planning, fostered by the same Mechai Viravaidya mentioned above. The family planning program was visible for years in Thailand, where condoms were a focal point of activities. In sum, condoms were not an innovation in Thai society.[6]

From a large-scale communication perspective the most important lessons to draw from both the Ugandan and Thai experiences are that comprehensive, multifaceted national programs, supported by top political leaders, well-financed and culturally competent within each society can make an important contribution to the large-scale behavior change required by complex social problems like STD and HIV epidemics. The stories of programs in Brazil, San Francisco, and Switzerland, three other vastly different cultural contexts, demonstrate similar lessons.

There is one more lesson that may be drawn from the analysis of the Thai experience. Figure 96-3 provides information about behavior change, health status, and intervention inputs over time. The figure includes the period prior to the major evaluation of the STD program cited above but also looks backward to the earlier, pre-AIDS period. There was a sharp decline in STDs associated with the launch of the program in 1989, but the figure also makes clear that STDs were already beginning to decline in Thailand, well before full implementation of any mass campaign or 100% condom use program. What explains that downward trend? It is not clear.

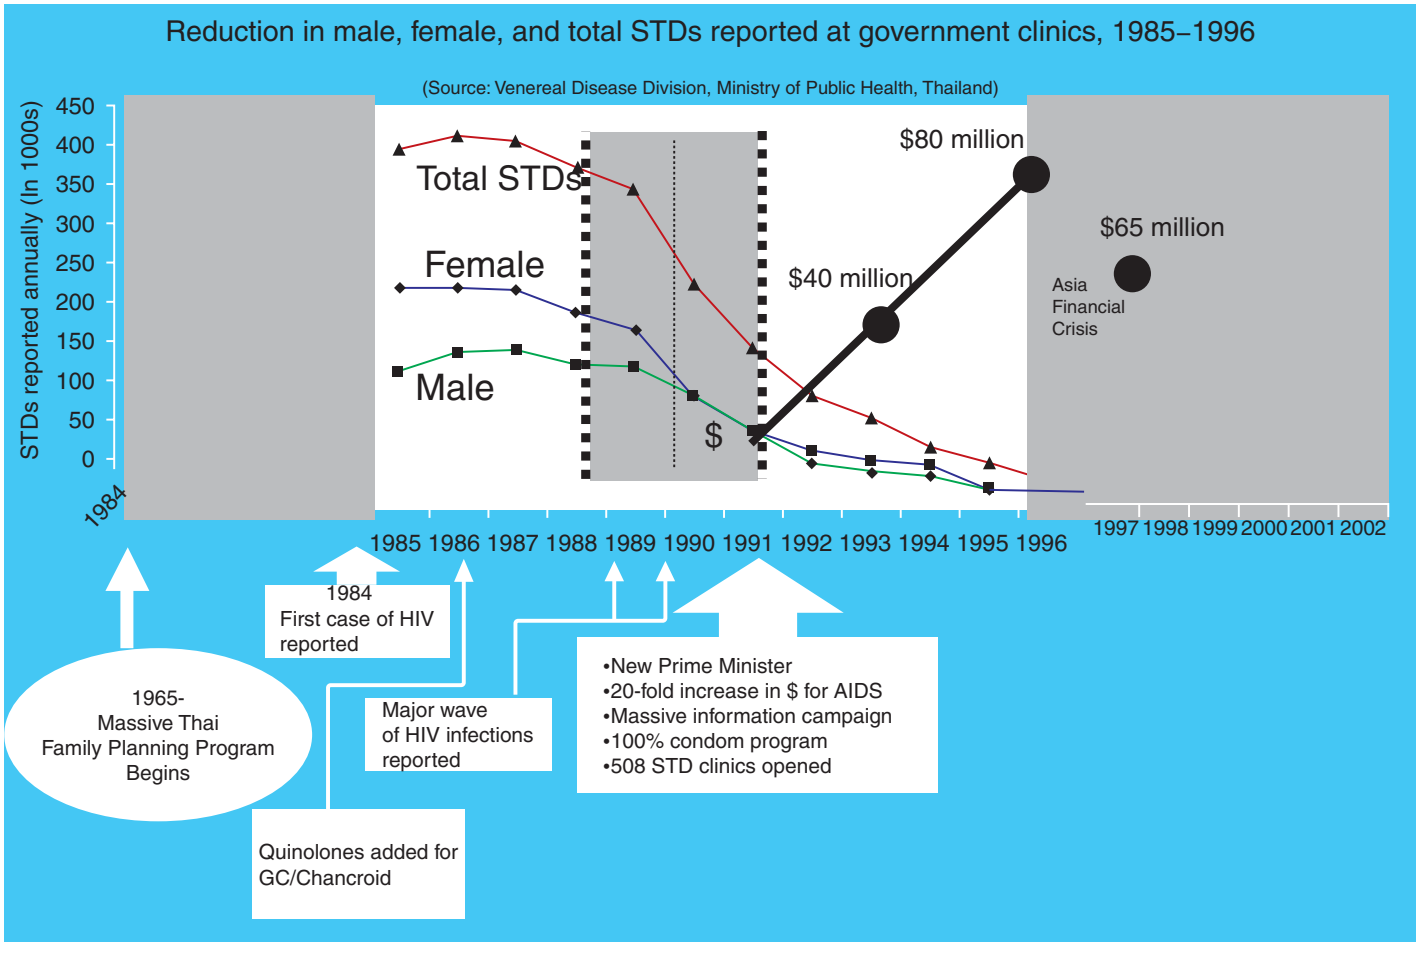

FIGURE 96-3. History of Thai STD program, 1985–2002.

