PART 10

Management of STD Syndromes in Men

This page intentionally left blank

59 Urethritis in Males

David H. Martin

DEFINITIONS

Urethritis, manifested by urethral discharge, dysuria, or itching at the end of the urethra, is the response of the urethra to inflammation of any etiology. The characteristic physical finding is urethral discharge, and the pathognomonic confirmatory laboratory finding is an increased number of polymorphonuclear leukocytes (PMNL) on Gram stain of a urethral smear or in the sediment of the first-voided urine. Urethritis is called gonococcal, or gonorrhea, when *Neisseria gonorrhoeae* is detected, and nongonococcal if *N. gonorrhoeae* cannot be detected. The term *nongonococcal urethritis* (NGU) is preferable to the term *nonspecific urethritis*, because NGU has specific causes and many of these have been elucidated. Of those that are clearly established as causes of NGU, *Chlamydia trachomatis* and *Mycoplasma genitalium* are the most frequent. NGU occurring soon after curative therapy for urethral gonorrhea is called *postgonococcal urethritis* (PGU).

HISTORY

In the 1800s, even prior to the discovery of *N. gonorrhoeae*, the existence of several types of urethritis was already suspected. By the 1880s, after the isolation of *N. gonorrhoeae* and the introduction of the Gram stain, differentiation of gonococcal from NGU became possible. In the early part of the twentieth century, intracytoplasmic inclusions, which today are considered characteristic of chlamydiae, were seen in urethral smears of some men with urethritis. The development that had the greatest impact on clinical differentiation of GU and NGU, however, was the introduction of the sulfonamides and penicillins for treatment of urethritis. With penicillin in particular, GU was curable, but NGU usually was not. Progress in therapy of NGU came with the introduction of tetracyclines and macrolides. Further insight into the etiology of NGU came with the discovery of *Ureaplasma urealyticum* in 1954,[1] the development of cell culture isolation techniques for *C. trachomatis* in 1965,[2] and the development of nucleic acid amplification tests (NAATs) for sexually transmitted diseases (STDs) in the 1990s.

ETIOLOGY

Organisms that are proved or are possible causes of sexually transmitted urethritis are listed in Table 59-1.

NEISSERIA GONORRHOEAE

The causal role of *N. gonorrhoeae* in male urethritis is well established. Several aspects that are important for management of GU deserve reemphasis here. These include the frequency of asymptomatic infection, the increasing resistance of isolates of *N. gonorrhoeae* to traditional treatments, and the high frequency of concurrent *C. trachomatis* infection. Although most new cases of GU are symptomatic, a number of studies have shown that GU can be asymptomatic or minimally symptomatic.[3] As many as two-thirds or more of men in the community who are found to have urethral gonorrhea by routine screening or by contact-tracing have no symptoms at all, or they have such mild symptoms that they ignore them. These men are likely to remain sexually active and to spread the infection. For example, a population-based study of 5867 men in rural Tanzania found that 27% had a positive urine leukoctye esterase dipstick test, and 2.5% reported a complaint of urethral discharge. Of those with a positive dipstick test or with symptoms, 158 had urethral gonorrhea (by Gram stain) or chlamydial infection (by antigen-detection immunoassay). Only 24 (15%) of those with either infection complained of symptoms or signs, and an additional 30 (19%) had a discharge on examination, leaving 66% with neither symptoms nor signs.[4] Asymptomatic men in a U.S. study appeared especially likely to have the arginine-, hypoxanthine-, and uracil-requiring auxotrophs of *N. gonorrhoeae* that have often been associated with disseminated gonococcal infection.[5]

N. gonorrhoeae is a textbook example of how overuse of antibiotics induces resistance that eventually spreads around the

HSV, 2–3% (in the absence of skin lesions)
Adenovirus, 2–4% (seasonal, associated with receptive oral sex)
Haemophilus sp., rare
Unknown

[a]Rare cases of *N. meningitidis* urethritis presenting like GU have been reported (see text). Question marks reflect uncertainty concerning the percent of cases attributable to the organism.

world resulting in increased morbidity due to treatment failures. Gradually increasing resistance of *N. gonorrhoeae* to penicillins in the 1960s resulted in the need for progressively higher doses of penicillin in conjunction with probenecid to obtain a cure. Penicillinase-producing *N. gonorrhoeae* strains appeared in 1976; they were initially most prevalent in Southeast Asia and Africa, but then spread worldwide. More recently, quinolone resistance also first appeared in Asia and from there has spread to become an increasing problem in the West including the United States. Treatment guidelines have changed significantly as a consequence (see Chapter 35 for details).[6,7]

CHLAMYDIA TRACHOMATIS

Since 1972, many studies have shown that *C. trachomatis* could be isolated from the urethras of 25–60% (usually 30–40%) of men who have NGU, 4–35% (usually 15–25%) of men with urethral gonorrhea, and 0–7% of men without obvious urethritis (see Table 59-2). *C. trachomatis* has been less frequently isolated from men who have sex with men (MSM) with NGU in most studies.[8,9] However, a more recent report based on an NAAT for diagnosis suggests that at least in some areas the organism is equally common among MSM with NGU as in heterosexual men.[10]

Most patients with NGU seen in STD clinics have existing antibody to *C. trachomatis* demonstrable in acute-phase sera by microimmunofluorescence (micro-IF). It is unusual to document seroconversion or a fourfold increase in micro-IF antibody in such patients.[11] However, in a selected group of men who had relatively few sex partners and no previous history of urethritis, and who have had symptoms of NGU for less than 10 days, 9 of 10 who were culture-positive for *C. trachomatis* seroconverted.[12] IgM micro-IF antibody, a transiently detectable antibody that allows diagnosis of recent infection despite preexisting antibody, was detected in specimens from 16 of 20 men whose cultures were *C. trachomatis*-positive, compared with 3 of 39 with NGU whose cultures were negative ($p > 0.0001$).[12] These results suggested that recent acquisition of chlamydia, rather than reactivation of latent infection, was associated with urethritis in these men.

PGU provides an opportunity for prospective assessment of the ability of *C. trachomatis* to produce urethritis. Gonorrhea has a shorter incubation period than chlamydial urethritis, so men with both infections can present with gonorrhea while the chlamydial infection is still incubating. When gonorrhea is treated with antimicrobials that do not eradicate *C. trachomatis*, such as single-dose penicillin, ampicillin, ceftriaxone, fluoroquinolones, or spectinomycin, PGU develops in most men who have concurrent *C. trachomatis* infections (see Table 59-2).

Selective eradication of *C. trachomatis* results in alleviation of urethritis in men infected with the organism.[12–14] Use of sulfonamides or rifampin that are active against *C. trachomatis* but which overall have a poor record in the treatment of NGU, resulted in clinical responses in most men infected with *C. trachomatis*, but in a significantly smaller proportion of men without *C. trachomatis*.[12–14] However, a better response in *C. trachomatis*-positive NGU patients than in chlamydia-negative NGU is also observed with a broader-spectrum antimicrobial, tetracycline.[15] Persistence or recurrence of NGU within 6 weeks of initiation of a 7-day course of tetracycline, 2 g per day, was seen in 17% of men whose cultures were *C. trachomatis*-positive, compared with 47% of those whose cultures were *C. trachomatis*-negative ($p = 0.01$). In a subsequent study with minocycline, persistent or recurrent NGU developed within 6 weeks of initiation of therapy in 17% of 78 *C. trachomatis*-positive men, compared with 35% of 133 men without *C. trachomatis* infection ($p > 0.005$).[8] In summary, the accumulated data unequivocally have established *C. trachomatis* as a cause of NGU.

Etiology of *Chlamydia trachomatis*–negative NGU

Chlamydia culture is difficult to perform optimally and it has always been thought that the sensitivity of culture is less than optimal. Because of this fact, it has been suspected that a certain proportion of *C. trachomatis*-negative NGU cases may have been false-negative cases of chlamydial urethritis. However, several different lines of evidence have suggested that this is not the case or at least is uncommonly so. It has

[a]Number culture or NAAT-positive/number examined (percent culture or NAAT-positive).

been shown that when initial urethral specimens are negative for *C. trachomatis* they usually remain negative when untreated patients are cultured repeatedly on follow-up.[15] It has also been shown that cervical cultures from female sex partners of men with *C. trachomatis*-negative NGU are likely to be *C. trachomatis*-negative.[11,16–19] Another study has shown that in most cases of *C. trachomatis* culture-negative NGU, there is no serologic evidence of recent *C. trachomatis* infection.[12] Finally, *C. trachomatis*-negative NGU cases have been demonstrated to respond poorly to certain antimicrobials that are active against *C. trachomatis* such as the sulfonamides, rifampin, and the tetracyclines.[8,12,13,15,20] Though NAATs have proven that *C. trachomatis* culture sensitivity is relatively poor (see Chapter 32), the data indicate that though a small proportion of *C. trachomatis* culture-negative NGU cases are actually caused by this organism, other organisms, some of which remain unknown, are more important.

MYCOPLASMAS

Of the 13 mycoplasma species known to infect or colonize humans, four are found in the genital tract. These are *Mycoplasma hominis, M. genitalium, Ureaplasma parvum*, and *U. urealyticum*. The latter two were included previously in the single species *U. urealyticum*. Recent genetic studies have shown that the genus actually comprises of the two species, a finding that eventually may help clarify the confusion surrounding the role of these organisms in NGU.[21] In reading the older literature, it is important to remember that whenever *U.* urealyticum is referred to, the authors are really talking about a mixture of the two. *Ureaplasma* sp. *M. hominis* does not appear to have a role in NGU having been found in numerous studies to be equally present in men with disease and in normal men.

The best evidence for a pathogenic role for *Ureaplasma* sp. in NGU, came from studies of men who were relatively inexperienced sexually and were having their first episodes of urethritis. In such men, the rate of isolation and the concentration of *Ureaplasma* sp. in first-voided urine were significantly greater in those with *C. trachomatis*-negative NGU than in those with *C. trachomatis*-positive NGU or in a comparison group without urethritis.[12] In that study, the comparison group without urethritis had actually had more sex partners than the other groups.[12] Data compiled from three Seattle studies[8,12,13] showed that *Ureaplasma* sp. were isolated significantly more often from men with a first episode of urethritis than from those who had a history of previous episodes or from men without urethritis.

The results of studies of selective eradication of *Ureaplasma* sp. also support a pathogenic role in NGU. Sulfonamides and rifampin are active against *C. trachomatis*, whereas spectinomycin and streptomycin are active against *Ureaplasma* sp., but not against *C. trachomatis*. In men whose cultures were *C. trachomatis*-negative but *Ureaplasma* sp.-positive, urethritis responded poorly to sulfonamides and rifampin.[12–14] Furthermore, urethritis responded well to streptomycin or spectinomycin when *Ureaplasma* sp. were eradicated, but not when they persisted.[13] In another study, NGU persisted 6–12 days after onset of minocycline therapy significantly more often in men infected with tetracycline-resistant *Ureaplasma* sp. than in those infected with tetracycline-sensitive strains, and persistent NGU correlated with persistence of the tetracycline-resistant strains.[22] Root et al. also demonstrated that there was a strong correlation between tetracycline resistance of *Ureaplasma* sp. and the persistence of the organism after tetracycline treatment.[23] In contrast to these results, the evidence for the involvement of *Ureaplasma* sp. in PGU is very weak.[11,24,25]

Intraurethral inoculation of *Ureaplasma* sp. has been performed in two men and several nonhuman primates. The first man developed dysuria and frequency of urination, associated with pyuria and positive cultures for *Ureaplasma* sp.[26] Symptoms and signs disappeared with eradication of the *Ureaplasma* sp. by minocycline. The second man developed PMNL-containing mucus threads in his urine, which persisted after minocycline treatment despite the eradication of *Ureaplasma* sp.[26] Intraurethral inoculation of *Ureaplasma* sp. into nonhuman primates has resulted in colonization of the urethra for various periods of time, and it has been associated with increased numbers of PMNL in the endourethral smear in some animals.[27,28]

Despite the evidence cited earlier, confusion has persisted concerning the role of *Ureaplasma* sp. in NGU. This has resulted largely from the relatively uniform finding in NGU survey studies among men at high risk for STDs that *Ureaplasma* sp. are found as often among controls as in cases. Case-control studies of the association of *Ureaplasma* sp. with NGU must account for the fact that urethral colonization is common in men without urethritis, and is strongly correlated with the total number of female sex partners.[29] In general, *Ureaplasma* sp. are isolated more often from patients with NGU than from control groups when the control group is less sexually active than the NGU group, but not when the sexual activity of the two groups is comparable (reviewed by McCormack et al.[30]).

As noted earlier and discussed in greater detail in Chapter 41, the genus *Ureaplasma* is now known to contain two species, *U. urealyticum* and *U. parvum*. The latter is named "parvum" as its genome size is significantly smaller than that of *U. urealyticum*. Limited studies have suggested that *U. urealyticum* but not *U. parvum* is associated with NGU. Deguchi et al. found *U. urealyticum* in 18% of men with chlamydia-negative NGU compared to 7.3% of controls while *U. parvum* prevalence was 9.9% and 13.2%, respectively.[31]

Povlsen used a different polymerase chain reaction (PCR) assay and found that *U. urealyticum* was associated with NGU, but after multiple regression analysis, the *p* value was only 0.15.[32] Another study utilizing molecular genotyping has suggested that only a subpopulation of *U. urealyticum* is actually associated with NGU.[33] These data combined with those from the earlier studies cited before support a role for *U. urealyticum* as a cause of NGU and suggest that *U. parvum* is a colonizer. However, it appears that the organism causes only a small proportion of chlamydia-negative NGU cases. Clearly, there is a need for further research to better understand the role of *Ureaplasma* sp. in urethritis and hopefully this will be forthcoming over the next few years.

In contrast to the strong association between PGU and *C. trachomatis*, the association between PGU and *Ureaplasma* sp. is weak. Among *C. trachomatis*-negative men with gonorrhea who received treatment with penicillins, which are not active against mycoplasmas, PGU developed in 11 (61%) of 18 who had *Ureaplasma* sp., compared with 5 (28%) of 18 without *Ureaplasma* sp. infection ($p = 0.09$).[24] In two other studies involving cultures for *C. trachomatis* and *Ureaplasma* sp., *Ureaplasma* sp. were not shown to be associated with PGU.[11,25]

The greatest advance in our understanding of the etiology of urethritis over the last 15 years has been the unequivocal establishment of the important role of *M. genitalium* in NGU. *M. genitalium* was first implicated as a cause of NGU in 1981.[34] Further understanding of the role of this organism had to await the advent of modern DNA amplification technology as this organism is very difficult to grow in vitro. Early studies using the PCR assay showed that *M. genitalium* is present in as many as 25% of men with NGU,[35,36] but it is present in only 6% of normal men.[37] These data have withstood the test of time and a number of studies supporting these early observations have been reported since publication of the last edition of this book as reviewed by Jensen (see Fig. 41-1 in Chapter 41).[38] Combining the data from 19 studies, the percentage of patients with NGU harboring *M. genitalium* is 21.1% as compared to 6.7% in controls without NGU. The pooled odds ratio for this difference is 3.8 (95% confidence interval 3.0–4.9) For combined chlamydia-negative NGU cases, the *M. genitalium* prevalence is 21.7% compared to 6.0% for a pooled odds ratio of 5.15 (95% confidence interval 3.6–7.4). Clearly, *M. genitalium* is a cause of a significant number of the NGU cases that were referred to as "etiology unknown" in the last edition of this chapter. At least, in part, *M. genitalium* may explain why nonchlamydial NGU cases appear to respond less well to treatment than cases caused by *C. trachomatis* (see the section on therapy for more details). Finally, based on genotyping analyses of concurrently infected couples, there is now strong evidence that *M. genitalium* is sexually transmitted.[39]

TRICHOMONAS VAGINALIS

As reviewed by Krieger, numerous studies largely from Europe have suggested that *T. vaginalis* is a significant pathogen in men causing a variety of genitourinary syndromes including urethritis.[40] In many cases, these studies were not controlled or poorly controlled and results varied widely (see Chapter 43). In North American studies from the 1970s, the proportion of cases of NGU in which *T. vaginalis* was detected was small.[11,41–43] For these studies, the diagnosis was entirely dependent on observing the organism by direct microscopy which is relatively insensitive or culture using a variety of media for which quality control was poor. However, in a cross-sectional study involving 447 men including 147 contacts to women with trichomoniasis and 300 randomly selected STD clinic clients, Krieger and colleagues convincingly demonstrated that the organism was associated with NGU. Among men with NGU in this study, 18% were infected with *T. vaginalis* compared to 8% of men without urethritis. Detection of *T. vaginalis* was optimized in this study by culturing both urethral secretions and urine in well-standardized Diamond's medium.[44,45] Though data accumulated over last decade largely based on PCR assays have supported these findings, the magnitude of the contribution of *T. vaginalis* is, if anything, even less clear. In another culture-based study, evidence was presented that the older the NGU patient, the more likely it was that *T. vaginalis* may have been the cause of the problem.[46] However, in a population-based study in Africa, Watson-Jones et al. showed that asymptomatic male carriage rates of *T. vaginalis* also increased significantly with age.[47]

The advent of PCR assays for the diagnosis of *T. vaginalis* infection has shown that the organism is found frequently in the urethra of both symptomatic and asymptomatic men. Schwebke and Hook found *T. vaginalis* in 17% and 13% of men with urethral symptoms and urethral inflammation, respectively, but also found it in 14% of asymptomatic men and 11% of men without Gram stain evidence of inflammation.[48] Wendel et al. found *T. vaginalis* in 17% of urethritis cases and 12% of those without evidence of disease.[49] The differences between cases and controls were not significant in both studies.

The prevalence rate of *T. vaginalis* among African women is high suggesting that *T. vaginalis* might play an even greater role in African men with NGU. *T. vaginalis* PCR assays have been used to address this question in several recent studies. Rates in NGU or nonchlamydial NGU varied from 15% to 23% while rates in controls varied from 6% to 11% and these differences were highly significant. Unfortunately these studies utilized controls from settings very different than those where cases were enrolled and it is possible that STD risk factors differed significantly between cases and controls. Therefore, the true relative risk of *T. vaginalis* infection in symptomatic versus asymptomatic men in these studies cannot be estimated.[50–52]

In summary, while it seems clear the *T. vaginalis* is a cause of urethritis in men, the relative contribution of the organism to urethritis-associated morbidity is difficult to estimate especially now that recent studies have found high carriage rates in men without urethritis drawn from the same populations as the cases. Additionally, these studies have shown high coinfection rates between *T. vaginalis* and the other known urethral pathogens further complicating the task of estimating the contribution of *T. vaginalis* to incident urethritis case rates.

As can be seen in Table 59-3, in a series of recent studies the median percent of NGU cases that are *C. trachomatis*-positive is 30% compared to 19% for *M. genitalium*. Though the data as yet are incomplete and are subject to the limitations discussed in the paragraph above, 10–20% of NGU cases are at least associated with *T. vaginalis*. Based on two studies that met criteria for inclusion in Table 59-3 and which included *U. ureaplasma* as diagnosed by a new, specific PCR assay, this organism may account for about the same number of NGU cases as does *T. vaginalis*. New studies of urethritis utilizing well-standardized NAATs for all four of these pathogens are needed to understand clearly the relative contribution of each to the NGU syndrome. Moreover, such studies should define more precisely the proportion of cases for which the causative agent or agents remain to be discovered.

OTHER CAUSES OF NGU

As noted earlier, despite recent advances in our understanding of the etiology of NGU, there remains a significant proportion of urethritis cases in heterosexual males for which the etiology is unknown. Moreover, in the majority of NGU cases in MSM, the etiology is unknown.[8]

Most studies of the aerobic and anaerobic urethral flora excluding the mycoplasmas have not yet revealed significant differences between *C. trachomatis*-positive and

Papers were chosen for inclusion in the table based on the following criteria: (1) Study published in the last 15 years. (2) GU clearly differentiated from NGU and at least one other putative NGU pathogen other than C. trachomatis was studied. (3) The data were presented in such a way that organism prevalence in NGU cases could be calculated. Urethritis was defined differently in several of the studies. Organisms were identified using NAATs in most of these studies.

[a]Seven West African countries were involved in this study.

[b]Percents exceed 100% as multiply infected cases are included two or three times.

[c]For studies in which the data were provided, this figure represents the proportion of urethritis cases attributable to *N. gonorrhoeae* seen in the facilities where each study was conducted (nd: data not available).

C. trachomatis-negative patients with NGU.[41,53] Early studies suggested a possible role for *Bacteroides ureolyticus*,[54,55] but more recent work has not demonstrated this organism more frequently among men with NGU than among normal men.[56] *Haemophilus influenzae* and *Haemophilus parainfluenzae* appear to cause urethritis infrequently.[57,58] Similarly, coliforms may cause a few cases of urethritis in MSM.[59] *Neisseria meningitidis* has been reported as a cause of urethritis relatively more often in areas such as Western Europe where the incidence of gonorrhea has dropped to very low levels. Today, men with urethral smears positive for Gram-negative diplococci in these countries may be relatively likely to have an infection caused by this organism in view of the rarity of *N. gonorrhoeae*.[60,61] Oral-genital sex is the presumed mode of transmission. This hypothesis has been strengthened recently by the isolation of an *N. meningitidis* strain from the pharynx of a woman which matched the strain isolated from her symptomatic male partner as determined by pulsed field gel elctrophresis.[62]

Recently, molecular approaches to the study of vaginal flora have revealed a number of previously unknown organisms such as *Atopobium vaginae* that are important members of the genital tract bacterial ecosystem.[63,64] Many of these organisms are most closely related to strict anerobes and some have never been cultivated. Keane et al. showed an association between NGU in males and bacterial vaginosis in their partners suggesting the possibility that one or a combination of the organisms associated with this syndrome could infect their male partners resulting in urethritis.[65] Molecular methods have been applied to a few patients with NGU and controls and, indeed, there is at least one unknown organism that is present in symptomatic men and not in controls.[66] More extensive investigations focusing specifically on the organisms now known to be associated with bacterial vaginosis is likely to advance our understanding of nonchlamydial NGU.

Only two viruses have been implicated as a cause of male urethritis. Urethritis occurs in approximately 30% of men with primary genital herpes simplex virus (HSV) infection and in a much lower percentage of men with recurrent genital HSV infection.[67] Most, but not all, such patients have penile lesions. HSV was not isolated at higher frequency from the urethra of men with NGU than from controls in two older studies.[11,42] Two recent studies using PCR assays were similar in that HSV was detected in 2–3% of cases.[68,69] However, only the Bradshaw et al. study had sufficient numbers of patients enrolled to demonstrate a significant difference between cases and controls. In this study, HSV-1 was more common than HSV-2 and unprotected oral sex was a major risk factor.[69]

Adenoviruses were first reported in men with urethritis in Perth, Australia.[70] Swenson et al. reported isolating adenovirus from 0.3% of 7000 patients attending the Seattle STD clinic and other health department clinics. Of 20 infected men, 75% had urethritis.[71] Six additional cases were reported more recently from New Zealand.[72] Bradshaw et al. studied 329 NGU cases and compared them to 307 controls in the Melbourne, Australia, Sexual Health Center. Adenovirus was identified in 4% of cases and only 0.3% of controls thus providing strong support for the addition of this virus to the list of urethral pathogens in men.[69] In summary, both HSV, especially type 1, and adenovirus appear to be causes of NGU though the proportion of cases is small.

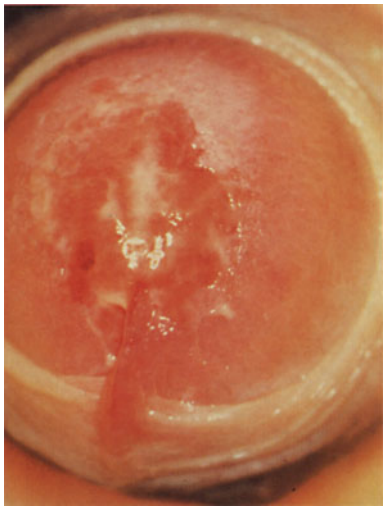

FIGURE 59-1. NGU and meatitis associated with Stevens–Johnson syndrome due to *Mycoplasma pneumoniae* pneumonitis. NGU also occurs as a manifestation of other systemic diseases, such as Reiter's syndrome.

■ NONSEXUALLY TRANSMITTED CAUSES OF NGU

The proportion of cases of NGU that are not sexually transmitted has not been defined since *C. trachomatis* was recognized as a cause of NGU. Bacterial urethritis may occur in association with urinary tract infection, bacterial prostatitis, urethral stricture, phimosis, and secondary to catheterization or other instrumentation of the urethra. In fact, a recent study from England suggested that as many as 6% of clinical NGU cases actually have a urinary tract infection.[73] Urethritis is also described with congenital abnormalities, chemical irritation, and tumors. Allergic etiologies have been postulated, but the supporting evidence is very meager. Similarly, there is no proof as yet that repeated stripping of the penis, masturbation, use of caffeine and alcohol, too little or too much sexual activity, or eating of certain foods will result in urethritis. Stevens–Johnson syndrome may produce urethritis (see Fig. 59-1).

EPIDEMIOLOGY

Details for the epidemiology of the various organisms causing male urethritis may be found in the chapters devoted to each. Surveillance of urethritis as a syndrome generally is not done.

France is an exception. There, a network of primary care providers reports urethritis cases to a national database. Nationwide, the annual incidence of urethritis dropped from 630 cases per 100,000 males older than 14 years to 180 cases between 1989 and 1995 and then rose to 270 cases per year between 1996 and 1998. Thereafter, the incidence rate has remained relatively stable.[74] GU is not differentiated from NGU in this surveillance system. Data from individual studies show that the relative proportion of GU cases versus NGU cases is strikingly different in different parts of the world. As can be seen in Table 59-3, which is based on recent studies of urethritis, GU is now uncommon in the Scandinavian countries while it predominates as a cause of urethritis in Africa. There have been no recent studies from the United States comparing GU rates to NGU rates, but generally areas with high STD rates tend to see relatively more GU cases than those such as the Northwest where gonorrhea is less common. In individual STD clinics during the 1970s, the relative proportion of cases of urethritis that were nongonococcal varied from 19% to 78%,[75] and, on college campuses, more than 85% of urethritis was nongonococcal.[76]

For both gonorrhea and NGU, the peak age group affected is 20–24 years, followed by 15–19 years, and then 25–29 years. Some behavioral and demographic characteristics of men with gonorrhea and NGU differ, but not to the extent that the differences are diagnostic in individual cases. In a comparison between 113 men with NGU and 69 men with urethral gonorrhea, those with NGU were more often white, better educated, more likely to be students and less likely to be unemployed, members of a higher socioeconomic stratum, older at the age of first intercourse, and involved with fewer total sex partners.[11] A history of previous gonorrhea was more frequent among men who had gonorrhea, while a history of NGU was more frequent among men with NGU.[11,77] Men with two or more previous episodes of NGU have a lower isolation rate of *C. trachomatis* than those with one or no previous episode.[17] Unfortunately, data comparing the epidemiology of gonorrhea in men and NGU more recent than the 1970s are not available.

CLINICAL MANIFESTATIONS

EXAMINATION OF THE MAN WITH URETHRITIS

A thorough examination is helpful in guiding appropriate therapy for all patients with STDs including urethritis. Details of the male examination are provided in a separate chapter (see Chapter 50). The quantity of discharge may be categorized as profuse (spontaneously flowing from the urethra), scant (apparent only after stripping the urethra), and intermediate (between profuse and scant). Unless an attempt has been made to "strip" or "milk" the urethra, it cannot be said that there is no discharge. The color or character of the discharge should be noted. A yellowish color (most common) or greenish color (seen only occasionally) can be described as "purulent." A grey or white discharge often mixed with clear fluid should be labeled "mucoid" or "mixed." The third category is "clear." The presence or absence of meatal inflammation (meatitis) should be noted. Finally, the presence or absence of penile edema and enlarged inguinal lymph node should be determined.

Although it is usually not done in practice, when patients give a history of dysuria and/or urethral discharge but a discharge is not detected, the patient should be examined the next morning, after not voiding overnight, to enhance the likelihood of reaching a firm diagnosis.[78] In a study by Simmons in an STD clinic, 200 men with genitourinary symptoms in whom no firm diagnosis was made on the first visit were asked to return for reexamination in the morning prior to voiding. Among these men, 108 infections were confirmed; 5 had gonorrhea and 103 had NGU.[78] Another study of symptomatic men with few or no PMNL on urethral smear also showed the value of repeat examination after a longer interval without voiding.[79] Furthermore, in that study, using pyuria as the criterion for urethritis, almost 80% of men with *C. trachomatis* had urethritis, whereas only one-third of symptomatic men without *C. trachomatis* had pyuria at the initial or on repeat visits. This approach is probably most useful in ruling out urethral inflammation as a cause of symptoms in a patient with chronic or multiply recurring urethritis or with minimal complaints. In practice, most clinicians treat patients complaining of dysuria and/or discharge as if they have urethritis regardless of the physical findings because of the difficulty of getting the typical STD client back for another examination and the increased probability of infection despite lack of objective evidences of urethritis.[78] The downside of this approach is overtreatment with antibiotics and potential problems with partner treatment.

COMPARISON OF THE CLINICAL PRESENTATION OF GU AND NGU

The symptoms and signs of GU and NGU are similar, but differ significantly in severity though there is a great deal of overlap. Both may cause urethral discharge, dysuria, or urethral itching. Discharges are more profuse and usually purulent in men with gonorrhea, but are generally scant and mucoid in men with NGU (see Figs. 59-2 and 59-3). Especially with NGU, discharge may be detected only in the morning or noted as crusting at the meatus or as staining on underwear. Frequency, hematuria, and urgency are infrequent with either infection. The usual incubation period is also shorter with gonorrhea. Gonorrhea usually develops 2–6 days after exposure, whereas NGU generally develops between 1 and 5 weeks after the likely time of acquisition of infection, with a peak at around 2–3 weeks. Longer incubation periods for both

FIGURE 59-2. GU. Note profuse purulent urethral discharge and meatal erythema.

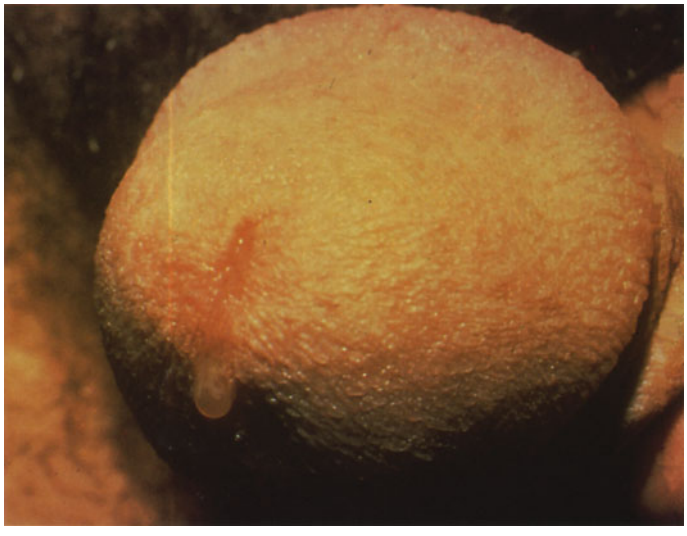

FIGURE 59-3. Chlamydial urethritis. Note the scant minimally purulent urethral discharge.

infections are seen, however, and a significant proportion of both groups of men remain asymptomatic.

In one study, 71% of 185 men with gonorrhea, but only 38% of 214 men with NGU, complained of both discharge and dysuria.[77] All but one man with urethral gonorrhea had urethral discharge, but 19% of men with NGU did not. Men with gonorrhea had a more abrupt onset and sought medical care sooner. More than three-fourths of the men who had gonorrhea, but less than one-half of those who had NGU, sought treatment within 4 days of onset of symptoms.[77]

CLINICAL MANIFESTATIONS OF NGU CAUSED BY ORGANISMS OTHER THAN *CHLAMYDIA TRACHOMATIS*

In urethritis caused by HSV and adenovirus, dysuria is usually severe, significantly more so than that reported on average by men with bacterial NGU.[69,80–82] Despite the severity of dysuria, discharge is scant and mucoid or clear rather than purulent. Most men with viral urethritis also present with meatitis, which is seen in a minority of cases caused by bacteria. O'Mahony has published an excellent color photograph of adenovirus-associated meatitis.[81] Adenovirus cases tend to occur in the fall and winter and are often associated with conjunctivitis.[69,72,80–82] Regional lymphadenopathy and constitutional symptoms may be seen with primary HSV urethritis.[82]

Kreiger presented detailed comparisons of the clinical manifestations of gonococcal, chlamydial, and trichomonal urethritis.[45] Only 55% of men with trichomoniasis had a discharge on examination compared to 82% of men with chlamydial infection and 93% of those with gonorrhea. The discharge caused by *N. gonorrhoeae* was almost always moderate to large in amount and was purulent in nearly 80% of cases. In contrast, the discharges associated with chlamydial and trichomonal infections were virtually indistinguishable with almost all patients having small or moderate amounts that were either clear or mucoid in character.

Relatively few studies have provided detailed clinical descriptions of *M genitalium*-associated urethritis. Based on the available data, however, it appears that this organism causes relatively mild disease and is indistinguishable from chlamydial urethritis.[51,68,83]

ASYMPTOMATIC URETHRAL INFECTION

It is important to recognize that asymptomatic urethral, gonococcal, and chlamydial infections in males are relatively common, especially the latter. These asymptomatic cases constitute a large reservoir of undetected infection in the general population. As shown in Table 59-2, the rate of isolation of *C. trachomatis* is lower in asymptomatic controls, but still substantial should they be representative of the male population as a whole. However, population rather than clinic-based studies are necessary to estimate the true burden of asymptomatic infections. In three studies, *C. trachomatis* was isolated from 11% of asymptomatic soldiers, 11% of asymptomatic men attending an urban emergency department, and 7% of asymptomatic college students.[84–86] More recent studies have used NAATs for chlamydial diagnosis rather than culture. Cecil et al. studied urine specimens in 2245 United States Army recruits and found that 4.6% had asymptomatic *C. trachomatis* infection and 0.2% had asymptomatic gonococcal infection. In a clinic-based study of MSM in San Francisco, it was found that 2.7% of nearly 5000 men had asymptomatic urethral *C. trachomatis* infections. Forty-two percent of all chlamydial urethral infections detected in this population were asymptomatic.[87] Among male contacts of infected women, Thelin et al. detected *N. gonorrhoeae* in 78% of male contacts of women with gonorrhea, and they detected *C. trachomatis* in 53% of male contacts

of women with *C. trachomatis*.[88] Only 50% of the male partners infected with either organism were symptomatic.[88]

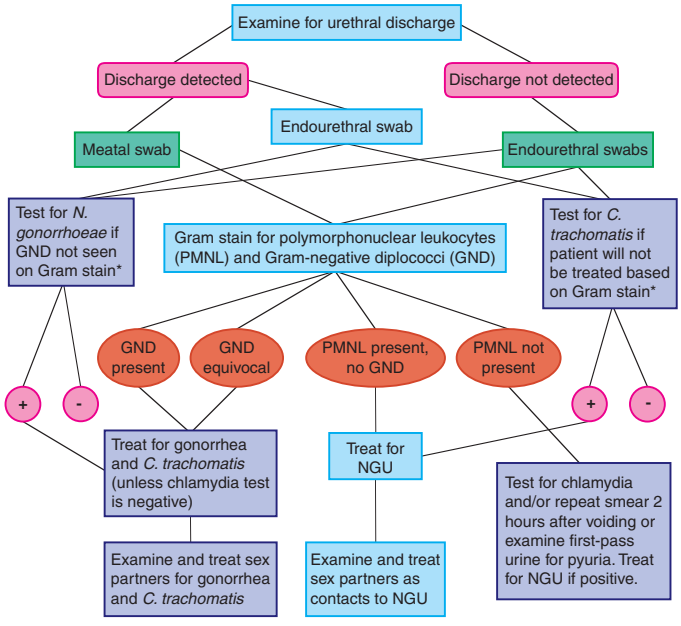
Clearly, a large reservoir of asymptomatic male urethral infection exists in the general population. The possibility of asymptomatic infection in the male partner should always be discussed with women who are being treated for proven or suspected chlamydial and gonococcal infections. Otherwise, male partners who believe they cannot have an STD unless they have symptoms are not likely to seek therapy.

OTHER MANIFESTATIONS OF URETHRITIS

Other manifestations of urethritis are unusual. A small proportion of patients with gonococcal or chlamydial urethritis will have conjunctivitis caused by *N. gonorrhoeae* or *C. trachomatis*, especially the latter, probably as a result of autoinoculation. Epididymitis develops infrequently today. Some patients with NGU present with the reactive arthritis syndrome (formerly known as Reiter's syndrome), or they develop it soon after their initial presentation. Inguinal lymphadenopathy is unusual, though it is occasionally seen in men with gonorrhea and a severely inflamed urethra. Severe gonorrhea may also produce edema of the foreskin and/or edema of the penile shaft. Rarely, a periurethral abscess involving the penile shaft may develop.[89] In the preantibiotic era, it was said that prostatitis was a frequent complication of gonorrhea, but this is not the case today. In a study by Holmes et al.,[11] prostatic enlargement or tenderness was not significantly more common among patients with NGU (13%) than among those with gonorrhea or with no urethritis (4%). If present, it was always of minimal severity. Symptoms of hematuria, chills, fever, frequency, hesitancy, nocturia, urgency, perineal pain, scrotal masses, postvoid dribbling, or genital pain other than dysuria or urethral pain are not typical of urethritis; these suggest the presence of other genitourinary abnormalities such as classic urinary tract infection, acute prostatitis, a flare-up of chronic prostatitis, or acute epididymitis or orchitis.

DIAGNOSIS

In men with symptoms of urethritis, the diagnosis of gonorrhea requires demonstration of *N. gonorrhoeae* by Gram stain, culture, or a reliable nonculture technique. The diagnosis of NGU requires exclusion of urethral infection with *N. gonorrhoeae* by microscopic examination of stained urethral secretions and objective demonstration of urethritis based on the presence of an abnormal discharge on examination and/or demonstration of PMNL in the urethral smear (Fig. 59-4, Table 59-4). Though there are now many reliable nonculture tests available for the diagnosis of *C. trachomatis*, unfortunately, there are no sufficiently sensitive point-of-care tests such as the Gram stain available for this organism (see Chapters 32 and 52).



*In many public health clinics, testing is performed on all or most patients for surveillance purposes.

FIGURE 59-4. Initial diagnosis and management in men with suspected urethritis.

CRITERIA FOR THE DIAGNOSIS OF URETHRITIS

For research purposes, the criteria used for diagnosis of urethritis in some of the first studies included presence of urethral discharge and of 20 or more PMNL in two or more of five random ×400 microscopic fields of the sediment of the first 10–15 mL of urine collected when the patient has not voided for 4 hours or longer.[12] In a study of men with minimal or no discharge, there was a bimodal distribution of the numbers of PMNL in Gram-stained urethral specimens and in the first-voided urine; the presence of 15 or more PMNL in any of five random ×400 microscopic fields of the sediment of the first-voided urine correlated with a mean of more than four PMNL per field in five ×1000 oil-immersion fields in Gram-stained specimens of urethral exudate.[90] Swartz et al. independently concluded that a mean of more than four PMNL per oil-immersion field on urethral smear correlated with urethritis.[53] In that study, there was more of a continuum from normal to abnormal. Thus, the criterion of ≥5 PMNL in at least five oil immersion microscopic fields became the more commonly used laboratory component of the definition of urethritis in the male.

Subsequent studies among symptomatic men with minimal or no urethral discharge showed similarly strong correlations between the Gram stain and the first-voided urine sediment.[79] However, *C. trachomatis* was isolated from some men when neither the urethral Gram stain nor the first-voided urine sediment contained PMNL. In many

Table 59-4. Management of Urethritis

1. Establish presence of urethritis
   a. Examine for urethral discharge
   b. Gram- stain urethral secretions for PMNL
   c. Reexamine if necessary in a.m. prior to voiding
2. Establish presence or absence of *N. gonorrhoeae*
   a. Gram stain
   b. Culture or nonculture test for *N. gonorrhoeae* if Gram stain is negative
3. Diagnostic test for *C. trachomatis* (optional)
4. If gonorrhea, treat with ceftriaxone 125 mg im or a single, oral dose of cefixime 400 mg, ciprofloxacin 500 mg, ofloxacin 400 mg, or levofloxacin 250 mg plus a single 1 gram dose of azithromycin or 7 days of doxycycline 100 mg p.o. twice daily. (see text for special considerations concerning quinolone resistance)
5. If NGU, treat with a single 1 gram dose of azithromycin or 7 days of doxycycline 100 mg p.o. twice daily.
6. Evaluate and treat partner(s) appropriately–generally with same regimen used to treat the patient with urethritis, or guided by results of additional diagnostic tests.
7. Follow-up examinations (optional–usually not done)
   a. 3–5 days after completing therapy with gonorrhea
   b. 2–4 weeks after completing therapy for NGU

other *C. trachomatis*-positive men, only the urine or the smear, but not both, showed increased PMNL. In another study, Root et al. noted that 7 of 18 *C. trachomatis*-positive men had five or fewer PMNL in "several representative fields" on urethral Gram stain.[23] More recent studies using NAATs for diagnosis demonstrated even greater proportions of infected men among those not meeting laboratory criteria for urethritis.[36,69,91]

Semiquantization of PMNL in urine or in stained smears is very much dependent on the skills and/or diligence of the microscopist. This fact no doubt explains much of the performance variation of the PMNL criterion for the diagnosis of urethritis reported in the literature.[92] Thus, the use of smears or urines to provide objective evidence of urethritis is only a rough guide to the presence of urethral pathogens. Therefore, for both *N. gonorrhoeae* and *C. trachomatis* in men with minimal or no evidence of urethritis, a sensitive diagnostic test is necessary to rule out infection. This is reflected in the urethritis diagnostic algorithm presented in Fig. 59-4.

In men who are symptomatic without objective evidence of urethritis (i.e., either discharge on examination or the presence of PMNL in the stained urethral smear), nonsexually transmitted causes of urethritis-like symptoms such as urinary tract infection should be considered. However, before initiating a more extensive evaluation for such problems, further evaluation for urethritis should be done. The patient should be reexamined in the morning without having voided overnight. The urethra should be stripped from the base to the meatus three or four times to detect urethral discharge. For Gram stain, any expressible urethral exudate can be obtained with a swab from the urethral meatus. When discharge is minimal or absent after an attempt to express discharge, a thin urethral swab should be inserted 3–4 cm into the urethra. The patient should be warned that the procedure is moderately painful and that the next urination will also be painful. The swab is then rolled gently back and forth over a glass slide to cover an area of approximately 1 cm^2. The slide is Gram-stained and scanned at a magnification of ×100. Areas that have the largest numbers of PMNL are examined under oil (×1000), and the number of PMNL in each of five such fields is recorded. While the PMNL are being enumerated, the slide should also be examined for gram-negative diplococci. For research purposes or for patients in whom the establishment of objective evidence of inflammatory urethritis is especially important (i.e., the male with recurrent urethritis), examination of a first-voided urine specimen is worthwhile. To detect PMNL in urine, the first 10–15 mL of urine voided should be collected and centrifuged at 400 × *g* for 10 minutes. All but 0.5 mL of the supernatant is decanted, and the sediment is resuspended in the residual urine. Sufficient sediment is placed on a slide to cover an area of approximately 1 cm^2, and a coverslip is placed on the slide. The area under the coverslip is examined at a magnification of ×400, and the number of PMNL in each of five randomly selected fields is enumerated. Based on two studies about half of the men having such follow-up evaluations, either GU or NGU will be confirmed.[78,79] Those without clear evidence of urethritis can then be referred for further evaluation.

LABORATORY DIFFERENTIATION BETWEEN GONORRHEA AND NGU

Although clinical suspicion that a patient with urethritis has either gonorrhea or NGU may be strong, the final distinction

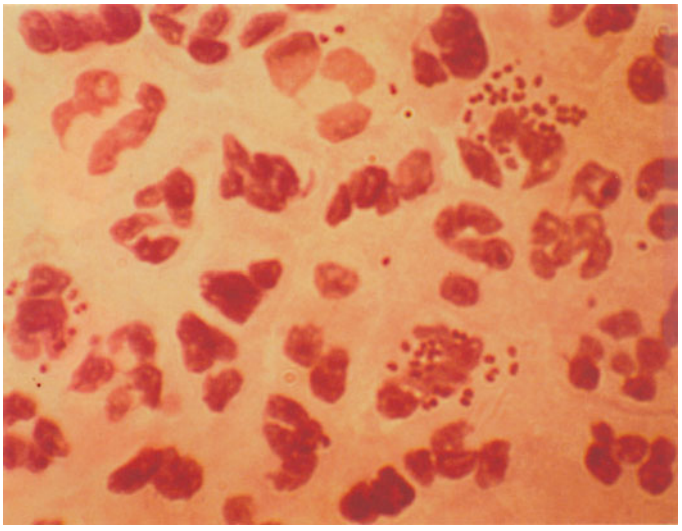


FIGURE 59-5. Gram stain of GU, showing number of gram-negative intracellular diplococci.

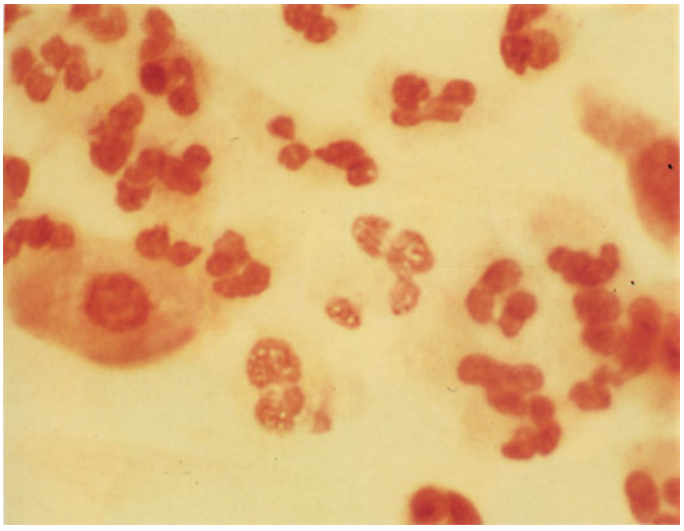

FIGURE 59-6. Smear from NGU. Note the presence of both PMNL and occasional mononuclear leukocytes in the absence of gram-negative diplococci.

requires laboratory examination to determine if *N. gonorrhoeae* is present. The most rapid and least expensive procedure is microscopic examination of stained urethral exudate or material obtained with an endourethral swab. For experienced microscopists, the sensitivity, specificity, and positive predictive value of the finding of typical gram-negative diplococci inside the PMNL for the diagnosis of gonorrhea are close to 100% in men with urethritis (see Fig. 59-5). A simple, one-step procedure using a stain such as methylene blue probably works equally well, though careful comparative studies have not been done. This procedure relies solely on morphologic characteristics, since color differences are not obtained with the single staining reagent. It should be noted that in most clinical settings there is insufficient time to enumerate PMNL carefully in the urethral smear. Therefore, most clinicians accept the presence of any PMNL in smears from symptomatic men as adequate support for the diagnosis of NGU (see Fig. 59-6). Thus, in a symptomatic case where the urethral smear contains increased numbers of PMNL, gonorrhea can be differentiated from NGU at the initial visit, and specific therapy can be given. Since the Gram stain misses up to 5% of gonococcal infections in men with urethritis under usual clinical circumstances, patients clinically diagnosed as having NGU on the basis of Gram stain should undergo further testing for *N. gonorrhoeae*. Specific tests for the agents known to cause NGU will not influence therapeutic decisions at this point. When Gram-stained specimens are interpreted as being equivocal, with only extracellular typical or intracellular atypical gram-negative diplococci being detected, cultures for *N. gonorrhoeae* have been positive in 25%.[77] Such patients should be treated for gonorrhea (see Fig. 59-1), but cultures or DNA-based tests will establish the diagnosis definitively. Cultures are necessary in cases that are positive by Gram stain when prior treatment has failed. The laboratory should be alerted that antibiotic resistance may be a problem, so that the organism can be referred to a laboratory that is able to perform susceptibility testing.

DETECTION OF SPECIFIC AGENTS ASSCOCIATED WITH NGU

Specific diagnosis of *C. trachomatis* urethritis requires culture or detection by a nonculture technique (see Chapters 23 and 52). While the diagnosis may be confirmed in some cases serologically, this approach is not practical.[12] Because *C. trachomatis* is an intracellular parasite of columnar epithelial cells, the preferable specimen is endourethral material rather than urethral exudate. NAATs have been studied extensively for the diagnosis of *C. trachomatis* infections over the last decade and there are several of these that were cleared by the FDA for clinical use (see Chapters 32 and 52 for details). However, in most clinical circumstances, identification of *C. trachomatis* as the cause of NGU is not necessary, as recommended antibiotic therapy currently is the same for both chlamydia-positive and chlamydia-negative disease (see Fig. 59-4). Furthermore, it is recommended that the partners of men with NGU be treated regardless of the etiology. As with the gonococcus, a specific diagnosis of *C. trachomatis* may be useful for the purposes of surveillance, partner notification, and may be desired by some patients who wish to know the specific etiology of their disease. The issue of who is paying for the test is often the deciding factor here. Diagnostic tests for *U. ureaplasma, M. genitalium*, and *T. vaginalis* either lack sensitivity or specificity or are for research use only at this point.

THERAPY

DUAL THERAPY FOR URETHRITIS: SYNDROMIC MANAGEMENT AND GONORRHEA

In many parts of the world, and in many smaller public health and primary care clinics, specific diagnostic tests for urethral pathogens are not available. Unfortunately, as noted previously, the clinical presentation is not adequately specific to differentiate between the causative organisms. In these circumstances, treatment should be based on the pathogens most likely to result in long-term sequelae, namely, *N. gonorrhoeae* and *C. trachomatis*. While this approach seems intuitively correct, clinicians in the past frequently attempted to provide specific therapy based on their clinical impressions. In many cases, this resulted in inadequate treatment and continued chronic infection with one pathogen or the other. Recently, increased emphasis has been placed on "syndromic management" of STDs as an alternative to specific disease treatment, particularly in resource-poor settings (see Chapters 48 and 102). In a study of syndromic management of all STD syndromes, this approach decreased rates of HIV transmission.[93]

Since the late 1980s, STD treatment guidelines from the Centers for Disease Control and Prevention (CDC) have recommended dual-antibiotic therapy of men with GU for the syndromic management of urethritis.[6] The primary rationale for this approach is that *C. trachomatis* is found in 15–40% of women with endocervical gonorrhea and 15–25% of men with GU. Providing effective therapy for *C. trachomatis* in these patients eliminates the major cause of PGU and also reduces the number of potential male carriers of *C. trachomatis* who would otherwise disseminate the organism to future sex partners. The hypothesis that this approach benefits society as a whole by decreasing the population prevalence of *C. trachomatis* is very reasonable, but it has never been tested. Nonetheless, decreases in the prevalence of *C. trachomatis* in the United States since this policy was put in place suggest that this policy may have had the desired effect, though a variety of public health measures designed to control chlamydial infections were also instituted during this time. Another theoretical benefit of antibiotic therapy with two drugs active against *N. gonorrhoeae* is that it could slow the development of antibiotic resistance though this approach did not prevent the emergence of quinolone resistance in the United States.

Arguments against dual therapy include increased cost and higher adverse event rates. Since the added cost of doxycycline is small and experience does not suggest substantial increases in toxicity rates, on balance, the arguments favor dual-antibiotic therapy for GU in males. In areas such as Western Europe, where the incidence of both gonorrhea and chlamydial infections have decreased dramatically in the past decade, the argument for dual therapy becomes less compelling.

Therapy for *N. gonorrhoeae* is described in detail in a separate chapter (see Chapter 35). The most convenient treatment is oral therapy with cephalosporins or quinolones. However, rising resistance rates to the latter worldwide including the United States is increasingly limiting the use of these drugs. Four hundred milligrams of cefixime orally as a single dose is an excellent choice but there are few companies that manufacture the drug resulting in unavailability in some regions of the world including the United States. Ceftriaxone given as a single 125 mg intramuscular dose is also highly effective for GU, but intramuscular administration is inconvenient and relatively expensive, since additional supplies and personnel time are required. There are two oral cephalosporins which studies have shown to be effective for treated GU, but the number of patients studied thus far has been relatively small. These are cefpodoxime proxetil and cefuroxime axetil.

Tetracycline, doxycycline, and azithromycin have been used most commonly as the antichlamydial component of dual-drug combinations for the syndromic management of male urethritis (see Chapter 32 for details). Doxycycline is easier to comply with than tetracycline as it is administered as two daily 100 mg doses with food, if desired, in contrast to tetracycline, which must be taken as 500 mg four times daily on an empty stomach. Alternatives to doxycycline or tetracycline that could be included as part of dual-treatment regimens are erythromycin, four times daily for a week, but the single 1 g oral dose of azithromycin is a much better alterative. There are few studies of dual-antibiotic therapy of urethritis, probably because there is little reason to doubt the efficacy of drugs already proven to be useful for treating *N. gonorrhoeae* and *C. trachomatis* infections individually. More data on tolerance would be helpful, though experience suggests that significant increases in adverse events have not been a problem. The combination of cefixime, 400 mg orally, and azithromycin, 1 g orally, given together for the treatment of GU has been evaluated in only one small pilot study; a relatively high rate of gastrointestinal toxicity was noted (HH Handsfield, personal communication).

Two drugs currently are approved in the United States for the treatment of both *N. gonorrhoeae* and *C. trachomatis*. Ofloxacin, 400 mg followed by 300 mg b.i.d. to complete a 7-day course, is effective for both organisms, as is azithromycin, 2 g as a single dose. However, cost and emerging antibiotic resistance have limited the use of the former while the single 2 g dose of azithromycin frequently causes gastrointestinal side effects.[94]

It should be remembered that empiric dual-antibiotic therapy of urethritis in males requires that sex partners also be treated empirically for both organisms.

TREATMENT OF NGU

Results of treatment for NGU are not as good as for gonorrhea, even though almost every antimicrobial in clinical usage has been tried. In the 1950s, tetracyclines, erythromycin, and a combination of sulfonamides and aminocylitols were recognized as being the most effective therapy for NGU. The basis for these observations was elucidated by subsequent research that showed that all three regimens were capable of eradicating *C. trachomatis* [12,13,15,95] and had significant activity against the mycoplasmas. In compliant patients who were not reexposed to new or untreated partners, all but 5% of men showed definite and often total improvement by the end of treatment. However, in one study, among men who initially responded and were followed for 4–6 weeks posttreatment, 30–35% had a recurrence or incomplete resolution of pyuria.[8] About one-half of these men had symptoms of urethritis. In this study, the critical determinant of response was the etiology of the NGU rather than the amount of drug given or the duration of therapy. Response to treatment was best in men infected with *C. trachomatis*, significantly worse in men infected with *U. urealyticum* alone, and significantly worse still in men from whom neither organism was initially isolated from urethral specimens.

In compliant patients, the high rates of recurrent urethritis or persistence following treatment for NGU are not due to failure to eradicate *C. trachomatis*. Tetracycline-resistant isolates of *C. trachomatis* have not been described. *Ureaplasma* sp. tetracycline resistance has been shown to be associated with treatment failure in one study done before it was known that the genus has two species rather than just one.[22] Preliminary data suggest that *M. genitalium* is relatively resistant to the tetracycline class of antibiotics[96,97] and that some strains may be resistant to the erythromycin class.[98] In an as yet unpublished randomized treatment study, we found that a 7-day course of doxycycline failed to eradicate *M. genitalium* in 20/31 (64%) of men with NGU who were examined at least once following treatment compared to a failure rate of 4/25 (16%) among men treated with a single dose of azithromycin (L. Mena, personal communication). These data clearly indicate a need for the development of better therapeutic approaches to NGU.

STD treatment guidelines from the CDC and the World Health Organization currently recommend doxycycline 100 mg twice daily for 7 days.[6,7] A few investigators have concluded that longer courses of antimicrobial therapy are more effective than shorter courses.[99–101] Holmes et al. showed that a 7-day course of tetracycline was more effective than a 4-day course,[99] and, in a nonblinded study, John showed that 21 days were better than 10 days, which, in turn, were better than 5 days.[100] Thambar et al. concluded that 3 weeks of triple tetracycline was better than 1 week of therapy, but patients on the longer regimen had a much shorter follow-up after cessation of therapy—a critical problem, as discussed later.[101] In contrast to these studies, others have not found a significant difference with longer courses of therapy.[8,102,103] Grimble and Amarasuriya did not show any marked differences between results with 4- to 10-day regimens of several different tetracyclines.[102] Helmy and Fowler had essentially identical results in a double-blind comparison between tetracycline, 500 mg four times daily for 7 days, and 250 mg four times daily for 14 days, and the results were also similar between 4- and 21-day regimens.[103] A double-blind comparison of two doses and two durations of minocycline has been performed in a study that included cultures for *C. trachomatis* and *Ureaplasma* sp.[8] Overall, persistent or recurrent NGU within 6 weeks of initiation of therapy was seen in 32% of men. Prolonging therapy from 7 to 21 days delayed, but did not diminish, the rate of recurrence, and the use of 100 mg daily gave results that were as good as those obtained with twice-daily treatment. More recently, it has been shown that minocycline, 100 mg nightly for 7 days, was equal to doxycycline, 100 mg twice daily for 7 days, for the treatment of NGU.[104] Whether regimens employing a tetracycline class drug for less than 7 days would be effective for eradicating *C. trachomatis* and *U. urealyticum*, and for producing similar clinical responses in NGU, requires further study, but the weight of evidence argues strongly against treating for more than 7 days.

A single 1 g dose of azithromycin is the other most frequently recommended therapy for NGU and has the advantage of directly observed treatment thus eliminating compliance as an issue though studies have not shown benefit in terms of bacterial eradication as compared to multidose doxycycline. Martin et al. clearly demonstrated the efficacy of azithromycin, 1 g orally as a single dose, for uncomplicated chlamydial infections in women and men, including those with NGU.[105] Two small nonblinded studies suggested that single-dose azithromycin would be effective also for chlamydia-negative NGU.[106,107] In a large randomized double-blind study of men with NGU regardless of etiology, Stamm et al. showed that the 1 g dose of azithromycin was equivalent to doxycycline, 100 mg twice daily for 7 days.[108] In this study, both chlamydia-positive and -negative cases did equally well with azithromycin. Azithromycin is now a generic drug and, therefore, cost is no longer a major impediment to its use.

Alternative choices are 7 days of erythromycin base or stearate, 500 mg orally four times daily, or erythromycin ethylsuccinate, 800 mg orally four times daily, which are very cheap but the gastrointestinal tolerance of these regimens is poor.

Trimethoprim-sulfamethoxazole is active against *C. trachomatis*,[109] but has poor activity against the mycoplasmas. Among the marketed quinolones in the United States, ofloxacin and its congener levofloxacin have the best in vitro activity against *C. trachomatis*. Quinolones, in general, have variable activity against genital mycoplasmas.[110] Clinically,

ciprofloxacin has been associated with frequent treatment failures in men with chlamydia-positive NGU,[111,112] while ofloxacin, 200–300 mg twice daily for 7 days, has proven to be effective.[113,114] The latter dose is recommended as an alternative therapy for NGU in the United States as is levofloxacin 500 mg once daily for 7 days.[6]

TREATMENT OF SEX PARTNERS

As part of the management of urethritis, every attempt should be made to evaluate and treat the patient's sex partner(s) as soon as possible. This approach is widely accepted for partners of men with either gonorrhea or chlamydial infection, and it is equally appropriate for partners of men with NGU. Waiting for the results of laboratory tests before treating the partners increases the time interval between patient and partner treatment and runs the risk of sexual reexposure to a potentially infected partner. This approach also decreases the probability that the partner will be treated at all. Though it has not been clearly demonstrated that treatment of the partner diminishes the rate of recurrence of NGU in men, female partners need treatment for their own benefit. *C. trachomatis* is isolated from 30 to 60% of the female partners of men with GU or NGU and has important sequelae in women.[11,15,16,19,115,116] Furthermore, infected women (and men) constitute a major undiagnosed and untreated reservoir of *C. trachomatis* infection; ultimate control of *C. trachomatis* infection is unlikely to be achieved without reduction of this reservoir of infection. In general, the same regimens used to treat males with urethritis should be used to treat their female partners, though the tetracycline class of antibiotics should be avoided in pregnant women.

MANAGEMENT OF RECURRENT URETHRITIS

As discussed earlier, recurrent NGU is a relatively common problem. If current dual therapy guidelines have not been followed for treating GU, PGU can be expected in 10–20% of cases. *C. trachomatis* is the most common cause of this problem as 10–20% of men with gonorrhea have *C. trachomatis* coinfection. It seems likely that *M. genitalium* would also contribute to this problem given that it too is found in men with gonorrhea, but how frequently this occurs is not yet known. Given the evidence discussed earlier that suggest that this *M. genitalium* may be relatively resistant to doxycycline, PGU following a doxycycline-containing treatment regimen might be particularly likely to be caused by this organism.

The median time for recurrence following treatment for NGU is about 2 weeks after completing therapy.[8] Most men with recurrences of NGU are culture-negative for *C. trachomatis* unless the interval following treatment is several weeks or more and they have had intercourse with an untreated partner. The initial step in management requires that the presence of urethritis again be documented by examining urethral secretions for the presence of PMNL to exclude patients with functional complaints or other disorders. The patient should be questioned about compliance and unprotected sexual intercourse. In persistent (as opposed to recurrent) NGU, the possibility of HSV urethritis should be considered. Primary HSV urethritis typically lasts about 2 weeks. Urethral foreign bodies, periurethral fistula, and abscess should be excluded by palpation. Cultures or nonculture tests for *N. gonorrhoeae* and *C. trachomatis* should be repeated. Since tetracycline-resistant mycoplasmas may be the cause of recurrent or persistent infection, treatment with azithromycin should be given if doxycycline or another tetracycline class drug had been used for initial therapy. Moreover, azithromycin would be expected to eradicate *C. trachomatis* should the patient have been reinfected with this organism. As the initial NGU treatment recommendations do not include metronidazole, men with recurrent or persistent NGU are more likely to have *T. vaginalis* than at the time of the initial presentation. When an exudate is present, *T. vaginalis* can be sought by mixing a drop of exudate with saline solution and looking for motile organisms, but this is not standard laboratory procedure and most healthcare providers are not proficient in performing this test. If possible, culture for *T. vaginalis* should be performed. Kreiger et al. recently pointed out that culture sensitivity is significantly enhanced by culturing both urethral secretions obtained by a swab and the sediment of a first-voided urine specimen.[44] Regardless of what studies are performed, it is recommended that men with their first episode of recurrent NGU be treated empirically with 2 g of metronidazole as a single dose. Tinidazole is a suitable substitute though more expensive.[6] If the female partner has been appropriately treated as a contact to NGU and intercourse has not occurred until both partners completed treatment, the partner does not require retreatment unless the man is proven to have a chlamydial, gonococcal, or trichomonal infection as the cause of his recurrence.

MANAGEMENT OF THE MALE WITH PERSISTENT URETHRITIS OR WITH MULTIPLE RECURRENCES

Most men will be cured after a second course of treatment, but some will have further recurrences or persistence of symptoms. Management of these men with NGU represents one of the most difficult problems in venereology. It is important to document that the cause of the symptoms is an inflammatory process. If, indeed, this is the case, there are several considerations. If the second round of chlamydial and gonococcal cultures were negative but *T. vaginalis* studies were not done, special effort should be made to do these tests. If the patient received metronidazole empirically for treatment of the first recurrence and persistent *T. vaginalis*

infection can be documented, the problem could be due to a metronidazole-resistant organism. The timing of the patient's treatment relative to that of the partner and to sexual reexposure should be reviewed carefully to eliminate any possibility of reinfection. The female partner should be evaluated carefully for all sexually transmitted infections (STIs) if this has not been done. Urinary tract infection and recurrent herpes should be ruled out with cultures' and/or NAATs. If there is no evidence of a known infectious agent, is there any value of further treatment with drugs normally effective for NGU? Hooton et al. suggested that a 3-week course of erythromycin, 500 mg four times daily, may be of benefit.[117] They found evidence of prostatic inflammation in many men with persistent urethritis, and it was this group that benefited most from treatment. Nonetheless, relapse rates were high. These observations may be explained, at least, in part, by the fact that *M. genitalium* is now known to be a common cause of NGU and that some strains of this organism may be relatively resistant to antibiotics. There is some experience suggesting that a 5-day course of azithromycin or a 10-day course of moxifloxacin may be successful in these cases.[97,98,118] Men with inflammatory urethritis that persists after the above treatment approaches have been tried should be evaluated by an urologist who is experienced in dealing with such patients. The urologist should be made aware of the details of the patient's workup and treatment history in order to avoid unnecessarily repeating expensive tests and, more important, to avoid further empiric antibiotic trials. After urologic evaluation has ruled out anatomic problems (as it usually does[119]), whether or not chronic suppressive antibiotic therapy is justified is unknown. The best advice is not to treat further, but to reassure the patient, using the counseling points listed below. Many cases will resolve spontaneously over time. In the future, it will be possible to use PCR techniques to evaluate these patients for antibiotic-resistant mycoplasmas and/or currently unknown urethral pathogens.

The following issues should be discussed with the patient:

1. The likelihood of long-term sequelae such as infertility or cancer appears to be exceedingly low even in men who continue to have recurrent urethritis after two or three treatment attempts have failed.
2. The risk of transmission of disease to partners is exceedingly low because these men do not have ongoing *C. trachomatis* infection, and other pathogens are usually not identified or are not important causes of sequelae in women. For example, as yet it is not known if *M. genitalium* causes significant morbidity in women.
3. Even if no further treatment is given, symptoms likely will disappear over time.
4. If the man has an ongoing monogamous sexual relationship (and this is true of the partner as well), there is no need for further treatment of the partner if both received an initial course of therapy active against the known STIs and refrained from intercourse until both completed treatment.
5. Most recurrences will arise independent of resumption of sexual activity, and these episodes do not mean that the partner has been "unfaithful."
6. Persistent or recurrent urethritis is not a presentation of AIDS.

It important to be aware of the fact that many patients complaining of persistent or recurrent symptoms of urethritis after treatment for a documented episode do not have any evidence of an inflammatory process, even after a careful search. In the authors' experience, these are often well-educated men who are very health conscious, sometimes to the point of being obsessive. Not infrequently this problem develops in a monogamous man who originally acquired a documented episode of urethritis following an illicit sexual encounter, suggesting that unresolved guilt feelings are a contributing factor. Typically, these patients self-refer to multiple "experts" either concurrently or sequentially. Since most of these simply represcribe antibiotics without attempting to document the presence or absence of an inflammatory process, the specialist often sees such patients after they have received many courses of a variety of antibiotics. Such inappropriate treatment reinforces the notion in the patient's mind that he has an "incurable" infection. These patients may benefit from an urological examination as much for reassurance as for anything else, though an urethral stricture occasionally may be discovered. However, the most important point to be made here is that, rather than launching into a prolonged series of evaluations and empiric therapies as recommended earlier for the patient with documented inflammatory disease, counseling should be initiated early in the course for the patient with symptoms but without objective evidence of urethritis.

PROGNOSIS

Although frequent in the preantimicrobial era, local complications of urethral gonorrhea are now unusual in developed countries. Epididymitis occurs in 1–2%, seminal vesiculitis is rare, and prostatitis and prostatic abscess are almost never seen. Other unusual complications include abscess of Tyson's glands, penile edema secondary to dorsal lymphangitis or thrombophlebitis, inflammation of the urethral wall including periurethral abscesses and fistula, and regional lymphadenitis. Urethral strictures secondary to urethritis rarely occur now in the developed countries, but remain significant problems in certain areas of the world. Other complications include inflammation of other concurrently infected sites such as proctitis or systemic spread as is seen with the disseminated gonococcal infection syndrome. NGU is generally a self-limited disease, and, even without therapy, the physical consequences to the individual are slight. One percent to two percent of

both *C. trachomatis*-positive and *C. trachomatis*-negative men with NGU develop epididymitis, and another 1–2% develop conjunctivitis.[116] Urethritis is a manifestation of the reactive arthritis syndrome (formerly known as Reiter's syndrome), but it is unclear how frequently this problem develops as a consequence of NGU. Two studies indicate that the rate of development of reactive arthritis is not high in HLA-B27-positive men after initiation of therapy with a tetracycline for *C. trachomatis*-positive or *C. trachomatis*-negative NGU.[120,121] In one of the studies, however, men who were positive for *C. trachomatis* had more reactive arthritis than men who were chlamydia-negative.[120] Although approximately 20% of men with NGU have an increased number of PMNL in expressed prostatic secretions,[11] development of overt prostatitis is rare. In contrast to the infrequent physical consequences, the psychological impact of persistent urethritis or frequent recurrences of urethritis may be great. A thorough discussion with the patient of the issues reviewed earlier will usually greatly alleviate this distress.

PREVENTION

Preventive measures offered by healthcare providers and health departments should include (1) diagnosis and treatment of patients with STDs, (2) treatment of gonorrhea with regimens that will eradicate *C. trachomatis*, (3) improved contact-tracing to detect and treat partners exposed to either *N. gonorrhoeae* or *C. trachomatis* infection, and (4) increased availability of adequate diagnostic tests, especially for asymptomatic *C. trachomatis* infection. Urine-based diagnostic tests are now available. These tests are useful for screening hard-to-reach asymptomatic populations such as adolescents who are unlikely to attend a clinic for screening by one of the conventional tests. Hopefully, the resources can be found to support the widespread application of this approach. Although much progress has been made in understanding the immunobiology of these infections, effective vaccines are not presently available.

A sexually active male can take several preventive measures. He can choose his sexual partners carefully, avoid multiple partners, and use condoms. There is no way that one can determine by intuition that a prospective new partner is free of genital pathogens. Proper use of a condom diminishes acquisition and transmission of many STDs. Prophylactic antimicrobials are partially efficacious for prevention of urethritis (for example, 200 mg of minocycline or doxycycline soon after intercourse),[122] but this approach cannot be justified from a public health point of view.

60 Epididymitis

William M. Geisler and John N. Krieger

DEFINITION, HISTORY, AND OVERVIEW

Epididymitis is defined as an inflammatory process involving the epididymis. Many cases are related to genitourinary tract infections, especially sexually transmitted infections and bacterial urinary tract infections. The process causes scrotal pain and swelling that is characteristically unilateral and relatively acute in onset.

Embryologically, the epididymis and vas deferens arise from the Wolffian system and mesonephric duct. The epididymis is a sausage-shaped structure positioned on the posterior aspect of the testicle. It consists of a single, delicate convoluted tubule 12–15 feet long. The epithelium of the epididymis possesses stereocilia that have no directional movement. Because of its embryological origin and associated anatomic structures, it is easy to understand why congenital genitourinary tract abnormalities are associated with an increased susceptibility to epididymitis in children and adolescents. Anatomists divide the epididymis into six sections based on histological characteristics, which likely correspond to different functional capacities. Fluid and particulate matter are both secreted and absorbed by the epididymis. During passage through the epididymis, sperm achieve motility and the potential to fertilize an ovum.

In 1804, Monteggro was probably the first to describe the gross pathology of epididymitis and to differentiate epididymitis from orchitis. In 1879, Despres suggested that epididymitis was due to retention of semen related to the pain of urethritis. Subsequently, specific infectious forms, such as tuberculosis and gonococcal epididymitis, have been well recognized. With the advent of specific diagnostic criteria and effective antimicrobial therapy for gonorrhea and tuberculosis in the 1940s and 1950s, an increasing proportion of cases were regarded as "idiopathic," often attributed to "straining" or reflux of sterile urine into the epididymis. More recent studies established the infectious etiology of most cases of epididymitis and the importance of sexually transmitted urethritis and bacteriuria as precursors of epididymitis.

With improved understanding of the etiology, the diagnosis and management of epididymitis is becoming more rational, leading to decreased morbidity and, possibly, to prevention of recurrences. Epididymitis usually occurs as a complication of urethral infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis,* or a complication of genitourinary infection with coliforms or *Pseudomonas aeruginosa* (Table 60-1). In rare cases, epididymitis may occur as a complication of systemic infection with various bacterial, fungal, viral, or parasitic pathogens or may be due to noninfectious causes. In children, epididymitis may be related to concomitant presence of genitourinary tract anomalies.

Effective management of epididymitis depends on accurate etiologic diagnosis. The responsible infectious causes must be identified, and attention must be directed toward correction of contributing anatomical, physiological, and behavioral factors. For example, for patients with sexually transmitted epididymitis caused by *N. gonorrhoeae* or *C. trachomatis,* this would most certainly include examination and treatment of the patient's sexual partners. Patients with epididymitis secondary to coliform urinary tract infection may benefit from correction of primary genitourinary disorders.

We prefer to avoid the term "nonspecific epididymitis." In the past this terminology was used to describe patients with epididymitis associated with "nonspecific" urethritis or without obvious infection. Only those unusual cases for which no etiologic agent can be determined after thorough investigation should be referred to as "idiopathic" or "nonspecific."

EPIDEMIOLOGY AND ETIOLOGY

Epididymitis is common, and it carries much morbidity in terms of suffering and loss of time from work. Because of epididymitis, an estimated 634,000 patients sought treatment by American physicians in 1977.[1] In 1981, the National Institutes of Health estimated 500,000 cases of acute epididymitis occurred annually.[2] Researchers have reported that the incidence of epididymitis may range from one to four per 1000 men per year.[3,4] In Great Britain, from 1963 to 1964,

Table 60-1. Classification of Acute Epididymitis

I. Epididymitis due to infectious agents
   A. Associated with urethritis
   B. Associated with bacteriuria
   C. Associated with systemic bacterial, fungal, viral, or parasitic infections
II. Epididymitis due to noninfectious causes
   A. Associated with trauma
   B. Associated with drugs (amiodarone)
   C. Associated with a postinfectious etiology
   D. Associated with a systemic vasculitis

From Berger RE. Acute epididymitis. *Sexually Transmitted Diseases*, 3rd edn. US: McGrall-Hill, 1999, pp. 847–858.

Table 60-2. Microbial Etiology and Predisposing Factors in Acute Epididymitis

Prepubertal children	
	Usual etiology: Coliforms, *P. aeruginosa*
	Unusual etiology: Hematogenous spread from primary infected site
	Predisposing factors: Underlying genitourinary pathology
Men younger than 35	
	Usual etiology: *C. trachomatis, N. gonorrhoeae*
	Unusual etiology: Coliform or *P. aeruginosis, Mycobacterium tuberculosis*
	Predisposing factors: Sexually transmitted urethritis
Men older than 35	
	Usual etiology: Coliforms or *P. aeruginosa*
	Unusual etiology: *N. gonorrhoeae, C. trachomatis, M. tuberculosis*
	Predisposing factors: Underlying structural pathology or chronic bacterial prostatitis

From Berger RE. Acute epididymitis. *Sexually Transmitted Diseases*, 3rd edn. US: McGrall-Hill, 1999, pp. 847–858.

13,600 claims were made for workman's compensation for epididymoorchitis.[5] In 1984, Baum garten reported that 82% of men with work-related epididymitis returned to work after an average of 6 days.[6] However, 18% had prolonged symptoms or required surgical therapy. Epididymitis was reported to account for more days lost from military service than any other disease, with over 20% of urologic admissions being caused by epididymoorchitis.[7–9]

EPIDIDYMITIS ASSOCIATED WITH BACTERIURIA

In prepubertal males, epididymitis is frequently associated with coliform or *Pseudomonas* infection of the genitourinary tract (Table 60-2).[10,11] These children frequently have predisposing structural, functional, or neurologic abnormalities, often congenital. Gierup et al. found that 10 (45%) of 22 children with epididymitis confirmed by surgical exploration had significant bacteriuria (e.g., $>10^5$ *E. coli*/mL of urine).[10] Prepubertal children had bacteriuria more often than postpubertal children, while pyuria with negative urine cultures occurred more often in older children. Cultures for *C. trachomatis* or *N. gonorrhoeae* were not performed, but these agents are important among sexually active adolescents. In a retrospective study, Gislason et al. found that approximately two-thirds of boys with epididymitis were postpubertal. Although 29% had pyuria, only 12.5% had positive urine cultures for conventional pathogens.[12] In adolescents with epididymitis, a detailed sexual history should be elicited, along with appropriate evaluation for sexually transmitted pathogens.

In postpubertal males younger than 35 years of age, epididymitis is usually not attributable to coliforms, and the presence of *P. aeruginosa* is unusual, unless the patient has a documented history of anatomic urinary tract abnormalities (i.e., neurogenic bladder or previous urinary tract surgery). In various series, from 0% to 35% of sexually mature young men with epididymitis had infection with coliform bacteria or *P. aeruginosa*.[1,9,13,14] This low prevalence may reflect the low frequency of structural disorders predisposing to urinary tract infections in this population. Most males with significant congenital urinary tract anomalies have been diagnosed and treated at an earlier age. In contrast, most acquired structural or functional disorders of the male urinary tract, such as benign prostatic hypertrophy, develop later in life.[1] Berger et al. reported that 6 (12%) of 51 men younger than 35 years had coliform infections and one (2%) had infection with *Haemophilus influenzae* (Table 60-3).[1,15] All seven of these patients were men who have sex with men (MSM) infected with Gram-negative rods, who regularly practiced anal-insertive intercourse.[15] No pathogen was identified in the two additional MSM in this series, but all nine MSM had many neutrophils per 400× microscopic field on Gram stain of midstream urine. Drach had previously noted that a history of anal intercourse was associated with chronic bacterial prostatitis.[16] Barnes et al. found that bacteriuria was more common among MSM than among heterosexual men in a venereal

Table 60-3. Etiology of Acute Epididymitis in 68 Consecutive Men

Etiology	Heterosexual Men >35 Years Old (*n* = 17)	Heterosexual Men <35 Years Old (*n* = 42)	MSM[a] <35 Years Old (*n* = 9)
Coliforms,	12	0	6
Pseudomonas			
N. gonorrhoeae	0	9	0

disease clinic population.[17] Of those with bacteriuria, 61% had urethral discharge, presumably owing to *E. coli* urethritis. Thus, the occurrence of *E. coli* epididymitis in MSM is most likely attributable to the more frequent exposure of the urethra to pathogenic enteric bacteria during anal intercourse. Although Stamey et al. showed in 1971 that enteric pathogens isolated from the urine of women with urinary tract infections could be isolated from the urethra of their male sexual partners, coliform epididymitis appears to be uncommon in young heterosexual men.[18]

In contrast, among men older than 35 years with epididymitis, up to 80% have coliform or *P. aeruginosa* urinary tract infection.[19] This high proportion of epididymitis caused by coliform infections in older men may reflect the decreasing prevalence of sexually transmitted disease and an increased prevalence of acquired genitourinary abnormalities. These patients may have a history of prostatic calculi, recent genitourinary or prostate instrumentation, neurogenic bladder, benign prostatic hypertrophy, or chronic bacterial prostatitis. Berger et al. identified only one sexually transmitted infection among 17 patients (6%) older than 35 years with epididymitis. In contrast, 12 of the 17 (71%) patients had coliform or *Pseudomonas* infections (Table 60-3).[1,15,19] Almost one-half of the patients older than 35 years had preexisting genitourinary pathology.

In military populations, epididymitis secondary to coliform bladder infections is unusual.[9,13,14,20,21] This may reflect the predominantly young age and low rate of underlying structural urinary abnormalities in the military populations. Mittemeyer found underlying urinary abnormalities in only 3.4% of 610 patients with epididymitis.[14] In this series, 70.1% were between the ages of 20 and 39; and in Shapiro's study, 75% of military patients were between the ages 18 and 32.[13,14]

It has been postulated that straining may cause reflux of sterile urine down the vas deferens leading to epididymitis. The popularity of this theory may partly reflect the previous inability to identify pathogens in many patients. However, Shapiro noted only 2 (4%) of 52 patients had a history of straining prior to the onset of epididymitis.[13] Similarly, Mittemeyer noted a history of straining in only 6.6% of his population.[14] Berger et al. studied two patients who had a history of strenuous lifting just before the onset of epididymitis. *C. trachomatis* was isolated from both patients.[19] Cathcart reported that 12 (86%) of 14 epididymitis cases had a history of "strain", but these patients also had urethral discharge.[22] Taken together, these observations suggest that reflux of infected urine into the vas deferens may be important in the pathophysiology of epididymitis. In contrast, reflux of sterile urine has not been shown to play an important role in causing epididymitis.

EPIDIDYMITIS ASSOCIATED WITH URETHRITIS

Epididymitis caused by *N. gonorrhoeae* or *C. trachomatis* is rare in prepubertal children and suggests the possibility of sexual abuse. In contrast, sexually transmitted infections represent important considerations in sexually active adolescents presenting with epididymitis. To date, no study of postpubertal children with epididymitis has assessed the sexual history, or has utilized appropriate diagnostic testing for sexually transmitted organisms as well as for conventional uropathogens.

Sexually transmitted organisms represent the most common cause of epididymitis in heterosexual men younger than 35 years old (Table 60-4).[1,15,16] In the preantibiotic era, Pelouze reported that epididymitis complicated 10–30% of gonococcal urethritis cases.[23] More recently, Watson found that 16% of patients with epididymitis in a young military population had gonorrhea, although only 50% of those with gonorrhea had urethral discharge.[24]

In a series of studies, Berger et al. reported that 28 (67%) of 42 men younger than 35 years had acute epididymitis secondary to *N. gonorrhoeae* or *C. trachomatis*.[1,15,19] *N. gonorrhoeae* alone was isolated from the urethra from nine, *C. trachomatis* infection alone was found in 18, and both agents were recovered from one patient (Table 60-3). *C. trachomatis* was isolated as the sole pathogen from the epididymis in 5 of 6 men with *C. trachomatis* infection who underwent epididymal aspiration.

Characteristically, patients with *N. gonorrhoeae* or *C. trachomatis* epididymitis are young and sexually active; they may have multiple sexual partners. Symptoms or signs of urethritis may not be present. Nonetheless, patients who deny symptoms of urethritis may have expressible urethral discharge. Gram-stained smear of an endourethral swab specimen may reveal ≥ 5 polymorphonuclear leukocytes per 1000 × field, or a urinalysis may reveal pyuria. Thus, either

or both of these evaluations are indicated routinely. Because underlying urinary tract abnormalities are seldom found in this population, routine structural urological evaluation is not indicated.

Berger et al. found that 13 (68%) of 19 men with *C. trachomatis* epididymitis were referred from sexually transmitted disease clinics.[1,15,19] This could represent a biased population that might overestimate the proportion of cases actually associated with *C. trachomatis.* However, other studies confirmed their findings.[25,26] Among men with acute epididymitis, *C. trachomatis* infection was found by Melekos and Asbach in 9 (53%) of 17 men younger than 40 years; by Colleen and Mårdh in 14 (33%) of 42 men younger than 35 years; and by Mulcahy et al. in 65% of men younger than 35 years.[25–27] Hawkins et al. and Lee et al. found that men presenting with epididymitis often had nongonococcal urethritis (NGU), even in the absence of positive tests for *Chlamydia trachomatis.*[28,29] These cases could be attributed to urethritis caused by less common pathogens. Eley et al. were unable to increase *C. trachomatis* detection in acute epididymitis by employing polymerase chain reaction-based (PCR) testing.[30] Future use of nucleic acid amplification testing for *C. trachomatis, N. gonorrhoeae*, and other urethral pathogens may facilitate more accurate determination of the role of these organisms in epididymitis.

■ MISCELLANEOUS CAUSES OF EPIDIDYMITIS

While most cases of epididymitis are due to bacterial pathogens associated with sexually transmitted urethritis or bacteriuria, less common causes include localized or systemic infectious and noninfectious disorders.

Bacterial infections

Epididymitis is well documented as a complication of hematogenous dissemination of a number of bacterial infections.

Mycobacteria. Epididymitis may occur in systemic tuberculosis. In Mittemeyer's military series, 0.8% of patients had epididymitis due to tuberculosis.[14] Ross found the age of patients with tuberculosis epididymitis to be between 20 and 40 years.[31] Tuberculosis epididymitis commonly presents with bilateral involvement. In contrast, epididymitis caused by coliforms, *N. gonorrhoeae,* or *C. trachomatis* is nearly always unilateral. Because tuberculosis epididymitis results from disseminated infection, patients may present with clinical disease involving other organs, including the kidneys,[32,33] adrenal glands,[34,35] lymphatics (retroperitoneal, abdominal, or mediastinal),[36,37] and other male accessory glands.[32] Halker reported that 75% of patients with renal tuberculosis had an episode of epididymitis.[32] Medlar reported that no case of tuberculosis epididymitis occurred without renal, prostate, or seminal vesicle involvement.[33] Tuberculosis epididymitis may also occur after intravesical Bacillus Calmette-Guerin (BCG) instillation for treatment of carcinoma of the bladder.[38–41]

Several clinical clues suggest the possibility of tuberculosis epididymitis. The two classic physical findings associated with tuberculosis epididymitis are "sterile pyuria" and "beading of the vas." While the presence of sterile pyuria should suggest the possibility of genitourinary tuberculosis, this finding may be confused with other causes of sterile pyuria, such as nonspecific urethritis or urinary stone disease (which may present with referred scrotal pain).[42] "Beading of the vas" is the physical finding of a "string of beads" on palpation of the vas deferens that occurs with tuberculosis. Another, less specific, finding that we have noted with genitourinary tuberculosis is prostatic calculi that may be detected on digital rectal examination. According to urologists who practiced before effective antimicrobial therapy, this was noted in a reasonable proportion of cases. (Victor Marshall personal communication to JNK, 1977.)

Several mycobacterial species other than *M. tuberculosis* have been associated with epididymitis, including *M. chelonae*, *M. avium-intracellulare*, *M. kansasii*, *M. xenopei,* and *M. bovis.*[43–46] Leprosy, especially erythema nodosum leprosum, may present clinically as a multisystem disorder that includes epididymitis.[47,48]

Other Bacteria. Numerous other bacteria have been reported as infrequent causes of epididymitis, probably due to hematogenous dissemination. These organisms include *Streptococcus pneumoniae* and *equisimilis, Brucella* spp., *N. meningitidis, Treponema pallidum, Nocardia* spp., and *Tropheryma whipplei.*[49–59] *H. influenzue* type B has been isolated from the epididymis of children with acute epididymitis as well as in an MSM with epididymitis.[15,60,61] Salmonella epididymitis has also been reported in children with enteric salmonella infection.[62] Epididymitis attributed to *Plesiomonas shigelloides* and to *Listeria monocytogenes* has been reported in immunosuppressed individuals.[63,64]

Fungal infections

Epididymitis may occur as a manifestation of disseminated fungal infections, such as histoplasmosis, coccidioidomycosis, blastomycosis, and cryptococcosis.[65,66] Candidal epididymitis (both *C. albicans* and non-*albicans* spp.) has also been reported.[67–70]

Viral infections

Epididymoorchitis is the most common complication of mumps in postpubertal men,[71] and is commonly unilateral.[71–73] Cytomegalovirus epididymitis has been reported in a patient with AIDS.[74]

Parasitic infections

Trichomonas vaginalis is an etiologic agent of NGU and, in case reports, has been reported to cause epididymitis.[75,76] Other parasitic etiologies for epididymitis, including schistosomiasis, sparganosis, and Bancroftian filariasis are typically endemic in regions outside the United States. Patients may present with eosinophilic urethritis or cystitis, and may have a more subacute or chronic clinical course.[77–79] Diagnosis of parasitic epididymitis is often made upon pathologic evaluation of surgical specimens.

■ POSTINFECTIOUS EPIDIDYMITIS

Studies of epididymitis in pediatric and adolescent patients suggest that a postinfectious etiology may account for some cases. Somekh et al. prospectively studied epididymitis in 44 patients 2–14 years old.[80] They found significantly higher serologic titers to *Mycoplasma pneumoniae*, enteroviruses, and adenoviruses compared with controls.[80] Epididymoorchitis has been reported as a complication of *Streptococcus pyogenes* pharyngitis.[81]

■ VASCULITIS

Systemic vasculitis represents an infrequent cause of epididymitis. Epididymitis has been reported in Behcet's disease, Henoch-Schõnlein purpura (HSP), and polyarteritis nodosa.[82–90] Epididmytis, sometimes recurrent, has been reported in 5–12% of patients with Behcet's disease.[84–87] In a large study of 780 male patients with Behcet's disease by Cho et al., 36 patients with epididymitis were significantly more likely to have genital ulcers, cutaneous involvement, arthritis, central nervous system involvement, and a positive pathergy test.[84] These findings suggest a tendency toward more severe Behcet's disease manifestations in patients who have epididymitis.[84] HSP may present with bleeding into the epididymis with associated inflammation and pain.[88,90] The scrotal pain and swelling in HSP-associated epididymitis may be severe, mimicking testicular torsion; clinical features and color and power Doppler ultrasonography can be useful in excluding torsion and preventing unnecessary surgery.[88] Our clinical experience also includes a few patients with epididymitis associated with Wegener's granulomatosis.

■ DRUG-ASSOCIATED EPIDIDYMITIS

A new cause of epididymitis was reported by Gasparich, Krieger, and colleagues, who reported a syndrome of epididymitis in 6 (11%) of 56 men taking the antiarrhythmic drug amiodarone.[3] Epididymal biopsy showed lymphocytic infiltration and fibrosis. Amiodarone levels in the epididymis were found to be 400 times higher than therapeutic blood levels in one patient. Reduction of the amiodarone dosage resulted in resolution of epididymitis. Subsequent reports have confirmed amiodarone as an etiology for epididymitis.[91,92] In amiodarone-associated epididymitis, pyuria and urethritis are absent. This sterile epididymitis is usually bilateral; however, it may be unilateral.[3]

PATHOGENESIS OF EPIDIDYMAL INFECTION

The route of spread of infection to the epididymis has been a subject of considerable debate. Much of the controversy arose with the original concept that "idiopathic" epididymitis was caused by "sterile" inflammation from urine refluxing down the vas deferens while straining with a full bladder. This theory had implications both for workman's compensation from results of injuries sustained while working, and for the military, where prevention of epididymitis and loss of time from service was of great importance. Currently, most cases of epididymitis are thought to be infectious in origin. Therefore, the route of spread to the epididymis may be of more than academic interest, since the spread of naturally occurring infection from the urethra, bladder, or prostate does not carry the same legal implications as reflux of sterile urine caused by strenuous work.

The second historical area of controversy concerns the recommendation for routine "prophylactic" vasectomy to prevent epididymitis following prostatectomy. Experimentally, infective epididymitis has been produced by inoculation and intralumenal spread.[93] On numerous occasions, it has been demonstrated that bladder urine can reflux first into the ejaculatory ducts, then into the vas deferens in patients undergoing prostatectomy or in those with serious urinary pathology. Thind et al. documented high voiding pressures and sphincter dysinergia in many patients with acute epididymitis.[94,95] In contrast, Kohler was unable to produce reflux of radiographic contrast into the vas in patients recovering from acute epididymitis.[96] Herwig was also unable to demonstrate urinary reflux into the vas in patients with sterile urine.[97] Pelouze pointed out that because the ejaculatory ducts lack circular muscles, retrograde peristalsis of urine down the vas would require the seminal vesicle to first fill with urine and then contract forcing urine down into the epididymis.[23] Inflammation of the seminal vesicle during acute epididymitis has been demonstrated by ultrasound.[98] Since the seminal vesicle is subject to the same intraabdominal pressures as the bladder, perhaps straining could force infected seminal vesicle contents down the vas and into the epididymis. Reflux of urine would not be necessary to explain the sudden onset of epididymitis with straining in these patients. Kendall documented positive vas cultures in only 15% of men with prostatic obstruction and positive urine cultures without a catheter, compared to 36% of infected patients who had a urethral catheter.[99] Orandi evaluated patients undergoing prostatectomy: 32 (48%) of 67 patients with positive urine cultures also had positive vas cultures.[100] In contrast, none of the

74 patients with negative urine cultures had a positive vas culture. Reeves ligated only one vas deferens in 505 preprostatectomy cases and found a higher rate of epididymitis on the nonligated side.[101] Perhaps a catheter or similar irritation from infection of the verumontanum may allow reflux of infected urine from the bladder down the vas deferens or lead to seminal vesiculitis with infection subsequently spreading to the epididymis. Taken together, these findings suggest that retrograde ascent of infected urine may cause postoperative epididymitis following urological procedures but that epididymitis is an unlikely complication of urological procedures in patients with sterile urine.

Other theories have been proposed to explain the pathogenesis of epididymitis. Wesson suggested that bacteria could reach the epididymis via lymphatics adjacent to the vas, and he noted frequent swelling of the spermatic cord in patients with epididymitis.[102] Since the epididymis drains to hypogastric and iliac nodes while the prostate and seminal vesicles drain to the same area, spread by the way of lymphatic drainage was postulated. Lack of testicular involvement in some cases was attributed to the different lymphatic drainage of the two organs. Rolnick suggested that bacteria could advance along the sheath of the vas, since this sheath is a continuation of the sheath of the prostate and seminal vesicles.[103] Thus, infection from the prostate or seminal vesicles could travel along the sheath of the vas to the tail of the epididymis. Some infections, such as tuberculous, pneumococcal, fungal, and other infections, might well spread to the epididymis by a hematogenous route. However, this route is probably unusual for coliform or sexually transmitted organisms because the infecting organism can usually be identified in the urethra or bladder.

CLINICAL MANIFESTATIONS

Characteristically, patients with epididymitis complain of testicular or scrotal pain and may also complain of inguinal pain.[19] In severe cases, acute swelling of the spermatic cord may result in flank pain from obstruction of the ureter as it crosses over the spermatic cord.[23] Of 92 men in the military service with epididymitis, one-third had a sudden onset, and two-thirds a gradual onset.[21] A history of lifting or straining on onset of pain is probably not significant in determining the etiology of the epididymitis or in its differentiation from other intrascrotal conditions.

In coliform epididymitis, a history of bacteriuria or symptoms suggestive of urinary tract infection may or may not be present. [21,104] Frequency, urgency, or dysuria may be present. There may be a history of symptoms suggestive of urinary tract obstruction (e.g., hesitancy or slow urinary stream), indicating conditions predisposing to urinary tract infection (e.g., stricture and benign prostatic hypertrophy). Men with epididymitis secondary to sexually transmitted pathogens often have a history of urethral discharge or dysuria, and they usually have a history of recent sexual exposure. Berger et al. found that only 1 (10%) of 10 patients with coliform infections versus 6 (43%) of 14 patients with *C. trachomatis* infections had dysuria.[1] Patients with tuberculosis epididymitis often have a prior history of pulmonary tuberculosis or a history of exposure to tuberculosis.

On examination, the scrotum on the involved side may be red and edematous. The testicle tends to lie in the normal position in the scrotum. The tail of the epididymis, which connects with the vas deferens near the lower pole of the testes, is swollen first. Later, swelling spreads to the head of the epididymis, near the upper pole of the testes. The groove between the epididymis and the testicle should be examined, as this will help to show whether the maximum swelling is in the testicle or the epididymis. The spermatic cord may be swollen and tender (termed, "funiculitis"). The degree of scrotal erythema and epididymal edema may be less in patients with chlamydial epididymitis compared with those with epididymitis of other etiologies.[105] However, massive erythema and edema may also occur with untreated *C. trachomatis* epididymitis. If the patient has not voided recently, a urethral discharge may be apparent. However, it is important to recognize that asymptomatic urethral infection without discharge may occur. Watson found that 50% of gonococcal epididymitis cases did not have urethral discharge.[24] If no spontaneous discharge is noted, the urethra should be stripped and examined again. Digital rectal examination may reveal abnormalities suggesting bacterial prostatitis in some cases.[13,20]

PATHOLOGY OF ACUTE EPIDIDYMITIS

The pathology usually begins in the tail of the epididymis, then spreads to the rest of the epididymis. Subsequent spread to the testicle may result in a diffuse pathologic process, properly termed "epididymoorchitis."

Pelouze noted in 98% of epididymitis cases that the clinical course suggested the epididymis was inflamed before the vas.[23] Initially, the epididymal ducts become distended with polymorphonuclear and mononuclear leukocytes that may actively phagocytize sperm.[106] The epithelium of the epididymis may be destroyed, and small abscesses form in the connective tissue, which is intensely hyperemic. In the stroma, lymphocytes may outnumber the polymorphonuclear leukocytes. Microabscesses may be present after 48 hours.[106] Later the columnar epithelium of the epididymis may become squamoid in appearance and plasma cells more frequent.

Cronquist reported seven cases of epididymitis in which sperm penetrated the epithelium and basement lamina of the epididymis with a marked inflammatory reaction.[107] In a biopsy study, Wolin noted that 13 (54%) of 24 patients had epididymal tubular destruction with microabscesses and a predominance of polymorphonuclear leukocytes.[9] However,

in the remaining 11 cases, there was predominantly lymphocytic infiltration with no tubular involvement. Perivascular mononuclear cell infiltration was prominent in some of these cases. Kiviat et al. also noted a mononuclear cell infiltrate in the epididymis of men with chlamydial infection proven by fluorescent monoclonal antibody staining.[108]

Often, the epididymal interstitium is infiltrated by neutrophils, small lymphocytes, plasma cells, and transformed lymphocytes. Neutrophils are often seen in the epididymal tubules and migrating through the epithelium.[108] Wolin and Nilsson et al. described testicular inflammation,[9,109] the latter reporting that Sertoli's cells were vacuolated with cloudy cytoplasm. Furthermore, the organism responsible for epididymitis was isolated from the testicle in four patients. After 2–7 months, repeat biopsies showed decreased inflammation with an increased proportion of lymphocytes, macrophages, and plasma cells. After 2–3 years, there was atrophy that was proportional to the degree of initial inflammation. There have been rare reports of xanthogranulomatous epididymitis, in which chronic bacterial infection of the epididymis leads to destructive granulomatous inflammation accompanied by a cellular infiltrate of lipid-laden macrophages.[110–112]

In summary, available data suggest that most cases begin in the tail of the epididymis, with an acute intralumenal exudate, tubular epithelial damage, and subjacent microabscesses formation. However, some cases show predominantly mononuclear and perivascular infiltration. Subsequently, testicular involvement occurs that may lead to testicular atrophy. Unfortunately, these pathological studies did not employ comprehensive microbiological studies of etiology.

EXPERIMENTAL PATHOLOGY

Møller and coworkers developed a primate model of *C. trachomatis* epididymitis.[93] Injection of *C. trachomatis* into the vas deferens of grivet monkeys produced marked infiltration with a polymorphonuclear leukocytes and lymphocytes through all layers of the spermatic cord, and in the epididymis. The ducts were filled with polymorphonuclear leukocyte exudate. Although *C. trachomatis* was isolated from the vas deferens, it was not isolated from the epididymis. Berger et al. used *Macaca nemistrina* as a primate model.[113] After inoculating *C. trachomatis* through the vas deferens, they observed mononuclear perivascular inflammation in the area of the epididymis.[113]

Other models for acute and chronic epididymitis have been developed in mice and rats.[114–116] Lucchetta et al. developed a model for epididymitis caused by *E. coli* in the rat, and Hackett et al. developed a similar model in the rabbit.[117,118] Both models demonstrated a marked decrease in spermatogenesis following epididymitis. In a rat model, See et al. found that the concentration of the antibiotic amdinocillin was actually increased in the infected testicle compared to the noninfected side.[119] Likewise, in a rat model, Tartaglione et al. found increased antibiotic concentrations on the infected side for sulfamethoxazole, tobramycin, doxycycline, and ampicillin.[120] Trimethoprim had similar levels in the infected and noninfected sides, and doxycycline had the best tissue penetration of any antibiotic evaluated. Vieler et al. compared the efficacy of different antibiotic regimens in rats with experimental *E. coli* epididymitis.[121] Ofloxacin was the most effective at decreasing the number of organisms and histologic changes; doxycycline was more effective than cefotaxime. Nielsen found that antibiotic therapy had no affect once abscess formation occurred.[122] Finally, in a study of *E. coli* epididymitis in rats, Ludwig et al. reported that sparfloxacin therapy eradicated the organisms and reduced the degree of epididymal damage compared with untreated controls.[123] However, the initial inflammatory reaction persisted as a nonbacterial process, possibly compromising fertility. These experimental observations suggest that acute epididymitis may resemble acute pyelonephritis, with persistent immunological processes causing ongoing tissue damage despite elimination of the infecting bacteria.

ETIOLOGIC DIAGNOSIS

Gram stain of a urethral swab specimen will often indicate the presence of urethritis and establish with a high degree of certainty whether its etiology is gonococcal or nongonococcal. Berger et al. demonstrated that the presence or absence of intracellular Gram-negative diplococci on Gram stain or urethral smear correlated with culture results for *N. gonorrhoeae.*[1] Two-thirds of the cases of epididymitis not caused by Gram-negative rods or *N. gonorrhoeae* in men younger than 35 years of age were secondary to *C. trachomatis.*[1] Urethral specimens should be tested for *N. gonorrhoeae* and *C. trachomatis* in all cases. While culture has been the traditional diagnostic test for chlamydia and gonorrhea, tests of first-voided urine for *N. gonorrhoeae* and *C. trachomatis* using highly sensitive and specific nucleic acid amplification techniques may prove just as or even more useful, though more experience with these tests is needed in men with epididymitis.

First-voided and midstream urine specimens should next be examined for bacteria and white cells. Comparison of the urinary sediments in the first-voided and midstream urine may reveal whether pyuria is coming from the urethra or the bladder. Gram stain of uncentrifuged midstream urine can be used to presumptively establish the diagnosis of bacteriuria in cases of coliform or *Pseudomonas* infections. Presence of greater than one Gram-negative rod per oil immersion field on Gram stain of unspun midstream urine correlates with the presence of greater than 10^5 coliform or *Pseudomonas* spp. per milliliter. Quantitative midstream urine culture should be obtained in all cases of acute epididymitis when bacteriuria is suspected because culture also provides antimicrobial susceptibility data.

In certain difficult cases, diagnosis may be facilitated by epididymal aspiration cultures.[124] Such cultures may be useful in patients with (1) indwelling urethral catheters, (2) failure to respond to initial antimicrobial therapy, (3) epididymitis found on surgical exploration for torsion of the testicle, and (4) recurrent epididymitis in which the etiologic agent is uncertain. If the patient had received prior antimicrobial therapy and the urine is sterile, the responsible pathogen may still be culturable from aspirate samples. Nucleic acid amplification tests for gonorrhea and chlamydia using epididymal aspirates may also be useful though little clinical experience has been reported. Patients with indwelling urethral catheters often have multiple organisms in the urine, and therapy may be best selected on the basis of the organism(s) found on epididymal aspiration.

DIFFERENTIAL DIAGNOSIS OF ACUTE EPIDIDYMITIS

An algorithm for the initial diagnostic evaluation of the patient with the acute scrotum syndrome is presented in Fig. 60-1.[125]

TORSION OF THE TESTIS

Acute epididymitis must be differentiated from torsion of the testicle. In infants and prepubertal children, torsion of the testicle is much more common than acute epididymitis. In these populations, any acute scrotal swelling must be presumed to be torsion of the testicle unless proven otherwise. Quinto found that only 12 (8%) of 158 pediatric patients with scrotal swelling had epididymitis.[126] Children with epididymitis often have pyuria. In contrast, children with torsion generally do not have pyuria.