Perhaps the advent in news stories of the first cases of HIV reported in 1984. This coupled with the prior history of a condom-friendly country began to break the back of STD growth in the country. The targeted campaign on syphilis that began in the late 1980s and the introduction of quinolones for treatment of gonorrhea and chancroid in 1986 certainly were additional explanatory factors. There may well be others we do not yet understand that explain the dramatic decline in STIs that began as early as 1987. It is doubtful that the decline post-1989 can be seen as independent of previous interventions. The most positive view is that the post-1989 activities accelerated a trend already in place, which might have otherwise leveled off.

IMPLEMENTATION STRATEGIES

Social Marketing. Social marketing can be defined as a program-planning process that promotes the voluntary behavior of target audiences by offering benefits they want, reducing barriers they are concerned about, and using persuasion to motivate their participation in program activity leading toward improved personal and social welfare.[7] Social marketing uses in-depth information about both consumers and the health system to (1) define products, services, and behaviors that are most acceptable to users; (2) organize delivery systems or places that ensure easy access and facilitate adoption of products and behaviors; (3) establish a price in terms of barriers (dollars, time, social status, or convenience) that users are willing to accept; and (4) create and diffuse messages about those products and behaviors that motivate and persuade.[8]

Health Communication. Health communication can be defined as a process for the development and diffusion of messages to specific audiences in order to influence their knowledge, attitudes, belief, and behavior in favor of a healthy behavioral choice.[9] Health communication has a long history in international public health and has many varied meanings. For the purpose of this discussion, health communication is considered largely a "message" approach to behavior change. While it recognizes that messages alone are insufficient to influence complex behavior change, health communication generally does not assume responsibility for the organization and management of new products/services or policy approaches. Health communication shares many characteristics with social marketing. For example, an emphasis on consumer research and a commitment to consumer-centered program development are common to both approaches.

Social Advocacy. Social advocacy, sometimes referred to as media advocacy, is defined as a process for influencing public policy and institutional structures leading to improved health behavior and health outcomes.[10] To address the increasing need for new policy and regulatory controls, social advocacy programs emerged as an approach to behavior change. Much of the legislative support to limit smoking and drunk-driving, and indeed support for HIV/AIDS prevention, has come from the determined, strategic, and creative work of social advocates. Advocates are often frustrated by social marketing and communications approaches, which they argue "blame the victim." Advocates place primary emphasis on public policy and institutional change to make it unnecessary or easier for individuals to change their behavior. Important examples of successful advocacy efforts include the 20-year fight for controls on the U.S. tobacco industry and the U.S. effort to reduce drunk-driving accidents and fatalities.[11]

The growing complexity of social problems has fostered a growing specialization within the social marketing, health communications, and social advocacy communities. However, many of the specific program tools, such as awareness campaigns, public advertising, public relations, demonstrations, audience segmentation, consumer research, and policy research are used by marketers, communicators, and advocates alike. More important, the central organizing approach shared by all three strategies remains (1) an in-depth understanding of their consumer (e.g., high-risk individual, influential family and friends, community, general public, or policymaker); (2) based on strategic consumer research; and (3) driven by a desire to satisfy what that consumer wants in order to make the right decision—whether that decision is to use a condom, talk supportively to a friend, or pass a law closing bathhouses. All three action strategies are fundamentally consumer-centered and focused on large-scale social and human behavior change.

Today there is a growing belief that comprehensive programs that strategically combine marketing, communication, and advocacy strategies do better than piecemeal and opportunistic efforts.[12] Lessons from three large-scale programs of health behavior change illustrate the importance of sustained integration of these three implementation strategies over time.

THE TOBACCO WARS

The history of smoking prevention in the United States represents a test case for the use of marketing, communication, and advocacy over a long period to confront a major public health threat. Very early, tobacco became one of the colonial America's first cash crops and a force in the introduction and spread of slavery. The first American cigarette factory opened in 1864. Camels were introduced in 1913, the year often credited as the birth of the cigarette. Dr. Ernst Wynder's first study identified a definitive biological link between smoking and cancer in 1954. The first public health statement about the dangers of smoking was published in 1957, and in 1966, the first warning labels appeared on cigarette packs.[13]

Over the next 20 years, from 1966 to 1986, there was a gradual increase in public education on the dangers of smoking in the face of strong pro-tobacco marketing by the

tobacco industry. In 1990, the era of pubic education ended and environmental smoke becomes the focus. Smoking was banned on all interstate buses and domestic airlines. For the next decade, the focus was on environmental controls until 1998, when Attorney Generals from 46 States, the District of Colombia, and 5 U.S. territories negotiated a $200 billion tobacco settlement agreement. In 1999, 46 years after the first biological link between smoking and cancer was discovered, the Phillip Morris Company admitted that smoking was addictive, that it caused cancer, and said there was no safe cigarette.[14]

The public health impact of this history is reflected in a trend in smoking prevalence in America that peaked around 1966 at 42.6 smokers per 100 and then fell to a prevalence rate in 2002 of 22.5 per 100. The largest single drop occurred between 1966 and 1970 when prevalence dropped from 42.6 to 37.4 per 100, a period when there was heavy antismoking advertising on television.

What makes the cigarette wars unique is the existence of a well-organized, counter-public health and well-financed force of industry professionals dedicated to defeat public health goals. On the one hand, they were a fierce foe and on the other hand, they gave pubic health advocates a clear target to demonize and blame for American smoking behavior.

Within this broad history of tobacco there are hundreds of studies throughout the world that have tested specific tactics, programs, tools, and approaches. It is important to note that many of these failed in the short-run to produce any public health effect. But the persistence and the continual creativity of the antismoking professionals in medicine, politics, community education and mobilization in meeting new threats from the tobacco industry are landmarks in the history of large-scale behavior change and public health. Perhaps one of the most important lessons of the tobacco wars is that "science" itself may not change behavior in the context of competing interests with substantial economic and political influence. Deliberate and persistent efforts to change institutional and individual behavior were required.

THE "VD" WARS

In *No Magic Bullet*, Allan Brandt documents the history of venereal disease (VD) in the United States since 1880.[15] In this compelling story, equally as complex as the history of smoking prevention in the United States, many of the same tools and tactics are used to both prevent disease and promote the treatment of "VD" or STDs. Mass media campaigns, legislation to control behavior, the marketing of products like condoms and services such as testing and treatment, all take center stage in the drama. The U. S. military plays a key role in both stories—in the tobacco wars they were part of an industry promotion strategy to introduce and addict young men and women to tobacco, while in the battle against VD the military was a frontline force to educate men about the dangers and prevention of "unholy" diseases.

The STDs wars were not against a highly organized and powerful industry but rather against a highly rewarding human behavior that is often morally scorned, driven underground and stigmatized. While tobacco was a celebrated American institution, STDs were a dangerous betrayal of America's ability to defend itself against German aggression—a threat to America's fighting capacity. Brandt marks a dramatic change in the history of STDs with the discovery of penicillin. Here was a proposed "magic bullet" that would allow men to engage in risk behavior and yet be "cured" of its health consequences. However, Brandt points out that it was society's continuing stigmatization of STDs that, despite the magic bullet of penicillin, drove people and the disease underground and made eradication all but impossible.

SIDS

The story of large-scale behavior change in the case of sudden infant death syndrome (SIDS) is another unique case. Here, a relatively simple behavior, placing sleeping infants on their backs rather than on their stomachs, was a message which resonated with millions of mothers, and within a matter of months mothers of newborns had made significant behavior change.[16] There was no organized opposition, no economic interests, and no stigma associated with the behavior. The problem was addressing long-held beliefs transmitted from mother to daughter about child-rearing. This behavior did not prove as resistant to change as tobacco use or the adoption of safe sexual practices.

The point here is that the characteristics of a particular behavior change may be as influential in determining the duration and effectiveness of a large-scale program of behavior change as the choice of strategic direction and the quality of execution. Within the field of STD alone, the differences among behaviors, such as condom use, testing and counseling, and needle exchange are significant and require different combinations of marketing, communication, and advocacy interventions.

As illustrated earlier in this chapter, the experience of Uganda's ABC program, along with other successful HIV/AIDS programs in San Francisco, Zambia, Thailand, and Brazil, again demonstrates the important difference that the choice of behavior (100% condom use for sex workers, versus ABC for a large generalized populations) continues to make in the effectiveness of any large-scale program of behavior change.

THE EVIDENCE FOR EFFECT

There is ample evidence for the effectiveness of large-scale social marketing, health communication, and advocacy

programs.[17] However, before considering these data, it should be understood that the evidence does not, and, more important, most often could not, satisfy a requirement for randomized controlled trials as the basis for inference about effects. One way that effective programs work is to reach their target audiences directly in face-to-face encounters, such as counseling. However, a complementary path of effect, one often deliberately incorporated into the best population-oriented programs, is to stimulate the activities of other channels that reach audiences, including the general mass and news media. The level and characteristics of these activities are beyond the control of the marketer or advocate. A program can direct its public service announcements (PSAs), but the occurrence of unplanned or unintended news events (such as an announcement by Magic Johnson that he is HIV-positive) is uncontrolled. An unplanned, breaking news event can stimulate attention to AIDS through a national or local talk show or a network news broadcast. Despite the benefit to social programs of unplanned events, measurement of their effects cannot be easily distinguished from the effects of the planned events. In this context, it serves no purpose to separate the effects of a deliberate social marketing PSA from those resulting from operations of the rest of the news media. This is true, in particular, because deliberate stimulation of the news media has, in fact, become a major strategy that many population-oriented interventions now use regularly. Thus, the way that the media cover health issues is often linked to efforts by advocates or public health authorities. Random assignment to condition is unhelpful and often meaningless in the context of a long-term program exploiting serendipitous events and engaging with what is often a national media machine. Definition of effects and causality, however, is hampered by our inability to isolate the size or importance of the inputs.

CDC's America Responds to AIDS (ARTA) campaign depended, in part, on PSAs. Evidence for the reach of that campaign includes estimates of the value of media time made available ($67 million between 1987 and 1991) and the number of times the average adult between 18 and 54 had the opportunity to view an ARTA PSA during the period (56 times per month).[18] However, it is likely that other elements of CDC's efforts to stimulate attention to HIV/AIDS, including a flood of press releases and video and audio format materials for use by local television and radio stations, were also responsible for a great deal of exposure. Similarly, the announcements by Rock Hudson, Magic Johnson, and Arthur Ashe of their personal HIV status—events not planned by CDC—had significant impact on public attention given to AIDS. Efforts by other agencies, including community organizations, state health departments, and national nonprofit organizations, along with expanded commercial marketing of condoms, operated simultaneously and with similar purposes.