Torsion of the testis requires urgent surgical exploration to perform detorsion and orchidopexy to preserve testicular viability. Cases of suspected epididymitis in adolescents or young adults should be confirmed by Doppler or radionuclide scanning, since the incidence of torsion is also higher than the incidence of epididymitis for most populations in this age group. In consecutive cases of acute testicular swelling, Devillar noted that 11 (85%) of 13 patients younger than 20 years old, had torsion of the testicle.[127] In contrast, among patients 20–30 years old only 10% had torsion of the testicle. Of 29 patients with acute epididymitis, only eight (28%) were younger than 20 years old. Barker also found that epididymitis was much more likely in patients older than 18 years old than in patients younger than 18 years old presumably because of increasing sexual activity and the decreasing incidence of torsion with age.[128] As the age at first intercourse has decreased, the incidence of epididymitis has increased in patients younger than 18 years old.

A history of previous scrotal pain is more common in torsion of the testicle than in epididymitis, presumably reflecting

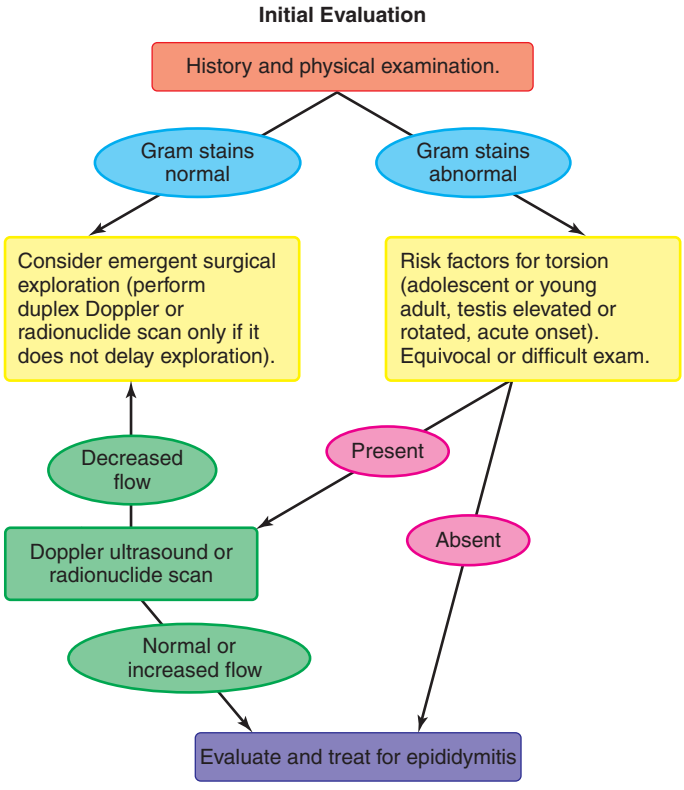

FIGURE 60-1. Algorithm for initial evaluation of the acute scrotum syndrome.

previous intermittent torsion. History of trauma to the testicle or of extreme exertion at the onset of pain may occur with either epididymitis or torsion. Unless performed early in the course of the acute scrotum syndrome, physical examination may be very similar in torsion and epididymitis. Devillar noticed swelling of the testes in 28% of patients with epididymitis and in 77% of cases of torsion.[127] Swelling of the epididymis alone occurred in 59% of cases of epididymitis and in 15% of torsion cases. In torsion, examination of the opposite testicle may reveal that the epididymis is anterior. This diagnostic clue indicates that the congenital abnormality that allows torsion of the testicle may also be present on the opposite side. Also in torsion, the testicle is often high in the scrotum, whereas in epididymitis this is unusual. In epididymitis, the spermatic cord in the inguinal canal may be quite tender, whereas in torsion tenderness is generally limited to the scrotal contents.

Examination of the urine and urethral smear may prove helpful in differentiating epididymitis from torsion. Barker and Raper noted that 31 (97%) of 32 patients with epididymitis had bacteriuria or leukocytes in their urine, compared to none of 38 patients with torsion.[128] In Doolittle's series, 8 (73%) of 11 patients with epididymitis had pyuria, compared to none of 19 with torsion.[129] Ideally, evaluation should include examination of the first-voided urine, which may demonstrate a higher concentration of leukocytes than the midstream urine in patients with urethritis. In Madsen's series, 49 (98%) of 50 patients with acute epididymitis had expressed prostatic secretions with increased leukocyte

counts.[130] Although Madsen did not examine urethral smears routinely, finding clear evidence of urethritis on smear would limit the need for prostate examination in most cases. Some authors consider a rigorous prostate exam to be contraindicated in patients with epididymitis because of the risk of exacerbating symptoms or because of a possible risk of causing bacteremia in men with coliform or *P. aeruginosa* infection. Neither Madsen nor Berger[1] reported such exacerbations. However, Berger avoided prostatic massage in older patients with suspected coliform or *P. aeruginosa* infection.[1]

Recent studies suggest that inflammatory markers may help distinguish epididymitis from noninflammatory conditions, such as torsion and tumor. Rivers et al. found that serum interleukin-6 (IL-6) was significantly elevated in epididymitis compared with testicular torsion, and had a positive predictive value of 79% in diagnosing epididymitis versus a negative predictive value of 100% for torsion.[131] Doehn et al. reported that 50 (96%) of 52 patients with epididymitis had at least a fourfold elevation in serum C-reactive protein, compared to none of the 17 patients with tumor and only 1 (9%) of 11 with torsion.[132] Thus, an elevated C-reactive protein had a sensitivity of 96%, specificity of 94%, negative predictive value of 94%, and positive predictive value of 94%.[132] Matalliotakis et al. found that in 82 infertile men, levels of soluble IL-6 receptor in the seminal plasma were significantly higher in cases of accessory genital gland infection than in other groups.[133] While these laboratory measures of inflammation may help support the diagnosis of epididymitis, diagnosis of epididymitis is primarily based on the clinical history and examination.

Doppler ultrasound has proven very useful in differentiating the diagnosis of torsion from epididymitis.[134] This examination may demonstrate increased blood flow to the acutely inflamed epididymis and decreased blood flow to a testicle that has undergone torsion, cutting off its blood supply. The opposite testicle is used as a control. Care must be exercised in interpreting Doppler ultrasound examinations, as hyperemia surrounding a necrotic testicle may produce a false positive signal for epididymitis. Compression of the spermatic cord at the external ring may cause the Doppler pulse to disappear if blood flow is coming from the testicle, but not if it is coming from scrotal vessels. Similarly, a hydrocele surrounding an inflamed epididymis may produce a falsely decreased signal. Ultrasound may also prove useful in evaluating complications of epididymitis, such as testicular abscess, testicular infarction, or pyocele of the scrotum.[135]

Color-coded duplex and power Doppler ultrasonography have also proven valuable in differentiating epididymitis and torsion, and currently, these are the imaging methods of choice in many institutions. Color and power Doppler ultrasound use visual coding of flow velocities in blood vessels superimposed on the gray scale ultrasonography. Increases or decreases in blood flow can be determined.[136,137] Wilbert et al. found that color-coded Doppler ultrasonography had a sensitivity of 82% and a specificity of 100% for torsion.[138] For epididymitis, the sensitivity was 70% and specificity was 88%. False negative scans in torsion generally resulted from intermittent or partial torsion with some residual blood flow in the testicle and epididymis. Magnetic resonance imaging has also been found to be accurate in the differential diagnosis of epididymitis and torsion in a small series.[139]

The use of radionuclide testicular scanning is also based on a finding of increased blood flow in epididymitis (Fig. 60-2). In Holder's series, all 22 patients with acute epididymitis had increased blood flow and were correctly diagnosed.[140] In a retrospective study of 4 patients with torsion, 13 patients with inflammatory testicular diseases, and 3 healthy persons, Wu et al. found all were correctly diagnosed by radionuclide imaging (based on the final surgical and pathologic diagnosis) and this imaging was more accurate than ultrasonography.[141] Abu-Sleiman et al. found that a correct diagnosis could be made in 86% of cases.[142] False positives were noted in hydroceles and false negatives in late torsions and patients with retracted scroti.[143,144] Testicular tumor may also produce increased flow on testicular scan, resembling epididymitis.[145]

In summary, multiple imaging modalities are available to assist in distinguishing torsion from epididymitis. In all cases, unless the examiner and imaging can unequivocally rule out torsion of the testicle, scrotal exploration should be undertaken. Some experts believe surgical exploration without

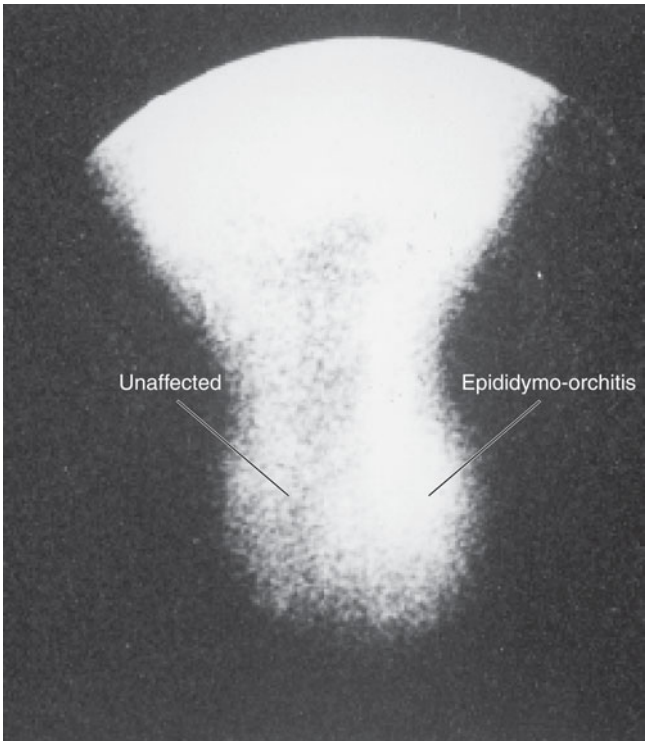

FIGURE 60-2. Technetium radionuclide scan of a patient with typical acute unilateral epididymoorchitis, showing increased uptake of Tc^{99} on the affected side, with normal uptake on the unaffected side.

prior imaging is appropriate for presumed torsion, given that after 4 hours of torsion, there is a significant risk of irreversible testicular infarction. A "wait and see" attitude is never justified.

TESTICULAR TUMOR

Testicular tumor is another important consideration in the differential diagnosis of epididymitis (Fig. 60-3). The peak incidence for epididymitis and testicular tumors occur in similar age groups. The presentation of a painless or persistent testicular mass suggests the possibility of testicular tumor. However, approximately one-quarter of patients with testicular tumors present with testicular or scrotal pain. Therefore, the presence of testicular or scrotal pain does not rule out a tumor, especially since hemorrhage or rapid tumor growth may, on occasion, cause such pain. In the early stages of epididymitis, swelling is limited to the epididymis, and differentiation from testicular tumor usually is not difficult. However, as epididymitis progresses and the testicle becomes more involved, the limits of inflammation are not easily defined. Further, a testicular tumor may invade the epididymis and thus, on physical exam, mimic exactly the findings of acute epididymitis. Reactive hydrocele formation may further limit the usefulness of physical examination. In testicular tumors, the urine and urethral smear should show no evidence of inflammation. Failure of improvement in the size of swelling or pain in any young man being treated for epididymitis should lead to the suspicion that an incorrect diagnosis has been made. Imaging, and possibly scrotal exploration through an inguinal incision, should be considered to rule out carcinoma of the testicle. Transscrotal open or needle biopsy should never be performed when carcinoma of the testicle is suspected for fear of spreading the tumor to the inguinal lymph system; the usual lymphatic drainage of the testis is to the nodes at the level of the renal hilum, and not to the inguinal nodes.

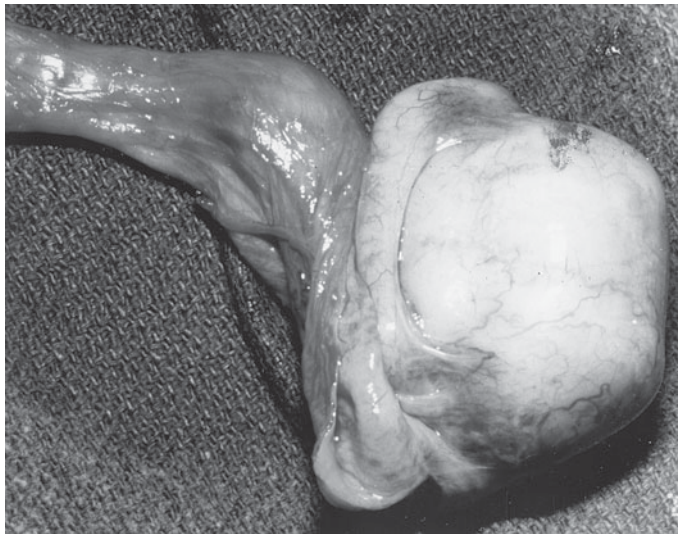

FIGURE 60-3. Testicular seminoma that was misdiagnosed as epididymitis by three urologists. The cancer is sausage-shaped and the epididymis is elevated.

MISCELLANEOUS

Other common intrascrotal conditions that may present difficulties in diagnosis are presented in Table 60-5. Spermatocele and hydrocele are easily differentiated by transillumination or by ultrasound. The scrotal varicosities of a varicocele disappear on assuming the supine position. A hernia protruding into the scrotum may sometimes present difficulties in diagnosis. However, this may be reducible as the patient lies down. Hernias are not transilluminable, and bowel sounds may occasionally be heard in the hernia contents.

TREATMENT

ANTIMICROBIAL THERAPY

Because most cases of acute epididymitis are caused by infections, antimicrobials are the cornerstone of therapy. Nilsson provided evidence that antibiotic treatment is superior to placebo in patients with and without coliform epididymitis.[146] Appropriate empiric antimicrobial therapy can be chosen based on whether initial Gram stain evaluation of an endourethral specimen and first-voided and midstream urine specimens suggest urethritis or bacteriuria as the inciting event, as outlined in Fig. 60-4.

In patients with bacteriuria, broad-spectrum antimicrobial therapy appropriate for a tissue-invasive urinary tract infection should be initiated promptly. For ambulatory therapy in those with mild or moderate epididymitis, either oral ofloxacin 400 mg twice daily or levofloxacin 500 mg once daily for a 10-day treatment course is appropriate;[147] if *P. aeruginosa* is a concern, then levofloxacin would be more appropriate. Because ciprofloxacin is less effective against *C. trachomatis* than ofloxacin or levofloxacin, it is not recommended. Traditionally, trimethoprim-sulfamethoxazole was recommended as an empiric option for treating uncomplicated epididymitis attributed to coliform infection. However, with increasing resistance of *E. coli* and other coliforms to trimethoprim-sulfamethoxazole, trimethoprim-sulfamethoxazole is no longer an ideal empiric antimicrobial option.

For febrile individuals or those with more severe or complicated epididymitis, intravenous broad-spectrum therapy directed against coliforms and *P. aeruginosa*, including the addition of an aminoglycoside, should be considered. Therapy can be modified based on susceptibility testing results for organisms cultured from the urine. In patients with indwelling urethral catheters who may have multiple organisms isolated from the urine and in patients who have

Table 60-5. Common Differential Diagnosis of Acute Epididymitis in Adult Men

	Usual Age	Pain	Onset	Past History of Pain	Spermatic Cord Tenderness	Scrotal Tenderness	Transill Umination	Decrease in Swelling on Lying Down	Fever	Location of Swelling	Urethritis, Pyuria, Bacteriuria	Activity on Testicular Scan	Blood Flow on Doppler Ultrasonic
Epididymitis	Any	Mild–severe	Gradual to sudden	Infrequent	Frequent	Severe	No	No	Frequent	Posterior to testes	Yes	≠	≠
Torsion of testes	<30	Severe	Sudden	Frequent	Infrequent	Severe	No	No	Infrequent	Testes[a]	No	Ø	Ø
Testes tumor	18–32	None–mild	Gradual	Infrequent	No	None–mild	No	No	No	Testes	No	≠ or Ø	Normal
Hydrocele	Any	None--mild	Gradual	Infrequent	No	None	Yes	No	No	Entire hemiscrotum	No	Ø	Normal or ↓
Spermatocele	Any	None–mild	Gradual	Infrequent	No	None	Yes	No	No	Above testes[b]	No	Ø	Normal or ↓
Varicocele	Any	None–mild	Gradual	Infrequent	No	None	No	Yes[c]	No	"Bag of worms"	No	Normal or ≠	Normal[d]
Hernia	Any	None–moderate	Gradual	Frequent	Frequent	None–mild	No	Yes[e]	No	Above testes	No	Normal	Normal

[a]In torsion of testicle, epididymis of normal testicle may be anterior.

[b]Spermatocele may feel like "third testicle."

[c]Varicocele should disappear on lying down.

[d]May get increased venous flow.

[e]Hernia may be reducible on lying down.

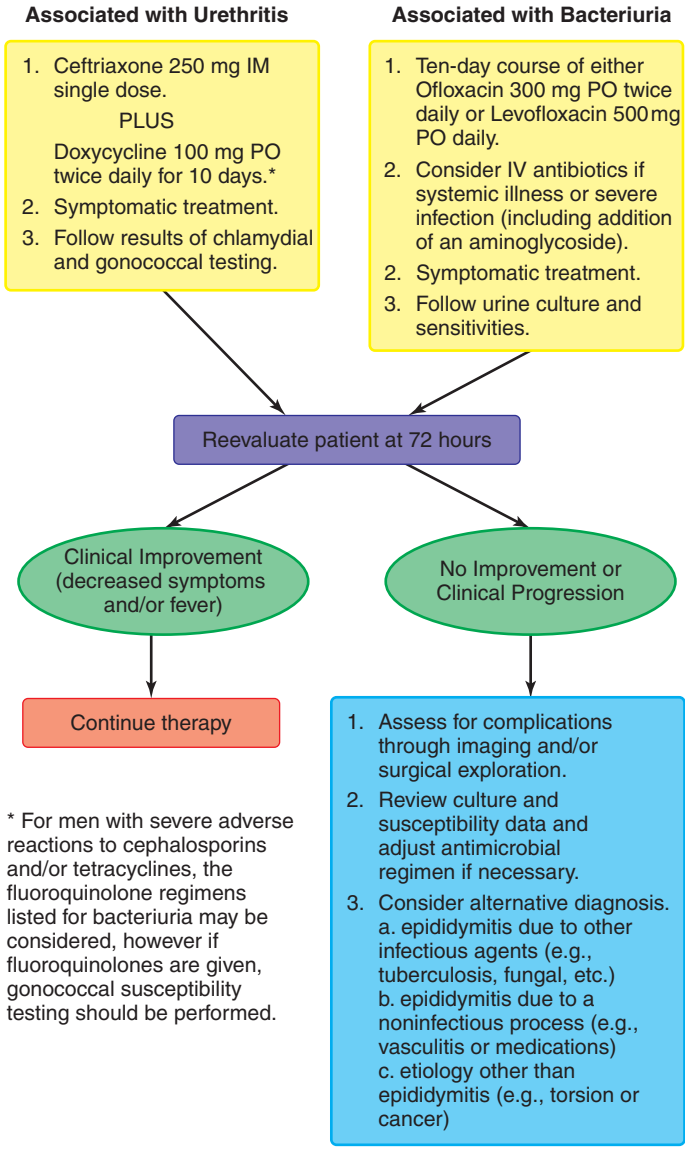

FIGURE 60-4. Algorithm for management of epididymitis.

been started on antibiotics who may have sterile urine, the use of epididymal aspiration cultures may identify the causal pathogen and also provide needed antimicrobial sensitivity information.[124] Antibiotic treatment may need to be prolonged in more complicated cases.

In patients with epididymitis associated with urethritis or a suspected sexually transmitted pathogen, antimicrobial therapy directed against *N. gonorrhoeae* and *C. trachomatis* should be initiated promptly. Treatment for both organisms is necessary because chlamydiae can be isolated from the urethra from approximately 20% of patients with gonorrhea, and theoretically could cause epididymitis even when *N. gonorrhoeae* is isolated. A treatment regimen active against beta-lactamase positive strains of *N. gonorrhoeae* (e.g., ceftriaxone 250 mg intramuscularly), followed by 10 days of oral doxycycline 100 mg twice daily to adequately cover chlamydial infection is recommended.[147] Due to an increase in fluoroquinolone resistance among *N. gonorrhoeae* strains, fluoroquinolones are no longer recommended as first-line therapy for epididymitis associated with urothritis (http://www.cdc.gov/std/treatment/2006/updated-regimens.htm). If fluoroquinolones are used in this setting, than susceptibility testing should be performed consultation with a specialist may be considered.

NONANTIMICROBIAL MEDICAL THERAPY

Symptomatic treatment of the patient with epididymitis is always indicated. Scrotal elevation provides for maximum lymphatic and venous drainage. The patient should be placed at bed rest with the scrotum elevated on a towel between his legs. The use of constricting scrotal supports while the patient is supine often only holds the scrotal contents between the patient's legs in a dependent position. If the patient is standing, gravity limits proper drainage of the tissues and may increase swelling. The patient should remain at bed rest until the scrotal contents are no longer tender. If the pain returns after ambulation, the patient should return to bed rest and scrotal elevation. Analgesics should be given as necessary for pain.

Several other nonantimicrobial treatments have also been proposed for epididymitis. Smith found that patients with epididymitis had dramatic relief of pain after one or two injections of the spermatic cord with procaine hydrochloride.[148] He noted that the pain relief was both immediate and lasting well beyond the period of local relief.[148] Kamat et al. reported on outcomes of medical therapy in three groups of patients: one group received antibiotics only; the second was treated with antibiotics plus oxyphenbutazone; and the third was treated with antibiotics plus infiltration of the spermatic cord with xylocaine hydrochloride.[149] The patients treated with antibiotics plus oxyphenbutazone or antibiotics plus spermatic cord infiltration recovered more quickly than patients on antibiotics alone.[149] His study was not blinded, however, and he did not report bacteriologic results. McClellan reported that the addition of paraenzyme or varidase also decreased the amount of swelling and percentage with residual chronic epididymitis.[150] Lapides found that 35 (74%) of 47 patients with acute epididymitis were relieved by oxyphenbutazone alone.[151] He described decreased pain in these patients but no decrease in the amount of erythema or swelling. In a multicenter, placebo-controlled study, Moore et al. found that prednisone had no value as an adjuvant to antibiotic therapy in the treatment of epididymitis.[152] Thus, some clinicians believe that anesthetic infiltration of the spermatic cord and the use of oxyphenbutazone in addition to antibiotics and oral analgesics may increase the comfort of a patient. However, it is not clear whether these other forms of treatment provide better symptomatic relief than the use of analgesics with antibiotics. The effect of such adjuvant therapy on the long-term sequelae of epididymitis remains uncertain.

SURGERY

Drainage of testicular abscesses or orchiectomy is seldom necessary in patients who receive early appropriate antimicrobial therapy with bed rest and scrotal elevation. Vordermark et al. found that in patients who do not respond to antibiotics within 4 hours, epididymectomy hastened convalescence.[153–155] However, this has not been subjected to a controlled study, and many patients with epididymitis will require up to 48–72 hours to show improvement, but then do well. Epididymectomy might be indicated in an older group of patients after unsuccessful conservative treatment. Prophylactic vasectomy of the contralateral testicle has also been advocated during such procedures.[156] Surgical therapy (generally orchiectomy) may be necessary for complications of severe epididymoorchitis, such as testicular infarction, abscess formation, of development of a pyocele of the scrotum (i.e., an infected hydrocele).

FOLLOW-UP

Patients should be reevaulated at 72 hours following initiation of antimicrobial therapy (Fig. 60-4). Failure to clinically improve within 72 hours of the initiation of medical treatment requires reevaluation of the initial diagnosis and the current therapy. Swelling and tenderness that persists following completion of antimicrobial therapy needs to be evaluated more comprehensively through other means, including imaging or surgical exploration. The differential diagnosis includes testicular tumor, abscess or infarction, or a different infectious etiology (e.g., tuberculosis or fungal epididymitis).

ADDITIONAL ASPECTS OF MANAGEMENT

In patients in whom the etiologic agent is a sexually transmitted pathogen, treatment of epididymitis is not complete without evaluation and treatment of the sexual partner(s). This limits the risk of reinfection of the patient and prevents disease in the partner. In a study by Berger et al., two (25%) of eight female partners of men with epididymitis had chlamydial infections.[1] Robinson et al. found that 14 (88%) of 16 female consorts of chlamydia-infected men had chlamydial cervicitis.[157]

Whether to evaluate possible anatomical or functional urological disorders depends on the clinical presentation. Svend-Hansen found abnormal excretory urograms in only 6 (14%) of 43 in patients younger than 50 years old of age; all six with abnormal findings had symptoms suggesting urologic disease.[158] He concluded that patients younger than 50 years old with epididymitis did not require radiographic evaluation. Berger et al. found that no patient younger than 35 years old had concurrent genitourinary pathology, whereas 7 (58%) of 12 patients older than 35 years old with coliform infections had underlying urological pathology.[1] Kaver et al. also identified urological abnormalities only in patients older than 50 years old. [159] All abnormalities were secondary to lower urinary tract outflow obstruction. Certainly, the presence of urethritis caused by *N. gonorrhoeae* or *C. trachomatis* does not suggest that the patient has an underlying anatomic problem. In contrast, a coliform urinary infection in a male always requires investigation. Patients with epididymitis caused by coliform or *P. aeruginosa* infection should also be considered, after completion of antimicrobial therapy, for further evaluation for bacterial prostatitis (see Chapter 61), as this may be a predisposing factor to recurrent epididymitis.

Recurrence of acute epididymitis may occur and usually reflects a lack of adequate treatment, failure to identify factors predisposing to recurrence (e.g., untreated sexual partners, persisting genitourinary abnormality, etc.), or inadequate suppression of a source of chronic infection. Evaluation of these patients should address these factors.

COMPLICATIONS OF ACUTE EPIDIDYMITIS

SURGICAL COMPLICATIONS

Since the availability of effective antibiotics, the incidence of surgical complications from epididymitis has decreased. From 1951 to 1955, Gartman infrequently used antibiotics and had a 30% incidence of surgical complications.[20] From 1955 to 1959, he used antibiotics much more frequently, and had an 8% incidence of surgical complications. He noted an overall 10% complication rate in patients with "idiopathic epididymitis", and a 16% rate when a definite pathogen was found in the urine or urethra.

The most serious local complications of epididymitis are abscess formation and infarction of the testicle (Fig. 60-5).

FIGURE 60-5. Infarcted testis with infected epididymis in a man with *Escherichia coli* epididymitis.

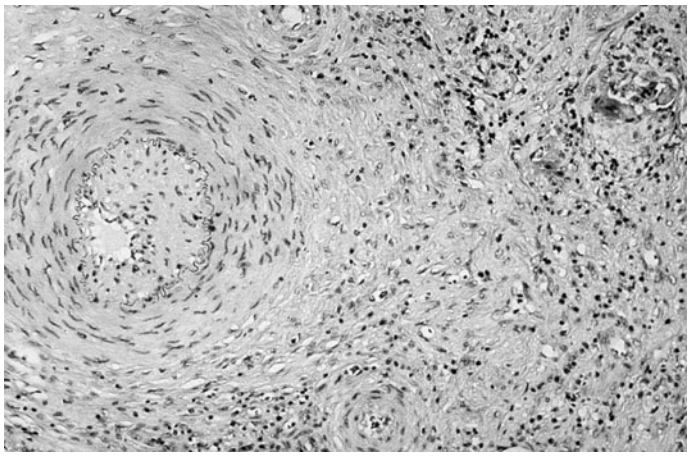

FIGURE 60-6. Thrombosed artery in spermatic cord of a man with *Escherichia coli* epididymitis.

FIGURE 60-7. Bilateral epididymitis in a young man with *C. trachomatis* infection.

Both complications are suggested by failure of the patient to improve clinically with appropriate bed rest and antibiotic therapy. Testicular infarction probably results from thrombosis of the spermatic vessels secondary to severe inflammation (Fig. 60-6).[19,160,161] Gangrene of the testicle may take place while the epididymis remains viable (Fig. 60-5). Costas suggested that the swollen spermatic cord may become compressed at the external ring and lead to vascular compromise of the testicle.[162] In Gartman's series, 3 (1%) of 310 cases resulted in gangrene of the testicle.[20] Abscess may be suggested by a "cold" area in the middle of a "hot" region on a radionuclide scan. See et al. found that serial gray scale ultrasonography revealing progressive inhomogeneity was highly correlated with the development of abscess and the need for orchiectomy.[135] In Mittemeyer's series, 19 (3%) of 610 patients developed abscesses that required surgical drainage.[14] Treatment requires surgical drainage and, often, orchiectomy. In Gartman's series, 22 (7%) of 310 patients developed hydroceles; however, only 11 of these failed to resolve after treatment of epididymitis and required surgical repair.[20]

INFERTILITY

Another complication of acute epididymitis, although poorly documented, is decreased fertility. Patients with bilateral epididymitis and bilateral occlusion of the vas deferens or epididymis have virtually no potential for fertility. In some parts of sub-Saharan Africa where urethritis often goes untreated, epididymitis is a leading cause of male infertility.[163] Campbell noted that 40% of patients with bilateral epididymitis secondary to gonorrhea were sterile.[164] Pelouze reported involuntary infertility among 11% of men with only a history of gonococcal urethritis, 23% of men with history of unilateral epididymitis, and 42% of men with history of bilateral epididymitis (Fig. 60-7).[23] Gartman reported that among 18 azoospermic men with normal testes biopsies and patent vasa deferentia, only four (22%) had histories of bilateral epididymitis, but all were found to have fine scars that transected the epididymal tubules.[20] Gerris et al. found elevated antichlamydia antibody titers in *tunica vaginalis* fluid from men with oligoasthenospermia, suggesting previous undetected chlamydial infection.[165] These data suggest that patients may have a subclinical form of epididymitis that may lead to asymptomatic scarring and decreased fertility. This intriguing observation may be analogous to the observation that in many infertile women who have bilateral tubal obstruction (many of whom have serological evidence of past *C. trachomatis* infection), only about half have a past history of salpingitis (see Chapter 56).

Since sperm transit through the epididymis is necessary for development of normal sperm function, it is possible that acute inflammation and damage to the epididymis could ultimately lead to decreased fertility even in the absence of occlusion of the epididymal tubules. Epididymal obstruction reverses spontaneously in some patients. Pelouze reported one patient who had a return of sperm and fertility after 5 years of apparent epididymal occlusion following gonococcal epididymitis.[23]

Inflammation with acute epididymitis is not limited to the epididymis but also involves the testicle. On testes biopsy during acute epididymitis, Wolin found that 20 (71%) of 28 patients had decreased spermatogenesis, and 9 (32%) of 28 had testicular inflammation.[9] Nilsson et al. did aspiration biopsies on testicles in patients with acute epididymitis, and found that 16 (73%) of 22 had inflammatory cells.[109] Follow-up biopsy of these testicles after 2–3 years showed that 5 (56%) of 9 had reduced or absent spermatogenesis. Bietz found nonspecific toxic changes in the opposite testis 150–280 days following the onset of epididymitis.[166] Osegbe found thickened basement membranes, decreased spermatogenesis, and fibrosis in the contralateral testicles of men with clinical unilateral epididymitis.[167] Both Tozzo and Berger et al. found low sperm counts in a high proportion of patients with acute epididymitis.[1,168] Ludwig followed

46 patients with unilateral epididymitis from 8 days to 1 year.[169] Initially, two-thirds had oligoesthenospermia. However, only 20% had long-term decreases in semen analysis parameters, and only one had persisting sperm agglutinins after 1 year.

Decreased fertility has been demonstrated in other unilateral testicular conditions, such as cryptorchidism and torsion.[170, 171] Whether unilateral testicular involvement in acute epididymitis can decrease fertility has not been definitively evaluated. However, several observations support this possibility. Bandhauer found that 9 (19%) of 48 men with acute unilateral epididymitis developed sperm agglutinins.[172] Ingerslev et al. found that following epididymitis, 27% of men developed serum antisperm agglutinating antibodies.[173] Heidenreich et al. and Ingerslev et al. both found that antibodies often appeared in the early period after acute epididymitis[173,174] Later, the titers usually decreased to insignificant levels. Greskovich et al. found experimentally that early antibiotic therapy suppressed the antibody response, perhaps through a direct immunosuppressive effect, or through decreased antigenic load of killed sperm secondary to eradication of infection.[175] Other studies found that men without a history of clinical epididymitis but with anti-*C. trachomatis* antibodies had a significantly greater chance (50%) of having antisperm antibodies than men without anti-*C. trachomatis* antibodies (16%).[176]

In summary, bilateral epididymitis may lead to bilateral epididymal occlusion, azoospermia, and infertility. Whether unilateral epididymitis, subclinical epididymitis, or epididymitis without occlusion, can result in infertility remains unproven.

CHRONIC EPIDIDYMITIS

Chronic epididymitis is a poorly defined clinical syndrome. Patients labeled as having chronic epididymitis account for a significant number of outpatient urology visits. Until recently, there was no clear definition of this syndrome or its clinical course. In 1966, Mittemeyer et al. reviewed 610 cases of epididymitis requiring hospitalization and reported that 15% of patients were diagnosed with chronic or recurrent epididymitis after the initial episode.[14]

A study by Nickel et al. in 2002 began to address many of the unknown or unclear aspects of chronic epididymitis, starting with the clinical definition.[177] Based on the available literature, chronic epididymitis was defined as: symptoms of discomfort and/or pain at least 3 months in duration in the scrotum, testicle, or epididymis localized to one or both epididymides on clinical examination.[177] Nickel et al. then performed a comprehensive clinical survey of 50 men meeting this definition and compared the findings to a control group. From their survey, a chronic epididymitis classification system (inflammatory, obstructive, and epididymalgia) and a symptom assessment index (based on pain and quality of life) were developed, that may provide the basis for further epidemiological and clinical studies.[177]

It remains unclear whether chronic epididymitis is related to persistence of bacteria or bacterial antigens in the epididymis or whether this syndrome reflects an ongoing immunological reaction (as occurs with chronic interstitial nephritis following some renal infections), scarring, neurological injury, or other factors. Chronic epididymitis is generally considered idiopathic and traditionally felt to be unresponsive to antimicrobial therapy, which in some instances has led to epididymectomy[178–180] and other procedures[181–184] for pain relief. Strebel et al. (Strebel RT, Luginbuehl T, Leippold T, Hauri D. Chronic Epididymitis – Management among Urologists in Switzerland, Abstract 118, American Urological Association Annual Meeting, San Antonio, May 2005) conducted a survey study of all urologists in Switzerland. The Swiss urologists see a median of five patients per month (range 1–30) with chronic epididymitis, with each patient having a mean of 2.5 visits. The treatments most often prescribed for chronic epididymitis were nonsteroidal anti-inflammatory agents and antibiotics. Of urologists surveyed, most considered surgery as the second line therapy, especially epididymectomy, "semicastration," microscopic spermatic cord dissection and dennervation. The estimated failure rates were 48% for medical treatment and 18% for epididymectomy.

Our clinical experience includes numerous patients who have failed such procedures. Thus, our current approach to chronic epididymitis is to evaluate possible contributing anatomical and infectious causes. We then evaluate the response to anti-inflammatory therapy, spermatic cord blocks using local anesthetics and/or steroids, and other measures. To our knowledge, there is little evidence-based data suggesting that a substantial proportion of patients benefits from more invasive therapies.

61 Prostatitis Syndromes: Causes, Differential Diagnosis, and Clinical Management

John N. Krieger

OVERVIEW

Although prostatitis and prostate disease have been well known since antiquity, these syndromes continue to present major diagnostic and therapeutic challenges. Prostatitis is the diagnosis given to a large group of adult men who present with a variety of complaints referable to the lower urogenital tract and perineum.[1,2] By one estimate, 50% of men experience symptoms of prostatitis at some time in their lives.[1] Data from the National Health Center for Health Statistics indicate that there were 76 office visits per 1000 men per year for genitourinary tract problems, with prostatitis accounting for approximately 25% of these visits.[3,4]

Many men remain symptomatic for prolonged periods. Patients frequently relate the onset of their condition to sexual activity, commonly to an episode of acute urethritis.[5] Antimicrobial treatment often results in transient relief of symptoms. Based on these observations, standard practice is to prescribe multiple courses of antibacterial therapy in the frequently vain hope that patients will experience lasting relief.[1,6,7] For example, in one report of 75 men with chronic prostatitis the average patient had received 10 weeks of unsuccessful antimicrobial treatment during the 3 months before evaluation.[8] Many other treatments are commonly prescribed for empirical therapy, with unproven success.

Clinical characterization of patients with prostatitis syndromes has not been carefully correlated with the pathologic classification of prostatitis.[1,7] Pathologic studies have not included sufficient clinical or microbiologic data. On the other hand, clinical studies rarely have found pathologic specimens to be helpful, probably reflecting the focal nature of the inflammatory response in patients with prostatitis.[9–11]

From a clinical standpoint, it is critical to distinguish men with lower urinary tract complaints associated with bacteriuria from the larger number of patients without bacteriuria.[7] Careful lower urinary tract localization studies classify most patients in four diagnostic groups: acute bacterial prostatitis, chronic bacterial prostatitis, chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS), and asymptomatic inflammatory prostatitis.[12–14] Considerable progress has been made in understanding the pathophysiology and developing rational approaches for treatment of patients with acute and chronic bacterial prostatitis. Unfortunately, few reliable data are available on the etiology of ether CP/CPPS or asymptomatic inflammatory prostatitis. Thus, current therapy is unsatisfactory for most patients with prostatitis syndromes. Occasionally, men develop granulomatous prostatitis, a characteristic histological reaction of the prostate to a variety of insults. Treatment of granulomatous prostatitis depends on accurate etiologic diagnosis.

HISTORY

Prostate disease, stones, obstruction, and infection were well known in antiquity. The Ebers Papyrus refers to prostatitis, urethritis, urinary retention, incontinence, and cystitis.[15] Bladder stones, often a consequence of prostatic or urethral obstruction, were found in Egyptian mummies. The ancient Egyptians used reeds, copper and silver tubes, and rolled palm leaves to treat urinary retention. This may have been due to stones or prostatic obstruction, or probably both. Practitioners who used these instruments most became known as lithologists, the first specialists in medicine.

The Hindu Vedas contain procedures to relieve obstruction caused by prostatic disease and bladder stones, which may be 4000–5000 years old. The Vedas also describe cannulas of wood and metal. Uroscopy, or examination of the urine, was a highly developed art before the time of Hippocrates (460–377 BC), who paid much attention to this examination. Herophilus of Chalcedonia, a well-known lithotomist, is credited with what is probably the earliest gross description of the prostate in his anatomic texts. Rufus of Ephesus described the "parastatus glandulus," meaning "standing before," a likely origin of the term prostate. Aristotle used the term "varicose parastatae," for what may well have been seminal vesicles.

At the beginning of the Christian era, Celsus (25 BC to 50 AD) described catheterization and urethrotomy. This procedure

would have been needed for treatment of obstruction related to prostate and urethral infection and inflammation. "Circumstances sometimes render it necessary to draw off the urine by an operation; as in retention, or when the urethra has become collapsed from old age, or when a calculus or grumous blood has produced internal obstruction; even a moderate degree of inflammation often prevents natural micturition. Now this operation is necessary not only in males, but sometimes in females, also. Hence, copper catheters are made for this purpose. The practitioner should keep by him three for men, and two for females...They ought to be somewhat curved."

By 1500, cystostomy, generally perineal, was in widespread use for removal of stones. On occasion, this approach would also treat prostatic obstruction, because it was necessary to remove portions of the prostate to obtain access to the stone (Fig. 61-1).[15] The first prostatic surgery was probably unintentional and through a perineal incision. In summary, prostatitis and urethritis were well recognized in antiquity and represented reasons for the development of medicine, surgery, and numerous specialties, especially infectious diseases, genitourinary medicine, dermatology, and urology.

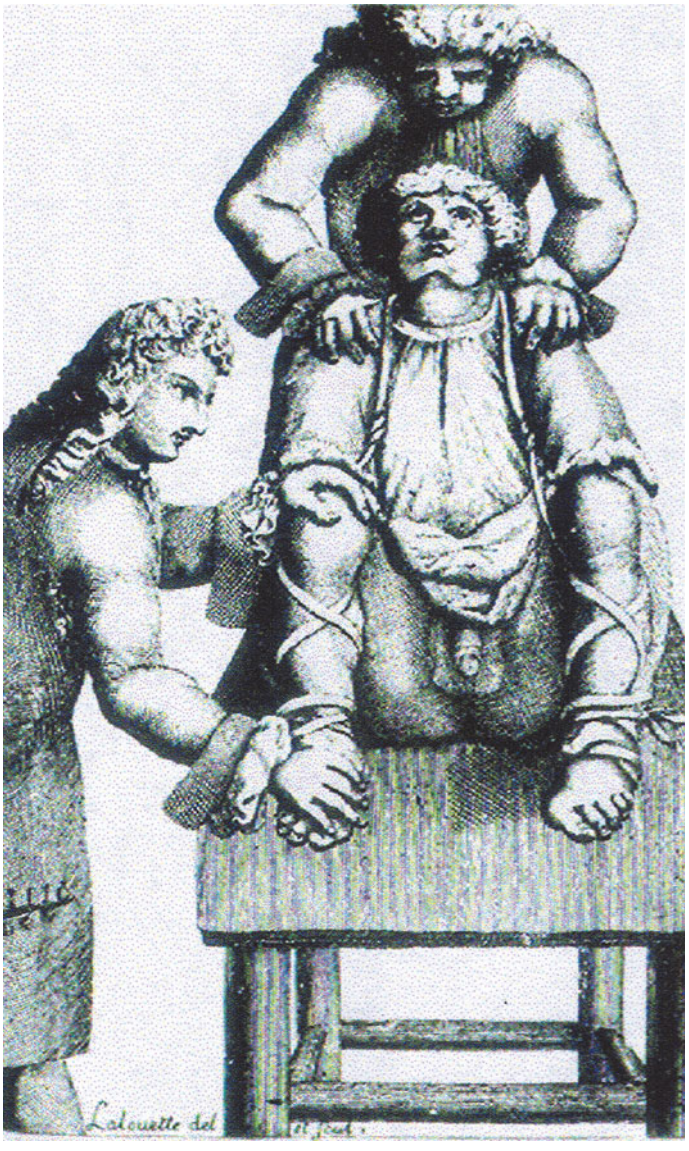

FIGURE 61-1. The arrogant Frenchman about to undergo lithotomy. Lithotomy position prior to surgery for removing a stone due to obstructing prostate adenoma. (From Tolet F. *Trait de la Lithotomie*, 4th edn. Paris, 1689; after Herman JR. *Urology: A View Through the Retrospectroscope*. Hagerstown, MD: Harper & Rowe, 1973, p. 27.) Lithotomy was developed for removal of bladder stones, usually resulting from prostatic and/or urethral obstruction due to previous infection and inflammation.

HOST DEFENSES

Prostatitis syndromes occur despite the wide variety of defenses of the male lower urogenital tract. These defenses include nonspecific mechanisms, such as mechanical factors and antimicrobial secretions, and the humoral and cellular limbs of the immune system.

NONSPECIFIC DEFENSES

Most infections of the urogenital ducts and accessory sex organs are caused by organisms that ascend through the urethra.[1] Thus, mechanical factors including urethral length, micturition, and ejaculation should provide some protection against infection, although the relative importance of such defenses is unclear. The oblique courses taken by some prostatic ducts and by the ejaculatory ducts have also been proposed as mechanical defense mechanisms.

Prostatic secretions contain several substances with activity against a wide spectrum of microorganisms.[1,16] A zinc-containing polypeptide, known as the prostatic antibacterial factor, is the most important antimicrobial substance secreted by the prostate. The prostate has higher concentrations of zinc than any other organ, and prostatic secretions of normal men contain high zinc levels.[17–21] The bactericidal activity of prostatic secretions against a wide range of Gram-negative and Gram-positive organisms is a direct function of zinc concentration. Zinc also inhibits other genital pathogens, including herpes viruses,[22,23] *Candida albicans*,[24,25] *Trichomonas vaginalis*,[6,26,27] and *Chlamydia trachomatis*.[28] Men with well-documented chronic bacterial prostatitis have significantly lower levels of zinc in their prostatic fluid than controls,[18,19] but their serum zinc levels are within normal limits.[19] It is unclear whether reduced concentrations of zinc in the prostatic secretions of men with bacterial prostatitis precede development of prostatic infection or reflect secretory dysfunction resulting from such infections.[20] Oral zinc supplements did not increase the concentration of zinc in prostatic secretions of men with bacterial prostatitis.[19]

The prostate gland secretes a number of other substances with antibacterial activity. Spermine and spermidine, which are responsible for the characteristic seminal aroma, have been studied in most detail.[21,29] These compounds possess activity primarily against Gram-positive bacteria and appear

to be of secondary significance in protecting the male lower genitourinary tract against infection.[21,30]

HUMORAL IMMUNITY

Many investigators studied the serologic responses of men with bacterial prostatitis. Sera obtained from men with acute bacterial prostatitis contain specific agglutinating antibodies against the infecting bacterial strains.[31–33] Titers remain elevated during persistent bacterial infection of the prostate, and changes in antibody titers reflect the response to antimicrobial therapy in some patients.[31,32] Controls had low titers of antibodies against Gram-negative organisms of their own fecal flora, and similar low titers are present in men whose urethras are colonized by *Escherichia coli*. Serologic studies of men with bacterial prostatitis have two significant technical limitations. First, most studies employed an assay that does not distinguish specific immunoglobulin classes. Second, some patients with well-documented bacterial prostatitis have low titers of agglutinating antibodies.[1,31]

Local immunoglobulin production by the prostate appears to be an important defense of the lower urogenital tract against infection. Prostatic secretions from men with bacterial prostatitis contain high concentrations of immunoglobulin.[34–36] Several studies demonstrated antigen-specific antibody coating of bacteria isolated from patients with prostatitis.[37,38] An indirect solid-phase radioimmunoassay was used to measure the local immunologic response in a limited number of patients with well-documented bacterial prostatitis.[39–42] The antigen-specific antibody response in prostatic secretions (predominantly secretory immunoglobulin A [IgA]) was significantly greater than the serologic response.[39,41,42] The antigen-specific IgA response in prostatic secretions persisted longer than either the prostatic IgG antigen-specific antibody or the serum antigen-specific responses.[40] Patients with nonbacterial prostatitis had a modest nonspecific increase in local class-specific immunoglobulins, whereas normal control men, with no history of urologic disease, had even lower levels of local prostatic antibodies.[42,43]

Men with prior episodes of *E. coli* bacteriuria, but with no bacteriologic evidence of prostatitis, had similar increases in antigen-specific antibody levels in their prostatic secretions.[42,43] These data suggest that bacteriuria in men may be associated with subclinical colonization of the prostate.[42–44] Comparable increases in local immunoglobulins were not detected in men with *Staphylococcus epidermidis* apparently localized to their prostates.[42] This finding suggests that Gram-positive cocci that occasionally appear to colonize the prostate (according to culture results) are predominantly urethral contaminants.

The data on immunological function in prostatitis patients with no history of bacteriuria are limited. One study compared monthly seminal fluid specimens from 35 prostatitis patients to 96 specimens from normal controls.[45] These investigators found that levels of interleukin-6 and IgA correlated with patients' clinical symptoms, consistent with an inflammatory process. Other investigators[46] found no significant difference in immune responses to the expressed prostatic secretions (EPSs) of 44 prostatitis patients without histories of bacteriuria and 25 control men.

CELLULAR IMMUNITY

Leukocytes

Presence of leukocytes characterizes many conditions of the male lower urinary tract, including cystitis, urethritis, and some prostatitis syndromes. Variations in prostatic leukocyte populations occur among men with prostatitis. Patients with acute disease have a predominance of mononuclear cells, while patients with chronic disease have few cells of the monocyte–macrophage series.[47] One longitudinal study of prostatic secretions from 106 patients with prostatitis found that inflammation resolved in most patients with acute bacterial prostatitis and was episodic in patients with chronic bacterial or abacterial prostatitis.[48] The observation of phagocytosis of abnormal sperm by leukocytes in infertile men with pyosemia suggests that leukocytes may have a functional role in inflammatory conditions of the male lower urogenital tract.[49,50] However, the clinical importance of lower urinary tract leukocytes in patients with prostatitis is currently the subject of intense controversy, as outlined below in the laboratory evaluation section.

Cytokines

Abnormal cytokine levels in EPS and/or seminal fluid occur in patients with chronic prostatitis.[51–57] EPS leukocyte count, the usual marker of inflammation measured by the traditional, qualitative method of counting leukocytes/high-powered microscopic field,[58] does not correlate with the predominant symptoms of prostatitis.[51] In contrast, quantitative assays suggest that prostatitis patients may have an imbalance toward increased proinflammatory and decreased anti-inflammatory cytokines that might correlate with pelvic pain symptoms.[51] In some men, this imbalance may result from polymorphisms at the cytokine loci.[51,54] Other data suggest that an autoimmune process might be involved, and experimental evidence indicates that this can be under hormonal influence, such as defects in the androgen receptor.[51,59–61]

PATHOLOGY

The pathologist's view of prostatitis differs markedly from the clinical picture of "prostatitis," as seen by most clinicians.[62] In the pathology literature, diagnosis and characterization of "prostatitis" is based entirely on the evaluation and

characterization of inflammatory infiltrates in prostate tissue. In clinical practice, such tissue is usually removed for diagnosis and treatment of prostate diseases, such as benign prostate hypertrophy (BPH) and cancer, or in the differential diagnosis of these conditions. Systematic evaluation of tissue removed for treatment of prostate cancer or BPH demonstrates presence of inflammatory infiltrates in almost every case, an observation that has led many investigators to hypothesize that prostatic inflammation, whether symptomatic or asymptomatic, may be important in the etiology and pathogenesis of cancers and BPH.[63–69]

Pathologically, prostatitis is usually a focal process, with areas of acute or chronic inflammatory cells in close apposition to areas with normal architecture (Fig. 61-2). Histological findings compatible with prostatitis occur commonly in adult males. In an autopsy series, McNeal[9] found evidence of prostatitis in 40 of 91 adult prostates. Two cases involved the central zone only, 24 cases involved the peripheral zone only, and 14 cases involved both zones. These data suggest that prostatitis usually arises as a focal inflammation in the peripheral zone that spills over into the periurethral zone in severe cases. Kohnen and Drach found some inflammation in 98% of 162 surgically resected hyperplastic prostates.[70] Both histological and bacteriologic evidences of prostatitis may occur without endoscopic signs of inflammation.[10] Blacklock suggests that these findings may be explained by differences in the drainage patterns of prostatic ducts.[10] The peripheral prostatic ducts tend to drain at right angles to the ejaculatory ducts and, therefore, are vulnerable to infection by organisms ascending through the urethra. In contrast, ducts draining the central zone tend to parallel the ejaculatory ducts and are more resistant to infection by organisms in the urethra.

Clinical characteristics of men with prostatitis syndromes have not been carefully correlated with pathologic criteria.[1,7] Pathologic studies rarely included sufficient clinical or microbiological data.[9,70] Conversely, clinical studies seldom found pathologic specimens helpful, reflecting the focal nature of inflammation in patients with prostatitis.[9,11] In one study, 60 men with "chronic abacterial prostatitis" had transrectal prostatic ultrasound with transperineal biopsy of abnormal areas. Histological examination revealed chronic inflammation, predominantly of low grade, in 53 (88%) of 60 patients.[71] No uropathogens were cultured. The same investigators found intraprostatic antibody deposition in men with chronic abacterial prostatitis but not in controls, suggesting an earlier active role of an infectious agent. Although the authors describe sonographic findings characteristic of "prostatitis,"[72] extensive clinical experience indicates that such grey-scale ultrasound findings lack specificity.[73–75] Other critical problems with these data include patient selection and limited attempts to correlate objective inflammation in EPSs with inflammation in prostatic parenchyma or with microbiological finding.

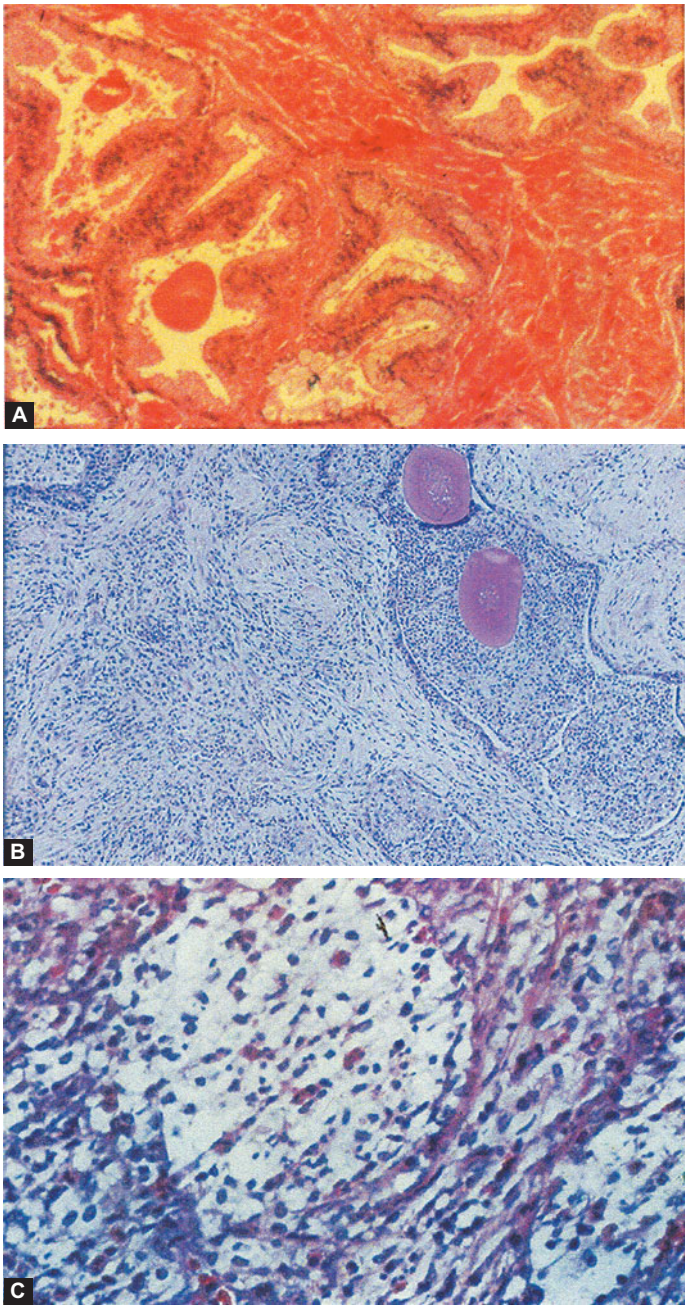

FIGURE 61-2. A. Benign prostatic adenoma (BPA) tissue removed during transurethral resection of the prostate for obstructive urinary symptoms. Note the glandular tissue with surrounding stroma (H and E stain). **B.** Chronic prostatitis. Note the intense active inflammatory infiltrate. This patient underwent prostatectomy following multiple episodes of acute urinary retention with bacterial urinary tract infection (H & E stain). **C.** Prostate biopsy showing granulomatous prostatitis. The patient had a prostate nodule suspicious for carcinoma. The biopsy revealed nonspecific granulomatous inflammation (H & E stain). (Data from Krieger JN, Nakagawa M and Nyberg LM. Epidemiology and pathogenesis of prostatitis. In: *6th International Consultation on Prostate Diseases*. Paris, France: International Consultation on Urological Diseases, 2005.)

A major difference between the clinician's view of "prostatitis" and the pathologist's diagnosis occurs in symptomatic patients with no history of bacteriuria. In one study of prostate histopathology in 368 needle biopsies from 97 patients, prostatic inflammation was detected in only 33% of patients.[62] In the

minority of patients with inflammation, 88% had only mild (less than 10 leukocytes per 1 mm field) and only 12% of the patients with inflammation had moderate (between 10 and 200) or severe (more than 200) infiltrate. Overall, only 5% of 97 patients had moderate or severe inflammation.

EPIDEMIOLOGY

We reviewed the epidemiology of prostatitis using evidence-based recommendations to identify 3848 references, including 65 that merited detailed review.[76]

INCIDENCE AND PREVALENCE OF PROSTATITIS SYMPTOMS

The nine studies included in our final analyses possessed at least four of the following five criteria[77]: (1) population based, excluding studies of referral patients from tertiary care institutions, (2) a clear and standardized case definition, (3) a standard survey strategy, (4) large enough population to provide reasonable statistical power, and (5) use of a recognized and validated survey instrument. Currently, the National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI, Table 61-1), described below, represents the most desirable survey instrument.[78] To facilitate evaluation of varied populations, the NIH-CPSI has been translated and validated for use in English,[78] Spanish,[79] Japanese,[80] Chinese,[81] Malay,[81] and German.[82] A recent population-based study documented low agreement between physician-diagnosed prostatitis and the NIH-CPSI, suggesting that the index, by itself, may have limited ability to document the presence or absence of prostatitis.[83] Thus, use of the NIH-CPSI was considered desirable but was not required for inclusion. Of the nine studies that met the inclusion criteria, five were from North America,[84–88] three were from Asia,[81,89,90] and one was from Europe[91] (Table 61-2).

The prevalence of prostatitis-like symptoms could be compared in six studies that surveyed varied ambulatory populations.[81,84,86,88–90] Of 9260 total men included in these studies, 636 participants met criteria for symptoms of prostatitis, representing an overall rate of 6.9%. In these studies, the prevalence of prostatitis symptoms ranged from 2.2%[88] to 9.7%,[86] with a median rate of 6.9%.

Three other studies met the inclusion criteria but were not directly comparable, because the studies employed different denominators or different outcome measures.[85,87,91] Collins and coworkers studied 58,955 outpatient physician visits by men >18 years old in the U.S. National Ambulatory Medical Care Survey database.[85] Randomly selected physicians completed visit forms documenting the reasons for patient visits and diagnoses. Of 58,955 visits, 5% included genitourinary symptoms. These data suggest that prostatitis was a diagnosis in 2,000,000 physician visits annually, including 700,000 visits by men 18–50 years old and 900,000 visits by men >50 years old. Of visits for prostatitis, 46% were to urologists and 47% were to primary-care physicians. Prostatitis was diagnosed in 8% of all visits to urologists and 1% of all primary-care visits. The odds of a prostatitis diagnosis were 13-fold greater for visits to urologists than for visits to primary-care physicians. Patients with prostatitis received antimicrobial therapy 45% of the time, compared to 27% of the time for patients without genitourinary symptoms.

Subsequently, this group evaluated the prevalence and correlates of prostatitis symptoms among U.S. health professionals without prostate cancer.[87] Of the 31,681 men, 16% reported a history of prostatitis. Men reporting a history of benign prostatic hyperplasia had a 7.7-fold greater odds of a history of prostatitis. Participants with severe lower urinary tract symptoms had 2.8-fold greater odds of a history of prostatitis, while men with moderate lower urinary tract symptoms had a 1.8-fold greater odds of prostatitis. Other factors associated with a history of prostatitis were a history of sexually transmitted disease (OR 1.8), stress at home (OR 1.5), and stress at work (OR 1.2). The 2163 men with prostatitis alone were younger and had less severe urinary symptoms than the 4575 men with BPH alone.

Mehik and associates determined the prevalence of prostatitis symptoms among 2500 randomly selected men living in the two most northerly provinces of Finland (Oulu and Lapland).[91] Surveys were completed by 1832 men 20–59 years old. The overall lifetime prevalence of prostatitis was 14.2%. The risk for prostatitis increased with age: Compared to 20–39-year-old men, the risk of prostatitis was 1.7 times greater for 40–49-year-old men and 3.1 times greater for 50–59-year-old men. The incidence of prostatitis was 37.8/10,000 person years. Among the 261 men who had symptoms of prostatitis, 27% suffered at least once a year, including 16% who suffered from persistent symptoms. These authors noted a seasonal variation, with 63% of participants with prostatitis experiencing their worst symptoms during the winter months. Divorced and single men had a lower risk of prostatitis than married men.

NATURAL HISTORY OF PROSTATITIS SYMPTOMS

We identified only two studies that considered the natural history of prostatitis symptoms and that met the criteria for inclusion in this systemic review.[92,93] Both studies evaluated North American patients after clinical treatment for symptoms of prostatitis.

Nickel and associates conducted a 1-year follow-up study of 40 prostatitis patients and 119 age-matched controls from Eastern Canada.[92] Fifteen men (38%) with prostatitis in the initial survey did not report similar symptoms 1 year later, while 25 men (63%) experienced persistent symptoms. Four men (3%) in the control group reported prostatitis-like symptoms in the follow-up survey. Thus, about one-third of men with prostatitis-like symptoms in this general population had

Table 61-1. National Institutes of Health Chronic Prostatitis Symptom Index[a,b]

1. In the last week have you experienced pain or discomfort in the (Yes/No):
   - Area between rectum and testicles (perineum)
   - Testicles
   - Tip of penis (not related to urination)
   - Below your waist, in your pubic or bladder area
2. In the last week have you experienced (Yes/No):
   - Pain or burning during urination
   - Pain or discomfort during or after sexual climax (ejaculation)
3. How often have you had pain or discomfort in any of these areas over the last week? (0–5 scale)
   - Never
   - Rarely
   - Often
   - Usually
   - Always
4. Which number describes your AVERAGE pain or discomfort on the days that you had it, over the last week? (0–10 scale)
   - 0 (no pain)
   - 10 (pain as bad as you can imagine)
5. How often have you had a sensation of not emptying your bladder completely after you finished urinating, over the last week? (0–5 scale)
   - Not at all
   - Less than 1 time in 5
   - About half the time
   - More than half the time
   - Almost always
6. How often have you had to urinate again less than two hours after you finished urinating, over the last week? (0–5 scale)
   - Not at all
   - Less than 1 time in 5
   - About half the time
   - More than half the time
   - Almost always
7. How much have your symptoms kept you from doing the kinds of things you would usually do, over the last week? (0–3 scale)
   - None
   - Only a little bit
   - Some
   - A lot
8. How much did you think about your symptoms, over the last week? (0–3 scale)
   - None
   - Only a little bit
   - Some
   - A lot
9. If you were to spend the rest of your life with your symptoms just the way they have been during the last week, how would you feel about that? (0–6 scale)
   - Delighted
   - Pleased
   - Mostly satisfied
   - Mixed (about equally satisfied and dissatisfied)
   - Unhappy
   - Terrible

[a]Of the nine items in the index, four concern pain or discomfort (items 1–4), three concern urinary symptoms (items 4 and 6), two concern the impact of symptoms (items 7 and 8), and one concerns quality of life (item 9). The index can be scored as a total score (maximum score of 43). Scores can also be obtained in each of three domains: pain domain (items 1–4, maximum score of 21), urinary symptoms domain (items 5 and 6, maximum score of 10), and the quality of life domain (items 7–9, maximum score of 12). (From Litwin MS, McNaughton-Collins M, Fowler FJ, Jr., et al. The National Institutes of Health Chronic Prostatitis Symptom Index: Development and validation of a new outcome measure. Chronic Prostatitis Collaborative Research Network. *J Urol* 1999;162:369–375.)

[b]Exclusion criteria for CP/CPPS include duration less than 3 months, presence of lower genitourinary tract cancer (e.g., transitional cell carcinoma, carcinoma in situ, and prostate cancer), active urinary stone disease, active genitourinary tract infection (e.g., bacteriuria genitourinary tuberculosis), gastrointestinal disorders (e.g., inflammatory bower disease and perirectal disease, such as fissure or fistula), radiation cystitis, chemical cystitis (i.e., postchemotherapy), active urethritis, acute epididymitis, acute orchitis, functionally significant urethral stricture, or neurological disease affecting the bladder.[12]

resolution after 1 year (usually those with a shorter duration and less severe symptoms). The severity of symptoms of men with persistent prostatitis symptoms remained relatively unchanged over the year.

Turner and associates studied 286 men with physician-diagnosed prostatitis in a large health-maintenance organization.[93] Interviews were conducted at baseline, 3-, 6-, and 12-month follow-up. On average, symptoms improved substantially from months 1 to 3, modestly from months 3 to 6, then remained unchanged. Men whose initial visit was for a first lifetime episode had better outcomes compared to men with a recurrent episode. Participants with more severe symptoms were more likely to report symptoms 1 year later. The authors concluded that men who make physician visits for new prostatitis episodes usually improve during the next 6 months. However, chronic or recurrent symptoms are common. Patients with previous episodes and more severe symptoms are at higher risk of chronic pelvic pain.

PROSTATITIS AS A RISK FACTOR FOR BPH AND PROSTATE CANCER

Limited epidemiological data suggest that a history of prostatitis may be associated with an increased risk of BPH and/or prostate cancer. In the health professionals' follow-up study outlined above, men reporting a history of BPH had 7.7-fold greater odds of a history of prostatitis.[87] This observation appears consistent with current concepts about symptomatic BPH. The natural history of BPH includes two phases: a pathologic phase and a clinical phase.[94] The pathologic phase may be subdivided further into two stages: a microscopic stage, developed by nearly all men if they live long enough, and a macroscopic stage, associated with enlargement. Because only half of men with microscopic prostatic hypertrophy develop macroscopic enlargement, it is likely that additional factors are necessary for progression. The second, or clinical BPH phase, involves progression of pathologic hypertrophy to clinical BPH, in which the patient develops symptoms. Of men with macroscopic prostatic hypertrophy, half progress to clinical disease. Although macroscopic enlargement of the prostate is necessary for development of clinical BPH, such enlargement is not sufficient by itself for progression. Prostatitis has been suggested as one possible factor leading to progression of pathological BPH to clinical BPH.[94] Clearly, further studies are needed to validate this theoretical connection between prostatitis and BPH.

Other epidemiologic data also suggest the possibility that prostatitis may be associated with an increased risk of prostate cancer.[95–97] Dennis and associates completed a meta-analysis evaluating available studies.[95] In this study, men with a history of prostatitis had an increased risk of prostate cancer (OR = 1.6), particularly with population-based case–control studies (OR = 1.8). This study also found an increased relative risk of prostate cancer among men with a history of syphilis and a history of gonorrhea (conditions that are also associated with prostatitis).

A recent report investigated the potential association between prostatitis and prostate cancer by reviewing the medical records of 409 residents of Olmsted County, Minnesota, with histologically proven prostate cancer and 803 matched controls.[98] The risk for prostate cancer was increased in men with history of any type of prostatitis (OR = 1.7; 95% CI = 1.1–2.6) or acute prostatitis (OR = 2.5; 95% CI = 1.3–4.7). The mean time from most recent episode

Data from Krieger JN, Nakagawa M, Nyberg LM. Epidemiology and pathogenesis of prostatitis. In: *6th International Consultation on Prostate Diseases*, Paris, France: International Consultation on Urological Diseases, 2005.

of acute prostatitis to diagnosis of prostate cancer was 12.2 years. Chronic bacterial prostatitis was weakly associated with prostate cancer (OR = 1.6; 95% CI = 0.8–3.1), while CPPS was not.

Although these associations suggest that prostatitis may represent one mechanism through which BPH and prostate cancer develop, causality is unclear. This is because recall bias and detection bias cannot be ruled out.[96] Self-reporting and review of medical records are the most common methods used to assess past exposures. However, studies have shown that such information may not be consistent. This problem appears to be especially common with prior genitourinary diseases that have less explicit diagnostic criteria, such as BPH and prostatitis.[99] These observations suggest that prostatitis may increase the risk of both BPH and prostate cancer but that additional studies are necessary to verify that there is indeed a biological relationship between these conditions.

These observations are controversial. For example, a recent study of the epidemiology of prostate cancer used random digit dialing to select a group of aged-matched controls aged 40–64 years without prostate cancer.[100] The "control group" was then divided into those who reported a diagnosis of prostatitis (cases) and those who denied ever having had prostatitis (controls). Of the 645 control men with no history of prostate cancer, 58 (9.0%) reported a prostatitis diagnosis. The prostatitis cases more frequently reported urinary ($P \leq 0.05$) or urethral infections ($P \leq 0.01$) before diagnosis. Men with prostate cancer reported a diagnosis of prostatitis more often than the noncancer controls (13.6% vs. 9.0%), but after controlling for the number of prostate-specific antigen tests this difference disappeared. Clearly, further studies are needed to determine whether prostatitis (symptomatic or asymptomatic) is indeed a risk factor for either BPH or prostate cancer.

LABORATORY ASSESSMENT

MICROBIOLOGY

Uropathogenic bacteria

The critical clinical issue is to distinguish patients with lower urinary tract complaints associated with bacteriuria, i.e., patients who may have bacterial prostatitis, from the larger number of patients without bacteriuria.[1,20] Careful studies have shown that <10% of men, given the clinical diagnosis of "prostatitis," have bacterial prostatitis.[8] Further classification of patients with prostatitis is based on careful bacteriologic assessment of the lower urinary tract, preferably using the technique of Meares and Stamey.[101,102] This method is based on cultures of sequential specimens that are obtained during micturition (Table 61-3).

Attention to several technical points is necessary to assure useful and reliable information.[1,2,7,102] Precise bacteriologic methods and rapid transport to the laboratory are critical. The midstream urine should be sterile during the localization procedure. The prepuce of uncircumcised men should be retracted, the glans cleansed, and the soap removed because small amounts of detergent may falsely reduce bacterial counts. It is important to collect the initial few drops of the first-void urine (VB_1) specimen, since the bacterial concentrations may be significantly reduced a few milliliters later. Finally, it may be necessary to repeat the localization procedure for men with inconclusive findings.

Table 61-3. Procedure for Localization of Infection in the Male Lower Urinary Tract by Use of Segmented Urine Cultures

Specimen	Abbreviation	Description
Voided bladder 1	VB_1	Initial 5–10 mL of urinary stream
Voided bladder 2	VB_2	Midstream specimen
Expressed prostatic secretions	EPS	Secretions expressed from prostate by digital massage after midstream specimen
Voided bladder 3	VB_3	First 5-10 mL of urinary stream immediately after prostate massage

Terminology is from Drach GW, Meares EM, Jr., Fair WR, Stamey TA. Classification of benign disease associated with prostatic pain: Prostatitis or prostatodynia? *J Urol* 1978;120:266.

Unequivocal diagnosis of bacterial prostatitis requires that the colony count in the postmassage (VB_3) specimen exceed the count in the first-void (VB_1) specimen by at least 10-fold.[1,7,12,101,102] However, many men with chronic bacterial prostatitis harbor only small numbers of bacteria in their prostates. Direct culture of the prostatic secretions is useful in this situation.[1,101,103] Often the colony counts in the EPS specimens are 1 or 2 logs higher than comparable counts in the VB_3 specimen. This difference reflects dilution of the small volume of prostatic secretions by urine in the VB_3 sample. A prominent characteristic of bacterial prostatitis is that the organism present in VB_3 or in EPS in significantly greater numbers than in the VB_1 may be isolated on multiple occasions and is identical to the uropathogen-causing episodes of bacteriuria.[101,103]

Under certain circumstances, lower urinary tract localization studies may be misleading.[3] False impressions concerning excessive concentrations of leukocytes in the EPS occur in urethral disorders, such as urethritis, strictures, condylomata, or diverticula; or in men with noninfectious conditions of the prostate, such as uninfected prostatic calculi; or after

ejaculation.[104] Isolated analysis or culture of the ejaculate without concomitant study of urethral and bladder specimens may be more misleading than isolated examination of prostatic secretions.[3] Semen contains fluids from several accessory glands besides the prostatic fluid. Further, cytological examination of semen is complicated by the difficulty of distinguishing immature sperm from leukocytes.[1,3]

Organisms not cultivated on routine urine cultures

Many other infectious agents, including sexually transmitted infections, have been implicated in prostatitis. These data are considered in the section below considering the etiology of CP/CPPS. Thus, it appears critical to consider an individual patient's risk factors and whether he has evidence or urethritis with appropriate diagnostic testing.

■ LEUKOCYTE EVALUATION

Microscopic evaluation of the EPS has traditionally been recommended to identify inflammation.[1,2,20] Presence of leukocytes and "oval fat bodies" (large lipid-laden macrophages) is characteristic of the prostatic inflammatory response. Various criteria have been used by researchers to define an abnormal number of leukocytes.[1,105,106] Most investigators agree that >20 leukocytes per high-power microscopic field (hpf) represent significant inflammation. Many reports use a criterion of $\geq$ 10 leukocytes/hpf.[2,20,105,107] There appears to be little value in counting the numbers of leukocytes in the EPS of men with objective evidence of urethral inflammation, especially among men at risk of sexually transmitted diseases.[7] Thus, we examine a urethral smear for inflammation, before proceeding with a lower urinary tract localization study.[8,58,102,108] Further, it is clear that the traditional method of counting leukocytes/hpf in an EPS wet mount is inaccurate compared to determining leukocyte concentrations in a counting chamber.[106] Recent studies comparing EPS wet mount to counting chamber concentrations have shown that the wet mount is especially inaccurate for distinguishing inflammation for patients with $\leq$20 EPS leukocytes/hpf.[58,108]

■ CONTROVERSIES

Gram-positive bacteria in prostatitis

Long-standing controversies surround the role of Gram-positive bacteria in prostatitis, whether (and how) to evaluate lower urogenital tract inflammation. Isolation of Gram-positive organisms, such as staphylococci and diphtheroids, that appear to "localize" to the prostate is a major source of confusion to clinicians and in the literature.[1,20,109,110] In most cases, such patients have neither a history nor a bacteriologic documentation of bladder infection with these organisms.[1,20,02] Technical problems, e.g., failure to collect the initial portion of the VB_1, or having some of the detergent used to cleanse the glans fall into the collection bottle for the VB_1, account for part of the problem.[1] Further, the VB_1 is the control for the VB_3. The EPS is useful in borderline cases only. Relying on the EPS may introduce some artifacts, since prostatic fluid may acquire organisms during transit through the urethra, especially if the EPS drops "hang" at the fossa navicularis.

Some authorities maintain that Gram positives are pathogens responsible for patients' symptoms when these bacteria increase by at least 10-fold (e.g., "localize") in quantitative cultures of "prostate-specific" specimens (EPS or VB_3).[111,112] Antimicrobial therapy is recommended to resolve "chronic bacterial prostatitis" and to ameliorate patients' symptoms. Others maintain that Gram positives rarely cause bacteriuria and that Gram-positive localizations usually represent non-pathogens that do not cause patients' symptoms.[1] To help resolve this issue, one recent study determined the rate of Gram-positive localizations in 470 chronic prostatitis patients and whether repetitive cultures demonstrated consistent localization of Gram-positive bacteria.[113] Tenfold increases in the concentrations of Gram-positive bacteria were noted when postprostate massage (VB_3) or EPS cultures were compared with first-void urine (VB_1) cultures from 29 patients (6%). This was similar to the 7% rate of Gram-negative chronic bacterial prostatitis. Of the 29 patients with Gram-positive localizations, 27 (94%) did not have consistent localization of Gram-positive species. These findings suggest that Gram-positive bacterial localization results were seldom reproducible in untreated patients. Gram-positive localizations may represent nonpathogens, transient bacterial colonization of the lower urinary tract, or intermittent shedding of prostatic pathogens. These limitations of traditional cultures highlight the need for better diagnostic approaches and improved recommendations for antimicrobial therapy.[113]

■ LEUKOCYTE EVALUATION

It is appealing to think that patients with objective evidence of inflammation differ from patients without inflammation. Traditionally, emphasis was limited to evaluation of the EPS.[1–3,16,40,102,105,114] The traditional classification of prostatitis classified patients with no history of bacteriuria and leukocytes in their EPS as having "nonbacterial prostatitis" to distinguish them from those with no evidence of inflammation in their EPS, termed "prostatodynia." However, despite more than 20 years of effort, no clinical difference either in etiology or in response to therapy was demonstrated between these two populations.

This lack of progress provided a major impetus, supporting reevaluation of the traditional classification scheme leading to development of the NIH consensus classification, emphasized in this chapter.[12,13,115] One critical aspect of these new prostatitis initiatives was expansion of the definition of

Table 61-4. NIH Consensus Classification of Prostatitis Syndromes[12-14]

Prostatitis Category	Systemic Illness[a]	Bacteriuria[b]	Inflammation[c]	Abnormal Prostate Examination[d]
I. Acute bacterial	+	+	+	+
II. Chronic bacterial	+/–	+	+	–
III. Chronic prostatitis/ chronic pelvic pain syndrome				
a. Inflammatory subtype[e]	–	–	+	–
b. Non-inflammatory subtype[f]	–	–	–	–
IV. Asymptomatic inflammatory	–	–	+	+/–

[a]Systemic findings frequently include fever and rigors and may include signs of bacteremia.

[b]Bacteriuria documented with the same organism that can be shown to localize to a prostatic focus of infection when the midstream urine culture is negative.

[c]Elevated concentrations of leukocytes in the expressed prostatic secretions, semen, postprostate massage urine, prostate tissue or semen.

[d]Abnormal prostate examination findings include exquisite tenderness and swelling that may be associated with signs of lower urinary tract obstruction. In asymptomatic patients, a prostate nodule may prompt biopsy.

[e]Formerly termed nonbacterial prostatitis (when limited to examination of the prostatic secretions).

[f]Formerly termed prostatodynia (when limited to examination of the prostatic secretions).

urogenital tract inflammation to include patients with increased concentrations of leukocytes in their EPS, postprostate massage urine (VB_3), or semen in a new "inflammatory" subtype (Table 61-4). Studies using a counting chamber and special stains to determine leukocyte concentrations in 100 chronic prostatitis patients found poor correlation between inflammation in the EPS and inflammation in the seminal fluid.[116] Another study of 235 subjects with symptoms of chronic prostatitis found that, compared with an examination of a urethral swab specimen, examination of either first-void urine or midstream urine had low sensitivity for detecting urethral inflammation. Thus, our preference is to examine both the EPS and the VB_3 proved best for detecting prostatic fluid inflammation. Combining the urethral smear with lower urinary tract localization ("four-glass test") represents an optimal approach for detecting urethral and prostatic inflammation.[58,108]

The critical question is to determine whether there is any clinical difference in the inflammatory response between prostatitis patients with inflammation and those with no evidence of inflammation. For example, the NIH Chronic Prostatitis Cohort Study evaluated 488 men.[115] Although 50% of participants had urethral leukocytes, they were not evaluated for recognized urethral pathogens. The prevalence of inflammatory chronic prostatitis ranged from 90% to 54%, depending on the composite set of cut-points. In a subsequent study, these investigators compared leukocyte counts and bacterial localization rates for 463 men enrolled in the NIH chronic prostatitis Cohort Study and 121 age-matched men without urinary symptoms.[117] Men with Chronic Prostatitis had statistically higher leukocyte counts in all segmented urine samples and EPS, but not in semen compared to asymptomatic control men. However, the control population also had a high prevalence of leukocytes. These investigators questioned the clinical usefulness of the standard four-glass test as a diagnostic tool. Thus, the optimal diagnostic approach to patients with chronic prostatitis is an area of intense debate.

CLASSIFICATION OF PROSTATITIS SYNDROMES

Until the last decade, the characteristic symptoms of prostatitis were poorly defined.[118,119] This situation changed dramatically following general acceptance of the concept that most cases of prostatitis are diagnosed clinically, based on patients' symptoms rather than physical findings or laboratory tests.

The preferred classification of prostatitis syndromes was developed by an NIH-sponsored conference that includes four categories: acute bacterial prostatitis, chronic bacterial prostatitis, chronic prostatitis/chronic pelvic pain syndrome CP/CPPS and asymptomatic inflammatory prostatitis (Table 61-4).[12] In addition, some patients develop granulomatous prostatitis, a category that is not considered specifically in the consensus classification.

ACUTE BACTERIAL PROSTATITIS (CATEGORY I)

Acute bacterial prostatitis is an acute, symptomatic bacterial infection of the prostate associated with bacteriuria and often with systemic signs and symptoms. Patients have evidence of an inflammatory response in their prostatic secretions and semen and often have an abnormal prostate on digital rectal examination.

CHRONIC BACTERIAL PROSTATITIS (CATEGORY II)

Chronic bacterial prostatitis is a persistent bacterial infection of the prostate gland that results in recurrent episodes of bacteriuria. During acute exacerbations, patients may have systemic symptoms, but this is uncommon. Inflammation characteristically occurs in the prostatic secretions. Patients seldom have an abnormal prostate on examination.

CHRONIC PROSTATITIS/CHRONIC PELVIC PAIN SYNDROME (CP/CPPS) (CATEGORY III)

Patients with CP/CPPS account for the largest population of patients presenting with prostatitis symptoms. Characteristic complaints include a variety of perineal and pelvic symptoms, voiding, and sexual dysfunction. These men have no history of bacteriuria and lack objective evidence of bacterial infection of their prostatic secretions on careful localization studies. On examination, their prostate glands are usually normal.

Currently, two subtypes of CP/CPPS are distinguished. There is an inflammatory subtype (category III a), characterized by objective evidence of inflammation in the prostatic secretions, postprostate massage urine, or semen. Patients with no evidence of inflammation in any of these specimens/samples are classified as having noninflammatory CP/CPPS (category III b).

ASYMPTOMATIC INFLAMMATORY PROSTATITIS (CATEGORY IV)

The consensus classification includes a category for patients who have histological evidence of prostatic inflammation. These patients often do not have symptoms associated with other prostatitis syndromes. Asymptomatic prostatic inflammation is usually diagnosed for patients with elevated prostate-specific antigen levels who undergo prostate biopsy to rule out prostate cancer, examination of prostate tissue removed for treatment of bladder outlet obstruction, or patients undergoing evaluation for infertility.

GRANULOMATOUS PROSTATITIS

Although not formally noted in the NIH consensus classification, granulomatous prostatitis represents a distinct and important prostatitis syndrome. Granulomatous prostatitis represents the characteristic histological reaction of the prostate to a variety of insults. Some patients have symptoms, while others present with a nodular prostate or with bladder outlet obstruction. Accurate diagnosis is important because any cases are related to infections requiring specific antimicrobial therapy.

CLINICAL MANIFESTATIONS, TREATMENT, AND COMPLICATIONS

The sections below consider diagnosis, clinical management, and potential complications of the major prostatitis syndromes.

CATEGORY I. ACUTE BACTERIAL PROSTATITIS

Acute bacterial prostatitis is characterized by the abrupt onset of symptoms and dramatic findings on physical examination. Laboratory findings include bacteria in the midstream urine, EPS, and post-massage urine passed after prostatic massage. Most patients respond readily to appropriate treatment, and the disease is self-limited in most cases. Rarely, patients develop complications, such as urinary retention, chronic bacterial prostatitis, prostatic abscess, or granulomatous prostatitis.

Clinical presentation

Acute bacterial prostatitis is seldom a subtle or difficult diagnosis.[1,20,103] Characteristic symptoms are those associated with lower urinary tract infection, such as increased urinary frequency, urgency, and dysuria. Patients may also complain of bladder outflow obstruction due to acute edema of the prostate. Signs of systemic toxicity are common and may include fever, malaise, and myalgias. Physical examination may show a high temperature and lower abdominal or suprapubic discomfort due to bladder infection or urinary retention. The rectal examination is frequently impressive, with an exquisitely tender, tense, "hot" prostate on palpation. Urinalysis is abnormal with pyuria, and cultures will be positive for Gram-negative aerobic rods or *Streptococcus faecalis*. Systemic leukocytosis is common, with increased numbers of segmented cells. Bacteremia may be present spontaneously or may result from vigorous rectal examinations.

Treatment

Antimicrobial therapy usually results in dramatic improvement of signs and symptoms of acute bacterial prostatitis. Many drugs that do not penetrate into the prostate under normal conditions have proven effective for treating acute bacterial prostatitis.[1,20] Thus, drugs appropriate for treatment of bacteremia caused by Enterobacteriaceae, pseudomonads, or enterococci should be started after specimens have been obtained for urine and blood cultures. For men who require hospitalization, conventional therapy is the combination of an aminoglycoside plus a beta-lactam drug.[3,7] However, the fluoroquinolones or third-generation cephalosporins represent attractive alternatives for monotherapy.[120,121] For men with

less severe infections, the conventional choice is the combination of trimethoprim and sulfamethoxazole.[1,20] However, the fluoroquinolones have proven useful as oral therapy for patients with acute bacterial prostatitis who do not require hospitalization, with most data being available for ciprofloxacin and levofloxacin.[112,122–126]

Patients with acute urinary retention require bladder drainage. In this situation, placement of a suprapubic cystostomy tube, either using a percutaneous trocar apparatus or by open surgery, is preferred. An indwelling transurethral catheter would pass through and obstruct drainage of the acutely infected prostate, increasing the risk for bacteremia and prostatic abscess.[1,7] However, there has never been a direct comparison between suprapubic and transurethral catheterization in this situation. Some authorities suggest that a transurethral catheter may work well in the absence of persistent fever or signs, suggesting a possible prostatic abscess.[127] General measures, including hydration, analgesics, and bed rest, are also indicated.[1,7,20,103]

Complications

A few patients with acute bacterial prostatitis experience complications.[1,6,121] Chronic bacterial prostatitis occasionally follows an episode of acute bacterial prostatitis. Men with chronic bacterial prostatitis often remain asymptomatic between acute episodes of bacteriuria.

Prostatic abscess is a rare complication among patients who receive appropriate antimicrobial therapy for acute bacterial prostatitis.[6,7,121,128,129] In one series of 28 patients referred for persistent fever following treatment for acute bacterial prostatitis, transrectal ultrasonography detected only two prostatic abscesses (7%).[130] The classical presentation of prostatic abscess is a fluctuant area in the prostate that is felt during rectal examination.[128,131,132] However, many patients present with more subtle findings. Transrectal ultrasound and computerized tomography are especially valuable for diagnosis of prostatic abscess in men with such subtle findings.[133–136] Treatment includes drainage of the abscess, using a perineal, percutaneous, or transurethral approach, besides appropriate antimicrobial therapy.[135,136] In most situations, the transurethral approach is optimal.

Granulomatous prostatitis may occur during resolution of an episode of acute bacterial prostatitis.[1,137] Usually, the patient is asymptomatic but has a hard area on rectal examination that arouses the suspicion of carcinoma. Areas of prostatic infarction may also complicate acute bacterial prostatitis. Such areas usually present as firm portions of the prostate, and their chief importance lies in the differential diagnosis of carcinoma.

CATEGORY II. CHRONIC BACTERIAL PROSTATITIS

Although chronic bacterial prostatitis is uncommon, it is critical to distinguish these patients. Chronic bacterial prostatitis is an important cause of bacterial persistence in the male lower urinary tract.[1,20,103] Patients characteristically experience recurrent episodes of bacteriuria caused by the same bacterial species.[1,102] It has been stated that the most common cause of relapsing urinary tract infections in adult men is the persistence of small numbers of bacteria in the prostate.[1] Patients are often asymptomatic between episodes of bladder bacteriuria. The prostate gland is usually normal on either rectal or endoscopic evaluation. Thus, careful lower urinary tract localization studies are critical for diagnosis of chronic bacterial prostatitis.[101] Diagnosis based solely on symptoms, numbers of leukocytes in EPS or semen, or prostate biopsy is inadequate. Appropriate antimicrobial therapy results in cure or amelioration of symptoms for the great majority of patients.

Clinical presentation

Men with chronic bacterial prostatitis occasionally present with signs of a systemic illness. Small numbers of bacteria in the prostate do not cause systemic illness. However, with acute exacerbations, bladder bacteriuria and secondary sepsis may result from the prostatic focus of infection. This is especially true among older men, who may have the combination of prostatic obstruction and infection.

Traditional thinking is that Gram-negative rods, Enterobacteriaceae, and pseudomonads are, by far, the most important pathogens in chronic bacterial prostatitis.[1,20,102,103] Gram-positive cocci, such as *S. faecalis or Staphylococcus saprophyticus*, may be the etiologic organisms in a few cases.[20,138] Reports implicating many other organisms in the etiology of chronic bacterial prostatitis are difficult to evaluate because of methodological problems with case definitions, lack of documentation of bacteriuria caused by the alleged pathogen, or lack of an immunological response by the prostate.[3,7,46,139]

This traditional view of the critical organisms has been challenged. First, electron microscopic studies suggest that some Gram-positive bacteria may be identified in intraprostatic biofilms in a few patients with antibiotic-refractory prostatitis.[140–143] Second, some investigators consider Gram-positive bacteria to be pathogens meriting antimicrobial therapy, if these organisms are shown to localize to the prostate on segmented cultures, despite absence of bacteriuria.[111,112] Third, Gram positives represented the preponderance of bacterial species treated in studies, leading to FDA approval of trovafloxacin, gatifloxacin, and levofloxacin for treatment of chronic bacterial prostatitis.[112]

Chronic bacterial prostatitis is associated with secretory dysfunction of the prostate gland.[20] Alterations include increased pH of prostatic secretions, changes in the ratio of LDH isozymes, and secretion of immunoglobulins. Other changes include decreased specific gravity of prostatic secretions, prostatic antibacterial factor, cation concentrations

(zinc, magnesium, and calcium), citric acid, spermine, cholesterol, acid phosphatase, and lysozyme. These findings suggest that bacterial prostatitis is associated with a generalized secretory dysfunction of the prostate gland.

Men with chronic bacterial prostatitis characteristically have episodes of symptomatic bladder bacteriuria caused by the same organism; these episodes are separated by asymptomatic intervals of varying length.[1,20] Lower tract localization studies during episodes of bladder bacteriuria are worthless[1,101]; patients must be evaluated when their midstream urine is sterile. Occasionally, it may be necessary to eradicate organisms present in the bladder urine and urethra with drugs, such as penicillin G or nitrofurantoin, to obtain diagnostic localization studies.[1]

Medical therapy

Medical management is effective in curing or suppressing bacterial prostatitis.[1,3,121] Effective antimicrobial therapy for localized bacterial infections depends on achieving sufficient levels of an appropriate drug at the infected site. Unfortunately, many drugs penetrate prostatic parenchyma poorly[114,144] and may even be less useful if the prostate gland contains bacteria within infected biofilms.[141] Other antimicrobials, such as erythromycin, which achieve good tissue levels, have an inappropriate spectrum for the pathogens in prostatitis.[2]

Trimethoprim–sulfamethoxazole is the traditional "gold standard" for treating chronic bacterial prostatitis.[3,121] Trimethoprim has two useful characteristics: It achieves adequate levels in prostatic parenchyma and is effective against the common bacterial pathogens. Available studies usually employed the combination of trimethoprim and sulfamethoxazole for men with well-documented chronic bacterial prostatitis. Long-term therapy with trimethoprim (80 mg) plus sulfamethoxazole (400 mg) taken orally twice daily for 4–16 weeks was superior to shorter treatment courses.[145,146] Follow-up studies showed that such long courses result in symptomatic and bacteriologic cure in approximately one-third of patients, symptomatic improvement during therapy in approximately one-third of patients (who relapse after stopping treatment), and no improvement in the remaining patients.[20,145–148] Single-agent treatment using trimethoprim alone has been studied less well. In theory, trimethoprim alone should produce comparable results to combination therapy, since sulfamethoxazole diffuses poorly into the prostatic parenchyma.[2,77]

During the last decade, considerable success has been reported using several newer fluoroquinolones to treat chronic bacterial prostatitis. In contrast to the beta-lactams, concentrations of many fluoroquinolones are high in prostatic fluid, in prostatic tissue, and in seminal fluid, compared to blood plasma levels.[124,125,149–152] Good results have been reported for men with chronic bacterial prostatitis, including some patients who failed therapy with trimethoprim–sulfamethoxazole.[124,125,149–151] Promising results have been described with a number of agents, including norfloxacin, ciprofloxacin, ofloxacin, enoxacin, temafloxacin, gatifloxacin, trovafloxacin, and levofloxacin.[123–126,150,151,153,154] Available studies are difficult to compare because investigators used varying diagnostic criteria, there was a considerable range in duration of treatment and of follow-up, and few studies compared effective agents. Because relapse rate is the critical issue for evaluating treatment of prostatitis, patients cannot be considered cured without long-term follow-up. On balance, the newer quinolone agents appear to provide the best results.[155,156] The largest clinical and clinical trials experience is with ciprofloxacin,[157] for which excellent, long-term data are available,[122] and with levofloxacin,[155,156] which has recently been approved by the FDA for this indication (Table 61-5).

Many other orally administered antimicrobials have been used to treat patients with chronic bacterial prostatitis. Most reports are hampered by imprecise case definitions, lack of sufficient microbiologic documentation or follow-up, or an abundance of patients "infected" with organisms generally considered urethral contaminants. Although it is difficult to draw definitive conclusions, the indanyl ester of carbenicillin,[158,159] doxycycline,[160] rosamicin,[161] erythromycin plus urinary alkalization with bicarbonate,[162,163] or drug combinations employing rifampicin plus trimethoprim[164] might prove useful for selected patients. Some investigators report success using aminoglycosides, administered parenterally[1] or by local injection into the prostate[165,166] for men with prostatitis who failed oral therapy.

Bacteria isolated from men with chronic bacterial prostatitis are generally antimicrobial-sensitive strains, even after multiple symptomatic episodes and prolonged courses of therapy.[1,7,20] However, these bacteria tend to have multiple virulence factors characteristic of invasive uropathogens.[167–171] Although bacterial resistance is seldom a major problem in chronic bacterial prostatitis, an infected prostate may become the focus of a persistent infection with recurrent bouts of bacteriuria and a risk for blood stream infection. Although often identified in the prostates of asymptomatic men,[75,172] some studies suggest that calculi occur more often among men with chronic bacterial prostatitis. Infection of prostatic stones may serve as a persistent focus for bacteria that is difficult to eradicate with antimicrobial agents.[3,173–177] Other reasons offered for the difficulty in curing chronic bacterial prostatitis include difficulties in achieving high levels of drug in areas of infection within the prostate, changes in the pH of the prostatic fluid associated with infection that influence the diffusion of drugs into the prostate,[178–180] and presence of biofilms[140,141] that protect bacteria from antimicrobial agents.

Men with chronic bacterial prostatitis who are not cured by antimicrobial therapy may be rendered asymptomatic by long-term suppressive treatment, using low-dosage antimicrobial agents.[1,20] Since most patients are asymptomatic between episodes of bacteriuria, the goal of suppressive therapy is to

Table 61-5. Prostatitis Treatment Strategies[a]

Category	*First-Line*	*Second-Line*	*Other*	Evidence
I. Acute bacterial prostatitis	Antimicrobial Fluroquinolone	Antimicrobial Trimethoprim-sulfamethtoxazole	Bladder drainage Supportive	Case series, multiple
II. Chronic bacterial prostatitis	Antimicrobial Fluoroquinolone	Antimicrobial Trimethoprim-sulfamethoxazole	Antimicrobial Suppression Various drugs	Case series, multiple
III. Chronic prostatitis/ chronic pelvic pain syndrome	Antimicrobial Fluoroquinolone–newly diagnosed	Alpha–blocker	Various	Case-series-variable results Expert opinion
IV. Asymptomatic inflammatory prostatitis	No therapy	Antimicrobial	Anti-inflammatory	Debate among Experts
Granulomatous	Antimicrobial Depending on etiologic agent	None-if asymptomatic with nonspecific findings		Case reports, small series

[a]Please refer to appropriate sections of the text for discussion of the diagnosis and treatment strategy for each category.

prevent symptomatic episodes, despite persistence of bacteria in the prostate. Very low doses of agents are remarkably effective in preventing episodes of symptomatic bladder bacteriuria among men with chronic bacterial prostatitis. Available drugs include penicillin G, tetracyclines, nitrofurantoin, naladixic acid, cephalexin, or trimethoprim–sulfamethoxazole.

The data above form the basis of a rational approach to antimicrobial therapy for men with chronic bacterial prostatitis (Table 61-5). It is important to document a prostatic source of organisms causing bacteriuria by careful lower urinary tract cultures. If cultures indicate chronic bacterial prostatitis, then a prolonged course of therapy should be employed in an effort to cure the infection, using an appropriate drug that achieves good levels in the prostate. During and after such therapy, lower urinary tract studies should be repeated to evaluate the therapeutic response. A second course of treatment using a different drug or a drug with a different mechanism of action may be indicated for men with a persistent focus of prostatic infection. Men who are not cured may be treated with long-term, low-dose, suppressive medication, to prevent colonization of the bladder and urethra with organisms from the prostate.

Surgical therapy

Surgery has a limited role in the treatment of patients with chronic bacterial prostatitis. Although complete surgical removal of the prostate by radical prostatectomy or cystoprostatectomy will cure bacterial prostatitis,[1] such surgery is a major undertaking that is associated with a significant incidence of complications. Thus, radical surgery is best reserved for patients with localized prostate cancer. For the rare men who have both carcinoma of the prostate and chronic bacterial prostatitis, radical prostatectomy may cure both conditions.

Subtotal prostatectomy (transurethral, retropubic, suprapubic, or visual laser ablation) is the most common procedure for treating benign prostate disorders. These procedures remove periurethral adenomatous tissue, leaving the surgical capsule of the prostate. The observation that most bacteria appear to be located in the peripheral prostatic tissue may explain why subtotal prostatectomy cures only about a third of patients with well-documented chronic bacterial prostatitis.[1,20,181] Therefore, transurethral or open surgical procedures for removal of prostatic adenomas are best reserved for patients who have symptoms of lower urinary tract obstruction that persist after sterilization of the midstream urine.

Occasional studies report higher cure rates using transurethral resection to remove infected prostatic calculi and periurethral adenoma in men with chronic bacterial prostatitis.[182–184] "Radical" transurethral resection is necessary to remove all infected stones, because the peripheral zone of the prostate contains the greatest foci of infection and stones.[10,177] The populations in most reports were defined poorly, and bacteriologic evaluation and follow-up were often inadequate to document the conclusion that 70–100% of patients were "cured."

Rare patients with chronic bacterial prostatitis associated with other obstructive lesions, e.g., urethral stricture disease, may benefit from surgery combined with antimicrobial therapy. Before recommending surgery, it is essential to document the functional significance of such lesions by appropriate urodynamic and radiographic studies when the patient is not bacteriuric.

CATEGORY III. CP/CPPS

A wide variety of infectious and noninfectious causes have been implicated in the literature, but the etiology of this condition has been poorly defined. Men with recognized uropathogens respond to specific treatment, but therapy is empirical and ineffective for many patients. Fortunately, the quality of treatment studies has improved dramatically, reflecting the development of standard diagnostic and outcome criteria.

Clinical presentation

CP/CPPS represents the largest category of patients presenting with prostatitis, accounting for more than 90% of patients evaluated.[185,186] These patients have no history of bacteriuria and lack objective evidence of bacterial infection of their prostatic secretions on careful lower urinary tract localization studies (Table 61-4).[12,187,188] Until recently, the characteristic symptoms were defined poorly.[118] However, a number of investigators have confirmed the observation that pelvic pain complaints represent the most characteristic symptoms, often with prominent voiding symptoms and sexual dysfunction.[118] These observations led to development of the National Institutes of Health Chronic Prostatitis Symptoms Index (NIH-CPSI) (Table 61-1).[78] This instrument has now been validated in multiple languages and populations.[79–82,92] Of the nine items in the index, four concern pain or discomfort (items 1–4), three concern urinary symptoms (items 4 and 6), two concern the impact of symptoms (items 7 and 8), and one concerns quality of life (item 9). The index can be scored as a total score (maximum score of 43). Scores can also be obtained in each of three domains: pain domain (items 1–4, maximum score of 21), urinary symptoms domain (items 5 and 6, maximum score of 10), and the quality-of-life domain (items 7–9, maximum score of 12). At this time, the precise NIH-CPSI cutpoints for diagnosis and the appropriate outcome for clinical trials remain the subjects of active investigation.

Sickness impact

Standardized interviews and psychological testing showed that many CP/CPPS patients met objective criteria for depression.[189] One study compared age- and education-matched men with chronic low back pain to patients with CP/CPPS.[190] Subjects were evaluated by the same psychologist with standardized interviews plus Minnesota Multiphasic Personality Inventory testing. Prostatitis patients were employed but reported that symptoms interfered greatly with their sexual and romantic relationships. In contrast, back pain patients reported that their pain interfered primarily with work; most had long-term marital relationships, whereas few prostatitis patients did. Half of the CP/CPPS patients met criteria for major depression, but back pain patients were more somatically focused, depressed, and anxious. Next, 39 CP/CPPS patients were evaluated using the sickness impact profile and several symptom measures.[191] Multiple regression analyses showed that pain was the only physical symptom that significantly contributed toward sickness impact. The sickness impact profile score of CP/CPPS patients was within the range of patients suffering from myocardial infarction, angina, or Crohn's disease. These findings were confirmed in the NIH Chronic Prostatitis Clinical Research Network cohort study.[192]

Etiology

The etiology of CP/CPPS is unclear for most patients. Many workers have examined microbiologic, urodynamic, and psychological aspects.[1,3,7] However, no study has been completely satisfactory with careful definition of the disease, adequate microbiologic evaluation, and psychological assessment. The generally accepted symptoms of CP/CPPS (Table 61-1) overlap typical symptoms associated with conditions such as persistent and/or recurrent urethritis. Half of participants in some important prostatitis studies had urethral leukocytes, but these studies did not evaluate accepted urethral pathogens.[115,117,193–195] The evidence for various proposed causes is summarized below, emphasizing genitourinary infection, the major focus of this text. We also consider the other prominent etiological theories.

Genitourinary tract infection

Several observations provide empirical support for the concept that genitourinary tract infection may be important in the etiology of CP/CPPS. Patients often relate the onset of their condition to sexual activity, commonly to an episode of acute urethritis.[8,117,186] Antimicrobial therapy often results in transient relief of symptoms. Based on these observations, standard clinical practice is to use multiple courses of antibacterial therapy, hoping that patients will experience lasting relief.[8,117,186] In addition, varied microorganisms, especially bacteria, have been implicated in CP/CPPS. The standard classification of prostatitis syndromes considers these agents as potential causes of CP/CPPS (category III) rather than acute bacterial prostatitis (category I) or chronic bacterial prostatitis (category II), because these patients do not have bacteriuria (urinary tract infection).

Chlamydia trachomatis. C. trachomatis is the most controversial infectious organism implicated in prostatitis. Mårdh and Colleen[196] obtained urethral specimens for culture of *Neisseria gonorrhoeae*, *T. vaginalis*, *Ureaplasma urealyticum*,

Mycoplasma hominis, *C. albicans*, anaerobic bacteria, and some viruses from 78 men with "nonacute prostatitis" and from 20 normal men. There were no significant differences between the cases and controls. One-third of the men with prostatitis had antibodies to *C. trachomatis*, compared with 3% of controls. Tetracycline treatment was superior to placebo in eliminating symptoms. However, in follow-up studies employing cultures and serology, these workers could not implicate *C. trachomatis* as the cause of idiopathic "prostatitis."[197–200] The authors concluded that chlamydiae were not important agents in "chronic prostatitis." Similarly, we could not culture *C. trachomatis* from the urethras of men with nonbacterial prostatitis or prostatodynia,[201] nor did we demonstrate a serologic or local immune response to *C. trachomatis* in a smaller number of such patients. Doble and associates evaluated 60 men with the diagnosis of "chronic abacterial prostatitis," using transrectal prostatic ultrasound with transperineal biopsy of abnormal areas.[202] Chlamydiae were not cultured from the prostatic tissue of any patient nor were they detected by immunofluorescence. In addition, no subject had serum antibody titers against *C. trachomatis*.

In contrast, Bruce et al.[203] examined early-morning urine, prostatic fluid, or semen from 70 men with "subacute or Chronic Prostatitis." Of these 70 men, 39 (56%) were infected with *C. trachomatis*. Criticism was directed against the microbiologic methods in this study and the high rate of positive chlamydial cultures in the control groups, i.e., nine (17%) of 54 men undergoing elective vasectomy had cultures positive for *C. trachomatis*.[204] In a follow-up study, Bruce and Reid[205] evaluated 55 men with "prostatitis," including 31 "believed to have chlamydial prostatitis." Only six cases met strict criteria for chlamydial prostatitis, based on identification of the organisms by culture or immunofluorescence techniques. Japanese investigators identified *C. trachomatis* in the urethras of 20% of men with prostatitis.[206] Other investigators reached similar conclusions.[207–209]

In support of a potential etiological role, Poletti and associates isolated *C. trachomatis* from prostate cells obtained by transrectal aspiration biopsy of men with "nonacute abacterial prostatitis."[210] Abdelatif et al. evaluated transurethral prostate specimens with histologic evidence of chronic abacterial prostatitis using in situ hybridization.[211] Intracellular chlamydiae were detected in seven (30%) of 23 cases. Shurbaji and associates also identified *C. trachomatis* in paraffin-embedded sections from five (31%) of 16 men with histological evidence of prostatitis, but in none of 19 cases of prostatic hyperplasia without significant inflammation.[212] Kobayashi and Araki found peroxidase–antiperoxidase staining for chlamydiae in prostate biopsy tissue following therapy.[213] These studies suggest that chlamydiae may invade the prostate that chlamydial antigen may persist in the prostate after treatment and that presence of such antigen might be related to prostatitis.

Important criticisms of previous studies include absent or inappropriate controls, that urethral specimens may not reflect prostatic infection, and that prostate tissue and secretions inhibit culture methods for *C. trachomatis* and other microorganisms. Other reservations are that direct methods (such as microscopy, immunofluorescence, or in situ hybridization) may be insensitive for identification of defective organisms or organisms present in small numbers. Demonstration of chlamydial DNA and RNA by PCR in culture-negative cases of trachoma (a chronic eye disease caused by *C. trachomatis*) suggests that "Live Chlamydiae may remain at a site of infection and produce inflammation beyond the time at which microbial techniques are able to detect them."[214] Similar events may occur in chronic prostatitis. Another problem is that biopsy studies sampled abnormal areas only. Thus, the precise role of *C. trachomatis* in nonbacterial prostatitis deserves further study.

Ureaplasma urealytimum. Weidner and associates[215] suggested that *U. urealyticum* may be associated with the development of "chronic prostatitis." In a study of >700 patients, high concentrations of *U. urealyticum* (>10^3/mL) in prostatic fluid, semen, or urine obtained after prostatic massage were associated with clinical signs and symptoms of "prostatitis." A recent study identified "significant" concentrations of *U. urealyticum* in 18 (13%) of 143 men with prostatitis.[216] Treatment with either ofloxacin or minocycline resulted in clearance of the organisms in all cases and resolution of symptoms in 10 patients (71%). Isaacs cultured *U. urealyticum* at concentrations >10^3 ccu/mL from prostatic secretions of 11 (8%) of 131 men in study with chronic nonbacterial prostatitis without other organisms, suggesting an etiological role.[217] Other investigators, however, have been unable to implicate the genital mycoplasmas in nonbacterial prostatitis.[181,196] Additional studies employing other, carefully defined patient populations and immunologic and/or molecular diagnostic techniques and methods for identification of multiple pathogens would be useful to assess the purported role of *U. urealyticum* in prostatitis syndromes.

T. vaginalis. It has been proposed as one cause of varied urological conditions. Studies outlined in the chapter on trichomoniasis suggest that *T. vaginalis* is, indeed, pathogenic in the male lower genitourinary tract. The protozoa may cause nongonococcal nonchlamydial urethritis and persistent infection. We isolated *T. vaginalis* and *C. trachomatis* with comparable frequencies from the urethras of men with CP syndromes.[8] *T. vaginalis* has been identified in urinary sediment, prostatic secretions, and prostatic parenchyma. In some studies, the prevalence of trichomoniasis has exceeded 85% among men with symptoms of prostatitis that persisted despite antibacterial therapy.[218,219] These findings support previous reports of an association between *T. vaginalis* and prostatitis.[218–223] Some suggest that the highest prevalence is in men with long-term symptoms and in those who have not

responded to standard antibacterial therapy.[219] However, the precise role of *T. vaginalis* as a cause of nonbacterial prostatitis remains undefined. Specific diagnosis is necessary because treatment of trichomoniasis requires antimicrobials seldom prescribed for urogenital infections in men.

Other microorganisms. Many other organisms are regarded as potential causes of prostatitis and urethritis syndromes, including viruses, fungi, and anaerobic and Gram-positive bacteria. In two Scandinavian studies, men with "chronic nonbacterial" prostatitis had prostate biopsies that were cultured for aerobic bacteria, anaerobic bacteria, and viruses.[224,225] Neither study demonstrated an etiologic role for such pathogens.

Gram-positive aerobic bacteria are the most controversial of these proposed microbial causes of nonbacterial prostatitis. Although the significance of Gram-positive cocci has been debated for over 20 years, until recently the consensus was that these organisms are rarely, if ever, causative.[7,20,102,226] Costerton and Nickel revived this debate by localizing coagulase-negative staphylococci to the prostates of three men with "prostatitis" that was refractory to antimicrobial treatment.[140] The bacteria were isolated in culture from prostate biopsies. Electron microscopy demonstrated, "sparse and focal microcolonies adherent to the prostatic ductal walls," suggesting sequestration of resistant staphylococci within intraprostatic biofilms. In contrast, other investigators found that such organisms disappeared without treatment in all cases.[227]

In the preantibiotic era, *N. gonorrhoeae* was a recognized cause of prostatitis and the most common cause of prostatic abscess.[228] However, gonococcal prostatitis has seldom been reported in the postantibiotic era. Two studies demonstrated antibody against *N. gonorrhoeae* in prostatic fluid of men whose cultures were negative.[199,229] In contrast, other studies seldom identified *N. gonorrhoeae* as a cause of prostatitis.[3,102,201]

Anaerobes were suggested as potentially important, but controlled studies showed no significant differences in anaerobic bacteriology between cases and controls.[227] However, these studies employed outdated bacteriological methods. Of viruses that may be cultured from genitourinary sites, herpes viruses types 1 and[2230–232] and cytomegalovirus[233–235] are the most likely causes of prostatitis, based on anecdotal reports.

Molecular data

The studies described above used culture or antigen detection in samples such as urine, urethral swabs, and EPS. Interpretation of the findings is complicated, since these samples can acquire organisms during passage through the urethra. These considerations led us to evaluate the urethra, EPS, segmented urine specimens, and prostate biopsy tissue from CP/CPPS patients. Potential subjects were excluded if they had evidence of bacteriuria, bacterial prostatitis, or urethritis.[236] Of the 135 subjects evaluated, 10 (8%) had positive PCR assays for *Mycoplasma genitalium* (four subjects), *C. trachomatis* (three subjects), and *T. vaginalis* (two subjects), and one man positive for both *M. genitalium* and *C. trachomatis* (Table 61-2). These data fit with previous studies indicating that both *C. trachomatis*[210–212] and *T. vaginalis* may be identified in prostate tissue.[222] To our knowledge, this is the first demonstration of *M. genitalium* in prostate tissue. These findings suggest that *C. trachomatis*, *T. vaginalis*, and *M. genitalium* may be associated with some cases of CP/CPPS, even among men who have no evidence of urethritis and men who have negative urethral cultures. Tetracycline-resistance encoding sequences were detected in 25% of subjects, and bacterial ribosomal RNA-encoding sequences (16S rRNAs) were detected in 77% of subjects tested. There was a strong correlation between inflammation in the EPS and detection of 16S rRNA in prostatic tissue ($P < 0.001$).

Other investigators confirmed that 16S rRNAs may be found in prostate biopsies from patients with prostate disease,[237] but not from prostate biopsies from healthy organ donors.[238] DNA cloning and sequencing indicated that prostate tissue from patients with CP/CPPS harbored multiple sources of 16S rRNA-encoding DNA. "Real-time" PCR assays suggest that a minority of patients have 16S rRNA high levels, consistent with active infection.[239,240] These studies should provide important insights into the causes of the CP/CPPS and may elucidate optimal clinical evaluation and treatment in patients. While it is impossible to determine cause and effect using a case–control design, these findings suggest that fastidious or noncultivable microorganisms might be important in inflammatory CP/CPPS.

Noninfectious causes

While several mechanisms have been proposed to be involved in the pathogenesis of CP/CPPS, there is currently no consensus. In addition to infection, neuromuscular dysfunction affecting voiding and/or ejaculation, immunological dysfunction, interstitial cystitis, and chronic pain have received considerable attention as potential etiological factors. Although these factors are likely important in individual patients, the precise proportion of cases related to these causes remains poorly defined and controversial. In part, the apparently contradictory and confusing literature appears to be related to previous treatment and the tertiary referral patterns of many patients enrolled in clinical studies.

Neuromuscular dysfunction and abnormal voiding

Ghobish et al. compared 238 uroflow studies from CP/CPPS patients to 71 studies from age-matched controls without lower urinary tract problems.[241] Most patients had varied urinary flow disorders. Some authors suggest that symptoms of CP/CPPS may reflect pelvic sidewall tenderness due to tension myalgia.[242–244] Persson and associates found increased concentrations of creatinine, urate, and leukocytes in EPS from 56

CP/CPPS patients.[245] They suggested that these findings most likely resulted from urinary reflux into the prostatic ducts. Hruz et al. found that 29 of 48 (60%) patients with refractory CPPS had significant bladder neck hypertrophy despite the absence of obstruction.[246] Similarly, Kaplan et al. described 43 men, 23–50-years-old, with chronic voiding dysfunction secondary to pseudodyssynergia who were misdiagnosed as having CP/CPPS and recommended routine videourodynamic evaluation.[247] In contrast, Mayo and associates found that only three (3%) of 123 CP/CPPS patients had urodynamic evidence of obstruction (definite in two [1.6%] and equivocal in one [0.8%]).[248]

In summary, the precise role of urodynamic and neuromuscular abnormalities remains controversial. If primary voiding or other neuromuscular dysfunction proves important in a substantial proportion of patients, then facilitate development of better diagnostic methods and specific therapies would prove beneficial for patients with CP/CPPS.

Immunological dysfunction

A wide range of immunological disorders has been associated with CP/CPPS, as outlined above in the section on host defenses. Abnormal host responses have also been related to DNA polymorphisms, such as cytokine production and/or regulation.[54,249] Other data support the possibility that autoimmune mechanisms may be important in the pathogenesis of CP/CPPS. Several workers have investigated animal models of autoimmune prostatitis.[250–252] For example, Pacheco-Rupil et al. reported that rats immunized with a mixed organ homogenate of ventral, dorsal, and lateral prostate, and coagulating glands developed a specific cell-mediated response with $CD4^+$ and $CD8^+$ T-cell infiltration of prostate lesions.[252] Ponniah and associates compared 14 patients with CP/CPPS to 12 normal volunteers, using recall proliferation assays with purified seminal plasma proteins as antigens.[61] Five patients showed a greater than twofold increase in proliferative response to prostate-specific antigen, while no response was seen in the controls. These investigators concluded that prostate-specific antigen may represent a candidate antigen and a target for immunotherapy.[61] In a subsequent study, this group compared 11 patients with granulomatous prostatitis to 540 controls.[59] Six (75%) of eight white patients were HLA-DR15 positive compared to 127 (28%) of 451 white controls, and one (33%) of three black American patients was HLA-DR15 positive compared to 23 (26%) of 89 black controls ($P = 0.0086$), consistent with an autoimmune etiology.[59]

Interstitial cystitis

The term "interstitial cystitis" is used to describe an idiopathic bladder pain syndrome that is most commonly diagnosed in women. Many etiologies have been proposed, including mast cell activation, defects in the urothelial glycosaminoglycan coating, autoimmune disease, toxic agents, neuropathic-mediated pain, presence of antiproliferative factor activity, or decreased levels of heparin-binding epidermal growth factor-like growth factor.[253–256] None of these hypotheses is generally accepted and results of therapy are generally poor.

Because the symptoms of interstitial cystitis and CP/CPPS overlap, one hypothesis is that these syndromes should be combined.[257–261] A proportion of CP/CPPS have been reported to have positive findings with various tests proposed for diagnosis for interstitial cystitis, including: cystoscopy with hydrodistension,[262,263] the potassium sensitivity test,[257,259] and various biomarkers.[264] The clinical implication is that diagnosis of interstitial cystitis in patients presenting with symptoms of CP/CPPS would facilitate effective therapy if there were a proven therapy for interstitial cystitis.

Neuropathic pain

A new theory is that CP/CPPS patients may have various initiating causes but that, once established, this syndrome represents a chronic pain syndrome.[51,265] Pain might arise from neurogenic inflammation in the peripheral or central nervous systems. Levels of nerve growth factor and cytokines that regulate inflammation may correlate with pain severity in CP/CPPS.[53] Nerve growth factor is a neurotrophin that plays a role regulation of nociceptive nerves by mediating and amplifying neurogenic inflammation. The clinical implication is that application of strategies directed at management of chronic pain might provide more benefit to patients than therapies directed at the underlying etiology. This remains an area of active investigation.[51,265]

Differential diagnosis

The CP/CPPS case definition for clinical studies contains a number of important exclusion criteria.[117,118,186,193,266] The exclusion criteria include duration <3 months, lower genitourinary tract cancer (e.g., transitional cell carcinoma, carcinoma in situ, and prostate cancer), active urinary stone disease, active genitourinary tract infection (e.g., bacteriuria genitourinary tuberculosis), gastrointestinal disorders (e.g., inflammatory bower disease and perirectal disease, such as fissure or fistula), radiation cystitis, chemical cystitis (i.e., postchemotherapy), active urethritis, acute epididymitis, acute orchitis, functionally significant urethral stricture, or neurological disease affecting the bladder.[12]

Of the CP/CPPS exclusion criteria, two merit special attention: transitional cell carcinoma and prostate carcinoma. Patients presenting with symptoms of prostatitis and irritative voiding symptoms, hematuria, or history of industrial exposure, or, perhaps, extensive tobacco use may merit additional evaluation for transitional cell carcinoma or carcinoma in situ. Appropriate studies include urinalysis and urinary cytology with cystoscopy for selected patients.[1,254,267] Patients with risk

factors for prostate cancer may also merit prostate biopsy. These risk factors include older age, a strong family history of prostate cancer, an abnormal rectal examination, or elevated prostate-specific antigen level.

The differential diagnosis of CP/CPPS also includes interstitial cystitis, a poorly understood pelvic pain syndrome that is associated with increased urinary frequency and urgency. As considered above, there some overlap between this syndrome and CP/CPPS. The precise amount of overlap and relationship between these two conditions is currently the subject of considerable debate. Thus, for selected patients, it may be reasonable to obtain urine specimens for cytology and to perform careful endoscopic examination under anesthesia (including bladder evaluation after hydrodistension), as well as to procure appropriate bladder specimens for histological evaluation.

Treatment

Therapy is unsatisfactory for most men with CP/CPPS.[268] Patients typically receive antibiotics, alpha-blockers, anti-inflammatory drugs, and other treatments.

Antimicrobial drugs

Antimicrobial drugs represent the first-line treatment (Table 61-5).[3,8] Patients with recognized uropathogens respond to specific therapy. However, few men receive an accurate diagnosis because lower urinary tract localization procedures and detection of fastidious organisms prove difficult in most clinical settings. For men without evidence of infection by recognized pathogens, antimicrobial treatment often results in temporary resolution. However, symptoms frequently return following treatment. Patients typically receive multiple courses of empirical antimicrobial therapy.[8,186] Patients and their physicians often became frustrated following multiple courses of unsuccessful empirical therapy.

To date, few studies have evaluated this clinical approach, primarily in heavily pretreated, referral patients. One series evaluated the effect of 12 weeks of oflocixin therapy in a nonblinded series of 102 referral patients, presenting with either chronic bacterial prostatitis or with CP/CPPS.[269] Of the patients, 57% believed that they had moderate-to-marked improvement and had significant improvement in the NIH-CPSI. Culture and EPS leukocyte count did not predict response. Subsequently, this group completed a multicenter trial of 6 weeks of levofloxacin therapy compared with placebo for 80 patients with CP/CPPS.[270] These referral patients had an average symptom duration of 6.5 years. Both groups experienced progressive improvement in symptoms as measured by the NIH-CPSI, but there was no difference in response at the end of the treatment (6 weeks) or at the end of the follow-up visits (12 weeks).

The NIH Chronic Prostatitis Clinical Research Network evaluated a heavily pretreated population of 179 patients.[193] The average duration of CP/CPPS symptoms was 6.2 years. Most participants had failed prior treatment with both antibiotics and alpha-blockers.[186] This multicenter, randomized, double-blind trial employed a 2×2 factorial design to compare 6 weeks of therapy with ciprofloxacin, tamsulosin, both drugs, or placebo in tertiary-care settings. NIH-CPSI total scores decreased modestly in all groups, and neither therapy provided statistically significant benefit.

In summary, antimicrobial therapy remains the first-line treatment for CP/CPPS. Documentation of a specific pathogen is valuable for selecting specific therapy. However, it appears that repeated courses of empirical therapy in the absence of a recognized pathogen provide minimal benefit, particularly for heavily pretreated, tertiary referral populations.

Alpha-blockers

The best rationale for nonantimicrobial therapy supports use of alpha-adrenergic blockade to treat the neuromuscular dysfunction that some workers describe with CP/CPPS.[6,271,272] Complaints of urinary hesitancy, poor or intermittent stream, or ejaculatory dysfunction may be manifestations of functional neuromuscular abnormalities. Small clinical series suggested that patients benefit from treatment with less-selective alpha-blocking agents, such as phenoxybenzamine,[1] phentolamine,[6] or terazosin.[273]

Three randomized controlled clinical trials reported variable results. The Chronic Prostatitis Research Network Study described above found that 6 weeks of tamsulosin, a subtype-specific alpha-1 blocker, was not significantly better than placebo in their heavily pretreated referral population.[186] In contrast, Mehik and associates demonstrated some benefit from afulzosin, a "uroselective" alpha-1 blocker. They compared alfuzosin with placebo and standard therapy in 66 CP/CPPS patients.[274] After 6 months of active therapy, the alfuzosin group had had statistically significant decreases in total and pain NIH-CPSI scores, compared with the placebo and control/standard groups. Of the 17 patients in the alfuzosin group, 11 (65%) had a >33% improvement in the mean NIH-CPSI total score, compared with 24% and 32% of the placebo and control/standard groups, respectively ($P = 0.02$). Unfortunately, at 12 months (6 months after treatment was discontinued), symptom scores deteriorated, and there was no significant difference between the treatment groups.

Cheah and associates evaluated 86 newly diagnosed patients who had not received alpha-blockers previously.[275] Subjects were randomized to receive terazosin, a non-subtype-selective alpha-1 blocker, or placebo for 14 weeks. Terazosin-treated patients had statistically greater reductions in NIH-CPSI total score and individual domain scores. There was no difference in urinary flow rate or postvoid residual between responders and nonresponders.

In summary, alpha-blocker therapy appears beneficial for patients with CP/CPPS, especially newly diagnosed and/or alpha-blocker naïve patients. The ideal agent and duration of therapy remain to be defined, but less selective alpha-1

blockers and therapy for 14 weeks or longer appear to be better than less selective agents or shorter duration of treatment.

Other therapies

Clinical studies suggest that a number of other drugs and treatments might benefit patients with CP/CPPS. Recommended drugs include anti-inflammatory agents such as rofecoxib to decrease prostate inflammation,[276] 5-alpha reductase inhibitors such as finasteride to decrease prostate size,[277,278] therapy for interstitial cystitis such as pentosan polysulfate,[279,280] allopurinol to treat high EPS urate levels due to urinary reflux into the prostate ducts.[281–284] muscle relaxants to reduce muscle tone, and anticholinergics.[1,20,182,183,244] Many phytotherapeutic agents have been recommended, based on anecdotal experience and small series,[285,286] such as pollen extract (Cernilton),[287] saw palmetto,[277] and quercetin.[288–290]

Recommended procedures include sitz baths, prostate massage,[111,291] acupuncture,[265,292] physiotherapy, behavioral therapy, and bladder training biofeedback for pelvic floor myalgia.[1,20,182,183,243,244] Case series recommend "multimodal therapy" with simultaneous use of multiple approaches combining antibiotics, prostatic massage, anti-inflammatory phytotherapy, alpha-blockers, and neuromuscular agents.[293–295] Some clinicians recommend increased frequency of ejaculation to relieve "congestion." Other physicians recommend abstinence from ejaculation, alcohol, coffee, tea, spicy foods, etc. There is little definitive evidence that any of these treatments affects the natural history of CP/CPPS.

Patients routinely undergo a wide variety of invasive diagnostic procedures, such as cystoscopy, transrectal ultrasonography, excretory urography, other imaging tests, urodynamic studies, and biopsies.[162,272,296] The recent literature contains many reports of surgical procedures to treat men with CP and related syndromes. These operations include transurethral and "subtotal resection" of the prostate,[162,182,183,297] balloon dilation of the prostate,[298] hyperthermia,[299–303] endourethral electrostimulation and laser radiation,[304,305] and even radical prostatectomy.[306,307] None of these small series includes adequate control groups and sufficient microbiological and clinical data. Although such procedures might be effective in certain, highly selected cases, our experience includes many men who failed surgical therapy.

CATEGORY IV. ASYMPTOMATIC INFLAMMATORY PROSTATITIS

The consensus classification of prostatitis syndromes includes a category for patients who have no genitourinary tract symptoms.[12]

Clinical presentation

Patients with category IV prostatitis have documented inflammation but have none of the usual symptoms associated with other prostatitis syndromes. Diagnosis occurs during evaluation for other conditions such as evaluation of prostate tissue obtained for other clinical indications or during evaluation of patients presenting with infertility.

Inflammatory infiltrates are commonly noted during evaluation of prostate tissue removed for treatment of lower urinary tract symptoms associated with BPH and surgical treatment of prostate cancer.[62,308,309] These observations have led some investigators to suggest that prostatic inflammation might play a role in the development of both BPH and prostate cancer.[64,65,95,96,98] In addition, patients with elevated prostate-specific antigen levels routinely undergo prostate biopsy for evaluation of possible prostate cancer.[310–312] The most common benign pathologic diagnosis is "prostatitis," based on the histologic finding of inflammatory infiltrates in the prostatic tissue. Many patients with such inflammatory prostate tissue infiltrates have no history of prostatitis symptoms, placing them in the asymptomatic category (Table 61-4).

Inflammation may be diagnosed among men undergoing evaluation for infertility (reviewed in Ref. 116). Many of these men have no genitourinary tract symptoms. On semen analysis, increased numbers of "round cells" may prompt a diagnosis of prostatitis. Other terms used in the infertility literature include "asymptomatic male genital tract infection," "male accessory gland infection," "prostatoseminal vesiculitis," "leukocytospermia," and "pyosemia." The consensus classification includes such patients in category IV, or asymptomatic inflammatory prostatitis.

Treatment

Some clinicians recommend antimicrobial and/or anti-inflammatory therapy for asymptomatic patients with elevated prostate-specific antigen levels and inflammation noted on prostate biopsy.[313–316] These recommendations are based on the observations that acute bacterial prostatitis and exacerbations of chronic bacterial prostatitis are associated with elevations of both serum prostate-specific antigen and prostatic acid phosphatase. Whether antimicrobial therapy is beneficial for asymptomatic patients with histologic evidence of prostatitis remains uncertain. The current consensus is that antimicrobial therapy is not indicated for asymptomatic patients (Table 61-5).[317]

Similarly, some infertility specialists recommend antimicrobial therapy for asymptomatic men with seminal fluid inflammation, but the proportion of these patients who have active genital tract infections is poorly defined.[116,318] Further, seminal fluid inflammation has been shown to resolve in many men over time, with frequent ejaculation only.[319] Thus, it would appear prudent to diagnose a specific genitourinary tract pathogen before recommending antimicrobial therapy for asymptomatic men presenting for infertility evaluation.

Complications

Animal studies[258] and data summarized above suggest that chronic prostatic inflammation may promote development of both BPH and prostate cancer.[68,95,320] Other investigators have proposed that asymptomatic prostatic inflammation represents a treatable cause of serum prostate-specific antigen elevation and that therapy with antibiotics and/or anti-inflammatory agents may reduce unnecessary biopsy rates.[316] Confirmation of these potential associations would support efforts to diagnose and treat both symptomatic and asymptomatic prostatitis syndromes. However, treatment of asymptomatic prostatic inflammation is associated with potential adverse outcomes and has not been proven to change the natural history of any prostate disorder.

GRANULOMATOUS PROSTATITIS

Most men with prostatitis syndromes may be classified into the four categories described above. However, granulomatous prostatitis is distinct from the four usual categories. Diagnosis of these unusual patients is important because specific therapy may be necessary to resolve the infectious causes of granulomatous prostatitis.

Clinical presentation

Granulomatous prostatitis is a characteristic reaction of the prostate to varied insults. Patients may present with findings suggesting prostate cancer on rectal examination.[321] Other men present with systemic symptoms or lower urinary tract obstruction due to prostatic enlargement. Biopsy or examination of tissue removed at surgery is often necessary for diagnosis. Thus, granulomatous prostatitis is a histologic diagnosis that does not correspond to a discrete clinical syndrome.

Histology

On gross examination, the prostate appears indurated, and, on rectal examination, it is frequently nodular. The histologic pattern is that of a granulomatous reaction with lipid-laden histiocytes, plasma cells, and scattered giant cells. A prominent eosinophilic infiltrate is apparent in some cases. Recent reports suggest that the histological findings range from a localized appearance, resembling rheumatoid nodules, often associated with a history of previous transurethral resection, to a more diffuse appearance, associated with systemic illness or idiopathic etiology.[322,323] Specific stains or cultures may be necessary to make an etiologic diagnosis.

Etiology

Granulomatous prostatitis is arbitrarily classified as "specific," when associated with particular granulomatous infections, or as "nonspecific," in other cases. Recognized causes of nonspecific granulomatous prostatitis include acute bacterial prostatitis, prostatic surgery, and disorders associated with vasculitis.

Nonspecific granulomatous prostatitis. In many cases, granulomatous prostatitis follows an episode of acute bacterial prostatitis or previous prostatic surgery.[1,137] Nonspecific granulomatous prostatitis occurs in two forms: a noneosinophilic variety and an eosinophilic variety. Although neither variety is seen frequently in clinical practice (the eosinophilic variety is especially rare), both types are important clinically, because they may be confused with prostatic carcinoma.

Some authors suggest that granulomatous prostatitis represents a tissue response of the foreign body type to extravasated prostatic fluid.[137] Acute signs and symptoms of bladder outlet obstruction associated with an enlarged, firm prostate that feels malignant characterize the clinical presentation. Fever and irritative voiding symptoms may occur.

Eosinophilic granulomatous prostatitis, associated with fibrinoid necrosis and generalized vasculitis, may present as a serious systemic illness.[324] Because it occurs almost exclusively in patients with allergies, especially asthmatics, this entity is also known as "allergic granuloma of the prostate."[226] Granulomatous prostatitis has also been associated with other rheumatoid disorders, particularly Wegener's granulomatosis.[325–328]

Specific granulomatous prostatitis. There are a number of specific infectious causes of granulomatous reaction by the prostate. Tuberculous prostatitis is usually secondary to tuberculosis elsewhere in the genital tract.[329,330] Most patients have no symptoms referable to prostatic infection. On biopsy, the granulomas frequently contain typical Langhans' giant cells and may be associated with caseous necrosis. Such infections are caused most often by *Mycobacterium tuberculosis* but have also been reported with atypical mycobacteria.[331,332] A similar histological picture may be noted following intravesical BCG therapy for transitional cell carcinoma.[333–336]

With many of the deep mycoses, mycotic prostatitis may be secondary to systemic involvement.[337,338] Most reported cases have been associated with blastomycosis,[337,339] coccidioidomycosis,[340–343] and cryptococcosis.[344,345] However, histoplasmosis and paracoccidioidomycosis also occasionally involve the prostate.[337,346] Cases of prostatitis due to candidiasis or aspergillosis have also been described.[347–349] Usually, mycotic prostatitis is part of a systemic hematogenous dissemination. This process may involve any organ of the genitourinary tract. Mycotic involvement of the prostate is probably more common than is generally appreciated, since such involvement is frequently asymptomatic and the prostate is often not specifically evaluated in autopsy protocols.[337]

Other unusual infectious causes of granulomatous prostatitis include actinomycosis, candidiasis, and syphilis

(F. Mantz, personal communication).[350] Cases of granulomatous prostatitis have also been associated with brucellosis[351] and can be sequelae of sacral herpes zooster.[352] Some reports suggest that AIDS and HIV infection may be associated with an increased risk of granulomatous prostatitis[353] and that the etiology may include pathogens such as *Mycobacterium avium complex*.[354]

Diagnosis and treatment

Granulomatous prostatitis is perhaps the most important in the differential diagnosis of an indurated, firm, or nodular prostate. Frequently, the rectal examination of such patients raises the suspicion of prostatic carcinoma. Other causes of a nodular prostate include prostatic infarction, nodular BPH, or a prostatic calculus. Biopsy of the prostate may be necessary for diagnosis. Use of appropriate stains and cultures to detect specific etiologic agents is important in cases where granulomatous prostatitis is a consideration.

Treatment of patients with granulomatous prostatitis includes appropriate and specific treatment of the primary disease. A few patients have symptoms directly referable to the granulomatous reaction in the prostate. Such men usually complain of obstructive voiding symptoms. In most cases, the symptoms resolve with systemic therapy. Patients with urinary retention may be managed initially by percutaneous placement of a suprapubic cystostomy tube. Prostatectomy may be necessary if symptoms persist after an appropriate course of antimicrobial therapy.

PART 11

Management of Dermatologic and Extragenital Manifestations of STD and HIV Infection

This page intentionally left blank

62 Generalized Cutaneous Manifestations of STD and HIV Infection: Typical Presentations, Differential Diagnosis, and Management

Roy Colven

INTRODUCTION

Generalized skin lesions in any patient can perplex both the patient and the medical practitioner. Evaluating generalized skin lesions in a patient who has a sexually transmitted disease (STD) or human immunodeficiency virus (HIV) infection can present special problems. For example, the STD may be associated with, but not necessarily a cause of, the generalized rash. Patients infected with HIV may present with unique dermatoses, unusual infections, and atypical manifestations of common skin diseases. Among HIV-infected individuals, some type of skin disorder will develop in at least 80%.[1] Certain common skin conditions—including herpes zoster, severe seborrheic dermatitis, persistent staphylococcal folliculitis, and generalized pruritus—occur with increased frequency in HIV-infected patients and may provide the first clue that an individual is HIV-infected.[2,3]

The first goal of this chapter is to outline a practical approach to the STD- and/or HIV-infected patient who presents with generalized skin disease (Fig. 62-1). Particularly important aspects of this approach are (1) to attempt to identify the primary lesion in a generalized skin condition, (2) to recognize any specific features of or patterns created by the primary lesion(s), and (3) to determine the distribution of the rash on the body surface. With this approach, the practitioner can usually generate a differential diagnosis. Evidence obtained from history and laboratory tests such as potassium hydroxide preparation or Gram's stain can then be applied to narrow the differential diagnosis. If necessary, a skin biopsy can be easily performed to add more specific information.

The second goal of this chapter is to familiarize the reader with the typical as well as the atypical presentations of a number of STD- and/or HIV-related generalized cutaneous manifestations. In addition, therapy of selected conditions will be discussed.

APPROACH TO A GENERALIZED SKIN CONDITION

GENERAL APPEARANCE

One's first glance at a patient often consciously or unconsciously starts the dermatologic assessment. Is the patient generally ill or overall well appearing? Is the patient obviously symptomatic with itching? Is there evidence of the skin condition on the face or scalp? Does the patient cover skin lesions with clothing or makeup? Does the patient have generalized edema? Vital signs, including the presence or absence of fever, are a critical part of this initial assessment. In order to examine the skin thoroughly, have the patient undress and put on a gown, thus allowing adequate exposure of the skin. One also needs good lighting, preferably natural lighting through a window to the outdoors.

The patient's normal skin pigmentation will influence the color of skin lesions. Erythema in darkly pigmented skin appears differently, and is often more subtle than in lighter skin.

Other factors to consider in this early assessment of a generalized skin condition are as follows:

- Is the condition acute, chronic, or in between?
- Is the patient known to be immunocompromised?
- How are the lesions distributed on the body?
- What is the primary lesion that best represents the condition?

This last query is discussed further and is the basis for organization in the remainder of the chapter.

PRIMARY SKIN LESIONS

A "primary lesion" refers to the initial stage in the evolution of a skin lesion. Identifying the primary lesion in a patient with a generalized skin condition provides critical information in

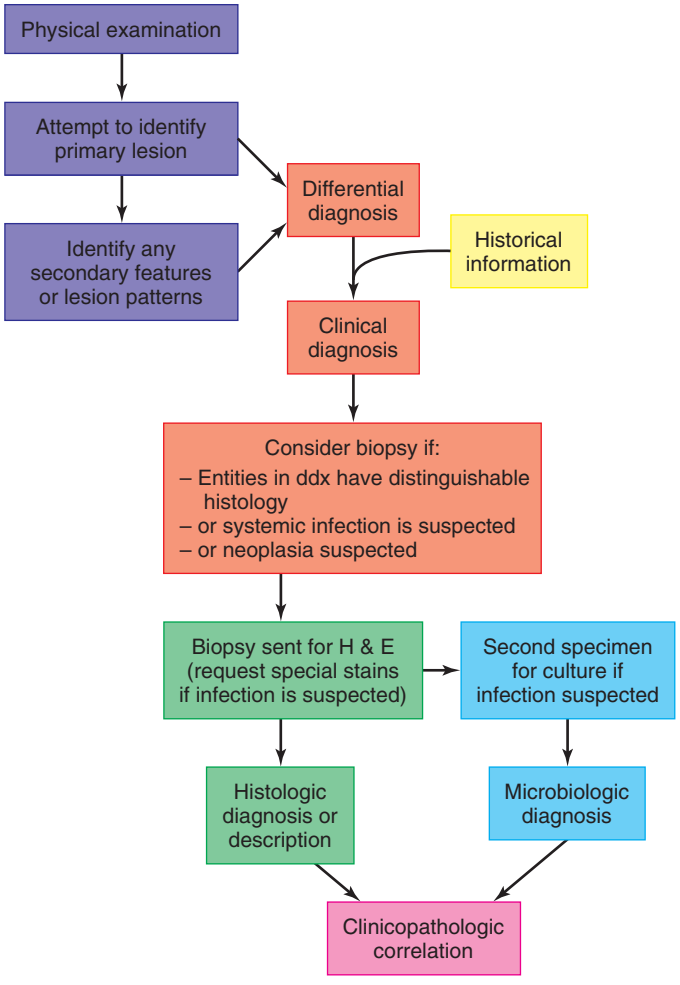

FIGURE 62-1. Approach to a patient with generalized rash.

making an accurate dermatologic diagnosis. Moreover, characterizing the appearance of the primary lesion directs the practitioner to a category of conditions based on lesion morphology. "Secondary lesions" refer to skin lesions altered, either naturally over time or by outside forces, to the extent that the primary morphology becomes obscured. For example, a patient with pruritic papules (primary lesions) may intensely scratch these lesions and turn them into erosions (secondary lesions), likely misleading the practitioner to formulate a differential diagnosis that does not include generalized papules. Alternatively, one should not assume the presentation of certain lesions, such as erosions, always represents secondary lesions. For example, the lesions could have been vesicles before the blister roof was either scratched away or naturally desquamated. Primary lesions are important in defining a generalized process and in communicating the appearance of a skin rash to another practitioner. A glossary of primary lesions is presented in (Table 62-1).

Table 62-1. Definition of Primary Lesions

- **Macule:** a small (< 0.5–1 cm diameter) area of color change without surface elevation
- **Patch:** a larger macular area
- **Papule:** a small (< 0.5–1 cm diameter) solid elevation
- **Plaque:** a broad, solid elevation
- **Nodule:** a solid elevation distinguished from a papule by deeper penetration and larger diameter
- **Wheal:** a smooth-contoured, edematous elevation, which is often transient
- **Vesicle:** a small (< 0.5–1 cm diameter), clear fluid-filled blister
- **Bulla:** a larger, clear, fluid-filled blister
- **Pustule:** a pus-filled blister
- **Abscess:** a collection of pus in the dermis and deeper tissues, often manifested by tenderness, fluctuance, warmth, and surrounding induration
- **Cyst:** a dermal sac with soft or fluid contents manifested by a soft, fluctuant, smooth-contoured elevation
- **Erosion:** moist or crusted, usually superficially depressed, area of partial or complete denudation of epidermis that generally heals without scarring
- **Ulcer:** depression in the skin surface caused by destruction of the epidermis (and at least part of the dermis) that generally heals without scarring
- **Atrophy:** a thinning of intact epidermis, dermis, or subcutaneous fat often resulting in wrinkling, translucency, or depression of the skin surface

Other useful terms, though not considered primary skin lesions:

- **Crust:** dried serous or serosanguinous transudate
- **Eschar:** adherent, often black or gray product of coagulation necrosis of the dermis, typically found at the base of an ulcer
- **Exanthem:** a generalized macular and popular rash on cutaneous surfaces mostly associated with a viral illness
- **Enanthem:** a mucous membrane-limited erythematous eruption mostly associated with a viral illness

SECONDARY FEATURES AND LESION PATTERNS

Unfortunately, relying solely on the primary-lesion morphology is often not sufficient to diagnose skin conditions accurately. The differential diagnosis of a papular eruption, for example, is extensive; knowing this information is not necessarily helpful when applied to an individual patient. If one can initially classify subsets of papular conditions based on other prominent features, the differential diagnosis quickly narrows. In (Table 62-2), certain secondary features and lesion patterns are defined; these definitions can assist in further classifying cutaneous conditions. With the primary lesion and secondary features in mind, the clinician can better generate a differential diagnosis. (Table 62-3) outlines generalized STD- or HIV-related cutaneous conditions based on the conditions' primary morphologies or

Table 62-2. Secondary Cutaneous Features Defined

- **Papulosquamous:** papules and plaques with prominent scale
- **Eczematous:** erythematous papules and plaques, often pruritic, with varying degrees of weeping, crust, and scale
- **Erythroderma:** < 90% total body surface area involvement with erythema, usually with some degree of scale
- **Xerosis:** generalized dry skin
- **Hyperkeratosis:** thickening of the straturn corneum producing visible scale
- **Ichthyosis:** flaking of skin with a distinct fish-scale pattern
- **Purpura:** dermal or subcutaneous bleeding producing a violaceous macule or patch

predominant lesion patterns/distributions. Note that diagnoses, such as secondary syphilis and scabies, appear in multiple categories. Also, exceptions to the categorization will occur because syphilis, particularly, can cause a wide range of skin lesions and patterns, and HIV can induce abnormal variations on common conditions and allow uncommon skin diseases, especially infections. Though (Table 62-3) distinguishes HIV- and STD-related conditions, this separation is arbitrary and is presented to help better organize one's differential diagnostic workup.

If the diagnosis cannot be established on clinical grounds, a skin biopsy often provides valuable information. Three- or four-mm punch biopsies sent for routine histology and/or culture can be performed with minimal discomfort (Fig. 62-2). Performing a biopsy of an early lesion generally gives the best diagnostic yield.

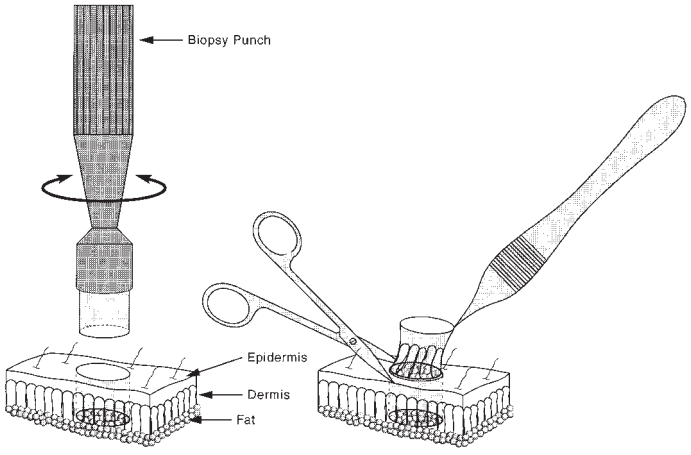

FIGURE 62-2. Technique of punch biopsy: After skin preparation and intradermal anesthesia, incises the skin with a twisting motion of a punch to the level of the subdermal fat. The specimen is then lifted carefully with teethed forceps, avoiding crushing, and the specimen is cut away from the fat using a fine scissors. A suture to close the wound is optional.

FIGURE 62-3. Erythematous macular and popular exanthem in acute HIV infection. (Reproduced with permission from Handsfield HH. *Atlas of Sexually Transmitted Diseases*. New York: McGraw-Hill, 1992.)

SELECTED CONDITIONS

MACULAR AND PAPULAR CONDITIONS

Exanthem of acute retroviral syndrome

During the period of viremia associated with primary HIV infection, a transient, erythematous macular and papular exanthem may appear (Fig. 62-3). Although the subtle nature of this rash has made it difficult to determine its true incidence, some investigators have estimated that as many as 75% of symptomatic acutely infected patients will develop this rash.[4] Constitutional symptoms, namely fatigue, fever, and weight loss, as well as generalized lymphadenopathy and pharyngitis, often coexist with the rash, making this syndrome difficult to distinguish from acute mononucleosis caused by Epstein–Barr virus.[5] In addition, patients may develop an enanthem.[6] Both the exanthem and enanthem generally resolve within 1 week. At this early stage, patients will have a negative HIV antibody test, but tests for viral replication, such as a plasma HIV RNA assay or a p24 antigen (in the setting of a negative antibody test), can confirm the diagnosis.

A similar rash and constellation of other symptoms and signs has occurred in HIV-infected patients who abruptly discontinue antiretroviral therapy.[7–10] Usually this is in the setting of relatively high CD4 counts and undetectable viral loads while on therapy. The rapid rise in viremia and sudden drop in CD4 count simulates the primary viremia of acute retroviral syndrome, with the subsequent immune response resulting in a macular and papular rash, malaise, pharyngitis, and even CNS symptoms. The key to diagnosis is ruling out other potential pathogens, and restarting antiretroviral therapy if possible.

Table 62-3. Differential Diagnosis Based on Lesion Morphology or Secondary Features

Lesion Morphology of Pattern	Possible HIV-Related Infections or Dermatoses	Possible STD or STD-Related Dermatoses
Macules/small papules	Exanthem of primary HIV infection, morbilliform drug eruption, measles, scabies	Morbilliform drug eruption, roseolar syphilis, popular syphilis,[a] Jarisch-Herxheimer reaction, prodrome of hepatitis B virus, viral exanthems (other than HIV), erythema multiforme (associated with HSV infection), scabies
Larger papules/nodules	Eosinophilic folliculitis, molluscum contagiosum, bacillary angiomatosis, popular syphilis, deep mycoses (disseminated cryptococcosis, histoplasmosis, coccidioidomycosis), scabies, Kaposi's sarcoma, verrucae, papular eruption of HIV	Scabies, nodular syphilis
Wheals/urticaria	Drug hypersensitivity, idiopathic	Drug hypersensitivity, prodrome of hepatitis B virus, idiopathic
Vesicles/bullae/erosions/crusts	Disseminated VZV, HSV, impetigo contagiosa, bullous impetigo, ecthyma, erythema multiforme, toxic epidermolytic necrolysis, porphyria cutanea tarda	Erythema multiforme, VZV (dermatomal or disseminated)
Ulcers	HSV, VZV, cytomegalovirus, ecthyma, fixed drug eruption, deep mycoses	Rupioid syphilis (lues maligna)
Pustules:		
hair follicle-based	Folliculitis (eosinophilic, staphylococcal, gram-negative, pityrosporum, demodex), acne	Folliculitis (especially staphylococcal), acne
not clearly hair follicle–based	Pustular psoriasis, Reiter's syndrome, disseminated HSV or VZV	Disseminated gonococcal infection, Reiter's syndrome (associated with chlamydial infection), pustular syphilis
Papules with scale (papulosquamous)	Seborrheic dermatitis, psoriasis, Reiter's syndrome, dermatophyte, scabies	Papulosquamous syphilis, Reiter's syndrome, pityriasis rosea, dermatophyte infection, seborrheic dermatitis
Eczematous	Seborrheic dermatitis, scabies, drug hypersensitivity, atopic dermatitis, dermatophyte	Scabies, atopic dermatitis, seborrheic dermatitis
Erythroderma	Seborrheic dermatitis, psoriasis, TEN, drug hypersensitivity	
Dry skin (xerosis), ichthyosiform	Ichthyosis, asteatosis, nutritional deficiencies, drug-related, atopic dermatitis	Atopic dermatitis
Purpura (including palpable purpura)	Kaposi's sarcoma, idiopathic thrombocytopenic purpura, vasculitis associated with hepatitis B or C virus	Disseminated gonococcal infection, vasculitic syphilis, vasculitis associated with hepatitis B or C virus
Pigmentary changes:		
hypo-/depigmentation	Postinflammatory hypopigmentation, vitiligo	Postinflammatory hypopigmentation with syphilis
hyperpigmentation	Postinflammatory hyperpigmentation, medication-related (zidovudine)	

[a]For any references to syphilis, assume the secondary stage unless otherwise specified.

Scabies

Scabies classically manifests as linear papules distributed in finger web spaces, flexor wrists, axillae, nipples, waistline, ankles, and genitals, but usually sparing the face and scalp (Figs. 62-4 and 62-5). The linear papules result from the burrowing of the adult mite into the epidermis (Fig. 62-6). Burrows, however, appear relatively infrequently compared with discrete papules, many of which are eroded from scratching (Fig. 62-7). In general, one should consider the diagnosis of scabies in any patient with a generalized pruritic rash. Though described here under the category of papular rash, scabies may appear eczematous or papulosquamous, depending on chronicity, presence of bacterial superinfection, and immune status of the patient. The diagnosis of scabies is covered in Chapter 46.

HIV-infected and other immunocompromised patients have an increased incidence of atypical manifestations of scabies, including face and scalp involvement, nodular lesions, and hyperkeratotic (often referred to as crusted or Norwegian) scabies (Fig. 62-8).[11] Because the diagnosis of scabies is often delayed in patients with atypical forms of the disease, community outbreaks and nosocomial infestations may result.[12]

The treatment of choice for most cases of scabies is a topical scabicide, such as permethrin 5% cream, applied from the neck down, left on overnight, and rinsed off in the morning. Most patients do not need a second application at a later time, as is common practice in the use of other scabicides. Patients with crusted scabies, however, require repeated total body (and head) applications. For those patients with crusted scabies who develop hyperkeratosis, adding ammonium lactate (12% lotion applied BID) can help to diminish the scale, though it may temporarily irritate

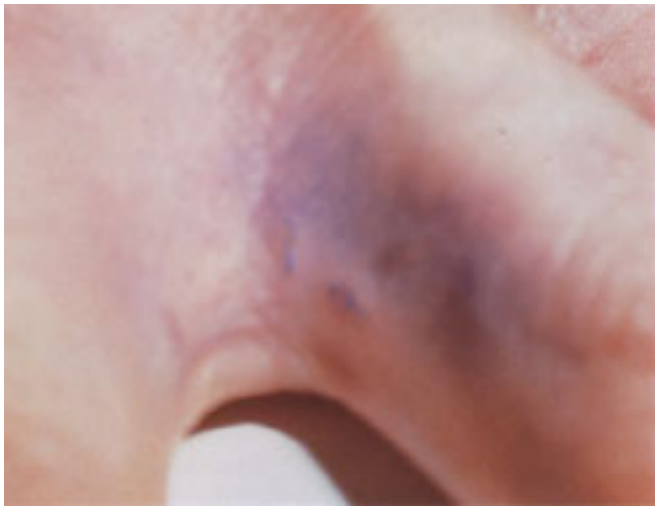

FIGURE 62-4. Intradermal burrow of scabies demonstrated by coating the skin with ink, then wiping away surface ink, leaving the intradermal burrow filled with ink.

FIGURE 62-5. Scabies of the penis. Pyoderma of the penis is highly suggestive of scabies.

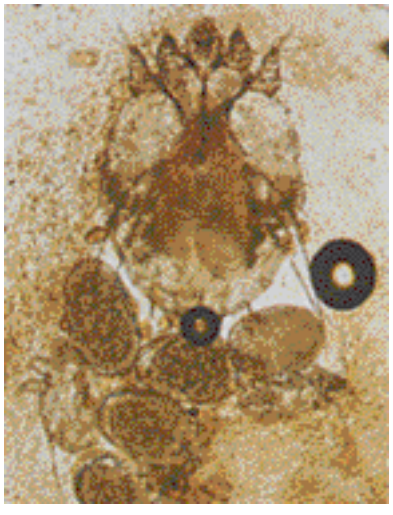

FIGURE 62-6. *Sarcoptes scabiei* mite with eggs in feces scraped from scabetic burrow.

FIGURE 62-8. Hyperkeratotic scabies involving the scalp and face.

the skin. The use of single-dose oral ivermectin, 200 μg/kg, has shown promising results, including patients with crusted scabies.[13]

Macular and papular secondary syphilis

An array of generalized rashes can develop in patients with secondary syphilis, including the macular (roseola-like) and papular variants. The macular lesions often appear as faint, pale, pink macules that do not have scale. Papular secondary syphilis occurs more frequently than the macular form, and probably represents an evolution from undetected macular lesions. The papular lesions are typically distributed on the face, flexural folds, and trunk. Involvement of the palms and soles is characteristic, with lesions often appearing brown-red in this location (Figs. 62-9 and 62-10). Several variants of papular syphilis have been described. Annular lesions, more commonly seen on the faces of blacks with secondary syphilis, can resemble sarcoidosis or tinea. Corymbose ("flat-topped flower bouquet") lesions appear as a central large papule or nodule surrounded by small satellite papules. Papulosquamous secondary syphilis is discussed later in this chapter. Later in the course of secondary syphilis, papules may occur at certain sites, such as the corners of the mouth ("split papules"), angles of the nose, and body folds. Patchy, "moth-eaten," nonscarring alopecia commonly manifests in secondary syphilis (Fig. 62-11). With all forms of secondary syphilis, patients develop varying degrees of generalized lymphadenopathy.

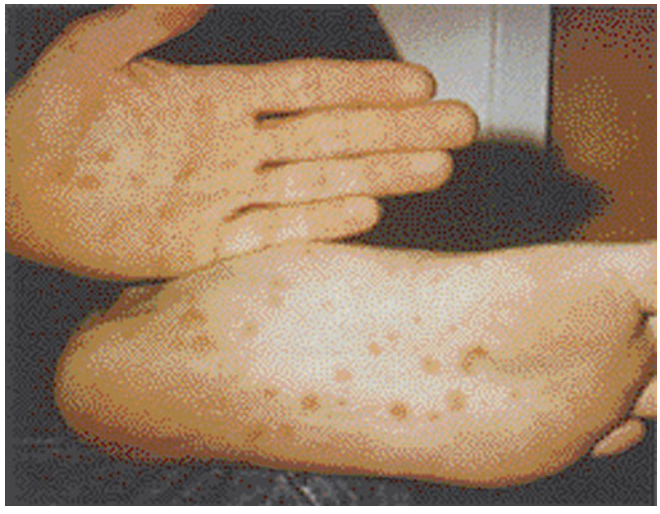

FIGURE 62-9. Secondary syphilitic rash of the palm and sole.

FIGURE 62-10. Secondary syphilitic rash of palm.

FIGURE 62-11. Patchy alopecia of secondary syphilis.

Jarisch–Herxheimer reaction

Two to eight hours after starting antimicrobial therapy for secondary syphilis, a febrile Jarisch–Herxheimer reaction

associated with malaise, headache, tender adenopathy, pharyngitis, and leukocytosis can occur and will alarm the unprepared patient and the unsuspecting practitioner. During this reaction, the existing rash may become more prominent, or a previously unrecognized rash of secondary syphilis may appear. The incidence of the Jarisch–Herxheimer reaction is approximately 95% in patients with seropositive primary syphilis or secondary syphilis. The incidence decreases in late secondary syphilis, and is frequently absent in latent syphilis.[14] This reaction is considered a therapy-associated response, but not a drug hypersensitivity reaction. The precise mechanism remains unknown (see Chapter 35),[15] though it seems to involve increased levels of tumor necrosis factor-alpha.[16] The sudden onset and associated systemic symptoms distinguish the Jarisch–Herxheimer reaction from most drug-associated eruptions, including the generalized morbilliform rash (see below) observed with penicillin hypersensitivity. Although the anaphylactic, urticarial reaction to penicillin has a rapid onset, one can easily distinguish it from the Jarisch–Herxheimer reaction on the basis of lesion morphology (a wheal in the case of urticaria). A similar Jarisch–Herxheimer reaction has been observed with the treatment of other infections, including Lyme disease and relapsing fever.

Drug hypersensitivity

Although cutaneous reactions to drugs can take many forms, the most common reaction is the generalized macular and papular eruption. Many authors have referred to this reaction as a "maculopapular" or "morbilliform" rash. Neither of these terms, however, is optimal—the former because true "maculopapules" do not exist and the latter because many medical providers in Western countries have little experience diagnosing the "morbilliform" rash associated with measles. A generalized macular and/or papular drug hypersensitivity rash often begins on the trunk and spreads peripherally (Fig. 62-12). Individual edematous and erythematous macules and papules will commonly coalesce and sometimes appear urticarial. Although this type of drug reaction most commonly appears within the first two weeks of introducing a new drug, it can occur after long term use. Patients often complain of pruritus, but much less frequently of fever or other constitutional symptoms. One example of this systemic involvement is seen in the drug hypersensitivity *syndrome*, now termed *drug reaction with eosinophilia and systemic symptoms* (DRESS). DRESS typically occurs three or more weeks after initiation of the culprit medication, and in addition to an intense erythematous papular rash that often involves 75% or more of the body surface, the patient also experiences fever, malaise, leukocytosis (or sometimes leukopenia) and eosinophilia. Various internal organ involvement, such as hepatitis, nephritis, and pneumonitis may also occur.

FIGURE 62-12. Generalized maculopapular rash due to drug hypersensitivity.

Common culprit drugs causing DRESS include sulfonamides, allopurinol, and aromatic anticonvulsants. Among the latter, cross-reactivity between phenytoin, phenobarbital, and carbamazepine is the rule. Authors have reported cases of DRESS from antiretroviral medications, particularly nevirapine and abacavir.[17,18]

Some drug hypersensitivity eruptions are photodistributed; that is, they appear predominantly in ultraviolet (UV) light–exposed skin. Photosensitivity due to medications is divided into phototoxic and photoallergic reactions. Phototoxic reactions, which account for most photosensitive drug reactions, typically present as an exaggerated sunburn within hours of UV light exposure and do not require prior exposure to the culprit drug. Photoallergic reactions are uncommon and present approximately 48 hours after UV light exposure. Photosensitizing drugs commonly used to treat STDs or HIV-related disorders include doxycycline (phototoxic) and trimethoprim-sulfamethoxazole (phototoxic or photoallergic).

Human immunodeficiency virus–infected individuals when compared with HIV-negative persons, develop cutaneous manifestations of adverse drug reactions with increased frequency, even when controlling the rate of usage of certain drugs, such as sulfonamides.[1] Moreover, the risk of drug hypersensitivity increases with advanced immune-system dysfunction. Proposed mechanisms for this apparent increased susceptibility to adverse drug reactions include enhanced T-cell susceptibility and/or decreased hepatic metabolism of drugs secondary to glutathione deficiency.[19]

The approach to a patient with a suspected drug-hypersensitivity reaction depends on the severity of the reaction, the need to continue the suspected drug, and the question of whether an equally effective alternative exists or not. In HIV-infected patients, approximately one-third of sulfonamide-induced hypersensitivity eruptions (not DRESS) spontaneously resolve, and allow continued use for long-term

Pneumocystis carinii pneumonia prophylaxis.[20] Symptomatic treatment with antihistamines and topical steroids can help relieve symptoms during the acute reaction. Close observation is recommended, however, because more severe reactions, such as DRESS, Stevens–Johnson syndrome, or toxic epidermal necrolysis (see below), may ensue. Short courses of systemic steroids are occasionally needed with severe reactions, including DRESS; these severe reactions generally mandate stopping the suspected medication.

Erythema multiforme/Stevens–Johnson syndrome/toxic epidermal necrolysis

Erythema multiforme (EM) refers to an epithelial vascular reaction pattern, and is traditionally considered to represent a spectrum of disorders. Erythema multiforme minor typically present as acrally-predominant papules that evolve to form classic target lesions, though atypical targets and urticarial plaques without targets sometimes form. Vesicles or bullae may develop within the center of these lesions (Fig. 62-13), which is surrounded by a zone of pallor that is further circumscribed by a ring of erythema creating the characteristic target pattern. Patients with EM "minor" generally do not have constitutional symptoms or mucosal involvement. Investigators have identified herpes simplex virus (HSV) infection, both genital and orolabial (including asymptomatic infection), as a precipitating event in some of the cases of EM minor. In addition, recurrent EM minor can occur with recurrent herpetic outbreaks.

Although most authors have traditionally equated EM "major" (or EM with mucositis) with Stevens–Johnson syndrome, recent investigation indicates that these two disorders may be distinct. Stevens–Johnson syndrome is characterized by a sudden onset of fever, constitutional symptoms, rash, and mucosal erosions. The cutaneous lesions appear as erythematous or purpuric macules, sometimes with superficial vesicles or erosions, that tend to generalize with truncal predominance. Mucosal involvement includes oral, ocular, or genital sites. Severe mucositis associated with acrally predominant target lesions is better termed as EM major.[21] Investigators have attempted to distinguish Stevens–Johnson syndrome histologically from EM major, with more epidermal necrosis favoring Stevens–Johnson syndrome and more dermal inflammation suggesting EM major.[22] Most cases of Stevens–Johnson syndrome are drug related, with sulfonamides and anticonvulsants most often incriminated, whereas most cases of EM major are HSV-related.[23]

Toxic epidermal necrolysis (TEN or Lyell's syndrome), conventionally considered to represent the most severe end of the EM spectrum, is characterized by the onset of painful erythroderma, followed by widespread sloughing of the epidermis (Fig. 62-14). Mortality is approximately 20%, though it varies widely depending on the population studied. The cause of toxic epidermal necrolysis is almost exclusively drugs, most of the culprits being the same as in Stevens–Johnson syndrome. An increased incidence of toxic epidermal necrolysis possibly exists among those with HIV infection,[24] but this may simply represent an increased use of medications, such as sulfonamides, known to cause toxic epidermal necrolysis. As with DRESS, an increasing number of reports implicate various antiretroviral agents in causing TEN.[25]

GENERALIZED PAPULES AND NODULES

Molluscum contagiosum

The papules of molluscum contagiosum caused by a pox virus are distinctive. The lesions are generally 2–5 mm in size, and may number from a few located on the face or genitals to numerous widely scattered lesions. They are flesh-colored to white-pink, domed, and centrally umbilicated (Fig. 62-15). Among HIV-infected individuals, the lesions tend to be more numerous and may be nodular (so-called "giant molluscum" if 1 cm or more) and disfiguring. Reports have described patients with disseminated cryptococcosis, coccidioidomycosis, or

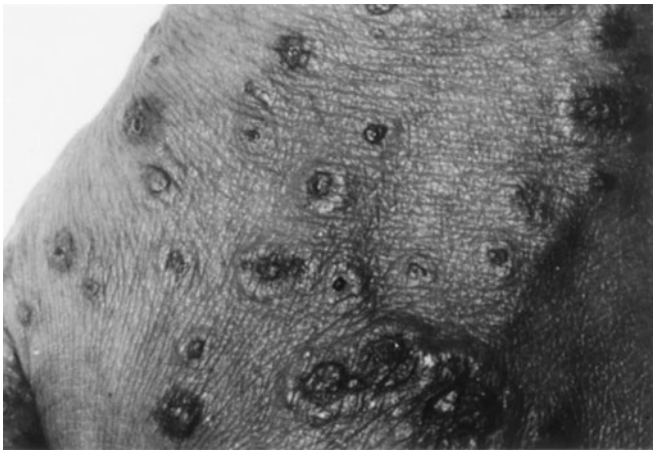

FIGURE 62-13. Typical target lesions in erythema multiforme on the wrist and hand. These lesions have central vesicles.

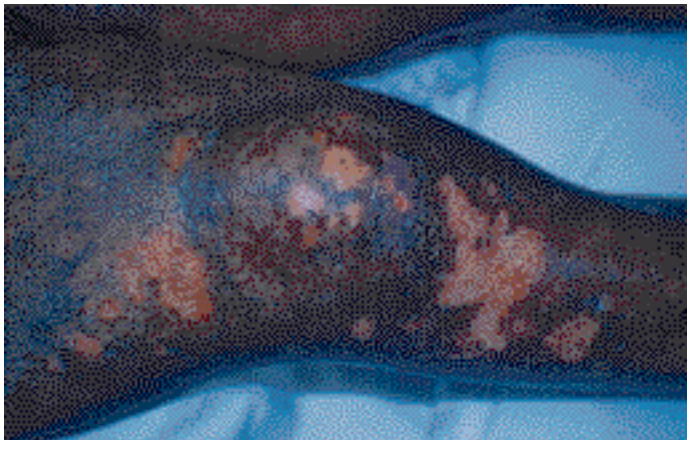

FIGURE 62-14. Toxic epidermal necrolysis due to trimethoprim-sulfamethoxazole. Initial confluent erythema progresses to epidermal sloughing.

FIGURE 62-15. Molluscum contagiosum of the lower abdomen and suprapubic area in a patient with coexisting genital molluscum lesions. Note central umbilication and pale salmon color.

Penicillium marneffei presenting with disseminated lesions that resemble molluscum contagiosum.[26–28] Treatment options for patients with molluscum include cryotherapy, electrodessication, gentle curettage, topical tretinoin, and superficial chemical peeling. Generally, these therapies produce excellent cosmetic results. One report describes disfiguring molluscum contagiosum in an HIV-infected patient responding to combination antiretroviral therapy.[29] In the author's experience, molluscum contagiosum in HIV-infected patients generally responds well to effective antiretroviral therapy.

Kaposi's sarcoma

Kaposi's sarcoma lesions are usually easily recognized, especially in the setting of patients with confirmed or suspected HIV infection. The lesions typically appear as violaceous papules and nodules that can be single, few, or multiple and widely scattered (Figs. 62-16 and 62-17). Incipient lesions commonly appear macular and may resemble a bruise. With isolated skin involvement, Kaposi's sarcoma lesions generally produce no symptoms; if, however, the lesions progressively extend into the subcutaneous and lymphatic tissues, chronic lymphedema may form.

Bacillary angiomatosis

Bacillary angiomatosis (BA) was first described in 1983 in HIV-infected patients with fever and subcutaneous nodules.[30] Since then, BA has been observed most commonly in the skin as solitary or multiple vascular lesions that clinically resemble Kaposi's sarcoma. Involvement of the liver (peliosis hepatis), spleen, lymph nodes, bones, lungs, and central nervous system (CNS) have all been attributed to BA. The causative organisms, *Bartonella henselae* and *B. quintana*, have been isolated using special culture techniques and identified with polymerase chain reaction (PCR) techniques.[31,32]

FIGURE 62-16. Kaposi's sarcoma in the palate as a manifestation of AIDS.

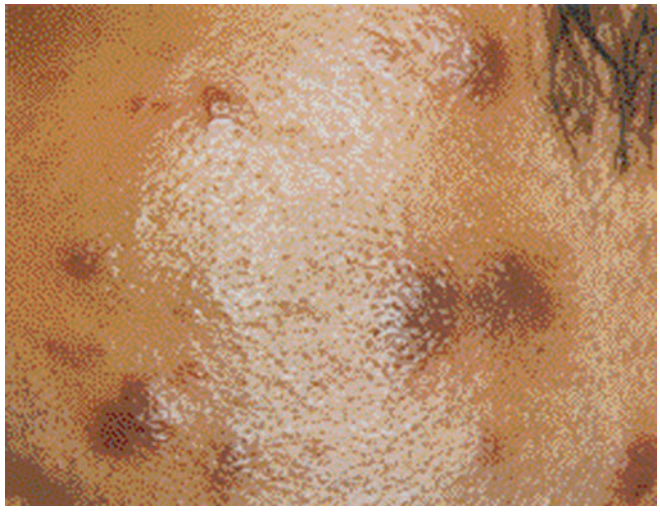

FIGURE 62-17. Kaposi's sarcoma on the face of a homosexually active man with AIDS.

Bartonella henselae is the most common cause of cat-scratch disease in immunocompetent patients.[23] Exposure to cats, especially kittens, is associated with a higher risk of contracting BA and cat-scratch disease.[33,34]

Bacillary angiomatosis most often involves HIV-infected patients with advanced immunosuppression (CD4 count >100 cells/μl), though BA has rarely been reported in immunocompetent patients and organ transplant recipients.[35,36] Perhaps due to prophylaxis for mycobacterial infection used in advanced stages of HIV infection, BA has become more rare than earlier in the AIDS pandemic. However, in some areas of the world where such prophylaxis is not widespread, BA appears to be quite prevalent.[37]

The skin is the most commonly involved organ in BA, though the infection may present only with fever.[38] The lesions are red papules that progress to exophytic papules and nodules. These tend to be friable, and are surrounded by a collarette of scale, resembling pyogenic granulomas.

Subcutaneous lesions are flesh-colored, usually nontender, and mobile, similar to epidermoid cysts. Fever, night sweats, weight loss, and fatigue are common, though patients have variable degrees of constitutional illness.

Biopsy is very helpful, particularly when the clinical differential diagnosis includes Kaposi's sarcoma. Histologic appearance of BA lesions typically shows dermal vascular proliferation, with plump endothelial cells lining the vessels, as well as neutrophils aggregated around eosinophilic material.[39] With Warthin–Starry staining, innumerable black bacilli become evident. In some instances, cultures confirm the diagnosis. Treatment with erythromycin, 500 mg po qid, results in gradual improvement. Duration of therapy is not clear, though most recommend a minimum of 8 weeks of therapy for cutaneous lesions in HIV-infected patients.[40,41]

Systemic mycoses in HIV

Although the lesion morphology may vary, the cutaneous lesions of disseminated cryptococcus, histoplasmosis, coccidioidomycosis, sporotrichosis, penicilliosis (due to *Penicillium marneffei*), and others often appear as widely scattered papules or nodules, though other morphologies, such as mucocutaneous ulcers, cellulitic plaques, and pustules are also seen. Indeed, these papular and nodular lesions of disseminated fungal infections, especially cryptococcus, may resemble molluscum contagiosum.[42,43] Patients infected with HIV who develop disseminated fungal infections have low CD4 counts, usually >100 cells/μl. Because primary cutaneous infections rarely occur with the systemic mycoses, the disseminated cutaneous lesions presumably arise from a noncutaneous focus, such as the lungs, and seed the skin from hematogenous spread. Other systemic mycoses that can rarely involve the skin in HIV-infected individuals include blastomycosis, primary cutaneous aspergillosis,[44] pneumocystosis, and paracoccidioidomycosis.[45]

Cryptococcus neoformans is found worldwide and is a major cause of morbidity and mortality among AIDS patients, primarily through CNS infection. Dissemination to the skin occurs in approximately 6–10% of immunocompromised patients and can be the presenting sign of cryptococcosis (Fig. 62-18).[42,46] The lesions often appear as flesh-colored papules and nodules, often with central umbilication resembling molluscum contagiosum. The lesions are most often located on the face and neck, though they can be found anywhere on the body. Less frequently, the lesions can present as ulcers of the skin or mucous membranes, cellulitic or violaceous plaques, palpable purpura, or Kaposi's sarcoma–like nodules.[42] The diagnosis of any suspected disseminated fungal infection presenting in the skin is confirmed by performing a biopsy and sending the specimen for histology and culture. In disseminated cryptococcosis, the yeast cells are found in the dermis, often within a gelatinous capsule. Special stains such as silver stain or mucicarmine will highlight the yeast cells or capsule, respectively.

FIGURE 62-18. Cutaneous cryptococcosis presenting as an ulcer with a rolled border. A biopsy at the border sent for H & E and special stains for organisms and a second biopsy for culture is indicated here.

One of the cornerstones in therapy of all of the disseminated mycoses, including cryptococcosis, in the HIV-infected patient is to enhance immune function by treating HIV with antiretroviral therapy. Specific initial therapy for HIV-infected patients with disseminated cryptococcal infection usually consists of amphotericin B. The addition of flucytosine helps to prevent relapse.[47] These patients generally require lifelong maintenance therapy with fluconazole, unless immune reconstitution with antiretroviral therapy intercedes.

Histoplasmosis is acquired in endemic areas by inhaling *Histoplasma capsulatum* microconidia or hyphae.[48] Disseminated infection can occur with primary exposure or by reactivating an old infection; the latter explains how cases occur outside of endemic areas. Skin lesions, with no site predilection, develop in approximately 11% of HIV-infected patients with disseminated histoplasmosis, and occurs more frequently than HIV-uninfected patients.[49,50] An array of lesions have been reported, including diffuse erythematous macules and papules, keratotic or ulcerated papules and nodules, and pustules. Ulcers of the oral and, rarely, rectal mucosa have been described. Biopsy with special stains offers a rapid, though relatively insensitive, method of diagnosis. Culture of the skin with other diagnostic methods (blood or urine antigen detection and cultures of other tissues, e.g., bone marrow or respiratory secretions) will usually confirm the diagnosis.[47] Initial therapy consists of amphotericin B, followed by maintenance therapy with itraconazole capsules.[51]

Coccidioides immitis is endemic to the southwestern United States, northern Mexico, and Central America.[45,47] Infection occurs after inhaling arthroconidia, with subsequent hematogenous dissemination of endospores. Skin lesions occur in approximately 5% of patients with disseminated infection. The primary lesion usually begins as a papule that evolves to a nodule, plaque, pustule, or ulcer. The lesions have

a predilection for the face and can resemble molluscum contagiosum. The oral cavity is spared. Biopsy for histology and culture is indicated when considering the diagnosis. Histologic examination shows large (30–60 μm) spherules filled with endospores. Cultures, DNA probes, and serologic testing also help confirm the diagnosis. Initial therapy is with amphotericin B for nonmeningeal disease, with or without an azole antifungal (fluconazole or itraconazole), or an azole for mild disease.[47]

Disseminated sporotrichosis, though rarely reported, presents most commonly with skin lesions, including diffuse papules and nodules, in the setting of advanced HIV disease and other forms of immunosuppression.[52,53] Other lesion morphologies include diffuse ulcers. Like the other disseminated fungi, skin biopsy for histology, and culture provides a convenient way to make this diagnosis. Amphotericin B and itraconazole have been the principal antifungals of choice.

Penicillium marneffei has emerged as an important fungal pathogen in HIV-infected individuals in Thailand, Vietnam, Myanmar, southern mainland China, Hong Kong, Taiwan, and India.[54–57] The bamboo rat is the reservoir for this dimorphic, red pigment-producing fungus. Patients generally present with fever, cough, and a generalized skin eruption characterized by papules that have central necrosis or umbilication. These skin lesions have a predilection for the face, ears, upper trunk, and arms. Several reports have also described patients with genital and oral ulcers. Amphotericin B, followed by itraconazole, is the treatment of choice.

Paracoccidioides, due to *P. brasiliensis*, can present with protean manifestations, including fever, mucosal changes, adenopathy, and skin lesions. This fungus is endemic to areas of Central and South America and affects 10 million people. However, reports of infection in HIV-infected patients are relatively rare, perhaps owing to the use of prophylactic antibiotics for other opportunistic infections preventing productive infection with *P. brasiliensis* and the lack of geographical overlap between areas of *P. brasiliensis* endemicity and HIV-infected populations.[47]

Cutaneous aspergillosis in HIV-infected patients has occurred as primary inoculation through the skin, especially at or near intravenous catheter sites or under occlusive dressings. It is frequently associated with neutropenia or malignancy. The infection leads to various lesion morphologies, including papular lesions that can resemble molluscum contagiosum. Interestingly, secondary cutaneous aspergillosis from disseminated infection has not been reported in HIV-infected patients.[44]

Several case reports have described cutaneous pneumocystosis, including reports of widespread violaceous papules and nodules.[58] Moreover, direct extension of the organism from the eustachian tubes can produce polypoid papules of the external auditory canal.

Pruritic papular eruption and eosinophilic folliculitis of HIV

There is controversy about the existence of the pruritic papular eruption (PPE) of HIV as a distinct entity. As originally described, this condition consists of variably pruritic, waxing, and waning skin-colored papules distributed over the extremities, face, and trunk.[59,60] Most authors have grouped the PPE eruption of HIV with various pruritic papular eruptions in HIV-infected patients, and refer to them collectively as "itchy red bump disease."[61] Some authors have postulated that the PPE represents an exaggerated response to insect bites[62] or is a type of folliculitis,[63] despite the histologic lack of follicular involvement. When considered as a distinct condition, PPE is common in those who are HIV-infected, especially those with low CD4 counts.[64] Despite the controversy of its existence as a distinct entity and a perhaps waning prevalence in North America, the United Kingdom and Europe, providers in sub-Saharan Africa and Haiti regularly encounter this frustrating condition.[62]

Eosinophilic folliculitis, discussed further below, is similar in its lesion morphology and somewhat overlapping distribution with that of PPE. Eosinophilic folliculitis is characterized by erythematous and edematous papules on the face, neck, upper trunk, and proximal upper extremities. Pustules are rare, and pruritus usually moderate to severe. Both PPE and eosinophilic folliculitis typically respond poorly to treatment with topical steroids, antihistamines, and most systemic antimicrobials. Ultraviolet light (UVB or psoralen with UVA) has been used with some success for PPE as well as for eosinophilic folliculitis.

LESIONS WITH VESICLES, EROSIONS, OR CRUSTS

Impetigo/ecthyma

Impetigo can manifest in one of the two forms: impetigo contagiosa or bullous impetigo (impetigo bullosa). Impetigo contagiosa is caused by *Staphylococcus aureus* or *Streptococcus pyogenes* (group A streptococci), though mixed infection with both of these organisms frequently occurs. Impetigo most often involves children, and the infection readily spreads via skin-to-skin contact. The primary lesion starts as a thin-roofed vesicle with an erythematous halo, though one typically sees the ruptured lesion as an erosion covered with a characteristic honey-colored crust. The lesions are painless, though often pruritic. In most instances, they involve the exposed skin of the face and extremities, but they may also complicate other skin diseases (secondary impetigo). In adults, secondary impetigo presents more commonly.

An analysis of trials of therapies for impetigo revealed that topical therapy, either mupirocin or fusidic acid, is more effective than systemic antibiotics in patients with localized impetigo.[65] In patients with more extensive disease, topical

therapy or treatment with an antistaphylococcal penicillin or first-generation cephalosporin effects resolution. Poststreptococcal glomerulonephritis is a rare but serious complication of streptococcal impetigo.

Bullous impetigo is caused by infection with specific phage types of *S. aureus* that produce within lesion an exfoliative toxin that leads to loss of cohesion of epidermal cells. This infection is common in infancy, but it also occurs among adults with poor hygiene, especially in hot, humid conditions. Lesions appear as flaccid, thin-roofed vesicles, and bullae, without an erythematous rim. They then become cloudy and pustular over 1–2 days, and rupture, leaving a dry, shiny, erythematous, varnish-like base. Lesions, typically pruritic, occur in the intertriginous areas of the axillae and groin. An oral antistaphylococcal antibiotic is preferred for this form of impetigo.

Ecthyma represents a deeper version of impetigo, with eventual formation of a superficial ulcer (Fig. 62-19). Group A streptococcus is most often the causative agent. The lesions are typically located on the lower extremities. Even with an appropriate extended course of antimicrobial therapy, the lesions heal slowly. Autoinoculation is common, and poststreptococcal glomerulonephritis develops with a frequency similar to that following impetigo contagiosa.

Disseminated vesicular viral infections

Disseminated herpes simplex virus (HSV) from hematogenous spread of the virus rarely occurs among HIV-infected patients, even those with advanced immunosuppression. Widespread HSV, known as eczema herpeticum, can occur in those with atopic dermatitis, or atopic-like dermatitis as seen with advanced HIV infection. Disseminated varicella-zoster virus (VZV) infection may occur concurrently with or following dermatomal zoster. The disseminated lesions resemble localized (dermatomal) disease—vesicles or pustules on an erythematous base (Fig. 62-20). Clinical appearance and a positive Tzanck preparation (for detection of multinucleated epithelial cells) help to make a presumptive diagnosis of either disseminated HSV or VZV (Fig. 62-21) though it does not distinguish between the two viruses. A definitive diagnosis is best made using direct immunofluorescence and viral culture. If a patient presents with typical vesicles in a generalized distribution, the practitioner should presumptively treat for varicella-zoster virus until receiving results of direct immunofluorescence and viral culture tests.

Patients with advanced HIV disease may present with atypical ecthymatous or ulcerative varicella-zoster virus lesions (Fig. 62-22).[66,67] These lesions often have a chronic course, even if the patient receives appropriate therapy for varicella-zoster virus infection. Disseminated herpetic infections generally warrant intravenous acyclovir in the immunosuppressed host. Oral acyclovir, valacyclovir, or famciclovir can be used for less severe infections. For confirmed

infections, failure to respond to the above warrants assessment for acyclovir-resistance.

Porphyria cutanea tarda

Porphyria cutanea tarda results from decreased activity of the hepatic enzyme uroporphyrinogen decarboxylase, either from acquired hepatic disease or from an inherited enzyme deficiency. This decreased enzyme activity leads to accumulation of intermediate substrates generated by heme synthesis, causing cutaneous photosensitivity and mechanical fragility. Skin lesions occur in sun-exposed areas or in areas incurring even trivial trauma, and include erosions, bullae, and hypo- and hyperpigmentation (Fig. 62-23). In addition, patients often develop facial hypertrichosis. Treatment consists of discontinuing all potential hepatotoxic agents, particularly ethanol, as well as having the patient undergo weekly phlebotomy to induce a mild iron deficiency anemia (a relative iron overload exacerbates the condition). Antimalarial medications are also used to treat porphyria cutanea tarda if phlebotomy does not lead to improvement or is contraindicated.

In recent years, investigators have increasingly recognized an association between porphyria cutanea tarda and viral infections, namely, hepatitis C virus[68] and HIV.[69] The association with HIV, however, may simply result from co-risk factors for acquiring hepatitis C virus.[70]

FOLLICULITIS AND THE DIFFERENTIAL DIAGNOSIS OF PUSTULES

Folliculitis

Folliculitis refers to inflammation of the hair follicle and encompasses a number of disorders seen in STD patients and in HIV-infected individuals. A hair follicle–based pustule is the primary lesion that typifies this group of conditions. Folliculitis, however, can present as papules, sometimes with erosions and crusts, especially if itchy and excoriated. It can be difficult at times to determine whether a lesion is follicular, though clues include distribution in hair-bearing areas, regular spacing between lesions, and the presence of a hair shaft in the center of a pustule or papule.

Causes of folliculitis include infectious agents (*S. aureus*, gram-negative bacteria, pityrosporum, and demodex mites), chemical irritation (chloracne), or physical injury. Examples of physical injury include occlusion of the skin, friction (e.g., "razor burn"), and pseudofolliculitis. The latter is a problem particularly in blacks, in whom regrowth of tightly curled hair penetrates the nearby skin causing foreign-body inflammation. Other types of folliculitis that are of multifactorial or unclear cause include acne vulgaris, steroid acne, and eosinophilic folliculitis.

Staphylococcus aureus folliculitis typically presents in areas of high hair density such as the scalp, buttocks, groin, thighs, forearms, or beard. The lesions often arise as painful pustules enclosing a central hair. The pustule is surrounded by erythema that extends beyond the pustule. In patients who develop a cluster of staphylococcal follicular pustules, the involved area may become confluently indurated and very tender. In some instances, abscesses may form and require drainage. A Gram's stain often reveals gram-positive cocci, either singly or in small clusters. If the patient has recently been hospitalized or recently taken antimicrobials, a culture with sensitivities would be indicated to exclude methicillin-resistant staphylococcus. An oral antistaphylococcal antibiotic will usually clear the condition. Bathing with soap and water and replacing the blade of the razor used for shaving may help to limit spread and decrease recurrences. In patients with recurrent staphylococcal folliculitis, eliminating nasal colonization with intranares application of 2% mupirocin ointment (bid × 5 days each month) may play an important role.[71]

In 1986, Soeprono first described HIV-associated eosinophilic folliculitis (EF),[72] a disorder that resembles Ofuji's eosinophilic pustular folliculitis.[73] When this HIV-related condition occurs, it virtually always involves those

with advanced stages of HIV disease (CD4 count less than 200 cells/Ìl). This disorder manifests as chronic pruritic, edematous papules distributed over the face, neck, and upper trunk. A preponderance of pustules should make one think of another diagnosis. Patients may have peripheral eosinophilia. Cultures from the lesions are negative, and this type of folliculitis responds poorly to antibacterials. Biopsy shows follicular inflammation with a predominance of eosinophils. Although difficult to treat, this condition sometimes responds to a combination of ultraviolet-B light therapy, high-potency topical steroids, and nonsedating antihistamines such as cetirizine (5–10 mg po qd). One study showed relatively favorable results with oral itraconazole (200–300 mg po qd).[74] After 1 month of itraconazole therapy, 17 of 28 patients had complete responses, and 4 patients had a partial response; at 6 months follow-up, 31% of patients had inactive disease, 13% required only topical steroids for control, and 56% remained on itraconazole with benefit (complete or partial control). Another report described the successful use of oral metronidazole (250 mg po tid × 3 weeks).[75] This report involved two patients who had lesions that contained gram-negative organisms that resembled *Leptotrichia buccalis*, a normal oral anaerobe. Aerobic and anaerobic cultures were negative, however. In the author's experience, metronidazole has been of little benefit for this condition.

Though eosinophilic folliculitis of HIV tends to affect those with CD4 counts less than 200 cells/µl, patients may experience EF after initiating antiretroviral therapy. Authors consider this a manifestation of immune reconstitution/inflame-matory syndrome.[76,77]

Nonfollicular pustules

The differential diagnosis of pustules also includes nonfollicular conditions, such as pustular secondary syphilis, pustular psoriasis, and acute generalized exanthematous pustulosis (AGEP). If one observes generalized pustules on areas such as the palms, soles, or lips, one may safely assume a nonfollicular process. The pustular eruption of secondary syphilis is typically located on the face and trunk (Fig. 62-24). The lesions begin as erythematous papules that subsequently develop a central pustule and finally erode with an overlying crust. Darkfield microscopy of a sample taken from a lesion shows treponemes; serologic tests generally confirm the diagnosis. Pustular psoriasis is an unusual and often eruptive form of psoriasis that mainly involves the palms and soles, and may strongly resemble keratoderma blennorrhagicum (of Reiter's syndrome). Pustular psoriasis also includes a generalized form (von Zumbusch), which may follow tapering or cessation of systemic corticosteroids used to treat severe plaque-type psoriasis. A number of medications, including beta-lactam antibiotics, cause AGEP. In contrast to most other cutaneous drug hypersensitivity eruptions, AGEP manifests within 2–3 days of drug exposure with high fever, red edematous skin with many tiny and superficial pustules. Distinction from acute pustular psoriasis can sometimes pose difficulty, though the temporal history of medication exposure supports AGEP. Discontinuation of the suspected drug, antipyretics, and topical steroids are usually enough to treat AGEP. Occasionally, one may need to use systemic steroids, thus eliciting an inciting medication history is crucial in distinguishing AGEP from pustular psoriasis.

FIGURE 62-24. Pustular and macular lesions in secondary syphilis.

Disseminated gonococcal infection initially appears as petechiae or palpable purpura, evolving to hemorrhagic pustules on an erythematous base (Figs. 62-25 to 62-27). The lesions are often tender, and typically they are few in number (>15) and acrally located, especially around the small joints. Cultures of material from the skin lesions of disseminated gonococcal infection are usually negative.

The natural evolution of many vesicular dermatoses includes a pustular stage. Thus, if one encounters a mixture of vesicular and pustular lesions, first consider the vesicular/bullous infectious diseases, such as varicella, disseminated HSV, and disseminated varicella-zoster virus.

PAPULOSQUAMOUS CONDITIONS

Seborrheic dermatitis

Seborrheic dermatitis presents as pruritic, erythematous, and scaly patches and plaques that involve the scalp (especially at the hairline), eyebrows, eyelash margins, nasal folds, beard area, and upper central trunk. The scale often appears greasy, particularly on the scalp and face. This condition is common, with 10–15% of the normal, healthy population afflicted.[78] Those afflicted will often recognize the condition as "dandruff" or "dry scalp". Seborrheic dermatitis afflicts up to 80% of HIV-infected individuals, depending on whether examination or history is used to determine incidence. In one study,

FIGURE 62-25. Typical distribution of skin lesions in disseminated gonococcal infection. Usually 5–20 such lesions are apparent on the extremities, generally sparing the face and trunk.

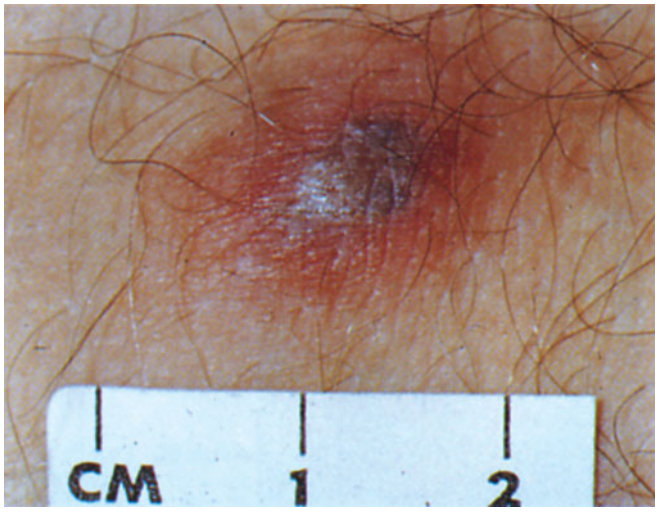

FIGURE 62-26. Hemorrhagic pustular lesion of disseminated gonococcal infection.

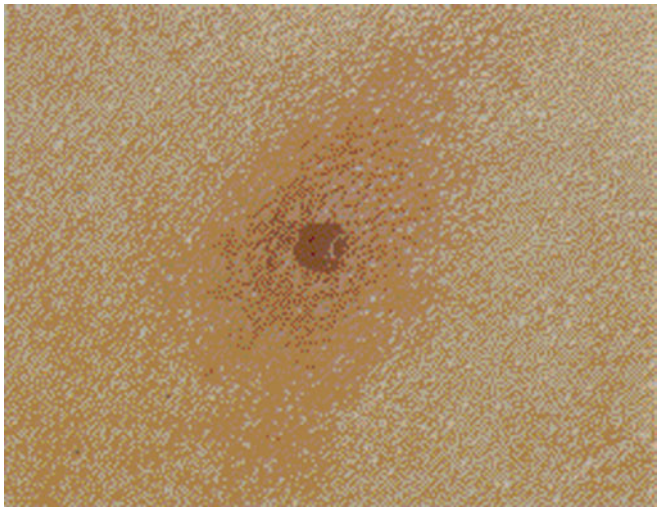

FIGURE 62-27. Crusted petechial lesion of disseminated gonococcal infection.

FIGURE 62-28. Sebopsoriasis. Erythematous papules and plaques with a greasy-appearing scale resembling seborrheic dermatitis.

53% of HIV-infected patients examined in a military-based study had seborrheic dermatitis.[79] Although most persons tend to have a waxing and waning course with seborrheic dermatitis, HIV-infected individuals generally have a more severe, persistent and recalcitrant condition, especially those with advanced stages of HIV disease.[80] Those patients treated with antiretroviral therapy enjoyed regression of the condition when compared to non-ARV-treated controls.[81]

The pertinent differential diagnosis includes psoriasis and dermatophytosis, the latter readily diagnosed by a positive potassium hydroxide preparation. When seborrheic dermatitis involves the axillae and groin, some authors prefer the term "sebopsoriasis" (Fig. 62-28).

The exact cause of seborrheic dermatitis remains unknown, but both enhance sensitivity to resident yeast on skin (*Malassezia species*) and overgrowth of this yeast within lesional skin appear to play an important role.[82] For this reason, therapy usually consists of a topical steroid (hydrocortisone 1% cream or lotion) and an antifungal or anti-seborrheic (dandruff) shampoo, such as one containing zinc pyrithione, selenium sulfide, or coal tar derivatives. Topical ketoconazole cream has also been used with success. Those HIV-infected patients with severe seborrheic dermatitis, especially those with advanced immunosuppression, may require therapy with oral ketoconazole, 200 mg per day for 4 weeks. Limited published experience exists with itraconazole (200 mg per day for 7 days) and fluconazole for seborrheic dermatitis.

Psoriasis

Psoriasis is the prototype of papulosquamous (scaly papules and plaques) disease, and affects 1–2% of the general population. The common plaque variety, psoriasis vulgaris, develops as salmon-colored plaques that have a silvery scale, typically located on the extensor surface of the elbows and knees, as well as on the trunk. Patients often have scalp, gluteal fold, umbilical, genital, and nail involvement, but only rarely does psoriasis develop on the face. Patients typically have minimal or no

pruritus. One should always consider psoriasis in the differential diagnosis of a patient with scaly papules or plaques on the genitals. Lesions may appear in sites of skin trauma, such as linear plaques at sites of picking or scratching—the so-called Koebner phenomenon. Other forms of psoriasis exist, including guttate (droplike) psoriasis (Fig. 62-29). This form of psoriasis most often presents in young persons and may resemble papulosquamous secondary syphilis. An infection with *Streptococcus pyogenes* (group A streptococci), sometimes asymptomatic, often precipitates guttate psoriasis.

Although one study found a psoriasis prevalence of 5% among HIV-infected individuals,[83] most studies have not shown HIV-infected individuals to have an increased prevalence of psoriasis when compared with the general population. Individuals infected with HIV do have an increased prevalence of arthritis associated with psoriasis, however, correlating with the presence of HLA B27 and C7 antigens. Some authors have placed HIV-associated psoriasis and Reiter's syndrome along the same spectrum of disease.[84]

The management of psoriasis is beyond the scope of this chapter, but therapy for HIV-related psoriasis has several unique aspects that warrant discussion. First, HIV-related psoriasis tends to respond to antiretroviral therapy. Although this was initially documented with zidovudine (AZT),[85] combination antiretrovirals produce similar responses. Second, despite initial reports of enhanced HIV replication and immune suppression caused by ultraviolet (UV) light treatment, subsequent studies have not found the use of UV-B or PUVA (psoralen with UVA) to accelerate HIV disease progression. Third, many systemic agents for psoriasis, such as methotrexate, azathioprine, and cyclosporine A, cause nonspecific or specific T-cell immunosuppression and should be avoided, until studies indicate otherwise. Lastly, the systemic retinoids, particularly acitretin, appear to help with moderate to severe psoriasis and do not exacerbate immunosuppression.

FIGURE 62-29. Droplike, or guttate, lesions of psoriasis. Such lesions are often seen with acute flares of the disease, often following streptococcal infection.

Reiter's syndrome (Reactive arthritis with mucocutaneous features)

Reiter's syndrome is a parainfectious reaction associated with urogenital infections (most often due to *C. trachomatis*) and enteric infections (*Shigella, Yersinia, Campylobacter*, and *Salmonella*) occurring in susceptible individuals, more often young men, with the HLA B27 genetic marker. The clinical syndrome is characterized by urethritis, conjunctivitis, and a seronegative spondyloarthritis. The cutaneous lesions keratoderma blennorrhagicum and circinate balanitis develop in 15% and 36% of patients, respectively (Figs. 62-30 and 62-31).[86] Mucocutaneous lesions may precede or follow the onset of extracutaneous illness (Fig. 62-32). The primary lesion of keratoderma blennorrhagicum begins as a dull red papule that rapidly forms a hyperkeratotic yellow surface. Lesions coalesce into plaques and may have a circinate collarette of scale. In some instances, pustular lesions form. Although keratoderma blennorrhagicum most often involves the soles of the feet, lesions may appear in other areas, such as the dorsa of the feet, legs, hands, fingers, nails, and scalp. Severe keratoderma blennorrhagicum can become generalized, especially in HIV-infected individuals; in this form, it resembles pustular psoriasis. On the penis, moist, red erosions merge to form circinate balanitis in the uncircumcised male; in the circumcised male, the lesions form hard crusts and plaques. Circinate vulvitis has been described.[87] Approximately 15% of patients with circinate balanitis have transient oral lesions, typically painless small vesicles that rapidly form superficial erosions or a patchy erythema. Reiter's syndrome often recurs without obvious relationship to new infections, although one should consider reinfection from untreated partners.

Dermatophytosis

Dermatophyte (tinea) infections typically manifest as a localized reaction on the feet, intertriginous areas, trunk,

FIGURE 62-30. Circinate balanitis in Reiter's syndrome.

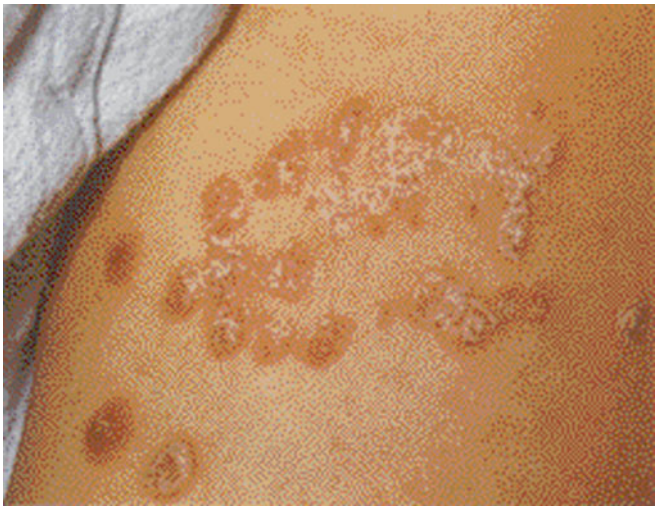

FIGURE 62-31. Keratodermia blenorrhagica in Reiter's syndrome.

FIGURE 62-32. Superficial ulcerations of the tongue in Reiter's syndrome.

scalp, or nails. The lesions generally appear annular with a relatively accentuated red, scaly edge (so-called "ring worm"). Infrequently, patients with tinea corporis present with a widespread rash, most often following use of topical steroids for misdiagnosed eczema ("tinea incognito"). The fungus most commonly responsible is *Trichophyton rubrum*. Scraping a lesion, especially at the accentuated edge and digesting the sample with potassium hydroxide sample usually confirms the diagnosis (Fig. 62-33). Sometimes a fungal culture is needed to confirm the diagnosis.

With localized dermatophyte infections, topical antifungals, such as 1% clotrimazole, 2% ketoconazole, 1% terbinafine, and others, are generally sufficient. When large surfaces are involved, systemic treatment, at least initially, may be warranted. The systemic azole antifungals (ketoconazole, itraconazole, and fluconazole), the allylamine terbinafine, and griseofulvin all have shown good efficacy.

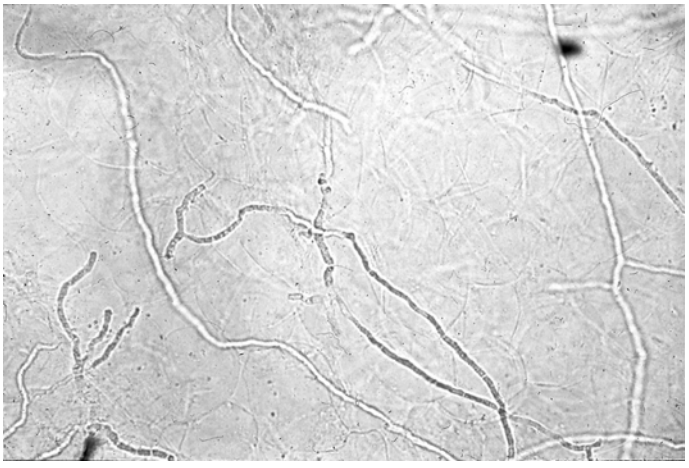

FIGURE 62-33. A potassium hydroxide preparation of scale from a patient with dermatophyte infection. Note abundant hyphae.

Patients infected with HIV tend to have more extensive dermatophytosis that can recur despite good initial response to therapy. Most of the time, one recognizes the lesions readily, but occasionally HIV-infected patients present with lesions that do not have the typical annular appearance. HIV-infected patients also more commonly acquire proximal subungual onychomycosis, an HIV-specific dermatophyte infection of the nails that is rare in individuals with intact immune systems.[88]

Papulosquamous secondary syphilis

Patients with secondary syphilis often present with copper-colored papules and plaques with varying degrees of scale (Figs. 62-34 to 62-36). The lesions can mimic other papulosquamous dermatoses, namely psoriasis (Fig. 62-36), lichen planus, and pityriasis rosea. The color and generalized distribution (including the palms and soles) in a patient with generalized lymphadenopathy should cause one to suspect secondary syphilis.

Pityriasis rosea (PR) is morphologically similar to papulosquamous secondary syphilis but generally without lymphadenopathy or constitutional symptoms. Although the etiology is unknown, investigators suspect an infectious agent based on case-clustering and accounts of experimental transmission. Most cases occur in the winter months in persons 10–35 years of age. Human herpes types 6 and 7 have been implicated based on PCR assessment of patients with PR.[89]

The first, and often the largest, lesion—referred to as the "herald patch"—usually appears on the thigh, upper arm, trunk, or neck. Initially, the lesion forms as an asymptomatic, well-defined, bright-red papule covered by a thin collarette of scale. After 5–15 days, crops of new lesions appear over a 7–10 day period. These lesions are oval, pale red with a dull, yellow-brown center; they are surrounded by a thin collarette of scale that points toward the center of the papule. The rash

FIGURE 62-34. Psoriasiform secondary syphilis.

FIGURE 62-35. Psoriasiform secondary syphilis.

FIGURE 62-36. Morphologically these lesions look like psoriasis. In fact, they are psoriasiform lesions of secondary syphilis.

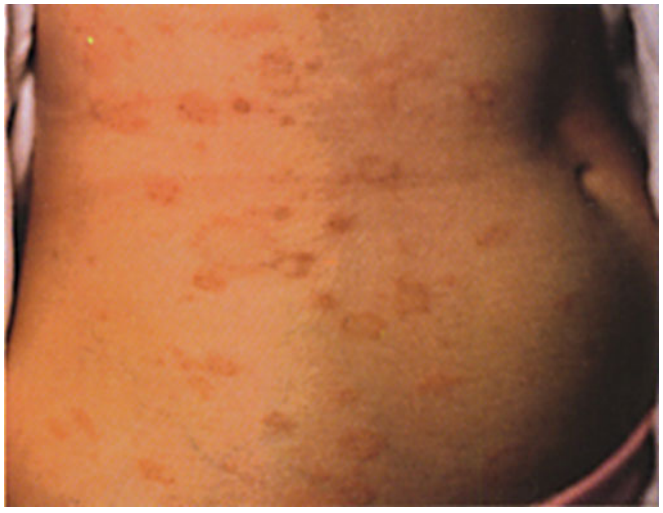

FIGURE 62-37. Characteristic lesions of pityriasis rosea.

is distributed over the trunk, upper arms, thighs, neck, and, infrequently, the face. On the posterior trunk, the long axes of the ovoid lesions follow the skin folds and give the typical "Christmas tree" appearance (Fig. 62-37). This pattern is inverted on the anterior trunk. The lesions typically persist for 3–4 weeks, though they may be present for 12 weeks or longer. Infrequently, patients develop an inverse form of pityriasis rosea, with lesions found in intertriginous areas as opposed to convex surfaces on the trunk. This variant may occur relatively more frequently in blacks than Caucasians. Patients with pityriasis rosea do not have constitutional symptoms, except for pruritus, usually mild to moderate, though occasionally severe. Topical triamcinolone, 0.1% cream or ointment applied twice daily, will relieve the symptoms of itching. The lesions fade after 3–6 weeks, and usually no other therapy is required. Ultraviolet light exposure is reported to hasten the resolution of PR.

PURPURA

Vasculitis

Vasculitis is a general term used to describe the inflammatory reaction to endothelial deposition of antigen–antibody complexes. The local inflammation and hemorrhage of cutaneous vasculitis produce the characteristic lesion of palpable purpura, a lesion that may progress to necrosis and ulceration. Lesions are commonly found first in areas of venous hypertension, most often the lower legs (Fig. 62-38). In addition to cutaneous lesions, patients with multisystemic vasculitis may have fever, arthralgias, gastrointestinal symptoms, and other constitutional manifestations. Vasculitis may develop as an acute disease with hemorrhagic, necrotic lesions that appear in crops and persist for 2–3 weeks; or as a more indolent disease in which purpura, erythematous macules, urticaria, and papules predominate and crops appear over months or years. Known associations with vasculitis

FIGURE 62-38. Purpuric papules and vesicles of vasculitis on the legs of a female intravenous drug user with the prodrome of hepatitis B.

include streptococcal and staphylococcal infection, prodromal hepatitis B, hepatitis C virus-associated mixed cryoglobulinemia, tuberculosis, persistent bacterial infection (such as dental abscess), certain drugs, malignancy, collagen vascular diseases, and pregnancy. It is important to exclude infectious causes before attempts are made to use corticosteroids or other immune suppressive agents.

In the prodromal stage of hepatitis B virus infection, patients can develop vasculitis and urticaria as well as macular and papular lesions. Hepatitis C virus (HCV) has been recognized as causing mixed cryoglobulinemia-associated vasculitis.[90,91] This usually presents in the skin as palpable purpura, but livedo reticularis and urticaria have also been described. As opposed to the prodrome of hepatitis B, HCV-related vasculitis occurs during the course of active hepatitis. Rarely, patients with syphilis can develop cryoprecipitates that elicit a cutaneous vasculitis. Disseminated gonococcal infection, mentioned above in the section on nonfollicular pustules, often initially produces skin lesions that clinically and histologically suggest vasculitis.