We know that there have been substantial changes in knowledge, attitudes, and behavior among Americans during this period, with resulting health benefits. For example, reported condom use during the last intercourse has increased from 25% to over 50% among young people since the onset of the epidemic, and reported gonorrhea rates have declined from 324/100,000 in 1987 to 247/100,000 by 1991, 150/100,000 in 1995, and 113.5/100,000 in 2004.[19] Similarly, in other countries with major public communication and social marketing programs, the evidence for a shift toward safer behavior is even stronger.

Although these programs have operated inseparably from the broader mass media environment, there are a few cases where the possibility of attributing effects to a more limited social marketing or health communication effort is plausible. Harvey provides evidence about 1991 condom sales in 24 condom social marketing programs in less developed countries, where condoms had relatively little usage before the introduction of these programs and where sales data refer to specific brands of condoms not previously in the marketplace.[20] Usage of these products was close to 0 at baseline. The sales vary a great deal across sites, but among those 12 programs where the cost of 100 condoms per year was less than 1% of GNP per capita, sales were between 0.2 and 1.0 condoms per capita. One condom per capita represents sales equivalent to 5% of the population using condoms for contraception but a much larger percentage use them on an irregular basis.[21] So, if a large proportion of condom use already achieved was focused on men who were having sex outside of marriage, a great deal of protection from HIV transmission could be achieved. This was the pattern in some contexts.[22,23]

Another type of evidence that allows direct attribution to specific social marketing efforts has to do with promotion of AIDS hotlines. There is evidence, for example, that the use of such hotlines is directly affected by increased promotion. In 1988, the number of calls monthly to the Surgeon General's AIDS hotline tripled (from 70,000 to 210,000) during the period when the Surgeon General's pamphlet, including the hotline phone number, was mailed out.

There are also important data on large-scale effects of social marketing, health communication, and advocacy programs from work done in other health areas. The National High Blood Pressure Education Program (NHBPEP) was a prototype for such efforts. Begun in 1972, it included institutional consensus building, education of health professionals, some public education through community organizations, and major efforts in mass media education. These media efforts included distribution of PSAs for broadcast on radio and television and stimulation of coverage of hypertension by various media outlets. The effects associated with this program were very great. Between 1960 and 1972, before the initiation of the NHBPEP, the age-adjusted stroke mortality rate was declining at 1.6% per year for all U.S. whites and from

1972 to 1984, the rate declined at 5.9% per year.[24] There is some controversy about the attribution of all of this decline to improvements in hypertension control associated with the NHBPEP. Nonetheless, the sheer volume of the effect precisely timed to the introduction of the NHBPEP is impressive. The National Cholesterol Education Program appears to have been associated with sharp declines in cholesterol consumption in an analogous fashion, as much because it changed the public agenda concerning cholesterol because of its direct educational programs.

Interventions often need to stimulate demand for services provided by the health system. The 1989–1990 Communication for Child Survival campaign in the Philippines used heavy television and radio advertising along with improvements in the system to encourage early immunization. The number of children with timely, complete coverage increased from 32% to 56% in 1 year. Much of the effect of this program was to reduce delay in coming for vaccination, with a smaller effect in reaching children who otherwise would have remained unvaccinated.[25]

Thus, in other areas of health, as well as STD-specific work, there is a good ecological evidence for an association between the large outreach operations of social marketing, health communication, and advocacy programs and effects on behavior and even health outcomes. However, while these examples focus on successful programs, we don't want to suggest that all such programs are successful—many programs are unsuccessful. For example, the U.S. government has spent more than $1 billion to address drug use (particularly marijuana use) among youth in its National Youth Anti-Drug Media Campaign. The carefully executed evaluation shows no evidence for a positive effect of the campaign, and there is some suggestion that the Campaign might have boomeranged, encouraging rather than discouraging marijuana use.

Programs are unsuccessful for a variety of reasons: they have chosen a behavior not susceptible to these sorts of behavior change efforts; the strategy itself was poorly chosen or not maintained for a long enough time; the strategy was poorly implemented. Nonetheless, well-designed, large-scale behavior change programs that integrate social marketing, health communications, and advocacy approaches may have substantial impact under some conditions.

AN APPROACH TO STD CONTROL AND PREVENTION

The first problem that any program of HIV/STD behavior change must face is understanding why some people are engaging in the recommended behavior and some people are not. For example, Fishbein et al. wanted to understand the determinants of condom use in two Caribbean islands prior to the development of a comprehensive intervention.[26] There were many possibilities for the intervention: the program might address the availability of condoms, the perception that AIDS was not a personal risk to the at-risk population, or the perception that there was a widely shared social norm not favoring condom use in risky sexual contact.

The results of a preprogram audience survey were clear: condom access was not a problem for this population, and the perception of the risk of AIDS was shown to be unrelated to whether or not an individual used condoms frequently.

In contrast, three types of reports of normative pressure to use condoms (talking with friends about condom use, reporting that friends used condoms, and reporting that sexual partners had ever requested the respondent to use a condom) were each substantially related to frequency of condom use. The authors recommended that the program focus on increasing the perception of normative pressure to use condoms and not waste resources on personal risk messages, or new condom distribution systems.