PIGMENTARY CHANGES

Hyperpigmentation associated with HIV infection

Treatment with zidovudine (AZT) can cause nail and, less commonly, cutaneous hyperpigmentation, especially among blacks (Fig. 62-39). Clofazimine, which has sometimes been used to treat disseminated Mycobacterium avium-complex infection in AIDS patients, can produce generalized orange or red-brown hyperpigmentation. Generalized hyperpigmentation, apparently independent of zidovudine or clofazimine therapy, has also been reported in AIDS patients.[92]

Postinflammatory pigment alteration

Postinflammatory hyperpigmentation or hypopigmention presents during and following any inflammatory skin condition,

FIGURE 62-39. Hyperpigmentation associated with zidovudine (AZT) therapy.

for example, atopic dermatitis, drug eruptions, and syphilis. More darkly pigmented patients are at higher risk. Time following the inflammatory insult and treatment of the inciting condition constitutes the treatment of these common pigmentary alterations. Postinflammatory pigment change lasts longest on gravity dependent areas, especially the legs, and can take months to years to resolve completely.

CONCLUSION

This chapter has attempted to introduce the STD or HIV/AIDS healthcare provider to an approach for a patient presenting with a generalized cutaneous condition. Visual inspection of the skin, even before receiving any medical history, is the most important diagnostic tool. Identifying the primary lesion, any secondary features, and the distribution of the rash are the keys to generating a differential diagnosis. This cannot be carried out without a thorough skin exam, which requires good lighting and adequate exposure of the skin.

The array of conditions that can present in patients with STDs or infected with HIV is vast and is certainly not restricted to those conditions listed in (Table 62-3). One must remember that in HIV-infected patients, common conditions may present with atypical variations, and more than one condition presenting together is a common scenario. It is critical to discern whether an infectious agent is the cause for the rash, since treatment is often specific and delay in treatment may result in significant morbidity.

An interesting aspect of generalized dermatoses in STD-afflicted and HIV-infected patients is the significant proportion of noninfectious inflammatory cutaneous conditions. These include parainfectious phenomena such as HSV-related erythema multiforme, Chlamydia-induced Reiter's syndrome, guttate psoriasis associated with streptococcal disease, and vasculitis associated with hepatitis B or C.

In HIV-infected patients, the high frequency of inflammatory conditions such as drug hypersensitivity, seborrheic dermatitis, and eosinophilic folliculitis defies clear explanation and seems paradoxical within the simple paradigm of immunosuppression related to HIV infection. Perhaps immunodysregulation is a better term to explain the simultaneous risks of opportunistic infection and inflammatory skin conditions. Further investigation into these parainfectious phenomena and the "hyperimmune" conditions of HIV-related skin disease will be needed to elucidate their pathogenesis.

63 Genital Ulcer Adenopathy Syndrome

Ronald C. Ballard

Genital ulcer adenopathy syndrome is a frequent presentation of sexually transmitted diseases (STDs), particularly in developing countries. The syndrome is usually caused by sexually acquired organisms gaining entry to the body via a breach in the epithelium of the genital skin or mucous membranes. Local multiplication of organisms, together with accompanying inflammatory reactions, results in the formation of open lesions. Under some circumstances, the regional lymph nodes may become involved leading to inguinal and/or femoral lymphadenopathy or ulceration. In cases of lymphogranuloma venereum (LGV), the reason for consultation may be the lymphadenopathy alone, owing to the transient nature of the initial lesion. There are a number of different causes of genital ulcer disease (GUD), and since the clinical presentation of each may be variable and the treatment for each different, genital ulcer adenopathy syndrome may create considerable diagnostic and management problems for clinicians. The relative importance of GUD and the need to provide prompt, effective treatment have increased as a result of the finding that these lesions are a major cofactor in the transmission of HIV.

EPIDEMIOLOGY

Epidemiological data on the genital ulcer adenopathy syndrome are incomplete, because diagnostic tests for all causes of the syndrome are usually not available at services where treatment is provided. Even when comprehensive services are available, notably during research projects, it is often not possible to determine the etiology of the disease in a significant proportion of cases, owing to lack of sensitivity of the laboratory tests used.[1–5] Of all causes of the syndrome, the recording of cases is probably the most complete for syphilis, owing to widespread use of serological screening tests and the recognition of the potential consequences of the disease if it is left untreated. However, overreporting of syphilis may frequently occur in some settings, since many patients presenting with proven nonsyphilitic lesions may prove seroreactive in tests for the disease.[6]

A total of 38,592 cases of genital ulceration were seen at Genitourinary Medicine Clinics in the UK during 2005. Of these, 35,451 (91.9%) were cases of genital herpes, 2,814 (7.3%) were classified as infectious syphilis, and the remaining 327 cases were chancroid, LGV, or donovanosis (0.8%).[7] Unfortunately, genital herpes, LGV, and donovanosis are not reportable diseases in the United States and, therefore, comparable figures are not available. However, approximately 266,000 cases of genital herpes were seen in physicians' offices during the same year, while 8,724 cases of primary and secondary syphilis and 17 cases of chancroid were reported to the Centers for Disease Control and Prevention (CDC).[8] In contrast, genital ulcerations are seen relatively more frequently at STD clinics and primary health-care facilities in developing countries. In sub-Saharan Africa and in Asia, genital ulcer disease may account for between 20% and 70% of STD clinic visits, whereas the comparable figure for Europe and North America is, at most, 5%.[9] In the past, the etiology of genital ulceration showed considerable geographical variability, with genital herpes the most frequent cause in North America and Europe and genital ulcerations caused by bacteria predominating in most developing country settings. However, in the past few years, the patterns of infection in many developing country settings have changed dramatically, with genital herpes becoming the leading cause of ulceration.[10] This may be due, in part, to the effective introduction of syndromic management for GUD resulting in a reduction in the relative prevalence of chancroid and syphilis and also to high rates of HIV infection with accompanying immunosuppression resulting in an increased rate of recurrence and severity of genital herpes. Despite these changes, chancroid remains a significant cause of GUD in sub-Saharan Africa—particularly in the south, Southeast Asia, India, South America, and the Caribbean. In North America, outbreaks of the disease have been associated with sex worker contact, particularly among minority populations.[11,12]

Classical LGV and donovanosis appear to be restricted to geographical foci in tropical countries, with LGV being documented in sub-Saharan Africa, South America and the

Caribbean, the Indian subcontinent, and Southeast Asia, while donovanosis has largely been restricted to India, Papua New Guinea, Northern Australia, southern Africa, and Brazil. These diseases are occasionally diagnosed in North America and Europe largely as a result of importation from endemic areas. However, LGV has reemerged as a cause of severe proctocolitis and anorectal ulceration among MSM both in Europe and the United States even though classical genital ulceration adenopathy syndrome is rarely encountered in this population.[13–14]

Overall, the proportion of STD patients with genital ulcerations and the causes of those ulcerations are probably dependent upon a number of factors, including geographical location, socioeconomic status, availability of diagnostic tests, sexual preference and practices, the relative importance of commercial sex in the spread of disease, the frequency of circumcision, and the prevalence of concomitant HIV infection.

Risk factors for genital ulceration inevitably vary according to etiology and population. The risk of acquisition of chancroid appears to be related to low socioeconomic status, geographic origin, commercial sex, and lack of circumcision.[15] In contrast, in the United States and Western Europe the majority of cases of primary syphilis occur among MSM and among disadvantaged minority populations,[16] while the disease has also reemerged as a significant public health problem among heterosexuals in many communities in Eastern Europe where sex work is often associated with illicit drug use.

Relatively recently, a considerable body of evidence has accumulated linking genital ulceration with increased transmission of HIV.[17–19] These studies, conducted among MSM in the United States and among heterosexuals in many developing countries, indicate not only that the presence of genital ulcers significantly enhances susceptibility to HIV infection but also that the presence of genital ulcers in HIV-positive individuals results in increased transmission of the virus to others. Chancroid, in particular, was initially identified as a significant cofactor in the heterosexual transmission of HIV in Africa and Southeast Asia, with cofactor effects per sexual exposure being estimated as high as 10–50% for male-to-female transmission and 50–300% for female-to-male transmission in sub-Saharan Africa.[20] However, more recently, genital herpes has been implicated as a major cofactor enhancing HIV transmission, particularly in geographical regions with a mature HIV epidemic.[21,22] As a result, prompt management and prevention of genital ulcer disease, including genital herpes, has been identified by the WHO as a priority within STD control programs aimed at reducing the incidence of HIV infection.[23]

ETIOLOGY

The most frequent infectious causes of genital ulceration include herpes simplex virus (both HSV-1 and HSV-2), *Treponema pallidum, Haemophilus ducreyi*, the L-biovar of *Chlamydia trachomatis,* and *Klebsiella* (previously *Calymmatobacterium) granulomatis*. In addition, *Phthirus pubis–Sarcoptes scabiei* pyoderma, *Trichomonas vaginalis*, *Entamoeba histolytica,* mixed nonsyphilitic spirochetes, and *Phthirus pubis* or *Sarcoptes scabiei* infestation with secondary bacterial infection may cause breaks in the genital epithelium. While *Neisseria gonorrhoeae* and non-L isolates of *C. trachomatis* may be detected in genital ulcerations, they may represent transient contamination or colonization of the site by urethral/cervical pathogens rather than a causal relationship. The differential diagnosis of infectious genital ulceration includes trauma, malignancy, fixed drug eruption, and Behçet's and Reiter's syndromes.

CLINICAL MANIFESTATIONS

Superficially, the textbook descriptions of the clinical features of the individual causes of genital ulcer adenopathy syndrome appear to be characteristic (Table 63-1). However, in practice, the clinical presentation of genital ulcerations often does not correspond to the classic description and even experienced clinicians can be easily misled.[24–26] This situation is particularly evident in developing countries, where genital ulcerations are common and mixed infections are frequently encountered. In addition, other factors such as secondary bacterial infection; the local application of antiseptics, antibiotic, or corticosteroid creams; the systemic use of inappropriate or incomplete courses of antibiotics; and the influence of concomitant HIV infection with associated immunosuppression may all modify the clinical appearance of lesions[12] (Fig. 63-1).

In general, the incubation period for chancroid and genital herpes is short (less than 7 days) whereas it is usually longer for syphilis, LGV, and donovanosis. Unfortunately, estimated incubation periods can often be misleading owing to the failure

FIGURE 63-1. Multiple, superficial, secondarily infected lesions of genital herpes which mimic chancroid ulcerations in an HIV seropositive patient.

Table 63-1. Clinical Features of Genital Ulcers and Associated Lymphadenopathy

	Syphilis	Herpes	Chancroid	LGV	Donovanosis
Incubation period	9–90 d	2–7 d	1–14 d	3 d–6 wks	1–4 wks (up to 6 mo)
Primary lesions	Papule	Vesicle	Pustule	Papule, pustule, or vesicle	Papule
Number of lesions	Usually one	Multiple, may coalesce	Usually multiple, may coalesce	Usually one	Variable
Diameter	5–15 mm	1–2 mm	Variable	2–10 mm	Variable
Edges	Sharply demarcated, elevated, round, or oval	Erythematous	Undermined, ragged, irregular	Elevated, round, or oval	Elevated, irregular
Depth	Superficial or deep	Superficial	Excavated	Superficial or deep	Elevated
Base	Smooth, nonpurulent, relatively avascular	Serous, erythematous, nonvascular	Purulent, bleeds easily	Variable, nonvascular	Red, velvety, bleeds easily
Induration	Firm	None	Soft	Occasionally firm	Firm
Pain	Uncommon	Frequently tender	Usually very tender	Variable	Uncommon
Lymphadenopathy	Firm, nontender, bilateral	Firm, tender, often bilateral with initial episode	Tender, may suppurate, loculated, usually unilateral	Tender, may suppurate, loculated, usually unilateral	None, pseudobuboes

of patients to identify the correct source of the infection, especially when long incubation periods are involved.

Most genital ulcers in men are found on the prepuce (Fig. 63-2), near the frenulum, in the coronal sulcus, or on the penile shaft. In women, lesions may occur on the labia, on the vaginal walls and cervix, and on the inner thighs and fourchette. In both women and MSM, lesions may be found in the rectum and in the perianal region. Extragenital ulcers may be detected on the lips or in the throat as a result of orogenital contact. Classically, the lesions of primary syphilis and LGV are solitary; while those of chancroid, donovanosis, and genital herpes tend to be multiple, but these and other features are often atypical as a result of secondary bacterial infection and mixed etiologies.

Although the characteristics of primary ulcerations may be misleading when one is endeavoring to establish a definitive diagnosis on clinical grounds, features of the associated regional lymphadenopathy, when present, may be helpful in differentiating diseases. In both sexes, the lymphatic drainage of the external genitalia is primarily to the inguinal and to a lesser extent the femoral lymph nodes. However, the inner two-thirds of the vagina and cervix and the rectum drain to the deep pelvic (sacral) and perirectal nodes. Inguinal/femoral lymphadenopathy may therefore be associated with genital ulcerations, which may be present either on the external genitalia or hidden within the vault of the vagina or in the urethra. Although there may be considerable overlap in the clinical characteristics of the lymphadenopathy, certain characteristics may aid the establishment of a diagnosis. Notably, the lymphadenopathy associated with primary syphilis is classically described as bilateral, discrete, rubbery, and painless, while the nodes associated with initial episodes of genital herpes are also bilateral but smaller and tender. In contrast, the lymphadenopathy associated with either chancroid or LGV is usually unilateral and painful and may frequently undergo suppuration to form inguinal abscesses, which may rupture[27] (Fig. 63-3). Involvement of both inguinal and femoral glands separated by the inguinal ligament results in the formation of the classic "groove sign," which was previously considered pathognomonic for LGV (Fig. 63-4). However, many cases of chancroid may present with similar gland involvement (Fig. 63-5). Swellings in the groin associated with cases of donovanosis are not due to an adenitis; rather, they arise as a result of subcutaneous spread of the granulomas, resulting in pseudobubo formation.

FIGURE 63-2. Preputial and subpreputial lesions of chancroid with associated phimosis.

FIGURE 63-3. Inguinal ulceration following rupture of an inguinal bubo in a case of chancroid.

It should be noted that, particularly in developing countries, discrete, painful inguinal lymphadenopathy may be associated with nonsexually acquired lesions of the lower limbs, and that chronic nontender lymphadenopathy in the absence of genital ulceration or associated with a persistent lesion may be suggestive of genital or lymphatic malignancy.

COMPLICATIONS AND SEQUELAE

Complications arising from sexually acquired genital ulcers include secondary infection, particularly with anaerobic bacteria, which may result in the formation of destructive or phagedenic ulceration, phimosis (Fig. 63-3) or paraphimosis, and local edema. Successful treatment of both chancroid and donovanosis may result in the formation of scars which, if sited on the foreskin, may cause a permanent phimosis that could require circumcision. In contrast, the lesions of primary syphilis and genital herpes usually heal spontaneously with no scarring within 6 weeks and 1–3 weeks, respectively.

FIGURE 63-4. Classical "groove sign" of lymphogranuloma venereum.

FIGURE 63-5. Left inguinal and femoral lymphadenopathy separated by the inguinal ligament. *Haemophilus ducreyi* was isolated from a subpreputial lesion.

If left untreated, patients with primary syphilis may develop a secondary syphilitic rash and subsequently, following a long period of latency, the sequelae associated with tertiary disease. Unfortunately, the majority of patients with primary genital herpes develop recurrent disease which, although less severe than the initial episode, may have considerable psychological consequences. These recurrences may occur frequently and be severe, particularly in those patients coinfected with HIV and who are severely immunosuppressed.

The most severe complications of chancroid and LGV are associated with lymph node involvement. Both chancroid and LGV may cause fluctuation and eventual ulceration of the inguinal and/or femoral glands, while autoinoculation of *H. ducreyi* may result in the formation of satellite chancroid

lesions both on the external genitalia and in the inguinal region.

In LGV, the genito-anorectal syndrome may result in pelvic and perirectal abscesses, rectal strictures, and fistulae. The chronic manifestations of LGV may result in scar formation resulting in blockage of the lymphatics draining the genitalia, causing severe edema. When the lymphatic edema is gross it is termed elephantiasis or esthiomene. A pseudo-elephantiasis also occurs in advanced cases of donovanosis when scarring results in occlusion of the lymphatics.

LABORATORY DIAGNOSIS OF GENITAL ULCER ADENOPATHY SYNDROME

Ideally, appropriate treatment of genital ulcer disease should be guided by the determination of the etiology of the genital ulcer, using all relevant laboratory tests available. In industrialized countries, where the majority of ulcerations are attributable to genital herpes or syphilis, these should include either darkfield microscopy, amplified molecular testing such as the polymerase chain reaction (PCR) or direct immunofluorescence staining of genital ulcer material for *T. pallidum,* culture, or PCR for herpes simplex virus or direct detection of HSV antigen with ELISA or direct immunofluorescence tests (DFA) and type-specific serological testing for HSV and for syphilis. In developing countries, where other causes of genital ulcer adenopathy syndrome are frequently encountered and establishment of a diagnosis on clinical grounds may be even more difficult, addition of tests for *H. ducreyi*, LGV infection, or *K. granulomatis* may be considered. However, in these situations laboratory facilities are usually either limited or not available. Under these circumstances syndromic management principles should be applied which take into account the local patterns of disease. Even so, serological tests for syphilis should be performed in each case.

A summary of laboratory tests used for diagnosis of genital ulcer adenopathy syndrome is outlined in (Table 63-2). Specimens taken directly from the base of ulcerations should be obtained with small, sterile Dacron or cotton swabs following cleansing of the lesions with sterile saline. When small lesions are being sampled, care should be taken to overcome the inherent problems associated with reduction in sensitivity following multiple sampling. Specimens of ulcer exudate for darkfield microscopy or DFA for *T. pallidum* can be obtained by using a platinum scraper, loop, capillary tube, or glass coverslip following expression of exudate from a cleansed lesion. Specimens for herpes culture, PCR, or HSV antigen detection are best obtained following disruption of vesicles and collection of vesicle fluid. Swabs obtained from the bases of ulcerations are somewhat less sensitive for detection of HSV but are generally the specimens of choice for detection of *H. ducreyi* and *C. trachomatis* by culture or the use of molecular methods. Specimens of pus obtained from fluctuant lymph nodes should be obtained by aspiration of material with a wide-bore needle through healthy tissue in order to prevent fistula formation. Low rates of detection of both *H. ducreyi* and/or *C. trachomatis* should be anticipated from such specimens.

MICROSCOPY

Darkfield microscopy has traditionally been recognized as the most appropriate technique for establishing a definitive diagnosis in cases of primary or secondary syphilis.

Table 63-2. Laboratory Tests for the Diagnosis of Genital Ulcer Adenopathy Syndrome

	Syphilis	Herpes	Chancroid	LGV	Donovanosis
Microscopy	Darkfield or direct immunofluorescence	Tzanck. Preparation has low sensitivity	Gram-staining has low sensitivity and specificity	Not available	Giemsa- or Wright-stained tissue smears and sections
Culture	Not available except by rabbit testicular inoculation	Cell culture	Sensitive, selective media available	Cell culture	Cell culture (experimental)
Serology	RPR/VDRL, FTA-ABS, TPHA, TPPA, ELISA	Type-specific ELISA	Experimental	Complement fixation and indirect micro-IF test	Experimental
Molecular techniques	PCR (experimental)	PCR (experimental)	PCR (experimental)	PCR (experimental)	PCR (experimental)

Unfortunately, the technique has major shortcomings since it requires a microscope fitted with a darkfield condenser and considerable technical expertise to discriminate morphologically between *T. pallidum* and the saprophytic spirochetes that may colonize genital lesions. In addition, a balanoposthitis associated with a nontreponemal fusospirochetal infection has been described in tropical areas, which may result in high rates of false-positive readings using this technique. Under these circumstances, direct immunofluorescence staining of ulcer material may represent a more convenient alternative. Although inherently more specific, this technique requires a higher level of expertise, an immunofluorescence microscope, and expensive reagents.

Scrapings obtained from the bases of ulcers or smears made from vesicle fluid may be examined for HSV infection by using immunofluorescence or immunoperoxidase techniques or by microscopic examination of Tzanck preparations which is less sensitive and specific but which may reveal characteristic multinucleated giant cells.

Establishment of a diagnosis of donovanosis is usually dependent upon the demonstration of encapsulated intracytoplasmic Donovan bodies within mononuclear cells in Giemsa- or Wright-stained smears of ulcer exudate or in sections made from scrapings obtained from the edges of active lesions or from punch-biopsy material. In contrast, microscopic examination of gram-stained smears obtained from genital ulcers exhibits both poor sensitivity and poor specificity for *H. ducreyi,* since many nonchancroidal lesions are colonized by gram-negative rods. As a result, this technique cannot be recommended for diagnosis of chancroid even in resource-poor settings.

ISOLATION OF CAUSATIVE AGENTS

Viral isolation remains a frequent means of establishing a definitive diagnosis of genital herpes but is time-consuming and requires special expertise. The most frequently used cell lines are Vero cells and human diploid cells, such as MRC-5 cells, or human foreskin or lung fibroblasts. Depending on the amount of viable virus in the specimen, a characteristic cytopathic effect may be detected in cultures 1–7 days following inoculation.

Isolation of *H. ducreyi* has been the most frequent method used to establish a definitive diagnosis of chancroid. A number of solid, semiselective media have been developed which, when used either singly or in combination in biplates, have achieved sensitivities of approximately 80%. However, recovery of *H. ducreyi* from bubo aspirates is less efficient, with sensitivities of 40–50%.[12] Since direct plating of exudates onto freshly prepared medium is essential to achieve optimal isolation rates, few laboratories are able to maintain culture capability on an ongoing basis. A transport medium, which maintains the viability of *H. ducreyi* in swabs stored at 4°C for up to 1 week, enables low volume laboratories to prepare fresh batches of isolation media following collection of the specimen.[28]

Isolation of the L-serovars of *C. trachomatis* from primary ulcers, the urethra, the endocervix, rectal lesions, or bubo aspirates is a common means of confirming a diagnosis of LGV. However, non-LGV strains of *C. trachomatis* associated with concomitant urethral or cervical infection may contaminate ulcerations and give false-positive results. If the vast majority of cells are infected in a tissue culture monolayer and the intracellular inclusions are large 48 hours after inoculation, it is highly likely to be a case of LGV. Despite frequent textbook references, bubo aspirates are probably the least appropriate source of material for chlamydial isolation since few patients present with fluctuant glands. When patients do present, the organisms can rarely be demonstrated in bubo aspirates by culture, owing to the paucity of infectious organisms in bubo pus and the toxicity of this material for cell culture monolayers. Isolation of *K. granulomatis* from cases of donovanosis has been achieved by inoculation of material obtained from the bases of ulcerations onto monolayers of human monocytes[29] or HEp-2 cells.[30] However, these techniques have not been widely adopted for routine diagnosis of the disease.

SEROLOGICAL TESTS

Ideally, serological tests for syphilis should be performed routinely in all cases of STDs but particularly in cases of genital ulcer adenopathy syndrome. Cardiolipin (reagin) tests such as the rapid plasma reagin (RPR), or venereal disease research laboratory (VDRL) test may be negative when a patient initially presents with primary syphilis, since seroconversion may occur as late as 6 weeks after infection. The fluorescent treponemal antibody absorption (FTA-Abs) test becomes positive earlier than the reagin tests (after about 3 weeks), but care should be taken in the interpretation of a positive FTA-Abs test, since treponemal tests remain positive even after successful treatment of disease and may represent a previously treated episode. In areas where syphilis is common, patients presenting with nontreponemal ulcerations may also present with both reactive reagin and treponemal tests. These results may occur in cases that are the result of either concomitant untreated syphilis or a later stage of syphilis (of more than 2 years' duration) that was successfully treated.[8] Quantitative RPR or VDRL tests should also be used as a baseline against which responses to treatment can subsequently be measured. In regions where syphilis is uncommon, it is necessary to confirm the results of positive cardiolipin tests by performing an FTA-Abs, *T. pallidum* hemagglutination assay (TPHA),*T. pallidum* passive particle agglutination assay (TPPA), or treponemal ELISA test, since false-positive reactions are frequently encountered. However, in regions where syphilis is commonly encountered the positive predictive value of the reagin (screening) tests is high, there are relatively few

false-positive reactions, and there is therefore little value in confirming the results with a more specific test.

Serological tests to detect type-specific antibody to glycoproteins G1 and G2 of herpes simplex virus can be used as an adjunct to the detection of HSV in lesions in the diagnosis of genital herpes to differentiate between primary and recurrent disease.[31] However, when used alone, the results of type-specific serologic investigations may be misleading either because negative tests are often recorded in cases of primary disease or because patients may be seropositive for antibody to HSV-2, but the presenting lesion may be due to infection with another pathogen, or the presenting lesion may be caused by HSV-1. The use of commercially available tests that are not type-specific is not recommended.[32]

The chlamydial complement-fixation test, which measures antibody to chlamydial group antigen, remains the most widely used serological test for diagnosis of LGV. Rising titers, or a single titer of ≥1/64, usually have been considered diagnostic. A microimmunofluorescence (micro-IF) test that measures type-specific antibody to *C. trachomatis* has also been widely used, and broadly cross-reacting antibody titers of ≥1/256 are frequently detected in cases of LGV.[33] Antibody to *H. ducreyi* may be detected in crude enzyme-linked immunoassays.[34] However, these tests are only useful for establishing lifetime exposure to the disease and are therefore only of value for epidemiological studies.

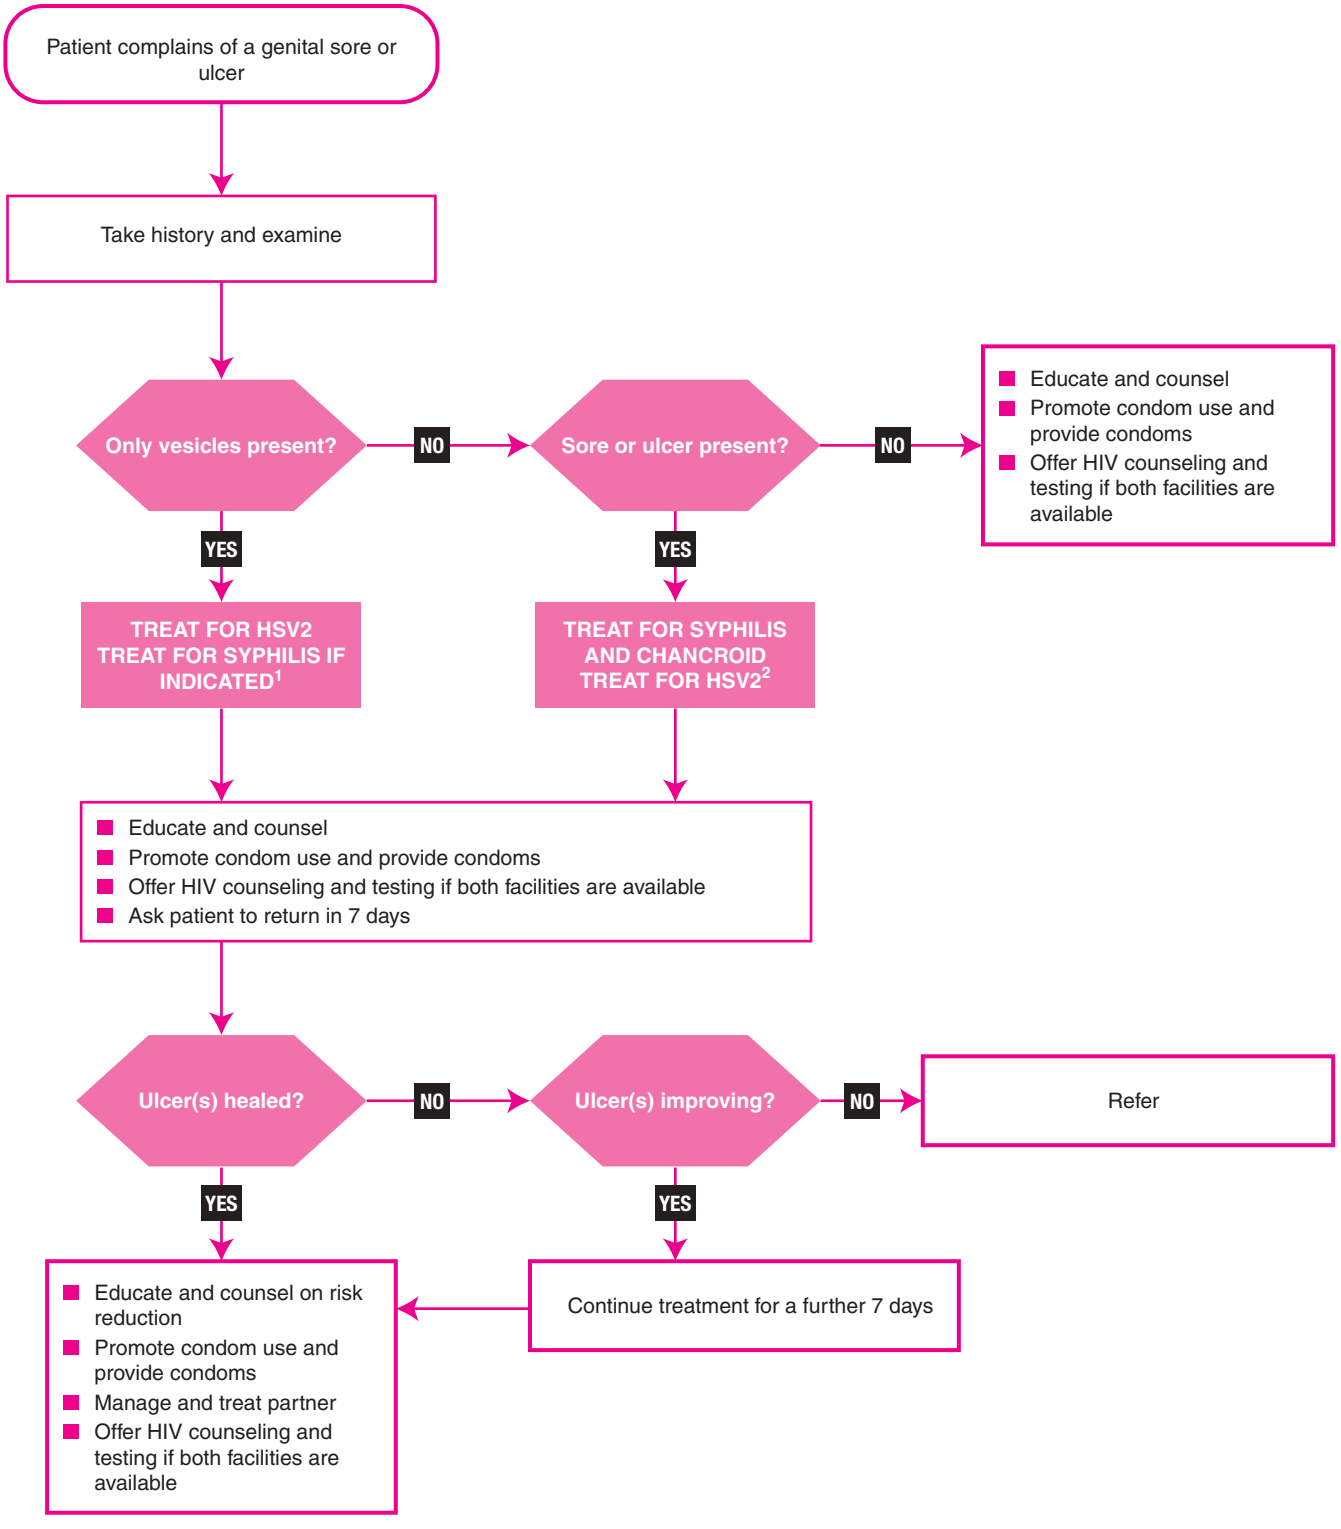
MOLECULAR TECHNIQUES FOR DIAGNOSIS

Although nucleic acid probes have been used to detect both HSV and *C. trachomatis* in clinical specimens, the development of amplified techniques such as the PCR has resulted in methods which are both sensitive and specific for the detection of agents associated with genital ulcer adenopathy syndrome. Separate PCR assays have been used to detect the presence of *T. pallidum*,[35] *H. ducreyi*,[36] and HSV[37] in clinical specimens, and a multiplex PCR (M-PCR) amplification assay has been described which is able to detect the presence of these three organisms in a single ulcer specimen.[38,39] In addition, PCR tests for *K. granulomatis*[40] and tests that can differentiate between the *L. biovar* of *C. trachomatis* and the less invasive D-K strains[41,42] have been developed. Collectively, these techniques represent a significant increase in the sensitivity of diagnostic testing for genital ulcer disease, which has resulted in fewer cases remaining unsolved. However, there is little chance that they will become commercially available in the foreseeable future.

MANAGEMENT

In an ideal situation, treatment for genital ulcer adenopathy syndrome should be initiated only after establishment of a definitive diagnosis by using appropriate laboratory investigations. However, in order to provide effective treatment at the initial consultation, it is often necessary for clinicians to provide therapy which will cover the majority of causes of genital ulceration/bubo formation known to be prevalent in the target population. This often results in provision of treatment for more than one infection. This approach, known as syndromic management, is necessary because no single antimicrobial agent affords reliable treatment for all causes of the genital ulcer adenopathy syndrome. In addition, the reliability of clinical signs is questionable, mixed infections are common, laboratory support for clinical services is limited, and there are few tests for these infections that can be provided on-site. Syndromic management is recommended by the WHO, particularly for developing countries, and suitable flowcharts representing appropriate management algorithms need to be developed on the basis of the patterns of disease presenting in a particular geographical location.[43] Two examples of flowcharts, published by the WHO, the first for syndromic management of genital ulceration and the second for management of inguinal buboes, are shown in Figs. 63-6 and 63-7, respectively. It should be noted that these flowcharts should be validated by using the most sensitive laboratory tests available to establish the relative frequency of the different causes of the syndrome within a particular geographical setting.[44]

Although all genital ulcers contain a mixed bacterial flora, it is usually not necessary to treat secondary infections in order to hasten healing. In cases that appear to be secondarily infected in developing country settings, some experts provide a nontreponemicidal antimicrobial such as cotrimoxazole. Unfortunately, topical antiseptics or antiviral or antibacterial agents are often dispensed by pharmacies without prescription or are administered by traditional healers. These topical agents are not recommended. In addition, topical corticosteroids should not be applied directly to lesions. Patients with genital ulcer adenopathy syndrome should be managed by appropriately trained health professionals since potentially serious consequences may arise as a result of poor management. Ulcerations usually commence healing within 48 hours of initiation of appropriate therapy, but fluctuant buboes, which are usually associated with chancroid or LGV, should be aspirated through healthy tissue to prevent spontaneous ulceration. Repeated aspiration may be necessary because the suppuration process may continue even after initiation of effective antibiotic therapy. Although incision and drainage of suppurating glands may be indicated in an industrialized country setting, aspiration may be more appropriate for resource-poor settings to prevent scarring and delayed healing. Aspiration should be performed with a large-bore needle because the initial exudate may be thick and purulent, while subsequent aspirations performed after initiation of effective therapy may yield serous or serosanguineous exudates.



1 Indications for syphilis treatment:
- RPR positive; and
- Patient has not been treated for syphilis recently.

2 Treat for HSV2 where prevalence is 30% or higher, or adapt to local conditions.

FIGURE 63-6. WHO algorithm for syndromic management of genital ulcerations.[43]

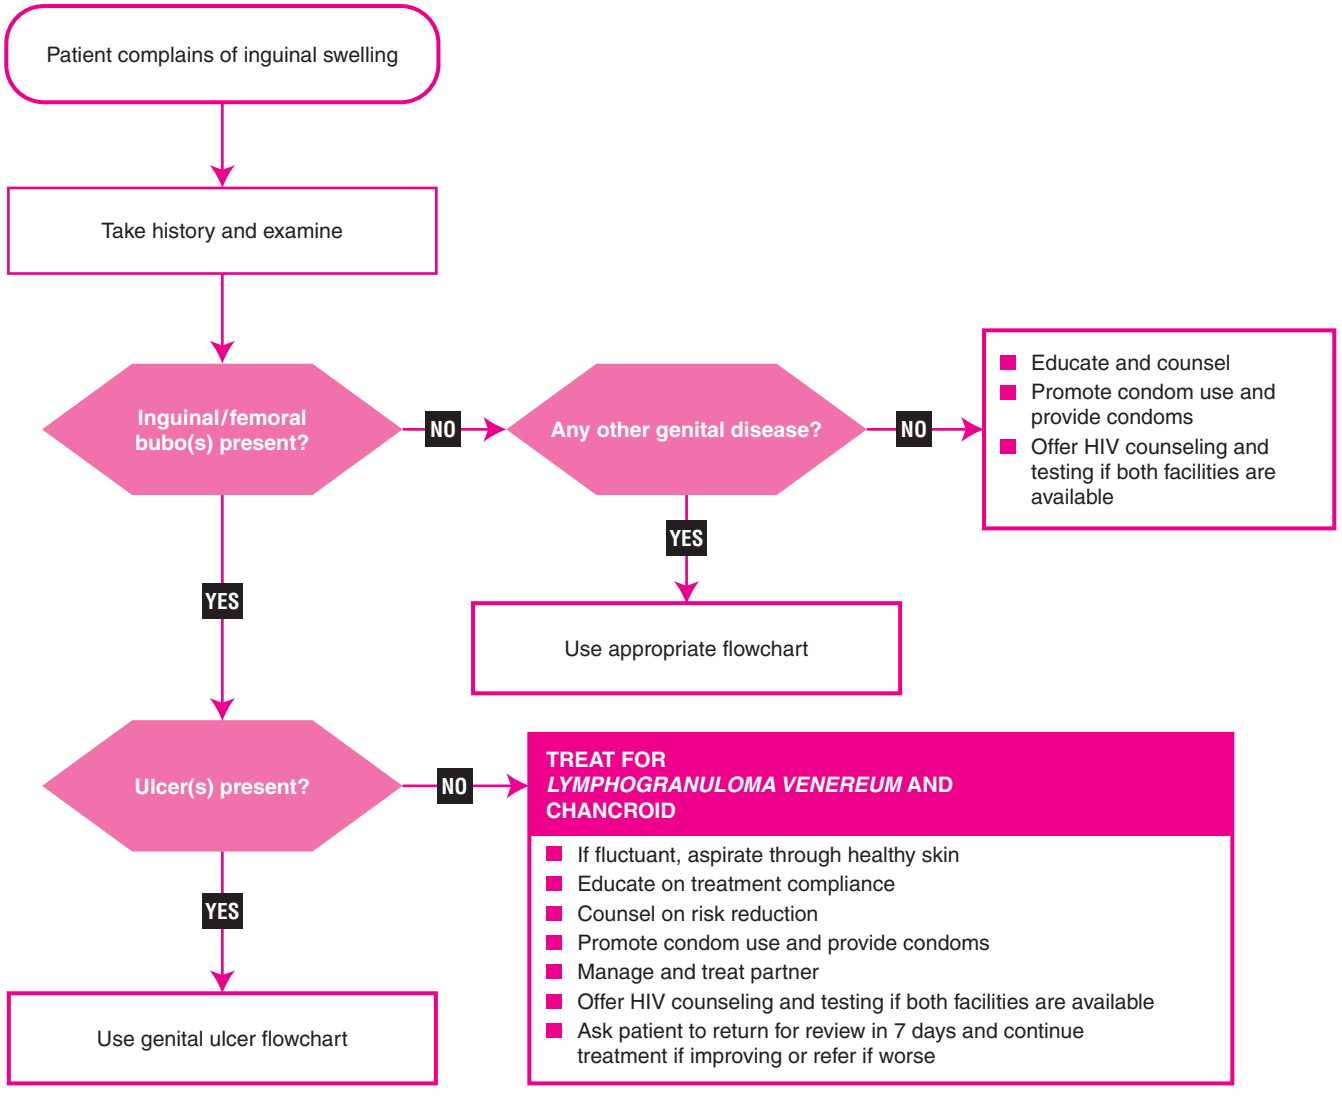


FIGURE 63-7. WHO algorithm for syndromic management of inguinal buboes.[43]

The specific treatments for individual causes of genital ulcer adenopathy syndrome are discussed in the disease specific chapters elsewhere in this book and in treatment guidelines published by the WHO[43] and the Centers for Disease Control and Prevention.[32] Antimicrobial resistance can be a cause of treatment failure in a minority of cases of syphilis where macrolide antibiotics are used to treat the disease, while treatment failure in cases of chancroid is usually associated with infection with multiresistant strains of *H. ducreyi*. Apparent treatment failure following antibiotic therapy may also occur as a result of mixed infection when one of the etiological agents is HSV.

64 Genital Dermatoses

Rochelle R. Torgerson and Libby Edwards

INTRODUCTION

The external genitalia are a common site for rashes, itching, and minor infections. This area is warm, moist, and occluded, and it is frequently exposed to irritating urine, feces, and vaginal secretions. In addition, concerns about hygiene and sexually transmitted diseases prompt some people to use overly vigorous cleaning regimens, deodorants, and specialized hygiene products. Abnormalities that, if they occurred elsewhere, would be considered trivial by the patient, suddenly become complicated due to both the local environment and psychological factors. Prompt recognition of the cause or causes of visible genital abnormalities or uncomfortable sensations not only minimizes the duration of pain or itching but also helps to avoid damage to self-esteem and sexual relationships.

Many physicians and patients assume that any genital abnormality is infectious. Although infectious processes certainly can affect the genitalia, there are many noninfectious causes of genital symptoms and abnormalities as well. It is often necessary to entertain a broad differential diagnosis. To assist with this process, we have organized this chapter by morphology. Some genital disease processes have more than one clinical presentation. Thus, some conditions are discussed several times.

RED PLAQUES AND PATCHES

The diseases in this section are characterized morphologically by large (generally >1.5 cm) areas of inflammation. Although these usually appear red, erythema is sometimes subtle and difficult to differentiate from the variable degree of normal background pinkness. Also, inflammation in black skin generally appears hyperpigmented rather than red. Whenever a patient complains of itching, burning, or pain, the skin is most likely inflamed, whether or not erythema is visible. In addition, normally scaly diseases such as eczema and psoriasis may lack visible scale owing to the damp nature of the skin in this area.

ECZEMA/NEURODERMATITIS

Eczema is an umbrella term often used to include atopic dermatitis, neurodermatitis, and lichen simplex chronicus, but the scope of the term is controversial. Lichen simplex chronicus is used here to describe a localized, lichenified eczema. Eczema is often called "the itch that rashes." Patients initially experience pruritus that may be caused by a yeast infection, heat, moisture, or any other irritant. Scratching produces inflammation that heightens the sensation of itching. As itching worsens, scratching increases until finally an itch–scratch cycle takes on a life of its own, even though the initial precipitating event may have resolved.

The morphology of eczema is consistent with skin that has been scratched or rubbed. Therefore, linear or angular erosions produced by fingernails are common. There is usually surrounding, poorly demarcated erythema, with or without visible scale.

Lichenification, or thickening of the skin as a result of rubbing, is extremely common (Fig. 64-1). Lichenification, or thickening of the skin induced by rubbing, is usually detected by the accentuation of skin markings and thickened appearance of the skin. This can be difficult to appreciate over the scrotum and labia majora, where the skin normally can be thickened and rugated. When lichenification or significant inflammation occurs on the modified mucous membrane of the vulva, the skin frequently becomes white—a clue to subtle disease (Fig. 64-2).

In men, eczema occurs most often on the posterior scrotum and relatively often in the crural crease and upper, inner thigh. The penis is a less common location for this condition. In women, the labia majora as well as the modified mucous membranes of the vulva are often affected.

The treatment of eczema requires attention to several specific facets of the disease. The most common cause of a poor response to therapy is the failure to address all factors simultaneously.

First, inflammation and itching should be treated with a topical corticosteroid preparation. A high-potency medication such as clobetasol 0.05% (Temovate®) is often required.

FIGURE 64-1. Remarkable thickening of the scrotum with white areas of postinflammatory hypopigmentation are typical of neurodermatitis in black skin.

FIGURE 64-2. Excruciating pruritus was associated with the relatively subtle thickening of the right inner labium majus, manifested by slightly lighter color, mild thickening, and drier appearance than seen on the contralateral side. In addition, excoriations are visible and fissures with scale suggestive of bacterial or yeast superinfection.

Patients should be examined at least monthly to identify any early signs of adverse local effects, such as atrophy, and to decrease the potency or frequency of application of the topical corticosteroid when disease control is attained.

Second, any irritant should be discontinued. This begins with the appropriate choice of a vehicle for the corticosteroid. Creams contain alcohol, so that patients with significant inflammation and excoriation are often best treated with an ointment base. Other common irritants include overwashing, washing with harsh soaps, and the application of various borrowed and purchased medications. An extremely common irritant, especially in women, is secondary infection. This is most often caused by *Candida albicans,* but occasionally infection or colonization by *Staphylococcus aureus* or *Streptococcus* spp. produces irritation. Often, treatment of the secondary infection requires ongoing, suppressive therapy until the skin disease and symptoms are controlled, because recurrent infections are extremely common in patients with eczema and in the setting of topical corticosteroid use.

Finally, scratching must be stopped. Daytime itching can be minimized by the cited measures but nighttime itching is often more severe. Sedation to produce deep sleep during the night can provide at least 8 hours of scratch-free time. This can be accomplished with oral diphenhydramine (Benadryl®) or hydroxyzine HCl (Atarax®), both at sedating doses of 25–100 mg. Some physicians prefer amitriptyline (Elavil®) at 10–100 mg because of the deeper and longer sleep induced.

Therapy should be continued until the patient looks and feels normal, although the potency of the corticosteroid can be decreased as the patient improves. Any remaining disease that is not treated will be scratched eventually, restarting the itch–scratch cycle. The patient should be warned that any future inflammation is also likely to induce itching and subsequent eczema.

IRRITANT CONTACT DERMATITIS

Inflammation produced by contact with irritating substances is a common problem. The patient usually describes irritation, soreness, stinging, or burning, although itching is present in some people. The most common irritants are soap and water, urine, feces, and infected or copious vaginal secretions. This mild chemical burn is manifested by erythema, sometimes with scale. More severe disease may exhibit edema, exudation, or even erosion (Fig. 64-3).

The treatment for irritant contact dermatitis consists primarily of the identification and the elimination of

FIGURE 64-3. This red, scaling and crusted plaque of irritant contact dermatitis was produced by washing the area several times a day with a disinfectant intended for cleaning floors.

irritants, which are sometimes surprisingly difficult. Patients must be asked specifically what they are using for any reason on their skin, including cleansing. Frequency is often important, because even clear water used multiple times daily serves as an irritant. In addition, a topical corticosteroid can hasten improvement.

ALLERGIC CONTACT DERMATITIS

An allergic contact dermatitis is a pruritic inflammatory eruption occurring in a previously sensitized patient in response to contact of the skin with a specific allergen. This condition usually occurs 1 or 2 days but sometimes up to 4 days following contact with the offending substance, unlike an irritant contact dermatitis, which occurs quickly.

An allergic contact dermatitis over the genitalia is usually indistinguishable morphologically from an irritant contact dermatitis and it often resembles eczema or neurodermatitis as well. This nonspecific picture is characterized by erythema, sometimes edema, and occasionally scale or desquamation (Fig. 64-4). With a very strong allergic response, vesicles can be present and erosions may be formed as vesicles break.

The most common causes of genital allergic contact dermatitis are ingredients in topical medications so that allergic contact dermatitis often complicates a preexisting process.[1] Topical antibiotics, anticandidal agents, local anesthetics, and even corticosteroids sometimes produce allergic contact dermatitis. Preservatives and stabilizers can also cause allergic reactions so that patch testing may be required to identify the specific allergen.

The treatment of allergic contact dermatitis includes the identification and elimination of the allergen. Topical corticosteroids, the elimination of irritants, and nighttime sedation as described for eczema/neurodermatitis are also necessary for maximal and rapid improvement.

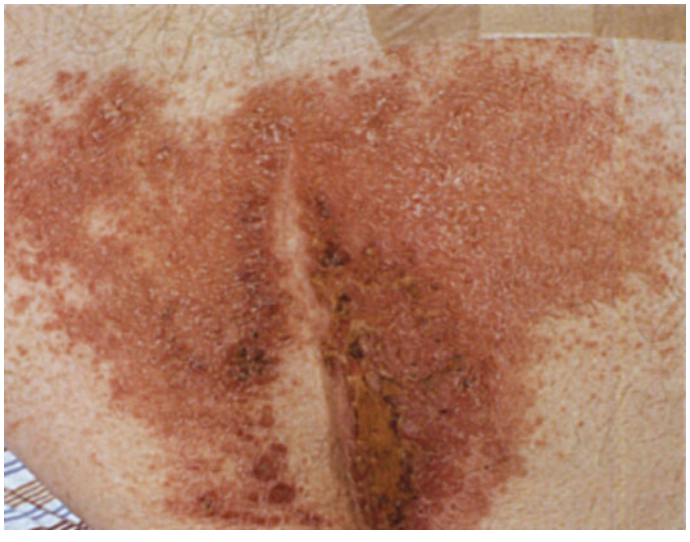

FIGURE 64-4. Erythema, exudation, and crusting are characteristics of allergic contact dermatitis in this patient who applied diphenhydramine (Benadryl) for itching. Positive results of patch testing, extreme pruritus, and time of onset are often more useful than morphology for differentiation from irritant contact dermatitis.

LICHEN PLANUS

Lichen planus is believed to be an autoimmune disease of cell-mediated immunity. Antigens recognized by Langerhans cells, epidermal antigen-presenting cells, may initiate the recruitment of activated lymphocytes, with epidermal damage likely produced by cytokines and cytotoxic T cells. This disease exhibits extremely variable morphology, which is partially dependent on location. Although lichen planus has been long recognized as a common condition on the penis, the frequency of erosive vulvovaginal disease has only been appreciated recently.[2,3]

Patients with milder, papular disease generally report pruritus or no symptoms at all. Those with more severe, erosive disease generally describe pain, particularly with intercourse. These patients usually have associated mouth lesions.

On keratinized skin, such as the shaft of the penis, the circumcised glans, and the clinically hair-bearing portions of the genital area, lichen planus usually appears as well-demarcated, red or dusky, flat-topped papules (Fig. 64-5). Although lichen planus is a scaly disease, scale is often very subtle. Sometimes, the surface of the papules shows a lacy or fern-like pattern of fine, white striae, a pathognomonic sign when present.

When occurring on moist skin, such as the uncircumcised glans, or the clinically non-hair-bearing skin of the vulva, lichen planus is characterized by either white papules and plaques or erosions. Although the white lesions are occasionally well formed, sharply demarcated and uniformly hypopigmented papules or plaques, much more often these are irregular, reticulate striae (Fig. 64-6). Erosive lichen planus often appears as nonspecific, shallow erosions located

FIGURE 64-5. Two nondescript, red, scaling papules over the edge of the corona are characteristic of lichen planus but could also represent candida infection, psoriasis, or even scabies. An examination of other skin surfaces and the mouth may produce the diagnosis without a biopsy.

FIGURE 64-6. These white, branching striae are pathognomonic of lichen planus.

FIGURE 64-7. Endstage scarring with obliteration of the labia minora and clitoris, with remaining erosions of the vestibule (introitus) are characteristic of erosive lichen planus but can be seen also with late lichen sclerosus, cicatricial pemphigoid, pemphigus vulgaris, or any other intensely inflammatory, chronic vulvar disease. The diagnosis requires the identification of specific lesions elsewhere or a characteristic biopsy.

most often at the introitus and inner labia minora of women and on the glans penis of men (Fig. 64-7). Although a diagnosis based on the erosions alone is difficult, often specific white, lacy papules of lichen planus are found on examination, or less specific coexisting white epithelium is present. These white lesions usually yield a definitive diagnosis of lichen planus on biopsy.

The white lesions of lichen planus are occasionally confused with Candida infection, but negative fungal smears and lack of response to anticandidal therapy distinguish these two entities. Erosive disease differs from a syphilitic chancre by its indolent nature and the superficial morphology of the erosion of lichen planus as compared to the indurated ulcer of syphilis. Unlike most skin diseases that affect the genitalia, lichen planus often affects other mucous membranes including the mouth and the vagina and may or may not cause symptoms. An examination of these areas can provide extremely valuable diagnostic information.

In the absence of erosions, genital lichen planus is usually treated satisfactorily with an ultra potent topical corticosteroid ointment (clobetasol propionate). Tacrolimus ointment (Protopic®) has also been shown to be effective in symptomatic patients without the risk of atrophy.[4] However, local irritation is usually limiting. Lichen planus does not resolve with these therapies but symptoms abate and lesions improve. Most patients with lichen planus require chronic therapy, although some with milder, nonerosive disease do well with intermittent treatment. Very mild papular lichen planus may not produce future symptoms, and further therapy is not required. Resolution of nonerosive disease generally occurs over months or years. However, patients should be followed carefully until remission occurs, to evaluate the patient both for local corticosteroid side effects and for transformation of the disease into progressive, erosive, and scarring lichen planus.

The management of erosive lichen planus is extremely difficult and often unrewarding. Moderate erosive lichen planus can be treated with a topical ultra potent corticosteroid such as clobetasol propionate (with careful follow-up to monitor local side effects, including atrophy). More severe disease may require oral prednisone at 40–60 mg each morning to induce healing so that topical medication can then be substituted.

Erosive vulvar lichen planus is usually accompanied by vaginal disease. Scrupulous treatment of secondary vaginal, bacterial, and fungal infections in conjunction with hydrocortisone acetate 25 mg suppositories used at bedtime can improve many patients. Unless the patient is having regular intercourse, she should insert a small vaginal dilator daily to prevent the formation of vaginal synechiae.

Other medications that have been used for unresponsive lichen planus, although not supported by definitive clinical trials, include oral hydroxychloroquine, methotrexate, retinoids, mycophenolate mofetil (CellCept®), azathioprine, thalidomide, and cyclophosphamide, as well as topical and oral cyclosporine.[5–7] In addition, etanercept (Enbrel®) has been used. Dapsone and griseofulvin have been used in the past with unimpressive results for vulvar lichen planus.

There is a risk of malignant transformation of lesions of lichen planus.[8] One of the authors (Edwards) has cared for two patients with squamous cell carcinoma (SCC) associated with erosive lichen planus. Because of this risk, close, long-term follow-up of patients is recommended.[9,10]

PLASMA CELL MUCOSITIS (ZOON'S)

Plasma cell balanitis and vulvitis are uncommon, medically insignificant inflammatory plaques that may represent a

variant of lichen planus. These lesions are located primarily over the glans penis or modified mucous membrane skin of the vulva. The plaques are red/rust, moist, well demarcated, and nonscaling. The diagnosis is made by clinical morphology and a biopsy that reveals a plasma cell infiltrate. Circumcision often improves or obliterates the lesion in men, and topical corticosteroids, retinoids, cyclosporine, and tacrolimus can be useful in others.[11,12]

PSORIASIS

Psoriasis is a red, scaling skin disease that occurs as a result of hyperproliferation of the epidermis. This disease tends to occur preferentially in areas of irritation or skin injury, such as the elbows and knees. Warmth, perspiration, irritating urine, and friction often precipitate psoriasis in the genital area.

Psoriasis is manifested by red, sharply demarcated, scaling plaques that occur primarily over the hairbearing skin of the vulva and the glans and shaft of the penis, as well as the crural creases (Fig. 64-8). Because of the inherently moist nature of skin in the genital area, scale is often relatively inapparent as compared to the heavy, silvery scale of psoriasis in other locations. In addition, lesions are sometimes less well demarcated than in other areas.

Because the skin lesions of psoriasis in the genital area may not be classic for this disease, an examination of other areas of the body is warranted to make the diagnosis definitively. Most patients exhibit typical plaques on the elbows, knees, or scalp. Fingernails often show pitting or lifting of the nails from the nailbed, resembling a fungal infection.

Psoriasis is most often confused with eczema/lichen simplex chronicus, candidiasis, and tinea infection. Usually, the general body exam, and, when needed, microscopic smears to rule out fungus allow for the correct diagnosis.

FIGURE 64-8. Psoriasis characterized by sharply demarcated, red, thickened plaques. Scale is present on the penis, although the classic heavy, silvery scale is often absent in the moist genital area.

The first-line treatment for genital psoriasis includes minimizing irritation and secondary infections and the application of topical corticosteroids. Low potency corticosteroids may not provide sufficient control. Patients with an inadequate response to hydrocortisone or triamcinolone can be treated with clobetasol propionate ointment, but careful follow-up to evaluate for atrophy is very important.

Because continuous use of topical corticosteroids can lead to tachyphylaxis, combination therapies are often used. Calcipotriene ointment (Dovonex®) is commonly used in rotation with topical corticosteroids. One method is to use clobetasol propionate ointment twice daily until clearance is achieved then maintain control with calcipotriene ointment twice daily on weekdays and clobetasol propionate ointment twice daily on weekends. More recently, tacrolimus ointment and pimecrolimus cream (Elidel®) have been reported to be effective for some patients with intertriginous psoriasis. Calcipotriene, tacrolimus, and pimecrolimus do not cause local atrophy but do have the common side effect of irritation.[13–16]

Patient education is crucial in treating psoriasis. Patients should be made aware that psoriasis is a chronic disease without a cure. Should psoriasis become widespread or severe, the more aggressive therapies, such as ultraviolet light, weekly methotrexate, oral retinoids, or newer biological medications instituted by a dermatologist usually improve the genital area as well.[17]

FUNGAL INFECTION

A classic and easily treatable cause of red plaques in the genital area is fungal disease.

Candida albicans, a yeast form, is the usual organism on the vulva or on the glans penis of uncircumcised men. *Dermatophyte fungi* (tinea cruris) produce the typical fungal infection over the proximal, medial thighs of men, and, less often, women.

Candida infection

Candida vulvitis can have several different morphologies (see also Chapter 45). Most often, there is simple, nonspecific erythema of the modified mucous membranes. Those with more severe or extensive disease, particularly obese women, may also have erythema and peeling of the hairbearing portion of their labia majora. Often, collarettes, a circular rim of scale, are found at the periphery of the involved skin. These represent very superficial pustules that have lost the blister roof. Candida vulvitis is regularly associated with Candida vaginitis unless the patient has treated her vagina without including the vulva. When occurring in men, Candida produces red papules or plaques over the glans of the uncircumcised penis or the crural crease. The shaft of the penis and the scrotum are generally spared since these areas are too dry to maintain a Candida infection.

The diagnosis of Candida is made on clinical grounds, generally with confirmation by a positive microscopic fungal preparation. In women, Candida can be confused (and sometimes coexist) with eczema, psoriasis, and lichen planus. Candida of the glans must be differentiated from psoriasis, lichen planus, and Bowen's disease. Therefore, any patient who does not respond to therapy should be referred to a dermatologist or undergo a skin biopsy.

Tinea cruris

Dermatophyte (tinea) fungal infections occur on drier, keratinized skin. Manifested by scaling, well-demarcated, red plaques located primarily over the inner thighs, tinea cruris is far more common in men (Fig. 64-9). The dermatophyte organism occasionally infects the stratum corneum of hair follicles, producing pustules or erythematous papules within the affected plaques. Unless the patient is immunosuppressed or using a topical corticosteroid on the area, a dermatophyte infection generally does not affect the scrotum or the penis.

Dermatophyte infections most closely resemble psoriasis, erythrasma, and eczema. Tinea cruris can be differentiated from these by a positive microscopic fungal preparation and the lack of psoriasis or eczema on other areas of the body.

The treatment of both Candida and dermatophyte infection can usually be achieved with topical antifungal agents. Azole creams such as miconazole, clotrimazole (both over the counter), ketoconazole, sulconazole, sertaconazole, and econazole treat both forms of fungus. However, nystatin is only effective against Candida and terbinafine (Lamisil®) is primarily used for dermatophyte infections. A very convenient therapy, a single dose of fluconazole 150 mg, clears most vulvovaginal Candida infections.

FIGURE 64-9. Red, scaling plaques with distinct margins and accentuation of disease at the borders are features of tinea cruris.

Oral therapy is required for patients with a dermatophyte infection and evidence of follicular involvement. Oral griseofulvin 500 mg twice a day until clearing occurs is usually sufficient for therapy but nausea, headache, and photodermatitis are common. Alternatively, but more expensive, are fluconazole 100 mg each day or 150 mg once weekly, or terbinafine 250 mg once daily until the skin clears.[18] Recurrences of fungal infections are common, especially in a setting of fungal infection of toenails.

SQUAMOUS CELL CARCINOMA IN SITU

In squamous cell carcinoma in situ (SCCIS), the entire thickness of the epithelium is replaced by undifferentiated cells. Depending on the anatomic location of the lesion, the equivalent terminology of vulvar intraepithelial neoplasia III (VIN III), penile intraepithelial neoplasia III (PIN III), or anal intraepithelial neoplasia (AIN III) can be used. Because SCCIS presents clinically in several settings, with morphology characteristic of each setting, traditionally these entities were given different names (Bowen's disease, erythroplasia of Queyrat, bowenoid papulosis) despite each being SCCIS.

Bowen's disease

Classic Bowen's disease refers to SCCIS occurring in older patients, usually manifested by an erythematous or hyperpigmented, scaling, sharply demarcated plaque (Fig. 64-10). This can occur anywhere over the vulva, perineum, or inguinal crease. In men, an additional common site is the glans penis. This form of Bowen's disease sometimes resembles a fungal infection, lichen planus, psoriasis, or eczema.

FIGURE 64-10. This sharply marginated, red, scaling and hyperkeratotic plaque of Bowen's disease could easily be mistaken for psoriasis. However, the existence of a solitary plaque and a poor response to topical therapy should prompt a skin biopsy. Lesions may be more moist and less thickened, particularly on damp skin such as the modified mucous membranes and uncircumcised penis (erythroplasia of Queyrat).

Although most often an isolated finding, Bowen's disease is sometimes associated with urogenital malignancy.

Erythroplasia of Queyrat

Erythroplasia of Queyrat refers to SCCIS occurring over the glans of the penis. This disease presents as an inflammatory, moist plaque. Erythroplasia of Queyrat is believed to result from chronic irritation of smegma and retained secretions.

Bowenoid papulosis

When SCCIS occurs in younger patients, it is most often multifocal, occurring in the distribution and with general morphology similar to flat genital warts. Sometimes referred to as bowenoid papulosis, these lesions are small, flat-topped, and either pink, pigmented, or sometimes skin-colored (Fig. 64-11). These lesions occur as a result of infection with specific types of human papillomaviruses (HPV). They are most easily confused with genital warts, pigmented nevi, or seborrheic keratoses. Although this form of SCCIS in immunocompetent patients is usually indolent, without progression into invasive and metastatic disease, associated lesions on the cervix and in the anus have a strong propensity for invasion and metastasis.

The diagnosis of SCCIS requires a high clinical suspicion and is confirmed by a skin biopsy. Management is by destruction or excision. However, any patient with areas of invasion should be managed by a gynecologic oncologist or a urologist.

EXTRAMAMMARY PAGET'S DISEASE

Extramammary Paget's disease is an epithelial malignancy suspected to be of apocrine gland origin that appears as red, scaling, or glistening plaques. Usually occurring in older patients, extramammary Paget's disease is most common over the perineum and hairbearing portion of the labia majora or scrotum. Morphologically, Paget's disease can be confused with SCCIS, eczema, tinea infection, or psoriasis. Diagnosis is by biopsy. Involved areas can be discontiguous, thus, many small sampling biopsies are often required to accurately map the extent of disease.

FIGURE 64-11. Bowenoid papulosis, a variant of squamous cell carcinoma in situ associated with human papillomavirus infection, resembles flat genital warts and may be pigmented, pink, or skin-colored.

Extramammary Paget's disease in women has recently been divided into three types. Type 1 is primary cutaneous extramammary Paget's disease. This can be further subclassified as (1a) intraepithelial, (1b) intraepithelial with dermal invasion, and (1c) intraepithelial associated with an underlying cutaneous adenocarcinoma of the vulva. Type 2 extramammary Paget's disease is a manifestation of an often associated, adjacent primary anal, rectal, cervical, or other noncutaneous adenocarcinoma. Type 3 extramammary Paget's disease (pagetoid urothelial epidermal neoplasia or pseudoPaget's disease) is now considered a unique entity associated with neoplasms of the urinary tract.[19]

Because of the possibility of dermal invasion with metastases, underlying cutaneous adenocarcinoma or associated noncutaneous adenocarcinoma, management for all patients with extramammary Paget's disease includes an evaluation for associated malignancies, as well as local excision or Mohs micrographic surgery.[20] Recurrence is usual.

RED PAPULES AND NODULES

CHERRY ANGIOMAS AND ANGIOKERATOMAS

Cherry angiomas are small, bright red, sharply demarcated papules that are extremely common in older, white patients. Although most heavily distributed over the trunk, these can occur over the perineum as well. Angiokeratomas are similar in appearance but usually more purplish in color. Genetically predisposed patients may have uncountable numbers of these lesions over the labia majora or scrotum. Neither require therapy.

LICHEN PLANUS

Lichen planus, particularly over the penis, is often papular (see previous section and Fig. 64-6).

PYOGENIC GRANULOMAS

Pyogenic granulomas are inflammatory vascular tumors that may be spontaneous or may occur at a site of injury. Mucosal forms are most common in pregnant women. Pyogenic granulomas are pedunculated, erythematous, often glistening

tumors. Observation may be warranted in pregnancy as lesions may resolve spontaneously after delivery. Persistent or symptomatic lesions require surgical removal. Histologic confirmation is essential since amelanotic melanomas can occasionally mimic this benign tumor.

URETHRAL CARUNCLES

Urethral caruncles are red, polypoid, and benign growths at the urethral meatus in postmenopausal women. These are generally asymptomatic and require no therapy. However, larger lesions can be excised and submitted for biopsy to rule out malignant change.

URETHRAL PROLAPSE

Urethral prolapse occurs both in prepubertal children and in older women. This erythematosus lesion is generally annular as the distal urethra is extruded circumferentially. When asymptomatic, this may require no therapy. Otherwise, surgical removal is sometimes required.

FOLLICULITIS/FURUNCULOSIS

Folliculitis is simply inflammation around a hair follicle. Furunculosis occurs when the inflammation increases to become a deeper, perifollicular abscess. These present as itchy or tender, erythematous papules and nodules on hair-bearing skin. The moist and occlude environment of the genital and inguinal areas is frequently affected. *Staphylococcus aureus* is a common inciting organism. Treatment includes washing with an antibacterial cleanser and using topical antibiotics (clindamycin or mupirocin). Recalcitrant cases may require oral antibiotics such as cephalexin or dicloxacillin, or as directed by culture. Warm compresses can provide relief in acute settings.

INFLAMED CYSTS

Cysts, including epidermal cysts, median raphe cysts, vestibular cysts, and Bartholin's duct cysts can sometimes become secondarily inflamed and appear red or cause tenderness. Although the inflammation is occasionally caused by infection (particularly with a Bartholin's abscess), most often the inflammation is due to friction or trauma.

Medical management can include a course of oral antibiotics for both the antibacterial and anti-inflammatory properties. Alternatively, or in conjunction, triamcinolone acetonide at a concentration of 5 mg per cc injected into the cyst can decrease inflammation easily and quickly. Surgical options include incision and drainage, and excision can be performed after inflammation has resolved. In Bartholin's duct cysts, a goal of management is to preserve gland function if possible. Insertion of a Word catheter or marsupialization, with a course of antibiotics, is effective. Marsupialization should not be used to treat a Bartholin's gland abscess.

INFLAMED TUMORS

Normally skin-colored tumors can become secondarily inflamed. Basal cell carcinomas, squamous cell carcinomas, intradermal nevi, and genital warts are more common lesions that sometimes appear red either owing to local friction, trauma, or because of necrosis within a tumor that has outgrown its blood supply. The diagnosis of an inflamed tumor generally requires a biopsy.

HIDRADENITIS SUPPURATIVA

Hidradenitis suppurativa is a relatively common condition that represents cystic acne of the axillae and/or genital area. Unlike acne on the face, hidradenitis suppurativa does not generally remit after the teenage years.

This condition is manifested by comedones and nodules that represent apocrine pilosebaceous units with follicles distended by keratin and apocrine secretions. As these enlarge and rupture, nodules become very painful and red, occasionally draining to the surface with chronic sinus tract formation. The disease spans the spectrum from occasional, tender nodules to extensive, severe, deep scarring disease with frequent superinfection.

Most often confused with staphylococcal furuncles (boils), this diagnosis is made on the basis of its chronicity and location. First-line therapy consists of decreasing friction from obesity and tight clothing as well as regular use of an antimicrobial wash with or without topical clindamycin. Oral antibiotics administered chronically can be beneficial for mild to moderate disease, partially for their antibacterial effect in eradicating secondary infection, but primarily for their antiinflammatory effects. Tetracycline and erythromycin at 500 mg twice a day, doxycycline and minocycline at 100 mg twice a day, and clindamycin at 150 mg twice a day as used for acne are all somewhat effective. If organisms are being cultured, sensitivities can be used to guide antibiotic therapy. Unfortunately, more severe disease is rarely controlled with these regimens.

Several systemic treatments have shown some benefit including isotretinoin (Accutane®), finasteride (Propecia®) and antiandrogen therapy (ethinyl estradiol, cyproterone acetate, spironolactone). In case reports, infliximab (Remicade®) has been reported effective for hidradenitis suppurativa associated with inflammatory bowel disease.[21,22] Although surgery is a treatment of choice for unresponsive axillary disease, the large area of apocrine glands over the genital area makes definitive surgery very difficult and sometimes mutilating. However, conservative excision of areas most troublesome is often very beneficial.

WHITE PATCHES AND PLAQUES

Lichen Sclerosus et Atrophicus

Lichen sclerosus (hypoplastic dystrophy) is a skin disease, probably of autoimmune origin, that preferentially affects the vulva and, less often, the penis and extragenital sites. The major symptoms are those of pruritus and eventual pain with more advanced disease. This disease occurs at all ages but is most often diagnosed in postmenopausal women.

Lichen sclerosus is most often characterized by well-demarcated, hypopigmented plaques of fragile skin. Usually, at least some areas of the skin show fine crinkling, and fragility is often manifested by purpura or erosions (Figs. 64-12 to 64-14). As lichen sclerosus progresses, scarring occurs, resulting in resorption of the labia minora and scarring of the clitoral hood over the clitoris. Narrowing of the introitus occasionally occurs, resulting in the nonspecific, late appearance of kraurosis vulvae, characterized by resorption of normal vulvar architecture and constriction of the vaginal opening. Uncircumcised males generally experience phimosis as a presenting abnormality. Although lichen sclerosus was once believed to spontaneously resolve at puberty when occurring in children, chronic disease is recognized now as a common occurrence.

FIGURE 64-12. The wrinkling of this white plaque covering the modified mucous membranes of the anterior vulva is an extremely useful finding that differentiates lichen sclerosus from vitiligo, the white lesions of lichen planus, and postinflammatory hypopigmentation.

FIGURE 64-13. Late lichen sclerosus displays the characteristic hypopigmentation and fine wrinkling in association with the loss of labia minora and clitoral hood to scarring.

FIGURE 64-14. Kraurosis vulvae consists of severe scarring of the vulvae and narrowing of the introitus due to lichen sclerosus. The erosions at the introitus were firm on palpation and proved to be squamous cell carcinoma.

Complicating factors in patients, particularly women, include superimposed eczema from rubbing and scratching and secondary bacterial infection, particularly in prepubertal and postmenopausal women who normally have thin skin in this area. About 3–5% of women with uncontrolled lichen sclerosus eventually develop an associated squamous cell carcinoma. However, a recent study showed 9% of patients with symptomatic vulvar lichen sclerosus developing VIN III and 21% developing invasive squamous cell carcinoma.[23] Reports of penile squamous cell carcinoma arising in men with lichen sclerosus are rare. However, when cases of penile squamous cell carcinoma are retrospectively evaluated, just over half have either pathologic evidence or clinical history of lichen sclerosus.[24] Thus, the risk of squamous cell carcinoma needs to be communicated to both men and women at the time of diagnosis.

Lichen sclerosus is sometimes confused with vitiligo, but vitiligo consists of otherwise asymptomatic color change, with no texture change, scale, or scarring. Eczema can occasionally appear white owing to hydrated, thickened skin from scratching, and sometimes a biopsy is required for diagnosis. The clinician should also understand that endstage scarring can occur with several diseases, including mucous membrane pemphigoid and erosive lichen planus, so that late vulvar scarring cannot be ascribed automatically to lichen sclerosus.

The treatment for lichen sclerosus consists of twice daily topical application of an ultra-high potency corticosteroid ointment such as clobetasol propionate (Temovate®) until skin texture normalizes (2–4 months), with careful monthly examinations. Nighttime sedation and infection control are also important. Topical testosterone propionate is no longer considered a treatment option.[25]

After lichen sclerosus has been controlled with a very potent corticosteroid, patients can be maintained with two or three times weekly applications. Patients should continue to receive twice yearly follow-up to monitor for continued disease control, local adverse reactions, and to evaluate for the development of squamous cell carcinoma.

POSTINFLAMMATORY HYPOPIGMENTATION

Some inflammatory diseases, particularly eczema, can produce secondary color change in the genital skin. Especially visible in normally dark-complexioned patients, light skin can result from damage to melanocytes both by inflammation and by the trauma of scratching (Fig. 64-2). Rarely, this white discoloration is sharply demarcated so that lichen sclerosus and vitiligo should be included in the differential diagnosis as well. The diagnosis is made by the setting and response to therapy, although sometimes a skin biopsy is necessary.

VITILIGO

The pathogenesis leading to an absence of epidermal melanocytes in patches of vitiligo is not known, but common theories include the autoimmune, antibody-mediated destruction, neurochemical eradication, and self-destruction by cytotoxic melanin precursors. The autoimmune hypothesis is most well supported by current data.[26] Occurring first around orifices and over extensor surfaces of joints, the genital area is sometimes affected early. Vitiligo is characterized by sharply demarcated patches of milk-white skin that have no evidence of texture change, inflammation, or scale.

At times, vitiligo can be difficult to distinguish from lichen sclerosus or postinflammatory hypopigmentation, particularly after the original inflammatory insult has resolved. The diagnosis can usually be made by an examination of other skin surfaces and by history. Therapy for vitiligo when occurring in the genital area is unnecessary although a mild topical corticosteroid occasionally induces some repigmentation.

ECZEMA/LICHEN SIMPLEX CHRONICUS

Thickened, lichenified eczema in moist areas often appears white owing to hydrated, hyperkeratotic skin (Fig. 64-3). Usually, the morphology is generally that of eczema (see the preceding discussion), which develops a whitish cast on thick, moist skin. Although the diagnosis can usually be made by the clinical appearance, a biopsy is occasionally required to differentiate between eczema superimposed on lichen sclerosus and eczema that is white simply because of hydrated, hyperkeratotic skin.

LICHEN PLANUS

Papular lichen planus on moist skin often appears white. White striae, sometimes in association with dusky red papules or plaques are most common (Fig. 64-7). However, sometimes solid white epithelium occurs. (see discussion of lichen planus in the preceding section).

VESICULOBULLOUS/EROSIVE DISEASES

Ulcers are differentiated from erosions by their depth. Whereas erosions are simply lacking epithelium with most of the dermis intact, an ulcer extends well into, or, occasionally, even through the dermis.

Most blisters on thin, genital skin quickly lose their blister roof and appear as round erosions. This is especially true of the moist, modified mucous membrane skin of the vulva and the uncircumcised glans penis. The most common vesicular or erosive disease of the genitalia, herpes simplex virus infection, is discussed in Chapter 24.

EROSIVE LICHEN PLANUS

A very common cause of nonspecific, chronic erosions, primarily over modified mucous membranes of the vulva and the vagina, is erosive lichen planus (see also discussion in the preceding section and Fig. 64-8). Most common, but not limited to middle-aged or older women, the primary symptom is one of irritation and dyspareunia, and sometimes itching. White epithelium or classic reticulate, white striae are occasionally present and provide clues to the diagnosis. More often, patients exhibit only introital erythema and erosions, frequently associated with a purulent vaginal discharge. These women usually have associated erosive, oral lichen planus that routinely affects the buccal mucosae and often involves the gingivae. Although erosive and scarring lichen planus occurs on the penis, especially the glans, this occurrence is much less common.

The diagnosis is made by the identification of classic associated lesions or by a biopsy of the edge of an erosion that includes some epithelial surface. Unfortunately, nondiagnostic biopsies are common.

The treatment of erosive genital lichen planus is discussed in the preceding section in this chapter.

MUCOUS MEMBRANE PEMPHIGOID (CICATRICIAL PEMPHIGOID)

Mucous membrane pemphigoid is an uncommon autoimmune blistering disease of older individuals that produces scarring, particularly of mucous membranes. This diagnosis

is relatively easy when nonmucous membrane surfaces are involved, because tense blisters are present and biopsies are generally diagnostic. However, the blistering nature is often not appreciated if only mucous membrane erosions are present. In addition, biopsies of these erosions are often nondiagnostic.

Mucous membrane pemphigoid of the genitalia is manifested by nonspecific erosions, skin fragility, and sometimes intact blisters over clinically hairbearing skin.[27] As time progresses, scarring ensues and the clinical picture can be nearly identical to the more common erosive lichen planus (Fig. 64-8). The labia minora are resorbed and the clitoris is buried under a scarred clitoral hood. Phimosis occurs in the uncircumcised male, and obvious scarring over the glans with loss of a sharp demarcation between the glans and shaft occurs in others. The severity of mucous membrane pemphigoid spans the spectrum from mild, chronic, nonspecific inflammation to rapidly progressive erosions, scarring, and blindness from eye involvement. The diagnosis of mucous membrane pemphigoid is made by the recognition and integration of multimucosal, scarring disease that includes the eyes, the mouth, and mucous membranes or modified mucous membranes of the genitalia. Disease is sometimes subtle so that a careful examination by an ophthalmologist may be required to identify conjunctival inflammation or scarring, and oral involvement may simply appear as mild gingivitis. The diagnosis can often be confirmed by routine biopsies from the edge of an erosion and an immunofluorescent biopsy from adjacent skin. If nonmucous membrane lesions are present, these usually are the easiest to biopsy and the most likely to yield a definitive diagnosis.

Initial therapy of mucous membrane pemphigoid is oral corticosteroids. Corticosteroid conspirator medications are often integrated for long-term suppression. There are small randomized controlled trials to support the use of dapsone in mild to moderate disease and cyclophosphamide in severe disease. Success has also been reported with sulfapyridine, minocycline, mycophenolate mofetil, and intravenous immunoglobulin.[28] Careful local care to control infections is crucial, and a vaginal dilator inserted once a day may help to prevent vaginal adhesions. Occasionally, a topical steroid adds some additional benefits to systemic therapy.

PEMPHIGUS VULGARIS

Pemphigus vulgaris is an autoimmune, superficially blistering disease that usually begins over mucous membranes, most often the posterior mouth. Most common in younger adults, this disease progresses to affect other mucous membranes, and, ultimately, nonmucous membrane skin. Because of the very superficial nature of the blister, tense bullae are rarely encountered, even over hair-bearing skin. Thinner, mucous membrane or modified mucous membrane skin displays erosions, and keratinized skin shows flaccid bullae and areas of denuded skin. Although pemphigus vulgaris does not usually scar when occurring on keratinized skin or in the mouth, long-standing pemphigus vulgaris can cause genital scarring, as described in the preceding section, for mucous membrane pemphigoid and lichen planus.

A routine skin biopsy from the edge of an erosion or the edge of a blister usually yields a diagnosis that can be confirmed with biopsy for direct immunofluorescence from adjacent skin.

Therapy consists of systemic corticosteroids. Immunosuppressant agents such as azathioprine and cyclophosphamide are often used as adjunctive, steroid-sparing medications. Again, local care and attention to infection as discussed for lichen planus can minimize scarring and maximize comfort for the patient.

There is an 80% mortality for pemphigus vulgaris when untreated. Although pemphigus vulgaris treated aggressively rarely causes death, the high doses of prednisone required for remission of the disease carry their own morbidity. After the disease is controlled, most patients can be maintained on medication that is slowly tapered to safer dosing schedules, and medication sometimes can be discontinued altogether.

IRRITANT/ALLERGIC CONTACT DERMATITIS

Contact dermatitis, either irritant or allergic, typically presents as inflamed, scaling plaques and was discussed in detail under red patches and plaques. However, with a very strong response, vesicles and erosions can occur.

FIXED DRUG ERUPTION

The fixed drug eruption is a peculiar and uncommon but characteristic disease that occurs in some patients in response to certain medications. Although the list of offending drugs is very long, the most common medications responsible include acetaminophen, barbiturates, nonsteroidal anti-inflammatory agents including salicylates, oral contraceptives, penicillins, tetracyclines, phenolphthalein, and sulfonamides.[29,30]

One or a few blisters or erosions ranging from 1 to 3 cm appear within 1–2 days following ingestion of the offending medication. Subsequent exposure to the medication produces recurrence of lesions precisely at the same location and occasionally additional areas as well. Fixed drug eruptions of the genitalia preferentially affect the glans penis and nonhair-bearing skin of the vulva. On nonmucous membrane skin, lesions are very round edematous plaques or blisters, and, with recurrences, sharply demarcated, round patches of postinflammatory hyperpigmentation develop. On mucous membranes, lesions tend to be smaller and they may lack their characteristic round shape (Fig. 64-15). Because blisters

FIGURE 64-15. This nonspecific erosion due to a fixed drug eruption can be differentiated from ulcers caused by STD by its superficial nature and association with several other round, edematous plaques or blisters on keratinized skin, or oral lesions.

FIGURE 64-16. Intense inflammation with resulting necrosis and loss of the epidermis, and exudation is characteristic of bullous erythema multiforme (Stevens-Johnson syndrome, toxic epidermal necrolysis).

are so short-lived on mucosal surfaces, well-demarcated, red erosions are usual. Hyperpigmentation generally does not occur on these areas.

The diagnosis of a fixed drug eruption is made by the characteristic appearance of these lesions that occur recurrently in the same area in conjunction with a compatible history of medication use. The most common disease mistaken for a fixed drug eruption is a herpes simplex virus infection because of the recurrent nature of both diseases. However, herpes simplex virus infection normally shows small, coalescing erosions rather than fewer, large, discrete erosions. In addition, most patients with a fixed drug eruption have either oral or classic nonmucous membrane lesions as well as genital lesions.

The treatment for fixed drug eruption is avoidance of the medication.

■ ERYTHEMA MULTIFORME, STEVENS-JOHNSON SYNDROME, TOXIC EPIDERMAL NECROLYSIS

Erythema multiforme is a hypersensitivity reaction that, when occurring as mucous membrane erosions, is produced by medication allergy or by hypersensitivity to recurrent herpes simplex virus infection. The classification scheme for these diseases is a subject of confusion and disagreement. For years, these three entities were considered to be a spectrum of the same disease, with erythema multiforme (EM) minor being the least inflammatory and rarely having mucous membrane involvement, and the more severe Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) having increasingly severe mucous membrane involvement. More recent distinctions have been made based on pathogenesis, causing further confusion, but ideally leading to a clearer classification scheme in time. Some now believe that all erythema multiforme minor is due to herpes simplex virus infection rather than triggered by other infections and medications as well. SJS and TEN are generally agreed to occur most often as a result of hypersensitivity to medication.[31]

Erythema multiforme is manifested by a range of severity and extent of skin lesions. Frequently, there are erythematous, usually target shaped red papules over the palms and soles. Sometimes, there are also erosions of the mucous membranes, particularly the oral mucosa. Treatment for erythema multiforme consists of addressing the trigger by treating or suppressing HSV infection using antiviral therapy. Prognosis is good, but recurrence is frequent.

SJS and TEN are hypersensitivity reactions as well but with different inciting factors and increased severity (Fig. 64-16). SJS and TEN are often caused by a drug but may be related to collagen vascular disease, HIV infection, or cancer.[31] Although uncountable numbers of different medications have been reported in association with SJS and TEN, a more limited number have a clinically significant association. These include penicillins, cephalosporins, sulfas, phenytoin, carbamazepine, phenobarbitol, hydrochlorothiazide, furosemide, procainamide, hydralazine, phenothiazines, allopurinol, nonsteroidal anti-inflammatory medications, and any related medications, particularly those containing a sulfa ring.

The lesions of SJS and TEN are much more extensive and can affect the modified mucous membranes of the vulva, vagina, and glans penis. Mucous membrane lesions can be severe and are associated with red, nonscaling papules with central blisters or large areas of coalescing bullae and erosions scattered over the entire skin surface. Morbidity is increased, and TEN has a mortality rate ranging from 30% to 50%. (Fig. 64-16).

Disease localized primarily to the genitalia and the mouth is most often confused with a herpes simplex virus infection

or fixed drug eruption. Very extensive disease is more suggestive of pemphigus vulgaris. The diagnosis is made by the setting, the abruptness of onset, and a confirmatory skin biopsy.

Treatment of SJS and TEN is controversial, but all agree that rapid diagnosis, discontinuation of any causative drug, and specialized, supportive care are most important. Immunosuppression by intravenous corticosteroids or cyclosporine or antiapoptic measures in the form of intravenous immunoglobulin may minimize severity if instituted in the first 24–48 hours, but there are no randomized, prospective data.[32] Continued use of intravenous corticosteroids, cyclosporine or immunoglobulin carries the risk of complications from systemic immunosuppression.[33]

NONINFECTIOUS ULCERS

The primary consideration in a patient, who presents with a genital ulcer, is a possibility of a sexually transmitted disease, especially primary syphilis, chancroid, granuloma inguinale, or herpes simplex virus infection occurring in an immunosuppressed patient. Infectious ulcers are discussed in Chapter 63 and noninfectious causes of erosions are discussed in the immediately preceding section of this chapter. However, there are several noninfectious diseases that can produce genital ulcers.

APHTHOUS ULCERS

Aphthous ulcers (sometimes called canker sores) are mucous membrane ulcerations that are extremely common on the oral mucosa, but less common over the genitalia. Although patients with genital aphthae nearly always report oral disease as well, oral and genital lesions do not necessary occur concurrently. Although oral aphthae are usually small, ranging from 1 to 2 mm, with an erythematous rim and a white fibrin base, genital aphthae are often larger and irregular. The base may be white, but deeper ulcerations may simply be red (Fig. 64-17). These are often quite painful and may heal with scarring. They are most common on the modified mucous membranes of the vulva and occasionally over the scrotum and penis.

When genital aphthae occurs in patients who have systemic signs of disease such as inflammatory eye disease, arthritis, meningoencephalitis, or pustular vasculitis, the diagnosis of Behçet's disease should be considered. Large aphthae alone do not constitute Behçet's syndrome. Patients with significant oral(genital aphthosis and gastrointestinal symptoms should be evaluated for inflammatory bowel disease, which can produce similar oral and genital ulcers.

Aphthae are diagnosed by appearance, the history of recurrent ulceration, and the exclusion of infectious and granulomatous causes, usually by skin biopsy.

Mild aphthae can be treated with a topical corticosteroid such as clobetasol propionate. For patients who have very occasional, painful disease, oral prednisone at 40–60 mg for 3–7 days usually induces prompt alleviation of pain and healing. The chronic administration of oral dapsone at 100–200 mg per day or colchicine beginning at 0.6 mg two or three times a day or are sometimes useful in suppressing frequent recurrences.

FIGURE 64-17. These aphthous ulcers show the characteristic larger size (as compared to oral lesions), peripheral red flare, and fibrin base. In the absence of a history of recurrence or oral aphthae, a biopsy may be required to rule out sexually transmitted causes.

CROHN'S DISEASE

Crohn's disease, a granulomatous disease of the small bowel, sometimes produces perineal ulcers or fistulas. Less often, Crohn's disease can produce diffuse firm edema or linear ulceration and skin creases of the vulva.

Occasionally, this disease resembles hidradenitis suppurativa, which also produces sinus tracts, and in fact these diseases are sometimes seen together. The diagnosis of Crohn's disease is made by skin biopsy and the demonstration of intestinal disease. Therapy consists of oral corticosteroids, sulfones, mycophenolate mofetil, and biological response modifiers such as infliximab.

PIGMENTED LESIONS

PHYSIOLOGIC HYPERPIGMENTATION

Physiologic hyperpigmentation is noticeable primarily in patients who are naturally dark complexioned and as a response to some hormones, especially sex hormones. Women experience hyperpigmentation of the perianal skin and the edges of the labia minora. Less common in men, the hyperpigmentation primarily involves the scrotum and perianal skin. The diagnosis is by pattern and therapy is unnecessary.

BENIGN GENITAL LENTIGINOSIS (MELANOSIS)

Benign genital lentiginosis is an uncommon, idiopathic cutaneous abnormality consisting of irregular, variegate patches and macules of hyperpigmentation. Many clinicians believe that this often represents unusually striking postinflammatory hyperpigmentation, especially when associated with lichen sclerosus. This totally flat hyperpigmentation sometimes displays frightening irregularity of browns, tans, and black that mimic cutaneous melanoma. Most common over the glans and shaft of the penis and the modified mucous membranes of the vulva, a biopsy is required to differentiate this condition from malignant melanoma. Although this condition is felt to be benign despite its worrisome appearance, there is one report of melanoma of the bladder in a patient with genital lentiginosis so that at least occasional follow-up is recommended by some.

HYPERPIGMENTATION OF LICHEN SCLEROSUS

Patients with lichen sclerosus, particularly those with longstanding, treated lichen sclerosus, occasionally exhibit flat, irregular hyperpigmentation that requires biopsy to differentiate from melanoma and squamous cell carcinoma in situ. There have been recent reports of melanoma occurring in association with lichen sclerosus that may be more than coincidence.

Pigmented nevi

Pigmented nevi (moles) do not have a predisposition for the genital area but they are found often in that area by virtue of their ubiquitous occurrence. In addition, nevi that occur on the vulva, particularly during pregnancy, sometimes have an atypical appearance on biopsy, although this does not necessarily portend malignant transformation. A benign nevus is a macule or papule that is smaller than 7 mm in diameter, with regular, sharply demarcated borders, and homogeneous, brown pigmentation. Although many nevi exhibit some irregularity of shape or color, several atypical features or one extraordinarily abnormal finding should prompt the physician to refer the patient to a dermatologist or to biopsy the lesion. Otherwise, therapy is unnecessary although nevi can be excised if desired.

MALIGNANT MELANOMA

Cutaneous melanoma is a malignant tumor of melanocytes. Arising in a preexisting nevus or de novo, these lesions are not especially common in the genital area. However, melanomas located in this area are often diagnosed late with a grave prognosis. Melanoma can occur anywhere over the genital area, including the modified mucous membranes and even within the vagina. Melanomas are usually greater than 7 mm in diameter with irregular and often poorly demarcated borders. The color is usually irregular and variegate. Most melanomas do not exhibit all of these clinical characteristics but generally several are present.

Diseases in the differential diagnosis of melanoma include pigmented nevi, pigmented genital warts, pigmented squamous cell carcinoma in situ, benign genital lentiginosis, and hyperpigmentation associated with lichen sclerosus. The diagnosis is confirmed by biopsy, and therapy consists of local excision with margins determined by the thickness of the tumor. Thin melanomas (those <0.86 mm thick) have a very good prognosis with most patients experiencing long-term, disease-free survival. However, as the lesions thicken, the risk of metastasis increases remarkably, and metastatic melanoma is an extraordinarily aggressive disease.

SQUAMOUS CELL CARCINOMA IN SITU

VIN III/PIN III can present as a hyperpigmented morphologic variants. These diseases are discussed in the preceding section covering red patches and plaques.

SEBORRHEIC KERATOSES

Seborrheic keratoses are benign tumors that do not exhibit a propensity for the genitalia but they are so common and sometimes so numerous that they may occur over this skin surface. Seborrheic keratoses are brown to skin-colored, keratotic, sharply demarcated, flat-topped papules. The firm, keratotic nature is sometimes not appreciated on the genitalia where the skin is damp. Seborrheic keratoses are most often confused with genital warts or nevi. At times, these require biopsy to differentiate from pigmented, intraepithelial neoplasms. Seborrheic keratoses have no malignant predisposition, and therapy is unnecessary. The lesions can be removed by liquid nitrogen therapy or light curettage.

SKIN-COLORED PAPULES

Genital warts, the most common skin-colored papules found in the genital area, are usually sexually transmitted and are discussed in Chapter 28. Most other skin-colored papules are medically trivial but nonetheless important to the patient.

PEARLY PENILE PAPULES

Pearly penile papules are common, skin-colored, monomorphous, dome-shaped papules or papillae arranged in rows around the edge of the corona (Fig. 64-18). These are most common in uncircumcised men. They are sometimes confused with genital warts, but the monomorphous nature and the arrangement in rows differentiate these from genital

FIGURE 64-18. Pearly penile papules are differentiated from genital warts by their regular, monomorphous appearance in rows around the edge of the corona and the dome-shaped rather than keratotic, acuminate tips to the papules.

warts, and virologic studies have shown no evidence of HPV.[34] These are asymptomatic and require no therapy.

VESTIBULAR (VULVAR) PAPILLOMATOSIS

Vestibular papillae are similar normal variants that occur over the modified mucous membrane of the introitus and medial labia minora. These tubular papillae are found in patches or lines that are bilaterally symmetrical. Like pearly penile papules, they are often mistaken for genital warts. However, these are very soft and monomorphous, and the papillae are discrete to the base, unlike genital warts that tend to be fused at the base.[35] In addition, the tips of the papillae are rounded rather than acuminate and keratotic. Although vestibular papillae often come to the patient's or physician's attention when vulvar itching or pain occur, these papillae are incidental findings present in about half of premenopausal women. They are asymptomatic and require no therapy.

FORDYCE SPOTS

Fordyce spots are enlarged sebaceous glands that occur primarily over the labia minora. Although usually subtle, at times these can be enlarged and may resemble small epidermal cysts or genital warts. However, Fordyce spots are usually monomorphous and slightly yellowish in color (Fig. 64-19). Enlarged pilosebaceous units are sometimes present on the shaft of the penis also. These are small, scattered, skin-colored papules 1–2 mm in size. These are most often noticed when a patient has genital warts and the physician has difficulty discerning whether these pilosebaceous units are normal irregularities in the skin or extremely small warts. They are asymptomatic and require no therapy.

FIGURE 64-19. Fordyce spots represent enlarged sebaceous glands located primarily over the inner aspect of the labia minora although they can be seen elsewhere, including the penis. Individual papules are lobular and white, yellowish, or skin colored.

CYSTS

Epidermal cysts

Cysts are common, benign tumors. Epidermal cysts (sometimes mistakenly called sebaceous cysts) are the most common. Although usually single or few in number, some patients exhibit large numbers of these firm, skin-colored to white, dermal nodules, particularly over the scrotum or the labia majora. These cysts generally represent hair follicles that have become plugged with keratin so that the proximal portion of the follicle has become distended with keratin and sebaceous material. Because pilosebaceous units are even found over the labia minora, epidermal cysts sometimes occur in this area. Epidermal cysts are usually asymptomatic and require no therapy. Surgical excision can be performed for those patients who wish removal.

Vestibular cysts

Vestibular cysts are skin-colored, slightly bluish, or slightly yellowish cysts found over the non-hair-bearing portion of the vulva. These are usually asymptomatic and unnoticed by the patient. They are dome-shaped without surface change.

Median raphe cysts

Median raphe cysts are innocuous, skin-colored, dome-shaped papules over the midline underside of the shaft of the penis.

Pilonodal cysts

Pilonidal cysts are small, dome-shaped papules most often located over the sacrum, coccyx, and near the clitoris. These can become inflamed and occasionally drain and develop a

sinus tract. Pilonidal cysts can be symptomatic and painful with chronic drainage. These may require excision.

SCLEROSING LYMPHANGITIS

Sclerosing lymphangitis consists of a firm, skin-colored cord located just proximal and parallel to the corona of the penis, sometimes encircling the shaft entirely. This asymptomatic, medically trivial, and self-resolving abnormality is believed to occur from trauma and friction.

PRURITUS

Genital pruritus is a common symptom. In predisposed, atopic patients, any inflammation or irritant can produce itching. Often, the physical examination shows a specific abnormality. However, genital skin is often normally pink, and scale can be masked by moisture so that sometimes the genitalia can appear amazingly normal in the face of significant inflammation. Any patient with pruritus should be examined specifically for the following causes of pruritus.

INFECTION

The most common cause of acute pruritus is an infection, particularly in women. The vagina should be carefully evaluated, especially for yeast infection. However, trichomoniasis and bacterial infection occasionally produce pruritus. Pinworms, found primarily in children, can cause itching.

ECZEMA/LICHEN SIMPLEX CHRONICUS

The most common cause of chronic itching is eczema. Erythema and lichenification can be extremely subtle so that in the absence of other abnormalities, the patient should be treated for eczema (see the preceding section).

OTHER SKIN DISEASE

Pruritus can occur with other skin diseases as well, especially lichen sclerosus, lichen planus, irritant contact dermatitis, and psoriasis.

NEUROPATHIC PRURITUS

Very occasionally, itching can occur in the absence of skin findings as a result of neuritis or neuralgia. This is a diagnosis of exclusion and is confirmed by successful treatment with medication for neuropathy, such as a tricyclic medication or gabapentin.

DEPRESSION AND ANXIETY

Finally, depression and anxiety occasionally cause and very often exacerbate itching. Psychological factors should be recognized and addressed. Nighttime use of amitriptyline or doxepin sedates the patient, preventing awakening owing to pruritus, and provides antidepressant and anxiolytic effects.

GENITAL PAIN

VULVODYNIA/PENODYNIA AND SCROTODYNIA

Chronic genital pain can be caused by infections and skin disease but it can also be experienced with no clinical or laboratory abnormalities. Vulvodynia, scrotodynia, penodynia, and anodynia are defined as chronic burning, stinging, soreness, aching, or stabbing (not itching) in the absence of an objective etiology. Before diagnosing a chronic pain syndrome, infection, inflammatory skin disease, tumor, and neurologic disorders should be ruled out. Because of the rarity of scrotodynia, this entity is poorly understood and there is little published information regarding causes and therapy. Some experienced clinicians feel that scrotodynia is usually a manifestation of psychosexual dysfunction, whereas others believe that male genital pain syndromes are analogous to vulvodynia.

Although the vast majority of women with vulvar pain are extremely depressed and experience major disruption in their sexual functioning, vulvodynia is generally not believed to result primarily from psychosexual pathology. There are several known specific physical causes for vulvar burning, and directive therapy often produces major improvement in symptoms. Vulvodynia is often multifactorial.

Vaginal infections of any kind can sometimes produce secondary vulvar burning. Although *Candida albicans* usually produces itching, non-*albicans Candida* infections are more likely to produce burning and often they are treated inadequately with the usual azole therapies. Vulvar burning can also result from bacterial vaginitis, not to be confused with bacterial vaginosis. Vaginal secretions of bacterial vaginitis are purulent rather than nonflammatory with clue cells, as occurs with bacterial vaginosis.

Rarely, subtle skin disease produces vulvar irritation, soreness, and burning. Although eczema can be painful, this pain only occurs as a result of erosions from scratching, and the patient's primary complaint is one of pruritus. Very subtle lichen sclerosus sometimes produces pain, and erosive lichen planus is very often associated with pain. Occasionally, lichen planus can affect only the vagina, with irritating and superinfected vaginal secretions irritating the vulva secondarily. Desquamative inflammatory vaginitis, a noninfectious inflammatory vaginal dermatosis, can also produce irritating, purulent vaginal secretions that cause vulvar burning.

Skin malignancies, postherpetic neuralgia, spinal compression syndromes, or dental nerve entrapment can also cause genital pain.

When the above processes have been ruled out, vulvodynia, scrotodynia, penodynia, or anodynia can be diagnosed. Most believe these represent neuropathic pain syndromes and pelvic floor abnormalities.

In 2003, the International Society for the Study of Vulvovaginal Disease established recommended terminology and a classification scheme for vulvar pain.[36] Vulvodynia is defined as vulvar discomfort in the absence of an objective etiology. Vulvodynia is further classified by the location (generalized or migratory versus localized) and the nature of discomfort (spontaneous, provoked by touch, or mixed). There are two primary patterns of vulvodynia; generalized pain that is present with and without touch, and vestibulodynia (vulvar vestibulitis syndrome) that is localized to the vestibule and primarily provoked by touch. These patterns probably exist on a spectrum. Multiple therapies are used, either individually or in combination for the treatment of vulvodynia. These include sensitive skin care, topical therapies, oral medications, pelvic floor rehabilitation, local injections, and surgery.[37]

Sensitive skin care simply emphasizes avoidance of irritants by cleansing the genital area with plain water and using mild soaps and shampoos on the rest of the body. Also, avoidance of unnecessary fragrances, medications, panty liners, and moisturizers can be important.

Topical therapies include plain petrolatum to improve barrier function and lidocaine ointment 5% or jelly 2% for symptom relief. Estrogen topically applied provides variable results.

Oral therapies include medications aimed at modulating both localized and generalized neuropathic pain. Amitriptyline, nortriptyline, desipramine, venlafaxine, and duloxetine at standard antidepressant doses have all been used effectively. Gabapentin (up to 3600 mg per day) is often useful, and pregabalin 150 mg each day is likely to prove beneficial in the future. For most of these medications, tapering from low to higher doses generally minimizes adverse reactions.

Pelvic floor rehabilitation is another therapy used for both localized and generalized vulvodynia. Physical therapy and exercises guided by surface electromyographic abnormalities can provide complementary benefits. This includes myofascial release, retraining of bowel, bladder, and pelvic floor muscles, ultrasound, electrical stimulation, and use of home vaginal dilators.

An occasional patient with very localized vulvodynia benefits from a local injection of corticosteroids, and there are reports of local interferon alpha being useful. Patients with vestibulodynia who are recalcitrant to the above measures usually respond well to a vestibulectomy, local excision of the painful area with advancement of the vaginal mucosa.

Scrotodynia and penodynia are much less common in vulvodynia and less well understood. There is little published information on these conditions. However, in one author's experience (Edwards), tricyclic antidepressants, and gabapentin have proved useful.

Patients with chronic pain, particularly chronic genital pain, are uniformly depressed. Counseling and attention to depression and anxiety are extremely important and overall management, not to treat pain, but to help patients cope with both the pain and the psychosexual repercussions.

65 Ocular Infections Associated with Sexually Transmitted Diseases and HIV/AIDS

William Lynn and Susan Lightman

INTRODUCTION

Sexually transmitted infections can present in a variety of ways, and many have the potential for ocular complications. All structures of the eye may be involved with severity ranging from minor irritation to rapidly progressive sight-threatening disease. Although many may have a minor problem and are not at risk of visual loss, patients who complain of visual disturbance or a red or painful eye are likely to have more serious disease, where delay in diagnosis and treatment could lead to serious visual loss. Such patients require prompt evaluation, including measurement of visual acuity and ocular examination. If there is any suggestion of intraocular inflammation, loss of visual acuity, or retinal involvement, then urgent specialist ophthalmological assessment is warranted. Ocular symptoms may be the presenting feature of an unsuspected sexually transmitted infection. In such cases, the patient is unlikely to be attending a genitourinary specialist, and it is essential that ophthalmologists and clinicians working in other fields, including primary care, are aware of the possibility of underlying sexually transmitted infection, when evaluating patients with eye signs.

Sexually transmitted pathogens may access the eye through a number of routes. Inoculation into the conjunctiva may occur directly through oculogenital contact or indirectly through autoinoculation with fingers, etc. Neonatal infection may be acquired transplacentally or during passage through the birth canal. Some pathogens, for example syphilis, may reach the retina by hematogenous dissemination. Underlying human immunodeficiency virus (HIV) infection may alter the presentation, including ocular manifestations, of some classical sexually transmitted infections. HIV may directly affect the eye, and if the patient is significantly immunocompromised, then the eye is vulnerable to other opportunistic infections.

Ocular inflammation may lead to permanent visual loss. It is, therefore, essential that clinicians treating patients with sexually transmitted infections and/or HIV/AIDS are aware of potential ocular manifestations and the appropriate clinical management.

GONORRHEA

Gonorrhea remains a serious threat to global public health and is one of the most commonly reported sexually transmitted infections in the United States, with 335,104 cases reported in 2003.[1] In the eye, the hallmark of gonococcal infection is a severe purulent conjunctivitis, but, as it is still relatively uncommon, diagnosis may be delayed. If not recognized and treated appropriately, permanent visual loss due to corneal scarring or perforation may occur.[2] *Neisseria gonorrhoeae* may be inoculated into the eye by direct oculogenital contact. More frequently this follows accidental self-inoculation, which occurs in approximately 1–2% of individuals with genital tract infection. Eye infection may be acquired in neonates from direct inoculation in the birth canal of an infected woman (see "Ophthalmia Neonatorum" section).[3] Hematogenous dissemination of *N. gonorrhoeae* has not been reported to cause ocular disease, but, because disseminated infection can be fatal, hospitalization and treatment with intravenous antibiotics such as ceftriaxone sodium or cefotaxime sodium are required.[4]

Occasional, nonsexually transmitted cases of gonococcal conjunctivitis occur, and the diagnosis should be considered in a patient with purulent conjunctivitis, even in the absence of a possible sexual exposure. Cluster outbreaks of nonsexually transmitted gonococcal conjunctivitis have been reported. A survey of conjunctival isolates from six cases in Cuba were serogroup WI, penicillin producing, and showed the same antimicrobial susceptibility pattern and plasmid profile (2.6-3. 2-24.5).[5] Four hundred and forty-seven cases of gonococcal conjunctivitis in Aboriginal communities, predominantly in Central and Western Australia, were identified, with chronic oropharyngeal carriage and spread of *N. gonorrhoeae* implicated.[6] In another study in this group, 432 cases were identified-the highest attack rate being in the 0–4-year age group (86 per 1000), and the risk of conjunctivitis decreased with age. Isolates were predominantly IA serovars, but the trigger for nonsexually transmitted gonococcal conjunctivitis epidemics remains obscure.[7]

FIGURE 65-1. Gonococcal conjunctivitis with profuse purulent exudate.

Gonococcal conjunctivitis is characterized by a rapid onset of a red sore eye with an extremely profuse purulent discharge. In most cases of eye involvement, infection is limited to a unilateral or bilateral purulent conjunctivitis (Fig. 65-1). Cases of corneal involvement (keratitis) with thinning of the cornea[8] or corneal necrosis requiring corneal grafting[9] have been reported. Preseptal cellulitis (Fig. 65-2) causing swollen eyelids has also been reported.[10] The incubation period of ocular infection is 3–19 days, and the urethral symptoms can precede the ocular symptoms by 1-3 weeks.[11] The diagnosis is made in someone with a relevant history and the characteristics of the ocular discharge and by taking samples of exudates and preferably conjunctival scrapings for Gram stain and laboratory culture.[2]

The outcome of gonococcal conjunctivitis is related to the severity of the disease at the start of adequate therapy.[12] To prevent serious ocular complications, the Centers for Disease Control and Prevention (CDC) recommend that all patients with gonococcal conjunctivitis are treated with parenterally administered antibiotics, for example ceftriaxone 1 g IM as a single dose.[13] Initial therapy should be based on local resistance patterns, and it is essential to obtain material for culture and antibiotic sensitivity testing. Treatment with spectinomycin (2 g IM for 3 days) or norfloxacin 1200 mg orally for 3 consecutive days has been reported to be effective. However, recent reports of increasing resistance suggest that quinolones should not be used empirically to treat gonococcal infection.[11,14,15] Topical antibiotics and saline lavage have been recommended as ancillary treatment but are not essential in treating adults or children with gonococcal conjunctivitis.[16] There is some evidence that doxycycline may help to attenuate the destructive activity of collagenases released during corneal infection,[17] but this is currently not recommended within clinical treatment guidelines.[13]

FIGURE 65-2. Preseptal cellulitis.

OPHTHALMIA NEONATORUM

Ophthalmia neonatorum is defined as conjunctivitis occurring in the first month of life. Many organisms can cause this including *N. gonorrhoeae, herpes simplex*, and *Chlamydia trachomatis* that may be acquired during passage through an infected birth canal.[18] Neonatal infection with *C. pneumoniae* and *N. meningitidis* have also been reported.[18,19] In the United States, *C. trachomatis* is the most common cause of neonatal conjunctivitis, although less common *N. gonorrhoeae* is the most significant pathogen, as it has the potential to cause severe ocular damage if not recognized and managed appropriately.[13] Microbiological analysis is vital to confirm the infecting organism, particularly as neonatal infection with multidrug-resistant *N. gonorrhoeae* has been reported.[20] However, treatment must be started immediately and should not be delayed whilst awaiting cultures.

The risk of gonococcal ophthalmia in infants born to infected mothers may be up to 30%, and gonococcal ophthalmia, if untreated, may progress rapidly to corneal ulceration, perforation, and eventually blindness. Topical therapy alone is insufficient and systemic treatment should always be administered. U.S. guidelines recommend a single dose of 25–50 mg/kg (up to a maximum of 125 mg) of ceftriaxone for gonococcal ophthalmia.[13] In a prospective study for treatment, 21 baby-mother pairs with culture-proven *N. gonorrhoeae* were treated with a single dose of ceftriaxone (62.5 mg for babies and 125 mg for mothers). *N. gonorrhoeae* was eradicated from all babies' eyes with no residual damage, as well as from the mothers' cervix.[21]

Recognition and treatment of gonorrheal infection during pregnancy may avoid infection of the baby during delivery, and various antibiotic regimes have been proposed. In a Cochrane review of two randomized trials involving 346 women, similar efficacy was found between amoxicillin plus probenecid compared with spectinomycin, amoxicillin plus probenecid compared with ceftriaxone, and ceftriaxone compared with cefixime, in achieving microbiological cure.[22]

Ophthalmia neonatorum can be prevented by antenatal screening and treatment for gonococcal infection, as described

above. However, screening is not routine in many antenatal settings, and screening will not prevent neonatal infection due to other organisms. Therefore, in areas of high-prevalence consideration should be given to disinfection of the infant's conjunctivae at birth by (1) use of 1% aqueous silver nitrate solution into each conjunctival sac or (2) instillation of benzyl penicillin solution into the infant's eyes or (3) use of tetracycline 1% or erythromycin 0.5% eye ointment. The safety and efficacy of povidone-iodine ophthalmic solution to prevent ophthalmia neonatorum have been evaluated in 3117 infants in Kenya. The infants received one of the ophthalmic preparations: a drop of 1% silver nitrate ophthalmic solution or a l-cm strip of 0.5% erythromycin ophthalmic ointment, or a drop of 2.5% povidone-iodine solution. Povidone-iodine was significantly more effective than silver nitrate and erythromycin in preventing infection,[23] and further studies have also shown this. No increased advantage was found by giving a second dose in the first postnatal day.[24]

CHLAMYDIA TRACHOMATIS INFECTION

Chlamydia trachomatis is one of the most common sexually transmitted diseases in the world and the most frequently reported sexually transmitted infection in the United States.[1] Up to 75% of women and 50% of men infected with *Chlamydia* are asymptomatic, so many are unaware that they have the disease. The commonest eye problem associated with chlamydial infection is inclusion conjunctivitis.[25] This can affect adults following contact with infected genital secretions or neonates who become infected during passage through an infected birth canal. Nonsexually transmitted *C. trachomatis* infection of ocular secretions is the leading cause of preventable blindness worldwide-trachoma. Eye-seeking flies carry the chlamydial infection from person to person, and it is also spread by hands, towels, and bedding.

C. trachomatis isolates can be differentiated into serovars, based on antigenic variation of their major outer membrane proteins.[26] Serovars A–C are etiologic agents of trachoma,[27,28] and serovars D–K cause the sexually transmitted genital infection. Serovars L1-3 cause lymphogranuloma venereum (LGV). Serovars A–K produce infections restricted to the mucosae, whereas the LGV serovars infect monocytes and disseminate to local draining lymph nodes.[28] A small number of genetic differences are responsible for the different behavior of the serovars.[29]

ADULT INCLUSION CONJUNCTIVITIS

This is caused by the serovars D–K, and transmission is by genito-ocular contact or autoinoculation. In contrast to all the other serovars that show tissue specificity, serovars B and Ba have been isolated from the eye and genital tract and have been found in trachoma and sexually transmitted infection-associated

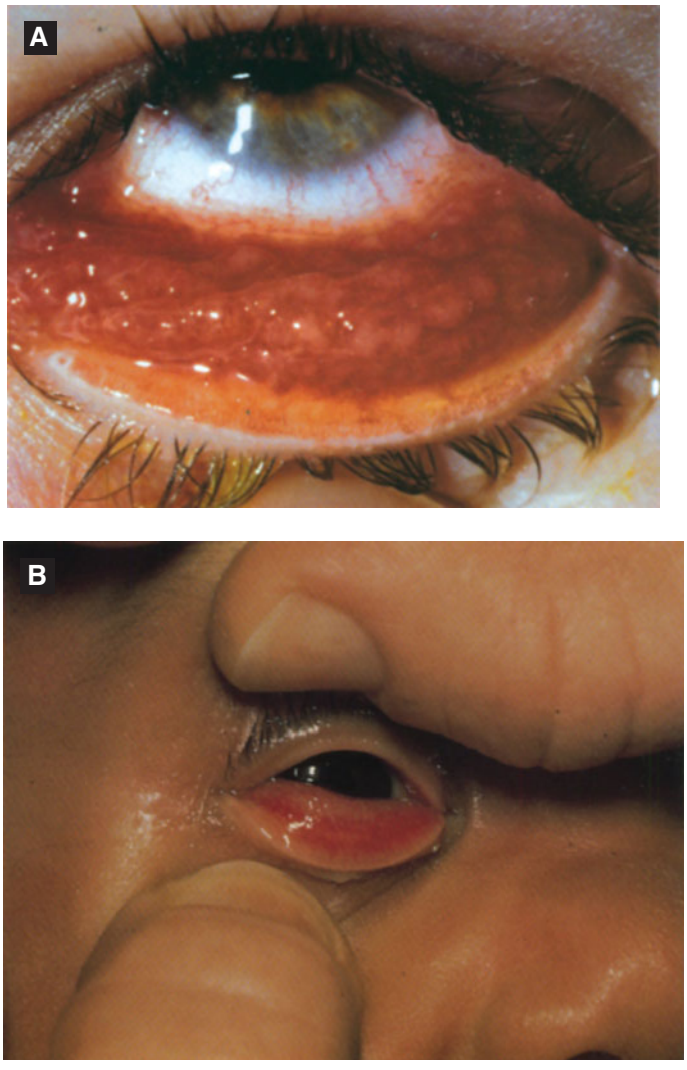

FIGURE 65-3. Inclusion conjunctivitis due to *C. trachomatis in,* **A,** an adult and, **B,** a neonate.

ocular disease. Inclusion conjunctivitis caused by the oculogenital serovars results in chronic conjunctival inflammation of mild-to-moderate severity, usually without the cornea being involved. Fifty percent to 90% of adults with ocular infection also have concurrent detectable genital tract infection.[30] Symptoms of conjunctival infection are noticed usually by 2 weeks after infection. These are nonspecific and include a unilateral red eye with a gritty foreign body sensation, which later develops a mucopurulent discharge. Both eyes may become involved, if left untreated.[25] The diagnosis is made on clinical signs of a follicular-type conjunctivitis (particularly in the inferior tarsal conjunctiva) (Fig. 65-3). Occasionally, an enlarged preauricular lymph node may be present. The clinical diagnosis may be confirmed by staining conjunctival smears with a direct immunofluorescent antichlamydia monoclonal antibody. The pathogen can also be cultured, identified by Giemsa staining, or detected by nucleic acid amplification techniques.[25] The disease is usually self-limiting, even if left untreated, but may persist for months or

years in the absence of antibiotic therapy.[25] Treatment is aimed at eradicating the infection from the eye and the genital tract, and topical and systemic antibiotics are required. Systemic therapy is required according to local guidelines, for example azithromycin 1 g as a single dose or doxycycline 100 mg BID for 7 days.[13] Erythromycin is a suitable alternative agent for pregnant women or children.[13] In addition to systemic therapy, erythromycin or tetracycline ointment may be added.[25] All sexual partners should be treated to prevent reinfection.

NEONATAL INCLUSION CONJUNCTIVITIS

Neonates develop conjunctivitis usually within 2 weeks of exposure.[31] Current U.S. guidelines recommend considering birth-related chlamydia in the differential diagnosis of all infants presenting with conjunctivitis within 30 days of birth.[13] Signs include discharge, conjunctival injection, and lid swelling. The eye appearance differs to that in adults, with diffuse papillary conjunctivitis being seen in contrast to the follicles seen in the adult (Fig. 65-3). This is because neonates do not have lymphoid cells in their conjunctiva at birth but acquire them later. One or both eyes can be affected, and, as in adults, the cornea is largely uninvolved. Untreated infection can persist for months and cause chronic or recurrent disease.[32] The infection needs to be rapidly distinguished from other causes of neonatal conjunctivitis such as gonococcal or herpetic infection, which require very different treatment strategies. If identified (using techniques as for adult ocular infection, see above) the organism should be treated locally and systemically, as the neonate may also have been infected in the respiratory or gastrointestinal tract. Treatment is with erythromycin antibiotic ointment for 1 week, in addition to erythromycin elixir for 2 weeks, or alternatively azithromycin is effective.[13,33]

REITER'S SYNDROME

Reiter's syndrome is classically defined as a triad of arthritis, urethritis, and conjunctivitis.[34,35] Although this triad can also follow gastrointestinal infection, many cases are triggered by infection with *C. trachomatis*.[36] Reiter's syndrome occurs in 1–3% of men following genital *C. trachomatis* infection,[37] and approximately 75–90% are positive for HLA B27.[36,38,39]

Reiter's syndrome is a clinical diagnosis, and the systemic manifestations usually appear within 1 month of infection. Although the original description was of conjunctivitis, these patients can actually have a variety of ocular problems. Conjunctivitis is the most common and is seen in around 60–90%.[40] It usually occurs within a few weeks of the onset of the arthritis and urethritis.[41] It is usually mild, symmetric, and bilateral with a mucopurulent discharge.[37] Cultures are negative, and it typically resolves within 10 days without treatment.

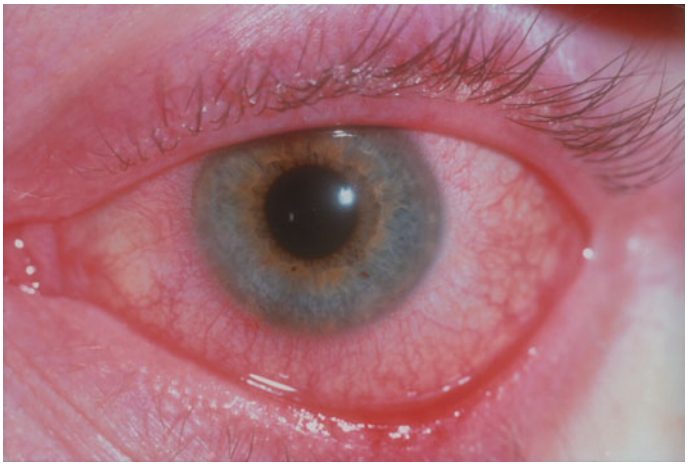

FIGURE 65-4. Anterior uveitis in Reiter's disease showing a diffusely red eye.

Up to 37% of patients with Reiter's syndrome develop anterior uveitis, even if they have had conjunctivitis previously.[37] Uveitis is usually of acute onset, with redness (especially around the limbus) (Fig. 65-4), pain, and photophobia; 68% of cases are unilateral with bilateral involvement in 32%.[42] Uveitis is more likely in those who are HLA B27+ and who have sacroilitiis.[41,43,44] A hypopyon (visible pus in the anterior chamber) may occur, showing how dramatic the inflammatory response within the eye can be.[45,46] Treatment is with topical corticosteroids to control the inflammation and mydriatics to control the ciliary spasm and to stop the iris sticking to the underlying lens during the inflammatory process due to the formation of posterior synechiae. Ocular inflammation may subside within 3 months, even if the patient is not treated but tends to recur after a variable length of time and may involve the other eye. Other reports include episcleritis, scleritis, keratitis, and posterior uveitis.[37,41,47,48] Those with sight-threatening sequelae may require treatment with periocular corticosteroid injections, oral corticosteroids, and immunosuppressive agents. The ocular prognosis is usually good if the inflammation is adequately controlled.[42] In all patients, the ocular inflammation is recurrent, with variable intervals between exacerbations, with some patients requiring treatment for many years.[42]

Reiter's syndrome may be an indicator of other sexually transmitted infections and has been reported as the presenting manifestation of patients with HIV/AIDS.[49] Reiter's syndrome has been reported in between 1.7% and 11.2% of patients with HIV, and there is some evidence that it may be more difficult to treat in this group.[49] Approximately 70–80% of white HIV-positive patients with Reiter's syndrome are HLA B27 positive.[50] In a recent report, Reiter's syndrome, due to *C. trachomatis*, developed shortly after the introduction of

anti-HIV therapy, suggesting a possible role for immune reconstitution in disease presentation.[51]

SYPHILIS

The eye can be involved in both congenital (see below) and acquired syphilis, and all structures of the eye may be involved. Recently, a resurgence of syphilis in some countries, including the United States and UK, has been followed by a rise in reported cases of ocular involvement.[52] Patients may present with an inflamed "red" eye or with visual loss in the context of known syphilis, but often the visual symptoms are the first manifestation of disease.[53,54] Eye symptoms or signs can also present after antibiotic therapy has been commenced as part of a Jarisch-Herxheimer reaction.[55] The eyelid or periorbital structures may rarely be the site of a chancre from primary infection after direct genital contact with infected genital secretions.[56]

Intraocular inflammation (uveitis) can occur at all stages of infection including primary infection[57] and may resolve spontaneously, but relapse is common. Several different types of uveitis may occur. Anterior uveitis is the most common and is nonspecific in type.[58] Patients with posterior uveitis may have vitritis, focal retinitis (Fig. 65-5), chorioretinitis,[53] periphlebitis, retinal hemorrhages, papillitis,[59] exudative retinal detachments,[60] neuroretinitis, and vascular occlusions.[61] Visual loss can occur from any of these, and patients may present with paracentral scotomas and blind spot enlargement. Pupillary enlargement may be apparent in optic nerve disease, and small miotic pupils (Argyll Robertson pupils) that react to accommodation but fail to react to direct light are seen in tertiary syphilis. Healing of the retinal lesions results in full thickness loss and a salt and pepper fundal appearance (Fig. 65-6). Orbital involvement can also occur from gumma in the posterior fossa invading the eye through the superior orbital fissure.[62] Intracranial involvement may result in papilledema and sixth nerve palsy.[63] Treatment with penicillin is usually very successful in eradicating the intraocular inflammation, but scarring may limit visual recovery. A Jarisch-Herxheimer reaction may occur in the eye with the initiation of treatment,[55] and corticosteroids are usually given to avoid further ocular damage, if this occurs. Topical steroids and mydriatics may be needed to control anterior uveitis. Most importantly, uveitis may persist or relapse after successful antimicrobial treatment of syphilis. Patients, therefore, require careful ophthalmological follow-up and may need further anti-inflammatory treatment.

FIGURE 65-5. Retinitis in syphilis.

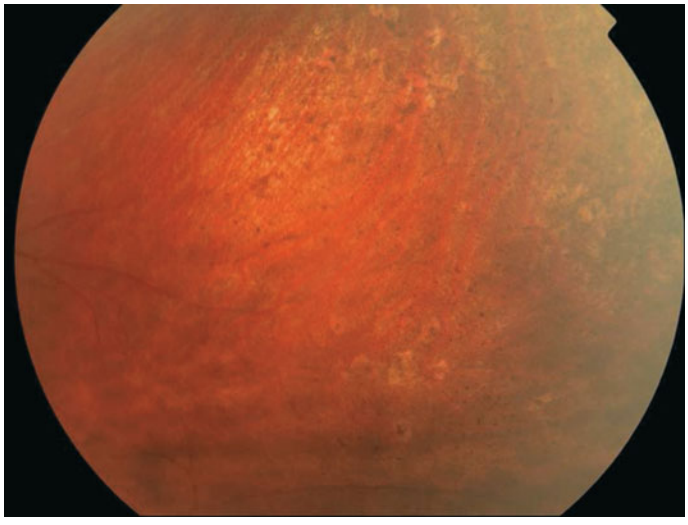

FIGURE 65-6. Salt and pepper appearance of the fundus occurring in healed syphilitic retinitis.

Concomitant infection with HIV[64] alters the appearance of the uveitis so that it is more severe with more common involvement of the retina and optic nerve than anterior uveitis,[65] as well as a dense vitritis being seen.[54] In addition, the syphilis serology may also be negative.[66] At this stage, it may be associated with tertiary syphilis, and treatment will require neurosyphilis drug strategies.[67]

CONGENITAL SYPHILIS AND THE EYE

This occurs when the mother contracts syphilis during pregnancy, and it passes across the placenta to the fetus.[68] The frequency of syphilitic involvement of the eye in early congenital syphilis is unknown. Occasionally, presentation is delayed until late childhood, with features of secondary or tertiary syphilis. Chorioretinitis, salt and pepper fundus, glaucoma, uveitis, keratitis, and chancres of the eyelid have all been described following congenital infection. Congenital glaucoma may also occur. Chorioretinitis rather than uveitis (as in the adult) is the more commonly diagnosed ocular problem in infancy, and the effect on vision depends on its location on the retina (Fig. 65-7). Interstitial keratitis is a common presentation in later life (Fig. 65-8) and can be

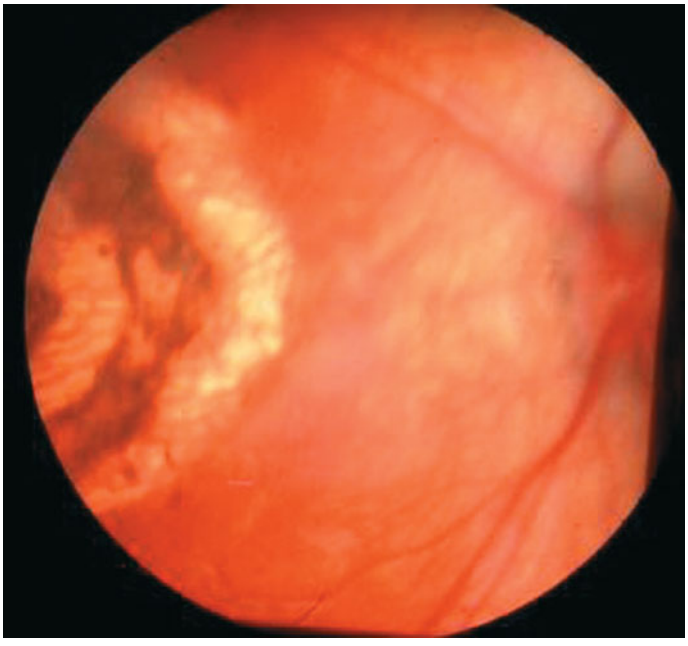

FIGURE 65-7. Chorioretinital scar in congenital syphilis.

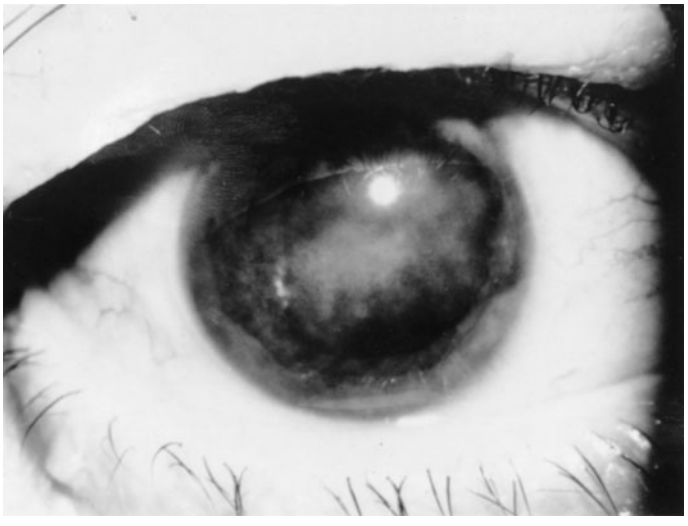

FIGURE 65-8. Interstitial keratitis in congenital syphilis.

prevented if the child is treated within the first 3 months of life. Interstitial keratitis presents with sore red eye(s), which are usually treated with topical steroids and cycloplegics. In one report, a child was successfully treated with oral cyclosporine 4 mg/kg/d, 6 days per week, and oral low-dose steroids suggesting involvement of the immune system.[69] Corneal grafting may be required to restore vision.[70]

HERPES SIMPLEX VIRUS

The commonest ocular infection with the herpes simplex virus (HSV) is keratitis. This is due to reactivation of latent infection and is not associated with a sexually transmitted infection. Both HSV type 1 and HSV type 2 can involve the eye. A rarer but potentially devastating type of ocular infection is acute retinal necrosis, which again is predominately reactivation of latent virus, either HSV 1 or HSV 2. Very occasionally, this occurs as a result of systemic dissemination.

Most people have been exposed to HSV, and their primary infection is subclinical. Even if clinically apparent, the lesions are self-limiting. In newborn infants, patients with eczema, or the immunocompromised patient, primary infection with HSV can become severe, disseminated, and life threatening.[71] Neonatal infection is usually acquired from maternal genital herpes, which may be asymptomatic or unrecognized in 60–80% women. The greatest risk of neonatal infection occurs when the mother has primary genital herpes involving the cervix at delivery and the infant is premature. The use of instrumentation including scalp electrodes further increases the risk. More than 80% of neonates infected in this way will have typical herpetic lesions of the skin, eye, or mouth, and most of the remainder will be very sick with encephalitis, pneumonitis, and sepsis.[72] The disease manifestations can occur days to weeks after delivery. The eyes first show conjunctival injection and swelling (chemosis), which is then accompanied/followed by an outbreak of vesicles on the eyelids (Fig. 65-9). A purulent discharge is variably present. Trifluridine 1% solution should be instilled 2 hourly until the infection has resolved and intravenous acyclovir 500 mg/m^2 (or 10mg/kg) given 8 hourly for 10 days.[73]

Much more rarely, HSV can be transmitted transplacentally, and disseminated infection of the fetus can occur. Many will die from this[74] or have congenital malformations. In the eye, this can include microphalmia, chorioretinitis, optic neuritis, and cataracts,[75] all of which can result in severe visual loss. Persistent fetal vasculature in the eye has also been reported.[76] Patients who had neonatal HSV infection, particularly associated with encephalitis, have been reported to develop acute retinal necrosis in adult life, presumably from reactivation of latent infection.[77,78]

Seventeen percent to 39% of patients with congenitally acquired HSV do not have skin lesions at presentation or during the course of the disease. This can make the diagnosis of HSV infection more difficult. A recent study has shown that no progress has been made in decreasing the interval between onset of symptoms and initiation of antiviral therapy since the early 1980s.[79] Of note in this study is that skin or conjunctival cultures were positive in 94% of patients, a much greater diagnostic yield than the culture of mouth/oropharyngeal swabs (48%) or 40% with CSF or brain biopsy. Treatment of the mother predelivery to prevent infection or recognition of vesicles present during labor so pre-emptive cesarean section can be undertaken and treatment with acyclovir started immediately are the best ways to prevent neonatal infection and its complications.

The International Herpes Management Forum (IHMF) has produced guidelines on the diagnosis, prevention, and effective management of neonatal herpes. They suggest that

FIGURE 65-9. Primary herpes simplex lesions on lids of neonate.

neonates with suspected HSV infection should be treated with intravenous acyclovir (20 mg/kg) every 8 hours for 21 days. If disease is localized to the skin, eyes, or mouth, treatment can be limited to 14 days.[80]

PUBIC LICE (*PHTHIRUS PUBIS*)

The head louse does not involve the eyelashes despite the close proximity to the hairline. The crab louse, however, can live in body hair including pubic, axillary, and chest hair or the eye lashes.[81] Eyelid involvement frequently causes symptoms of itching and burning, and the white eggs or egg cases are clearly visible to the naked eye (Fig. 65-10). The egg cases are made of chitin and are firmly attached to the eyelash. After a week, the eggs hatch into lice, which are transparent, firmly attached to the eyelash by thick claws, and not easily visible without magnification. Secondary infection, with associated preauricular lymphadenopathy, can occur at the sites of lice bites.[82]

There are several treatment options, none of which are ideal.[83,84] The eggs can be removed with forceps, but this is very time consuming. Alternatively, the lashes can be maximally trimmed to remove both eggs and lice, but they take some time to regrow and this is cosmetically unacceptable for many patients. The lice can be smothered with the application of a thick layer of ophthalmic ointment, but this does not kill the eggs. Ointment containing physostigmine is sometimes suggested, but, although effective in killing lice, the eggs are unaffected, necessitating repeat treatment for up to 14 days to kill lice emerging from the eggs.[85] One percent gamma-benzene hexachloride (Lindane) is effective if repeated 5–6 days later to catch newly hatched lice; however,

FIGURE 65-10. Lice eggs on eye lashes.

this solution may irritate the eyes.[82] More recently, a 4% pilocarpine solution (usually used to control intraocular pressure) has been used to scrub the eyelashes twice daily for 4 days and successfully eradicated both lice and eggs.[86] Pilocarpine is thought to induce cholinergic toxicity of the nervous system of the louse. If pilocarpine gets onto the ocular surface it can cause temporary miosis and reduced vision from induced myopia, so it is very important to give clear instructions on its use.

The finding of lice in the eyelashes is often indicative of a generalized infestation, and other affected areas of the body must also be treated, usually with 1% permethrin cream or 1% gamma-benzene hexachloride shampoo, together with all bedding, clothing, and contacts.

HIV INFECTION

The era of HIV/AIDS has dramatically altered the clinical presentation of many infections, and this is also true of those that may affect the eye. Eye complications are seen at all stages of HIV infection and may be the first clue to unsuspected underlying infection with HIV. Eye involvement is uncommon at the time of seroconversion, although there are a few reports of HIV retinopathy presenting during seroconversion.[87] The type of eye involvement in HIV/AIDS depends on the level of immune function, particularly related to the CD4 count,[88,89] and other systemic diseases/infections that may be present. Before the advent of effective antiretroviral therapy, blindness due to cytomegalovirus (CMV) retinitis was one of the most feared complications of AIDS. With effective anti-HIV treatment, CMV retinitis is much less common except in patients who present late in the course of the disease.[90,91] However, CMV and other retinal infections such as those due to toxoplasmosis, herpes simplex, and herpes zoster still occur, and a thorough knowledge of their presentation and treatment is important. The eye may also be involved in an immune reconstitution reaction following initiation of antiretroviral therapy, resulting in inflammation within the eye.

Visual symptoms should always be taken very seriously in patients with HIV/AIDS, due to the potential for visual loss. Prompt, expert ophthalmological assessment is essential in any patient with reduced visual acuity, visual field defects, or a painful red eye. The diagnosis of most intraocular infections is clinically based on the appearance of the lesions and clinical features of the patient. It is ideal, therefore, that an ophthalmologist who is experienced in HIV-related eye disease is asked to evaluate patients. Where there is doubt as to the correct diagnosis, then intraocular fluid (especially vitreous) specimens can be obtained for PCR and culture. It is useful to consider the eye complications seen at different levels of immune function and then to consider specific pathogens.

Patients with a high CD4 lymphocyte count greater than 500 cells/μL have a minimal or no risk of opportunistic infections, and many patients are asymptomatic. However, a number of inflammatory eye problems may be seen, possibly due to dysregulation of the immune system. The clinical spectrum includes allergic conjunctivitis, Sjogren's syndrome, Reiter's syndrome, uveitis, retinal vasculitis, HIV microvasculopathy, and optic neuropathy. HIV microvasculopathy rarely causes visual symptoms and causes hemorrhages, microaneurysms, and cotton wool spots, which come and go, occurring predominately around the optic disc and macula (Fig. 65-11).

As the CD4 count falls (200–500 cells/μL) and susceptibility to infection increases, the eye may start to be involved. Many infections seen at this stage are also seen in non-HIV-infected patients, but, in the context of moderate immunodeficiency, they tend to be more prevalent and persistent. Thus, eye problems should be considered part of the "symptomatic HIV" complex and, along with other clinical findings, might alert an astute clinician to the possibility of underlying immunodeficiency. Bacterial infections include conjunctivitis and blepharitis (infection of the eyelids). Syphilis may present with uveitis or necrotizing retinitis (see above). Molluscum contagiosum are common and can occur on the eyelids. Molluscum, however, are rarely severe unless the CD4 count falls to less than 100 cells/μL.

As the CD4 count falls below 200 cells/μL, the patient becomes susceptible to a wide range of infections, including opportunistic infections, and also to malignant disease. The risk of ocular infection is particularly high as the CD4 count falls below 75 cells/mL. Ocular manifestations include retinitis (CMV, toxoplasmosis, HSV, and varicella zoster virus [VZV]), choroiditis (candida, pneumocystis, cryptococcosis, and TB), and tumors (Kaposi's sarcoma, lymphoma, and squamous cell carcinoma [SCC] of the conjunctiva).

CMV RETINITIS

Before antiretroviral therapy, up to 40% of patients with AIDS would develop invasive CMV infection, with retinitis accounting for 75–85% of CMV disease in these patients. The risk of CMV retinitis is particularly high, 20–40% with a CD4 cell count <50 cells/μL.[92] Anti-CMV drug therapy is not virocidal, and, therefore, in the absence of immune restoration, progression of CMV retinal destruction is inevitable, despite continuous treatment.[93,94] The advent of effective antiretroviral therapy has seen a significant fall in both new cases of CMV retinitis and disease relapse.[91,95,96]

CMV infection results in full-thickness retinal necrosis, which appears clinically as a white necrotic lesion with accompanied hemorrhages (Fig. 65-12). Although the diagnosis is usually established on clinical grounds, CMV can be confirmed by PCR of a vitreal aspirate, and where possible this is usually undertaken. In immunocompromised patients not on antiretroviral therapy, there is little or no intraocular inflammation, and the diagnosis is easy to make on the appearance. In contrast, patients on antiretroviral therapy in

FIGURE 65-11. Cotton wool spots in HIV infection.

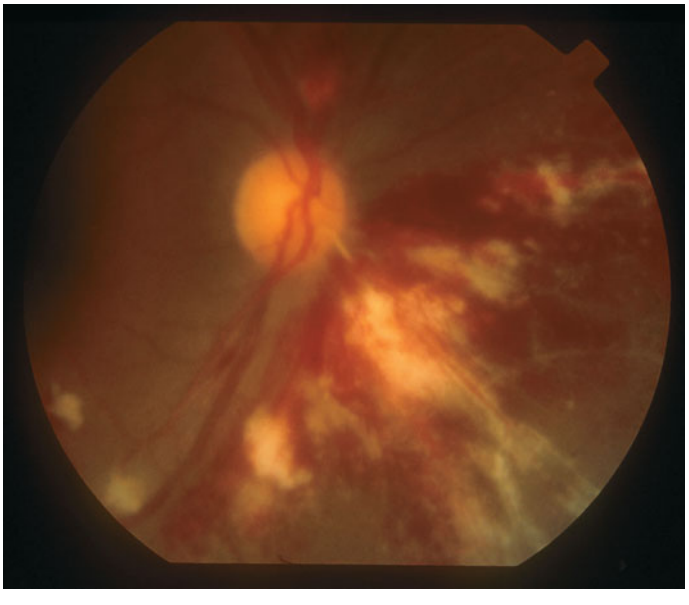

FIGURE 65-12. CMV retinitis.

whom immune reconstitution is occurring may exhibit a marked inflammatory response, which can induce vitritis and macular edema, resulting in further visual loss[97] and an atypical appearance that may be more typical of infection with HZV or HSV.

The best long-term management is the use of antiretroviral therapy to increase the CD4 cell count and thereby provide immunological control of CMV replication. However, with patients presenting with CMV retinitis and very low CD4 cell counts, this will take several months to achieve, and specific anti-CMV therapy is required to preserve vision. The therapeutic decision is based on the site of the retinal lesion (lesions close to the macula or optic nerve present a high risk of permanent visual loss), evidence of systemic infection, and whether the disease is unilateral or bilateral.[98] Ocular disease is better managed with intraocular treatment either with an intravitreal ganciclovir or foscarnet or with a ganciclovir implant that can release drug into the eye for up to 6–8 months (Fig. 65-13). Intraocular therapy is advised for all patients with immediately sight-threatening disease. Patients with isolated peripheral lesions may be managed with systemic therapy alone and the eye monitored regularly. Systemic anti-CMV therapy is indicated for the majority of patients, to protect the uninfected eye and to treat/prevent disease elsewhere. For small peripheral lesions, some authorities would initiate antiretroviral therapy alone and monitor progress carefully. The risk of second eye involvement in patients with unilateral CMV retinitis is substantial in the months after initiation of antiretroviral therapy, and close monitoring is vital.[99] Even in the era of antiretroviral therapy, CMV disease as manifested by CMV retinitis and a detectable CMV viral load are associated with an increased risk of mortality, even after adjusting for demographic, treatment, immunologic, and HIV virologic factors.[100]

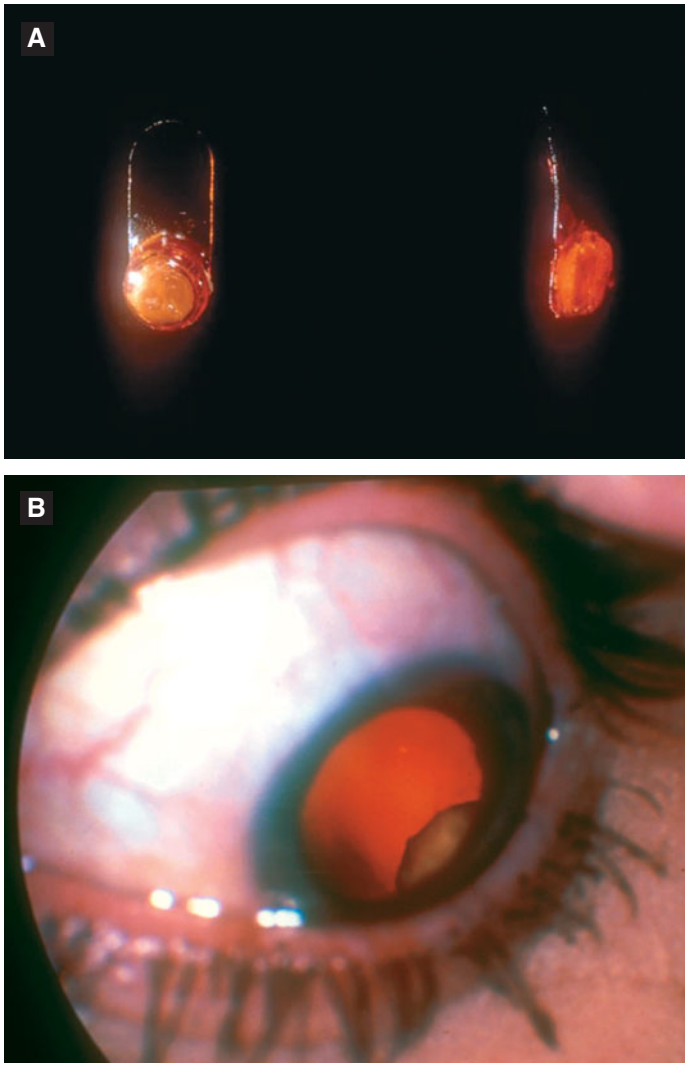

FIGURE 65-13. Ganciclovir implant, **A.,** device and, **B.,** in situ in eye.

Anti-CMV therapy is summarized in Table 65-1. Induction anti-CMV therapy may be with intravenous ganciclovir, intravenous foscarnet, or oral valganciclovir. Oral ganciclovir is inferior to valganciclovir for induction and should not be used. Maintenance therapy is best given with oral valganciclovir, although there are a number of alternative regimens (Table 65-1). Cidofovir is effective in CMV retinitis and may be considered where there are contraindications to other agents. Cidofovir may cause a uveitis, particularly in patients on antiretroviral therapy, and is less commonly used now.[101-103] Formiversen, a novel antisense drug, is approved for use in patients with CMV retinitis, is given as an intravitreal injection, and can be useful if drug resistance is a problem.[104] Discontinuation of all anti-CMV therapy is usually possible when the CD4 count rises to >150 cells/μL and is maintained for more than 3 months.[98,105] CMV resistance may develop to all of the agents in current use due to specific mutations.[106,107] Ganciclovir-resistant CMV (mutation in the UL97 or genes) is often cross resistant to cidofovir but generally remains susceptible to foscarnet. Routine monitoring of peripheral blood CMV viral load is of poor sensitivity in predicting CMV disease progression; however, a negative blood CMV viral load whilst on therapy has a high negative predictive value for CMV drug resistance.[108]

The best timing for initiation of antiretroviral therapy in patients with CMV retinitis has not been determined. These patients all have low CD4 counts, and therefore, it is important to start therapy quite quickly. However, immune reconstitution vitritis in which there is a vigorous intraocular inflammatory response, can be very difficult to treat, as a good response to steroids may not occur.[109,110] Thus, many clinicians will defer antiretroviral therapy for a short time (generally 2–4 weeks) to allow anti-CMV therapy to bring the retinitis under control first. For this reason, it is wise to evaluate high-risk patients (CD4 < 75 cells/μL) for ocular CMV prior to initiating HAART. Retinal detachment remains a problem in any eye infected with CMV, and the risk increases with increasing area of retinal destruction.[111] Damage to the

Table 65-1. Drugs Available for the Treatment of CMV Retinitis

Drug	Mechanism	Induction[a]	Maintenance[a]	Intravitreal Dose	Adverse Effects
Ganciclovir—IV, oral and intravitreal use	Deoxyguanosine nucleoside analog inhibits CMV DNA polymerase	5 mg/kg q12h IV for 2–3 wk	5 mg/kg qd IV 1 g TID PO	2 mg weekly until disease controlled Ganciclovir implant lasts for up to 6 months	Anemia, leucopenia, and pancytopenia
Valganciclovir—oral only	Deoxyguanosine nucleoside analog inhibits CMV DNA polymerase	900 mg q12h PO for 2–3 wk	900mg qd	n/a	Anemia, leucopenia, and pancytopenia
Foscarnet—intravenous and intravitreal only	Pyrophosphate analog inhibits CMV DNA polymerase	90 mg/kg q12h IV for 2–3 wk–hydrate well	90 mg/kg/qd hydrate well	2.4 mg weekly until disease controlled	Renal toxicity in 20–60%, hypocalcemia, hypokalemia, convulsions, and genital ulceration
Cidofovir—intravenous only	Cytosine nucleotide analog inhibits CMV DNA polymerase	5 mg/kg IV weekly for 2–3 wk–(hydrate well + probenecid)	5 mg/kg IV every 2 weeks–(hydrate well + probenecid)	n/a	Renal toxicity, fanconi syndrome, ocular hypotony, and uveitis
Fomiversen—intravitreal only	Antisense oligonucleotide inhibits CMV mRNA	Intravitreal injection every 2 wk	Intravitreal injection injection every 4 weeks	165/330 µg	Increased intraocular pressure and blurred vision in 5%

[a]Ganciclovir, valganciclovir, and foscarnet require dose modification in patients with renal impairment.

retina may result in detachment long after the CMV retinitis has been controlled, and sudden loss of vision in a patient with previous CMV retinitis should always prompt an urgent review to exclude retinal detachment.

HERPES SIMPLEX VIRUS

Patients with and without HIV may suffer from recurrent HSV infection of the cornea (HSV keratitis). HSV keratitis may be difficult to treat in patients with HIV;recurrences are common and vision may be lost if the central part of the cornea is involved (Fig. 65-14). The diagnosis is usually established by examination with fluoroscein instilled into the eye, demonstrating the typical appearance of a dendritic ulcer. Rarely is culture undertaken but may be useful in atypical cases. Management consists of topical antiviral agents and prompt treatment of recurrences. The most serious complication of HSV in the eye is acute retinal necrosis. Acute retinal necrosis (necrotizing retinitis) can lead to rapid visual loss and may be caused by VZV or HSV (Fig. 65-15). Acute retinal necrosis generally occurs in patients with higher CD4 cell counts and can also occur in the immunocompetent host. The diagnosis is established on clinical grounds and confirmed by PCR of a vitreal aspirate. Therapy is with high-dose acyclovir given intravenously until control has been achieved, when treatment can be changed to oral acyclovir. The optimum duration of therapy has not been defined, and long-term maintenance treatment is sometimes required. Necrotizing retinitis can lead to retinal detachment and loss of vision.

VARICELLA ZOSTER VIRUS

VZV can affect the eye in a number of ways in patients with HIV. VZV involving the first division of the trigeminal nerve (herpes zoster ophthalmicus) can cause severe lid infection and necrosis and/or intraocular inflammation with marked vitritis obscuring the retina. VZV may cause acute retinal necrosis as

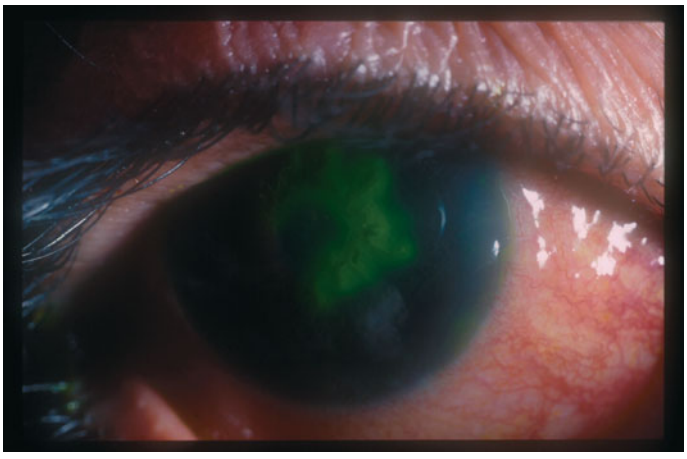

FIGURE 65-14. Herpes simplex keratitis in HIV infection.

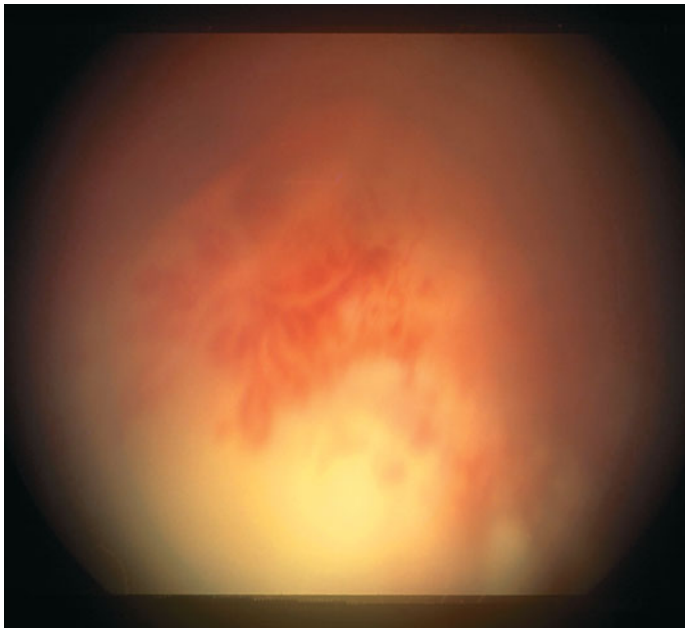

FIGURE 65-15. Acute retinal necrosis.

above. In addition, cerebral vasculitis can occur and cranial nerve palsies such as VI (Fig. 65-16) and III may result.

In patients with very low CD4 counts, VZV can cause a fulminant outer retinal necrosis (previously known as progressive outer retinal necrosis or PORN but now called VZV retinitis) without vitritis in contrast to acute retinal necrosis, which is usually associated with marked intraocular inflammation. The retinitis starts as discrete lesions (Fig. 65-17), which rapidly coalesce and involve the central part of the retina. The disease is usually bilateral, with early involvement of the second eye when uninvolved at presentation. Severe visual loss and retinal detachment occur within weeks.[112,113] VZV retinitis may, on occasion, be preceded by aseptic meningitis or retrobulbar optic neuritis.[114] Patient may have a recent history of shingles, but frequently there is no sign of VZV elsewhere. Recommended systemic therapy is the

FIGURE 65-16. Left herpes zoster ophthalmicus with sixth nerve palsy.

FIGURE 65-17. Progressive outer retinal necrosis.

combination of high-dose intravenous acyclovir and foscarnet.[98] Intravitreal therapy is also frequently used and provides an opportunity to take samples for PCR. Treatment of retinal detachment requires intraocular surgery with vitrectomy and silicone oil tamponade, but the prognosis for vision is poor.

TOXOPLASMOSIS

Infection with *Toxoplasma gondii* is common worldwide, with a prevalence varying from 15% to 80%, depending on the population studied. Infection may be primary (positive IgM), reactivation of previous ocular infection (based on the finding of old chorioretinal scars), or metastatic from another part of the body.[115] Toxoplasma retinitis in AIDS patients is most commonly due to reactivation of latent infection and may occur at any CD4 count, although it is uncommon at CD4

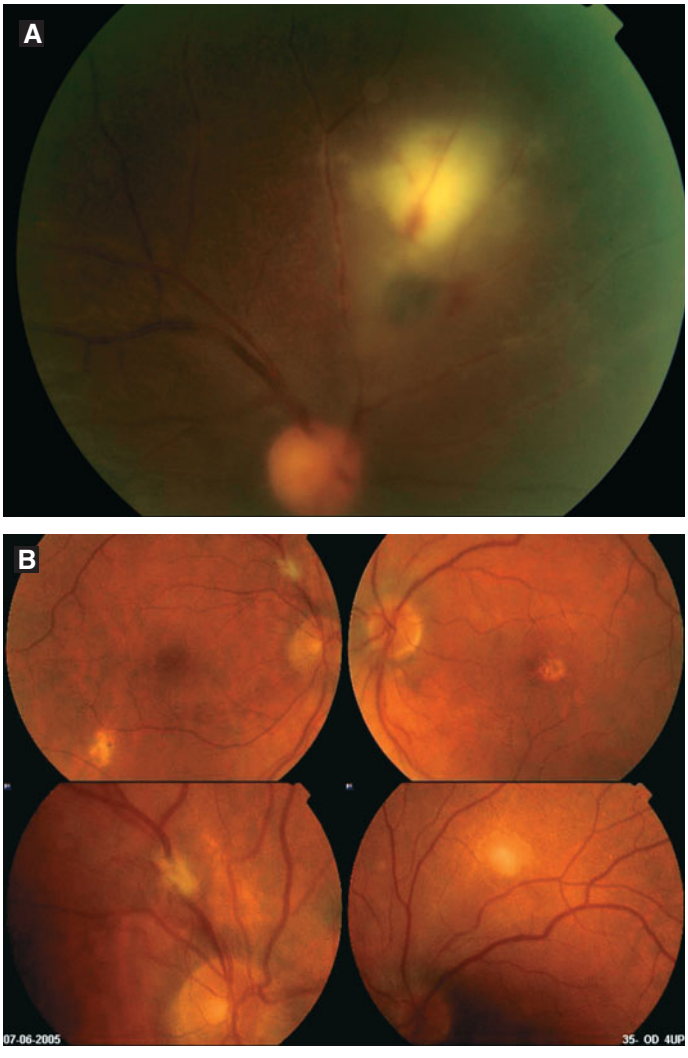

FIGURE 65-18. Toxoplasmic chorioretinitis: **A**. Singe focus. **B**. Multiple active foci.

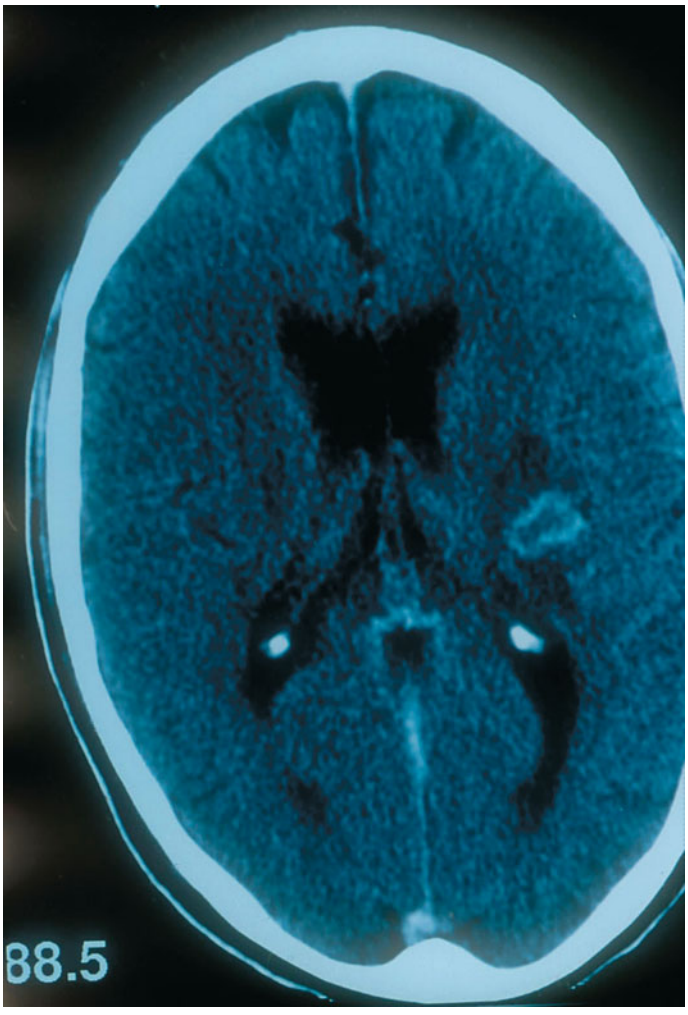

FIGURE 65-19. CT scan showing toxoplasma lesion in brain.

counts of above 150 CD4 cells/μL. All HIV-positive patients with a CD4 count of less than 200 cells/μL should be given prophylactic antibiotics to prevent pneumocystis carinii infection. Sulphonamide antibiotics such as trimethoprim-sulphamethoxazole (septrin and bactrim) used for this purpose also afford protection against toxoplasmosis.

The clinical appearance varies and may be a focal necrotizing retinitis or diffuse or multifocal lesions (Fig. 65-18). Inflammation with anterior uveitis and vitritis is usually present but is quite variable.[116] Concomitant CNS toxoplasmosis is frequently present, and CT or MRI (more sensitive than CT) brain imaging should be performed (Fig. 65-19). Patients with cerebral lesions and raised intracranial pressure may have papilledema and/or cranial nerve palsies. Treatment of ocular toxoplasmosis follows the same regimen as that of CNS disease, as the drugs have good ocular penetration. Sulphadiazine plus pyrimethamine or clindamycin plus pyrimethamine are the preferred treatment.[98] Oral corticosteroids are not indicated for ocular toxoplasmosis complicating HIV. Treatment duration will depend on the clinical response to therapy, with full-dose treatment generally being required for 4–6 weeks. All patients with ocular toxoplasmosis must receive secondary antimicrobial prophylaxis until the CD4 cell count is sustained for at least 6 months over 200 cells/μL.[98]

PROGRESSIVE MULTIFIOCAL LEUKOENCEPHALOPATHY

Progressive multifocal leukoencephalopathy (PML) is a demyelinating disease caused by the human neurotropic JC virus[117] (Fig. 65-20). PML is characterized by progressive lysis of oligodendrocytes with demyelination. A rapid clinical course ensues with focal neurological deficits and a median time to death of 3.5 months without treatment. Prior to highly active antiretroviral therapy, there was no effective therapy. Since the advent of antiretroviral therapy, the prognosis for PML has much improved;however, a significant number of patients appear unresponsive to antiretrovirals, and some worsen because of the development of immune reconstitution disease.[118] Eye involvement may occur in terms of eye movement disorders and visual field

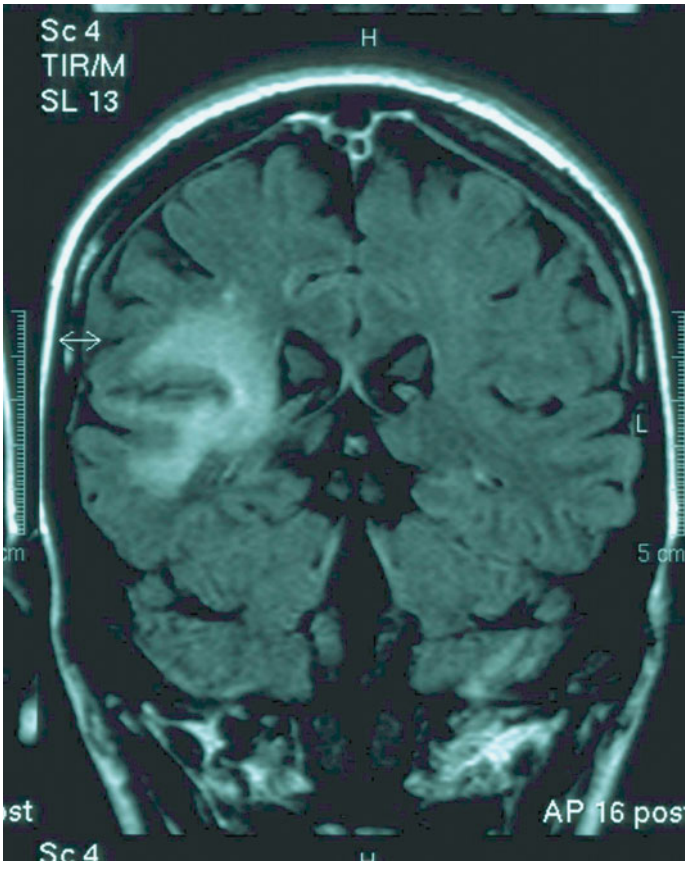

FIGURE 65-20. MRI brain scan showing lesions of PML which resulted in a homonymous hemianopia.

defects. JCV DNA has been detected in ocular tissue of AIDS patients at a significantly higher level than in eyes of nonimmunosuppressed patients, but the clinical significance of this is unknown.[119]

SYPHILITIC RETINITIS

Syphilis and AIDS are epidemiologically associated.[64] Syphilis is described in detail earlier in this chapter. Ocular involvement by syphilis in AIDS patients is more aggressive and includes necrotizing retinitis with vitritis, retinal vasculitis, serous retinal detachment, and neuroretinitis. The diagnosis is based on clinical presentation with positive serology. Treatment includes high-dose intravenous penicillin for 10–14 days.

INFECTIVE CHOROIDITIS

This is seen in patients with systemic infections and therefore indicates miliary spread. It can be seen in TB, fungal infection such as candidemia, bacterial sepsis, and *Pneumocystis jirovecii*.[120] Candidemia is rare in patients with HIV/AIDS unless there are additional factors such as neutropenia, intensive care treatment, or intravenous drug abuse.[121] The widespread use of prophylaxis for *P. jirovecii* and the introduction of antiretroviral therapy have contributed to the dramatic fall in the incidence of *P. jirovecii* choroiditis. Choroidal lesions are usually found on routine

FIGURE 65-21. Pneumocystis choroiditis.

examination: one to several yellow-white lesions (Fig. 65-21), located mostly in the posterior pole and up to the equator. Visual function is not compromised, even if the lesion is under the fovea.

TUBERCULOSIS

In many countries, TB has become one of the commonest presenting opportunistic infections in patients with HIV.[122] Tuberculosis can cause uveitis as well as choroidal granulomas, which may be single or multiple or may involve the optic nerve (Fig. 65-22).[123] The eye signs of tuberculosis are frequently overlooked and can provide an important clue to the diagnosis in the febrile patient. For example, in a recent report, 4/17 patients with HIV and TB were found to have ocular involvement (one uveitis and three retinal granulomas).[122] In acute disseminated TB, 60% were found to have ocular involvement (83% chroroidal tubercles and 16% retinal vasculitis), and detection of these lesions allowed a lead time of 12–72 hours, in which earlier appropriate therapy was started.[124] TB involving the eye should be treated with standard antituberculous therapy, as recommended for patients with HIV.[98]

CRYPTOCOCCUS

Ocular involvement in cryptococcal meningitis, which is a life-threatening infection in AIDS patients, is mainly related to papilledema or optic neuropathy. Occasionally, there are multifocal choroidal lesions (Fig. 65-23) similar to *Pneumocystis jirovecii*, without anterior chamber or vitreal inflammation. The choroidal lesions respond to treatment, with optic nerve disease being the limiting factor for visual outcome.[125]

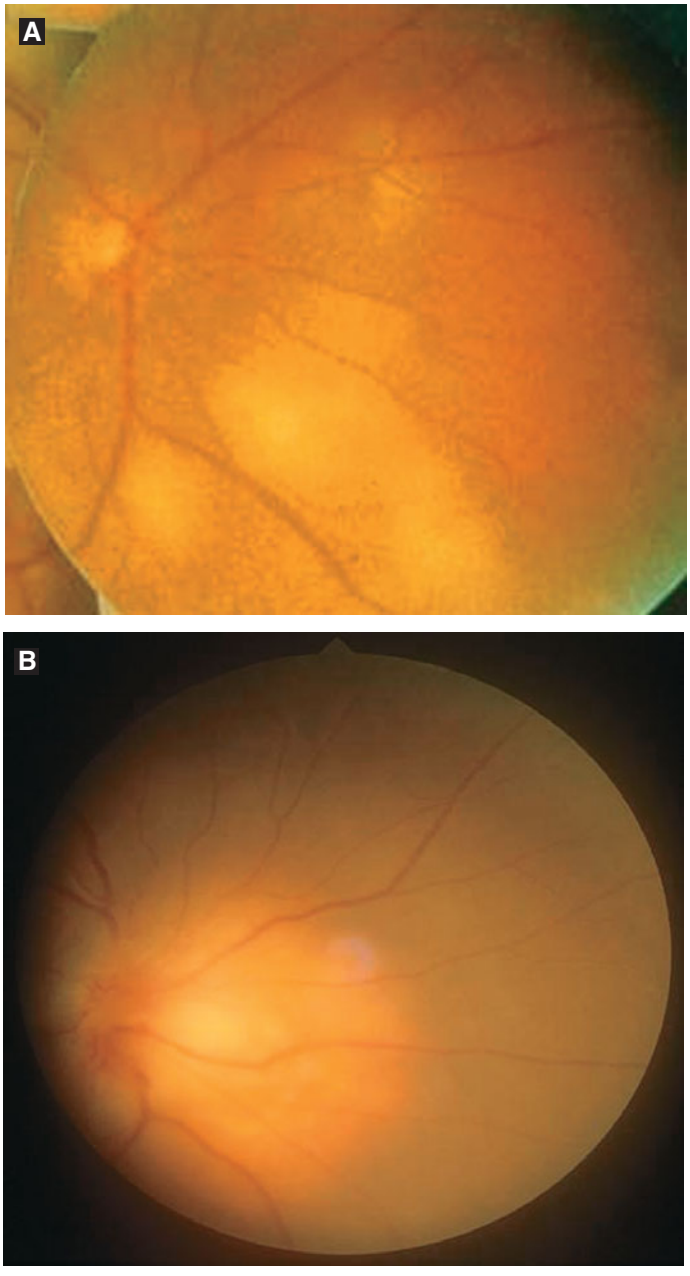

FIGURE 65-22. Tuberculosis, **A.,** in choroid and, **B.,** involving optic nerve.

FIGURE 65-23. Cryptococcal choroidal lesions.

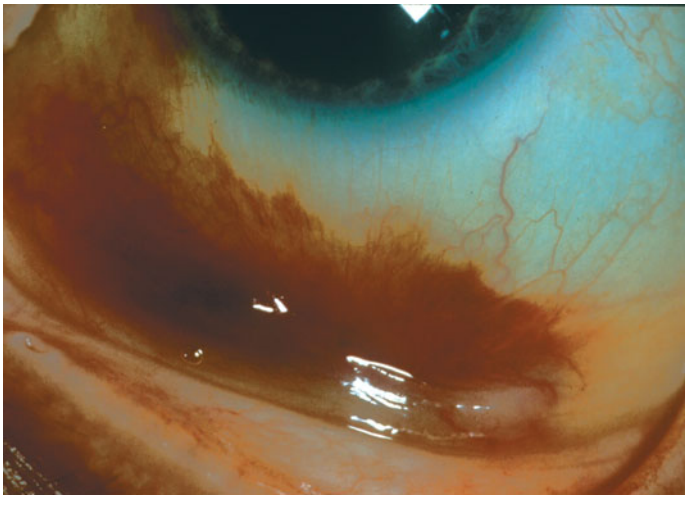

FIGURE 65-24. Kaposi's sarcoma.

MALIGNANCY ASSOCIATED WITH HIV

KAPOSI'S SARCOMA

Although this used to be fairly common in AIDS patients, its incidence has declined, as shown by Rutherford et al.[126] It has been strongly associated with human herpes virus type 8. The clinical appearance is of multicentric vascular red-purple nodules, which typically involve the skin. The ocular involvement includes the eyelids, the conjunctiva (Fig. 65-24),[127] and rarely the lacrimal sac and the orbit. Spontaneous regression has been documented following antiretroviral therapy, so deferral of treatment for a few months after commencement of treatment is possible. Other treatment options include local excision, cryotherapy and focal irradiation, and intralesional injection.[128]

LYMPHOMA

AIDS patients are at increased risk of developing non-Hodgkin's lymphoma as their life span increases and are particularly at risk when their CD4 count has fallen below 50 cells/μl at any stage. The lymphoma is mostly of a high-grade B-cell type and is associated with EBV infection. Historically, increased risk was observed in patients treated

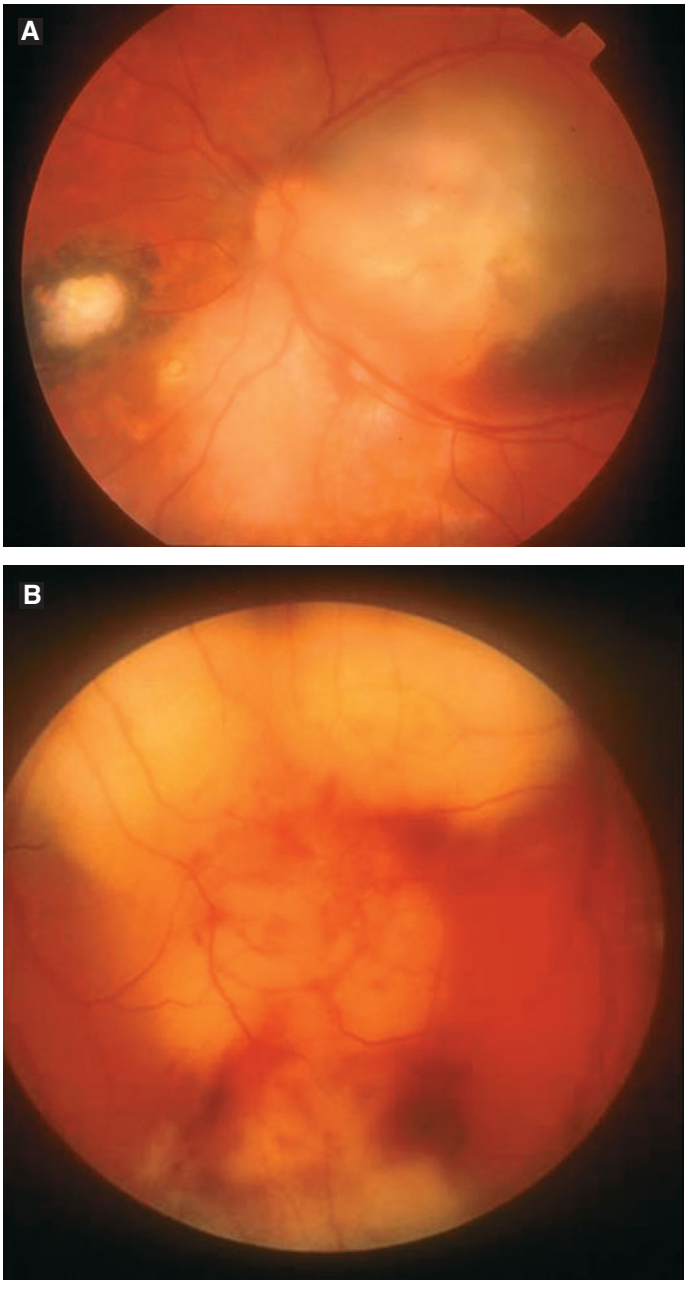

FIGURE 65-25. Lymphoma, **A,** intraocular with retinal involvement–note old inactive toxoplasma scar and, **B,** systemic with choroidal involvement.

with zidovudine (AZT), but this association has not been reported where zidovudine forms part of an antiretroviral regimen. The most common presentation in the eye is from a primary CNS lymphoma with ocular involvement, and less frequently from spread to the eye by systemic lymphoma. Intraocular involvement of CNS lymphoma involves the vitreous and retina and may resemble viral retinitis, in contrast to systemic lymphoma, which more commonly spreads to the choroid (Fig. 65-25) or presents as an orbital mass.[129,130] Treatment of lymphoma includes chemotherapy, with intrathecal methotrexate for CNS involvement,[131] and fractionated radiotherapy. Intravitreal methotrexate may be used for intraocular disease when recurrence occurs after radiotherapy, but in general the prognosis is poor.

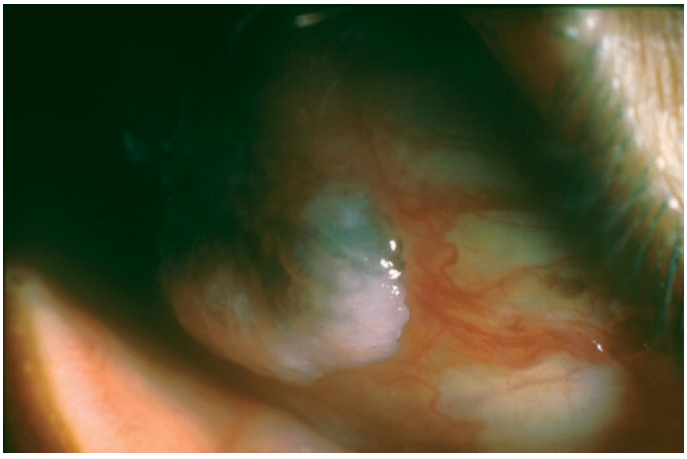

FIGURE 65-26. Squamous carcinoma of the conjunctiva.

SCC OF THE CONJUNCTIVA

SCC of the conjunctiva is associated with sun exposure and can occur in HIV-positive individuals (Fig. 65-26). It is rarely seen in Caucasians but is much more common in Africans. HIV and genus beta HPV types have been associated with SCC. A recent study did not confirm a specific association with SCC and HPV but suggested that infection with genera beta or gamma HPV types in conjunctiva is common, but not greatly enhanced by the presence of HIV.[132] Metastatic SCC may occur and, as conjunctival SCC may be difficult to distinguish on clinical appearance alone, patients with a history of high ultraviolet-B radiation exposure should be given a low threshold for excision biopsy of suspicious lesions particularly.[133] Analysis of TP53 mutations confirmed at the molecular level the causal role of solar UV rays in the etiology of SCC of the conjunctiva and suggested that infection with epidermodysplasia verruciformis types of human papillomavirus may act as a cofactor to increase the sensitivity of conjunctiva cells to UV-induced mutagenesis.[134]

DRUG-INDUCED EYE PROBLEMS

Patients with mycobacterium avium intracellulare infection may receive the drug rifabutin. Clarithromycin and fluconazole block the hepatic metabolism of rifabutin, and high levels of rifabutin may accumulate in the eye, resulting in a sudden profound loss of vision. The eye looks as if it is infected with bacteria with an intense inflammatory response that may include a hypopyon. This quickly quietens with topical steroids, rifabutin dose reduction, or discontinuation of the additional agents.[135]

CONCLUSION

Sexually transmitted infections can involve the eyes in a variety of ways. A high index of suspicion and prompt investigation of visual symptoms are necessary to allow prompt diagnosis and treatment so as to avoid potentially sight-threatening complications. This is particularly true for patients with HIV/AIDS with very low CD4 lymphocyte counts who are at risk of severe ocular complications.

66 Treatment of Chronic Viral Hepatitis

Mark W. Russo and Ian Grimm

INTRODUCTION

Prior to the development of interferon therapy in the mid-1980s, no drug had shown efficacy in treating chronic viral hepatitis. Unmodified alpha interferons showed modest efficacy against hepatitis C. The addition of ribavirin and the development of pegylated interferons (peginterferon) were major breakthroughs in the treatment of hepatitis C. The addition of ribavirin to interferon increases response rates to therapy and pegylated interferons are not only associated with higher response rates; they are also more conveniently dosed at once weekly. Unfortunately, not all affected patients are candidates for therapy, and although there have been advances in therapy many patients fail to respond to treatment. More effective approaches to treatment of chronic hepatitis C with fewer side effects are clearly needed. Advances have also been made in the treatment of chronic hepatitis B with the development of peginterferon-α, oral nucleoside, and nucleotide analogs.

The short term goals of therapy for chronic viral hepatitis are to terminate viral replication and to prevent the progression of chronic hepatic inflammation to fibrosis. Approval of interferon-α therapy was based primarily on the drug's effect on intermediate markers of disease progression, such as serum aminotransferase levels and hepatic histology. In the current era, successful therapy for hepatitis C is defined as a sustained viral response (SVR) that is undetectable serum levels of virus 6 months after completing therapy. Data regarding long-term outcome measures such as morbidity and mortality from liver disease are emerging or under study. Results of antiviral therapy on hepatocellular carcinoma have been reported, and studies on the effect of antiviral therapy on the development of cirrhosis, liver failure, or death are underway.[1]

This chapter summarizes current approaches to therapy in chronic viral hepatitis, focusing on peginterferon, oral nucleoside and nucleotide analogs for chronic hepatitis B, and peginterferon plus ribavirin for chronic hepatitis C. Because this is a rapidly evolving area, treatment recommendations are likely to change.

APPROACH TO THERAPY OF CHRONIC HEPATITIS

Chronic hepatitis is a syndrome defined by persistent necroinflammatory liver disease with viremia, typically lasting more than 6 months. In addition to the major viral causes, hepatitis B virus (HBV) and hepatitis C virus (HCV), a diverse group of nonviral causes of chronic hepatitis must be considered in the differential diagnosis, including alcohol abuse, nonalcoholic fatty liver disease, and drugs. It is possible that additional, yet unidentified, viral causes of chronic hepatitis exist. If so, these would account for only a small proportion of cases.

The histologic classification of chronic hepatitis has been revised to reflect advances in the understanding of the etiology and prognosis of chronic liver disease. Natural-history studies of HCV-infected patients have demonstrated that even a mild necroinflammatory lesion can eventually progress to cirrhosis.[2,3] For this reason, older terms such as "chronic persistent" and "chronic active" hepatitis, which have prognostic implications, have been replaced with specific scales for grading necroinflammatory activity and for staging the degree of fibrosis present.[4]

The 6-month definition of chronicity, while arbitrary, allows a reasonable time for spontaneous resolution of a self-limited process. Spontaneous resolution of hepatitis B or C after 6 months of infection is rare. In practice, 20–30% of patients who test positive for the hepatitis C antibody do not have chronic hepatitis C.[2,3] A positive anti-HCV may be a false positive result or indicate prior infection in a patient who has spontaneously cleared the virus. The chance of having chronic hepatitis C with a positive hepatitis C antibody is higher if a risk factor(s) for hepatitis C is identified, such as a history of intravenous drug use or blood transfusion. False positive anti-HCV is more common in patients without risk factors where there is a low prevalence of disease. Radioimmunoblot assays (RIBA) were commonly used before the availability of polymerase chain reaction (PCR) for hepatitis C RNA. RIBA is rarely used now that PCR is available. RIBA may be useful in distinguishing false positive from true positive ELISA tests in

patients who test antibody-positive with ELISA and have undetectable serum HCV RNA by PCR.

Acute hepatitis C is very rarely encountered because it is usually asymptomatic, and blood products are screened for antibodies to HCV. In contrast, patients with acute hepatitis B may seek medical attention because they are more likely to develop symptoms, such as malaise, nausea, or jaundice. Symptomatic exacerbations in patients with hepatitis B can be a harbinger of spontaneous seroconversion and subsequent termination of the replicative state. Therefore, a 6-month period of observation may be considered before recommending therapy for patients with well-compensated chronic hepatitis B. Exacerbations of chronic hepatitis B can usually be distinguished from acute hepatitis B by the absence of IgM anti-HBc in chronic infection. However, reactivation of chronic hepatitis B infection in patients with chronic infection can be associated with detectable serum IgM anti-HBc.

DIAGNOSIS

Chronic hepatitis is often discovered incidentally, with a positive serologic test during blood donation, during routine office visit, an employment or life insurance screening, or in patients with elevated serum aminotransferase levels. Symptoms are frequently absent, even with advanced liver disease. Nonspecific complaints such as fatigue, weakness, or anorexia may occur, but these correlate poorly with the severity of the disease.

Correctly interpreting hepatitis B and C serology is essential in making an accurate diagnosis (Table 66-1). Serologic diagnosis of chronic hepatitis B or hepatitis C is usually straightforward, but not all patients with persistently elevated aminotransferases and HBsAg or anti-HCV in serum have chronic hepatitis. A patient may have a false-positive serologic test for anti-HCV or spontaneously cleared hepatitis C and remain positive for anti-HCV. A patient may be mistakenly diagnosed with chronic viral hepatitis when his or her aminotransferase elevations are due to another cause, such as nonalcoholic fatty liver disease or alcoholic liver disease. Because multiple potential causes of persistent liver inflammation or elevated serum aminotransferases can coexist, it is essential to arrive at a firm diagnosis before initiation of therapy. Thus, testing for virus in serum is essential using PCR. Hepatitis B DNA and hepatitis C RNA can be measured in serum using PCR, which is now widely available. The presence of hepatitis C RNA in the serum indicates chronic infection with hepatitis C, whereas the presence of hepatitis B DNA in the serum may indicate acute or chronic infection. It is the presence of hepatitis B surface antigen in the serum for more than 6 months that defines chronic infection with hepatitis B.

Table 66-1. Blood Tests for Hepatitis B and C

Test	Interpretation
Hepatitis B surface antigen	Either acute infection or chronic infection if present for >6 mo
Hepatitis B surface antibody	Indicates immunity
Hepatitis B e antigen	Indicates infectivity and replication
Hepatitis B e antibody	Usually indicates patient has low level of infectivity and replication unless patient has precore mutant virus
Hepatitis B core IgM antibody	Acute hepatitis B infection or reactivation of chronic hepatitis B
Hepatitis B core total antibody	Indicates prior infection
Hepatitis B DNA	Typically measured with PCR, if greater than 100,000 copies/mL patient should be considered for treatment
Hepatitis C antibody (ELISA)	Indicates prior infection or current infection or false-positive test
Hepatitis C RNA	Typically measured with PCR, any level indicates chronic infection and patients should be considered for treatment. An undetectable level indicates patient may have spontaneously cleared virus or false-positive antibody test
Hepatitis C genotype	6 genotypes. Genotype 1 most common in United States and most difficult to treat

IS A LIVER BIOPSY NECESSARY?

Previously, a liver biopsy had been considered essential before initiation of antiviral therapy. With the recent development of accurate and sensitive assays for the presence of viremia (HBV-DNA, HCV-RNA), however, recommendations on pretreatment biopsies are now individualized. A liver biopsy before initiation of therapy allows for histologic confirmation of chronic viral hepatitis and exclusion of other causes of liver inflammation. In addition, histologic grading and staging of hepatic inflammation and fibrosis are used to provide prognostic information and to establish the relative urgency for therapy. These benefits must be weighed against the costs and potential morbidity associated with the procedure. In general, liver biopsy is very safe and associated with very low rates of complications, such as bleeding.[5] In patients with significant coagulopathy, such as hemophilia A, or coagulation defects associated with advanced liver disease, the risks of a biopsy may outweigh the potential benefits. In this situation, treatment without a biopsy may be appropriate. Commercially available blood tests are available that claim to correlate with the amount of fibrosis on liver biopsy.[6] These blood tests for liver fibrosis have not replaced liver biopsy but may be a useful alternative in patients at high risk for complications from a liver biopsy.

The rationale behind performing a pretreatment liver biopsy may vary depending on the hepatitis virus involved and has evolved with the ability to measure virus in the serum.[7] Liver biopsy may not be necessary with chronic hepatitis B because the decision to treat is not only based on the histologic severity of inflammation or stage of the disease. The presence of ongoing viral replication and alanine aminotransferase levels are important determinants for therapy.

In contrast, histologic criteria determined from liver biopsy may play a greater role in guiding therapeutic recommendations for patients with chronic hepatitis C, specifically patients with genotype 1. Patients with no fibrosis may defer treatment, but they should be made aware that individuals with mild chronic hepatitis are more likely to respond to treatment with pegylated interferon and ribavirin than patients with cirrhosis.[8] Although response rates are lower in patients with cirrhosis, antiviral therapy can be effective in 20–30% of cirrhotic patients, and patients with advanced liver fibrosis may have the most to gain from therapy.[9] A liver biopsy may not be necessary in patients with chronic hepatitis C who have genotype 2 or 3 because response rates are high and the biopsy may not change the decision to treat.

BIOLOGY OF INTERFERONS

There have been continued advances in the treatment of chronic HBV and HCV. Chronic HBV was initially treated with alpha interferons. The development of oral agents active against HBV became a much more attractive alternative to IFN-α because they are associated with fewer side effects and do not require subcutaneous injection. IFN-α monotherapy was initially used to treat chronic HCV infection until the addition of ribavirin was shown to improve efficacy.

Interferons are a group of naturally occurring cytokines that are released in response to viral infections. After binding to specific cell surface receptors, they induce profound antiviral, antiproliferative, and immunomodulatory effects. The viral life cycle is inhibited at several phases, including cell entry, uncoating, RNA synthesis, and protein synthesis. Induction of HLA class I antigens on the liver cell membrane by IFN-α promotes lysis of infected hepatocytes by $CD8^+$ cytolytic lymphocytes.[10]

Many natural and recombinant interferons have been studied for the treatment of viral hepatitis. IFN-α and IFN-β both bind to the same cell receptor and thus have similar effects. Natural interferons (lymphoblastoid IFN, leukocyte IFN) and recombinant products of one or more IFN-α genes (r-IFN α_{2a}, r-IFN α_{2b}, r-IFN α_{2c}, consensus interferon) all appear to have similar efficacy in clinical trials.[10] Neutralizing antibodies to recombinant interferons may develop during therapy and lead to loss of efficacy. Patients with chronic hepatitis C who develop a relapse during treatment with r-IFN α_{2a} are typically found to have IFN-α binding antibodies. Switching these individuals to natural lymphoblastoid interferon has been reported to rapidly restore a complete response.[11] Others have failed to find a significant correlation between the presence of neutralizing antibodies and a loss of IFN-α efficacy.[12]

Adding a polyethylene glycol molecule to IFN-α prolongs the half life of the drug and the need for only once a week dosing. Increased exposure to IFN-α increases the efficacy of the drug in treating chronic hepatitis B or C.[13–15] Two formulations of pegylated interferon are approved for the treatment of chronic hepatitis C: pegylated interferon alfa-2a (Pegasys, Roche Pharmaceuticals, Baisel Switzerland) and pegylated interferon alfa-2b (Pegintron, Schering Plough, Hackensack, NJ). The polyethylene molecule attached to interferon alfa-2a is a 40 Kilodalton (kD) molecule and the polythene ethylene molecule attached to interferon alfa-2b is 12 kD. Both peginterferons are used in combination with ribavirin. There is a clinical trial underway comparing the two formulations of peginterferon in combination with ribavirin.

RIBAVIRIN

Ribavirin is a guanosine analog that has antiviral properties against hepatitis C. The antiviral mechanisms of ribavirin are unknown. Ribavirin is an inosine monophosphate dehydrogenase (IMPDH) inhibitor and one proposed mechanism of its antiviral action is that IMPDH is necessary for HCV viral

replication.[16] Other proposed mechanisms of action include modulation of the host's Th1/Th2 response and impairment of viral entry or viral budding. Ribavirin should be used in combination with peginterferon if there are no contraindications to ribavirin because combination therapy is associated with higher response rates in monoinfected and coinfected patients compared to interferon monotherapy.[17,18]

THERAPY OF CHRONIC HEPATITIS B

INTRODUCTION

Chronic hepatitis B is a major cause of cirrhosis and hepatocellular carcinoma worldwide. Thirty to forty percent of patients with persistent liver inflammation will progress to cirrhosis.[19] Progressive liver injury occurs most rapidly during the phase of active viral replication, marked by the presence in serum of hepatitis B e antigen (HBeAg) and HBV-DNA. Individuals with chronic hepatitis B may experience a spontaneous cessation of viral replication, which is followed by a histologic and biochemical remission of disease. Spontaneous clearance of HBV-DNA (by hybridization assay) and HBeAg from serum, with seroconversion to anti-HBe, occurs at a rate of 10–25% per year. Termination of viral replication is associated with a significant improvement in survival, even in patients with cirrhosis.[20,21] IFN-α therapy appears to hasten the rate of loss of viral replication. As with spontaneous remissions, successful IFN-α therapy leads to the loss of markers of viral replication, followed by biochemical and histologic improvement. Therapy rarely results in the loss of hepatitis B surface antigenemia.

UNMODIFIED AND PEGYLATED INTERFERON-α

Therapy for chronic hepatitis B includes treatment with alfa-interferons or nucleoside analogs that inhibit hepatitis B DNA polymerase and viral replication (Table 66-2). A meta-analysis of 15 randomized controlled studies (837 patients) concluded that approximately one-third of patients treated with IFN-α have a favorable outcome, defined as a sustained disappearance of HBeAg and HBV-DNA from serum.[22] Loss of these markers of viral replication occurred significantly more often in those receiving IFN-α than in controls (33% vs. 12% for loss of HBeAg, and 37% vs. 17% for the loss of HBV-DNA). The absolute difference for disappearance of markers of viral replication was about 20%, indicating that only one of five patients benefited from treatment. Higher IFN-α doses were more effective but they were also associated with more side effects.

Because pretreatment host characteristics associated with a response to IFN-α, such as a history of acute hepatitis, high alanine aminotransferase (ALT) levels, and low levels of HBV-DNA are the same characteristics associated with spontaneous seroconversion, it is conceivable that many individuals who "responded" to IFN-α would have had the same eventual outcome without therapy. After adjusting for the effect of pretreatment variables on IFN-α response rates, a meta-analysis of 10 European trials (751 patients) found that the effect of treatment was less than previously assumed.[23] The rate of disappearance of HBeAg in treated patients was increased but only by a factor of 1.76 compared to untreated patients.

Pegylated interferons are effective against hepatitis B. In 307 hepatitis B-eAg positive subjects randomized to pegylated interferon alfa-2b with or without lamivudine for 52 weeks, loss of e antigen occurred in 36% of subjects treated with peginterferon alfa-2b monotherapy.[15] Subjects treated with peginterferon and lamivudine had a similar response rate at 35%. Interestingly, this is one of the first trials demonstrating differences in response by hepatitis B genotype, with the highest response rate seen in subjects infected with hepatitis B genotypes A or B.

Long-term outcomes following IFN-α therapy have been analyzed retrospectively in a cohort of 103 patients followed for a mean of 5 years after treatment.[24] Cumulative clearance of HBeAg was estimated to be 56% after 5 years in IFN-α treated patients compared to 28.1% in a nonrandomized group of controls. Six of the treated patients died of liver failure and two required liver transplantation; all eight had remained persistently positive for HBeAg. In contrast, none of the patients who lost HBeAg developed severe complications

Table 66-2. Treatment for Hepatitis B

Treatment	Outcomes
Lamivudine 100 mg/d orally for 52 wks	Seroconversion[a]: 17% Undetectable HBV-DNA[b]: 44% Histologic response: 52% Resistance: 16%
Adefovir dipivoxil 10 mg/d orally for 52 wks	Seroconversion: 12% Undetectable HBV-DNA: 21% Histologic response: 53% Resistance: 0%
Entecavir 0.1 mg/d orally for 24 wks	Seroconversion: 13% Undetectable HBV-DNA: 26.5%
Pegylated interferon alfa-2b	Seroconversion: 29%
100 μg SQ/wk for first 32 wks then 50 μg/wk until end of treatment	Suppression of HBV-DNA: 32% (while on treatment) Histologic response: 22%

[a]Seroconversion from hepatitis B e antigen to hepatitis B e antibody.

[b]HBV-DNA measured using DNA hybridization assay, which is less sensitive than PCR.

of cirrhosis or required transplantation. Overall survival and survival without complications of cirrhosis were significantly greater in patients who lost HBeAg following therapy. These data strongly suggest that IFN-α therapy improves the outcome of patients with chronic hepatitis B, even in the presence of cirrhosis.

PATIENT SELECTION FOR INTERFERON-α THERAPY

The decision to treat a patient with chronic hepatitis B is generally straightforward. Virtually all patients with compensated liver function who have had persistent elevation of serum aminotransferases and ongoing HBV replication should be considered candidates for therapy. The risks of disease transmission and development of hepatocellular carcinoma in individuals with long-standing HBV infection provide a rationale for treatment regardless of the presence of symptoms or the degree of necroinflammatory activity on biopsy. Even patients with mild histologic liver injury are susceptible to spontaneous exacerbations and disease progression, and thus they should be treated. Carriers of hepatitis B surface antigen with persistently normal aminotransferase levels without replication are not currently treated. In the Western world, these individuals have an excellent prognosis and do not require therapy unless there is a reactivation of disease, but surface antigen carriers without replication are at increased risk for hepatocellular carcinoma compared to uninfected individuals.[25,26] In general, patients with advanced cirrhosis or decompensated liver disease should not be treated with IFN-α but should be considered for treatment with an oral nucleoside or nucleotide inhibitor (see below).

PREDICTORS OF RESPONSE

Several patient characteristics correlate with the probability of success with IFN-α therapy in patients with chronic hepatitis B. Individuals with high aminotransferase levels, active liver disease, and relatively low levels of replicating virus in serum respond more frequently, presumably because these features are associated with a greater immune response to HBV infection.[27] Poorer results are seen in patients with disease acquired during early childhood and in patients from areas of the world where perinatal transmission is common. Individuals infected early in life with HBV appear to have immune tolerance to the virus, often associated with very high levels of viral replication but normal aminotransferases and minimal necroinflammatory activity on biopsy. Patients with this pattern, which is common where hepatitis B is endemic, rarely respond to IFN-α. Similarly, treatment of individuals who are immunocompromised is rarely successful.

Hepatitis B genotypes have been identified and associated with differences in disease progression and response to treatment.[28] Genotypes A through G represent the different variants, with genotype A most common in the United States, genotype B most common in Western Europe, and genotype D most common in Africa. Genotype A is associated with greater response to treatment with pegylated interferon compared to the other genotypes.

PRESCRIBING INTERFERON-α FOR HEPATITIS B

Before the development of pegylated interferons, the unmodified alpha interferons were prescribed for patients with chronic hepatitis B. The recommended therapy consists of 5 million units of IFN-α daily, administered subcutaneously for 4 months. Alternatively, 10 MU of IFN-α can be administered 3 times weekly with equal efficacy. Larger doses appear to be marginally more effective, but they probably do not warrant the additional cost and side effects. Pretreatment with a tapering dose of corticosteroids is not recommended.

Pegylated interferons are the preferred form of interferon for the treatment of chronic hepatitis B because they are administered once weekly. Pegylated interferon alfa-2b is administered at 1.5 μg/kg for 32 weeks with lamivudine 100 mg/day for 52 weeks. A 48-week course of pegylated interferon alfa-2a 180 μg subcutaneously weekly was associated with 32% rate of hepatitis B e antibody seroconversion.[29] The addition of lamivudine to pegylated interferon alfa-2a did not provide any additional benefit.

PATTERNS OF RESPONSE TO INTERFERON-α THERAPY

An exacerbation of liver disease, with increases in serum aminotransferases to more than twice the baseline level, may occur during the second or third month of therapy. This flare-up is seen in 25% of patients treated with pegylated interferon.[30] Fifty-eight percent of patients with flares due to medication respond to treatment compared to 20% of patients with flares due to virus. It is believed that the flare in aminotransferases indicates lysis of infected hepatocytes by an activated immune system, and it often precedes loss of HBV-DNA. Typically, this "seroconversion hepatitis" is asymptomatic. It should be regarded as a favorable sign and should not prompt discontinuation of therapy unless significant hepatic dysfunction occurs. Following the loss of HBV-DNA from serum (by hybridization assay), most responders have a clearance of HBeAg, seroconversion to anti-HBeAb, and eventual improvement in liver histology. All of these endpoints occur in 80–90% of responders, though loss of HBeAg may be delayed for several months following discontinuation of IFN-α. Retreatment of nonresponders is rarely effective. Only about 7% of responders lose HBsAg from serum in the first year after therapy with peginterferon alpha-2b.[15,31] In a long-term follow-up study in the United States, however, 65% of patients who lost HBeAg eventually lost HBsAg a mean of

3 years later.[15,32] In endemic areas, rates of loss of HBsAg have been much lower.[33,34]

IFN-α responders may not have a durable remission of liver disease. Relapse may occur in 13–16% of patients, typically in the first year following therapy.[34] As long as HBsAg persists in serum, minute quantities of HBV-DNA are usually also detectable by the PCR. Following the disappearance of both HBsAg and HBV-DNA by PCR from serum, HBV-DNA may still be detectable in liver and in peripheral blood mononuclear cells. Thus, a potential for late relapse remains, especially in the setting of immunosuppression or chemotherapy. Reactivation of hepatitis B may occur with chemotherapy or immunosuppression leading to symptoms similar to severe acute hepatitis. Prophylaxis with oral nucleoside analog therapy should be strongly considered in patients with chronic hepatitis B who are about to receive chemotherapy, even if the patient appears to be in virological remission.

SPECIAL PATIENT CATEGORIES

Hepatitis B cirrhosis

Most studies of IFN-α for chronic hepatitis B have excluded patients with evidence of advanced cirrhosis, such as jaundice, hepatic synthetic dysfunction, ascites, encephalopathy, or variceal hemorrhage. Prescribing IFN-α for individuals with marginal liver function is hazardous, because flares in liver enzymes during seroconversion can lead to decompensation and liver failure. Furthermore, these patients are susceptible to life-threatening infections and intolerable IFN-α side effects. These patients should generally be managed by experienced hepatologists at centers providing liver transplantation. Nonetheless, some Child's class A and B cirrhotics have been successfully treated with low-dose IFN-α, resulting in stabilization of disease.[35,36] Lamivudine and adefovir appear to be well tolerated in decompensated cirrhosis and are safer alternatives.[37,38]

PRECORE MUTANTS AND DELTA HEPATITIS

The absence of detectable HBeAg in a patient who has high levels of serum HBV-DNA suggests the presence of a precore mutant, an HBV strain with a mutation in the upstream HBeAg reading frame that blocks the synthesis of the envelope protein. These strains, which are often associated with severe liver disease, are prevalent in Mediterranean countries and are becoming more common in the United States. Patients with precore mutants may have higher response rates to IFN-α compared to patients with wild type hepatitis B.[39,40] Treatment of patients superinfected with the hepatitis delta virus (HDV) with high doses of IFN-α may lead to a gradual normalization of aminotransferase levels in up to one-half of treated patients.[41,42] With cessation of therapy, however, relapse is also frequent. Nonetheless, IFN-α therapy or an oral agent is generally advocated for delta hepatitis, as it is often rapidly progressive without therapy.

HUMAN IMMUNODEFICIENCY VIRUS COINFECTION

Because HBV and the HIV share routes of transmission, coinfection with both viruses may occur in as many as 10% of HIV-infected individuals. Response to IFN-α is possible if CD4 counts are well preserved, but unfortunately, a high level of HBV replication is common in the setting of immunosuppression, and responses to IFN-α are generally poor. Although HIV infected patients with chronic hepatitis B have lower response rates to interferon, treated patients have a reduced risk for progressing to cirrhosis.[43]

Administration of lamivudine at doses of 300–600 mg daily as therapy for HIV infection markedly suppresses serum HBV-DNA to undetectable levels. During continued therapy for up to 1 year, breakthrough of viral replication appears uncommon. Mean ALT levels decline significantly, but the effect on disease progression has not been determined.[44] Thus, lamivudine should be considered in HIV antiviral therapy for individuals coinfected with HBV, but patients with hepatitis B coinfected with HIV have lower response rates to treatment and higher rates of resistance to lamivudine on long-term therapy.[45,46] Tenofovir and emtricitabine have activity against hepatitis B and HIV and are alternatives to lamivudine that should be considered as part of the treatment regimen in patients coinfected with HIV and hepatitis B.[47,48]

ORAL NUCLEOSIDE AND NUCLEOTIDE ANALOGS FOR CHRONIC HEPATITIS B

Over the last several years, there has been development of oral nucleoside analogs that inhibit hepatitis B replication by inhibiting hepatitis B DNA polymerase (Table 66-2). Progress in the development of animal models and cell culture systems for studying HBV replication has facilitated the identification of nucleoside analogs with activity against hepatitis B. Lamivudine (3-thiacytidine) is a potent inhibitor of HBV replication that causes termination of the nascent proviral DNA chain. Lamivudine is effective in reducing serum levels of hepatitis B DNA initially in almost all patients. Seroconversion from hepatitis B e antigen to antibody occurs in 15–20% of patients, and histologic improvement is seen in 50% of treated patients, but relapse and resistance to lamivudine occurs in 16% of patients at 1 year and 40% on 3 years of therapy.[49,50] The mutation associated with lamivudine is frequently due to a mutation in the HBV-DNA polymerase termed the YMDD variant.

In a 52-week randomized clinical trial of patients with chronic hepatitis B, 17% of subjects on lamivudine and 6% of subjects treated with placebo seroconverted to hepatitis B e antibody.[50]

HBV-DNA rapidly becomes undetectable in serum but it rebounds promptly after discontinuation of the drug. Patients need to be aware that discontinuation of therapy may result in reactivation and flare of symptomatic hepatitis. Therefore, therapy with oral nucleoside analogs may need to be indefinite in patients who do not seroconvert to anti-HBe.

Famciclovir is a nucleoside analog developed to treat herpesviruses that also have activity against HBV. However, with the development of more effective agents it has virtually no role in the treatment of hepatitis B.

Adefovir dipivoxil is a nucleotide analog approved by the FDA for the treatment of chronic hepatitis B infection that inhibits hepatitis B replication. Initially there was concern of nephrotoxicity associated with adefovir prescribed in patients with HIV, but at lower doses used in hepatitis B nephrotoxicity is rare. Adefovir has been shown to be effective against hepatitis B eAg positive and eAg negative patients.[51,52] At 10 mg/day histologic improvement and hepatitis B eAg seroconversion have been reported in 52% and 12% of subjects, respectively. Although resistance to adefovir has been reported, it is much less common than resistance to lamivudine.

Entecavir is the most recently FDA approved oral agent for chronic hepatitis B infection; it is effective at reducing serum hepatitis B DNA, and is well tolerated. Entecavir achieved viral suppression in 83.7% of treated patients compared to 57.5% of patients treated with lamivudine.[53] Seroconversion of hepatitis B eAg with entecavir is rare.

The strengths and limitations of interferons compared to nucleoside and nucleotide analogs are related to side effects, resistance, and duration of therapy (Table 66-2). It is likely that therapy for hepatitis B will evolve to combination therapy analogous to the approach used in HIV infection.

SUMMARY

Treatment of chronic hepatitis B has advanced substantially in recent years. Peginterferon should be considered initially for patients with chronic hepatitis B and replication because of higher seroconversion rates, lower resistance, and a finite duration of therapy compared with oral agents. However, patients may have contraindications to interferon or elect for therapy with fewer side effects. The development of safe and effective oral nucleoside and nucleotide analogs that can chronically suppress HBV replication represents a major milestone in HBV therapy. Therapy for chronic hepatitis B is evolving to combination nucleoside therapy in order to minimize resistance. The role of hepatitis B genotypes is likely to be an important factor in guiding treatment.

THERAPY FOR CHRONIC HEPATITIS C

INTRODUCTION

In contrast to hepatitis B, there are fewer treatment strategies for hepatitis C. IFN-α or pegylated alfa interferons alone or in combination with ribavirin are the only FDA approved therapy. SVR, defined as undetectable serum hepatitis C RNA by PCR, is the goal of therapy and thought to represent a cure. Marked improvements in SVR rates have occurred over the past decade, with rates of less than 10% seen with interferon monotherapy to rates of 50% with pegylated interferon and ribavirin combination therapy. Selection of candidates for treatment is individualized. Clinicians differ in their views regarding PEG-IFN-α and ribavirin therapy and patients vary in their willingness to receive it. Frequently the decision for treatment is based on the amount of fibrosis on liver biopsy and the hepatitis C genotype.

PEGYLATED (PEG) INTERFERON-α AND RIBAVIRIN

Pegylated interferons have largely replaced unmodified interferons for the treatment of hepatitis C. Pegylated interferon with ribavirin has greater efficacy against hepatitis C compared to interferon and ribavirin, specifically in patients infected with genotype 1 (Table 66-3). SVR rates in genotype 1 patients treated with unmodified interferon or peginterferon plus ribavirin increased from 36% to 46% in the pegylated interferon alfa-2a trial and 34–42% in the pegylated interferon alfa-2b trial.[13,14] An improvement in SVR rates was seen in genotype 2 or 3 infected patients treated with pegylated interferon alfa-2a plus ribavirin compared to unmodified interferon alfa-2a plus ribavirin but not with pegylated interferon alfa-2b plus ribavirin. A clinical trial comparing pegylated interferon alfa-2a to pegylated interferon alfa-2b is currently underway.