This approach to analysis is totally situation specific. Its relevance relates entirely to particular audiences at particular times for particular behaviors. For example, if STD clinics are inaccessible and ordinary clinics are ineffective at diagnosing or treating STDs, public education to increase treatment-seeking alone may be counterproductive. An intervention, in this case, might better target providers whose skills are problematic or legislators who must allocate funds for expanded STD facilities. In another situation, if knowledge about the negative outcomes of a particular disease is low (e.g., infertility associated with untreated chlamydia), yet those who know about the risks are much more likely to obtain treatment, an information campaign to increase knowledge of the risks of untreated STDs makes sense.

The principle is clear. Before the program is designed, the nature and complexity of the behavioral problem must be well understood. This information guides the definition of audience(s) to be reached (legislators, medical providers, individuals engaging in high-risk behaviors) and the social networks that surround those individuals and suggests strategies to best influence their behavior.

Any strategy must also be well executed to be effective. Many programs fail, despite good messages and good definition of target audiences, because they do not achieve the exposure they need in order to affect the thinking and behavior of those audiences. Chang et al. interviewed STD clinic clients in 1988 and found that they were quite knowledgeable about AIDS.[27] However, only 30% said they acquired information from the clinics. Similarly, poorly implemented provider training, poorly supplied condom distributors, or poorly positioned advocacy approaches produce poor results.

A particularly striking example of this issue of gaining audience exposure to messages comes from the National

Cancer Institute–sponsored Community Intervention Trial for Smoking Cessation (COMMIT)[28]. This was a major smoking education intervention that tried to affect the smoking cessation rates among heavy smokers. Twenty-two cities were randomly assigned to receive the intervention or be in a control condition. At completion, there was very little difference between intervention and control cities in smoking cessation rates (both were around 18%). This apparent failure of outcome belied a more fundamental failure: there was little difference between the intervention and control communities in the level of reported exposure to messages on the five major channels used. The intervention communities did not do any *better* than the control communities because they did not do any *more* than the control communities.

DOING IT RIGHT. DOING IT ENOUGH

In Connecticut, a survey of members of the target audience for community AIDS outreach programs noted that more than 30% had heard of the program, but only 6% of those who described themselves at medium or high risk of AIDS had actually made use of the services of those agencies.[29] The problem in some communities has been assuring contact with the audience on a continuing basis. This has led some experts to argue that these socially marginalized groups might be reached through mass media-based programs, both to encourage safer sexual and needle-use behavior and to encourage involvement with available outreach programs.[30]

Evidence exists that some of these populations are commonly exposed to the mass media and do not conform to the stereotypes of street people isolated from common channels of communication. Jason et al. report that among a sample of Baltimore Intravenous Drug Users (IDUs), the median television viewing was 4 hours a day in a home setting.[31] Ross et al. found that among Australian IDUs, general media habits looked much like those of the general population.[32]

Although exposure to AIDS information through the mass media is apparently as common for these groups as for others, there is only tenuous evidence about the effect of organized mass media-based programs on the behavior of these groups. The examples that follow show evidence of effects of general campaigns and general messages on groups frequently targeted in narrowly focused campaigns. We do not discuss the large number of campaigns that address narrowly focused groups alone. Van den Hoek et al. reported on the changes in sexual behavior among a cohort of IDUs in Amsterdam before (1988–1989) and after (1989–1990) a large national AIDS prevention campaign.[33] They found some increases in regular condom use for casual sex and a reduction in the number of female IDUs working as FSWs. Similarly, de Fine Olivarius et al. found substantial declines in gonorrhea (but not other STDs) at an "inner city STD clinic" in Copenhagen, Denmark, comparing women studied before (1984) and after (1988) a general campaign for safer sex.[34] Neaigus et al. found evidence in New York that behavior changes among IDUs enrolled in an outreach program were partly attributable to the outreach intervention and partly attributable to external trends, including, presumably, the general education efforts then prevalent.[35] Similarly, Swiss researchers found in a 1989–1990 study that "drug users and ex-drug users used condoms more often than the rest of the population," with the implication that the several years of campaigning prior to that study had produced that effect.

There are several conclusions that may be drawn from this and other evidence about social marketing, health communication, and advocacy for STDs. Crucial to program success is the need for planners to understand their audience well: what the audience is doing now and how it perceives the new proposed behavior; what the major determinants of current behavior are; promising routes to influencing those behaviors; and what channels of outreach are likely to reach and influence them. Appropriate research approaches for investigating these issues will reflect the resources available and the scale of the program. Informal interviewing may be all a small individual clinic can justify before launching a program for its clientele. Major surveys, multiple focus groups, continuous monitoring of exposure to messages, and effects on knowledge and behavior can easily be justified, however, by national programs with a long-term agenda.

No less central is a clear plan for assuring adequate exposure to messages to affect behavior. There is, unfortunately, little systematic evidence about dose-response to exposure, i.e., how much exposure is required to produce how much behavior change. It is clear that programs that achieve high levels of exposure have shown substantial effects. Programs with little or no exposure have little or no effects. The dose-response curve surely is a reflection of the presence of countervailing influences, the quality of the messages to which an individual is exposed, and the complexity of the behavior change being addressed. Cigarette smoking has yielded only slowly to growing exposure from multiple sources. This slow yield is in the context of an addictive behavior and an extensive promotion of cigarettes. In the area of STD-relevant behavior, it appears that condom use in casual sex has proved susceptible to comprehensive broad-based programs, but behavior favoring abstinence has been slow to change.