PREDICTORS OF RESPONSE

Several pretreatment host factors are associated with increased rates of response to IFN-α therapy. Hepatitis C genotype is the strongest predictor of SVR. HCV genotypes 2 or 3, younger age, female gender, lower serum HCV-RNA levels, shorter duration of infection, milder histologic lesions, and smaller body weight are positive prognostic indicators, whereas high hepatic iron concentration, HCV genotypes 1a or 1b, and cirrhosis are negative indicators.[54–56] Of these variables, viral genotype is the strongest independent predictor of sustained response. Viral genotypes 1a and 1b, which together account for more than 70% of infected patients in the United States, show sustained response rates of 42–46%, whereas rates for genotypes 2 and 3 are approximately 60–80%.[13,14]

Table 66-3. Sustained Response Rates to Pegylated Interferon and Ribavirin in Monoinfected and Coinfected Patients

Regimen	Sustained Response Rate by Genotype	Dose and Duration
Pegylated interferon alfa-2a + ribavirin[13]	Genotype 1: 46%	Peginterferon alfa-2a 180 μg SQ q wk +ribavirin 1000–1200 mg/d for 48 wks
	Genotypes 2 and 3: 76%	Peginterferon alfa-2a 180 μg SQ q wk + ribavirin 800 mg/d for 24 wks
Pegylated interferon alfa-2b + ribavirin[14]	Genotype 1: 42% Genotypes 2 and 3: 82%	Peginterferon alfa-2b 1.5 μg/kg SQ q wk + ribavirin 800 mg/d for 48 wks Peginterferon alfa-2b 1.5 μg/kg SQ q wk + ribavirin 800 mg/d for 24 wks
Studies in Patients with HIV and Hepatitis C		
Pegylated interferon alfa-2a + ribavirin[73]	Genotype 1: 29% Genotypes 2 and 3: 62%	Peginterferon alfa-2a 180 μg SQ q wk plus ribavirin 400 mg po bid for 48 wks for all genotypes
Pegylated interferon alfa-2a + ribavirin[72]	Genotype 1: 14% Nongenotype 1: 73%	Peginterferon alfa-2a 180 μg weekly + ribavirin 600 mg QD for 4 wks then 800 mg/d for 4 wks then 1000 mg/d until completion of study

Thus, viral genotype is useful in deciding to proceed with therapy. A lower threshold may be used to initiate therapy in patients infected with genotype 2 or 3, not only because sustained response rates are higher but also because the recommended duration of therapy is 24 weeks compared to up to 48 weeks for genotype 1 infected patients.

PATTERNS OF RESPONSE TO PEGYLATED INTERFERON-α THERAPY

One of the most important predictors of response to treatment with antiviral therapy is the early virologic response (EVR). EVR is defined as undetectable or a 2-log or greater decline in hepatitis C RNA by PCR at week 12 of therapy as compared to baseline. Patients treated with peginterferon plus ribavirin, who achieve an EVR, have an SVR rate of 63–90%,[57] whereas patients who do not achieve an EVR will rarely achieve an SVR. Of genotype 1 patients who achieve an EVR, 63% reached an SVR. Of the genotype 2 or 3 patients who achieve an EVR, 86% reach SVR.[57]

Biochemical response to antiviral therapy was previously monitored by following serial ALT levels. Patients who respond to therapy with IFN-α typically develop a decline in serum aminotransferases and HCV-RNA levels. Most responders to antiviral therapy have normalization of ALT levels by 8–12 weeks of therapy.[58] Unlike with HBV, an increase in aminotransferase levels shortly after initiation of IFN-α is not characteristic of HCV treatment. Such a response should lead to discontinuation of therapy and a search for evidence of autoimmune hepatitis. Failure to attain complete normalization of aminotransferase levels is usually associated with persistence of viremia. Similarly, an elevation of serum aminotransferase levels following an initial normalization indicates a resurgence of viremia. However, the role of ALT in following patients for a virologic response is limited, especially with the widespread availability of PCR assays for measuring HCV-RNA.

Biochemical remission of hepatitis during IFN-α therapy may correlate with histologic improvement, characterized by a reduction in lobular and periportal inflammation. However, sustained normalization of ALT levels during therapy does not always indicate a virologic remission, as evidenced by the high relapse rate following discontinuation of IFN-α[59]. Even individuals with persistently normal aminotransferase levels following IFN-α are at risk for late relapse. Up to one-fourth of such patients ultimately relapse.[60]

The goal of therapy is to reduce mortality from hepatitis C associated deaths, specifically end stage liver disease and complications from portal hypertension and hepatocellular carcinoma. However, because favorable outcomes from these end points would take decades to demonstrate, eradicating hepatitis C viremia is the end point used in clinical trials. Compelling data have emerged demonstrating that sustained viral responders and even patients treated with interferon who are nonresponders have a significantly lower risk of hepatocellular carcinoma compared to infected, untreated patients.[61]

SVR, defined as undetectable HCV-RNA by PCR 6 months after completion of therapy is defined as a cure and seems to be durable. Late relapse, after SVR is achieved, occurs in 5%

of patients 5 years later and 1% of patients with SVR followed for more than 5 years.[62]

PATIENT SELECTION FOR (PEG) INTERFERON-α THERAPY

Consideration of IFN-α therapy is appropriate in all patients with evidence of active HCV infection. Individuals with normal aminotransferase levels may have significant liver fibrosis and should be considered for therapy.[63] The decision to initiate therapy should be based on a candid discussion with the patient regarding the natural history of his or her disease, as well as the risks, contraindications, and benefits of IFN-α therapy. In addition to viral load and genotype, the patient's age, medical condition, psychiatric history, and the stage of fibrosis on biopsy are important. Symptoms of chronic hepatitis do not correlate with disease severity or prognosis and should not be used as a guide to treatment.

Patients with cirrhosis on liver biopsy have lower response rates compared to patients with mild liver fibrosis, although they may have the most to gain from therapy. Those with well-compensated cirrhosis should be considered for antiviral therapy because they may respond to treatment.[9] Young patients have the most potential life-years at stake, and treatment of this subgroup of patients may be most cost-effective.[64] Consideration of liver transplantation should not be postponed in favor of IFN-α therapy in cirrhotic patient with decompensation.

INITIATION OF PEGINTERFERON-α AND RIBAVIRIN THERAPY

Contraindications

Psychiatric symptoms are among the most frequently encountered side effects and uncontrolled depression or suicidal ideation are contraindications to therapy.[65] Patients with decompensated cirrhosis may develop serious complications with therapy and should not be treated outside of a clinical trial. Patients with hepatitis C on methadone maintenance therapy have been effectively treated with interferon based therapy and should be considered as potential treatment candidates.[66]

PEGINTERFERON-α AND RIBAVIRIN SIDE EFFECTS

Side effects of IFN-α therapy occur frequently, but most symptoms are tolerable (Table 66-4). Adverse effects are typically dose-dependent and abate rapidly with reductions in dose or with temporary discontinuation. Only about 5–10% of patients need to stop PEG-IFN-α entirely.[13,14] Early side effects include fatigue, fever, chills, myalgias, and arthralgias. These flu-like symptoms occur almost universally after the first few doses but administration at bedtime and use of acetaminophen or ibuprofen help alleviate these effects. Fatigue and irritability may continue throughout therapy. Dose reduction or discontinuation should be considered for significant neuropsychiatric side effects or for symptoms that interfere with the patient's lifestyle. Bone marrow suppression and bacterial infections are potentially life threatening but are rare. Autoimmune thyroid disease develops in about 1–5% of patients and may be irreversible despite discontinuation of IFN-α.[65] Patients already taking thyroid medication may require adjustments in their dosage. Injection site reactions with erythema and mild tenderness are more common with peginterferons compared to unmodified interferons but rarely require discontinuation or dose modification.

MONITORING PEGINTERFERON-α AND RIBAVIRIN THERAPY

Regular follow-up visits are recommended to monitor for side effects and to obtain complete blood counts with differential

Table 66-4. Side Effects of Pegylated Interferons and Ribavirin

Thrombocytopenia
Endocrine
Hypo or hyperthyroidism
Hyperglycemia in diabetics
Other
Teratogen (ribavirin)
Retinopathy (peginterferon)
Intractable cough
Rash

and liver tests. Visits are typically scheduled after the first and second weeks of therapy and monthly thereafter. During the first 4 weeks, complete blood counts are obtained weekly or every 2 weeks to monitor for neutropenia. Dose reduction should be considered for platelet counts below 50,000/mL or granulocyte counts below 750/mL. For platelets less than 30,000/mL or granulocytes below 500/mL, treatment should be interrupted until counts return to their baseline levels. Thyroid-stimulating hormone (TSH) levels should be checked at baseline and every 3–6 months on therapy.

Ribavirin

Hemolytic anemia with a 2–4 g/dL decrease in hemoglobin typically occurs after the first 3–6 weeks of therapy. Erythropoetin has been used to help maintain hemoglobin levels and improve quality of life in patients who become anemic while on therapy.[67] Ribavirin is a teratogen. Therefore, two forms of contraception should be used by sexually active patients. Chronic cough or rash are infrequently seen with interferon or ribavirin but if they do occur and are persistent then the dose of each medication needs to be decreased or discontinued if symptoms persist.

■ PRESCRIBING PEGYLATED INTERFERON-α FOR HEPATITIS C

The most effective FDA-approved regimen of antiviral therapy for HCV is pegylated interferon alfa-2a 180 μg weekly subcutaneously plus ribavirin or pegylated interferon alfa-2b 1.5 μg/kg weekly subcutaneously plus ribavirin. The dose of ribavirin is 800–1200 mg/day in divided doses depending upon body weight and genotype. Patients with genotype 1 are treated with 1000–1200 mg/day of ribavirin. Genotype 2 or 3 infected patients are treated with 800 mg/day of ribavirin. Therapy is for up to 48 weeks for genotype 1 patients and 24 weeks for genotype 2 or 3 patients. Patients infected with genotype 1 are monitored with HCV-RNA by PCR every 12 weeks for the first 24 weeks of therapy. Patients with an EVR at week 12 continue therapy, and patients with undetectable serum HCV-RNA at week 24 of therapy complete 48 weeks of treatment. Patients with detectable serum virus at week 24 of therapy discontinue treatment. Increasing the dose of interferon is not justified in individuals who have failed to demonstrate a response at 12 weeks of therapy because it is not associated with increased efficacy in initial nonresponders and higher doses are associated with increased toxicity.[68] Patients infected with genotype 2 or 3 are treated for 24 weeks, and currently EVR is not used to guide therapy although 4-week viral load identifies patients who are most likely to respond to therapy.[69]

The treatment of patients who did not respond or relapse after treatment with IFN-α monotherapy, IFN-α plus ribavirin, or PEG-IFN-α plus ribavirin has been disappointing. Retreatment of relapsers to IFN monotherapy or combination therapy with peginterferon plus ribavirin may be justified in some patients who are motivated for retreatment who did not experience serious side effects. Retreatment of nonresponders to interferon monotherapy, interferon/ribavirin, or peginterferon/ribavirin is associated with low response rates and is generally not justified.[70]

COINFECTION WITH HIV OR HBV

Hepatitis C is more aggressive and more difficult to treat in patients coinfected with HIV. It appears that concurrent HIV disease portends a more aggressive course, especially in those with declining CD4 counts, as evidenced by cohort studies of both IV drug abusers and hemophiliacs.[71] Additionally, patients with HCV and HIV have significantly higher viral loads than those with HCV alone.[72]

Clinical trials in patients coinfected with HCV and HIV comparing peginterferon alfa-2a plus ribavirin to interferon alfa-2a plus ribavirin demonstrate significantly higher SVR rates with the peginterferon regimen (Table 66-3).[72,73] In patients infected with genotype 1, the peginterferon/ribavirin regimen results in an SVR of 14–29% compared to 7% with the interferon/ribavirin regimen.[72,73] However, sustained response rates are lower than those reported in patients with HCV alone.

CD4 counts may drop by approximately 100 cells/cc during therapy. After discontinuation of peginterferon and ribavirin, CD4 counts return to baseline. There is no appreciable effect of peginterferon and ribavirin on HIV viral loads or HIV disease progression.

Concomitant HCV infection occurs rarely in patients with chronic active hepatitis B, and liver disease may be more severe in coinfected individuals than those infected with a single virus.[74] Coinfection may lead to the suppression of one virus such that replication of the suppressed virus cannot be detected. Both HCV and HBV viral loads should be measured before therapy in the coinfected patient. Because pegylated interferon is effective against both hepatitis B and hepatitis C, peginterferon should be considered in combination with ribavirin in coinfected individuals if there are no contraindications to therapy.

ACUTE HEPATITIS C INFECTION

Patients who develop acute hepatitis C and do not spontaneously clear the virus should be strongly considered for therapy. A compelling study of 44 patients with acute hepatitis C who were treated with standard IFN-α reported that 43 patients cleared virus with therapy.[75] Patients were treated with IFN-α 5 MU subcutaneously daily for 4 weeks followed by 3 times a week for 20 weeks. Based on these data treatment of acute hepatitis C infection with IFN-α is recommended.

OTHER APPROACHES TO TREATING HEPATITIS C

A variety of agents have been tested for use in HCV, either alone or in combination with IFN-α, including corticosteroids, nonsteroidal antiinflammatory drugs (NSAIDS), acyclovir, ursodeoxycholic acid, thymosin, phlebotomy, and ribavirin monotherapy.[76–82] Although some of these drugs have shown promise in initial trials, none has emerged as a viable single-agent treatment strategy for HCV. The structure of the HCV protease enzyme has been elucidated.[83,84] However, trials of protease inhibitors have been discouraging thus far due to the emergence of rapid resistance or associated toxicity.[85,86] Development of more specific anti-HCV chemotherapeutic agents is anxiously awaited. Phase I and II trials of inhibitors of the HCV protease are underway. The recent development of a transfected cell culture system with genotype 1a hepatitis C should facilitate the development of new drugs and a vaccine.[87]

SUMMARY

Standard or pegylated IFN-α with ribavirin is currently the only approved treatment for chronic hepatitis C infection. Advancements in antiviral therapy over the past decade have increased response rates from 10% to 50%. However, there is a need for more effective, less toxic therapy.

Treatment of chronic hepatitis C before the development of significant fibrosis is probably necessary if the natural history of this condition is to be altered. Patient selection and treatment strategies continue to evolve as additional data become available. The ultimate goal is to develop a vaccine with the potential to eliminate the disease. An effective vaccine exists for hepatitis B and widespread administration of the vaccine has led to reduced rates of hepatocellular carcinoma in Taiwan.[88] The development of an effective vaccine against hepatitis C has been challenging. Whereas the focus of current clinical research is on combination therapies, major therapeutic advances will probably require development of novel antiviral compounds against enzymes involved in hepatitis C replication.

67 Arthritis Associated with Sexually Transmitted Diseases

Peter A. Rice and H. Hunter Handsfield

INTRODUCTION

Acute arthritis is a common clinical problem, and in some settings disseminated gonococcal infection (DGI) and sexually related reactive arthritis together may account for more than one-half of all new cases of acute nontraumatic arthritis in sexually active young adults.[1,2] The association of acute arthritis with urethritis in men had been recognized repeatedly from antiquity to the eighteenth century. Gonococcal arthritis and sexually acquired nongonococcal arthritis were characterized as distinct entities after that in the nineteenth and early twentieth centuries. The patient described by Hans Reiter in 1916[3] was one of several such cases[4] that had been reported by then. Owing to revelations of Reiter's human rights record,[5,6] recently the term reactive arthritis has been adopted to describe variations of the syndrome that had borne his name.

Reactive arthritis is the general term for inflammatory arthritis that follows a localized infection with a number of pathogens, which usually involves a mucosal surface.[7,8] Reactive arthritis is an immune-mediated aseptic synovitis that may be associated with extra-articular manifestations and affects patients with a specific genetic predisposition. The term reactive arthritis encompasses the disorders commonly referred to as sexually acquired reactive arthritis, reactive spondyloarthropathy, reactive uroarthritis, postgonococcal arthritis, and postdysenteric arthropathy.[2,7,8] The reactive arthritides occur predominantly in persons of the HLA-B27 haplotype, particularly in whites.

Other sexually transmitted diseases (STDs) associated with acute arthritis include syphilis, lymphogranuloma venereum (LGV), hepatitis B virus (HBV) infection, HIV infection and, rarely, genital herpes, cytomegalovirus, and genital mycoplasma infections. Arthritis may also result from allergic reactions to drugs used in the treatment of sexually transmitted infections.

DISSEMINATED GONOCOCCAL INFECTION

ETIOLOGY AND PATHOGENESIS

Neisseria gonorrhoeae is the most commonly recognized sexually transmitted pathogen that causes infective arthritis, and in parts of the United States and Scandinavia it may have been the most common of all causes of infective arthritis during the 1970s and 1980s.[1,2,9,10] Septic or purulent monoarticular or oligoarticular gonococcal arthritis is often associated with positive synovial fluid cultures for *N. gonorrhoeae*. This form of the disease accounts for less than 50% of cases of disseminated gonococcal infection (DGI), and most patients present with polyarthralgias and tenosynovitis and experience clinical courses that may resolve spontaneously. Although these features might suggest an immunologic pathogenesis,[11,12] several lines of evidence indicate that this form of DGI, in fact, results from direct synovial or periarticular infection: (1) Gonococcemia is commonly documented; positive blood cultures may occur in up to 50% of patients with tenosynovitis accompanied by polyarthralgias who are examined within 2 days of onset, giving rise to the possibility that the synovium and periarticular tissues may be seeded early in the disease.[1,10,13–16] (2) Other common systemic manifestations of DGI, including skin and visceral lesions, are more likely due to localized infections at these sites.[10,11,16–19] (3) *N. gonorrhoeae* is occasionally identified histologically or by immunochemical methods in apparently sterile synovial fluid and periarticular tissues of patients with DGI or in skin lesions.[16,17] (4) Antimicrobial therapy is often followed by rapid clinical resolution (within 48 hours) of polyarthralgias, consistent with a direct therapeutic effect.[10,13,14,16,20–23] (5) Finally, attempts to identify circulating immune complexes in patients with DGI have yielded conflicting results. Reduction of complement (presumed to be due to consumption) to subnormal levels is uncommon, although modest decreases in complement may be frequent.[10,24–26] Nonetheless, the question

of pathogenesis is still not settled, and immune-complex deposition or other immunologic mechanisms may play pathogenic roles in some patients. For example, it has been hypothesized that immune-complex synovitis early in the course of DGI may predispose to later entry of circulating gonococci into the joint space.[27] Alternatively, gonococcal cell wall constituents, such as lipooligosaccharide or peptidoglycan fragments, may circulate from the site of a mucosal infection to initiate arthritis in the absence of viable gonococci.[28] Host factors and characteristics of *N. gonorrhoeae* that predispose to dissemination are discussed in Chapter 34.

EPIDEMIOLOGY

The risk of acquiring DGI in patients with gonorrhea had been estimated to be 0.5–3.0% in the 1970s, depending principally on the regional prevalence of specific strains of *N. gonorrhoeae* that possessed features that enabled them to disseminate,[10,16,17] as discussed in Chapters 34 and 35. These strains were endemic in the northwestern United States and Scandinavia at that time, where DGI apparently occurred in up to 3% of patients with gonorrhea.[29] It is likely that the rate of DGI now is substantially lower at least in part because today such strains are not so prevalent. In the preantibiotic era, DGI was documented primarily in men,[30] but studies in the 1960s and 1970s reported a female predominance of 78–97%.[10,13–16,29,31] A potential explanation for this change may have been a past misdiagnosis of reactive arthritis, which until recently was believed to be uncommon in women. Dissemination of *N. gonorrhoeae* in women may be most probable during menses. Possible explanations include hormonal factors and a more alkaline pH of genital secretions at the time of menses,[32] conditions which are permissive to the growth of *N. gonorrhoeae*, and phenotypes of gonococci that may disseminate more readily.[33] Gonococcal dissemination appears to be uncommon in homosexually active men, perhaps because strains of *N. gonorrhoeae* that cause anorectal infection typically lack the features usually associated with DGI strains (Chapter 35).[34,35]

CLINICAL AND LABORATORY MANIFESTATIONS

The musculoskeletal manifestations of DGI are prominent and sometimes have been classified into two stages: a bacteremic stage and a joint-localized stage with suppurative arthritis. Although some cases apparently evolve sequentially from a bacteremic phase characterized by polyarticular involvement and dermatitis to a later oligoarticular stage often with overt septic arthritis,[1,13,16] an obvious progression from one stage to the other usually is not evident.[10] Whereas a single, hot, swollen joint is characteristic of gonococcal septic arthritis, skin lesions, tenosynovitis, and polyarthralgias are more typical of the bacteremic stage of DGI (Table 67-1).

Table 67-1. Differential Features of Gonococcal and Nongonococcal Bacterial Arthritis

Gonococcal Arthritis	Nongonococcal Bacterial Arthritis
Usually healthy, young adults	Often compromised host, often very young or aged
Tenosynovitis often	No tenosynovitis
Polyarthritis common	Monoarthritis common
Skin lesions in two-thirds	No associated dermatitis
Wrists and small joints common	Large joints predominate
Migratory polyarthralgias	No prodromal joint symptoms
Synovial-fluid cultures usually negative	Synovial-fluid cultures usually positive
Blood cultures rarely positive, except in prodromal phase patients	Blood cultures positive in 50% of patients
Rapid and complete response to antibiotics; synovial-fluid drainage usually unnecessary	Slower response to antibiotics; synovial-fluid drainage important

Painful joints usually include the knees, elbows, and the more distal joints; the axial skeleton is usually spared. About 75% of patients with polyarticular involvement or bacteremia typically have 5 to 40 lesions, including papules, sometimes macules and pustules, often with a hemorrhagic component. Most lesions are painless and are usually unrecognized, except at pressure points or in tightly bound skin, such as the fingertips (Fig. 67-1). Skin lesions appear predominantly on the extremities, sometimes on the trunk and infrequently on the face. Papules or small macules are the most common lesions, followed by pustules; occasionally skin lesions resemble vasculitis. However, all forms of skin lesions have been associated with DGI, including vesicles and bullae (Fig. 67-1) and other lesions that are usually not directly involved with infection such as erythema nodosum or erythema multiforme and urticaria. *N. gonorrhoeae* usually cannot be recovered from skin lesions by culture and lesions sometimes may appear after appropriate antibiotic therapy has been started. Nevertheless, directly cutaneous inoculation as the result of bacteremia is implied as the usual pathogenesis by the frequent ability to identify gonococci in skin lesions by polyclonal fluorescent antibody.[18]

Suppurative gonococcal arthritis usually involves one or two joints; the knees, wrists, ankles, and elbows are involved in decreasing order of frequency. Most patients who present with gonococcal suppurative arthritis do so without prior

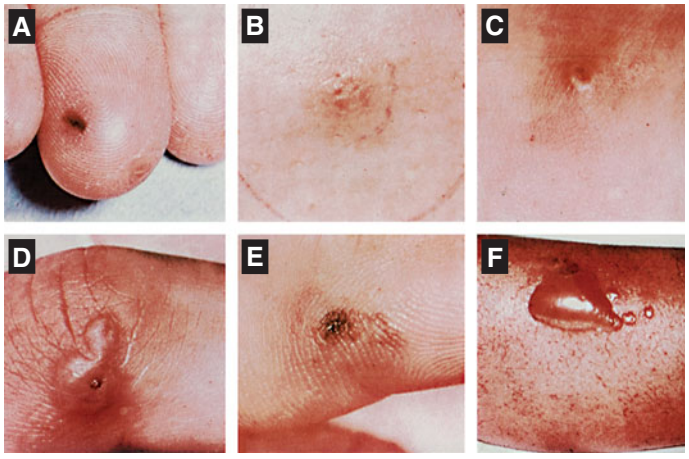

FIGURE 67-1. Characteristic skin lesions of gonococcal bacteremia in various stages of evolution from patients with proved gonococcal bacteremia. **A.** Very early petechia on finger. **B.** Early papular lesion, 7 mm in diameter, on lower leg. **C.** Pustule with central eschar resulting from early petechial lesion. **D.** Pustular lesion on finger. **E.** Mature lesion with central necrosis (black) on hemorrhagic base. **F.** Bullae on anterior tibial surface. (Reprinted with permission from Holmes KK et al. Disseminated gonococcal infection. *Ann Intern Med 1971; 74: 979.)*

FIGURE 67-2. Gonococcal arthritis: dactylitis secondary to gonococcal bacteremia. (Reprinted with permission from HS Lambert et al: *Slide Atlas of Infectious Diseases: Disseminated Infections.* 1982, Fig. 10.46 [Slide 46].)

polyarthralgias or skin lesions. In the absence of symptomatic genital infection, this form of the disease cannot be distinguished from septic arthritis caused by other pathogens. Other joints, such as the sternoclavicular and temporomandibular joints and the small joints of the hands (Fig. 67-2) or feet are occasionally involved. Rarely, direct extension of an infection results in osteomyelitis.[20] Synovial fluid leukocyte counts are similar in gonococcal suppurative arthritis compared with septic arthritides caused by other bacteria, typically with 40,000–60,000 cells/mm^3, with >80% polymorphonuclear leukocytes.[36] Synovial fluid analysis and tests for *N. gonorrhoeae* (ideally, using both culture and DNA amplification) are important in identifying patients with gonococcal septic arthritis.

The concept of sequential clinical stages in DGI has been controversial. Several investigators[1,13,16] believed that an initial bacteremic phase, typically with polyarticular tenosynovitis and arthralgias accompanied by skin lesions ("arthritis-dermatitis syndrome"[29]), was followed by a localization of infection in the form of purulent arthritis in one or two joints as bacteremia resolved. Others, however, concluded that there may be too much overlap in these manifestations, and that too many patients presented with septic arthritis as the initial manifestation, to be consistently explained by such a temporal sequence.[10] Although skin lesions are common in patients with tenosynovitis (80%), these may also be found in up to 30% of those with purulent arthritis. Most probably, there is a clinical and pathogenetic continuum of DGI, during which signs of sepsis (fever accompanied by tenosynovitis and skin lesions) may be more prominent earlier in the disease. In addition, some patients have polyarthralgias that resolve spontaneously, and others present with monoarticular septic or purulent arthritis without preceding polyarthralgias or skin lesions. It is also interesting to speculate that geographic differences in the distribution of gonococci with selected genotypic or phenotypic characteristics might have influenced the observations made in the northwestern United States and Scandinavia[1,13,16] compared with the northeastern United States.[10] Whatever the explanations, it is clear that such clinical progression is by no means universal and may be the exception.

The variable descriptions of the musculoskeletal manifestations in DGI, e.g., the proportions of cases reported to present with tenosynovitis, polyarthralgias without objective inflammatory signs or overt suppurative arthritis, may also be related to differences in the definitions employed by different authors. For example, a common criterion for arthritis requires the demonstration of purulent synovial fluid defined by >25,000 leukocytes/mm^3. Using this definition, suppurative arthritis may be less common than tenosynovitis accompanied by arthralgias.[10] Therefore, it remains unclear whether the increased frequency of tenosynovitis is related to a true change in the clinical manifestations or whether it results from a greater appreciation and definition of tenosynovitis instead of classifying all joint inflammation as arthritis. In the preantibiotic era, suppurative arthritis, confirmed by joint aspiration, was reported often; tenosynovitis was reported less frequently.[30] Inflamed tendons (tenosynovitis Fig. 67-3) usually cross multiple joints, especially the wrists, fingers, toes, and ankles. The differential diagnosis of the bacteremic stage of DGI includes reactive arthritis, acute rheumatoid arthritis, sarcoidosis, erythema nodosum, drug-induced arthritis, and viral infections (e.g. Hepatitis B and acute HIV infection). The distribution of joint symptoms in reactive arthritis, perhaps the most common differential diagnosis, differs from DGI (Fig. 67-4) as do the skin and genital manifestations.[37,38]

FIGURE 67-3. Gonococcal tenosynovitis of the left thumb secondary to gonococcal bacteremia. Note erythema and swelling of thenar eminence. (Reprinted with permission from HS Lambert et al: *Slide Atlas of Infectious Diseases: Disseminated Infections.* 1982, Fig. 10.44 [Slide 44].)

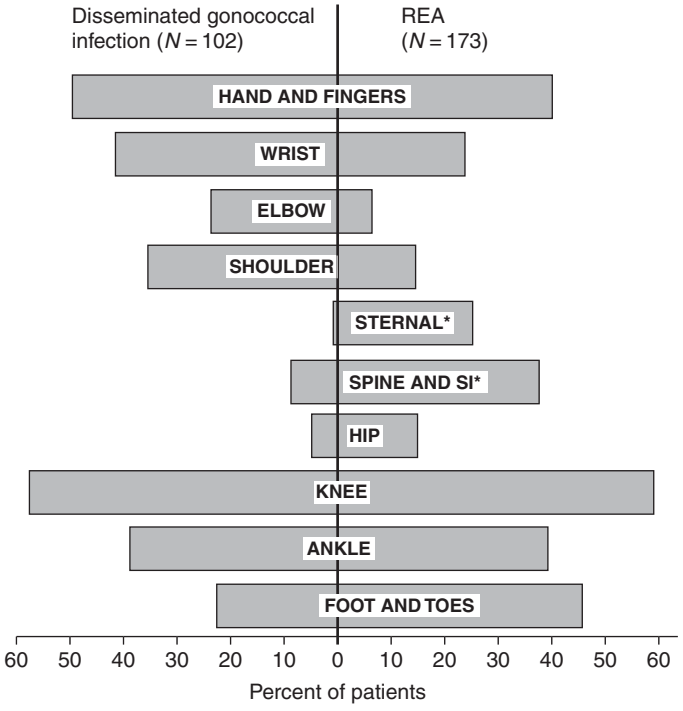

FIGURE 67-4. Distributions of joints with arthritis in 102 patients with DGI[1] and 173 patients with reactive arthritis (REA).[37] "Sternal" includes the sternoclavicular joints. *SI denotes the sacroiliac joint. (Reprinted with permission from Kousa M et al. Frequent association of chlamydial infection with Reiter's syndrome. *Sex Transm Dis* 1978; 5: 57.)

Gonococcal endocarditis, rare today,[39,40] was relatively common in the preantibiotic era, causing about one-quarter of reported cases of endocarditis.[41,42] Whether this change simply reflects more effective early diagnosis and treatment of DGI or other factors is unknown. Central nervous system infections including meningitis[43] and epidural abscess[44] are also rare. There have been a few reports of a presumed immune-mediated glomerulonephritis secondary to DGI.[40] Mild hepatitis has been reported in up to 50% of patients with DGI but usually it is not clinically apparent.[16,45]

Patients in the bacteremic stage of DGI have higher temperatures than those with suppurative arthritis and may have shaking chills, but up to 40% of patients with DGI are reportedly afebrile.[1,10,12] Most DGI patients deny local genitourinary, rectal, or pharyngeal symptoms, even though genital, anorectal, or pharyngeal gonococcal infection can be identified in 70–80% of patients with DGI or in their sex partners. In a series assembled in Seattle, *N. gonorrhoeae* was identified by culture or by antigen detection using a direct fluorescent antibody test on blood, synovial fluid, or skin lesions in 52 of 102 (51%) subjects with DGI[1]; in Boston 23 (47%) of 49 patients were so identified.[10] This observation is at least partly explained by the association of selected genotypic and phenotypic characteristics of different strains of *N. gonorrhoeae* with the propensity to cause subclinical mucosal infections, to resist nonimmune serum bactericidal activity, and to cause bacteremia (Chapter 34).

REACTIVE ARTHRITIS SYNDROME

■ ETIOLOGY AND PATHOGENESIS

The pathogenesis of reactive arthritis is multifactorial and not fully understood. A preceding infection, usually of a mucosal surface, likely serves as a trigger in a genetically predisposed host, and the syndrome may then persist or recur despite eradication of the initial infection.[2,7,8] Infectious agents that have been implicated include *Chlamydia trachomatis, Shigella flexneri, Salmonella* spp., *Yersinia enterocolitica*, and *Campylobacter* spp., perhaps *N. gonorrhoeae*, the genital mycoplasmas or other organisms. In several studies, genital *C. trachomatis* infection has been documented in approximately 50% of men with sexually acquired reactive arthritis.[7,8,37,46] Antichlamydial antibody is common in these patients, usually in higher titer than in patients with uncomplicated chlamydial infection.[7,46] Enhanced cellular immunity against *C. trachomatis* is also present, as evidenced by increases in lymphocyte-transformation responses to chlamydial antigen.[46]

A few reports have documented the occurrence of reactive arthritis after successful treatment of gonorrhea.[1,3,47–50] Often associated with postgonococcal urethritis, reactive arthritis is distinct from DGI and may be involved in a syndrome that is accompanied or followed by conjunctivitis or mucocutaneous lesions. Although simultaneous genital infection with *C. trachomatis* may occur in 10–40% of heterosexual patients with gonorrhea, chlamydial infection has not been sought in most reported cases of postgonococcal arthritis. In one report, three patients who developed the typical reactive arthritis syndrome following gonococcal urethritis lacked both culture and serologic evidence of chlamydial infection. Thus, *N. gonorrhoeae* itself may initiate some cases of reactive arthritis.

The failure to demonstrate an immune response to *C. trachomatis* in one-fourth of patients or to isolate any sexually transmitted pathogen from urethral specimens of one-third to one-half of those who had sexually acquired the reactive arthritis syndrome[37,46] suggests that other infectious agents may sometimes cause urethritis. In some cases of reactive arthritis, urethritis may be noninfective. For example, urethritis occurs in many patients with the enteric form of the disease,[7,51–53] and recurrence of urethritis may be a part of the late exacerbation of reactive arthritis in the absence of recent sexual exposure.[3]

How inflammation at a mucosal surface initiates a sustained systemic illness is not completely understood. A commonly accepted hypothesis is that genetically susceptible individuals, particularly those who express certain subtypes of the major histocompatibility-complex class 1 molecule HLA-B27, may develop exaggerated or aberrant immune responses that result in the inflammatory manifestations of reactive arthritis.[7,53,54] The HLA-B27 haplotype is found in 70–80% of white patients with reactive arthritis,[46,51,55,56] compared with 6–8% of whites in the general population. In African American patients with reactive arthritis, the reported prevalence of HLA-B27 has varied from 15–75%,[57–59] compared with about 2% in African Americans in the general population.[60] In one small study, 7 of 10 HLA-B27-negative patients with reactive arthritis possessed other HLA antigens that cross-reacted with B27, such as B7, BW22, and BW42.[57]

It has been suggested[8,57] that HLA-B27, and perhaps cross-reacting antigens, induce recognition of B27 as a foreign antigen,[61,62] resulting in a self-perpetuating autoimmune process.[63] Alternatively, HLA-B27 or related antigens may present bacterial antigenic peptides to disease-causing CD8-positive cytotoxic T lymphocytes.[64–66] Another hypothesis suggests that the HLA-B27 antigen itself may be immunologically cross-reactive with certain bacterial proteins.[67,68] Several such proteins have been identified[68–70] (although not in *C. trachomatis*), and perhaps a search of the human and the chlamydial genomes would reveal homologous sequences encoding for similar proteins. The term heat shock protein (hsp) refers to a family of peptides with considerable homology among bacteria, including *C. trachomatis*. These proteins may incite T-cell-mediated immunopathogenic responses involving local sites (e.g., endometrium and pelvic adnexa) as well as distal sites (e.g., the joints in reactive arthritis). The gene for *hsp60 of Mycobacterium tuberculosis*, which shares homology with hsp expressed by *C. trachomatis*, when transfected into an HLA-B27 cell line, resulted in the generation of peptide complexes that were shown to be recognized preferentially by antibodies present in HLA-B27-positive reactive patients with arthritis.[71]

The HLA-B27 haplotype is not the only determinant of disease expression because no more than 25% of HLA-B27-positive individuals with nongonococcal urethritis (NGU) or shigellosis develop reactive arthritis. However, the initial manifestations of reactive arthritis may be more severe and the natural course more aggressive in persons with the HLA-B27 haplotype than in those without it.[7,72] Experimental studies have directly implicated the B27 antigen in the disease process. Transgenic rats that overexpress the B27 gene spontaneously develop a disease characterized by diarrhea that is followed by arthritis. Clinical manifestations begin earlier in male rats than in females and are accompanied by genital inflammation.[73] Histopathologic examination has shown enthesitis (inflammation at tendon insertion sites) and anterior uveitis.[73] Adoptive transfer of bone marrow cells from transgenic rats to normal rats also transfers the disease. The disease cannot be reproduced in this model using athymic (nude) mice,[74] showing that T lymphocytes (probably CD8-bearing cytotoxic T cells) are critical to its pathogenesis.

Data also suggest that *C. trachomatis* may be directly involved in the pathogenesis of synovitis. The organism can be delivered to the joints from the genital tract via circulating monocytes[75]; monocytes/macrophages are the host cells for *C. trachomatis* during prolonged infection of synovial tissues. Persistence in these cells occurs when the organisms are metabolically active but morphologically aberrant.[76,77] *C. trachomatis* can enter the persistent state 48 hours after infection of normal human peripheral monocytes, thereupon altering expression of several important genes, including increasing transcription of Chlamydia *hsp60*-encoding genes.[78–80] Acute arthritis develops after 1 week or more following genital infection,[81] suggesting that the organism is already in the persistent state when it reaches the joint and that reactive arthritis, even acutely, is elicited by persistent, rather than actively growing, organisms. This observation further suggests that the immunogenic hsp60 protein produced by persistent Chlamydiae is largely responsible for eliciting synovial inflammation in both the acute as well as the relapsing forms of reactive arthritis.

Antimicrobial therapy, though often used, has not generally been clinically beneficial in treating the articular

manifestations in most patients with reactive arthritis that has flared long after the initial infection.[82] Nevertheless, prompt antimicrobial therapy of chlamydial infection may help prevent reactive arthritis, as suggested by a retrospective review of 224 patients with sexually acquired urethritis or cervicitis.[83] In that study, 68 patients were treated for presumed chlamydial infection with tetracycline or erythromycin; acute reactive arthritis developed in 7 (10%) of these patients. The other 156 patients had gonorrhea, or they had no identified pathogen, and were untreated or received only penicillin therapy; 57 (37%) of these patients developed reactive arthritis ($p < 0.001$).[83]

OTHER IMMUNOLOGIC STUDIES IN REACTIVE ARTHRITIS

Many immunologic phenomena have been associated with reactive arthritis, but their importance and pathogenic roles have not yet been well established. Synovial fluid lymphocytes from patients with reactive arthritis may be more reactive than peripheral blood lymphocytes from the same patients when incubated with a variety of potential triggering agents, particularly *C. trachomatis*, or with a number of enteric organisms, *N. gonorrhoeae, or Ureaplasma urealyticum*.[84,85] The ratio of T to B lymphocytes is higher in synovial fluid from patients with reactive arthritis than in synovial fluid from normal controls.[86] The blastogenic response of circulating lymphocytes to *C. trachomatis*[46] or *Y. enterocolitica*[87] in reactive arthritis associated with these pathogens is elevated relative to the response in patients who have chlamydial or yersinial infections without reactive arthritis. CD4-bearing (helper-inducer) lymphocytes outnumber CD8-positive (suppressor-cytotoxic) lymphocytes in the synovial fluid of patients with reactive arthritis, even though stimulation of CD8-positive cytotoxic-cell populations results from antigen presentation by, for example, HLA-B27 class 1 molecules. Further evidence favoring a pathogenic role of CD8-positive cytotoxic cells is represented by the occurrence of reactive arthritis in AIDS patients who have profound depletion of CD4-positive lymphocytes.[88] These observations are concordant with those in the athymic (nude) mouse model[74] and suggest that an intact helper-inducer CD4 system may not be central to the pathogenesis of reactive arthritis.

Immune complexes of the IgG class are present in the blood of up to 76% of patients with reactive arthritis,[89] and synovial biopsies often reveal exudative synovitis with interstitial and intracellular deposits of IgG, IgA, and the third component of complement (C3).[90,91] Nonetheless, the clinical features of the arthropathy and the usual absence of glomerulonephritis, vasculitis, and other manifestations of immune-complex deposition suggest that this mechanism also may not be central to the pathogenesis of this disease.

EPIDEMIOLOGY

Epidemiologically, reactive arthritis is characterized by an endemic form, usually sexually acquired, and a less common epidemic form, most often associated with enteric infection. Although endemic reactive arthritis commonly follows sexual contact with a new partner, clear evidence of sexual transmission of individual cases has been uncommon. One report[92] described the simultaneous occurrence of NGU and reactive arthritis in two HLA-B27-positive men after both had intercourse with the same woman. The enteric form of reactive arthritis typically follows shigellosis,[2,7,8,53,93] salmonellosis,[94,95] yersiniosis,[96–98] or infection with *Campylobacter* spp.[99] Although sexual transmission of enteric reactive arthritis has not been reported, such cases are likely to have occurred, perhaps especially in men who have sex with men (Chapter 68).

The incidence and prevalence of reactive arthritis is uncertain and may vary geographically.[2,7,72] In one series reported more than 30 years ago,[1] the diagnosis was made in 16 (11%) of 151 consecutively hospitalized adults with acute nontraumatic arthritis, second in frequency only to DGI as a cause of arthritis (Fig. 67-5). Septic arthritis related to injection drug use has become much more frequent in the past three decades and undoubtedly is now among the most common causes of acute arthritis in young adults. Because a corresponding decrease in DGI cases has occurred during this period, reactive arthritis may now be the most common cause of acute arthritis in young persons who are not injection drug users. The overall risk of acquiring reactive arthritis has been estimated to be 1–3% among men with sexually acquired NGU[100,101] and among patients with acute shigellosis,[50] rising to as high as 20–37% for individuals with the HLA-B27 haplotype.[52,82,101]

Although enterically acquired reactive arthritis may occur in children (in whom infectious diarrhea is most common), most patients are adults. The modal age of patients with sexually acquired reactive arthritis is in the fourth decade, compared with the third decade for patients with DGI and most other STDs. This may be partly because some series have included patients whose reactive arthritis was not sexually acquired or patients with recurrent disease. In most series, 80–90% of patients with reactive arthritis have been whites, and most of the remainder have been African Americans.[8,58,59,100] Differences in racial susceptibility remain poorly defined because many studies do not report the racial compositions of the patients studied. It is likely that African Americans are less susceptible, however, in part because they have a lower prevalence of the HLA-B27 haplotype than whites.

Enteric reactive arthritis has been recognized to affect women somewhat less frequently than men, with reported

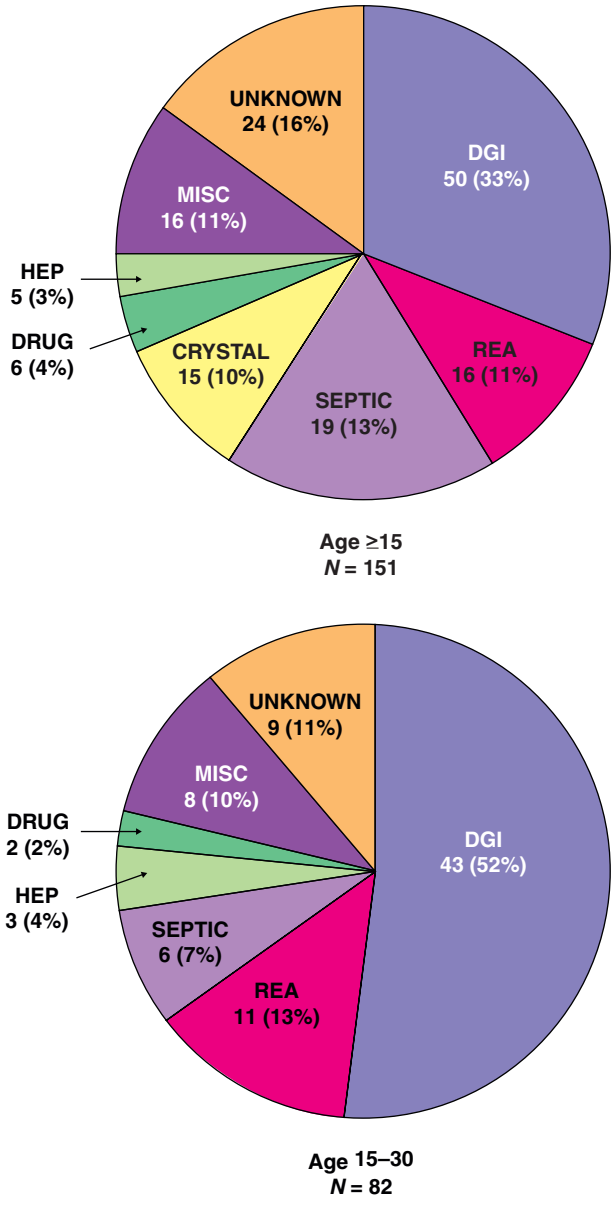

FIGURE 67-5. Diagnosis in 151 consecutive adults (age >15 years) hospitalized in Seattle because of acute, nontraumatic arthritis of <14 days duration. REA (reactive arthritis) includes postgonococcal arthritis; DRUG denotes drug-induced arthritis; HEP denotes hepatitis B infection (From Handsfield HH. Disseminated gonococcal infection. *Clin Obstet Gynecol* 1975; 18: 131.).

male-to-female ratios that vary from 1:1 to 10:1.[7] Many series of patients with reactive arthritis have been drawn predominantly from male populations (e.g., from military installations, ships' companies, and military or veterans' hospitals). By contrast, few women have been included in most series of sexually acquired reactive arthritis; in one example, women accounted for only 20 (3.6%) of 557 cases.[7] In another series, however, 13 (52%) of 25 patients with reactive arthritis were women.[102] Clinical presentations of reactive arthritis described in 29 women, as well as their HLA haplotypes and their clinical courses, were reported to be similar to those in men.[103] Nonspecific rheumatic complaints and overt reactive arthritis have also been documented in women with histories of salpingitis, gonorrhea, bacterial urinary-tract infection, and trichomoniasis.[104] A high prevalence of musculoskeletal disorders in the sexual partners of men with reactive arthritis was found, and an association of salpingitis with radiologic evidence of sacroiliitis has been reported.[7,105] These observations suggest that reactive arthritis may be more frequent in women than commonly realized, and that it may be sexually acquired.[106]

CLINICAL AND LABORATORY MANIFESTATIONS

The clinical manifestations of reactive arthritis may be accompanied by urethritis and perhaps cervicitis, conjunctivitis, and mucocutaneous inflammatory lesions. Although it is uncommon for all of these manifestations to be observed at the time of presentation, most patients eventually develop all four features, especially if they are HLA-B27-positive.[51,56,107] Estimated frequencies of these manifestations at presentation and during follow-up are shown in Table 67-2. The articular, mucocutaneous, and ocular manifestations usually follow onset of urethritis or diarrhea by 1–4 weeks, although delays of several months may be seen.[7,51,53,55] The American College of Rheumatology (ACR) and the Third International Workshop on Reactive Arthritis[108] have established criteria for the diagnosis of reactive arthritis (Tables 67-3 and 67-4). The Third International Workshop proposed that the criteria should include specific clinical features, such as oligoarthritis or asymmetric arthritis of the lower limb, with or without inflammation of tendons or the sacroiliac joint, plus evidence of gastrointestinal or genitourinary infection within the past 4 weeks with known reactive arthritis-inducing organisms. The ACR criteria require the presence of peripheral arthritis occurring in association with urethritis (men) or cervicitis (women), or with conjunctivitis.[109]

Urogenital inflammation

Patients with sexually acquired reactive arthritis frequently give histories of recent sexual contact with a new partner, followed by the development of urethritis that is indistinguishable from uncomplicated NGU.[51,55] Gonococcal urethritis has been reported in up to 20% of patients, but concomitant chlamydial infection has not always been excluded. Furthermore, culture and other tests for *C. trachomatis* may miss infections,[5,110] and increasingly, studies of reactive arthritis using more sensitive nucleic acid amplification tests of joint fluids and synovial tissues are reporting the presence of Chlamydia.[111-114] Some studies suggested that many patients with reactive arthritis had had nonbacterial prostatitis,[49,51,115,116] but prostatitis was not always clearly differentiated from urethritis, cystitis, or other forms of lower urogenital tract inflammation.

Urethritis occurs in up to 90% of patients with enteric reactive arthritis[51,52,96,99] and has been documented in children[117]

Table 67-2. Frequencies of Clinical Manifestations in Patients with Reactive Arthritis Syndrome

	Percent of Patients	
	Initial Attack[a]	Entire Course[b]
Urogenital Inflammation		
Urethritis (criteria not specified)	85	87
Cervicitis (criteria not specified)	71	NA
Arthritis		
Monoarticular	14	3
Polyarticular	81	86
Arthralgia only	0	9
Sacroiliitis or back pain	49	21
Heel pain	40	Not recorded
Tendinitis or tenosynovitis	25	25
Fusiform dactylitis	17	Not recorded
Ocular involvement		
Conjunctivitis	57	50
Uveitis	0	12
Mucocutaneous involvement		
Balanitis/vulvovaginitis	39	69
Stomatitis	31	17
Keratoderma blennorrhagica	21	18
Nail changes	9	16
Other		
Cardiac	0	9
Neurologic	1	2
Diarrhea	14	12

and in sexually inactive adults with enteric reactive arthritis, observations that imply an immunologic pathogenesis of urethritis. Therefore, genital inflammation in reactive arthritis should not always be assumed to be sexually acquired,[7,8] especially when reactive arthritis follows infectious diarrhea. Nevertheless, the possibility of sexual acquisition should be explored even in these cases, and patients' sexual partners should be examined. Symptoms or signs of urethritis or pyuria have been documented in 30% of women with reactive arthritis[102,103] but standardized criteria for lower genital tract inflammation often were not used (Chapter 55). A number of studies[7,104–106] suggest that cervicitis, urethritis, cystitis, and salpingitis may all be important, but the spectrum of urogenital inflammation in women with reactive arthritis remains undefined.

Arthritis

A wide range of articular disease occurs. Asymmetric polyarticular synovitis and tendinitis are often seen initially, followed by persistence of signs and symptoms usually referable to a few joints. Arthritis typically begins in the distal weight-bearing joints (knees, ankles, feet), often with knee effusions and fusiform dactylitis ("sausage digits") (Fig. 67-6). Chlamydial reactive arthritis, which more often encompasses a monoarticular or oligoarticular clinical picture with predominant distal extremity involvement, may differ from nonchlamydial disease, where more joints are involved, usually in the upper extremities.[118] Sacroiliitis is common in reactive arthritis, occurring in up to 10% of cases acutely and in higher proportions of those with chronic relapsing reactive arthritis; often it is detected as asymmetric subclinical radiographic abnormalities (Fig. 67-7), especially in sexually acquired cases.[7,51,118,119] Tendon-insertion sites (entheses) are common sites of inflammation, the basis for the rheumatologic classification of reactive arthritis as an enthesopathy.[72,120]

FIGURE 67-6. Reactive arthritis (REA): severe chronic swelling of the metacarpalphalangeal and interphalangeal joints, part of the widespread involvement of joints which may occur. (Reprinted with permission from HS Lambert et al: *Slide Atlas of Infectious Diseases: Sexually Transmitted Diseases.* 1982, Fig. 9.12 [Slide 12].)

FIGURE 67-7. Reactive arthritis (REA); sacroiliitis: Sacroiliac joints are shown in Ferguson (top view) and posteroanterior projections (bottom). Moderate narrowing and sclerosis appear on adjacent margins of the middle third of the sacroiliac joint on the left; the sacroiliac joint on the right is relatively normal. Asymmetry is more common in reactive arthritis and psoriatic spondylitis than in idiopathic ankylosing spondylitis. (From Berens DL. Roentgen features of ankylosing spondylitis. *Clin Orthop Relat Res* 1971; 74: 20–33.)

Common enthesopathic sites include the insertion of the Achilles tendon and the plantar fascia. In contrast to ankylosing spondylitis and other spondyloarthropathies, spinal involvement is uncommon in reactive arthritis. Radiographic evidence of sacroiliitis has been reported in association with chronic prostatitis[115] and salpingitis[105,106] without other manifestations of reactive arthritis; it remains to be determined whether this represents a variant of reactive arthritis.

Mucocutaneous manifestations

Mucocutaneous lesions are common in sexually acquired reactive arthritis and in disease following shigellosis, but reportedly they are uncommon in reactive arthritis associated with *Salmonella, Campylobacter,* or *Yersinia* infections.[7] These lesions are usually painless and are easily overlooked. Circinate balanitis is the most common cutaneous manifestation, typically occurring in 20–40%[7] and perhaps up to 85%[51] of men with sexually acquired reactive arthritis. In uncircumcised men, circinate balanitis typically appears as a painless, serpiginous, "geographic" dermatitis of the glans penis (Fig. 67-8) and is diagnostic of reactive arthritis. In circumcised men, circinate balanitis often takes the form of hyperkeratotic papules that, except for their location, closely resemble the other characteristic skin lesion, keratoderma blennorrhagica (Fig. 67-9). Erosive vulvitis, perhaps the female equivalent of circinate balanitis, has been documented in some women with reactive arthritis.[119]

Lesions of keratoderma blennorrhagica can begin as erythematous macules that gradually thicken and enlarge to form hyperkeratotic papules and plaques, sometimes with red halos and occasionally with central clearing. The lesions of keratoderma blennorrhagica resemble those of psoriasis both clinically and histologically, and some well-documented cases of reactive arthritis have evolved to become clinically indistinguishable from chronic psoriatic arthritis.[7,8,72,121,122] Keratoderma blennorrhagica most commonly involves the

FIGURE 67-8. Circinate balanitis in reactive arthritis (REA).

plantar surfaces of the feet (Fig. 67-9) and occasionally the palms of the hands, but it may occur anywhere. Cutaneous manifestations have been reported to be more common (up to 20%) in patients with sexually acquired reactive arthritis than in those with the enteric form.[7]

In up to 30% of patients with reactive arthritis, especially those with sexually acquired form, shallow, painless ulcers occur on the palate, tongue, buccal mucosa, lips, tonsillar pillars, or pharynx (Fig. 67-10).[56,123] The nails are involved in up to 15% of patients, manifested by thickening and brown-yellow discoloration due to subungual hyperkeratosis.[2,3,37,51,56] Erythema nodosum occasionally occurs in reactive arthritis following yersiniosis but seems to be rare in other forms of the disease.[7]

Ocular inflammation

Ocular manifestations occur in up to half of patients with acute sexually acquired reactive arthritis and in up to 90% of cases following shigellosis.[7] Conjunctivitis, often sufficiently

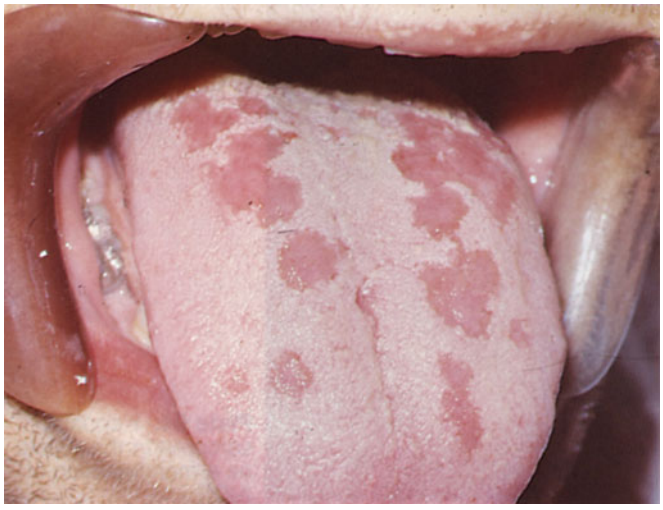

FIGURE 67-10. Superficial ulcerations of the tongue in reactive arthritis (REA).

mild to escape detection in a cursory examination, is the most common ocular manifestation.[37,51,56] Iritis or more extensive uveitis ultimately develops in up to 10% of patients,[2,7,51,56] although these are uncommon at presentation.

■ OTHER SYSTEMIC MANIFESTATIONS

Acute reactive arthritis is often accompanied by malaise, fever, anorexia, and weight loss. Transient and usually benign electrocardiographic abnormalities, including atrioventricular conduction disturbances, ST-segment elevations or depression, or nonspecific T-wave changes, occur in 9–30% of acute episodes.[51,124] Complete heart block, myocarditis, pericarditis, acute aortitis with aortic-valve incompetence, and heart failure are rare but well-documented sequelae, especially in sexually acquired cases.[125,126] Rare complications, each occurring in fewer than 1% of patients, include peripheral neuropathy, hemiplegia, meningoencephalitis, generalized lymphadenopathy, pleuritis, pneumonitis, thrombophlebitis, and amyloidosis.[2,51]

Laboratory features

Several laboratory abnormalities are common although not specific. The erythrocyte sedimentation rate is typically elevated, exceeding 50 mm/hour in nearly one-half of patients, [51] but the degree of elevation does not correlate with the severity of clinical manifestations. Leukocytosis, with up to 20,000 leukocytes/mm^3, and mild anemia are common. Antinuclear antibodies, rheumatoid factor, cryoglobulins, or circulating immune complexes are occasionally present.[2,7,51] C-reactive protein (CRP) is usually elevated during the acute phase; in one study patients with chlamydial reactive arthritis had lower CRPs than patients with nonchlamydial reactive arthritis.[118]

Synovial fluid analysis is seldom specific. The results often mimic those of septic arthritis. Leukocyte counts range from 500 to >50,000 cells/mm^3 and are >20,000/mm^3 in about

50% of patients; differential counts usually demonstrate >90% neutrophils. Decreased viscosity, normal or elevated complement levels, decreased ratio of synovial fluid to serum complement concentration,[90] and elevated protein levels are common. Synovial fluid glucose levels are usually normal.

Clinical course

Most initial episodes of acute reactive arthritis resolve completely over 2–6 months, but recovery may be delayed for more than 1 year in up to 35% of patients and indefinitely in a few cases.[7,51] Subsequently, the annual risk of recurrent acute episodes has been estimated at about 15%.[7,51,100] Recurrences may be manifested by any of the clinical features alone or in combination. In one series of 122 patients followed for a mean of 5.6 years, arthritis persisted or recurred in 83%, urethritis or cervicitis in 42%, ocular disease in 31%, circinate balanitis in 29%, and other mucocutaneous lesions in about 25%.[55] The severity of functional impairment caused by chronic or relapsing reactive arthritis is variable. In one study, 34% of patients had sustained disease activity; almost 16% required a change of job, and 11% were disabled for further employment.[55] Other investigators have reported similar rates of persistence or recurrence but with substantially less functional impairment.[127] Death from reactive arthritis is rare, occurring primarily as the result of aortic valve incompetence,[125,126] amyloidosis,[128] or complications of drug therapy.[51]

HEPATITIS B VIRUS INFECTION

The occurrence of articular symptoms early in the course of viral hepatitis was first reported by Robert Graves in 1843 and was "rediscovered" in the 1970s.[129–134] Although HBV may invade the synovium,[130] several studies have confirmed the pathogenic role of immune-complex deposition in this syndrome. For example, complement levels are low in serum and synovial fluid during active joint inflammation and return to normal as the arthritis abates. Peak serum hepatitis B surface antigen (HBsAg) titers, synovial-membrane and fluid viral antigen, and cryoprecipitates containing HBsAg, complement components, IgA and complement-fixing IgG antibodies, all have been detected during acute arthritis.[131–133]

Generalized arthralgias occur in up to 50% of patients during the prodrome of hepatitis B. Ten to twenty percent of patients have overt polyarthralgias or polyarthritis, usually with symmetric involvement of the hands, knees, ankles, shoulders, wrists, and feet.[129–134] A urticarial rash, usually involving the lower extremities, occurs in about 25% of patients with arthralgias and in 50% of those with overt arthritis. Vasculitis is not associated with acute heptatitis B infection but can be seen in the chronic form of the disease after the development of polyarteritis nodosa. The acute clinical syndrome closely parallels classical descriptions of serum sickness.[12] The onset of overt hepatitis usually coincides with resolution of the musculoskeletal and cutaneous manifestations. Because many patients with hepatitis B are anicteric, laboratory assessment of hepatic function and laboratory tests for HBV infection are indicated for all patients with acute polyarthritis or other manifestations consistent with immune-complex disease, regardless of the presence or absence of jaundice or hepatomegaly.[134]

SYPHILIS

A small minority (probably 1%) of patients with secondary syphilis have overt osseous or synovial involvement.[135] Acute periostitis, sometimes mimicking acute arthritis, is the most common of these lesions but some cases of true arthritis result from synovial invasion by *Treponema pallidum*, as demonstrated by darkfield examination.[136] Indirect immunologic mechanisms may be involved in some cases; complement consumption, circulating immune complexes, and immune-complex glomerulonephritis all have been documented in patients with primary, secondary, and congenital syphilis.[12,137] In late syphilis, acute or chronic arthritis is usually the result of direct spread of infection into the synovial space from adjacent osteomyelitis or periostitis.[135] The Charcot joint is believed to be traumatic in origin, the indirect result of syphilitic neuropathy and, perhaps, microvascular disease.[135,138,139] Neuropathic joints almost always involve the lower extremities, although multiple neuropathic joints in the upper limbs and spine were documented in one patient whose occupation required heavy use of the upper body.[139] A case of vertebral syphilitic osteitis in an adult has also been reported.[140]

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum (LGV) occasionally has been associated with a syndrome that resembles serum sickness, including polyarthritis, rash, cryoglobulinemia, and circulating rheumatoid factor.[141–144] It is uncertain whether direct synovial infection occurs; *C. trachomatis* antigen may have been demonstrated in synovial fluid of patients with LGV,[141] but specific identification of LGV strains in synovial fluid has not been reported.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Rheumatic manifestations occur with modest frequency in persons with AIDS and earlier stages of infection with HIV.[145,146] Table 67-5 lists the most common conditions seen in these patients. Typical and limited forms of reactive

Table 67-5. Rheumatic Manifestations Associated with HIV Infections

- Nonspecific arthralgia
- Septic arthritis-bursitis

arthritis may be common; these have been documented both in HLA-B27-positive and -negative persons with AIDS.[147–149] In particular, seronegative spondyloarthropathy occurs in patients with advanced AIDS. This condition develops in the face of depletion of CD4-positive lymphocytes, indirectly emphasizing the possible role of CD8-positive cytotoxic T cells and their interaction with HLA-B27.[88] Most AIDS patients with reactive arthritis exhibit a syndrome that lacks conjunctivitis and urethritis. Asymmetric oligoarthritis is usual, accompanied by enthesitis. Extra-articular features may include circinate balanitis, keratoderma blennorrhagica, and uveitis. In those who develop sacroiliitis or spondylitis, 70% are HLA-B27-positive.[146,149] The prevalence of rheumatologic manifestations thought to be reactive arthritis in HIV-infected persons varies in different reports and in different demographic groups, however, and it remains a matter of some disagreement. Reactive arthritis has been reported to range from 0.1% to 11% in prevalence. In one prospective study, the prevalence of reactive arthritis was low at the onset of the study (0.5%), and the incidence over the next 5 years was no different in HIV patients compared to an HIV-negative matched cohort.[150]

Patients with other HIV-associated arthropathies often present with oligoarticular or polyarticular asymmetric arthritis without extra-articular manifestations. These arthropathies may resemble those of reactive arthritis, rheumatoid arthritis, or psoriatic arthritis. These patients, who are usually men, are often HLA-B27-negative. Significant clinical improvement may occur in response to antiretroviral therapy. In HIV-infected women, the rheumatologic manifestations seem to be less frequent and clinically different than in men. Raynaud's phenomenon and livedo reticularis are the most common features in women, followed by vasculitis, lupus-like syndromes, and myositis.[151] The association of psoriasis and psoriatic arthritis with AIDS has also been well recognized.[152,153] The skin condition may precede AIDS or it may occur at any of its stages, and it may worsen as immunodeficiency progresses.

OTHER STDs ASSOCIATED WITH ARTHROPATHY

Mycoplasma hominis has rarely caused septic arthritis, often in association with postpartum fever and bacteremia.[154–156] *U. urealyticum* is an occasional cause of acute monoarticular or polyarticular septic arthritis in patients with hypogammaglobulinemia.[157–160] Herpes simplex virus, Epstein-Barr virus, and cytomegalovirus infections are rarely associated with acute monoarticular arthritis that results from direct synovial infection. However, these infections are more commonly associated with polyarthritis, probably related to circulating immune complexes.[161–165] Acute arthritis is a major manifestation of chronic meningococcemia and may also occur during or following acute meningococcemia, which may rarely be transmitted sexually[166]; the clinical picture may mimic that of DGI.[166–170] In addition, acute noninfective arthritis occasionally follows meningococcemia. This syndrome is not associated with the HLA-B27 haplotype and probably results from immune-complex deposition. Finally, antimicrobial therapy of STDs occasionally causes allergic reactions manifested by serum sickness-like illnesses with dermatitis, arthralgias, or arthritis-associated with high concentrations of circulating immune complexes.[12]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of acute arthritis is broad, but many cases are related to sexually transmitted infections. Fig. 67-5 shows the diagnoses for 151 consecutive adults (age >15 years) who were hospitalized in the 1970s for acute, nontraumatic arthritis or tenosynovitis of 14 days duration.[1] DGI was documented by isolation of *N. gonorrhoeae* from 38 patients (25%) and was suspected on the basis of clinical features and response to antibiotic therapy in 12 others (8%). Sixteen patients (11%) had reactive arthritis, including postgonococcal arthritis; none of these had symptoms or signs of enteritis. None of five patients who had arthritis associated with acute HBV infection gave histories of drug injection use, and arthritis in two of six patients was attributed to reactions to antimicrobial agents used to treat gonorrhea. Thus, 73 (48%) of the patients in this series had arthritis that was directly or indirectly related to an STD. Among the subset of 82 patients who were 15–30 years of age, 43 (52%) had DGI and 58 (71%) were related to sexually transmissible infections. In recent years, however, the decreasing incidence of gonorrhea and the marked decline in prevalence of gonococcal strains that are likely to disseminate have reduced the frequency of DGI in many geographic areas. Nevertheless, in most settings the proportion of acute arthropathy that is directly or indirectly due to an STD undoubtedly remains high. Sexually active younger persons (e.g., ≤40 years) in particular who present with new onset of unexplained

arthralgia or arthritis should routinely be evaluated for common STDs. Infection with HIV should also be considered in persons who present with otherwise unexplained acute arthritis.

Reactive arthritis and DGI probably remain the two most common causes of sexually acquired arthritis and either may present with a combination of arthropathy, genitourinary inflammation, dermatitis, and conjunctivitis or iritis. Sometimes this poses a diagnostic dilemma, but in most cases, the correct diagnosis can be made readily using clinical criteria. The two syndromes can usually be differentiated from one another by their characteristic mucocutaneous lesions, if present. Several surveys have documented differing predilections of reactive arthritis and DGI for various joints or groups of joints, but the overlap in affected joints is considerable (Fig. 67-4) so that the pattern of joints involved is nonspecific. The exceptions are sacroiliitis, typical fusiform dactylitis (Fig. 67-6), or calcaneal enthesopathy, which are common in reactive arthritis and have not apparently been observed in patients with DGI.[51,120] Tenosynovitis is often considered evidence for DGI, but it may also be the sole feature in reactive arthritis and does not reliably distinguish DGI from reactive arthritis or other acute arthritides. The presence of NGU, conjunctivitis, or radiographically confirmed sacroiliitis almost always indicates reactive arthritis rather than DGI.

Genital, anorectal, or pharyngeal gonococcal infection can be identified in 70–80% of patients with DGI or in their sex partners, but it has also been documented in up to 20% of patients with the initial presentation of reactive arthritis.[51] These proportions might be higher with more sensitive DNA amplification tests, but no data have been reported. All potential mucosal sites of infection should be tested for gonococcal and chlamydial infection, regardless of the presence or absence of local symptoms. *N. gonorrhoeae* was identified by culture or by the direct polyclonal fluorescent antibody test in blood, synovial fluid, or skin lesions of 52 (51%) of 102 patients with DGI in a Seattle series and in 23 (47%) of 49 patients studied in Boston.[10] Recent sex partners should also be examined; DGI is sometimes confirmed bacteriologically only by detection of gonorrhea in a partner.[1,171] Similarly, *C. trachomatis* should be sought in patients with reactive arthritis and their sex partners.

Synovial-fluid analysis and tests for *N. gonorrhoeae* (ideally, both culture and DNA amplification) are important in distinguishing patients with crystal-induced arthritis from those with gonococcal septic arthritis. Other forms of septic arthritis should also be sought routinely with specific tests for other bacteria. Synovial fluid leukocyte and differential counts are useful in establishing the presence of inflammation but do not establish its cause. Protein, glucose, and complement levels provide nonspecific but sometimes useful information. Radiographs of peripheral joints, tests for serum uric acid levels, C-reacive protein, an erythrocyte sedimentation rate and assays for rheumatoid factor, antinuclear antibodies, complement levels, and circulating immune complexes usually are not indicated as routine tests in acute arthritis, although they may be diagnostic in selected clinical settings. It has been argued that HLA typing is not diagnostically useful[172] because the diagnosis of reactive arthritis is more reliably based on clinical criteria and because the results of typing seldom affect therapy. On the other hand, a positive test may solidify an otherwise equivocal diagnosis of reactive arthritis.[173]

The diagnosis of DGI is unequivocal if *N. gonorrhoeae* is identified in blood, synovial fluid, a skin lesion, or cerebrospinal fluid. The diagnosis is also secure if a mucosal gonococcal infection is documented in the presence of a typical clinical syndrome that responds promptly to appropriate antimicrobial therapy,[1,22] especially if other causes of acute arthropathy are excluded. The presence of gonorrhea in a sex partner also supports the diagnosis.

As indicated above, the ACR defines reactive arthritis as an episode of peripheral arthritis of >4 weeks duration occurring in association with urethritis or cervicitis or occurring simultaneously with conjunctivitis.[56] These criteria will accurately classify the majority of patients with sexually acquired reactive arthritis. The occurrence of ocular inflammation or the typical mucocutaneous lesions, documentation of the HLA-B27 haplotype, and clinical or radiologic evidence of sacroiliitis helps to confirm the diagnosis. The pattern of joint involvement and other clinical and laboratory features can help distinguish the reactive arthritides from rheumatoid arthritis and arthropathies due to immune-complex deposition.

Although most cases of DGI and reactive arthritis can be diagnosed by the above criteria, neither set of criteria is completely satisfactory for the initial evaluation of patients presenting with acute arthritis. The criteria for DGI require up to several days to obtain microbiologic results, and those for reactive arthritis may require a month or more of clinical observation. The algorithm illustrated in Fig. 67-11 represents a diagnostic approach to reach a tentative diagnosis at the time of presentation of a sexually active patient with acute arthritis. The algorithm represents the logic used in analyzing the results of the initial clinical and laboratory examinations, not necessarily a procedural sequence. For example, evaluation for genital inflammation is indicated for all patients, regardless of whether a probable diagnosis is reached before the relevant branching point.

Examination for crystals by polarizing microscopy and for bacteria by Gram's stain should be performed on synovial fluid taken from patients with arthritis; occasionally these will lead to an immediate diagnosis. If no synovial fluid is available or its analysis is nondiagnostic, the results of a careful examination of the skin may be helpful. The presence of typical papular, pustular, or hemorrhagic lesions (Fig. 67-1) in various stages of evolution, located primarily on the

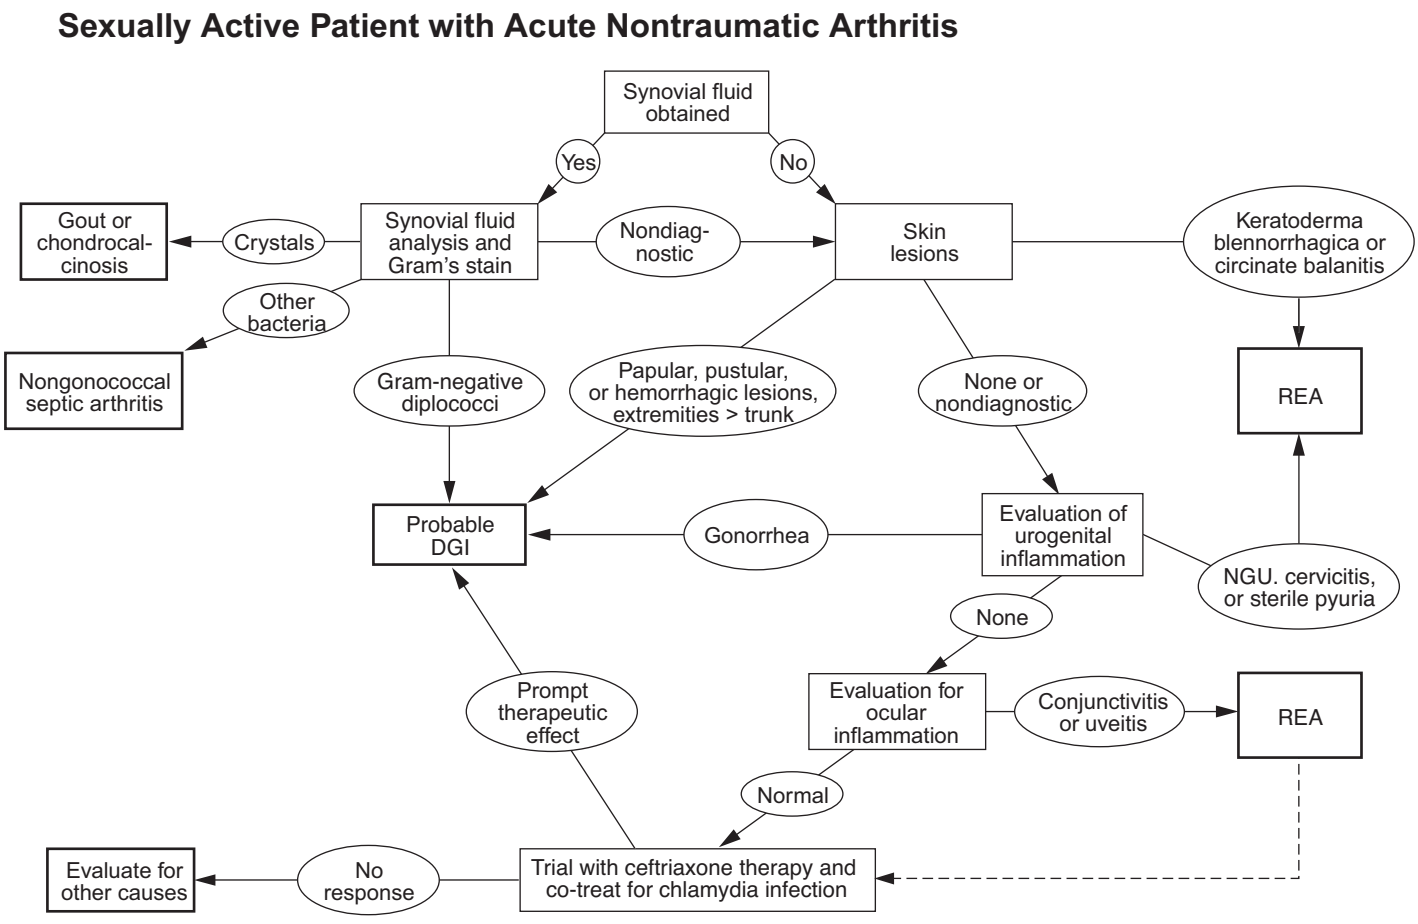

FIGURE 67-11. Algorithm for the presumptive diagnosis of acute nontraumatic arthritis in sexually active patients.

extremities, is strong evidence of DGI. On the other hand, circinate balanitis (Fig-67-8) or keratoderma blennorrhagica (Fig.67-9) in patient with acute arthralgias or arthritis are diagnostic of the reactive arthritis syndrome. In the absence of typical skin lesions, the results of the evaluation for genital inflammation may provide additional support in establishing a diagnosis. Gonococcal urethritis or cervicitis, identified by the presence of intracellular gram-negative diplococci, supports a tentative diagnosis of DGI in these patients; the presence of NGU or other nongonococcal genital tract inflammation implies reactive arthritis. For patients who lack both diagnostic mucocutaneous lesions and urogenital inflammation, conjunctivitis or uveitis may accompany reactive arthritis, although the diagnosis may remain uncertain if ocular inflammation is not present. Regardless of the preliminary diagnosis, it is essential to obtain cultures or other sensitive and specific tests (e.g., nucleic acid amplification tests for *C. trachomatis* and *N. gonorrhoeae*) from the cervix, urethra, and rectum and, in addition, specimens from the pharynx, blood, and synovial fluid for *N. gonorrhoeae*. Other potentially useful tests, not presented in the algorithm, include HLA typing, tests for HIV and HBV infection, and radiographic imaging of the sacroiliac joints.

In some cases, a trial of antibiotic therapy is warranted. Antibiotic-responsive, culture-negative acute arthritis in a sexually active young person may be due to DGI, although probably less frequently than found in older case series when DGI was more common than it is today. Failure of response to treatment at this point necessitates further evaluation for an acute presentation of a connective tissue disorders such as rheumatoid arthritis or systemic lupus erythematosus. Blood cultures must be obtained before the therapeutic trial not only to detect gonococcemia but also to help exclude other septic arthritides and infective endocarditis as a cause of arthritis. If monoarticular arthritis persists during continued observation, synovial biopsy may be required to exclude tuberculosis, fungal infection, or a synovial tumor.

MANAGEMENT

The treatment of DGI is discussed in Chapter 35. Ceftriaxone is the mainstay of antibiotic therapy. DGI may require higher dosages of antibiotics and longer durations of therapy. Hospitalization is indicated when the diagnosis is uncertain, the patient has localized joint disease that requires aspiration, or the patient cannot be relied upon to comply with treatment.

Closed drainage of purulent effusions should be performed once or twice, which is all that is usually necessary. Nonsteroidal anti-inflammatory drugs (NSAIDS) may be indicated to alleviate pain and are often useful to prevent recurrent joint effusions. Open drainage of suppurative joints is rarely necessary[1,22] but may be needed for joints that are difficult to drain percutaneously, such as the hip.[10] All persons who experience more than one episode of DGI should be evaluated for complement deficiency.

In reactive arthritis, NGU or cervicitis should be treated, usually with doxycycline or azithromycin, as described in Chapter 32. Similarly, antimicrobial therapy may be indicated for infectious enteritis, depending in part on the specific microbial etiology. In most cases, treatment of the triggering infection after the signs and symptoms of reactive arthritis have appeared is unlikely to affect the course of established arthritis, mucocutaneous lesions, or ocular manifestations; the mainstay of treatment is administration of NSAIDS, which are used for control of the articular symptoms of reactive arthritis but do not shorten the course or diminish the extent of disease. Therapeutic trials with different NSAIDS and at different doses may be necessary to balance efficacy and tolerance in individual patients. Corticosteroids do not benefit axial symptoms but may provide short-term relief for peripheral joints particularly when they are injected into the joint(s).[176] Corticosteroids may be useful to treat certain of the extra-articular manifestations such as iritis; topical applications of corticosteroids may be useful for circinate balanitis and keratoderma blenorrhagica.[174,175] For recalcitrant cases that resist treatment with these drugs, treatment with disease-modifying antirheumatic drugs may be attempted. Sulfasalazine is effective for limited time in some cases, particularly in the treatment of peripheral joints. Methotrexate or other immunosuppressive agents (e.g., azathioprine and cyclosporine) have also been advocated to shorten the duration of symptoms.[109,175] Treatment with biological tumor necrosis factor antagonists, such as infliximab or etanercept might have promise for the treatment of reactive arthritis in view of their documented efficacy against psoriatic arthritis and other spondyloarthropathies. On theoretical grounds, however, patients with reactive arthritis have lower levels of circulating TNF alpha than patients with other types of spondyloarthropathies[176,177] (although higher than in normal volunteers[178]), and inhibition of this cytokine may not provide the same level of benefit. No control trials have been reported, but a small open label study and case reports have suggested clinical benefit.[179,180] Most cases of reactive arthritis should be managed in consultation with a rheumatologist.

Arthritis due to HBV infection is self-limited and usually does not require drug therapy, although symptoms may be ameliorated by transient use of aspirin or other nonsteroidal antiinflammatory drugs. Patients with arthritis due to syphilis, LGV, or other sexually transmitted infections should be treated with standard antibiotic regimens. Arthritis associated with HIV is best managed symptomatically with NSAIDS and may also respond to antiretroviral therapy.

68 Sexually Transmitted Intestinal Syndromes

Anne M. Rompalo and Thomas C. Quinn

Sexually transmitted intestinal syndromes involve a wide variety of pathogens infecting multiple sites of the gastrointestinal tract. Infections of the anus and rectum are frequently sexually transmitted and occur primarily in men who have sex with men (MSM) and heterosexual women who engage in anorectal intercourse. STD pathogens such as syphilis, gonorrhea, condyloma acuminata, lymphogranuloma venereum (LGV), granuloma inguinale (donovanosis), herpes simplex virus (HSV), and non-LGV strains of *Chlamydia trachomatis* have been recognized as causing anorectal infection[1–6] (see Fig. 68-1). In addition, infections with pathogens that have traditionally been associated with food or waterborne acquisition or with foreign travel (for example, *Giardia lamblia, Entamoeba histolytica, Campylobacter, Shigella,* and hepatitis A) are known to occur via sexual transmission.

Over the past several years, the array of sexually transmitted intestinal disorders has become even more complex, with the recognition of opportunistic infections within the gastrointestinal tract of patients with acquired immunodeficiency syndrome (AIDS).[7–9] Prominent among these infections are *Candida, Microsporidia, Cryptosporidium, Isospora, Cyclospora, Mycobacterium avium* complex (MAC), and cytomegalovirus (CMV).[10–12] This diverse array of sexually transmitted infections responsible for intestinal disease remains a challenge to the clinician.

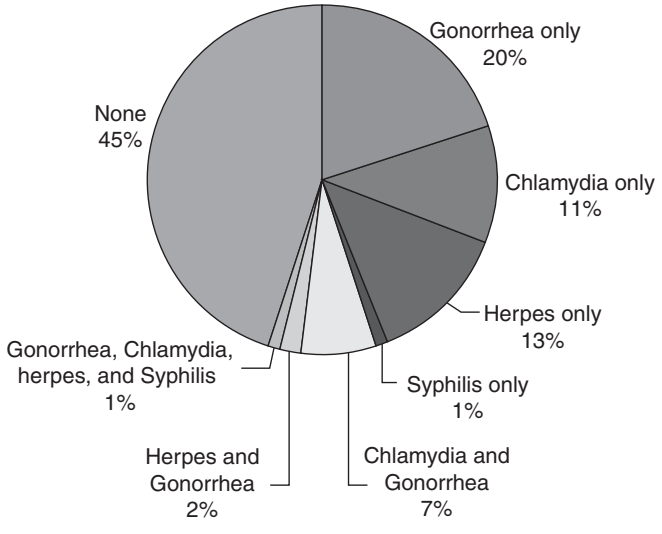

FIGURE 68-1. Frequency of diagnosis of sexually transmitted diseases in male patients with proctitis (n = 101), San Francisco City Clinic, 2001–2002. Data are percent of patients. (From Klausner JD, Kohn R, Kent C. Etiology of clinical proctitis among men who have sex with men. *Clin Infect Dis* 2004; 38: 300.)

DEFINITIONS

Depending on the pathogen and the location of the infection, symptoms and clinical manifestations vary widely. The normal anorectal anatomy is illustrated in Figs. 68-2 and 68-3. The perianal area up to the anal verge is lined by keratinized, stratified squamous dermal epithelium. Thus, perianal lesions caused by syphilis, HSV, granuloma inguinale, chancroid, and condyloma acuminata generally resemble the corresponding lesions as they appear elsewhere in the genital area. The anal canal, which extends 2 cm from the anal verge internally to the anorectal (pectinate or dentate) line, is lined by epithelium which gradually changes from stratified squamous to stratified cuboidal epithelium and is supplied with one of the richest networks of sensory nerve endings in the body. Infection of this area is commonly very painful and results in constipation and tenesmus (ineffectual straining to defecate) due to spasm of the anal sphincter muscle. The external hemorrhoidal venous plexus surrounds the anal verge.

At the anorectal line, the separation of the anal canal from the rectum is indicated by the longitudinal folds called the columns of Morgagni. The internal hemorrhoidal venous plexus occurs at the level of the columns of Morgagni. In this area, the epithelium consists of transitional cuboidal cells, mucus-producing columnar cells, and blind-end crypts.

From the anorectal line cephalad is the rectum, which is lined by columnar epithelium. The term proctitis refers to inflammation of the rectal mucosa. Symptoms include constipation, tenesmus, rectal discomfort or pain, hematochezia (passage of bloody stools), and a mucopurulent rectal discharge which is occasionally misinterpreted by the patient as diarrhea.

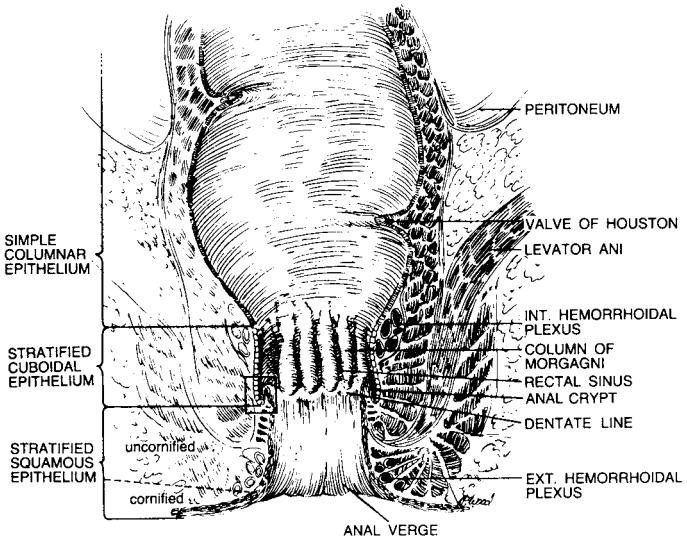

FIGURE 68-2. Diagram of the rectum and anal canal, showing normal anal and rectal structures with the types of epithelium lining the anus and rectum. The box outlining the anal crypt is enlarged in Fig. 68-3.

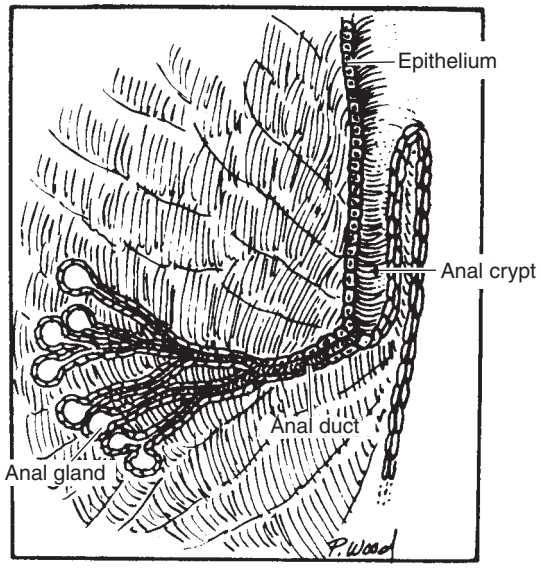

FIGURE 68-3. Diagrammatic representation of the anal crypt. The anal crypts are located along the dentate line and consist of anal ducts which penetrate into muscle. These ducts are lined by both stratified squamous and mucus-secreting cells.

Although stretching of rectal tissue causes pain, the area is insensitive to other direct stimuli such as a rectal biopsy. Hence, infections which involve the rectum but spare the anus are relatively painless. Sigmoidoscopic findings may range from normal mucosa with only mucous present to diffuse inflammation of the mucosa with friability or discrete ulcerations. If these sigmoidoscopic findings are limited to the rectum and further passage of the sigmoidoscope reveals normal mucosa above 15 cm, the condition is properly termed proctitis; if the mucosa is abnormal as high as the sigmoidoscope is passed, the condition probably represents proctocolitis, which could be confirmed by colonoscopy. Proctitis and proctocolitis generally have different infectious etiologies. Rectal biopsy provides histologic confirmation of proctitis, and findings may reveal nonspecific inflammation or changes highly suggestive of certain infections such as LGV, HSV, or syphilis.[13]

Enteritis is an inflammatory illness of the duodenum, jejunum, and/or ileum. Sigmoidoscopy shows no abnormalities. Infectious enteritis is usually contracted either by ingestion of pathogens present in feces,contaminated water or food, or by certain sexual practices or other forms of human contact which result in fecal ingestion. Symptoms of enteritis consist of diarrhea, abdominal pain, bloating, cramps, and nausea. Additional symptoms may include flatulence, urgency, a mucous rectal discharge, and in severe cases melena. Systemic manifestations such as fever, volume depletion with orthostatic hypotension, acidosis, hypokalemia, malabsorption syndrome, weight loss, and myalgias may also be present. The presence of fecal leukocytes, as determined by Gram stain or methylene blue stain of stool or rectal swabs, usually implicates an invasive inflammatory process but does not differentiate between various sites of involvement of the intestinal tract.

Esophagitis is an inflammatory process of the esophagus which may or may not extend to involve the oral cavity. Infections of the esophagus are most commonly seen in immunocompromised individuals in whom opportunistic pathogens such as *Candida albicans,* CMV, and HSV infections proliferate and induce ulcerations. Symptoms of esophagitis typically consist of dysphagia and odynophagia. Esophograms may reveal irregularity of the mucosa, dilatation, and abnormal motility, and endoscopy frequently reveals either ulcerations or cottage-cheese exudates, depending upon the infecting organism.

ETIOLOGY AND EPIDEMIOLOGY

Microorganisms not requiring an intermediate host may be transmitted by the oral–anal or genital–anal routes.[14] Those pathogens that may cause gastrointestinal illness and have been proven to be or have the potential to be sexually transmitted are shown in Table 68-1. Those enteric pathogens that are infectious at low inoculums, such as *Shigella* (10–100 organisms), *Giardia lamblia* (10–100 cysts), and *E. histolytica* (10–100 cysts), all occur commonly in men who have sex with men (MSM) and are thought to be sexually transmitted through oral–anal sex. Hepatitis A virus appears to be transmitted by oral–anal sex as well.[15]

Sexual transmission of enteric pathogens that are shed in feces may be attributable to ingestion of feces during anilingus or during fellatio of a fecally contaminated penis or to direct intrarectal inoculation of organisms by a fecally contaminated penis. Anorectal infection with conventional STD

Table 68-1. Sexually Transmissible Causes of Intestinal or Anal Infections in Homosexual Men

Bacterial pathogens
Neisseria gonorrhoeae

Adenovirus[a]
Human papilloma virus
Human immunodeficiency virus
Hepatitis A and B viruses

[a]Commonly seen in HIV-infected homosexual men; not necessarily sexually transmitted.

pathogens in men is caused by rectal intercourse. Fomite transmission may occur with the shared use of unsterile equipment for rectal douching and colonic irrigation, or with use of fecally contaminated sex toys. An outbreak of amebiasis has been traced to use of unsterile equipment for colonic irrigation.[16]

In the pre-AIDS era, the role of homosexual transmission of certain enteric infections was recognized with increasing frequency.[17] For example, in San Francisco between 1975 and 1977 the reported cases of amebiasis, shigellosis, hepatitis A, and hepatitis B showed a marked predominance in males between the ages of 20 and 39. Many of these individuals acknowledged MSM contact, including anilingus and fellatio. Fecal cultures of male sexual contacts of men with *Shigella* infection revealed that their contacts were often asymptomatic carriers of *Shigella* of the same serotype. Similarly, several men with *Salmonella* infection reported sexual relations with men who were asymptomatic carriers of the same serotype.[18] A marked predominance of men in this age group was reported for these infections in other parts of the United States as well.[19–23]

In the post-AIDS era, the incidence of acute, sexually transmitted proctitis and proctocolitis initially decreased steadily until the 1990s, but over the past 5 years sexually transmitted gastrointestinal infections have begun to increase worldwide. For example, the US rates of rectal gonococcal infections decreased dramatically, particularly among MSM from 1985 to 1995, but according to the Centers for Disease Control and Prevention's (CDC) MSM Prevalence Monitoring Project, median gonorrhea positivity rates have increased between 1999 and 2003 from 13.7% to 15.3%.[24] Gonorrhea positivity was higher in HIV-positive MSM compared with MSM who were HIV-negative or in those with unknown HIV status: 17.8% versus 12.1%. Recent resurgence in syphilis among MSM has been reported in Western Europe and the United States, with an HIV coinfection rate ranging from 20% in Ireland to nearly 60% in Belgium.[25,26] In 2004, hepatitis A outbreaks as well as LGV outbreaks among MSM have been reported from several countries.[27,28] High levels of concurrent STDs have been reported as common among the recent LGV cases. Current surveys report that safer sexual guidelines are not being followed, particularly in the practice of anal intercourse.[27,28] Other recent reports of sexual behavior among homosexual and heterosexual adolescents, illicit drug users, and heterosexual adults suggest that unprotected anal intercourse is quite common.[27–30]

Heterosexuals could also be at risk for acquiring enteric infections by anilingus, and women can acquire anorectal STD by anal intercourse.[31] However, sexually transmitted anorectal infections with *Neisseria gonorrhoeae, C. trachomatis,* HSV, and human papillomavirus in women

may also result from contiguous spread of infection from the genitalia.

There are very few reports on the prevalence of anorectal infection with the infectious agents named above in patients seen in the STD clinic setting. In a study of 260 MSM with anorectal symptoms, specific infections, including gonorrhea, syphilis, hepatitis, amebiasis, *Shigella*, and LGV, were present in only 21% of the patients.[17] The remainder had condylomata acuminata, hemorrhoids, "nonspecific proctitis," and a variety of rectal conditions such as polyps, fissures, fistulas, perirectal abscesses, ulcers, and foreign bodies. However, in a more detailed microbiologic study of 194 MSM presenting to an STD clinic in the pre-AIDS era with anorectal and/or intestinal symptoms, specific anorectal or enteric infections with one or more pathogens were demonstrated in 80%.[32] In comparison, significantly fewer MSM without such symptoms who were seen in the same clinic were found to be infected with these pathogens. The prevalence of specific infections in each group is shown in Table 68-2.

The same study examined the association of specific pathogens with specific symptoms and signs (Table 68-3). Prominent pathogens in patients with symptoms and signs of proctitis were *N. gonorrhoeae*, HSV, *C. trachomatis* (non-LGV), and *Treponema pallidum*. The only pathogen associated with symptoms and signs of enteritis was *Giardia lamblia*. *Campylobacter* species, *C. trachomatis* (LGV), and *Shigella flexneri* were associated with evidence of proctocolitis. In this study, 22% of symptomatic patients had multiple infections (see Table 68-2). For example, 48% of patients with anorectal gonorrhea were also found to have one or more additional pathogens present, and four or more pathogens were found in several patients. In the absence of a history of foreign travel, the demonstration of infections with multiple enteric pathogens, including "nonpathogenic" protozoa, should suggest sexual transmission. Histories of homosexual behavior have been recorded in other community outbreaks of shigellosis, *giardia*sis, and amebiasis.[21,22,33–35]

In the post-AIDS era, reports of sexually transmitted proctitis and proctocolitis declined markedly, but within the past several years this trend has reversed.[36] A retrospective review of cases of clinical proctitis as documented in medical records of men presenting to the San Francisco municipal STD clinic with symptoms of rectal pain, itching, tenesmus, rectal bleeding or discharge was conducted between January 2001 and December 2002. Gonorrhea and chlamydia infections diagnosed using nucleic acid amplification tests (NAATs) were the most common STDs identified, followed by herpes and syphilis.[37] Although this is the most recent evaluation published, no other pathogens were tested.

Table 68-2. Infectious Pathogens Identified in 194 Homosexual Men With and Without Anorectal or Intestinal Symptoms

Anorectal and Intestinal Pathogens[a]	Symptomatic group, % ($N = 119$)	Asymptomatic group, % ($N = 75$)
Neisseria gonorrhoeae	31*	23
Herpes simplex virus	19*	4
Chlamydia trachomatis	10	5
Treponema pallidum	5	1
Entamoeba histolytica	29	25
Giardia lamblia	14	4
Campylobacter jejuni/C. fetus fetus	7	3
Shigella flexneri	3	1
Clostridium difficile cytotoxin	3	1
Enterovirus (Echovirus 11)	3	1
Patients with any of the above pathogens	80*	39
Patients with more than one of the above pathogens	22*	4

[a]Other infectious agents identified were campylobacterlike organisms, nonpathogenic protozoans, *Candida albicans, Neisseria meningitidis, Ureaplasma urealyticum*, and *Mycoplasma hominis*.

IMPACT OF HIV ON SEXUALLY TRANSMITTED INTESTINAL INFECTIONS

Many studies have documented the interaction of HIV with other STDs. HIV transmission has been associated with a history of syphilis and HSV infections, antibodies to HSV-2[38–41] and *T. pallidum*,[42,43] anal warts,[44] *C. trachomatis*[45] and *N. gonorrhoeae* genital infection,[46] and rectal gonorrhea.[47] Law et al. demonstrated an independent association between HIV seropositivity and histologically diagnosed proctitis in MSM.[48] Although the association between HIV and other STDs is clear, methodological variables have made it difficult to determine whether these infections truly facilitate HIV infection or serve as markers for other risk factors such as unprotected anal intercourse which have a significant impact on HIV transmission.[49]

Evidence is accumulating from in vitro data that STD pathogens may directly facilitate HIV transmission. Activation of HIV-1 from latency by coinfection with HSV-2 has been demonstrated. Recently, Ho et al. showed that neutrophils from HIV-seronegative donors induced HIV-1 replication in chronically infected mononuclear cells in the presence of *C. trachomatis*.[50] Additionally, Moss et al. have shown that successful treatment of gonococcal urethritis is associated with a

twofold reduction in urethral HIV-1 DNA, indicating that treatment of other STDs may decrease HIV-1 transmission.[51]

Other STDs may act as cofactors for HIV-1 transmission, and HIV infection may alter the clinical course of a variety of sexually transmitted gastrointestinal syndromes. Anorectal infections appear to have a more aggressive course in HIV-infected patients. Several studies have demonstrated failure of chancroid ulcers to respond to standard therapy,[52,53] more aggressive course of HSV-2 ulcers with development of giant ulcers,[54] more rapid progression to neurosyphilis,[55] atypical clinical and serologic response to syphilis,[56–58] failure to respond to standard syphilitic therapy,[59,60] and increased rates of anal intraepithelial neoplasia (AIN) in patients coinfected with HPV and HIV-1.[61–64]

Several recent reports of HIV-infected patients referred to colorectal surgery clinics for anorectal diseases from 1983 to 1995 confirm the findings by Quinn et al.[32,65–68] The majority of these patients were MSM with AIDS. Approximately 63% of these patients had more than one lesion on presentation and 20% had more than one pathogen identified.[65,66] The authors describe a wide variety of anorectal lesions, including ulcers, condylomas, fissures, fistulas, and abscesses. The most common etiologies were condylomas and CMV and HSV-2 ulcerations. Idiopathic anorectal ulcerations have also been described, usually in patients with CD4 counts of less than 20/mm^3. No etiology for the lesions was found after routine microbiologic, sigmoidoscopic, and histological examination. These ulcerations appear less responsive to steroid therapy than was previously reported for idiopathic esophageal ulcers.[69]

The gastrointestinal tract appears to be a major target organ in HIV infection.[70,71] In MSM the intestinal tract is a primary site of inoculation. Many reports have been recently published documenting intestinal pathology in HIV-infected patients, and the subject has been well reviewed by Smith.[72] HIV-infected mononuclear cells are found throughout the gastrointestinal tract, and in situ hybridization has detected HIV RNA in presumably neuroendocrine cells from the rectum, duodenum, and esophagus.[73,74] HIV infection is associated with villus atrophy, with or without crypt hyperplasia, decreased villus surface, dysmotility, decreased level of brush border enzymes, gastric acid secretory failure, and bacterial overgrowth.[72,75] It is believed that this is the pathogenesis of the chronic, nonbloody diarrhea with weight loss and malabsorption seen in some AIDS patients without detectable pathogens, which has been termed AIDS enteropathy.[72]

Recent studies indicate that a pathogen is identified in 50–85% of patients with HIV-associated diarrhea.[76–80] Limited studies evaluating the microbiology of HIV-associated gastrointestinal disease found oral–esophageal candidiasis was evident in 80% of the cases, cryptosporidiosis in 30%, *Isospora* in 10%, and *E. histolytica*, *Strongyloides stercoralis*, *G. lamblia*, *Salmonella*, *Mycobacterium*, and CMV infections in approximately 5–10% of patients.[80–82] Evidence of CMV infection of the gastrointestinal tract by culture of biopsy is evident in 30–50% of AIDS patients.[79,80] Recent studies have suggested that in addition to CMV, other viruses such as adenovirus, astrovirus, and picornavirus may play an etiologic role in diarrhea in HIV-infected patients.[83–85] Janoff et al. identified adenovirus in 5 of 67 (7.4%) of infected patients with diarrhea compared with none of 10 AIDS patients without diarrhea.[83] Grohmann et al. identified astroviruses and picornaviruses in 35% of HIV-infected patients with diarrhea compared with 12% without diarrhea ($p < 0.001$).[84] Greenson et al. found that microsporidia and MAC are the pathogens most commonly identified following extensive evaluation for occult enteric infection in patients with AIDS.[77] Kotler et al. found that 62% (27 of 43) of AIDS patients with chronic diarrhea of over 1-month duration had partial villus atrophy with or without crypt hyperplasia on jejunal biopsy.[86] Seventy percent of these patients (19 of 27) had cryptosporidia or microsporidia identified. The villus architecture was normal in most of the AIDS patients without parasitic infection, even if they had other pathogens such as CMV, bacterial enteritis, or mycobacteria. Extensive *M. avium*–complex (MAC) infection was associated with villus atrophy. Malabsorption, as demonstrated by abnormal d-xylose and C14-glycerol-tripalmitin absorption, is likely due to this derangement of the villus architecture. In addition to protozoan parasites, MAC, and HIV-1, chronic bacterial enteropathy due to adherent bacteria alone may produce these symptoms in up to 17% of AIDS patients.[86,87]

The prevalence of gastrointestinal symptoms varies with the stage of disease as well as the population at risk for HIV infection. In developed countries, 40–50% of MSM with AIDS have a history of a clinical prodrome characterized by progressive weight loss of >10% of body weight and diarrhea of unexplained origin, while this clinical presentation is much less frequent among intravenous drug users, transfusion recipients, hemophiliacs, and heterosexual partners of other groups at risk for AIDS. In developing countries, gastrointestinal symptoms are observed in over 80% of AIDS patients, perhaps reflecting a greater exposure and susceptibility to gastrointestinal pathogens common to the specific geographic location, as well as less antibiotic therapy.[81,88,89] Because of the frequency of gastrointestinal complaints in many of these patients, AIDS has been commonly referred to as "slim disease" in many developing countries.

RECTAL GONORRHEA

Klein et al. reviewed the literature on gonococcal infection in women from 1966 to 1977. Rectal gonorrhea was documented in 26–63% (mean 44%) of women with gonorrhea and in 0–20% (mean 4%) the rectum was the only site from which

the organism was isolated.[90] Rectal gonococcal infection in women may be attributable to receptive rectal intercourse.[91,92] Historically, in most cases of rectal gonorrhea among women there is no history of rectal intercourse,[93,94] and the infection is thought to have resulted from contiguous spread of infected secretions from the vagina. However, US survey and other data suggest that, in terms of absolute numbers, approximately seven times more women than MSM engage in unprotected receptive anal intercourse,[95] and clinicians should query regarding specific sexual acts in order to appropriately direct testing. The clinical manifestations of rectal gonococcal infection in women, therefore, have not been well defined.