It is sometimes suggested that the major work of public awareness in HIV prevention is done and that future shifts in behavior will all reflect work done locally and directed specifically to high-risk individuals and their communities. Thus, the role for large-scale social marketing programs is over. An alternative view is that this shift will have a major cost. If national social marketing efforts end, the support they provide for maintaining and increasing the patterns of safer behavior that have been adopted in the general population will be lost. The COMMIT study suggests not that the target

intervention was weak but that the control intervention was strong. The strength of that control intervention was largely due to a broad national effort. A national effort provides continued attention in the national media. A critical goal is that STD/HIV prevention continues to be supported as an area of political and popular attention and budgetary priority. If the national focus is softened, the funds and political will that underpin local programs also may be lost.

FUTURE APPLICATIONS TO STD/HIV CONTROL AND PREVENTION

STD/HIV control and prevention programs are already using social marketing, communication, and advocacy extensively. Social marketing of condoms, for example, is now a widespread enterprise with significant documented success (as in Portland, the Caribbean, India, and Switzerland, among others).[36] Communication approaches, including the management of the news media, have greatly increased the world's understanding of HIV/AIDS. Polls consistently indicate high levels of AIDS knowledge. Advocacy was successful in the United States in protecting funding for HIV prevention during a period of political skepticism about prevention. Other STDs might well benefit from a strategic review of program goals using a broad marketing, communication, and advocacy framework and in addition, the application of specific intervention techniques, such as (1) integrating targeted audience research; (2) developing lifestyle profiles for high-risk populations; (3) long-range planning and integrating services, messages, and policies targeted to a narrow, high-priority problem; (4) maintaining program intensity levels that could incorporate all tactics into existing and new programs; and (5) increasing attention to policy change and advocacy approaches.

Finally, there is the question of message fatigue and behavioral recidivism. Even in areas where HIV/AIDS prevention messages have been widely diffused and behavioral change documented, such as San Francisco, there is evidence that new populations of young gay men are not practicing safe sex. From a communication perspective, this is a well-documented characteristic of human behavior and certainly to be expected. Even with simple behaviors, such as using a seat belt, studies have documented that without regular reminders and new tactics to maintain behavior, behavioral compliance degrades sharply. With addictive behaviors, like smoking and drug use, recidivism has also been widely documented. Similarly, relapse to riskier sexual behaviors or behavioral disinhibition has been observed, particularly with the advent of new interventions such as antiretroviral therapy that may alter risk perceptions. It will be a challenge to refresh public attention, develop new tactics, messages, and services to address the needs of new populations who were not convinced by the original arguments or not exposed to these campaigns.

A NEW RESEARCH PARADIGM

Social marketing, communication, and advocacy research continue to be dominated by a "vaccine" paradigm that attempts to establish the "efficacy" of various communication interventions so that those interventions can be discarded, improved, or replicated in other communities. Studies continue to compare different interventions (peer education vs. mass media approaches) as though these were competing "behavioral vaccines" or they attempt to establish the efficacy of a particular intervention in a real-world setting (community trials of smoking cessation interventions) as though those interventions would be widely applicable to diverse audiences in different cultural and political setting. This vaccine approach to behavioral intervention research has led to disappointing results. Behavioral interventions are not like biological vaccines. The variability of hosts (social groups vs. human anatomy) over time is much greater in social institutions than biological entities. The replicability of intervention effectiveness is much less robust in social communities than in biological laboratories. New forms of research are needed that respect the characteristics of effective behavioral interventions, such as: (1) the importance of multiple interacting forces; (2) the need for responsive changes in interventions to meet unpredictable changes in the social and political environment; and (3) the importance of both intensity and long-term durability of interventions to produce measurable effect. Behavioral intervention research might better turn to marketing research models or the practice of clinical medicine, where a set of best practices are applied by highly trained and experienced practitioners and adapted by them to meet the needs of different patients or clients. Research, in this case, is formative as well as evaluative. It helps shape programs as well as document their apparent success or failure.

97 Innovations in Public Health Surveillance for HIV/AIDS and Other STDs: Guideposts for Prevention and Care

Patrick S. Sullivan, William C. Levine, Matthew T. McKenna, and Hillard Weinstock

Public health surveillance is the ongoing and systematic collection, analysis, and interpretation of outcome-specific data for use in the planning, implementation, and evaluation of public health practice.[1] Surveillance data are collected in order to describe the needs for prevention, treatment, and care programs; to characterize populations at greatest risk of infection and in greatest need of services; and to describe the impact of prevention and treatment programs. Dissemination of data from surveillance systems is a critical aspect of public health surveillance,[2] and surveillance data are used by health departments, local planning bodies, managers of treatment and prevention programs in communities, and politicians at all levels of government for decision making and resource prioritization (Fig. 97-1).

There are many kinds of surveillance systems that collect data to characterize the HIV/AIDS epidemic and the epidemics of other STDs. These systems include *case surveillance systems* (or disease registries) and *supplemental surveillance systems.* Case surveillance systems are primarily concerned with the enumeration of unique cases of reportable diseases and the description of the characteristics of those cases. Typically, HIV/AIDS and other STD case surveillance systems collect information about demographic and geographic characteristics of cases, as well as limited information about risk behaviors that may represent routes of acquisition. Case surveillance systems also collect information to identify the cases, so that summary data are available on unique (unduplicated) persons diagnosed with disease. Case surveillance relies primarily on the collection of existing information for medical records or laboratory reports.