The prevalence of rectal infection in MSM attending bathhouses in the pre-AIDS era was between 6% and 8%, and among MSM seen at STD clinics it was between 13% and 45%.[90,94,95–97] Although prevalence declined steadily during the 1980s, resurgence of rectal gonorrhea has been noted among MSM in several countries as well as in many US cities since the mid-1990s.[98–102] For example, increases in rectal gonorrhea, unprotected receptive anal intercourse, and multiple, anonymous sexual partners among MSM have been reported in a 12-year trend analysis at the Denver Metro Health Clinic.[103] In previous studies, the rectum was more commonly found to be infected than the pharynx or urethra,[104,105] however, recent studies using nucleic acid amplification testing at all exposed sites report high rates of gonorrhea at all sites.[106,107] Those men identified as sexual contacts for MSM with gonococcal urethritis are usually found to have asymptomatic rectal gonorrhea.[108] However, in MSM who have not been named as gonorrhea contacts and who attend an STD clinic, rectal gonorrhea is more often symptomatic.[109] In 2002, a survey of 564 MSM presenting to the San Francisco City Clinic was conducted before rectal gonococcal culture results were known. Rectal signs and symptoms were determined by clinicians at the time of screening and were defined as rectal discharge, anal fissures, and/or pus identified on anoscopy. Of the 564 men screened, 40 (7.1%) had rectal gonorrhea and 12 of the 40 (20%) had symptoms.[110] Behavioral risks for rectal gonorrhea varied significantly by HIV serostatus. HIV-infected MSM engaging in anonymous sex were at highest risk for rectal gonorrhea. Drug use during anal sex was the strongest risk factor for rectal gonorrhea infection among HIV-negative or unknown HIV status MSM. Thus, asymptomatic infection of the rectum constitutes the main reservoir of gonococcal infection in MSM, and screening based on exposure is warranted for both HIV-infected and uninfected individuals as recommended by the US Department of Health and Human Services and the CDC.[111]

Symptoms, when present, develop 5–7 days after exposure. They are usually mild and include constipation, anorectal discomfort, tenesmus, and a mucopurulent rectal discharge which may cause secondary skin irritation resulting in rectal itching and perirectal erythema.[3] Occasionally, the patient may only notice strands of mucus on his stool or small amounts of blood commonly mistaken for hemorrhoidal bleeding. The relatively high rates of asymptomatic infection and coinfection suggest that isolation of *N. gonorrhoeae* from a homosexual man with anorectal symptoms does not prove causation. Although asymptomatic or mild local disease is common, complications such as fistulas, abscesses, strictures, and disseminated gonococcal infection (DGI) may occur. DGI is typically associated with isolation of arginine, hypoxanthine, and uracil (AHU)—auxotypes, and patients with terminal complement component deficiency are at increased risk.[112, 113]

There is also evidence that specific gonococcal strains may cause preferential infection of the rectum. Compared with heterosexuals, MSM are more likely to be infected with strains with the *mtr* mutation, which confers antibiotic susceptibility and is associated with decreased membrane permeability.[114] These traits are believed to enhance the ability of this strain to survive in the rectum. A study from the United Kingdom evaluated gonococcal isolates from 383 episodes of infections in women and found one serovar, Bajk, isolated with significantly higher frequency in rectal (27%) than genital (17%) infections.[115] In a study of gonococcal infections among MSM in Seattle, utilizing serovar and auxotyping strain typing, Proto/IB-1, Proto/IB-2, and Proto/IB-3 accounted for 70% of anorectal infections among MSM, whereas these same auxotype/serovar classes accounted for only 40% of urogenital gonococcal infections.[116] In this same study, the proportion of anorectal isolates that was erythromycin-resistant (48%) was higher than urogenital isolates from men and women (15%).

Findings of rectal gonorrhea during proctoscopy are nonspecific and limited to the distal rectum.[117–119] The most frequent finding is the presence of mucous in the rectum. The rectal mucosa may appear completely normal or demonstrate generalized erythema with localized areas of easily induced bleeding primarily near the anorectal junction. Histologically, abnormal findings are especially prominent at the anorectal junction around the anal crypts and columns of Morgagni.[117,120] However, only limited histologic studies of gonococcal infection of the distal rectum have been conducted because of the hazards of biopsy of this area with its surrounding venous hemorrhoidal plexus. With gonococcal infection there is patchy disorganization and derangement of these mucus-secreting cells, vascular engorgement, and an infiltration of neutrophils, plasma cells, and lymphocytes throughout the lamina propria.[117,118] These findings are not pathognomonic and concomitant rectal infection with another pathogen may alter the proctoscopic and histopathologic findings.

Although NAATs are quickly replacing traditional diagnostic methods, diagnosis of rectal gonorrhea is usually made by Gram stain and culture of material obtained by swabbing the

epithelial mucosa of the distal rectal area. In men with anorectal symptoms, the anoscope should be used to examine the rectum and obtain exudate for culture and gram staining. In a study of men with symptomatic rectal gonorrhea,[121] the sensitivity of the Gram stain of rectal exudate for identification of gonococci was 79% when obtained through an anoscope versus 53% for blindly inserted swabs. A positive smear showing intracellular Gram-negative diplococci is usually reliable when the smear has been taken and analyzed properly, and therapy can be instituted while awaiting culture results. In men without anorectal symptoms, a sterile cotton swab can be inserted blindly 2–3 cm into the rectum. Cultures performed on material obtained in this way appear to be as sensitive as cultures performed on material obtained by anoscope.[122]

The actual sensitivity of a single rectal culture for gonorrhea is unknown and probably is no greater than the estimated 80% sensitivity of a single endocervical culture in women. Quinn et al. noted that the Gram stain missed 7 of 52 (14%) culture-positive infections in MSM. Selective media used to isolate *N. gonorrhoeae* contain antimicrobials active against other bacteria (for example, vancomycin and colistin). Since none of these antimicrobials inhibits swarming *Proteus* species, which are often present in feces, trimethoprim is commonly added to inhibit *Proteus* in selective media used for rectal cultures.[123]

DNA detection assays are now widely available for detection of gonorrhea in urogenital specimens and are being studied for rectal specimens.[124–129] A recent study compared ligase chain reaction (LCR) with culture for detecting rectal and pharyngeal gonorrhea in MSM attending a genitourinary medicine clinic in London (ref-comment A19). Duplicate rectal samples were obtained from 227 MSM and the results of LCR and culture were concordant in 219 samples (96.5%). The prevalence of rectal gonorrhea by LCR and culture was 7.0% (16/227) and 4.0% (9/227), respectively. The specificity of rectal LCR was 99.5%.[126]

Quinolone-resistant *N. gonorrhoeae* (QRNG) continues to spread. QRNG is now common in parts of Europe, the Middle East, Asia, and the Pacific. In the United States, QRNG has become increasingly common with reports starting in California and Hawaii.[130] According to 2006 data from the U.S. Gonococcal Isolates Surveillance Project (GISP) QRNG has continued to increase among heterosexual males as well as MSM and is present in all regions of the country.[131] Therefore, quinolones should not be used for the treatment of gonorrhea among MSM, regardless of site of infection. Current STD treatment guidelines recommended therapy for urogenital gonococcal infection include a single 125 mg intramuscular injection of ceftriaxone which cures 98.9% of uncomplicated urogenital and anorectal infections,[131] or cefixime in a single 400 mg oral dose cures, which cures 97.4% of uncomplicated infections. Cotreatment for chlamydial infection should always be given, if it has not been ruled out by appropriate testing. Empiric treatment for acute proctitis/proctocolitis syndromes is ceftriaxone 125 mg IM plus doxycycline 100 mg PO twice a day for 7 days.[132] This regimen offers coverage for the most common sexually transmitted pathogens that cause these symptoms (Table 68-1) and is especially effective against gonorrhea, Chlamydia, and incubating syphilis.

ANORECTAL HERPES SIMPLEX VIRUS INFECTION

Although genital herpes infection is well recognized, and HSV is second only to *N. gonorrhoeae* in frequency of association with proctitis in MSM, there have been few descriptions of anorectal herpetic infections.[133–139] Clinical description of anal herpes was recorded in 1736 by Astruc, physician to the king of France.[136] He stated, "[It is] observed in catamites and pathics, if they contract foul ulcers in the anus by the unnatural use of venery; from these ulcers they are tormented by a grievous inflammation upon the extremity of the rectum...hence the evacuation of the faeces becomes difficult and painful." In one study, 236 MSM with anorectal herpes were seen in one genitourinary medicine clinic in England over a 2-year period.[5] In two Seattle studies, HSV was cultured from the anorectal area of 32% and 20% of MSM with anorectal symptoms.[140,141] Limited data are available on the risk of HSV anorectal infection in women. Koutsky et al. recently found serologic or virologic evidence of HSV-2 infection in 47% of 779 women seen at a Seattle STD clinic.[138] HSV-2 was isolated from the anus or rectum of 26 women (3%). In this study, a history of anorectal intercourse was not more common in women with anorectal HSV than in women with genital HSV infection or no infection. Anorectal herpes is usually acquired by anal intercourse, although oral–anal contact with an individual who has HSV type 1 (HSV-1) infection of the mouth or lips presumably could lead to anorectal infection with HSV-1. In the Seattle studies, 37 of 39 isolates from the rectum were HSV type 2 (HSV-2) and the remaining two isolates were HSV-1.[3,140]

The complete clinical spectrum of anorectal herpes ranges from asymptomatic shedding to ulcerative proctitis. Clinically, herpes infection may involve the perianal area, the anal canal, and/or the rectum. While symptoms are quite prominent in some cases, many individuals may be totally asymptomatic.[139] In one study, HSV was isolated from the anal canal of 3 of 75 asymptomatic MSM.[3] In a more recent study of HSV-2 seropositive, HIV-negative MSM, 30 men collected daily HSV culture samples from genital, perianal, and oral areas for 100 days and maintained diaries of signs and symptoms.[140] Sixteen men shed HSV-2 (53%) and 9 of 16 (56%) who were HSV-1 seropositive shed HSV-1. HSV-2 shedding was predominantly perianal (83%), while HSV-1 shedding was primarily oral. Thus, asymptomatic anorectal HSV shedding may contribute to transmission of the infection to other individuals.

When symptomatic, anorectal HSV infections may be characterized by severe, often debilitating, anal pain, present in 94% of patients in one study.[137] Constipation, a nonspecific manifestation of proctitis, is usually present. The occurrence of constipation, anorectal pain, and urinary retention in a homosexual man strongly suggests herpetic proctitis.[137,139] Samarasinghe et al.[5] described 11 patients with herpetic proctitis, all of whom developed urinary difficulty of varying severity associated with sacral paresthesias, neuralgia, and impotence. Such symptoms are uncommon with HSV infection of the genitalia, which leads to latent infection of the S2 and S3 dorsal root ganglia. Urinary retention, constipation, and impotence in anorectal herpes are suggestive of a sacral radiculopathy, perhaps due to infection of lower-level sacral nerves and dorsal root ganglia; alternatively, urinary retention and constipation could be ascribed to a pain-induced reflex spasm of the anal and vesical sphincters caused by the severe anorectal pain associated with the syndrome. The dermatomic distribution of sacral dysesthesia or neuralgia has not been well characterized or compared in genital versus anorectal herpes.

Other symptoms of anorectal herpes include tenesmus, hematochezia, and rectal discharge. Constitutional symptoms such as fever, chills, malaise, and headache are common with primary anorectal HSV infection. Tender inguinal lymphadenopathy occurs in nearly one-half of men with primary anorectal herpes. Although initial attacks of genital herpes differ clinically from recurrent attacks (see Chapter 21), initial and recurrent attacks of anorectal herpes have not yet been carefully compared. However, clinical experience suggests that recurrent anorectal attacks are often mild, of shorter duration, and rarely associated with constitutional symptoms. The presence of concomitant HIV-1 infection can adversely affect the clinical course of HSV proctitis. Unlike immunocompetent hosts, who have spontaneous resolution of lesions, in the absence of treatment HIV-infected patients tend to develop chronic progressive disease leading to large, destructive perianal ulcers.[141] Chronic mucocutaneous HSV with positive HIV serology is diagnostic of AIDS.[141]

Clinically, many infected individuals will not have any visible ulcerative perianal lesions but instead will present with ulcerative findings deep in the anal canal or involving the rectal mucosa.[3,137] Quinn et al. noted only 4 of 15 (27%) patients with anorectal herpes had visible perirectal lesions.[3] When present externally, the initial lesion is a small vesicle or cluster of vesicles, each surrounded by a red areola. The vesicles soon rupture and may become confluent, particularly near or in the anal canal. With HSV infection of the rectum, the lower 10 centimeters of the rectum may appear edematous, with discrete focal vesicular or ulcerative lesions occasionally present (see Figs. 68-4 and 68-5). HSV proctitis is more likely than other causes of proctitis to cause diffuse friability, primarily involving the distal 10 cm of the rectal mucosa. The rectal mucosa is characteristically normal above this level, although occasionally involvement may occur above 10 cm. Histologic examination of rectal biopsies reveals acute nonspecific inflammation with focal ulcerative changes. The histologic findings which are characteristic of rectal herpes, though not found in all cases, are perivascular mononuclear cell infiltration, intranuclear inclusion bodies, and extensive nuclear debris (Fig. 68-6); multinucleated cells can also be seen occasionally but are not uniquely associated with this infection. Other rectal infections are commonly associated with HSV infection and may cause a more diffuse proctitis.

The clinical diagnosis of genital herpes is both insensitive and nonspecific. Diagnosis of anorectal herpes should be suspected on the basis of proctitis with focal ulcerative changes of the distal rectum in a patient with severe anal pain, constipation, inguinal adenopathy, constitutional symptoms, and

urinary retention. Cultures of external lesions, of rectal swabs, or of rectal biopsy are confirmatory. Immunofluorescent staining of tissue biopsy is also useful. Polymerase chain reaction (PCR) assays for HSV DNA are very sensitive and can be used instead of viral culture with viral typing. Commercially available enzyme immunoassays (EIAs) do not distinguish well between antibody subtypes.[142] Accurate type-specific assays for HSV antibodies must be based on the HSV-specific glycoprotein G2 for the diagnosis of infection with HSV-2 and glycoprotein G1 for diagnosis of infection with HSV-1. Recently, FDA-approved, gG-based type-specific assays have been shown to be highly specific and accurate for detection of these antibodies.[143] Isolation of HSV is the most specific means of confirming a first episode of infection, but detection of HSV-2-specific antibody is the most sensitive way to confirm symptomatic reactivation and to detect asymptomatic infection.[138]

The clinical course of an initial attack of anorectal herpesvirus infection is self-limited, but manifestations may last for 2–3 weeks. Secondary bacterial superinfections, which are uncommon in genital herpes, may be more common in anorectal herpes, although this has not been determined. Treatment includes analgesics and sitz baths, and one study suggests that oral acyclovir may be efficacious in shortening the duration of symptoms and viral shedding of anorectal herpes.[144] Initial cases of infection should receive acyclovir orally 400 mg five times per day for 10 days. The newer antiviral agents famciclovir and valacyclovir have been used for genital HSV infection and may be efficacious for anorectal infection, although they have not been studied for this specific indication (see Chapter 21). Acyclovir 400–800 mg orally twice to three times daily, famciclovir 500 mg orally twice daily, or valacyclovir 1 gram daily or 500 mg orally twice daily have been recommended for daily suppressive therapy in HIV-infected persons. While antiretroviral therapy reduces the severity and frequency of symptomatic genital herpes, frequent subclinical shedding still occurs. Subclinical mucosal HSV is associated with higher loads of mucosal HIV[146,147] and HIV-infected persons are likely to be contagious for HSV. As HIV-infected persons are evaluated on entry to care, type-specific serologies should be offered during initial staging and suppressive antiviral therapy considered. In AIDS patients with severe mucocutaneous herpes, 5–10 mg/kg of intravenous acyclovir should be administered every 8 hours until clinical resolution is attained. The patient may then be placed on oral antiherpetic therapy for suppression of recurrences, as these are more frequent and severe in AIDS patients.[133] If lesions persist or recur in a patient receiving HSV antiviral treatment, HSV resistance should be suspected and a viral isolate obtained for sensitivity testing. If resistant to acyclovir, foscarnet, 40 mg/kg body weight IV every 8 hours is often effective. Topical cidofovir gel 1% applied to the lesions once daily for 5 consecutive days may also be effective, but this preparation is not commercially available and must be compounded at a pharmacy.[145]

ANORECTAL SYPHILIS

As with other STDs, the incidence of syphilis appears to be increasing among MSM in industrialized countries.[148–154] Although the rate of primary and secondary syphilis reported in the United States decreased during the 1990s and in 2000 was the lowest since 1941, in the years from 2000 to 2004 primary and secondary syphilis cases increased and this increase was observed primarily among men.[149,152,154]

T. pallidum is commonly seen in its earliest infectious stages, with the primary anorectal lesion appearing 2–6 weeks after exposure by rectal intercourse. However, clinicians often fail to recognize anorectal chancres. Consequently, early syphilis in MSM is diagnosed in the secondary or early latent stage much more often than in the primary stage. It is not certain what proportion of anorectal chancres is asymptomatic. Careful perianal examination can reveal unsuspected perianal chancres, while digital rectal examination and anoscopy may be required to detect asymptomatic chancres higher in the anal canal or rectum. The variable appearance of the lesion accounts for the high rate of misdiagnosis. When anorectal syphilis causes symptoms, it is commonly misdiagnosed as a traumatic lesion, fissure, or hemorrhoiditis.[155]

Anorectal chancres due to syphilis have been recognized at least since the early 1900s. In 1925, Martin and Kallet found 20 patients (6.7%) with anorectal chancres among 300 proctologic cases.[156] Over the next 20–30 years there were several reports which stated that anorectal chancres represented

0–15% of extragenital chancres.[157,158] However, as STD clinicians have more frequently examined the anal area for chancres, the proportion of chancres found to involve the anorectal area has also increased.

As previously mentioned, symptoms are commonly absent in the primary stage of anorectal syphilis, but when symptoms are present they include mild anal pain or discomfort, constipation, rectal bleeding, and occasionally a rectal discharge. Primary anorectal syphilis may appear as single or multiple eccentrically placed or mirror image ("kissing chancres") perianal ulcers.[159] It can also present as ulcerated masses, typically located on the anterior wall of the rectum.[160] Inguinal adenopathy with rubbery, nonsuppurative painless nodes may be associated with anorectal syphilis and helps distinguish it from fissures. Within the rectum, secondary syphilis may cause discrete polyps,[161,162] smooth lobulated masses,[163,164] mucosal ulcerations, and nonspecific mucosal erythema or bleeding, as well as submucosal irregularities with rubbery nodes which may be confused with lymphoma.[164,165] Syphilitic inflammation of the gastrointestinal tract is usually limited to the distal 15 cm but may be as high as 20 cm with secondary syphilis.

In secondary syphilis, condylomata lata may be found near or within the anal canal. These are smooth warty masses and must be differentiated from the more highly keratinized condylomata acuminata. Condylomata lata are often pruritic and produce a foul discharge, which is highly infectious. The term condyloma latum has generally been limited to morphologically characteristic lesions involving stratified squamous epithelium, and we therefore do not use the term to include lesions of the columnar epithelial mucosa of the rectum. It is probable that secondary syphilis frequently involves the gastrointestinal tract, particularly the stomach. Constitutional symptoms, skin rash, and mucous patches can also occur. The lesions of primary and secondary syphilis may also coexist.[165,166]

Late syphilis may uncommonly involve the gastrointestinal tract, and the involvement can range from infiltrative, constrictive, or polypoid masses within the stomach to lesions of the lower bowel.[167,168] Anal sphincter paralysis and severe anal pain may develop with tabes dorsalis. Most past descriptions of gastrointestinal syphilis should be interpreted cautiously, since many of these lesions were ascribed to syphilis solely on the basis of serology, clinical responses to therapy, and compatible histology. Only a few reports have demonstrated *T. pallidum* in gastrointestinal lesions by silver stain or indirect immunofluorescence.[168–172]

Diagnosis of anorectal syphilis is based on serology, perirectal and digital rectal examination, and anoscopy. Detection of motile treponemes by darkfield examination is useful for evaluation of perianal and anal lesions but may be less specific for rectal lesions, since nonpathogenic treponemes can be found in the intestine. However, the number of species of nonpathogenic treponemes which have been described is greater in the mouth than in the intestine.[169] Additionally, since 10^5 treponemes/mL are required for visualization, a negative test does not rule out the diagnosis. Immunohistochemical stains of exudate from lesions may be useful in darkfield-negative specimens.[170] Biopsies of any rectal lesions or masses should be processed for silver staining, as well as routine histology, if syphilis is suspected. Although Nazemi et al.[162] described a case of syphilitic proctitis by demonstrating a spirochete on silver stain of a rectal biopsy, some investigators believe that silver stains are unreliable and recommend identification of *T. pallidum* by immunofluorescence using anti–*T. pallidum* antisera.[166,169] Figure 68-7 illustrates a positive immunofluorescent stain for *T. pallidum* in a rectal mass lesion found in a homosexual man who had secondary syphilis associated with anorectal pain and discharge.

In addition, the histopathology of anorectal syphilitic lesions is also quite characteristic. As shown in Fig. 68-8, a hematoxylin and eosin preparation of the same tissue shown in Fig. 68-7 demonstrates at low magnification a uniform infiltrate of mononuclear cells throughout the submucosa and lamina propria. At higher magnification these are seen to be predominantly plasma cells, lymphocytes, and histiocytes. This degree of plasma cell infiltration is characteristic of gummas, syphilitic gastritis, condylomata lata, and syphilitic chancres.[166,170] Presumably, this intense plasma cell infiltrate in early syphilis represents an immune response to the large number of treponemes demonstrated throughout the tissue

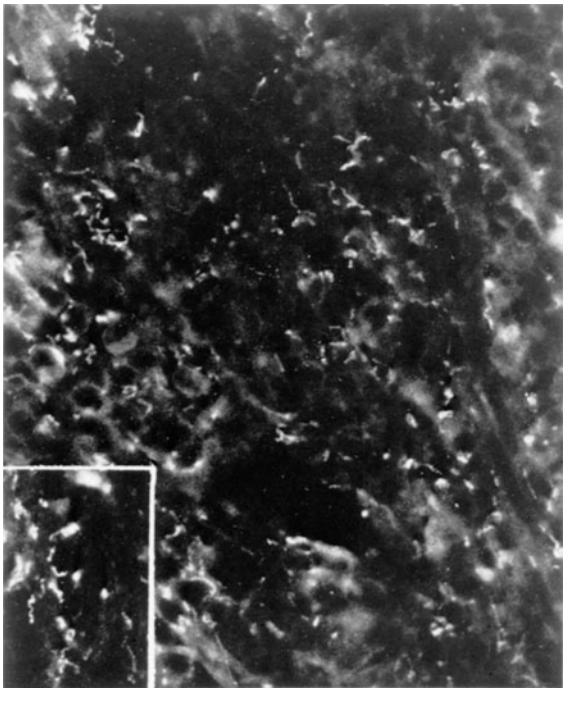

FIGURE 68-7. Immunofluorescent staining for *Treponema pallidum* reveals numerous brightly stained organisms scattered throughout the mucosa and submucosa of a rectal biopsy from a patient with a rectal mass and secondary syphilis. (*Courtesy of S. Lukehart.*)

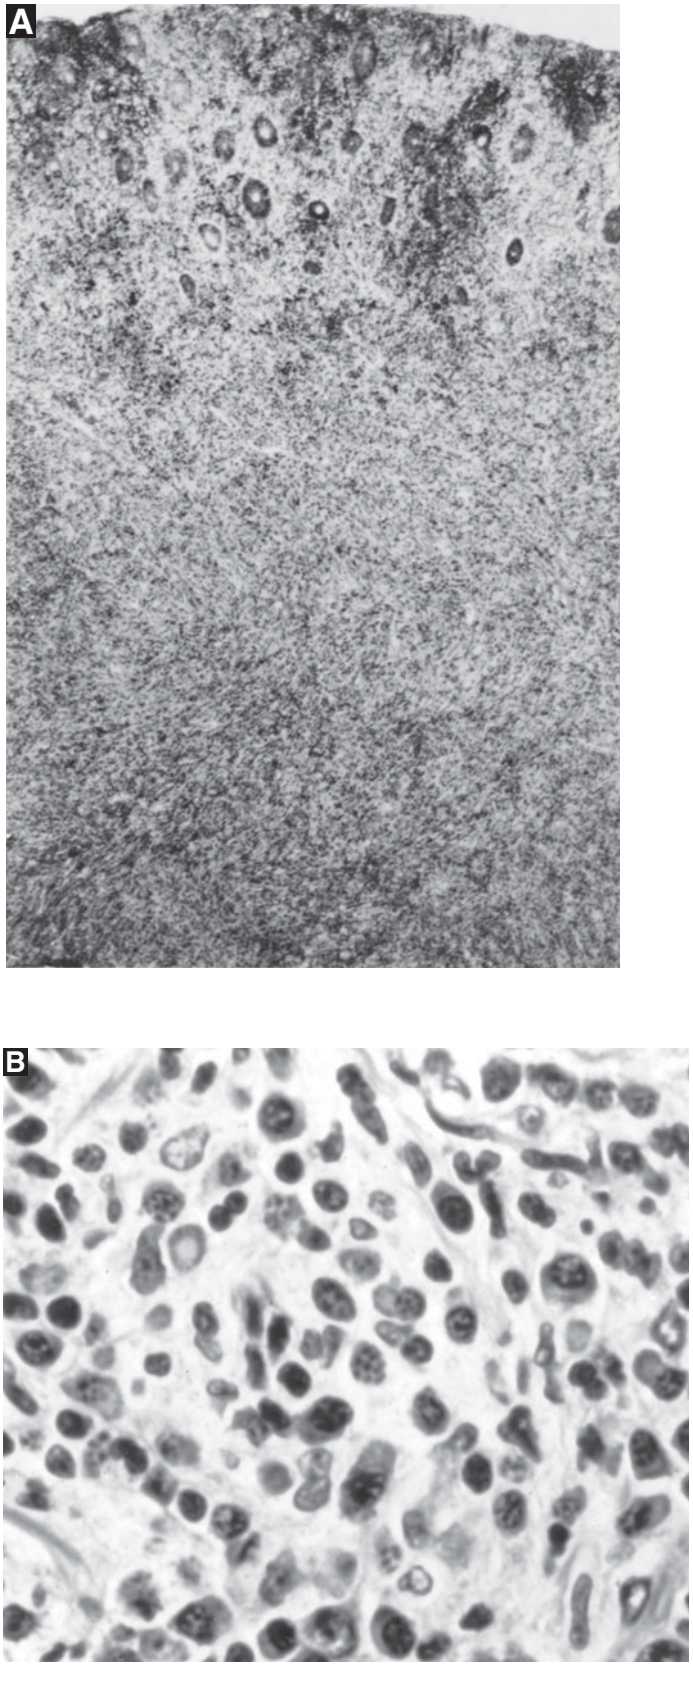

FIGURE 68-8. Biopsy of a rectal mass from a patient with secondary syphilis. **A.** An extensive uniform cellular infiltrate has replaced the submucosa and lamina propria and has disrupted the muscularis mucosa. **B.** The infiltrate consists of plasma cells, histiocytes, and lymphocytes.

by immunofluorescent antibody staining.[171,172] These lesions often show an obliterative endarteritis with capillary proliferation and occasionally granulomas and crypt abscesses.[13,58]

Serologic diagnosis of syphilis is based on presence of antibodies to nontreponemal and treponemal antigens. A positive VDRL or RPR must be corroborated by a positive test specific for antibody to *T. pallidum* antigens, such as the fluorescent treponemal antibody absorption (FTA-ABS) test or the *T. pallidum* particle agglutination (TP-PA). Treponemal antibody titers do not correlate with disease activity and usually remain positive after the infection. The VDRL test detects approximately 50–85% of cases of primary syphilis, 100% of cases of secondary syphilis, and 85–100% of cases of tertiary syphilis. The FTA-ABS is the first serologic test to become positive and is present in 70–90% of patients with a chancre. This test is generally 100% sensitive in secondary and tertiary syphilis. The specificity of the VDRL varies with the population tested and is higher in healthy than in sick persons.[172]

Concomitant HIV-1 infection may alter the serologic manifestations of syphilis. There has been delayed or absent serologic test reactivity in patients infected with HIV-1 and proven secondary syphilis, particularly at a later stage of HIV infection.[56,57] Higher VDRL titers in patients with earlier-stage infection and secondary syphilis have also been noted.[58] Biological false-positive tests, VDRL- or RPR-positive, and FTA-ABS- or MHATP-negative, which occur in a wide variety of infectious and noninfectious conditions, have been associated with HIV-1 infection.[173,174]

The differential diagnosis of anorectal syphilis includes ulcers due to HSV infection, chancroid, granuloma inguinale, LGV, trauma, and malignancy. Syphilitic lesions may be commonly misdiagnosed as anal fissures, fistulas, hemorrhoids, traumatic lesions, rectal polyps, condylomata acuminata, and even rectal carcinoma.[160–162] Indeed, there have been several reports of patients who underwent surgery for removal of lesions which were initially thought to be malignant but were later diagnosed as syphilitic lesions.[175]

Treatment for early syphilis is discussed in Chapter 35. Benzathine penicillin, in a single dose of 2.4 million units IM, remains the treatment of choice for early syphilis. Penicillin-allergic patients may be treated with a 14-day course of doxycycline, l00 mg orally given twice daily, or tetracycline 500 mg four times daily. A single 2-g oral dose of azithromycin was reported effective in treating syphilis in a Tanzanian study, but recent reports of azithromycin-resistant *T. pallidum* among MSM in North America and Dublin have prompted caution and close follow-up of persons receiving this therapeutic option.[176] All patients should be offered HIV testing. All sexual contacts should be screened and treated.

Although the standard regimen for early syphilis may be adequate for some patients coinfected with syphilis and HIV-1, several reports have documented poor response to standard therapy in this setting.[177,178] Following treatment, the serologic

titer may decrease more slowly in some HIV-infected patients.[179,180] These patients should have repeat serologic testing 3, 6, 9, 12, and 24 months after treatment to evaluate for response to therapy. Examination of CSF fluid is indicated in patients with neurological symptoms or if there is a rise or a less than fourfold decrease in the serologic titer within 6–12 following treatment.[181]

C. TRACHOMATIS PROCTITIS

Several studies in the pre-HIV era demonstrated prevalences of 4–8% for anorectal *C. trachomatis* infection in men and 5–21% for anorectal infections in women.[182–186] Rates were higher for patients with symptoms of proctitis than for asymptomatic patients. In women with anorectal *C. trachomatis* infection, rectal intercourse was associated with the presence of symptoms. Most studies describing the clinical manifestations of chlamydial proctitis have been conducted among MSM, and in the pre-AIDS era, *C .trachomatis* was responsible for up to 15% of proctitis cases seen in MSM. In a recent study of the etiology of clinical proctitis among MSM, 19% of 101 patients had chlamydial proctitis.[37] Barnes et al. compared serovars causing anorectal infection in homosexual and bisexual men with those causing cervical infections in heterosexual women in the same STD clinic.[187] They found D/D´ in 53% of rectal and 18% of cervical isolates, while serovar E was found in 32% of cervical and 6% of rectal isolates.[187] The highly significant difference in isolates from the two sites may be attributed to limited transmission between the two populations or to a decreased capability of certain serovars of surviving at one or the other mucosal site. Since the clinical manifestations and histopathology of *C. trachomatis* rectal infections differ according to the infecting immunotype, these will be discussed separately.

Rectal infections with LGV immunotypes of *C. trachomatis* have been recognized since 1936.[188] Infections with the LGV biovar of *C. trachomatis* are endemic in East and West Africa, South America, and the Caribbean, but they have been seen only sporadically in the United States and Europe and more often in MSM than in heterosexual men or in women until recently. In 2003, a cluster of LGV cases among MSM was reported in Rotterdam, the Netherlands,[189] and since then there have been numerous reports or similar outbreaks in large cities in Western Europe, Australia, and the United States. Initially referred to as the anorectal syndrome of LGV, rectal involvement was generally believed to be a late, or secondary, manifestation of a genital infection. Secondary anorectal involvement does occur: After contact with an infected individual, a transient papule or ulcer sometimes appears on the genitalia, followed by systemic symptoms and prominent inguinal adenopathy; without treatment, the infection progresses to destructive granulomatous lesions of the lymph nodes and lower intestinal tract, which progresses to the formation of fistulas, strictures, and perianal abscesses and fistulas. The rectal strictures often form 2–5 cm above the anocutaneous margin, where there is a rich supply of lymphatics. Obstruction of lymphatic and venous drainage may cause perianal outgrowth of lymphatic tissue similar to hemorrhoids, called lymphorrhoids or perianal condylomas.[190]

Primary anal or rectal infections have been described in women and MSM who practice anal intercourse. In these infections, rectal involvement is initially characterized by severe anorectal pain, a bloody mucopurulent discharge, and tenesmus. Inguinal adenopathy, which is characteristic of genital LGV, is often present. A study by Bauwens et al. suggests that the severity of infections may be associated with specific serovars and that infections with the L1 serovar may be less severe than those caused by L2.[191] However, a recent case-control study comparing the clinical characteristics of 87 MSM who had LGV to 377 MSM who had non-LGV anorectal chlamydia and 2677 MSM who did not have anorectal chlamydia found that a small number of patients with LGV presented with self-reported anorectal problems, with only 4 reporting anorectal pain or discharge.[192] Proctoscopic signs of proctitis, enlarged inguinal lymph nodes, and the presence of >1 anorectal ulcer upon examination were significant predictors of LGV infection, irrespective of the control group used. In addition, the number of white blood cells in the Gram-stained anorectal smear specimen was a significant predictor of LGV anorectal infection.

In both primary and secondary anorectal LGV, sigmoidoscopy reveals diffuse friability with discrete ulcerations in the rectum that occasionally extend to the descending colon.[193,194] Strictures and fistulas may become prominent and can be easily misdiagnosed clinically as Crohn's disease or carcinoma.[190,195] Histologically, rectal LGV may also be confused with Crohn's disease. Commonly, there is diffuse inflammation throughout the mucosa and submucosa, with plasma cells, neutrophils, and eosinophils, as well as giant cells, crypt abscesses, and granulomas (Fig. 68-9). Due to

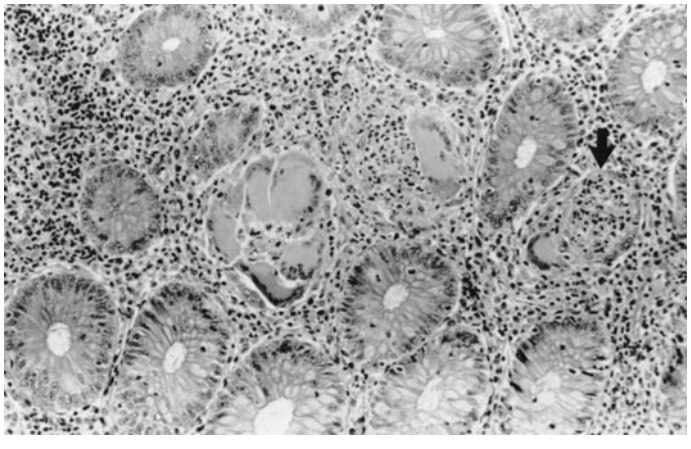

FIGURE 68-9. Rectal biopsy of a patient with rectal LGV (*C. trachomatis*, LGV-2 immunotype). There is diffuse inflammation throughout the mucosa and submucosa. Giant cells, crypt abscesses (arrow), and granulomas are present.

these similarities, Crohn[196] and others[197,198] speculated about a possible relationship between the two disorders. Schuller et al.[199] later demonstrated antibody to LGV strains in over 70% of patients with Crohn's disease and in less than 2% of healthy controls. At least three subsequent studies have failed to document such a relationship.[200–202] However, in our own analyses of rectal biopsies from MSM with proctitis, histopathologic findings were interpreted as consistent with Crohn's disease in two of three men from whom LGV immunotypes of *C. trachomatis* were isolated.[4] From these data, it appears that LGV infection should be suspected and ruled out in MSM with unexplained proctitis.

The non-LGV immunotypes of *C. trachomatis* are less invasive than LGV and can cause a mild proctitis characterized by rectal discharge, tenesmus, and anorectal pain.[3] Anal lesions have not been described. Many infected individuals may be asymptomatic and can be diagnosed only by routine culturing. Data from Dean et al. suggests that serovar F may be associated with more severe female genital infections than serovar E.[203] This association of specific serovars and severity of infection has not been seen with non-LGV *C. trachomatis* anorectal infections. Even in asymptomatic cases, abnormal numbers of fecal leukocytes are usually present. Sigmoidoscopy may be normal or may reveal mild inflammatory changes with small erosions or follicles in the lower 10 cm of the rectum. Histology of rectal biopsies generally shows anal crypts and prominent follicles, as well as a neutrophilic infiltration of the lamina propria.

Diagnosis of chlamydial proctitis is best made by isolation of *C. trachomatis* from the rectum, together with response to appropriate therapy. Direct fluorescent antibody staining of rectal secretions using monoclonal antibodies can also be used to make the diagnosis.[204] Rompalo et al. used the direct fluorescent antibody technique to evaluate rectal swab samples for *C. trachomatis* and found a 90% sensitivity and 100% specificity for DFA compared with culture.[204] EIAs for chlamydial antigens have been attempted on rectal samples but give high false-positivity rates due to cross-reacting antigens on other fecal bacteria.[205] NAATs testing has been used with good reported sensitivity and specificity, but is not currently FDA approved for rectal specimens.[206,207] Serology is considered useful for the diagnosis of LGV and a complement-fixation titer of greater than 1:64 is considered suggestive of LGV infection.[208–211] Specificity of microimmunofluorescent antibody titers, however, has been questioned recently and requires further study. Serology for the diagnosis of non-LGV rectal chlamydial infection has been less useful, often confusing, and not commonly used. The CDC LGV Project has specific instructions for specimen collection and transport for LGV testing at the CDC and the procedure is available on the web.[208]

Doxycycline, or azithromycin, are the drugs of choice for infection with *C. trachomatis*. Doxycycline 100 mg twice daily for 7–10 days may be used; azithromycin 1 g as a single dose is effective for urethritis and cervicitis and has been recommended for uncomplicated rectal infections.[212,213] Patients should be followed carefully with repeat sigmoidoscopy, particularly when there is any question about the differential diagnosis of LGV versus inflammatory bowel disease. Therapy for LGV is discussed in Chapter 30.

PROCTOCOLITIS AND ENTERITIS DUE TO ENTERIC PATHOGENS

Epidemiologic and anecdotal reports have suggested the sexual transmission of several enteric pathogens, including *Shigella, Salmonella*, and *Campylobacter jejuni*.[214–217] Since these organisms are described in depth in Chapter 41, we will only briefly review some of the clinical and epidemiologic data concerning the role of these pathogens in MSM with symptoms and signs of enteritis or proctocolitis.

Although bacterial enteric infections account for fewer than 5% of opportunistic infections in AIDS patients in developed countries, these infections are significantly more common in AIDS patients than in similar patients without AIDS. In developing countries, persistent diarrhea of greater that 7 days has been reported to affect up to 95% of AIDS patients.[218] Further, these infections tend to be more prolonged in AIDS patients and are associated with more frequent recurrences, more frequent bacteremia, and more antibiotic resistance than in non-AIDS patients. Diarrhea in the setting of HIV infection can have many causes. It may be a consequence of HIV infection directly and it is likely that the gastric hypoacidity which develops with AIDS predisposes to bacterial overgrowth and opportunistic enteric infections.[214] Diarrhea in HIV-infected patients on highly active antiretroviral therapy (HAART) may also be a drug sideeffect, especially with the use of protease inhibitors.[219]

Although several species of *Shigella* are responsible for human disease, *S. sonnei* and *S. flexneri* account for most infections in the United States. Since *Shigella* is highly infectious, transmission of the organism can occur rapidly and is commonly seen in children and travelers, in people in mental or penal institutions, and in populations where localized outbreaks are traced to contaminated food or water. The sexual transmission of *Shigella* was recognized in 1972, when reports from San Francisco and later from Seattle and New York documented that 30–70% of patients with *Shigella* were MSM.[215, 220] Contact tracing demonstrated recovery of the same serotype from sexual partners, and no contaminated food or water source could be shown to be common to any of the cases.

Shigellosis presents with an abrupt onset of diarrhea, fever, nausea, and cramps. The diarrhea is usually watery but may contain mucus or blood. The infection may be complicated by the development of toxic megacolon. Sigmoidoscopy usually reveals an inflamed mucosa with friability not limited to

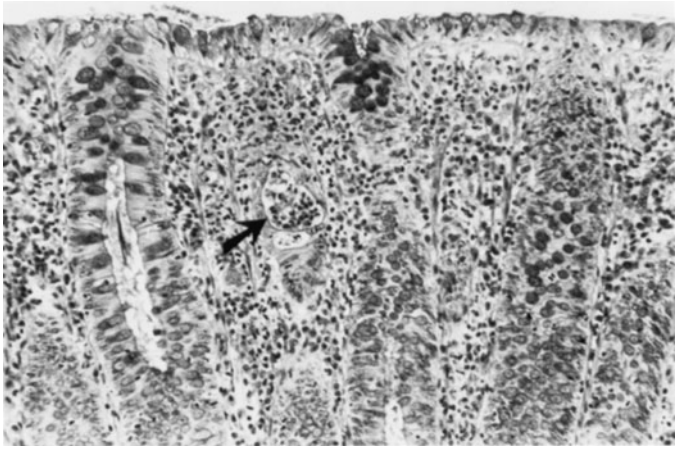

FIGURE 68-10. *Campylobacter* colitis. The colonic mucosa is acutely inflamed, with polymorphonuclear leukocytes in the epithelium and lamina propria. A crypt abscess is also present (arrow). These findings are not specific for *Campylobacter* and may be found in the acute colitis caused by other invasive pathogens. H&E stain, ×340 magnification. (*Courtesy of M. Schuffler.*)

the distal rectum, and histologic examination shows diffuse inflammation, with bacteria scattered through the submucosa and muscularis mucosa (Fig. 68-10). Diagnosis is made by culturing the organisms from the stool on selective media. Treatment is usually supportive, and antimotility agents should be avoided, but antibiotics are generally recommended to prevent complications in immunocompromised patients. Due to widespread development of resistance, selection of antibiotics should be based on regional antibiotic sensitivities. Ciprofloxacin 500 mg orally twice daily for 7 days is usually effective. As recurrences are common, antibiotic resistance may develop.[214] Repeat cultures of stool and blood are necessary to monitor response to therapy. Since asymptomatic carriers of *Shigella* exist, contact tracing is an important public health measure. Studies are needed on the value of tracing sexual contacts of MSM with shigellosis. Recent guidelines for treating opportunistic infections among HIV-infected persons recommend that household contacts of HIV-1-infected persons who have shigellosis should be evaluated for persistent asymptomatic carriage of either organism so that strict hygienic measures or antimicrobial therapy can be instituted and recurrent transmission to the HIV-1-infected person can be prevented.[221]

Campylobacter jejuni is one of the most commonly isolated bacterial agents from patients with acute diarrhea in the United States. In a survey of AIDS cases in Los Angeles from 1983 to 1987, *Campylobacter* was reported in 29 of 4433 (0.7%) AIDS cases. There was a 39-fold increased annual incidence in AIDS patients compared with other men aged 15–55 years.[222] It is believed that the 5 or 6 per 100,000 population rate reported to the CDC significantly underestimates the true incidence of 1000 per 100,000 per year.[223] The underestimation is likely due to frequent asymptomatic infections and underutilization of the appropriate culture techniques. This pathogen is generally acquired by ingestion of contaminated water or food, particularly chicken and unpasteurized milk, or by close contact with infected animals.[224,225] Infection rates peak in the late summer and early fall. This is a significantly less infectious organism than *Shigella*, as 800×10^6 organisms are needed for infection in 10–50% of patients.

Sexual transmission has been documented in animals and was suspected in early reported cases of human abortion,[226,227] and a few reports have recently addressed the possible sexual transmission of *Campylobacter* in humans.[227–231] Campylobacter species or "atypical" campylobacter organisms have been recovered from the stools of 24% of symptomatic MSM and 10% of asymptomatic MSM.[25] In a subsequent study performed in 1986 in Baltimore, *Campylobacter* species were isolated from 4% of asymptomatic MSM, from 20% of MSM with intestinal symptoms, and from 9% of MSM with AIDS.[228] The most frequent isolates were *C. jejuni*, followed by campylobacter-like organisms.

These studies have clearly documented the frequent occurrence of "atypical" campylobacter organisms in MSM. In the AIDS era, "atypical" campylobacter organisms have been recovered less often from rectal or stool cultures of MSM with diarrhea (Table 68-4) but have caused bacteremic illness in AIDS patients.[229] Although 99% of reported *Campylobacter* isolates in the United States are *C. jejuni*, there is a growing list of atypical *Campylobacter* and related species which have been shown to cause diarrheal syndromes. These include *C. coli, C. upsaliensis, C. lari*, *Arcobacter cryaerophilia*, and *A. butzleri*, *Helicobacter fennelliae*, and *H. cinaedi* (previously classified as *Campylobacter* species) have been associated with chronic mild diarrhea and proctitis in MSM.[229–231] Although blood culture systems will generally grow these organisms, routine stool cultures performed by most laboratories will fail to identify these more fastidious *Campylobacter* species. Even when isolated from asymptomatic MSM these organisms are significantly correlated with the presence of neutrophils in rectal secretions, which suggests clinical disease.

Clinically, *C. jejuni* produces an acute diarrheal illness of several days duration, with fever, chills, myalgias, and abdominal pain. Gastrointestinal infections may mimic inflammatory bowel disease or acute appendicitis and may be complicated by pseudomembranous colitis, gastrointestinal hemorrhage, toxic megacolon, cholecystitis, and pancreatitis. Postinfectious complications include reactive arthritis[232] and Guillain-Barré syndrome.[233] Although the infection usually involves the small intestine, involvement of the colon and rectum has also been described.[234–236] The sigmoidoscopic and rectal biopsy findings are nonspecific and similar to those described for shigellosis (see Fig. 68-10). Fecal leukocytes are uniformly present and diagnosis is confirmed by isolating the organisms from the stool by culture on selective media in a microaerophilic atmosphere.[224]

Table 68-4. Comparison of Gastrointestinal Infections Among Homosexual Men Attending the Seattle STD Clinic in Two Time Periods

% of patients positive for each pathogen[a]	1980–1981 (n = 119)	1983–1984 (n = 184)	p value
Neisseria gonorrhoeae	31	14	$p = .0003$
HSV	19	30	$p = .05$
Chlamydia trachomatis	10	14	NS
Treponema pallidum	5	6	NS
Entamoeba histolytica	29	15	$p = .02$
Giardia lamblia	14	7	$p = .07$
Campylobacter jejuni	7	7	NS
Campylobacterlike organisms	18	7	$p = .005$
Shigella	3	5	NS
Any pathogen	80	66	$p = .02$
≥ 2 pathogens	22	19	NS
HIV seroprevalence	14	58	$p < .001$

[a]Data from TC Quinn et al.[25] and WE Stamm (personal communication).

Although the need for antimicrobial therapy has not been fully established in human *Campylobacter* infection of the intestinal tract, treatment with azithromycin 500 mg daily for 3 days or erythromycin 500 mg four times daily for 1 week has been recommended for severely symptomatic cases and for immunocompromised patients.[225] Antimicrobial therapy started within the first 3 days of the illness reduces the duration of excretion of the organism in the stool. A cluster of erythromycin- and ciprofloxacin-resistant *Campylobacter jejuni* subsp. *jejuni* was recently reported among MSM from 1999 to 2001 in Quebec[237] and ciprofloxacin- and azithromycin-resistant isolates from Thailand have recently been described.[238] Bacteremia and recurrent diarrhea following specific therapy have been reported.

There are several species of salmonella with more than 2000 different serotypes that cause a variety of clinical entities in humans. There is an estimated 20-fold increased incidence of salmonellosis in AIDS patients.[239] These infections, which are primarily due to *S. typhimurium* and *S. enteritidis*, are often more severe and more frequently associated with bacteremia and relapse despite therapy in AIDS patients. *Salmonella* bacteremia in an HIV-infected individual is diagnostic of AIDS. Only anecdotal reports have commented on the possible sexual transmission of *Salmonella*; in one report,[240] *S. typhi* was recovered from the stools of MSM and the same serotype was recovered from asymptomatic sexual partners with whom no housing, food, or water was shared. These organisms can survive in the environment for up to 30 months; therefore, fomite transmission may occur.[240] It appears that these organisms have different capabilities for invasiveness in different populations. A review of salmonellosis in New York City found that *S. enteritidis* was more competent in causing septicemia and less competent in causing gastroenteritis than *S. typhimurium* in HIV-infected patients, the reverse was true for HIV-uninfected patients.[241]

Diagnosis is made by culturing the organisms from the stool on selective media. Treatment must be individualized, depending on severity of symptoms and antibiotic sensitivity of the isolate. For AIDS patients with bacteremia, ciprofloxacin 750 mg twice daily for 14–30 days is generally recommended.[242] As with all enteric pathogens, resistant strain are always a concern and recently three cases of community-acquired *Salmonella* bacteremia were reported with resistance to quinolones and extended-spectrum cephalosporin resistance.[245]

As additional important feature of *Salmonella* bacteremia among patients with AIDS is its propensity to relapse. The rate of recurrent bacteremia is approximately 45% unless chronic suppressive therapy is administered.[221] If relapse occurs, ciprofloxacin 500 mg twice daily is given indefinitely. Isolates sensitive to ampicillin and trimethoprim–sulfamethoxazole may be treated with these drugs. In immunocompetent patients with mild illness, supportive therapy without antibiotics is appropriate. Since asymptomatic carriers are common and may be employed as food handlers in public establishments (as were the reported cases), tracing of sexual partners of infected individuals is particularly important. Household contacts of HIV-1-infected persons who have salmonellosis or shigellosis should be evaluated for persistent asymptomatic carriage of either

organism so that strict hygienic measures or antimicrobial therapy can be instituted and recurrent transmission to the HIV-1-infected person can be prevented.[221]

Recent reports suggest that enteroadherent bacteria may produce a chronic diarrheal syndrome in AIDS patients.[243] In one review these organisms were found in 17% of AIDS patients evaluated for chronic diarrhea in a 1-year period.[244] Typically, these patients have less than 100 CD4 cells/mm^3 and present with diarrhea with malabsorption and weight loss. The right colon is most commonly involved. Histologically, three types of adherence patterns have been described: bacteria intercalated between microvilli, aggregates of bacteria loosely attached to damaged epithelium, and attaching and effacing lesions.[244,245] Cultures of biopsy samples have yielded *E. coli* in 67% of cases.[244] These infections have been described in MSM with AIDS, but the mechanism of transmission is not certain.

PARASITIC INFECTIONS

Although reports of cutaneous amebiasis of the penis, vulva, and cervix suggested sexual transmission of amebiasis,[246–248] it has only been within the last two decades that sexual transmission of certain parasitic infections has been fully appreciated.[21,22] In 1972, it was suggested that *Giardia lamblia*, *Iodamoeba bütschlii*, *Dientamoeba fragilis*, and *Enterobius vermicularis* were sexually transmitted among homosexuals.[249–252] In two separate surveys in New York City, the prevalence of infection with giardiasis and/or amebiasis was between 30% and 40% in selected MSM.[21,22] The presence of infection correlated better with a history of anilingus than with travel history.[21] In Seattle, 25% of MSM we have studied with anorectal or intestinal symptoms have had either *Giardia*, *E. histolytica*, or both present in their stools.[25] *G. lamblia* was associated with symptoms of enteritis, while *E. histolytica* was equally common in symptomatic and asymptomatic men. In addition, mixed infections with a variety of intestinal parasites, including other protozoans and nematodes, have also been described in MSM.[249–253] More recently, Peters et al. found that 48.5% (33 of 274) of MSM with symptomatic diarrhea in a community-based clinic in Chicago had at least one intestinal protozoan.[254] *E. histolytica* and *G. lamblia* were isolated from 26% to 8%, respectively, of these men and represented 53% and 16%, respectively, of positive isolates. Other parasites frequently isolated in this study were *E. nana* (39%), *E. coli* (14%), and *E. hartmanni* (9%). *D. fragilis*, *I. bütschlii*, *Chilomastix mesnili*, cryptosporidia, and *Isospora* were isolated in less than 1% of patients.

The etiologic agent of amebiasis is *E. histolytica*. *E. dispar* is a recently distinguished morphologically similar but nonpathogenic species and together, it is estimated that these two species infect 10% of the world's population.[255] High rates of infection occur in India, Africa, the Far East, and South and Central America; in the United States, the prevalence is approximately 4%.[256] Although *E. histolytica* is primarily a waterborne agent, sexual transmission may be responsible for its high prevalence in MSM. In 1977, 40% of all reported cases of amebiasis in the United States were from New York City. Eighty percent of these cases were located in Manhattan, and its large male homosexual community had the highest morbidity rate.[23] Similarly, in San Francisco, 89% of the reported cases of amebiasis were in males 20–39 years of age.[1] In a retrospective review of records of patients with *E. histolytica* infection seen at New York Hospital, Schmerin et al.[27] noted that 20 of 20 men who had not traveled were homosexual, while only 2 of 30 men who had traveled were homosexual. More recent studies have identified *E. histolytica* in 21–32% of selected MSM populations in North America and in 12% of MSM in the United Kingdom.[257–259] Among HIV-infected patients in the United States, the incidence of diagnosed *E. histolytica* is low (13.5 cases per 10,000 person-years) with the diagnosis most common among MSM.[255]

The majority of infections is asymptomatic and only 10% of those infected develop invasive disease with amebic dysentery or liver abscess. There has been considerable recent debate about whether, in most cases, *E. histolytica* actually causes illness in MSM who are positive by stool wet-mount examination.[260–261] The prevalence of *E. histolytica* is approximately equal in symptomatic and asymptomatic groups of MSM,[25] and many of those who are symptomatic have other pathogens in addition to *E. histolytica*. Additionally, AIDS patients do not seem to be at increased risk of invasive amebiasis.[262]

E. histolytica trophozoites have recently been divided into pathogenic and nonpathogenic zymodeme types using isoenzyme patterns. Most *E. histolytica* strains isolated from MSM are the nonpathogenic *E. dispar*, which are not usually associated with gastrointestinal symptoms, invasive disease,[258,261,263] or a serologic response.[264] Conversion from nonpathogenic to pathogenic zymodemes has been reported in culture but has not been seen in serial isolates from infected patients.[265] Pathogenicity of *E. histolytica* strains has been recently linked to the presence of a galactose-inhibitable adherence protein. An ELISA which detects this antigen in serum and feces may be useful in distinguishing pathogenic and nonpathogenic strains.[267,] The high rate of occurrence of asymptomatic infection facilitates transmission of infection within the MSM community, as inadvertent transmission occurs from patients unaware of their infection.

When present, symptoms may vary from mild diarrhea to fulminant bloody dysentery. Extension of the infection to the liver, lung, or brain occurs rarely. Amebic proctocolitis causes diffuse inflammation and ulceration of the distal colon, often clinically indistinguishable from inflammatory bowel disease, shigellosis, *Campylobacter jejuni* infection, or *Yersinia* enterocolitis.[268,269] These symptoms may wax and wane for weeks to

months. Fulminant dysentery is uncommon and is associated with steroid use.[270] Amebomas, which are chronic localized amebic infections, may present as painful abdominal masses. They are usually located in the cecum and descending colon.[256] Complications of amebic colitis include peritonitis; hemorrhage; strictures of the anus, rectum, and sigmoid; and painful perianal ulcerations which are due to contiguous spread of intestinal infection.

Diagnosis is based on the demonstration of *E. histolytica* in the stool, in a wet mount of a swab, or in a biopsy of rectal mucosal lesions. Occasionally, multiple fresh stool examinations are necessary to demonstrate the cysts or trophozoites of *E. histolytica*. Barium, laxatives, antibiotics, and enemas should be avoided at the time of sample collection. Samples not evaluated immediately should be fixed with polyvinyl alcohol or refrigerated, to avoid disintegration of trophozoites. Sensitivity of stool examination can be increased with concentration techniques and with trichrome and iron hematoxylin stains.[256] Definitive diagnosis of amebic colitis is by colonoscopy with scraping or biopsy of the ulcer edge; however, there is a risk of perforation. Serology (indirect hemagglutination) is useful in acute amebic colitis because it is positive in 82–98% of infected patients.[256] Indirect hemagglutination tests may remain positive for years following infection.[270] Agar gel diffusion, counterimmunoelectrophoresis, and EIA techniques are quite sensitive (87–95% for proctocolitis, 95–100% for amebic liver abscess) and have the benefit of becoming negative 6–12 months following infection.[270] Newer diagnostic methods are also being tested. A single-round PCR assay was developed for detection and differential diagnosis of the three *Entamoeba* species found in humans, *E. moshkovskii*, *E. histolytica*, and *E. dispar*, that are morphologically identical as both cysts and trophozoites.[271] Point-of-care tests for rapid diagnosis of amebiasis are also being developed. In Bangladesh and Vietnam, a novel and simple-to-use *E. histolytica* rapid antigen test had 97% sensitivity and 100% specificity when compared to a standard ELISA antigen detection method, and a rapid antibody test had 89–100% sensitivity and 89–95% specificity.[272]

Treatment for amebiasis is discussed further in Chapter 44. Asymptomatic carriage of the organisms should be treated to prevent continued infection with a possible pathogenic strain and to prevent continued transmission of the infection. At present, three luminal amebicides are available to treat this type of infection. Iodoquinol 650 mg orally three times daily for 20 days is the regimen of choice.[273] Paromomycin 25–30 mg/kg/day in three doses for 7 days and diloxanide furoate 500 mg three times per day for 10 days are additional options.[274] Diloxanide furoate is presently available only from the CDC. Invasive intestinal disease should be treated with metronidazole 750 mg three times daily for 10 days.[273] This drug is well absorbed and does not eradicate organisms in the intestinal lumen, so iodoquinol 650 mg three times daily for 20 days should be given subsequently. Dehydroemetine 1.5 mg/kg/day (maximum 90 mg/day) IM, plus tetracycline 500 mg 4 times daily up to 5 days, may be used as an alternate regimen, followed by iodoquinol.

Giardia lamblia, another frequent waterborne disease, also appears to be sexually transmitted through oral–anal contact. In a review of giardiasis in men seen at New York Hospital, 19 (22%) had not traveled recently, and all were homosexual.[275] In 1977, Meyers et al. documented giardiasis in 6 of 8 MSM who were sexual partners.[28] Giardiasis is typically an infection of the small intestine, although it is often found in association with amebiasis. Symptoms of giardiasis include diarrhea, abdominal cramps, bloating, and nausea. Multiple stool examinations are necessary to document infection with *G. lamblia*. *Giardia* antigen detection by immunofluorescence ELISAs, nonenzymatic immunoassays, and direct fluorescence antibody tests are becoming the standard diagnostic tests in the United States. Sensitivities of these tests range from 85% to 96% compared with microscopy with specificities in the 98–100% range. Other option, when stool examination has been negative, include sampling of jejunal mucus by the Enterotest[276] or small bowel biopsy so as to confirm the diagnosis.

Metronidazole 250—500 mg three times a day for 7 days is presently recommended in the United States but is associated with a 10–20% failure rate.[273,277] Tinidazole, another 5-nitroimidazole, is considered by some authorities as first-line therapy since it is given as a 2-g single dose and may be more effective.[277] Paromomycin 500 mg orally three times daily or furazolidone 100 mg four times daily for 7–10 days may also be used as an alternative.[278] Quinacrine hydrochloride, previously used to treat giardiasis, is no longer available in the United States. Nitazoxanide has been approved for the treatment of giardiasis and cryptosporidiosis. When given at a dose of 500 mg twice a day for 3 days, it has a 71% reported parasitologic cure rate.[278] Follow-up stool examinations are particularly important in management of *G. lamblia* and *E. histolytica* infection. Examination of sex partners of MSM may be important in reducing the reservoir of infection in the community; asymptomatic cyst passers should be treated.

Several reports have commented on the identification of *Enterobius vermicularis*, or pinworms, in MSM,[252,278] although this infection is commonly found in children. Adult pinworm infection is usually acquired by contact with an infected child or by sexual transmission via anilingus. Ova are deposited by the adult worm in the perianal area and are infective for several hours. Pruritus ani is a common symptom. Diagnosis is made by demonstrating the ova, collected on cellophane tape from the anal area. Ova are rarely seen in stool examinations. Mebendazole 100 mg, pyrantel pamoate 11 mg/kg orally, or albendazole 400 mg—all as a single dose, then repeated once after 2 weeks, are usually effective and well tolerated.[273]

Although many helminth infections cannot be transmitted person to person because of their particular life cycle, *Strongyloides stercoralis* could be transmitted sexually, since the infective filariform larvae are often found in the feces. However, there has been no published evidence as yet that this infection has been sexually transmitted.

Intestinal infection with three protozoan parasites—cryptosporidium, *Isospora*, and microsporidium—has been identified in MSM with AIDS.[279–281] Although there has been no documentation of sexual transmission of these parasites, this mode of transmission is highly suspectable due to the relatively high frequency in MSM compared to other select populations with AIDS.

Cryptosporidium is a tiny protozoan parasite that primarily inhabits the microvillus region of epithelial cells. This parasite has been known to cause diarrhea in various animals, especially calves and other domestic animals.[282] In 1976, the first human infection with cryptosporidium was reported, and until 1983 this pathogen was identified only in immunosuppressed patients.[283,284] In 1983, however, investigators reported identification of this parasite in immunocompetent persons exposed to infected calves.[285] The prevalence of infection by stool samples is approximately 1–3% in Europe and North America; however, serology suggests that 32–58% of European and North American adults may be infected. The prevalence is significantly higher (5–10%) in Asia and Africa.[286,287] Worldwide the organism can be isolated from the stool of 10–20% of patients with AIDS-associated diarrhea.[287] In developed countries that have good sanitation and where HAART is available, cryptosporidiosis occurs at an incidence rate of <1 per 100 person-years among persons with AIDS.

Isospora belli is endemic in Africa, Asia, South America, and the Caribbean. The organism is isolated from 8% to 20% of Haitian and African AIDS patients; however, it has been associated with only 0.2% of cases of diarrhea in AIDS patients in the United States.[288] It is possible that *Isospora* is less frequently seen in the United States because drugs used for prophylaxis of *Pneumocystis carinii* and *Toxoplasma* are also effective against this organism.

Cryptosporidial infection may cause asymptomatic, transient, chronic, or fulminant infection.[287] The majority of immunocompetent patients develop profuse diarrhea with abdominal cramps, which is self-limited and subsides in 7–10 days. *Isospora* also can cause a self-limited diarrhea in immunocompetent hosts. Chronic, severe infection is associated with CD4 counts of less than 100 cells/mm^3.[289] In AIDS patients, both infections can produce an illness characterized by intermittent episodes of abdominal cramps, bloating, and nausea in association with either steatorrhea or a profuse secretory diarrhea. Weight loss is usually profound and the infection is unresponsive to any therapeutic attempts to eradicate it or to sustain nutritional status.[279,280] In addition to AIDS, IgA deficiency is an additional risk factor for severe cryptosporidial diarrhea.[290]

Diagnosis of either *Cryptosporidium* or *Isospora* can be rapidly established by a modified acid-fast stain or auramine stain of the stool or by concentration and identification of the organisms by the sugar-flotation method.[291] The large size of *Isospora* cysts helps differentiate them from the smaller *Cryptosporidium* cysts (4–5 ìm). A commercially available fluorescein monoclonal antibody assay increases the sensitivity for detection of cryptosporidia.[292] Intestinal biopsies are also useful in confirming the diagnosis. Primarily, parasites of the small bowel, *Cryptosporidium* or *Isospora*, can be present throughout the small bowel, colon, or both in AIDS. Mucosal biopsies usually reveal the organisms clustered on the surface epithelial cells of the villi with little or no mucosal destruction, ulceration, or inflammation. Consequently, fecal white blood cells are rarely seen in these protozoal infections as they are in infection with enteric bacteria. Improved diagnostic techniques will provide useful information on the epidemiology of these infections in MSM populations and other populations at risk for infection.

Treatment of *Cryptosporidium* or *Isospora* infections in immunocompetent patients with self-limited diarrhea is rarely required. ART with immune restoration is associated with complete resolution of cryptosporidiosis in HIV–infected patients, and all patients with cryptosporidiosis should be offered ART as part of the initial management of their infection.[221] Despite numerous attempts to treat symptomatic infection in immunocompromised individuals, no drugs have been shown to be fully efficacious. In limited studies, the antiprotozoal drug spiromycin was reported to be effective in several AIDS patients with cryptosporidiosis,[293] but subsequent studies have not confirmed this finding. Paromomycin, a nonabsorbable aminoglycoside, given as a dose of 500 mg four times daily for 14–28 days may improve symptoms; the response rate varies from 30% to 70%.[292,294,295] Relapses are common, with long-term success rates of only 33%. Current efficacy data do not support a recommendation for paronomycin's use.[221] Nitazoxanide has documented increased cure rates compared with controls with HIV-infected patients with CD4$^+$ T lymphocyte counts >50 cells/L, but not in those with lower counts.[296] *Isospora* infection does respond to antifolates, but the organism is rarely eradicated, and relapse occurs in 50% of treated AIDS patients. The treatment of choice is trimethoprim (160 mg) and sulfamethoxazole (800 mg) (Bactrim DS), given four times a day for 10 days.[297] Doses of two tablets twice daily for 2 days is as effective and better tolerated. No effective alternative treatment is available for those patients who cannot tolerate sulfonamides, although pyrimethamine 50–75 mg daily with folinic acid for acute infection appears comparable to treatment with trimethoprim and sulfamethoxazole.[298] ART is recommended as part

of the treatment since immune restoration is associated with more rapid symptom resolution and less relapse.

Like cryptosporidia and *Isospora*, *Cyclospora cayetanesis* is a cause of chronic diarrhea in immunocompetent and immunocompromised hosts. Previously called cyanobacterium-like body (CLB), blue-green alga, and "Big Crypto," this organism is found worldwide.[288,299,300] The epidemiology of this infection is not fully elucidated; however, in the United States it has been identified as a cause of traveler's diarrhea[301] and has been associated with outbreaks due to ingestion of unwashed raspberries.[305] Evaluation of stool samples from patients with diarrhea in Chicago and Massachusetts found a prevalence of *Cyclospora* of 0.3–0.5%, similar to that of *Isospora*.[299,303] Pape et al. found cyclospora to be the cause of diarrhea in 11% of 450 HIV-infected Haitians but in no HIV-uninfected patients with diarrhea.[304] The clinical syndrome of watery nonbloody diarrhea is indistinguishable from cryptosporidiosis and isosporosis.

The diagnosis of *Cyclospora* infection can be made by identification of the 8- to 10-μm nonrefractile oocysts in fresh or preserved stool samples. The oocysts have variable acid-fast staining and with UV epifluorescence they autofluoresce as neon blue circles. Bactrim DS four times daily for 10 days followed by suppressive therapy three times per week usually produces symptomatic improvement in AIDS patients.[304]

Microsporidia are obligate intracellular protozoa, and before AIDS only 10 cases of human infection had been documented. Since 1981 several hundred cases have been reported, most since 1991.[305,306] As with other protozoal infections, the incidence of microsporidiosis has declined dramatically with the widespread use of effective ART. Two species of microspordia are associated with diarrhea in HIV-infected patients: *Enterocytozoon bieneusi* and *Encephalitozoon (Septata) intestinalis*.[306,307] The mode of transmission of these organisms is not known; however, they are ubiquitous organisms and are likely zoonotic and/or waterborne in origin. They have been identified as a cause of diarrhea in MSM, and the majority of cases of infections are in adult males, suggesting sexual transmission.

Microsporidia cause a spectrum of disease from asymptomatic infection to severe diarrhea and malabsorption.[308] Rabeneck et al. recently identified *E. bieneusi* in the intestinal epithelial cells of HIV-infected patients without diarrhea. Self-limited diarrhea occurs in patients without severe immunodeficiency, and chronic watery diarrhea with malabsorption occurs with severe immunodeficiency when the $CD4^+$ T lymphocyte count is <100 cells/μL.[309,310]

The diagnosis can be made by identification of the small (1–2 μm) spores in stool and duodenal fluid by light or electron microscopy. The organisms are well visualized by light microscopy with chromotrope staining.[311] Light- or electron-microscopic examination of semithin plastic sections of biopsy samples from the duodenum and jejunum demonstrates infection confined to enterocytes covering the villi, along with villous atrophy and cell degeneration. Electron microscopy is required for species identification or by PCR using species- or genus-specific primers.[312]

At present, there is no reliably effective therapy for microsporidial infection and the best approach to resolution of symptoms is immune restoration. Albendazole has been curative in some cases of infection with *Encephalocytozoon* and disseminated *Septata*.[313] Albendazole treatment of *E. bieneusi* may alleviate symptoms, but it does not seem to eradicate the organism and is associated with a high rate of relapse.[314] Oral fumagillin (60 mg/day) is a water insoluble antibiotic made by *Aspergillus fumigatus* which may have promise, and nitazoxanide might resolve chronic diarrhea caused by *E. bieneusi*.[315,316] Symptomatic treatment with antidiarrheal agents such as lomotil, loperamide, octreotide, and nutritional supplements is helpful in refractory cases.[317]

CONDYLOMATA ACUMINATA

Anal warts due to human papillomaviruses are common in individuals who practice anal intercourse.[318] In one series of 260 MSM seen by proctologists, 134 (51.5%) had anal warts.[17] Warts due to papillomaviruses may occur anywhere in the anal or genital area but are particularly common in the anus in MSM. Of those individuals with warts in the study just cited, 6% had them in the perianal area, 10.5% had them only in the anal canal, and 83.5% had them in both areas. These warts rarely, if ever, extend beyond the pectinate line into the rectum. Perianal condylomata acuminata appear as raised pink-to-brown papules, usually in clusters, and occasionally as large cauliflower-like masses. Patients immunocompromised due to malignancy or HIV infection are more likely to have frequent recurrences of extensive lesions which are recalcitrant to therapy.[319]

Diagnostically, warts should be differentiated from squamous cell carcinoma and from condylomata lata, the moist, flat papules of secondary syphilis. These may be diagnosed by a reactive serology for syphilis and by a dark field demonstrating spirochetes in the lesions. Papanicolaou smears of mucosal lesions for dyskeratosis and koilocytes is less sensitive than DNA detection techniques such as dot blot and in situ hybridization.[320,321] These assays are less specific than Southern blot hybridization. Formal guidelines recommending anal Pap smear screening have not been adopted. If uncertainty exists about the etiology of visible lesions or the presence of high-grade dysplasia or malignancy prevails, biopsy should be performed.

Therapy of genital warts is discussed in Chapter 25. Topical podophyllin (20% solution), commonly used for genital warts, is also effective in some cases of perianal warts; however, it can cause burns with subsequent stenosis when used intra-anally. A 0.5% podophyllin solution (podofilox) or a 0.5% gel is effective and has the benefit of being able to be applied by

the patient.[322] Imiquimod in a 5% cream formulation can be self-applied to lesions at bedtime and removed in the morning by washing. It is applied on three nonconsecutive nights per day up to 16 weeks. Cryotherapy with liquid nitrogen clears up to 90% of treated warts. Laser-beam therapy and surgical excision have been used in refractory cases. Interferons alpha, beta, and gamma have been successfully used,[323–325] but are not generally recommended because of high cost and administration difficulty.

There has been a recent increase in the number of cases of AIN in MSM and a growing body of evidence to support the role of HPV in this malignancy. HPV types 16 and 18 have been found in 56% and 5%, respectively, of anal cancers.[326] Additionally, there appears to be an increased incidence of HPV infection and AIN in HIV-infected individuals. High-grade intraepithelial neoplasia has been found in 0.5–5.4% of HIV-seronegative MSM compared with 4–15.2% of HIV-seropositive men.[327] Risk of high-grade AIN was associated with HPV types 16 and 18 in both HIV-seronegative and seropositive men and was 2.9-fold higher for HIV-seropositive men with fewer than 500 CD4 cells/mm^3, compared with men with more than 500 CD4 cells/mm^3.[328] Although data are limited, effective ART does not appear to substantially influence the short-term natural history of AIN.

MYCOBACTERIAL INFECTIONS

MAC is a group of "atypical" mycobacteria that has been identified in severely immunocompromised patients, including MSM with AIDS.[10] Ninety-eight percent of these isolates are *M. avium* (usually serovars 1, 4, and 8); the remainder include *M. intracelullare*. The gastrointestinal tract and lymph nodes appear to be the most common organs infected by this organism. Infections of the intestinal tract are usually part of disseminated infection which presents with fever, night sweats, abdominal pain, watery diarrhea, steatorrhea, and malabsorption. Both the clinical and the radiographic features of this disease may mimic Whipple's disease.[329] The major risk factor for this disease is severe immunocompromise, with less than 75 CD4 lymphocytes/mm^3 or previous opportunistic infection, especially CMV disease.[329]

It has been postulated that the gastrointestinal symptoms of MAC infection are due to defective macrophage processing of the MAC pathogens, which leads to accumulation of macrophages and secondary malabsorption, as seen in Whipple's disease. The defective T-cell activation of macrophages has been proposed as a mechanism in the pathogenesis of Whipple's disease, an immunologic defect which is also characterized by depression of T-cell function.[329,330] The characteristic findings seen in MAC infection of AIDS patients, such as severe lymphopenia and anemia, reduction of circulating helper-T cells, skin test anergy, and polyclonal hypergammaglobulinemia, are not classically seen in Whipple's disease.

The diagnosis of MAC infection is based on stool culture, acid-fast staining of the organism in the stool, and histologic examination of small bowel biopsy specimens. Although some patients are asymptomatic excretors of MAC, histologic evidence of gastrointestinal involvement is indicative of disseminated infection. Fine, white mucosal nodules noted on endoscopy are highly suggestive of MAC disease.[331] The main histologic features on small bowel biopsy include increased numbers of macrophages filled with PAS-positive and acid-fast bacilli within the lamina propria, villous atrophy, and exudative enteropathy.[329] Blood and bone marrow cultures are positive in 85–90% of patients with gastrointestinal involvement. Blood cultures using the lysis centrifugation techniques for mycobacterial organisms are frequently positive in AIDS patients with disseminated MAC.[331]

The following combination drug regimes have been found to decrease bacteremia and improve symptoms: Clarithromycin 500 mg twice daily and ethambutol 15–25 mg/kg/day with or without ciprofloxacin 750 mg twice daily and rifabutin 300 mg daily, *or* azithromycin 500–600 mg daily and ethambutol 15–25 mg/kg/day with or without ciprofloxacin 750 mg twice daily and rifabutin 300 mg daily. Prophylaxis with clarithromycin 500 mg twice daily, azithromycin 1200 mg weekly, or possibly rifabutin 300 mg daily for AIDS patients with less than 50 CD4 lymphocytes/mm^3 is recommended to decrease the frequency of disseminated disease and improve survival.[332–334]

CYTOMEGALOVIRUS INFECTION

Gastrointestinal CMV disease may be sexually transmitted and can occur in immunocompromised and immunocompetent patients, involving any area from mouth to anus. Several case reports have described CMV proctitis or proctocolitis following sexual intercourse and as part of a primary CMV infection.[335–338] Gastrointestinal symptoms of CMV disease have been reported in 2–16% of organ transplant recipients, but AIDS patients with advanced immunosuppression, typically those with CD4$^+$ T lymphocyte counts <50 cells/μL, are at risk of developing CMV disease.[339] This is usually due to reactivation of latent infection, but a few cases may be due to primary infection or reinfection. In one autopsy series before potent ART, gastrointestinal CMV was identified in 90% of AIDS patients, and in AIDS patients with intestinal symptoms CMV has been identified—in stool cultures or in rectal or intestinal biopsy samples at autopsy—in up to 50%.[7,12] CMV infection of the gastrointestinal tract may be associated with esophagitis, esophageal ulcerations, enteritis, colitis, or proctitis.

CMV most often presents as a diffuse colitis associated with fever, abdominal pain, anorexia, and watery or bloody

diarrhea.[340–342] Occasionally, patients with CMV intestinal symptoms may present clinically with a solitary intestinal ulcer, occasionally resulting in toxic dilatation and rarely in intestinal perforation.[343] Barium enema may show a picture of segmental colitis or pancolitis.[344] Sigmoidoscopy or colonoscopy frequently shows erythema, ulceration, or occasionally plaques, nodules, polyps, or violaceous lesions resembling Kaposi's sarcoma. Biopsy of these lesions reveals CMV vasculitis giant cells with large pleomorphic nuclei containing basophilic intranuclear CMV inclusions; these are usually endothelial cells and fibroblasts. Biopsy also shows acute hemorrhage and inflammation in the lamina propria. The presence of intranuclear inclusion bodies suggests that CMV is present in the tissue, but its role in disease pathogenesis remains unclear, since its presence is documented in both inflamed and noninflamed tissue. Marked involvement of endothelial cells can be associated with frank vasculitis and secondary mucosal ischemic changes.

Diagnosis of CMV infection is confirmed by histologic demonstration of intranuclear inclusion bodies or by viral cultures or immunofluorescent stain of intestinal biopsies.[345] Abnormal cytopathology is more likely than isolation of the virus in culture to correlate with significant disease. Systemic CMV can be determined by viral culture of the white blood cell buffy coat or urine.[344] New techniques using labeled nucleic acid probes and PCR have been effective in detecting CMV in tissue and other specimens; however, detection of the organism by PCR does not distinguish infection from disease.[346,347]

Therapy for CMV disease has been best evaluated for CMV retinitis. Treatment with ganciclovir, foscarnet, and cidofovir has been effective in suppressing viral replication with subsequent negative cultures and stabilization of clinical disease, but relapses are common after therapy is discontinued.[348] Symptomatic improvement has been reported in 93–100% of solid organ transplant recipients with CMV gastrointestinal disease treated with ganciclovir. In AIDS patients, ganciclovir treatment of CMV esophageal ulcers produces improved symptoms in 75%; therapy for CMV colitis appears to be less effective.[35] Nelson et al. noted that while 15 of 18 (83%) patients with esophageal disease treated with foscarnet had complete response, only 11 of 18 (61%) patients with colitis had a complete response.[349] Pancytopenia is the major toxicity of ganciclovir; it may be alleviated with granulocyte colony–stimulating factor and erythropoietin. Nephrotoxicity is the major side effect of foscarnet and cidofovir.[348] Foscarnet also causes significant electrolyte wasting and may produce seizures. Without treatment and with continued immunosuppression, CMV may result in intestinal complications such as intestinal perforation, toxic megacolon, and acalculous gangrenous colitis.[346–347] Oral ganciclovir 1 g three times daily may be effective in reducing the risk of CMV disease.[350] Chronic maintenance therapy is not routinely recommended for gastrointestinal disease but may be considered if relapses occur.

INTESTINAL SPIROCHETOSIS

Spirochetes other than *T. pallidum* were documented in the human intestinal tract as early as the nineteenth century. In humans, *Brachyspira aalborgi* and *Bracyspira pilosicoli* predominate. However, the pathologic and clinical significance of this condition remains unclear.[351–354] McMillian and Lee reported the identification of intestinal spirochetes on biopsies of 36 of 100 MSM.[355] There was no attempt to correlate symptoms with the presence or absence of spirochetes, and a comprehensive search for other pathogens in these patients was not carried out. Surawicz et al. diagnosed intestinal spirochetosis in 15% of MSM and no heterosexual men. Rectal spirochetosis was not associated with other histopathologic abnormalities or symptoms.[353] Law et al. diagnosed rectal spirochetosis in 39% of healthy unselected MSM attending an STD clinic. Rectal spirochetosis was associated with a history of oral–anal contact (OR 3.45), detection of three to five different nonpathogenic protozoans in feces (OR 11.7), and positive HIV-1 serology (OR 4.48).[354,355]

The association of intestinal spirochetosis with symptomatic disease remains largely anecdotal. Usually, gastrointestinal symptoms are attributed to intestinal spirochetosis if no other cause can be identified. Kostman et al. described two AIDS patients with diffuse colitis who on histopathology had spirochetes overlying abnormal mucosa.[356] No other pathogen was identified. Both patients responded to metronidazole therapy. Gebbers et al. also reported on two patients with mild intestinal symptoms in whom rectal spirochetosis was the only abnormality diagnosed.[357] Their histopathologic findings, as with the previous study, indicated invasion of the organism, with spirochetes within epithelial cells and subepithelial macrophages. They also found numerous partially degranulated mast cells and an increased proportion of IgE plasma cells, all suggesting an immune response to the infection. Antibiotic therapy was associated with clearance of the organisms and symptomatic improvement.[357] Additional studies have identified intestinal spirochetosis by biopsy in 28 of 100 symptomatic MSM[13] and by culture in 13 (39%) of 33 symptomatic, and 33 (16%) of 203 asymptomatic men.[70] Identification of spirochetes by culture was more commonly associated with symptoms of diarrhea than with symptoms of proctitis. Although these data are not definitive, they suggest that intestinal spirochetosis is more prevalent in MSM and that it may be associated with diarrhea.

Intestinal spirochetosis is readily diagnosed histologically by the presence of a prominent hematoxophilic band adjacent to the luminal surface of mucosal epithelial cells.[13] Morphologically distinct from *T. pallidum*, intestinal spirochetes can be demonstrated by darkfield microscopy of fresh material or cultured anaerobically in selected medium. Serological tests for syphilis (VDRL and RPR) are negative.

Since the clinical significance of human intestinal spirochetosis remains in question, the treatment is controversial. No controlled trials have been undertaken to examine the efficacy of antibiotics and whether eradication of the spirochetes leads to resolution of symptoms. Anecdotal reports suggest that treatment with metronidazole 400 mg three times daily for 10 days is effective in eliminating spirochetes and may afford some symptomatic relief. Consequently, until adequate clinical antibiotic studies are performed, metronidazole should be recommended for the treatment of symptomatic human intestinal spirochetosis following the exclusion of other known pathogens. Treatment is not recommended for asymptomatic intestinal spirochetosis.

OTHER PERIANAL SEXUALLY TRANSMITTED DISEASES

Donovanosis (or granuloma inguinale) is a chronic ulcerative disease which generally involves the skin and subcutaneous tissue of the genital, inguinal, and anal regions. Described in Chapter 39, donovanosis is believed to be caused by *Calymmatobacterium granulomatis*, a bacterium which multiplies within tissue histocytes and monocytes.

Donovanosis is rare in industrialized countries but relatively common in tropical and subtropical countries such as New Guinea, India, central Australia, and the Caribbean. The disease occurs more often in males than in females, and it is more common in homosexual than in heterosexual men. Although donovanosis is probably sexually transmitted, the exact mechanism of transmission is still debated. Perianal lesions occur predominantly among those who practice anal intercourse,[358,359] although the disease can also spread contiguously from the genital area to the anal region. Very little is known concerning involvement of the rectum or gastrointestinal tract. Within the perianal and anal area, the infection starts as a small, commonly pruritic, papule and later ulcerates to form a granulomatous beefy-red ulcer. Opposing (kissing) lesions are common. Lesions can become hypertrophic, at which point they are similar in appearance to condylomata lata. Most of the lesions are painless. Lesions that are located in the anal canal may be associated with rectal bleeding, and they may lead to stenosis of the anal canal.

Diagnosis is based on demonstrating the intracellular organisms (Donovan bodies) on Giemsa-stained impression smears or sections of biopsies from a lesion. Treatment consists of doxycycline 100 mg twice daily for 10 days or longer.

Chancroid occasionally causes perianal lesions in women and MSM. Although anorectal chancroid has not been well studied, it is likely that the painful lesions produced by *Haemophilus ducreyi* would most closely resemble herpetic lesions in the anorectal area, as they do in the genital tract. Diagnosis and therapy of anorectal chancroid are analogous to the management of genital chancroid (discussed in Chapter 38).

ANORECTAL TRAUMA AND FOREIGN OBJECTS

Complications of anal intercourse include prolapsed hemorrhoids, fissures, rectal ulcers, tears, and foreign bodies.[19] Rectal tears, and occasionally rectal perforation, may be caused by rectal intercourse, by insertion of a closed fist and part of the forearm into the rectum, or by insertion of foreign bodies.[360,361] Typically, patients with anorectal trauma present with the acute onset of rectal bleeding, or with signs of an "acute abdomen" if rectal perforation has occurred above the peritoneal reflection. Medical attention may be sought because the patient is unable to remove a foreign object. Retained foreign bodies have included vibrators, rubber phalluslike devices, bananas, bottles, apples, billiard balls, light bulbs, a Bermuda onion, and a variety of other unusual objects.[361]

Management of such cases is based on the clinical history, evidence of an acute abdomen, the degree of rectal trauma, and the type of retained object. If an object is present, digital and radiographic examination should confirm the position of the object. The object may be removed through a proctoscope with biopsy forceps, snare, or Foley catheter. Occasionally, local or general anesthesia may be required to remove a foreign body manually or with obstetric forceps.[361]

DIFFERENTIAL DIAGNOSIS

Many agents that infect the gut in MSM cause similar pathology, and differentiation as to the causative agent is sometimes possible only by laboratory tests. Further, infection with several pathogens is not uncommon and overlapping symptoms make differentiation on clinical grounds even more difficult. However, characteristic features of some infections are helpful in narrowing the diagnostic possibilities. It seems apparent that the majority of MSM with anorectal symptoms who consult an STD clinic have a specific infection, and diagnoses such as "idiopathic rectal ulcer," "nonspecific proctitis," or "trauma" are usually unwarranted unless specific infections are excluded. In general, it is clear that in MSM proctitis or discrete ulcerative lesions of the rectum are usually caused by conventional STD agents such as *N. gonorrhoeae*, *C. trachomatis*, HSV, and *T. pallidum* and are probably acquired by receptive rectal intercourse. Infections associated with proctocolitis are caused by enteric pathogens such as *E. histolytica*, *C. jejuni*, *Salmonella*, and *Shigella*, which may be acquired most often among MSM by anilingus. Symptoms of enteritis, without sigmoidoscopic evidence of proctocolitis, are most often attributable to *G. lamblia* infection in homosexually active men.[27]

In immunocompromised MSM with HIV infection, additional organisms should be considered, such as cryptosporidia, microsporidia, *Isospora*, *Cyclospora*, MAC, and CMV, in addition to HIV-1. In these immunosuppressed patients, esophagitis may develop secondary to *Candida*, HSV, and CMV.

The constellation of fever, severe anorectal pain, constipation, urinary retention, and sacral neuralgias in a patient with ulcerative rectal mucosa strongly suggests HSV infection. The presence of nonpainful anorectal ulcers, rectal polyps, or nonspecific anorectal symptoms in a patient with a rash should suggest the possibility of anorectal syphilis. LGV proctitis or proctocolitis should be considered in MSM who have severe anorectal symptoms such as hematochezia, rectal discharge, diarrhea, and fever and who may have severe ulcerative rectal mucosa with granulomas present on rectal biopsy. LGV should also be considered in MSM who are suspected to have Crohn's disease of the rectum. Since *N. gonorrhoeae* and non-LGV *C. trachomatis* cause nonspecific anorectal symptoms without symptoms of enteritis and result in nonspecific pathology of the lower rectum, these pathogens should be considered in most individuals who present with anorectal symptoms, have only mild proctitis on sigmoidoscopy, and acknowledge receptive anorectal intercourse.

Campylobacter, *Salmonella*, and *Shigella* should be suspected in those individuals with a history of acute diarrhea associated with bloody stools and fecal leukocytes, especially if sigmoidoscopic findings are not limited to the distal rectum and if stools are negative for ova and parasites. *Giardia* infection will more often cause diarrhea which is more chronic and nonbloody and is associated with nausea and bloating. *E. histolytica* infection presents with symptoms ranging from acute bloody diarrhea to chronic diarrhea with intermittent exacerbations.

A heavy concentration of *Candida albicans* in stool has been associated with pruritus ani or rectal itching in MSM in our studies, and topical and oral therapy with appropriate antifungal agents may be beneficial in such patients. The presence of perianal dermatitis with or without pustulae may suggest anorectal candidiasis. However, perianal erythema extending over an area of several centimeters in diameter is commonly associated with rectal discharge caused by a variety of agents and is not specific for anorectal candidiasis. When symptoms of proctitis or enteritis occur during or after antimicrobial therapy, *C. albicans* infection or pseudomembranous enterocolitis with *Clostridium difficile* infection should be considered.

When the patient is known to be immunocompromised secondary to HIV infection or AIDS, a more extensive evaluation for opportunistic infections should be undertaken. *Candida*, HSV, and CMV should be evaluated in those patients with symptoms of esophagitis. Intestinal protozoans such as cryptosporidia, *Isospora*, and microsporidia, as well as MAC and CMV, should be considered in those immunocompromised patients presenting with a diarrheal illness of a chronic nature (longer than 2–3 weeks).

If no infectious etiology is demonstrated despite appropriate tests and a trial of antimicrobial therapy (see below) has no effect, then idiopathic inflammatory bowel disease, such as ulcerative colitis or Crohn's disease, or HIV-1 infection of the intestine should be considered. Because of clinical similarities between enteric infections (a common problem) and inflammatory bowel disease (much less common), all appropriate infectious agents should be ruled out before a diagnosis of inflammatory bowel disease is made. Additional noninfectious conditions that could be confused with enteric infections include radiation colitis, chemically induced colitis (due to drugs, gold therapy, soaps, lubricants, or other chemicals), and neoplasm.

MANAGEMENT

The large number of infectious agents that cause enteric and anorectal infections in MSM necessitate a systematic approach to the management of these conditions. The medical history should attempt to differentiate among proctitis, proctocolitis, and enteritis and should assess the constellations of symptoms that suggest one or another likely infectious etiology. The history should also investigate types of sexual practices and possible exposure to the pathogens known to cause proctitis, proctocolitis, or enteritis. Examination should include inspection of the anus, digital rectal examination, and anoscopy (avoiding or minimizing use of bacteriostatic lubricants, which might interfere with microbiologic studies) to identify general mucosal abnormalities. Such abnormalities, including easily induced bleeding and exudate and discrete polyps, ulcerations, or fissures, should be cultured and biopsied if appropriate. Anal warts are frequently detected, but if proctitis is present, therapy of these warts should usually be deferred until the proctitis is resolved.

Initial laboratory tests should include a Gram stain of any rectal exudate obtained with the use of an anoscope; if no exudate is seen, material should be obtained for the Gram stain from the rectal mucosa or from any abnormal appearing stool. The demonstration of leukocytes provides objective evidence for the presence of an infectious or inflammatory disease. Until NAATs are approved for rectal specimens, cultures for *N. gonorrhoeae* should be obtained from the rectum, urethra (if NAAT is not done), and pharynx, and if possible a rectal culture for *C. trachomatis* should be performed. A serologic test for syphilis should be performed in all cases. If any external ulcers, rectal mucosal lesions, or suspected condylomata lata are seen, darkfield examination of these lesions and a rapid plasma reagin test should be performed in the clinic. HSV cultures should be performed if ulcerative lesions are

present. If proctocolitis is likely on the basis of either symptoms or sigmoidoscopic examination, then additional cultures for *Campylobacter*, *Salmonella*, and *Shigella* and stool examination for *E. histolytica* are indicated.

If symptoms and signs suggest enteritis rather than proctitis or proctocolitis, stool should be cultured for *Campylobacter* and examined (in addition to jejunal aspirate, perhaps) for *Giardia*, cryptosporidia, *Isospora*, mycobacteria, and microsporidia. Additionally, endoscopy and biopsy can aid in diagnosis of HIV, microsporidia, CMV, and MAC enteropathy. Cultures for *Salmonella*, *Yersinia*, and *V. parahemolyticus* and attempts to demonstrate *C. difficile* toxin or enterotoxigenic *E. coli* are sometimes indicated in MSM, as in heterosexual men and women, although these agents have not been found with greater frequency in MSM.

If a diagnosis of gonorrhea is initially made by a positive Gram stain, or if syphilis is confirmed by darkfield examination or rapid plasma reagin serology, appropriate treatment should be instituted promptly. Similarly, anyone with sexual contact with a person with known gonorrhea, syphilis, or chlamydial infection should be treated appropriately on an epidemiologic basis after complete physical examination, while results of cultures for *N. gonorrhoeae* and serology for syphilis are pending. A presumptive diagnosis of HSV can often be made initially on clinical appearance alone or by history, but laboratory confirmation of suspected herpetic lesions is always desirable unless the clinical appearance of vesicular lesions is diagnostic. If the patient remains symptomatic and a careful search reveals no pathogen, or if the patient remains symptomatic despite appropriate therapy for any pathogen found or after empiric therapy, then the patient should be evaluated by a specialist for the possibility of inflammatory bowel disease or other diseases which are not sexually transmitted.

In those patients found to be immunocompromised and infected with HIV, a more extensive evaluation of the intestinal tract is required. A careful oral examination should evaluate for the presence of thrush and/or oral lesions of Kaposi's sarcoma. Dysphagia or odynophagia may suggest the presence of esophageal candidiasis and/or esophageal involvement with CMV or HIV infection. Systemic and/or abdominal lymphadenopathy and the presence or absence of gastrointestinal blood loss should suggest gastrointestinal neoplasms, including Kaposi's sarcoma and gastrointestinal lymphomas. Careful radiographic examinations of the esophagus, small bowel, and colon, as well as endoscopy and colonoscopy, may be warranted in these highly suspect patients. Stool examination should be carefully studied for the presence of cryptosporidia, *Isospora*, and mycobacteria, as well as the other enteric pathogens described above. Intestinal biopsies may be obtained of suspicious lesions and examined for CMV, mycobacterium, intestinal protozoans, and other histologic features of infection or malabsorption.

Identification of any of the enteric pathogens should result in specific therapeutic regimens. Failure to respond to any specific antimicrobial regimens may represent drug resistance or, more commonly, the presence of additional pathogens, necessitating more comprehensive microbiologic and immunologic evaluation. If symptoms persist after eradication of infection or if no pathogens are identified, one must consider idiopathic inflammatory bowel disease, neoplastic lesions, or antibiotic-resistant opportunistic infections and institute diagnostic and therapeutic approaches to these diseases.

Because of the complexity of diagnosis and treatment of enteritis and proctitis in an STD population and the different levels of laboratory support at STD clinics and in office practice, we have outlined two algorithms. Algorithm A (Fig. 68-11) represents a systematic approach to diagnosis and treatment that is comprehensive and employs treatment only for identified pathogens. It basically represents a stepwise progression toward specific diagnosis and treatment of patient and exposed contacts. The major problem with this algorithm is that the microbiologic evaluation is expensive and time consuming, factors which may indirectly allow continued

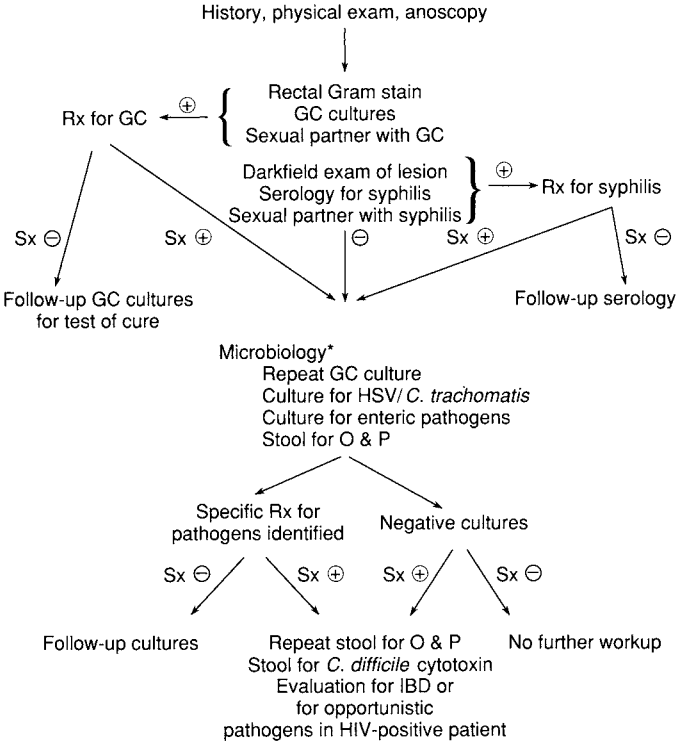

FIGURE 68-11. Algorithm A: Evaluation and treatment of anorectal and/or intestinal symptoms in homosexual men. This algorithm emphasizes a full diagnostic evaluation and treatment for the specific pathogens identified. Ideally, microbiologic evaluation should be based on presenting symptoms and sigmoidoscopy findings. Rx = treatment, Sx = symptoms, GC = *N. gonorrhoeae*, O & P = ova and parasites, a IBD = inflammatory bowel disease.

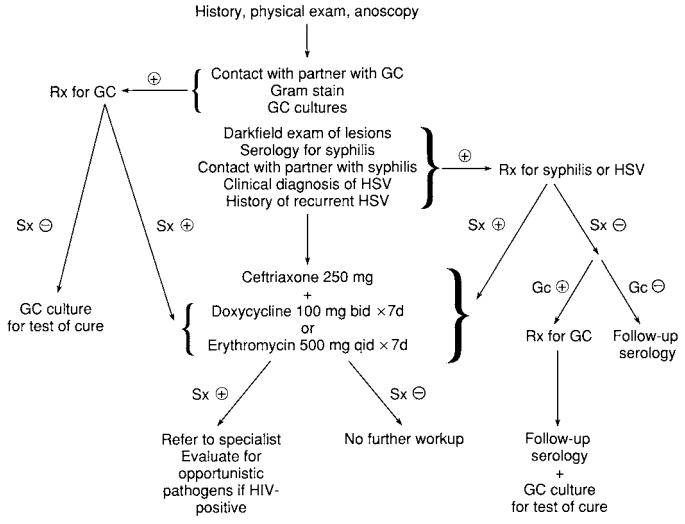

FIGURE 68-12. Algorithm B: Evaluation and treatment of anorectal and/or intestinal symptoms in homosexual men. This algorithm emphasizes empirical therapy after an initial evaluation for gonorrhea and syphilis. Empirical therapy consists of intramuscular ceftriaxone 250 mg, followed by either azithromycin 1 gm, doxycycline, or erythromycin. If the patient remains symptomatic, he is referred for more complete evaluation. GC = *N. gonorrhoeae*, Rx = treatment, Sx = symptoms.

discomfort of the patient and transmission of the pathogen before final diagnosis and treatment.

Algorithm B (Fig. 68-12) is based on empirical therapy, which has the advantage of decreasing the cost of laboratory tests and provides immediate therapy to patients who may not return for follow-up visits. Such empirical therapy has recently been shown to produce more rapid resolution of the symptoms and signs of acute proctitis in MSM than specific therapy.[362] Empirical therapy has the disadvantage, however, of treating a patient before the diagnosis is known. In the study just cited, unrecognized HSV proctitis was the major reason for the failure of an empirical therapy. The treatment may also convert the patient to an asymptomatic carrier, and most important, it interferes with public health efforts to trace contacts of the patient who may harbor a specific pathogen. Such public health efforts would be possible only if a specific diagnosis is made in the patient.

Selection between these two approaches must be based on clinic and public health priorities, budget, laboratory support, and patient population. Alternative approaches will undoubtedly become preferable as more is learned about the etiology and epidemiology of enteritis, proctitis, and proctocolitis in MSM.

REVENTION

Because of the relatively high prevalence of asymptomatic anorectal carriage of pathogenic organisms in MSM, a concerted effort involving the clinician and public health authorities is necessary to control these infections. Examination and treatment of the sexual partners of MSM with STDs such as gonorrhea or syphilis is a conventional practice, yet similar management of the sexual contacts of MSM with enteric infection is not a routine procedure. Such an approach must be evaluated, not only for cases that come to medical attention through the STD clinic but also for those that are reported from other sources. We believe that when a specific pathogen is identified in a symptomatic homosexually active male patient, epidemiologic investigation of all sexual contacts within a time frame appropriate to the incubation period of the pathogen in question should be performed, and appropriate diagnostic tests for the pathogen(s) involved should be obtained from the contacts. This is especially important for those agents which can be eliminated by treatment, such as gonorrhea, *C. trachomatis*, syphilis, and the enteric pathogens. Because of the intermittent nature of virus shedding, HSV cultures in sex partners of men with rectal HSV infection is frequently unrewarding.

Most of the pathogens we have discussed should be reported to local public health workers, whose assistance in coordinating efforts to identify and examine culture contacts is helpful. Household as well as sexual contacts should be screened for infection when investigating the spread of enteric pathogens. After the acute infection subsides or following therapy, repeat laboratory tests should be performed to detect possible development of a carrier state. Infected individuals should abstain from sexual practices that might spread infection until repeat cultures are negative. Infected persons should also be educated regarding safe sex practices in the AIDS era.

Effective education of both physicians and patients about the different modes of transmission of these pathogens is necessary, along with more reliable and available laboratory techniques for diagnosis of some of them. Recognition of the importance of sexual transmission in the spread of these infections is a prerequisite to designing public health programs that will effectively prevent their spread in the community at large. In addition, recognition of the role that some of these pathogens (especially HSV and syphilis) may play in facilitating the spread of HIV infection provides added incentive for their prevention.[363,364]

PART 12

Clinical Management of HIV Infection

This page intentionally left blank

69 Counseling and Testing for HIV Infection

Freya Spielberg and Ann E. Kurth

IMPORTANCE OF HIV TESTING

The importance of HIV counseling and testing for early clinical intervention has been clearly established, both to initiate highly active antiretroviral therapy (HAART) to delay progression to AIDS, as well as to prevent opportunistic infections once a diagnosis of AIDS has been established.[1]

More recently the importance of early identification of HIV infection for HIV prevention has been established, through both biological and behavioral mechanisms. In acute HIV infection high viral titers lead to greater infectivity.[2] People who receive HAART have decreased viral titers and so are potentially less infectious.[3] As importantly, people who learn that they have HIV are much less likely to engage in high-risk behaviors.[4]

To impact the HIV pandemic, testing is critical even in resource poor settings where HIV treatment is not yet available for all. Thus, in the 2006 guidelines from the Centers for Disease Control and Prevention (CDC) and the 2007 guidelines from the World Health Organization (WHO), a greater emphasis has been placed on expanding access and removing barriers to HIV testing in order to stem the continuing pandemic.[5,6]

In the United States the CDC recommends opt-out screening for HIV among all people visiting health-care facilities, and no longer requires a separate written consent or risk-reduction counseling in these settings.[5] For populations at highest risk the CDC continues to recommend expanded access to outreach HIV counseling, testing and referral services with integrated client-centered HIV risk-reduction counseling.