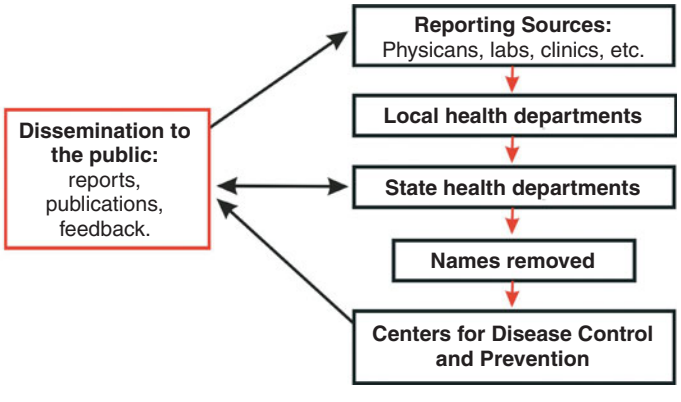

FIGURE 97-1. HIV/STD surveillance system flow of information.

Supplemental surveillance systems differ from case surveillance systems in several important ways. First, supplemental surveillance systems may not endeavor to collect information on all diagnosed cases of disease but may, instead, collect data from a subset of those with disease. Second, supplemental surveillance systems may collect more in-depth information than case surveillance systems. Third, supplemental surveillance systems may collect data beyond what exists in medical records—for example, data collected from interviews with patients or data from supplemental laboratory tests on biologic specimens from patients. Finally, supplemental systems that estimate the prevalence of disease may collect more information about the populations in which disease is identified.

The legal authority for surveillance resides in state laws and public health regulations that authorize states to collect data for the purposes of disease control.[3] In the case of case reporting for HIV/AIDS, most states have specific laws or regulations requiring disease reporting. In the case of case reporting of other STDs, legal mandates for case reporting may be embodied in more general statutory language about reportable diseases. For supplemental surveillance systems, the extent to which legal authority to collect data is conferred by statute or regulation varies by state.

Although the legal authority for surveillance resides in states, and state health department staff collect case surveillance data, other institutions play important roles in the supporting and coordinating surveillance activities. In order to assure the collection of surveillance data in a consistent and comparable way across states, the United States Public Health Service and states work together to establish surveillance case definitions that comprise the national

standards for surveillance systems. The Council of State and Territorial Epidemiologists and the Association of State and Territorial Health Officers serve critical roles in providing consultation and recommendations for which diseases should be nationally notifiable, and for changes to surveillance case definitions for those diseases.[3] This consultative process also seeks a broad range of input from professional, community, and policy-oriented organizations. The Centers for Disease Control and Prevention (CDC) publishes case definitions for reportable diseases, makes recommendations to states on best methods for implementing surveillance programs, and provides financial support and technical assistance to state health departments to conduct surveillance activities.

The data collected by state and local health departments are reported to CDC on a voluntary basis, with the caveat that all information that could identify a particular person is removed from the data before transmission to CDC.[4] Surveillance data shared with the federal government are protected from release by a federal Assurance of Confidentiality; surveillance data retained in states, where names and other identifying information are held, are protected by state laws. In most states, release of confidential surveillance information is punishable by criminal penalties.[5]

HIV/AIDS SURVEILLANCE

CASE DEFINITION—UNITED STATES

The case definition for AIDS has changed six times since the original case definition was established in 1982; the major revisions of the case definition are summarized in Table 97-1. The evolution of the case definition has followed increased understanding about the natural history, pathogenesis, and treatment of HIV infection. For example, the morbidity associated with infection with HIV was first recognized in 1981, when clusters of relatively young, homosexual men who did not have predisposing

Table 97-1. Major Revisions of the Case Definition for Surveillance of HIV and AIDS in the United States

Year (Reference)	Main Features and Changes
	Adults and adolescents ≥13 yr of age
1981[6]	Informal case definition in response to reports of Kaposi's sarcoma (KS) and *P. carinii* pneumonia (PCP) in young, homosexual men.
1982[7]	No known cause for diminished cell-mediated immunity with the onset of serious opportunistic infections (OIs) including but not limited to PCP, KS.
1985[143]	Positive serologic or virologic test for the human T-cell lymphotropic virus type III/lymphadenopathy associated virus (HTLV-III/LAV) with expanded list of OIs. Persons with positive HTLV-III results and no opportunistic infections were included.
1986[144]	Classification system for severity of immunosuppression among persons with HTLV-III infection based on CD4 count and OIs.
1987[145]	Expansion of the list AIDS indicator OIs to include human immunodeficiency virus (HIV) encephalopathy and wasting syndrome as well as acceptability of presumptive OI diagnoses in the presence of HIV infection.
1993[62]	AIDS definition expanded to include immunologic criteria (CD4 cell count <200 cells/μL) and additional OIs including cervical cancer, recurrent bacterial pneumonia, and pulmonary tuberculosis.
1999[16]	Guidelines for integrating HIV and AIDS case surveillance including an updated HIV case definition that included newer virologic detection tests (e.g., HIV nucleic acid, p-24 antigen, and viral culture).
2005[9]	AIDS case definition limited to persons with documented laboratory evidence of HIV infection regardless of the OIs identified or other immunologic markers.
	Children <13 yr of age
1985[143]	Updated case definition included specific conditions for children.
1987[144]	Classification system for severity of immunosuppression for children.
1994[146]	Updated case definition included improved testing technology and information about progression of HIV among children.
1999	Updated case definition to include virologic detection tests to identify perinatally exposed infants as *not infected with HIV.*

Adapted from Nakashima AK, Fleming PL. HIV/AIDS surveillance in the United States, 1981–2001. *J Acquir Immune Defic Syndr* 2003; 32(Suppl 1): S68–S85.

immunosuppressive diseases developed *Pneumocystis carinii* pneumonia (PCP; now known as *Pneumocystis jiroveci*) and/or Kaposi's sarcoma (KS).[6] Four years later, all state and territorial health departments in the United States had instituted surveillance for the clinical conditions (such as PCP and KS) associated with immune dysfunction that became known as the acquired immunodeficiency syndrome (AIDS) using a standardized case definition.[7] In 1993, the case definition was expanded to include CD4 lymphocytopenia, with CD4 counts less than 200 cells/μL, as an AIDS-defining condition. This expansion was based on the recognition that severe immunosuppression at this level required medical intervention for prevention of opportunistic infections, and, therefore, this morbidity should be documented for resource planning purposes. Notably, many other industrialized countries did not adopt this aspect of the 1993 case definition.[8]

Most recently, the case definition was modified in 2005 to require that all AIDS case reports contain documentation of a laboratory diagnosis of HIV infection.[9] Before this most recent change, AIDS was reportable even when diagnostic tests for HIV were negative. This was because surveillance of the HIV epidemic began before the identification of the etiologic agent of AIDS and because of the incremental nature of changes in the AIDS case definition. The current case definition for HIV and AIDS is shown in Table 97-2 but will continue to evolve, in order to accommodate the ongoing advances in diagnostic and therapeutic technologies.

CASE SURVEILLANCE: METHODS, ISSUES, MAJOR FINDINGS—UNITED STATES

Methods of case surveillance

Surveillance for AIDS and HIV employs a combination of passive and active case ascertainment methods. In passive methods, local and state health departments receive reports from multiple sources, including physicians and other healthcare providers, hospitals, clinics, and laboratories. In active surveillance methods, health department staff supplement information from passive reports through follow-up by reviewing medical records and, on occasion, interviewing patients and providers. Active case surveillance also includes health-department-initiated review of administrative, clinical, and laboratory records in facilities that care for large numbers of persons with HIV infection. Formal evaluations have consistently found that AIDS case reporting is one of the most complete and accurate population-based registration systems for diseases or health conditions in the United States.[10]

AIDS case reporting was historically the standard method for surveillance of the HIV epidemic and was used until the mid-1990s, as a distant proxy for trends in HIV transmission. All U.S. states have collected data on AIDS cases using consistent methods since 1985.[11] AIDS data were used to model trends in the incidence of HIV infection,[12] underpinned by the fact that there was a relatively consistent 8–10-year interval from time of HIV infection to onset of AIDS. The assumption of the constancy of the time lag from HIV infection to onset of AIDS produced two serious limitations to the use of AIDS case reports to describe HIV incidence. First, analysis of contemporary data reflected trends in transmission a decade earlier. This limited the usefulness of the data for planning prevention activities. Second, the duration of the lag time was increased by effective therapies, as they became available.

The introduction of effective antiretroviral therapy in 1996 resulted in welcome delays in disease progression[13] but changed the meaning of a new AIDS diagnosis. Whereas before 1996 a new AIDS diagnosis represented a new HIV infection a decade earlier, after 1996 a new AIDS diagnosis became more indicative of failures in treatment, poor access to health services, and delays in diagnostic testing. Therefore, AIDS surveillance data alone no longer provide adequate information about trends in the transmission of HIV.

In order to describe more recent trends in the epidemic in the setting of effective therapy, reporting of cases of asymptomatic HIV infection is required. Several states implemented mandatory reporting of HIV infection shortly after the licensure of the first diagnostic test in 1985. However, not all states implemented HIV case reporting systems, because of concerns in some communities about the stigma and discrimination associated with HIV infection, and concern that HIV reporting registries would be used for political retribution, criminal prosecution, or discrimination in employment, housing, and insurance. Some also speculated that mandatory reporting of HIV diagnoses would deter high-risk persons from seeking diagnostic testing.[14] Over the past two decades, significant advances in legal protections against discrimination have been made,[5] and studies have demonstrated little correlation between disease reporting policies and the extent of HIV testing among high-risk persons.[10,11,15]

In 1999, CDC recommended that all states implement reporting of HIV infections as part of an integrated HIV/AIDS surveillance system.[16] By 2004, every state and the District of Columbia mandated reporting for persons diagnosed with HIV, even if AIDS has not developed—but with inconsistent methods. The method recommended by CDC—the use of patient name as the identifier in the surveillance system[16]—was not implemented in all areas. Some states implemented HIV reporting systems based on codes derived from patient characteristics such as birthdate, race, and partial identifiers such as the last four digits of the social security number, rather than names.[10] Systematic, population-based evaluations of coded identifiers have not established that systems using non-name methods can maintain data equivalent