In global settings, the WHO has made similar recommendations for routine provider-initiated testing in populations with "generalized epidemics" (HIV prevalence among pregnant women >1%). Whereas in populations with "concentrated epidemics" (HIV prevalence in sub populations >5%, but <1% in pregnant women) or in "low-level epidemics" (HIV <5% in all populations, HIV <1% among pregnant women), the WHO advocates offering provider-initiated testing to people with signs or symptoms of HIV, and to high risk populations.[6]

HIV EPIDEMIOLOGY

The estimated number of people with HIV has reached more than 1 million in the United States[7] and over 40 million worldwide.[8] Those who are aware of their risks and are willing to test have been identified, yet approximately one-fourth of the people infected with HIV in the United States (252,000–312,000)[9] and over 80% globally are unaware that they are infected.[8] Without the knowledge of their status, many people with HIV are likely to transmit the virus unknowingly[4] and to miss early monitoring benefits.

Since 1998, in the United States, the estimated number of new infections has remained stable at 40,000 per year.[10] Since 1980, however, the demographics of the HIV epidemic in the United States has changed, with increasing proportions of young people (<20 years), women, racial, or ethnic minorities, people who live outside metropolitan areas, and heterosexual women and men becoming infected.[11] Thus, the initial strategy of risk based or geographical testing for HIV is no longer effective.

An estimated 4.1 million new people globally were infected with HIV in 2005.[8] The HIV incidence rate is believed to have peaked in the late 1990s, now decreasing in some countries, stable in many, and increasing in others.[12] In order to reduce HIV incidence globally, both the CDC and WHO/UNAIDS are promoting increased access to HIV testing in both health-care settings and in community settings.[5,6]

TRANSMISSION OF HIV

Current evidence suggests that between 54% and 70% of the estimated 40,000 new HIV infections each year in the United States (and a higher percentage globally) occur through transmission from persons who are unaware of their HIV-positive status.[13] Many persons receive their HIV diagnosis late in the course of the disease. In the United States, as many as 40–45% of persons testing positive for HIV received their

first positive test results less than a year before AIDS was diagnosed.[14] In the United States and many low- and middle-income countries, people often first present for testing with symptoms of AIDS.

The efficiency of transmission of HIV varies greatly with the stage of disease.[2] Patients with the greatest viral burdens (acute HIV, AIDS, and rapid progressors) are most contagious. Subjects with acute HIV may be responsible for nearly half of new cases of HIV[2] and clusters of cases are easily detected.[15] However, Fraser et al. and other mathematical modelers have argued that patients with established infection and moderate set-point viral burden may live so long (sexually active) that they will dominate the epidemic.[16]

TIME COURSE OF ASSAY DETECTION OF HIV INFECTION

To diagnose HIV infection, in most health-care settings in the United States a rapid enzyme linked immunoassay (EIA) or standard EIA is used, followed by Western blot for confirmation. In many global settings two to three rapid HIV tests are used for screening and confirmation.[17] Initially the window period (the time during which someone is infected and antibody negative) was estimated to be 6 months. Third-generation antibody tests narrowed that window to 20–30 days after viremia (Fig. 69-1), with recombinant-DNA-based, antigen-sandwich assays sensitive to IgM becoming positive on day 20, as compared to viral-lysate EIAs insensitive to IgM that become positive on average 10 days later.[18]

With each generation of antibody assay, the timing of identification of HIV infections is reduced. Newer fourth-generation assays combine antibody and p24 antigen detection, and may simplify identification of chronic and acute HIV infection. One study[19] that examined the timing of detection of HIV for a third- and fourth-generation assay on 92 seroconversion panels, showed that the fourth-generation assay detected HIV a mean of 4 days earlier than the third-generation assay and a mean of 3 days later than a HIV-1 RNA RT–PCR assay. HIV can be detected earliest with RT–PCR for HIV-RNA on day 10 after infectious viremia. HIV DNA (PCR) in PBMC and P24 antigen assays lag behind and do not detect HIV infection until on average day number 15.[18]

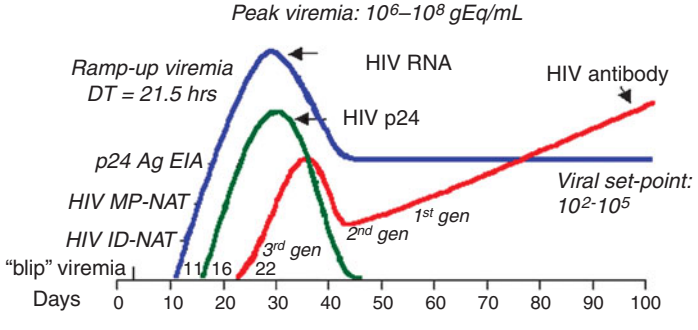

FIGURE 69-1. HIV viremia during early infection. DT, doubling time; gen, generation of enzyme immuno-assay (EIA); Ag, antigen; MP, mini pooled specimens; ID, individual specimens; NAT, nucleic acid testing. (M.P. Busch, Blood Systems Research Institute and University of California, San Francisco; and E.W. Fiebig, San Francisco General Hospital and University of California, San Francisco (Private Communication 3–2007)).

In high-risk populations, pooling sera for nucleic acid amplification testing (NAAT) can be a cost-effective method for diagnosing acute HIV infection.[20–22] In some public health clinics, pooled RNA testing is now routinely performed on specimens that are negative on EIA tests. In Atlanta,[21] 2202 people receiving HIV testing at three sites were tested with third-generation antibody test, and if negative pooled specimens were tested with HIV NAAT. The prevalence of HIV in this population was 3.2%. Adding NAAT increased the sensitivity of the testing algorithm from 94.3% to 100% (by definition) and increased case identification by 6%. A smaller study among men who have sex with men (MSM) in Seattle demonstrated that adding NAAT testing of pooled specimens increased case identification by 13.5%.[22]

BARRIERS TO TESTING

The reasons more people are not getting tested are varied.[23] Some have poor access to HIV testing. Others are unaware of their risks. Many remain afraid to find out their test results[24,25] or they avoid testing due to stigma.[26] Others avoid testing because of a dislike of counseling, or because of the anxiety associated with waiting for their test result. Some are unaware that they would have access to effective treatment for HIV and so see no point in testing.[24]

In health-care settings, reasons for late testing are complex and multifactorial, including a low index of suspicion on the part of the provider, client denial of risk, lack of awareness, or of access to HIV testing, and limited confidence in the benefits of early clinical intervention.[27] In a recent South Carolina study[28] the majority of patients with newly diagnosed HIV infections had been provided health care one or more times in the preceding months, especially in emergency rooms (ERs).

Other studies have attempted to compare the characteristics of persons who have been tested for HIV to those never tested. During May 2000 to February 2003, persons at 16 U.S. sites who were tested early in the course of HIV disease (early testers) were compared with persons who were tested late in the course of HIV disease (late testers). Late testers were more likely than early testers to be black or Hispanic, less educated, and exposed to HIV through heterosexual contact.[29]

Even among those who test, there are additional barriers to getting HIV test results. Many HIV testing programs have reported that a high proportion of persons who are tested for HIV do not return for their test results. According to data from publicly funded HIV clinics, 30% of persons who tested HIV-positive during 2000 and 39% of persons who tested HIV-negative did not return.[30] But many of these individuals

were seeking STD services rather than HIV C/T, which was recommended by providers and not specifically sought. More recently this barrier has been overcome by the provision of rapid HIV testing that allows people to learn their status during the first visit.[31] However, many clinical settings have been slow to implement rapid testing technology. Although rapid testing has been shown cost-effective from a payer perspective,[32] some clinics are hesitant to implement because of the higher costs of the kits or the need for additional staff training. It is necessary for health-care providers to consider that the higher acceptability and effectiveness of rapid testing improves testing rates and staff efficiency[33] and costs less per test result provided than standard testing, even when the price of the rapid test is higher than that of the standard blood test.[32,34]

Overcoming many of the barriers to HIV testing may require large-scale social marketing campaigns as well as modifications of counseling and testing programs. It will be important to develop interventions to address HIV-related stigma, especially in developing country settings. It will be necessary to make acceptable HIV counseling and testing strategies conveniently available. And it will be important to make people aware that the benefits of knowing one's status clearly outweigh the risks of testing. This is true even in countries where HAART is unavailable, because knowledge of HIV status is necessary to prevent further spread of the infection.[35]

ROLE OF HEALTH-CARE PROVIDERS

Health-care providers can play a large part in increasing the number of people who are aware that they are infected with HIV. System changes will be necessary to ensure that patients are screened and offered HIV testing. One national survey showed that less than one third of the physicians routinely screen for STDs.[36] Judgmental providers have been cited as a barrier to eliciting honest information regarding past sexual behaviors.[37]

In response to the recognition in the late 1990s that nearly two thirds of inpatients newly diagnosed with AIDS had received care in their health system during the year preceding admission, Grady Hospital in Atlanta, GA, began to routinely recommend HIV testing to patients presenting to the urgent-care clinic. Compared with 1999 when testing was based on symptoms or risk behaviors, the Grady study found that more patients were tested, more HIV infections were detected, and more infected persons learned their diagnosis and entered into care.[38]

Studies examining the prevalence of unidentified HIV infection in urban and suburban emergency departments (ED) provide insight into the missed opportunities for risk assessment. A systematic review of seven ED-based testing studies found HIV seroprevalence rates of 2–17% with rates highest among MSM or injection drug users (IDUs). The authors concluded that the data supported the prior recommendation that EDs offer HIV screening to high-risk patients (i.e., those with identifiable risk factors) or high-risk populations (i.e., those where HIV seroprevalence is at least 1%).[39] More recent studies have provided evidence that routine HIV testing in populations where prevalence is 0.1% would still be cost-effective,[40] and that's the threshold CDC recommended for routine testing.[5] Universal testing can be justified based on this cost-effectiveness analysis, especially in clinical venues that lack accurate data on HIV prevalence.

HISTORY OF HIV COUNSELING AND TESTING RECOMMENDATIONS

The first diagnostic test for HIV, an EIA was approved by Food and Drug Administration (FDA) in 1985 to screen transfusion donors to keep the blood supply safe (see Table 69-1). Within the following 2 years, publicly funded HIV counseling and testing clinics were established so that people with suspected infection had an alternative to blood banks for diagnosis.

Early in the epidemic, prior to the availability of treatment, the benefits of testing were less clear. Some believed the stigma and public risks, such as loss of jobs or insurance, associated with having HIV outweighed the benefits of knowing one's status. Protections were developed for confidentiality, a separate consent form for testing was mandated in most states, and anonymous testing was made available.

A counseling model was developed with HIV testing to accommodate the 1–2 week delay for the required confirmatory testing with a Western blot test or Immuno-fluorescence assay (IFA). The standard model of HIV counseling and testing was designed to encompass four primary goals: (1) to identify HIV-infected persons for clinical interventions; (2) to provide counseling about risk reduction for HIV-negative persons at risk of HIV acquisition and for HIV-positive persons at risk of HIV transmission; (3) to provide referrals for medical and case management services for HIV-seropositives and for prevention interventions for those at high risk of HIV acquisition; and (4) to initiate partner notification with counseling and referral to prevention services for partners of HIV-positive clients.

Within 2 years of the first HIV antibody test in 1985, alternate testing sites were developed to provide high-risk persons places for HIV antibody testing other than blood banks. Over time, the alternate testing sites evolved to provide a greater emphasis on risk reduction counseling. After the first reports in 1989 of zidovudine's efficacy for HIV-positive persons with CD4 counts of less than 500,[41] the focus of the counseling and testing sites (CTS) shifted to early detection of seropositive persons for clinical interventions.

By 1998 HIV counseling and testing was provided in 11,640 CDC-funded sites, up from 5149 sites in 1989. By 2002 nearly 40% of the U.S. adult population has been tested for HIV, according to telephone-based surveys of households.[42] To

2004	FDA approved first rapid test to distinguish between HIV 1 and HIV 2.	Rapid test distinguishes between HIV 1 and HIV 2	Greenwood JL, Burnstein GR, Pincus J, Branson B. A Rapid Review of Rapid HIV Antibody Tests. *Curr Infect Dis Rep* 2006; 8(2)125–131.
2004	FDA approved first oral fluid rapid HIV test in the United States.	A rapid oral fluid test received FDA approval for use in point-of-care HIV testing. The test is as simple to perform as a pregnancy test. The test received a CLIA (Clinical Laboratory Improvements Amendments of 1988) waiver so that minimally trained health workers can provide rapid testing and counseling in outreach and/or clinical settings.	http://www.fda.gov/cdrh/oivd/CLIA-oraquick.html
2005	WHO/DHHS/CDC provided guidelines for assuring the reliability of HIV rapid testing: Applying a quality system approach.	The WHO, DHHS and CDC collaborate to publish guidelines for programs implementing rapid HIV testing, so that adequate training and ongoing quality assessment is ensured.	http://www.who.int/diagnostics_laboratory/publications/HIVRapidsGuide.pdf
2005	Research showed that HIV testing in U.S. health-care settings would be cost effective at prevalence >0.1%.	New research provided evidence that recommendations for routine HIV testing should be expanded in lower prevalence settings.	Paltiel AD, Weinstein MC, Kimmel AD, et al. Expanded screening for HIV in the United States – An analysis of cost-effectiveness. NEJM 2005; 352: 586–95.
2006	FDA approval of a qualitative RNA test.	Gen Probe Aptima qualitative RNA test FDA approved for diagnosis of acute infection (and for confirmation).	http://www.fda.gov/fdac/departs/2007/107_upd.html#hiv1
2006	Revised recommendations for HIV testing of adults, adolescents and pregnant women to expand routine testing in health-care settings to populations > 0.1%, in the United States.	In response to evidence documenting ongoing barriers to HIV testing in health-care settings, and in recognition of studies, which showed that routine HIV testing in health-care settings is cost effective even at prevalence's >0.1%, new recommendations were made to offer all sexually active individuals aged 14–65 years HIV testing in health-care settings, and to use an "opt out" strategy, so that testing would be performed unless patients declined. Annual screening was recommended for people at high risk. The guidelines stated that a separate consent for HIV testing should not be required, nor should prevention counseling, with HIV testing in health-care settings. These recommendations did not apply to outreach testing programs in high-risk populations.	Revised recommendations for HIV testing of adults, adolescents and pregnant women in health-care settings. *MMWR* 2006; 55(RR14); 1–17.

2006	FDA holds hearings on over-the-counter HIV testing and urges companies to move forward through the FDA approval process.	The availability of simple oral fluid and fingerstick rapid HIV tests has brought the possibility of an over the counter (OTC) HIV test closer to reality. Hearings at the Blood Products Advisory Committee of the FDA in 2005 and 2006 reviewed the evidence supporting the potential effectiveness and safety of an OTC HIV test, and agreed that if an OTC test could be designed that was accurate and allowed access to adequate counseling services, the public health benefits would likely outweigh the risks. Clinical trials are now being planned and an OTC rapid HIV test kit is anticipated to be available in the United States in the near future.	http://aidsinfo.nih.gov/ContentFiles/FDA-3-3-06.pdf
2007	UNIADS published new Guidance for Provider-Initiated HIV Testing and Counseling in Health Facilities.	The draft recommendations focus on basic operational guidance for provider-initiated HIV testing and counseling in health facilities. HIV testing is recommended as a routine part of medical care with an "opt-out" approach in settings with generalized HIV epidemics. They recommend priority clinic venues for phasing in routine HIV testing.	http://www.unaids.org/en/MediaCentre/PressMaterials/FeatureStory/20070530_testing_counselling_guidance.asp. May 5 2007

determine the number of persons who were tested for HIV during the preceding 12 months, the CDC analyzed data from both the 2002 National Health Interview Survey (NHIS) and the 2002 Behavioral Risk Factor Surveillance System (BRFSS) survey. BRFSS is an ongoing, state-based, random-digit-dialed telephone survey of the U.S. civilian, noninstitutionalized population aged ≥18 years. In 2002, 37.8% of adults aged 18–64 years (95% confidence interval [CI] = 37.0–38.6%) reported that they had been tested for HIV at least once in their lifetime, compared with 5.7% in 1987 (CI = 5.3–6.1%).

Initially, HIV testing had been offered mainly at publicly funded HIV test sites and in clinical settings that serve populations at high risk of acquiring HIV infection.[43] However, by 1996, only 2 million of the approximately 24 million HIV tests performed were performed at HIV test sites; most were performed in medical-care settings such as the offices of physicians or health maintenance organizations (HMOs).[44] The majority of HIV counseling and testing still occurs in private settings.[42]

Data from the 2002 National Health Interview Survey interviews regarding the most recent HIV tests indicated the majority of tests were obtained from physicians and HMOs (43.5%) or hospitals (22.4%). Of 5.1% of tests reported as taking place "at home," 93.4% were administered by a nurse or health-care worker. Testing sources that usually receive public funding (e.g., public health department clinics, family planning clinics, and prenatal clinics) accounted for 23.6% of tests during the preceding 12 months. Sources of HIV testing typically funded by CDC's HIV-prevention programs accounted for 17.3% of the tests, yielding an estimated 3.4 million to 4.3 million tests.[42]

The demographics of clients tested in public settings differ from those tested in private settings. Clients who are tested in publicly funded HIV testing sites are often uninsured; in fact, approximately half of the 885,046 clients who had HIV tests performed at publicly funded sites in 1992 were uninsured.[45] Although some states have enacted programs to provide early basic diagnostic and therapeutic services to HIV-infected persons without insurance or Medicaid, this coverage is far from universal or adequate and must be addressed to ensure adequacy of referrals from publicly funded counseling and testing sites.

Despite increases in HIV testing over the past decade, many people at risk were not accessing these services, and many were accessing testing only through blood transfusion centers. Data from the CDC 2002 BRFSS[42] indicated that 43.5% of the 188,952 respondents from 50 states, the District of Columbia, Puerto Rico, Guam and the Virgin Islands had ever been tested for HIV outside of blood or plasma donation.[42]

In 2001, the CDC revised the guidelines for HIV counseling, testing, and referral and highlighted the importance of early knowledge of HIV status and of making HIV testing more accessible. This guideline also addressed ways to improve the quality of HIV counseling testing and referral in diverse settings.[46]

Based on data showing the benefit of HIV screening in ERs, hospitals, and urgent-care settings,[40,47–49] in 2003 the CDC created additional recommendations that advocated HIV testing and counseling be incorporated into routine medical care and in high-prevalence areas outside medical settings, such as jails.

Despite these recommendations, many health-care settings found it difficult to implement routine testing. Regulations that proscribed client-centered pre- and posttest counseling with HIV testing made it impossible for many health-care settings to do anything other than refer patients to public testing sites for HIV counseling and testing, resulting in many missed opportunities as described above. Lack of staff skilled in counseling and lack of time for counseling implementation was a major barrier, as were requirements for a separate informed consent as that required additional staff time.[50] Another barrier, especially in ERs and Urgent-care settings, was the inability to follow up with patients to provide test results.

These barriers lead to the most recently revised recommendations for HIV testing of adults, adolescents, and pregnant women in health-care settings.[5] The new guidelines for health-care settings recommend that routine opt-out HIV testing be offered to sexually active people aged 13–64 years in all health-care settings, offered without a separate written consent (but with verbal consent and the option to refuse), and offered in the absence of risk reduction counseling. A recent study in San Francisco showed that when policy was changed to allow provider documentation of verbal consent for HIV testing, rather than written consent, testing rates and identification of people with HIV significantly increased.[50] The goal of the new recommendations are to ensure that HIV testing is now treated in medical settings like testing for any other chronic disease. These recommendations did not apply to outreach testing programs in high-risk populations, where HIV risk-reduction counseling remains and important HIV prevention strategy.

Internationally, WHO/UNAIDS recently revised their guidelines to follow suit. The current[6] recommendations focus on basic operational guidance for provider-initiated HIV testing and counseling in health facilities. HIV testing is recommended as a routine part of medical care with an "opt-out" approach in settings with generalized HIV epidemics where peri-natal HIV prevalence is greater than 1%. They recommend priority clinic venues for phasing in routine HIV testing.

Although these recommendations will eliminate some of the barriers to routine provision of HIV counseling and testing in clinic settings, systems need to be developed to facilitate the process. For example the CARE interactive computer tool provides risk assessment, HIV consent, HIV risks reduction counseling, and recommended health referrals.[51] In an urban urgent-care setting in Seattle that was not routinely offered HIV testing (because of inadequate counseling staff and concern about follow-up with standard antibody testing) a randomized trial ($n = 517$) offering computer assisted rapid testing versus no intervention showed that this program was both acceptable, effective, and relatively inexpensive.[52] Nearly all (97%) of those randomized to computer-assisted rapid HIV testing received test results, as compared to those in the no intervention arm where no HIV tests were done and only two HIV test referrals were noted.

Other new strategies to overcome HIV related stigma may include inexpensive over-the-counter home HIV self-tests, which appeal to some populations, because of the increased privacy self-testing affords. Currently studies are underway to determine the necessary packaging and associated counseling support so that people who have positive screening tests for HIV will ultimately safely reach appropriate counseling and health care.

Studies evaluating the cost-effectiveness of conventional voluntary counseling testing and partner referral programs have shown that these programs are cost-saving in the United States[53] and in developing country settings.[35] In the United States a recent study suggested that it would also be a cost-effective HIV prevention strategy to test every person in the country for HIV once[40] as compared to other well accepted health-related screening strategies, such as breast and colon cancer screening programs. However, to achieve this goal, novel policies would be needed to (1) provide expanded access to HIV testing among people at risk in clinical and outreach settings, (2) provide alternative testing options that are more acceptable, more effective, and less costly, such as rapid oral fluid HIV testing, (3) eliminate requirements for extensive individual pretest counseling in settings where it is a barrier to testing and provide alternate counseling options such as videos or interactive computer counseling, and (4) provide alternative options for results disclosure such as same-day results or through telephone counseling when conventional testing is performed by health workers, and self-test results when an accurate and safe over the counter test becomes available.

CLINICAL GUIDELINES

Routine testing, at least once, is advocated for all sexually active individuals. Repeat testing is recommended annually for people in high-risk groups such as MSM, people with

multiple or untested sex partners, and injection drug users. Testing is recommended more frequently, every 3 to 6 months, for people with reported recent risks. People who require repeat testing for ongoing exposure should be provided or referred for additional HIV prevention services to assist them in reducing their risk behaviors. Various effective prevention-counseling methods exist, which are cost-effective to implement in the highest risk groups.[54]

The following discussion will describe three important aspects of HIV counseling and testing for providers conducting counseling: (i) clinical indications for testing (ii) components of pre- and posttest counseling; and (iii) issues in providing and documenting HIV antibody test results.

CLINICAL INDICATIONS FOR TESTING

The CDC recommends offering testing to all sexually active adults aged 13–65 years and annual testing for those in high risk groups.[5]

After effective treatments became available to prevent perinatal HIV infection in 1994,[55] the IOM recommended opt-out testing for all pregnant women. As the epidemic spread into heterosexual populations, with higher prevalence among people of color, the populations being offered HIV testing needed to be expanded.

Relative contraindications to HIV antibody testing are few, and include acute psychiatric illnesses or active suicidal ideation. Unless needed for medical evaluation of management decisions, HIV testing of asymptomatic persons with acute psychiatric impairment or acute suicidal ideation should be postponed until those issues can be addressed by appropriate providers.

POSSIBLE OCCUPATIONAL OR NONOCCUPATIONAL EXPOSURE

Persons should seek HIV counseling and testing after a possible exposure to HIV. These persons are often highly distraught, and the clinician or interviewer must obtain detailed information about the event to assist in appropriate counseling and postexposure prophylaxis,[56,57] and establish the absence of prior infection.

PREGNANT WOMEN

After the discovery that zidovudine (ZDV) during pregnancy dramatically reduced perinatal HIV infection, in August 1994, a U.S. Public Health Service (USPHS) task force first issued recommendations for the use of ZDV for reduction of perinatal HIV-1 transmission.[58]

Several studies documented the difficulty in identifying HIV-positive pregnant women based on HIV risk history alone.[59–62] Thus in July 1995, USPHS issued recommendations for universal prenatal HIV counseling and HIV testing with consent for all pregnant women in the United States.[58] To further reduce barriers to prenatal identification of HIV infection, in 2006 revised guidelines were published, which stressed routine, opt-out testing, with no need for separate written consent. Repeat testing in the third trimester was also recommended for women at high-risk (IDUs, sex workers, high-risk or positive sex partner, and women with new sex partner during pregnancy). In addition, all women in jurisdictions with rates of HIV infection among pregnant women >0.1% should be repeat tested in the third trimester (preferably <36 weeks). Finally, for those who had not gotten prenatal testing, rapid testing during labor can enable pregnant women with undocumented HIV-1 status to learn their HIV-1 infection status so they can receive antiretroviral prophylaxis and be referred for comprehensive medical care and follow-up.[63]

The rationale behind these recommendations is that the knowledge of HIV status will enable HIV-infected pregnant women to make informed choices about their own health care. In addition, HIV-infected pregnant women should be counseled about the benefits of intrapartum antiretroviral use[64] and breast-feeding choices to reduce the likelihood of transmitting HIV to the infant (see Chapter 85).

COMPONENTS OF PRE- AND POSTTEST COUNSELING

Pretest risk reduction counseling

As detailed in Chapter 47, brief clinic-based risk reduction interventions have been shown to reduce incident STIs,[65–69] particularly among women. However, clinicians do not always have the resources to consistently deliver counseling[36] nor are such interventions translated widely into practice.[70–72] Risk reduction counseling has been shown in a meta-analysis to reduce unprotected anal sex among MSM,[73] and to reduce injecting drug transmission behaviors.[74] If clinician resources are limited, abbreviated elements of some of these successful risk reduction counseling interventions may still be feasible to implement.[75] Simply asking the patient (without forcing the provider's agenda on the patient) what risk reduction behavior change step they might be willing and able to undertake (e.g., abstain from sex, reduce sex partners, use condoms correctly and consistently, get HIV/STI tests for oneself or one's partners, etc.) initiates the discussion and can help get the patient to a first step. When a risk reduction plan is defined, it can be charted and then reviewed at follow-up visits, to discuss behavioral successes, barriers, and new risk reduction plan(s) as appropriate.

While required counseling should not be a barrier to HIV testing, when possible, pretest counseling should be offered that is tailored to the individual, taking into account whether the client has been counseled and tested for HIV previously, his or her knowledge about HIV diagnosis and transmission, and

the client's level of reported risk. For the clients who are being tested for HIV for the first time, the discussion of HIV transmission and natural history may need to be more detailed than for persons who have been counseled previously. Several publications detail methods of ascertaining HIV risk and providing pretest counseling in primary-care settings.[76–78] In-depth counseling about risk behavior may be less feasible in busy office settings than in publicly funded clinics, but at a minimum should include verbal informed consent and when possible should include a discussion of individual risk patterns and the creation of a personalized risk reduction plan.[79] If standard testing is performed, follow-up appointments for posttest counseling may provide an additional opportunity for reinforcement of risk reduction plans. However, in many settings the majority of patients will not return for their results. Thus, rapid testing for HIV with modified pre- and posttest counseling is encouraged,[80] or the provision of telephone results when rapid testing is not available.[5]

When providing HIV counseling it is helpful to enquire about the patient's knowledge regarding the difference between HIV (the virus) and AIDS (the clinical condition) and to determine if they are aware that a positive antibody test indicates HIV infection but not the clinical syndrome of AIDS. The clinician should clarify that the antibody test can be either positive, negative, or indeterminate, and that the risk of false-positive or false-negative antibody tests is extremely low.[81] For clients with possible exposure to HIV in the past 3 months, the clinician should explain tests are generally positive within 1 month after exposure but may take up to 3 months to become positive (the "window period"). Therefore, repeat testing should be recommended 3 months after exposure, if the initial test is negative. If clinical suspicion of primary HIV infection is high an RNA test can be performed, which can detect presence of the virus as early as 11 days after exposure.[82]

For clients with ongoing risk behavior despite adequate knowledge of safe behaviors, the clinician should assist the client in identifying factors related to his or her continued risk behavior (e.g., substance use, new relationship, difficulties with communication or safe sex negotiation, low self-esteem, and depression). The clinician may then either make appropriate referrals for more in-depth counseling or work with the client to develop a personal plan for risk reduction. Such a plan should pay attention to the triggers and context for high-risk behavior for that client. This client-centered approach[83] to counseling is more likely to be effective than simply admonishing the client to follow safe sexual or drug use practices or repeating a summary of HIV transmission.[65] Chapters 53, 95, and several reviews provide a more detailed discussion of behavioral intervention approaches.[73,74,79,84]

To ensure receipt of test results rapid testing for HIV has now become the standard among high-risk populations. For those who test positive with rapid tests, it is critical that during the pretest-counseling visit the clinician emphasizes the preliminary nature of the rapid test results and the importance of following up for confirmatory results. In sites with low HIV prevalence where standard testing may be less costly, offering the option of telephone results is now recommended to promote receipt of test results.[5] Those with positive HIV results should be encouraged to follow up immediately for in-depth face-to-face counseling.

POSTTEST COUNSELING

Posttest counseling is usually provided 1–3 weeks later in the case of conventional antibody testing and 20–40 minutes later when rapid HIV tests are performed. During posttest counseling the clinician should inform the client of the test result and its interpretation, reinforce the individualized risk reduction plan for both seronegative and seropositive individuals, and provide clinical and psychological follow-up for the newly identified HIV-seropositive person. For the HIV-seronegative person, the clinician should reinforce the seronegative individual's plan for staying HIV-negative and determine the need for repeat HIV counseling and testing, depending on the time of the last possible exposure.

Occasionally clinicians will be faced with counseling individuals about indeterminate results, which occur in up to 10% of reactive EIA specimens.[85–90] Indeterminate HIV test results can occur during acute HIV seroconversion and in the absence of HIV infection.[82,85–90] In acute HIV, an initial p24 band develops on Western blot followed by additional envelope (gp41, gp120, and gp160) bands and then other anti-HIV bands over the next several weeks. This underscores the need for careful HIV risk assessment and serologic follow-up of high-risk persons with indeterminate Western blots.[88,89] When possible, RNA testing should be used to diagnose acute HIV infection.

The majority of persons with indeterminate HIV Western blots are not infected with HIV and have cross-reacting alloantibodies or autoantibodies.[89,90] Low-risk persons can be reassured of their very low likelihood of being infected and should be retested at 3 and 6 months to confirm the lack of seroconversion. Pregnant women with indeterminate Western blots are often understandably anxious about the significance of their tests; clinicians can explain the production of alloantibodies during pregnancy and obtain supplemental HIV tests (e.g., RNA testing) to resolve the indeterminate results more promptly.[87]

While the importance of pre- and posttest counseling has been demonstrated, opt-out testing has the major advantage of speeding and routinizing diagnosis of HIV.[5] The CDC has now moved for nationwide opt-out testing in all public sectors and for high-risk subjects.[5] WHO has followed suit[6] for communities with generalized epidemics, but continues to recommend symptom-based and risk-based screening for

communities where the HIV prevalence among pregnant women is less than 1%.

HANDLING OF POSITIVE HIV TEST RESULTS

The clinician who is counseling a client about a new diagnosis of HIV infection must allot adequate time to handle potential emotional distress and to ensure that the client has had the opportunity to ask all questions and express his or her reaction to the test result. If the confirmed positive antibody result is unexpected given the client's history, repeat serum should be drawn for confirmatory testing to rule out laboratory error. Some clinicians routinely confirm newly identified HIV-seropositive results, given the clinical and psychosocial importance of a positive test result. The clinician should again ensure that the client understands the difference between HIV infection and AIDS, discuss the natural history of HIV infection and immunosuppression, and emphasize the potential for slowing disease progression by early intervention with regular monitoring of the immune system and viral load, antiretroviral therapy, and prophylaxis against opportunistic infections. The provider should talk with the HIV-seropositive patient about their personal plan to follow safer sex practices, both to avoid HIV transmission to seronegative partners, to avoid acquisition of other STDs that theoretically may accelerate HIV disease, and to avoid acquiring a new strain of antiretroviral-resistant HIV (super-infection). Medical referrals should be made if follow-up for HIV care is not available at that site and the need for social and psychological services should be assessed. A follow-up appointment is advisable to reassess the client's ability to cope with the positive result, address the client's concerns, and discuss partner counseling and referral services. At this visit, the provider should ascertain the newly diagnosed HIV positive person's reaction to the diagnosis, and discuss in more depth the importance and means to have partners of HIV unknown or negative status referred for HIV counseling and testing, and for HIV positive partners, clinical care and counseling. The rationale and methods for partner counseling and referral services are outlined in the CDC Operational Guidelines for Partner Counseling and Referral Services,[91,92] and discussed in more detail in Chapter 54.

Most states have passed legislation that allow clinicians to chart positive test results and share test results with other clinicians, provided the disclosure is related to clinical care and the patient has signed a release of information form. The clinician should be familiar with the laws governing confidentiality of positive test results and name-based reporting in the state or jurisdiction in which they are practicing.[93] By the end of 2007, All U.S. states and Washington, D.C., will begin recording HIV cases using name-based reporting systems rather than code-based reporting[94] in order to receive federal funding for treatment. The CDC rejected code-based systems after finding they could lead to double counting and were cumbersome for health-care providers. The CDC announced its support for names-based HIV reporting in 1999, and strengthened that recommendation to a requirement for Ryan White funding eligibility in 2005. Although there has been much concern expressed about the impact of mandatory named reporting on test seeking behavior, to date there has been little evidence demonstrating a negative impact on HIV testing uptake or care seeking behaviors.

As a result of the clinical and social importance of a positive HIV antibody test, it is advisable to document a positive test before providing HIV-related clinical or social services, particularly before beginning antiretroviral therapy. Occasionally individuals who come in for HIV care believe they are HIV-positive based only on rapid test results or on a standard EIA-positive with either a negative or indeterminate Western blot.

National guidelines recommend that all HIV testing and counseling programs and laboratories perform confirmatory testing with an FDA-approved confirmatory assay such as a Western blot or immunofluorescence assay for all repeatedly reactive HIV EIA samples. Confirmatory testing differentiates those who have false-positive EIAs (those with negative confirmatory tests) from those with actual HIV infection (positive confirmatory tests). In Global settings, WHO recommends two to three accurate rapid EIAs for screening and confirmation,[95] rather than more costly Western blots or IFA confirmatory tests. The number of tests recommended for confirmation is dependent on local HIV prevalence.

The recent advent of expanded access to rapid HIV testing and the unlicensed use of home testing kits from overseas vendors may result in an increase in people presenting with unconfirmed positive EIA results. Providers should inquire about the type and timing of prior positive HIV tests.

NEW TESTING STRATEGIES FOR HIV SCREENING IN HARD-TO-REACH POPULATIONS

Testing technologies

Since FDA approval of the first EIA, this methodology has been standard for screening for HIV infection. Conventional EIA technology worked well for blood banks, which screened large numbers of specimens concurrently, using automated equipment. The specimens that have reactive EIA test results are confirmed using a Western blot assay, which shows reactivity with two of three HIV specific antigens, p24, gp41, or gp 120.

In developing country settings where blood is not stored, rapid HIV antibody tests were developed and shown to be accurate for screening transfusion donors.[96] Rapid tests are based on EIA and flow through technology where a membrane with antigen binds antibody in whole blood, plasma, or oral fluid. In most of the rapid assays either enzyme conjugate or a colloidal gold conjugate is then added, which results in

one or two colored bands within 10–20 minutes to indicate a working internal negative control and a reactive test. Agglutination tests have also been developed based on latex or red blood cells, which clump together when specimen is added that contains HIV specific antibody. If used in combination two different rapid EIAs can have close to 100% specificity and over 99% sensitivity.

While rapid tests have been used since the late 1980s in many countries both for screening blood products and for individual diagnosis, until recently in the United States there was only one agglutination test with relatively poor sensitivity, and one EIA that was cumbersome to perform. Thus, only in recent years has rapid testing positioned to become the standard of care for screening for HIV infection in clinical and outreach settings. Research has shown that rapid testing for HIV is both more effective in terms of test uptake and receipt of results[33,80,97,98] and more cost-effective[40,99–102] than standard testing in clinic and outreach settings.

As the epidemic progressed additional assays were designed to improve the acceptability of HIV testing. Oral fluid EIAs were FDA approved in December 1994, oral fluid Western blots in June 1996, urine EIAs were FDA approved in August 1996, and urine Western blots in May 1998. These specimens make mass testing in outreach settings easier to implement. If surveillance is the goal, conventional (non-rapid) oral fluid testing is an optimal strategy because of the increased acceptability and the ease of collection. However, if increasing the number of people who are aware that they are infected is the priority, rapid tests are more effective and more cost-effective. In November 2002, the OraQuick® test was FDA approved for use with fingerstick whole blood. In March 2004, the OraQuick® test became the first FDA-approved oral rapid HIV EIA. One early study showed the cost of the test itself ($15–20) was more expensive than standard ($1–10) or other rapid EIA tests ($3–18). Yet, in outreach settings where staff costs are fixed, the increased acceptability of rapid tests made the overall cost per test result provided lower than for standard blood or oral fluid testing, and lower than for some other rapid tests that use finger-stick or venipuncture specimens.[102]

As of February 2007,[103] six rapid HIV tests have been approved by the U.S. FDA: (1) OraQuick® (and its newer version OraQuick® Advance) Rapid HIV-1/2 Antibody Test (OraSure Technologies, Inc., Bethlehem, PA); (2) Reveal™ (and its newer version Reveal™ G2) Rapid HIV-1 Antibody Test (MedMira, Halifax, Nova Scotia); (3) Uni-Gold Recombigen® HIV Test (Trinity BioTech, Bray, Ireland); (4) Multispot HIV-1/HIV-2 Rapid Test (Bio-Rad Laboratories, Redmond, WA); (5) Clearview HIV 1/2 Stat Pak (Clinical Laboratory Improvement Amendments [CLIA]-waived version, Inverness Medical Professional Diagnostics, Princeton NJ); and (6) Clearview Complete HIV 1/2 (Inverness Medical Professional Diagnostics, Princeton NJ).[103]

Of the currently available rapid HIV tests OraQuick is the only FDA-approved test for oral fluid. The Unigold and Clearview tests can be performed on whole blood from fingerstick specimens and are also CLIA-waived so that clinicians and outreach workers can use them in nonlaboratory settings. Studies are needed, which compare the relative acceptability, cost, and effectiveness of rapid oral fluid versus rapid whole blood tests to assist providers in test choice globally.

The price for the U.S. FDA-approved rapid HIV test kits, as of July 2005, range from $14 to 25.[104] Costs for multidose external control vials range from $20 to 26.25. According to the Centers for Medicare and Medicaid Services 2005 Clinical Laboratory Fee Schedule, average reimbursement for a CLIA-waived rapid HIV-1 antibody test (procedural terminology [CPT] code 86701QW) was $12.41/test and for a CLIA-waived rapid HIV-1/2 antibody test (CPT code 86703QW) was $19.17. Providers offering point-of-care, rapid HIV testing may be challenged by reimbursement not keeping pace with the list prices of the tests. However, competition between rapid testing providers may drive the cost of the test down. In addition, comparable with counseling for other health issues, HIV counseling by a nonphysician is not reimbursable. Physicians performing HIV counseling may attempt to collect reimbursement for it by billing for prolonged services. In global settings, many additional non-FDA-approved tests exist, which are accurate, can be used with whole blood and which costs less than U.S. $1.00. Inexpensive rapid oral fluid tests, which are more acceptable and easier to use then fingerstick tests, are needed for HIV testing programs globally.

The rapid HIV tests may be particularly suitable for HIV testing sites and outreach testing programs with particularly poor follow-up rates, such as ERs, STD clinics, hospitals with high HIV prevalence, and HIV testing sites in developing countries. Rapid HIV tests may also be useful in labor and delivery suites to identify HIV-infected women who were not tested in pregnancy and who could benefit from interventions to reduce peripartum HIV transmission.

In clinical settings where acceptance rates of HIV testing is high and follow up for test results nears 100%, it may cost less to continue to offer conventional blood testing. However, in most test sites acceptance rates with rapid testing will be higher and the heightened rates of receipt of test results make rapid testing the most effective and most cost-effective strategy.[101,102,105]

Other options for HIV testing include home specimen collection kits, first approved by the FDA in 1996.[106,107] Home specimen collection using fingerstick specimens was developed to provide alternative anonymous testing options in areas where there was poor access to HIV testing or where stigma prevented people from requesting HIV tests in clinical venues. Currently there is one FDA-approved home specimen

collection kit (Home Access) that allows for people to collect a fingerstick specimen on a filter paper, mail it to a central laboratory, and receive results within a week via the telephone with verification through an anonymous code. Negative results may be given over the telephone by a prerecorded message, although clients may also have the option of speaking with a telephone counselor. Positive test results are generally provided by a counselor who conducts a standard posttest counseling session by telephone and provides referrals for both medical and psychosocial services. Persons receiving positive test results may have the option of receiving follow-up telephone counseling sessions.

Oral fluid kits have been licensed for provider use for EIA and Western blot antibody testing, and could be used for home specimen collection using a similar method of reporting test results.[108] One study,[109] that trained people to collect specimens using a video, showed that both home oral fluid and home fingerstick collection was feasible and highly accurate for frequent HIV testing among people at high risk; however, oral fluid collection was preferred by most, thus, may be utilized by more people if made available. However, no companies have announced plans to pursue FDA approval of an oral fluid home specimen collection test.

The role of home collection and testing in the United States and the potential for benefit and abuse through this system has been the subject of much debate.[107,110–112] Although some of the issues are specific to HIV testing, Bayer[107] points out that much of the debate raises broader policy issues about "the role home-diagnostic techniques should have in the evolving practice of medicine in America and the extent to which federal regulatory bodies should protect people from technically accurate devices that may produce psychologically burdensome results."

Home collection and self-testing could increase the proportion of at-risk persons who avail themselves of HIV antibody testing and potentially decrease the likelihood that persons would use blood donation as a mechanism for HIV antibody testing.

A concern that has been raised is whether telephone counseling is as effective as face-to-face counseling in assisting high-risk persons to decrease their risk behaviors. However, the efficacy of face-to-face counseling in promoting sustained risk reduction is under debate, as described previously, since few people who test actually receive the patient-centered counseling that has been proven effective. One national evaluation of the implementation of recommended client-centered counseling in public HIV testing sites revealed that only 61% of sites routinely completed personal risk reduction plans with clients.[71]

Another concern raised about home collection is that inadequate resources or follow-up will be available for persons learning of HIV-positive test results, particularly if large numbers of HIV-seropositive persons are newly identified. However, Ryan White and other HIV care funding is linked to the number of HIV and AIDS cases, so increased detection could be accompanied by increased local resources for care services. Although there were early concerns that notification of positive test results may precipitate attempted suicides, to date there are no studies that validate those concerns. Vulnerable groups, such as adolescents, may need particular assistance when learning of positive test results. Mechanisms must be built into the counseling to provide local referrals for clients, including crisis counseling.

Concerns have also been raised about the likelihood and mechanisms for dealing with false-positive test results. In postmarketing studies of the OraQuick test on 135,724 whole blood and 26,066 oral fluid rapid tests, overall specificity was comparable with that of clinical trials (99.98% for blood and 99.89% for oral fluid). Although there were some sites that had lower than average specificity, a field investigation suggested that these were isolated clusters, and did not find a reason for the lower specificity.[113] The sensitivity of the oral fluid HIV EIA for detection of antibodies during acute seroconversion is not known.

The future of HIV testing technology may be in over-the-counter rapid HIV tests which could, like home specimen collection kits, be provided by public health, sold in drug stores or purchased over the internet. Self-tests have been reported as significantly more acceptable than home specimen collection to populations at risk in two studies because of the rapid results and enhanced anonymity that self-testing offers.[114] If low cost, this testing method could better serve populations who do not have access to standard VCT services or who because of privacy concerns, stigma, transportation costs, or other barriers do not use facility-based, standard HIV testing.

HIV counseling and testing is cost-effective in most populations in the United States[40,115] and abroad[35] by any measure, because of the savings that result from preventing a case of HIV. Using conventional HIV counseling and testing strategies, the funds that would be required to test every person in a community may exceed national and international budgets for HIV prevention.[99] Over-the-counter rapid HIV tests have the potential to both dramatically improve access to HIV testing, as well as decreasing the public health cost of providing this service. One small study among people with HIV showed that oral fluid and fingerstick self-tests with only written instructions using the OraQuick device had fairly high sensitivity (94%) when participants interpreted blinded self-tests, somewhat lower specificity (88%) when participants interpreted blinded weak negative controls, and very high acceptability (61% would have preferred learning their status at home with a self-test rather than in a clinic).[114] Even higher sensitivity will likely be possible with additional guidance in test performance and interpretation through the use of improved instructions, and video or web-based demonstrations.

While several of the currently available rapid HIV tests are simple enough to be used as self-tests, to date no company has designed a system to ensure adequate follow up and referral services for those who test positive. Models of counseling proposed include written educational materials, interactive computer counseling, and 24 hour access to telephone counselors.[117] One company, OraSure Technologies, has announced their intention to consider the development of an over-the-counter rapid HIV test. Illegally available self-tests, which are currently advertised on the Internet, should be avoided because of questionable accuracy. Research is needed to determine the accuracy of self-testing for HIV and to understand what types of associated counseling may be required to ensure safe dissemination of self-testing for HIV both in developed and developing country settings.

Testing settings

Early in the epidemic it was necessary to go to a blood bank or a public testing site for a diagnostic HIV test. Now that widespread testing is recommended, it is acknowledged that testing should be made more widely available. Currently access to HIV testing can be improved through expanding the availability of testing in primary-care settings, ERs, and through mobile outreach to high-risk venues. While general HIV testing is clearly cost-effective, limited public health dollars should be targeted toward identifying populations at highest risk who otherwise would not access HIV testing, while others should be provided access to HIV testing through their primary health-care providers. For people who are concerned about confidentiality or for those with minimal access to clinical services, home specimen collection kits are available for those who can afford them.

For communities at high risk who do not access care in traditional clinical venues, outreach testing is recommended.[118] For example mobile testing programs that utilize oral fluid and rapid testing, have successfully reached previously untested populations.[119] Rapid testing for HIV has been found more acceptable and more cost-effective than standard blood or oral fluid testing among populations at risk for HIV and can overcome barriers to testing for those who dislike the anxiety that they experience while waiting for test results.[120]

Components of successful outreach programs include the use of culturally similar recruiters, mobile testing, incentives, rapid or oral fluid testing, and convenient results disclosure through the telephone when nonrapid tests are used. Determining the best model for connecting clients who test in mobile outreach settings to clinical care is an ongoing challenge and merits further research.

Overcoming stigma[26,121] for HIV testing will come as community norms change. In the meantime, some strategies to avoid this barrier include providing routine testing, or monetary incentives for HIV testing, so that people are able to accept HIV testing without publicly indicating their risk. Other options for people who delay testing due to stigma include home specimen collection and, in the near future, over-the-counter rapid tests.

NEED FOR STATE ADMINISTRATIVE CODE REFORM

Early in the HIV epidemic in the United States, many states developed administrative codes to ensure that HIV counseling and testing was offered in a standardized manner with detailed written consent of people testing and prescriptive counseling. These regulations made testing more difficult to implement in many clinical settings. Some ERs and clinical venues elected to refer clients elsewhere for HIV testing rather than train or hire staff to provide the required counseling. Unfortunately, referral results in many missed opportunities for testing those at high risk, and follow-up rates for referrals are notoriously low. In recent years the awareness that the epidemic is being fueled by those who are unaware of their HIV status has resulted in changes in CDC recommendations and in State administrative codes.

New CDC guidelines[5] recommend that providing knowledge of HIV status is the highest priority, and that while client-centered HIV risk-reduction counseling is recommended, when possible, it is not mandatory for HIV testing to be performed. Some people have expressed concerns that requiring explicit consent for HIV testing treats it differently than other medical tests, creates barriers to testing, and may contribute to the stigmatization of HIV. Requiring explicit detailed pre- and posttest counseling may make some health providers less likely to offer HIV testing. In response, states are revising their administrative codes to eliminate regulations that may create barriers to the provision of HIV testing. For example, Washington State recently made revisions to remove the requirement of a separate written consent. While explicit verbal consent is still required, eliminating the extra paperwork may make HIV testing easier for providers to offer. In addition, the requirement for prevention counseling with HIV testing has been deleted from the administrative codes, so that settings without the time or resources to provide prevention counseling will now be able to offer HIV testing.

New HIV counseling and testing strategies, and associated policy reform, is generating a new era of widespread HIV testing that will impact the spread of HIV globally within the next decade.

70 Clinical Laboratory Diagnosis of HIV-1 and Use of Viral RNA to Monitor Infection

Robert W. Coombs

INTRODUCTION

Shortly after exposure to HIV-1, virus replication can be detected in the blood plasma or cells (Fig. 70-1). A cellular and humoral immune response develops thereafter. Most persons infected with HIV-1 are identified by the immune response, through a series of sensitive and specific tests that demonstrate antibodies reactive with this human retrovirus. However, HIV-1 infection can also be detected by nucleic acid target or nucleic acid target-signal amplification assays of viral RNA or proviral DNA in nearly all HIV-1-seropositive persons, and such tests may be particularly important in the person with very recent infection (before antibodies develop) or in the exceedingly rare person with antibody-negative infection.

Clinical suspicion of new (acute) HIV infection is raised by appropriate signs and symptoms, such as a self-limited mononucleosis-like illness, prolonged fever, fatigue or weight loss, onset of opportunistic infections, and/or high-risk behaviors: male-to-male sex; injection drug use; a recipient of multiple blood-product transfusions (in resource-constrained settings); heterosexual or homosexual contact with a high-risk or HIV-1-seropositive partner; residents of certain areas of Africa, Asia, or the Caribbean where HIV prevalence is exceptionally high; male or female prostitution; or a child born to parents who are members of these risk groups. However, physicians face a major challenge in diagnosing HIV infection in a person who may be acutely infected, who is asymptomatic, who has atypical signs and symptoms, or who denies being in a high-risk group.[1]

Current U.S. government recommendations are to increase HIV screening of patients, including pregnant women in health-care settings,[2] and, once the decision is made to initiate antiretroviral therapy, to decrease vertical transmission,[3] reduce HIV-related morbidity and mortality, improve quality of life, restore and preserve immunological function, and maximally and durably suppress viral load.[4] These recommendations raise additional challenges to the clinician and the clinical laboratory not only to diagnose infection as early as possible but also to assess quantitatively viral RNA, which provides prognosis for disease progression and the success or failure of therapy.

The current approach to the clinical management of HIV-1 infection is driven by clinical trial data that plasma viral RNA level and CD4 cell count are the most suitable biological markers of clinical progression and therapy efficacy.[4] Although the adequacy of viral RNA alone as a surrogate for clinical outcome has been questioned,[5,6] in patients with untreated HIV infection a single HIV-1 RNA measurement is still the strongest baseline predictor of time to AIDS and death and generally explains about half of the variability in these clinical outcomes.[7] The antiretroviral management of HIV-1 infection is based on monitoring both viral RNA levels in plasma and CD4 cell counts in whole blood.[4,8] To understand the usefulness and limitations of HIV-1 RNA measurement in clinical practice, the reader must be aware of caveats that pertain to the use of plasma HIV-1 RNA as a marker of viral replication and clinical prognosis. These caveats will be discussed later in this chapter.

For descriptive and technical purposes, laboratory detection of HIV-1 or HIV-2 infection can be stratified into assays that identify HIV-specific antibodies and those that identify infectious HIV virus, viral antigen, or viral nucleic acids. (The reader is referred to recent reviews for the technical details of the detection methods used for the laboratory diagnosis of HIV infection.[9,10])

ACUTE HIV INFECTION

Recent improvements in the sensitivity and specificity of anti-HIV assays have resulted in a significant shortening of the preseroconversion window period from the 42–45 days (the mean infectious window period documented in the post-1987 look-back studies) to 20–25 days.[11] Introducing direct-virus detection assays into the testing algorithm would reduce the window period by 9 days for p24 antigen

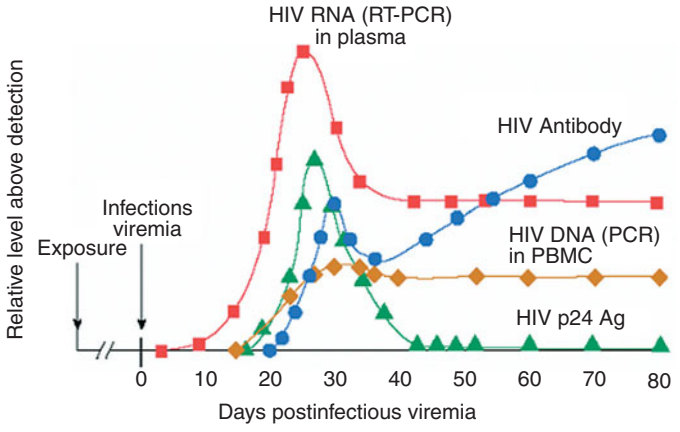

FIGURE 70-1. Sequence of the virological and serological time course associated with acute HIV infection–"seronegative window." Following exposure to and infection with HIV-1, there is a variable period of viral replication in mucosal and lymphoid tissue that drains the inoculation site. This phase is referred to as the "eclipse phase," usually lasts 1–2 weeks but is typically 10 days and occasionally up to 6 months. This is followed by the appearance of infectious viremia, as determined by infectious blood donation studies (time 0), which marks a consistent sequence of virological and serological events. Infectious viremia is followed by a viral RNA-only phase lasting 3–5 days, which is then followed by a 5-day period during which both viral RNA and p24 antigen are detected but the enzyme-immuno (EI)-assay antibody is negative–the "seronegative window" phase. Once p24 antigen is detected, viral RNA levels exceed 10,000 copies/mL. The detection of infected PBMCs coincides with the detection of PBMC-associated viral DNA. Anti-IgM appears between days 20 and 30 post viremia, peaks, and is followed by a slow rise in the anti-HIV IgG levels. During the first 4 months of infection, the level of anti-HIV may not be detected by less-sensitive EI assay formats–the so-called "detuned" assay; thus, the detuned assay may be used to estimate the point incident infection rates. Over the ensuing 3–6 months, seroconversion is associated with the suppression of the viral replication to a stable viral RNA level or "set point" that is prognostic of the risk for subsequent disease progression in the untreated person. (Adapted from Busch MP, Satten GA. Time course of viremia and antibody seroconversion following human immunodeficiency virus exposure. *Am J Med* 1997; 102: 117–124; Bush MP, Kleinman SH. Nucleic acid amplification testing and disease transmission. *Transfusion* 2000; 40: 143–159; and Coombs RW. Human immunodeficiency virus infection and the acquired immunodeficiency syndrome: Viral pathogenesis, laboratory diagnosis and monitoring. In: Morse SA, Ballard RC, Holmes KK, Moreland AA, eds. *Atlas of Sexually Transmitted Diseases and AIDS,* 3rd edn. New York: Mosby, 2003, pp. 177–194.)

or DNA PCR and 11 days for RNA PCR (Fig. 70-1). Although the majority of seroconversions occur within 2 months of exposure, delayed seroconversion is well established, with approximately 5% of occupational infections taking more than 6 months after the exposure to seroconvert.[11]

Viremia, as detected by p24 antigen or HIV RNA, precedes anti-HIV seroconversion consistently by 1–3 weeks. The delay between exposure and infectious viremia (the viral "eclipse" phase) likely represents a period of localized viral replication at the mucosal site of inoculation and possibly in lymphoid tissues that drain inoculation sites, prior to systemic viremia and subsequent seroconversion.[12,13]

HIV ANTIBODY ASSAYS

GENERAL CONSIDERATIONS

The HIV-1 testing algorithm recommended by the U.S. Public Health Service comprises initial screening by a Federal Drug Administration (FDA)-licensed enzyme immunoassay (EI assay) followed by confirmatory testing of repeatedly reactive specimens with an FDA-licensed supplemental test, e.g., immunoblot (Western blot) or immunofluorescence assay (IFA).[14,15] Although the EI assays are highly sensitive and specific, the positive predictive value of the EI assay is highly dependent on the seroprevalence of HIV-1 antibody in the population to which the individual being tested belongs. Therefore, use of both the EI assay and a further supplementary test increases the accuracy of detecting HIV-1 infection. Clinical laboratory practice dictates that the results of a repeatedly reactive HIV EI assay should never be released to the clinician or patient by the clinical laboratory without the results of the more specific confirmatory testing.[16,17] For the maximum diagnostic accuracy, the laboratory HIV test results should be interpreted by the clinician in conjunction with the clinical and epidemiological history of the person being tested.[17]

EI ASSAYS

EI assays were first developed to detect HIV-1 antibodies in infected potential blood donors. These tests have now been adopted for screening high-risk groups for HIV infection. Following the initial screening procedure, more specific tests confirm the diagnosis.

There are four basic formats for commercially available EI assays. First-generation assays use antigens derived from whole disrupted virus and an enzyme-conjugated anti-human IgG sandwich technique for capture and detection of anti-HIV antibodies. Second-generation assays use recombinant (rDNA) viral protein (antigen) and conjugated anti-human IgG, or they use rDNA antigen for both capture of anti-HIV antibodies and detection of these antibodies, using enzyme-conjugated rDNA proteins as probe.[18,19] Third-generation assays use synthetic peptides.[20,21] For example, the Genetic Systems™ HIV-1/HIV-2 Peptide EIA (Genetic Systems Corp., Redmond, WA) is comprised of four highly conserved, immunodominant peptide sequences of envelope (*env*) and polymerase (*pol*) gene products for HIV-1 and HIV-2 that are adsorbed onto the surface of a microwell plate. If IgG or IgM antibodies to either HIV-1 or HIV-2 are present, they bind to the adsorbed peptides and are recognized by an enzyme-conjugated anti-human IgG sandwich technique. Fourth-generation assays combine the attributes of the third-generation assay with detection of HIV-1 p24 antigen.[22]

The median time interval between infection and confirmed seropositivity is approximately 3 months with the first-and second-generation EI assays, with 95% or more of subjects serconverting by 6 months.[23] However, the more sensitive third- and fourth-generation assays have shortened the estimated antibody-negative "window period" of primary infection to 20 days or less.[24] The specificities of the current commercial EI assays are above 99.5%.[25–28] False-positive reactions result from nonspecific cross-reacting antibodies in persons with underlying immunological disease, gravidity, multiple transfusions, or recent immunization for the first-generation assays[29,30] and from cross-reacting antibodies to the yeast and bacteria that produce the commercial peptides used with the other generation assays. Several commercially available EI assays screen for both HIV-1 and HIV-2 antibodies. For epidemiological purposes, specialized EI assays are available to evaluate the level of anti-HIV antibody and estimate HIV-1 seroincidence.[31]

IMMUNOBLOT

As already mentioned, the positive predictive value of the EI assays are highly dependent on the seroprevalence of HIV antibody in the population from which the person being tested is from. Therefore, to prevent a false-positive diagnosis of HIV infection, confirmation of a reactive EI assay is required, using an independent testing method with high specificity. The immunoblot (or Western blot) is the most commonly used confirmatory test in the United States.[15]

The Western blot detects the serum antibodies directed against specific HIV proteins of varying molecular weights following their separation by gel electrophoresis and blotting onto nitrocellulose paper. The Western blot detects antibodies to the following specific HIV-1 proteins: core (p17, p24, and the gag precursors p40 and p55), polymerase (p31, p51, and p66), and envelope (gp41 and gp120/160). The reported analytic specificity of the immunoblot assay is 97.8%.[15,25] The Western blot is interpreted as negative when no antibody–antigen band is present, positive when antibodies are present to core (p24) and envelope (gp41 or gp120/160) and, in some cases, integrase (p31). Although several organizations, including the World Health Organization[32] and Consortium for Retrovirus Serology Standardization,[33] have proposed criteria for interpreting Western blot reactivity, the Centers for Disease Control and Prevention (CDC) endorses interpretative criteria that require the presence of antibodies to at least two of three HIV-1 antigens: p24, gp41, or gp120/160.[15,17,34]

Regardless of the HIV-1 antibody seroprevalence, a reactive EI assay and confirmatory Western blot together have a positive predictive value of greater than 99.99%.[35,36] In the blood donor population, approximately 10 of 10,000 persons (0.1%) without risk of HIV-1 infection will be repeatedly reactive by the HIV-1 EIA. However, 8/10 low-risk persons with repeatedly reactive HIV-1 EI assays will be negative by the HIV-1 Western blot and 2/10 will be Western blot indeterminate.[36] False-positive results for HIV-1 antibody, when both the EI assay and the Western blot are reactive in a person who is not infected with HIV-1, are extremely rare (<1 in 100,000 persons screened).[35] Therefore, indeterminate Western blots (IWBs) are more common than false-positive Western blots in screening persons from populations with low HIV-1 antibody seroprevalence.[37] Fortunately, other HIV-1 detection tests (see below) allow for resolution of confusing serological results.

The combination of HIV-1 EI assay and confirmatory immunoblot has clearly established evidence against the "seroreversion" of HIV-1 antibody in seroreactive individuals.[38] In a retrospective cohort study that reviewed the results of 5,446,161 HIV-1 antibody tests performed on 2,580,974 individuals (the U.S. Army HIV Data System) from 1985 through 1992, only six of 4911 individuals were identified as potential seroreverters. Furthermore, in all six instances errors in specimen attribution or testing were identified.[39]

OTHER CONFIRMATION METHODS

The indirect IFA is also approved for confirmatory testing,[40] but it is used less commonly than the immunoblot confirmation method.[15,34] Other confirmation strategies have been reported.[41] For example, the use of a first- or second-generation EI assay as a screen followed by a native HIV-1 gp160 EI assay,[42] a recombinant DNA-derived antigen-based peptide EI assay,[43,44] or an immunoblot assay (RIBA),[45] have all reported comparable results but are not FDA approved for this purpose. Nevertheless, the combination of rapid tests, for example, could be a cheaper and faster alternative to the conventional testing algorithm in developing countries.[46]

INDETERMINATE IMMUNOBLOTS

With the increased use of HIV-1 antibody screening in low-risk populations, including health-care workers,[47] it is essential for the primary care provider to be able to interpret HIV-1 test results accurately.[37] Between 4% and 20% of serum samples that are repeatedly reactive by HIV-1 EI assay are interpreted as indeterminate by Western blot.[17,36,48] IWBs in HIV-1-infected persons may result from early antibody formation against viral core antigens during primary infection,[49] from early detection of HIV-1 antibody by the more sensitive third- and fourth-generation EI assays before there is confirmation by immunoblot,[50,51] and, rarely, from the loss of core-specific antibody late in infection due to severe immunosuppression.[38,52,53] In HIV-1-negative persons, cross-reacting antibody to HIV-2 has been implicated.[54] False-positive

immunoblots are extremely uncommon and occur with a frequency of <1 per 135,000 tests.[35,36]

In the only population-based case–control study (244 cases, 131 controls, and 83 sexual partners of cases) to assess risk factors for IWBs, Celum, and coworkers found that IWBs were associated with a low risk of HIV seroconversion (3.0%; 95% confidence interval, CI, 0.7–5.3%) for those with recent risk behaviors for HIV-1 acquisition and that for low-risk persons, the major risk factors identified for IWBs related to alloimmunization (i.e., parity or recent immunization) or autoantibodies (i.e., antinuclear antibodies and rheumatoid factor).[55] Of interest, conditional logistic regression analysis indicated that an additional independent risk factor for IWBs among male cases and controls was a recent sexual contact with a prostitute (odds ratio, 3.0; 95% CI, 1.0–9.5). Contrary to other reports, however, no cross reactivity was detected with HIV-2, human T-lymphotrophic virus type 1, feline immunodeficiency or feline leukemia, or bovine immunodeficiency viruses.

Celum and coworkers suggested four important principles for facilitating the management of IWBs for HIV-1 in the clinical setting.[55] First, approximately one-third of persons who present with IWBs will not be repeatedly reactive by EI assay and Western blot testing.[48] There is no need for further testing or follow-up of this group. Second, the most important factor for the association of seroconversion with an IWB was a p24 antibody band (approximately an 18% risk of seroconversion) and high-risk behavior, which could be determined from the risk history.[48] Repeat Western blot and selective supplemental testing with HIV-1 culture, p24 antigen, HIV-1 DNA polymerase chain reaction (PCR) amplification (and quite possibly RNA[51,56]), or third- (and fourth-) generation recombinant EI assays were also useful in identifying persons with no history of high-risk behaviors who proved to have false-positive Western blots. Third, no cross reactivity with known human or animal retroviruses was shown. Fourth, in most cases the medical history is extremely important in identifying subjects with significant risk factors for IWBs (parity and autoantibodies among females, tetanus booster in the past 2 years, and sexual contact with a prostitute since 1978 among males).[55]

In summary, the following recommendations are made for the clinical management of patients with an IWB. Low-risk individuals with a nonreactive EI assay upon repeat testing do not need further follow-up. High-risk individuals should be followed serologically for at least 6 months, especially those with a p24 band on Western blot. The early, selective use of supplemental tests such as HIV-1 p24 antigen, HIV-1 culture, HIV-1 proviral DNA, or plasma RNA may help determine the infectious status of high-risk individuals before full seroconversion occurs.[48,57,58] Negative supplemental tests may also help alleviate the anxiety associated with an indeterminate HIV-1 serology.

SIMPLE/RAPID SEROLOGIC TESTING

Simple, rapid, reliable, and less expensive alternatives to the EI assay with confirmatory immunoblot have been sought for use in acute care settings, emergency rooms, sexually transmitted disease clinics, medical field settings, and developing countries.[59] Test designs are based on three formats: immunoconcentration (flow-through devices); immuno chromatography (lateral-flow devices), and particle agglutination.[60–62] Currently, a total of six rapid HIV tests have been approved by the Food and Drug Administration (FDA) and are available in the United States; however, only three, the OraQuick Advance Rapid HIV-1/2 Antibody Test device (OraSure Technologies), the Uni-Gold Recombigen HIV Test (Trinity Biotechnologies), and the Clearview HIV-1/2 Stat-Pak (Chembio Diagnostics Systems), are CLIA waived and suitable for point-of-care (POC) testing; the others are of moderate complexity and thus more suitable for the laboratory setting.[62] The procedure take less than 30 minutes, and negative results are available immediately. Positive tests must be confirmed with a Western blot or IFA. Generally, the positive predictive value of these assays is comparable to the standard EI assays (>80%), and the negative predictive values approach 100% in some circumstances[61,63–66] but not in others.[67] The relative sensitivity (99.9%) and specificity (99.6%) of these tests and their ability to detect both IgM and IgG antibody may make them particularly useful for detecting early infection.[63] However, as some of these simple/rapid assays rely on detecting antibody to gp41 (e.g., OraQuick), any delay in producing anti-gp41 could reduce the sensitivity of these assays in early HIV infection (Joanne Steckler, MD, personal communication).

The CDC now recommends that diagnostic HIV testing and opt-out HIV screening be part of routine clinical care in all health-care settings, as this will greatly enhance testing programs by preventing the need for delayed counseling of seronegative patients and by providing preliminary results to seropositive patients, thus ensuring optimal clinical and preventive care.[2,68] These preliminary results may encourage patients to return for confirmatory test results and to adopt risk-reducing behaviors sooner than occurs, using currently accepted testing algorithms.[69] In addition, the rapid HIV-1 screening of source contacts following occupational exposures to blood will minimize the duration of antiretroviral prophylaxis therapy for the exposed health-care worker, thus minimizing cost and alleviating anxiety following the exposure sooner if the test is negative.

OVER-THE-COUNTER TESTING

Only one over-the-counter HIV-1 test kit is available for home collection (Home Access™, Home Access Health Care). The test is based on previous evaluations of blood collected on filter paper for stability and for detection of

antibodies to HIV-1 by EI assay and confirmatory Western blot.[70–72] The kit consists of instructions and equipment for obtaining blood from a finger-stick. The blood-spot specimen is sent to a commercial laboratory for testing with an EI assay and confirmatory IFA. The results and counseling are provided over the phone; for positive results, patients are referred by a counselor to a physician for additional counseling and care.

DETECTION OF HIV-1 ANTIBODY IN SALIVA AND URINE

HIV-1 antibodies can be detected reliably in the oral fluids of HIV-1-infected persons.[73] There are a number of obvious advantages to collecting specimens for HIV-1 testing using a noninvasive specimen collection procedure,[74] for example, greater safety, increased patient compliance, and an alternative to phlebotomy.[75] Earlier problems with low sensitivity have been corrected by using special collection devices that concentrate and stabilize the salivary-associated immunoglobulins.[75] Modification of the EI assay and Western blot have increased the sensitivity to 97–100% and the specificity to 98–100%, depending on the study.[73,75,76] In June 2004, the FDA approved the OraQuick® Advance Rapid HIV-1/2 Antibody Test (OraSure Technologies) for the detection of HIV-1/2 antibodies in oral fluid as a POC test.

Early reports of discordant HIV-1 antibody results between antibody-negative blood serum and antibody-positive urine,[77] and the detection of the first case of HIV-1 group O in a patient who had urine antibody confirmed by Western blot but was serum Western blot seroindeterminate,[78] have suggested a compartmentalized antibody response to early HIV-1 infection. As such, there has been an interest in using urine for HIV-1 antibody screening.[79] This has led to the testing of an experimental urine HIV-1 envelope-based EI assay, Calypte™ Aware HIV-1/2 U rapid test (Calypte Biomedical, Berkeley CA; not available in the United States), which has demonstrated a positive predictive value of >99.2% and negative predictive value of >99.9% when combined with confirmatory immunoblot or immunofluorescence testing.[80,81] At this time, the absence of an FDA-licensed Western blot for urine testing requires that urine reactive for HIV-1 antibody be confirmed by testing of a blood specimen.

HIV ANTIBODY TESTING IN RESOURCE-CONSTRAINED SETTINGS

Several challenges exist for HIV antibody testing in the resource-constrained setting. For example, approximately 80% of people living with HIV in low- and middle-income countries do not know that they are HIV positive, and recent surveys in sub-Saharan Africa showed that just 12% of men and 10% of women have been tested for HIV and received their test results (http://www.who.int/mediacentre/news/releases/2007/pr24/en/print.html; last accessed 07/04/07).

In this setting, HIV testing should follow recommended CDC–UNAIDS–WHO HIV testing strategies and relevant national HIV testing algorithms for which a brief summary follows (http://www.who.int/diagnostics_laboratory/publications/HIVRapidsGuide.pdf; last accessed 07/04/07).

Testing algorithms involve either sequential (serial) testing or parallel testing (http://www.who.int/diagnostics_laboratory/en/; last accessed 07/04/07). EI assay-based algorithms are generally serial and require confirmation by a second positive test result that uses either different antigens or testing platform (or both) from the first test. A second reactive test result is considered confirmatory of the first reactive test result if the seroprevalence is 5% or more. In low seroprevalence settings, where false positives are more likely, a third confirmatory test may be required (e.g., HIV-1 RNA or DNA). Serial testing is less expensive, and a second test is only required when the initial test is reactive.

Parallel (simultaneous) testing is only recommended when using whole blood finger stick samples rather than venous blood and is suitable for simple/rapid testing, although serial testing may also be used. A parallel testing algorithm uses two tests based on either different antigens or platforms (or both), and the assays are conducted simultaneously. Concordant negative or positive results are considered as true negatives or positives, respectively.

When two test results are discordant, specialist laboratory advice may be required. The WHO and UNAIDS also recommend that specific tests have sensitivities of at least 99% and specificities of at least 98% and that combination testing algorithms need to be evaluated in the context of use before wide-scale implementation. To illustrate this point, a recent study from Uganda suggested that weak bands detected by simple/rapid antibody assays, and which otherwise should be reported as positive by the manufacturer, decreased the positive predictive value of the assay algorithm used in this study.[236] As such, the presence of weak positive bands should be confirmed by EI assay and western blot before releasing the results, and quality control of the simple/rapid assays should use standard serological assays.[236]

DETECTION OF HIV-1 SUBTYPES

The envelope protein of HIV-1 isolates from different geographic locations worldwide can differ in more than 35% of amino-acid positions.[82] As a consequence of this diversity, HIV-1 strains are divided into three groups: M (major, which is responsible for most of the infection in the Americas and Europe), O (outlier, a rare form found in Cameroon and

Gabon), and N (novel or non-M-non-O). Within the "major" group M, nine subtypes (or clades) designated A–D, F–H, J, K and 16 major circulating recombinant forms havebeendefined(http://hiv.lanl.gov/content/hibdg/CRFs/CRFs.html), e.g., AE, prevalent in Southeast Asia; AG, from west and central Africa; AGI, from Cyprus and Greece; AB, from Russia; FD, from Democratic Republic of Congo; BC, from China; BF, from South America; and several additional complex and unique recombinants that combine three or more subtypes.[83,84,237] Group M and its subtypes are more clearly defined than others. Subtype B is the most common subtype in the United States and Europe, while subtypes A, C, and AE are prominent in Africa and Asia.[82] Non-B subtypes are of increasing importance in the United States and may comprise approximately 5% of HIV infections nationally and even higher proportions in some local areas.[238]

Phylogenetic clades equivalent to group M subtypes have been described for viruses from the highly divergent "outlier" group O.[239] The group O virus stain has been isolated from persons of west-central African origins[85,86] with reports of group O virus from Europe[78,87,88] and the United States.[89] Because the commercial EI assays and confirmatory immunoblot assays are based on the predominant HIV-1 clade B virus, not all early commercially available diagnostic assays could detect the divergent group O strains.[90–92] Thereafter, diagnostic kit reagents were modified to ensure optimal sensitivity and specificity for group O virus antibody.[93,94]

Since most of the primer pairs for HIV-1 DNA PCR amplification have been optimized for group B viruses (see below), it is not surprising that HIV-1 DNA PCR may also fail to detect HIV-1 group O and some group M subtypes.[95–97] To accommodate this deficiency, primer pair modifications have been incorporated into the recent Roche Amplicor(TM) HIV-1 DNA and Roche Monitor(tm) HIV-1 RNA version 1.5 assays. Because of the large number of *pol*-specific synthetic oligonucleotide target probes used by the bDNA assay (Bayer Versant HIV-1 RNA 3.0 assay), detection of group O and different group B subtypes has not been a quantitative problem for the bDNA assay.[97]

DETECTION OF HIV-2 ANTIBODIES

Although HIV-2 infection is less geographically dispersed than HIV-1, and the epidemic is primarily focused in western Africa, HIV-2 is present in the epidemic in India.[98,99] In the United States, only a relatively few cases of HIV-2 have been reported.[100] HIV-2 among U.S. blood donors is extremely rare, with only three cases detected from screening 74 million donations up to June 1995.[101] Of the 62 persons reported with HIV-2 infection in the United States, 44 (77%) were born in, had traveled to, or had a sex partner from western Africa.[101] Nevertheless, diagnosis of HIV-2 infection will continue to be an emerging problem in the United States;[102] thus, antibody screening for both viruses is warranted.

HIV-1 and HIV-2 genomes share about 60% homology in conserved genes such as *gag* and *pol* and 35–45% homology in the *env* genes.[103] The core proteins of HIV-1 and HIV-2 display frequent cross reactivity, whereas the envelope proteins are more type specific.[104] Despite this cross reactivity, anti-HIV-1 EI assays used for screening blood donors in the United States are estimated to detect 55–91% of HIV-2 infections.[105] Western blots for HIV-1 antibodies may be positive, negative, or indeterminate with HIV-2-positive sera. (For the confirmation of HIV-2 EI assay reactivity, p26 and gp36 correspond to their HIV-1 counterparts p24 and gp41, respectively.[106]) Busch and coworkers tested 913 anti-HIV-1-reactive blood donor sera using an anti-HIV-2 screening EIA, with confirmation by an anti-HIV-2 env-peptide EIA and an anti-HIV-2 Western blot. These 913 sera were derived from anti-HIV-1 screening of approximately 242,000 donations over a 3-year period. No HIV-2 infections were identified.[105]

To examine HIV-2 seroprevalence in a higher-risk population, a sentinel surveillance for HIV-2 was conducted by testing 31, 533 anonymous blood specimens from patients at sexually transmitted disease clinics, injecting drug users at treatment centers and clients at HIV counseling and testing sites in 14 U.S. cities where West African immigrants often settle.[100] Specimens were tested by HIV-1 and HIV-2 whole virus and synthetic peptide EI assay and confirmed by HIV-1 and HIV-2 Western blots. Nearly 10% of 31, 533 sera were positive for HIV-1. In addition, two heterosexual male patients from West Africa were infected with HIV-2, and one of the HIV-2-positive specimens did not cross react on HIV-1 EI assay screening.[100]

When HIV testing is indicated, tests for antibodies to both HIV-1 and HIV-2 should be obtained if epidemiological risk factors for HIV-2 infection are present, if clinical evidence exists for HIV disease in the absence of a positive test for antibodies to HIV-1, or if HIV-1 immunoblot results exhibit the unusual indeterminate pattern of *gag* plus *pol* bands in the absence of *env* bands.[54,100,107] The following procedures are recommended if testing for both HIV-1 and HIV-2 is performed by means of a combination HIV-1/HIV-2 EI assay.[54] A repeatedly reactive specimen by HIV-1/HIV-2 EI assay should be tested by HIV-1 immunoblot (or another licensed HIV-1 supplemental test). A positive result by HIV-1 immunoblot confirms the presence of antibodies to HIV-1, and testing for HIV-2 is recommended only if HIV-2 risk factors are present. If the HIV-1 Western blot result is negative or indeterminate, an HIV-2 EI assay should be performed. If the HIV-2 EI assay is reactive, an HIV-2 supplemental test such as an HIV-1-specific Western blot should be performed.[54] In addition, HIV-2 DNA PCR has been used to determine infection with HIV-1, HIV-2, or both viruses[108,109] (see below).

DETECTION OF HUMAN IMMUNODEFICIENCY VIRUS

CULTURE

The detection of HIV-1 by mixed-lymphocyte coculture is a specialized procedure that has extremely high specificity but lower sensitivity in patients with high $CD4^+$ cell counts[110–112] compared to viral nucleic acid detection methods (see below). HIV-1 coculture may be particularly useful as a supplemental test for assessing indeterminate immunoblots associated with primary infection, where culture has a comparable specificity to viral RNA detection.[113] In the diagnosis of HIV-1 infection in perinatally exposed infants, a sequential-sample, combination assay algorithm comprising an HIV-1 DNA PCR on the first specimen followed by a culture of the second specimen was recommended over HIV-1 DNA PCR for diagnosis alone[114] by Paul and coworkers.[115] In a study of 208 HIV-1-exposed infants, they found that a positive HIV-1 DNA PCR result followed by a positive culture in the second sample confirmed infected status, while two consecutive negative PCR results reconfirmed as negative at 6 months of age established uninfected status.[115]

The lower sensitivity of HIV-1 coculture (other than for pediatric diagnosis) compared to currently available nucleic acid detection methods, as well as its greater cost, time requirements, and highly specialized technical nature, leaves HIV-1 culture restricted primarily to research laboratories. However, there may be a rekindled interest in using HIV-1 coculture for assessing viral containment following potent antiretroviral therapy[116–118] and for obtaining primary clinical HIV-1 isolates for viral syncytium-inducing and drug susceptibility phenotypes.[119]

HIV-1 P24 ANTIGEN

With the advent of nucleic acid amplification methods for monitoring HIV-1, the measurement of HIV-1 p24 antigen has a much more limited role than it once had. Now the primary use for p24 antigen detection is for identifying subjects in the antibody-negative window period of acute HIV-1 infection, but this has more or less been supplanted by HIV nucleic acid testing (NAT). Although antigen detection is a less expensive alternative to viral RNA detection in this setting, both viral RNA and peripheral blood mononuclear cell (PBMC) culture are significantly more sensitive than detection of p24 antigenemia,[50,51,113] even with the added sensitivity of p24 antigen acid dissociation.[120,121] However, a tyramide signal amplification-boosted EI assay for quantification of heat-dissociated p24 antigen reportedly has equivalent sensitivity to viral RNA reverse transcriptase polymerase chain reaction amplification (RT-PCR) at 200–400 RNA copies/mL.[122] The reactivity of the p24 antigen EI assay requires confirmation by a neutralization assay; this is similar to the HIV-1-specific antibody by the EI assay.[123]

With the advent of a licensed HIV NAT screening test, p24 antigen screening of the U.S. blood supply was discontinued.[124]

VIRAL NUCLEIC ACID

The detection of viral nucleic acid (proviral DNA or viral RNA) by commercially available amplification technologies provides a specific and sensitive direct detection method to identify persons who are infected but who have not seroconverted,[12,125] to identify infected infants,[126] and to resolve indeterminate HIV-1 antibody serologies.[48,50,127] In addition, the quantification of plasma viral RNA has assumed a critically important role in assessing disease prognosis and response to antiretroviral therapy.[128–130]

VIRAL DNA IN PBMCs

Qualitative HIV-1 DNA PCR amplification is a commonly used assay method for the diagnosis of HIV-1 infection in neonates and infants.[131,132] The Roche Amplicor™ HIV-1 test kit (Roche Diagnostic Systems, Inc., Branchburg, NJ) is FDA licensed for this clinical use.

The major advantages of HIV-1 DNA PCR over culture are its increased sensitivity and more rapid reporting time, that is, 1 day compared to 2–4 weeks. However, the diagnostic performance of HIV RNA detection may match or exceed that of culture and HIV DNA detection.[133] There is always a possible risk of false-positive reactivity due to contamination of the specimen with amplicons (the so-called carryover product contamination),[134] although this is decreased somewhat by the use of the uracil *N*-glycolsylase enzyme in the commercial assay.[135] False negatives can also occur because of inhibition of the PCR reaction by hemoglobin or heparin[136] or when there are fewer target cells in the assay than expected. To control for the latter, and to improve the precision of the assay, testing for HIV-1 DNA should also include concurrent amplification of a cell-associated host gene such as HLA-DQa or globin locus.[137] Participation in a quality assurance program will also ensure that problems with sensitivity and specificity are quickly identified.[138–141]

The use of HIV-1 DNA PCR for diagnosis was assessed recently for 96 studies for which reported sensitivities for HIV-1 DNA PCR range from 10% to 100% and specificities range from 40% to 100%.[142] The authors of this review concluded that the HIV-1 DNA PCR assay is not sufficiently accurate to be used for the diagnosis of HIV-1 infection without confirmation. Use of HIV-1 DNA PCR for the diagnosis of infection in adults should be limited to situations in which antibody tests are known to be insufficient[48,143] or as a confirmation test when low levels of HIV RNA (<5000 RNA

copies/mL) are detected with suspected HIV primary infection.[144] HIV DNA level during early infection in adults helps to independently predict disease progression in some[240] but not in other studies.[241]

VIRAL RNA IN PLASMA

The detection of plasma HIV-1 RNA by RT-PCR amplification, nucleic acid sequence-based amplification (NASBA), bDNA signal amplification, or transcription-mediated amplification (TMA) is more sensitive than p24 antigen EI assay or culture for detecting virus.[124,143–147] There is, therefore, much interest in using plasma HIV-1 RNA as a diagnostic test.[57,148] As mentioned above, HIV-1 RNA has replaced HIV-1 p24-antigen screening of all donor blood in the United States.[124] However, only one commercial HIV-1 RNA assay is currently licensed for blood bank donor-screening purposes (APTIMA HIV-1 RNA Qualitative Assay, Gen-Probe). To avoid false-positive diagnosis, the HIV-1 RNA assay should be used diagnostically only as a supplemental test for detecting antibody-negative acute infection.[57,142,144,149] Thus, in this particular diagnostic setting, a reactive HIV-1 RNA assay (particularly one with a low viral RNA copy number, <5000 copies/mL)[57,144] should be confirmed by another nucleic acid technology, preferably HIV-1 DNA PCR—or HIV-1 p24 antigen or HIV-1 culture if available. Alternatively, one can retest for the development of HIV-1-specific antibody, which should generally occur within 2 or 3 weeks after viral RNA is detected.[12,113] The presence of HIV-1 RNA alone requires a correlation with the medical and epidemiological history and, importantly, a repeat blood draw for confirmatory HIV-1 testing.

HIV-1 RNA quantitative assays

Three different FDA-approved commercial assays are available to detect and quantify viral RNA in plasma; each approaches the quantification of viral RNA differently. These assays quantify HIV-1 RNA by either amplifying the target RNA or the signal. The limits of quantification provide an acceptable sensitivity and range for most clinical purposes. The limit of quantification represents the level at which the intra-assay variation is less than 0.15 $\log_{10}$ RNA copies/mL such that the 95% confidence limits for the difference between two estimates is equivalent to ±0.5 $\log_{10}$ RNA copies/mL or approximately a threefold difference in viral RNA that can be reliably measured.[150] This interpretation differs from the kit manufacturers who claim a lower level of quantification based on less strict criteria. A more detailed overview of the different methodologies may be found elsewhere.[151]

Briefly, the NASBA assay involves first obtaining nucleic acid isolation by lysis and binding of the viral RNA to silicon dioxide (silica) microparticles, followed by isothermal amplification (the so-called target amplification) using a reverse transcriptase, RNAse H, and T7 RNA polymerase.[152–154] Three internal calibrators are added to the specimen and adsorbed along with the specimen prior to the lysis step. Amplification covers approximately 1200 bases in *gag* and *pol*. Detection is by means of chemiluminescence. The sensitivity of the assay is approximately 80 RNA copies/mL, the quantification limit is 500 copies/mL, and the dynamic range is up to 10,000,000 RNA copies/mL (bioMérieux NucliSens™ QT HIV-1 RNA assay). Acceptable whole blood anticoagulants include EDTA (lavender-top Vacutaner(tm) tubes [Becton Dickinson, Franklin Lakes, NJ]), ACD (acid citrate dextrose, yellow-top tubes), and heparin (green-top tubes).

The branched-chain DNA assay (Bayer VERSANT HIV-1RNA 3.0) is a nonisotopic sandwich nucleic acid hybridization assay that uses a series of target probes to span 1200 bases in *gag* and *pol* and hybridize the viral RNA target onto a series of capture probes attached to the surface of the microwell plate and also to the bDNA amplifier molecules.[155] Multiple alkaline phosphatase probes amplify the signal (the so-called signal amplification); detection is by chemiluminescence. An external standard curve is used to calculate the HIV-1 RNA copy number. The dynamic range is up to 1,000,000 RNA copies/mL, the sensitivity is 50 RNA copies/mL of plasma, and the limit of quantification is 75–100 copies/mL.[156] The whole blood anticoagulant of choice is EDTA.

The Roche Amplicor® HIV-1 Monitor™ Test uses the *Thermus thermophilus* rTth enzyme, which serves to catalyze both reverse transcription and DNA amplification of a 142-base *gag* sequence in a single reaction tube. An internal quantitative standard is used to adjust for recovery and calculate the final HIV-1 RNA copy number. The assay has an analytic sensitivity of 200 RNA copies/mL and a quantification limit of 400 RNA copies/mL, with a dynamic range of up to 750,000 RNA copies/mL. A centrifugation step (Amplicor HIV-1 Monitor™ Ultra Sensitive specimen preparation protocol, Roche Molecular Systems, Somerville, NJ) can be used to concentrate virus and thus increases the sensitivity of the assay to approximately 50 RNA copies/mL, with a lower quantification limit of 200 copies/mL.[157,158] The whole blood anticoagulant of choice is EDTA or ACD. Two automated specimen preparation and real-time PCR amplification assay instruments, the Roche COBAS AmpliPrep/COBAS TaqMan HIV-1 Test (based on amplification of *gag* targets) and the Abbott RealTime HIV-1 assay (based on amplification of a *pol* [integrase] target), have been FDA approved for monitoring HIV-1 infection and should facilitate the processing of large numbers of clinical specimens for HIV-1 RNA quantification. Both automated assays detect and quantify HIV-1 subtypes across a broad dynamic HIV-1 RNA range (50–10 million RNA copies/mL of plasma).

Specimen considerations for HIV-1 RNA quantification

In order to minimize the variability of quantitative HIV-1 RNA test results, samples collected for a particular assay should be processed at the same time post blood draw, using the same anticoagulant blood-draw tube type.[159] In general, EDTA is the preferred anticoagulant. Based on the work of Holodniy and coworkers,[159] the general recommendation has been to separate and store plasma at ~70°C within 6 hours of collection. This rapid specimen processing may place a considerable burden on the laboratory. Moreover, a 6-hour processing requirement may be too stringent, and a recent study is reassuring in this regard.[160] For the Amplicor HIV-1 Monitor™ assay, viral RNA copy numbers were maintained within 0.5 $\log_{10}$ (threefold) in both blood and plasma samples held at ambient temperature or 4°C for up to 3 days and remained stable despite limited freezing and thawing.[161]

As in the serologic diagnosis of HIV infection, the use of filter paper to collect and store whole blood for later analysis of viral nucleic acid is an attractive alternative to phlebotomy. Studies by Cassol, Fiscus, and others have shown that both HIV-1 DNA and RNA can be detected reliably from blood dried on filter paper; moreover, RNA quantification, corrected for the hematocrit, was comparable in terms of sensitivity and reproducibility to plasma.[162–164] This collection method appears to be suitable for both quantification and sequencing of HIV specimens obtained under field conditions.[164,165]

DETECTION OF HIV-1 SUBTYPE NUCLEIC ACID

As HIV-1 subtypes establish within different geographical areas, primer pairs and probes used for HIV nucleic acid detection and quantification have been modified to detect non-B subtypes. For example, the APTIMA HIV-1 RNA Qualitative Assay (Gen-Probe, San Diego, CA) is reported to show sensitive detection of all major HIV-1 group M subtypes, in addition to variants from groups N and O.[166] Primer pair modifications have been incorporated into the Roche Amplicor HIV-1 DNA and Monitor HIV-1 RNA assays (version 1.5)[167] and Abbott RealTime assays. Because of the large number of *pol*-specific synthetic oligonucleotide target probes used by the bDNA assay (VERSANT HIV-1 RNA 3.0 Assay, Bayer Corporation, Norwood, MA), detection of group O and different non-B subtypes has been less of a problem for the bDNA assay.[168]

DETECTION OF HIV-2 NUCLEIC ACID

Specific primers and probes are necessary to detect HIV-2 nucleic acid.[169] Significant genetic diversity of HIV-2 divides this virus into five genetic subtypes, A–E, with subtype A being the most common. Similarly to HIV-1, recombination of phylogenetically distinct HIV-2 viruses occurs but genetic recombination between HIV-1 and HIV-2 has not been reported.[170] In contrast to HIV-1, HIV-2 RNA levels in plasma and semen are generally lower, corresponding to a slower immunological deterioration and lower transmission rates.[171]

ANTIRETROVIRAL DRUG SUSCEPTIBILITY GENOTYPE AND PHENOTYPE

Incomplete inhibition of HIV-1 replication in vivo may arise because of poor drug absorption, patient noncompliance with therapy, variations in host antiretroviral drug pharmacokinetics, and compartmentalization or infection with drug-resistant virus variants (termed primary drug resistance). This incomplete inhibition may result in the emergence of drug-resistant HIV-1 variants (secondary drug resistance) and thus is an important cause of therapy failure.[172] An assessment of drug resistance may be helpful in selecting antiretroviral therapy, but this has not been rigorously proven.[173] Nevertheless, commercial assays for antiretroviral drug resistance are available, and clinical studies suggest that viral drug resistance is often associated with poor virological response to therapy. Expert interpretation is recommended, given the complexity of results and assay limitations.[174,175]

Antiretroviral drug susceptibility is determined either phenotypically, by assessing for the susceptibility of the virus isolate (or *pol*-recombinant) ex vivo, or genotypically, by assessing for mutations that confers resistance.

There are two phenotypic approaches.[151] The first approach tests the sensitivity of the proviral population present in the PBMCs of the patient but is no longer used because it is too labor intensive and has been replaced by the second more rapid approach that uses recombinant technology. In the second approach, PCR-amplified *pol* gene-amplicons containing reverse transcriptase and protease are obtained from the plasma or serum-associated virus (vRNA) or from the cell-associated provirus (vDNA). These amplicons are inserted into a laboratory HIV DNA clone that has the RT and protease genes deleted.[176,177] The infectious HIV DNA clone is then propagated in a permissive cell line to create a pool of infectious recombinant virus. This recombinant virus is used to determine the susceptibility to single antiretroviral drugs (unfortunately, the use of combinations of antiretroviral drugs is beyond the assay's capacity). A modification of this approach uses a recombinant test vector (RTV) HIV DNA that contains the patient's viral *pol* gene and an indicator gene (luciferase) that is inserted into the *env* gene, thus preventing the RTV from expressing HIV-1 envelope protein. Pseudo-typed virus particles are produced by cotransfecting permissive cells with RTV DNA and a plasmid that expresses the envelope proteins of amphotropic murine leukemia virus (MuLV). The ability of these pseudo-typed

virus particles to complete a single round of replication is assessed by measuring luciferase production in susceptible target cells. The antiviral activity of a protease inhibitor (PRI), for example, is measured by adding a PRI to the cotransfected cells, which results in the production of noninfectious pseudo-typed virions incapable of infecting new target cells. The antiviral activity of a reverse transcriptase inhibitor (RTI) is measured by adding an RTI to target cells and preventing the infection of these cells by the pseudotyped virus that arises from the original cotransfected cells.[178]

Genotypic methods to detect HIV resistance include DNA sequencing of the entire viral population or clones, selective PCR assay, determination of point mutations, and differential probe hybridization; enzyme-immunoassay modification of the oligoligase detection reaction assay; and the commercially available HIV-1 reverse transcription line probe assay.[179] Several kits are commercially available for genotypic resistance testing. HIV-1 Trugene (Visible Genetics/Bayer Healthcare, Suwanee, GA) and Viroseq (Celera/Abbott Laboratories, Rockville, GA, and San Fransisco, CA) are FDA approved. However, genotypic changes may not always correlate with changes in drug susceptibility of the clinical isolate.[180] Therefore, before these techniques can be applied most effectively in the clinic, much still needs to be learned about the genotype–phenotype correlation in patients who receive antiretroviral therapy. While some advisory panels have recommended routine use of susceptibility testing in clinical practice,[4,174] many clinicians continue to base decisions to start or change therapy on the viral RNA level, $CD4^+$ cell count, and previous antiretroviral drug history, with careful attention to patient education about adherence to the prescribed therapy regimen.[173]

It should be noted that primary HIV resistance can also be observed in viruses recovered from a substantial number of people with newly diagnosed infection; this is called "transmitted drug resistance." Transmitted drug resistance is a clear demonstration of the failure of HIV prevention efforts. In addition, the risk of such resistance clearly requires consideration by the clinician for the patient about to start therapy.

USE OF HIV-1 RNA TO MONITOR INFECTION

PROGNOSTIC ABILITY OF HIV-1 RNA IN INFECTED ADULTS

Natural history

The assessment of immune dysfunction, as evaluated by the CD4 T-cell count, and the level of virological containment, as assessed by the plasma HIV-1 RNA level, assist the clinical assessment of patients with HIV-1 infection. The HIV-1 RNA level has become the premier laboratory marker of viral replication in vivo;[181] however, to appreciate the benefits and limitations of using viral RNA as a measure of disease progression requires an understanding of several critical elements of viral pathogenesis.

First, cell-free viral RNA in plasma represents a minority population of infectious virus and a majority population of noninfectious virus particles.[141] The infectious to noninfectious particle ratio is higher for viruses with higher replicative efficiency and lower with an effective cytotoxic CD8 T-cell response and high levels of HIV-1 antibody.[182,183] Second, the level of plasma viral RNA may not reflect the level of cell-associated infectious virus. Cell-associated infectious virus can be recovered from the majority of patients who have had plasma viral RNA levels suppressed to below the level of detection after prolonged, potent antiretroviral therapy.[118] Third, the viral RNA level in plasma may not reflect the level of virus and kinetics of viral replication in other sites and compartments[184–187] such as latently infected cells in the lymph nodes,[188] central nervous system,[189] and genital tract.[190] Fourth, independent of viral RNA level, syncytium-inducing viral phenotype (X4) is strongly and independently associated with disease progression.[191] Fifth, coinfection with the flavivirus GB virus C (GBV-C, also designated as hepatitis G virus) is associated with reduced mortality rate and may lead to an inhibition of HIV replication in GBV-C viremic patients.[192,193] Finally, patient attributes such as age,[194] gender, HLA phenotype,[195] and immune status[196] may cause substantial variability in the level of viral replication.[197] Together these factors may explain, in part, the differences in disease progression among patients with similar plasma viral RNA levels, and they represent a limitation to the use of plasma viral RNA as the sole marker of therapeutic efficacy and clinical outcome.

Nonetheless, one of the most important concepts to emerge from our understanding of HIV-1 disease pathogenesis is that the magnitude of HIV-1 replication in infected persons is associated with the rate of disease progression.[181,198,199] The level of plasma HIV RNA reflects the infected person's ability to contain viral replication such that the replication and clearance of virus reaches a quasisteady state[184–187] and thus defines, in part, the subsequent rate of disease progression.[198–201] This quasisteady state has been referred to as the viral "set point" and appears to be established in the first 3–6 months following primary infection, during which time an HIV-specific humoral and cytotoxic lymphocyte response is established.[202–204] Interestingly, the plasma viral RNA level prior to the establishment of the steady state is not predictive of subsequent disease progression.[202] The viral steady state represents the nadir of viral containment, after which time the plasma viral RNA level may increase slowly, conferring additional risk for the development of AIDS.[202] However, some patients may continue to have a decline in plasma viral RNA from the steady state, conferring additional clinical benefit.[205]

The viral steady state is not absolute, and each plasma viral

RNA level describes a range of times to the development of disease progression. To illustrate this point, Ioannidis and coworkers constructed a model to ascertain the predictive value of serum viral RNA in asymptomatic patients with >500 CD4 cells/μL, an unknown time since seroconversion, and no prior antiretroviral therapy.[197] They found that the minimum and maximum estimated time to progression to AIDS varied considerably at assigned serum viral RNA levels. For example, patients with a viral load of 10,000 (10^4) RNA copies/mL of serum could take from 2.8 to 19 years to develop AIDS, and those with 30,000 ($10^{4.5}$) RNA copies/mL could take anywhere from 1.9 to 8 years.

In general, patients who are more likely to progress rapidly have a higher plasma viral RNA steady state than those who progress more slowly. However, the predictive value of high plasma viral RNA levels decreases over time, while the predictive value of low $CD4^+$ cell count and $CD4^+$ cell function increases over time. Thus, in the later stages of infection, immune deficiency is most predictive of disease progression.[205] There is a monotonic relationship between the plasma viral RNA level and the rate of $CD4^+$ cell decline, such that higher plasma viral RNA levels are associated with a greater rate of $CD4^+$ cell decline.[198,201] For example, the Multicenter AIDS Cohort Study of the natural history of HIV-1 infection showed that the mean (95% confidence interval) decrease in $CD4^+$ cell count per year was −36.3 (−42.3 to −30.4) cells for subjects with less than 500 viral RNA copies/mL of plasma compared to −76.5 (−82.9 to −70.5) cells for subjects with greater than 30,000 viral RNA copies/mL of plasma.[201]

In most untreated subjects, the plasma viral RNA steady-state level lies within a relatively narrow range between 1000 (10^3) and 100,000 (10^5) RNA copies/mL of plasma.[181,191,198,205] For example, in the largest cohort study, 74.3% of 1531 untreated patients had plasma viral RNA levels of <30,000 RNA copies/mL by the bDNA assay.[201] Mellors and coworkers also defined five risk categories for disease progression based on the arbitrary distribution of 1531 subjects into HIV-1 RNA level quintiles. Highly significant differences in the proportion of patients who progressed to AIDS within 6 years of diagnosis were seen in these five risk categories: 500 copies/mL or less, 5.4% (95% CI, 0–17%); 501–3000 copies/mL, 16.6% (12–21%); 3001–10,000 copies/mL, 31.7% (7–43%); 10,001–30,000 copies/mL, 55.2% (25–84%); and more than 30,000 copies/mL, 80.0% (58–100%).[201]

Clinical trials

Importantly, because there is a continuous gradient of risk of disease progression associated with the viral RNA steady-state level, one of the objectives of antiretroviral therapy is to "reset" this plasma viral RNA steady-state level to one with a lower risk of disease progression. Results from HIV-1 therapy trials show that inhibition of HIV-1 replication (as assessed by plasma HIV-1 RNA level) is associated with a delay in clinical disease progression.[129,130] Although the relative clinical benefit of any given decline in plasma viral RNA does not depend on the baseline level of plasma viral RNA, the absolute risk of clinical disease progression remains higher in the patient with the higher pretherapy plasma viral RNA level.[181] In summarizing the data from seven large clinical trials involving 1330 subjects who received primarily nucleoside therapies, Marschner and coworkers[181] showed that a 10-fold decrease in plasma viral RNA level from baseline to week 24 yielded a 72% reduction in the risk of progression (95% CI, 61–81%, $p < 0.001$) and that large reductions in plasma viral RNA level were the most desirable. Importantly, any reduction in excess of the natural variability of plasma HIV-1 RNA measurement (approximately threefold, or 0.5 $\log_{10}$) was associated with a delay in disease progression. However, in this study and others, the prognostic interpretation of any given plasma viral RNA reduction also depended on the treatment response of the $CD4^+$ cell count.[181,206,207] Even though the change in plasma viral RNA is a better predictor of clinical progression than is the $CD4^+$ cell response,[7] together the viral RNA and $CD4^+$ cell count responses more fully characterize the risk of disease progression than does either one alone.[181,206,208] These clinical trial data indicate that a more complete assessment of a patient's prognosis is achieved by monitoring the plasma viral RNA level and $CD4^+$ cell count together.

MONITORING THERAPEUTIC RESPONSE

In general, nadir responses in plasma viral RNA occur in most patients 4–12 weeks following initiation of potent antiretroviral therapy. With some potent antiretroviral regimens, plasma viral RNA values will decrease to less than 500 RNA copies/mL by 16 weeks in 60–80% of subjects and to less than 50 viral RNA copies/mL by 24 weeks in approximately 70%. The number of patients in these categories will depend on the study population and their prior antiretroviral experience.[130,209] With a stable response, continued monitoring at 3–4-month intervals seems warranted, with more frequent monitoring if a critical plasma viral RNA value is approached.[210] It is advisable to plot the plasma viral RNA values on a $\log_{10}$ scale and only repeat the plasma viral RNA measurement for values that are greater than the upper 95% confidence interval found for the expected variation in plasma viral RNA level (that is, 0.5 $\log_{10}$ above the mean nadir response value), thus ensuring that a change in plasma viral RNA level will lead to a change in therapy.[211–214]

The target of therapy must be a durable reduction in the plasma viral RNA by at least threefold (0.5 $\log_{10}$) from pretherapy levels[210,213] to below 1000 copies/mL[181] and, by current consensus guidelines, preferably to an "undetectable" level.[4] An analysis of 1083 patients from ACTG 320[130] showed

that only seven (5.6%) of 126 clinical events were associated with a preceding plasma HIV-1 level below 500 copies/mL, and for the remaining 119 clinical events, the plasma viral RNA level was above 500 copies/mL.[215] Nevertheless, the target for therapy should be at least one $\log_{10}$ value lower than this, i.e., <50 RNA copies/mL of plasma.[4]

Importantly, therapy should also stabilize or increase the $CD4^+$ cell count, at or above the expected level of biological variation, by more than 30% in the absolute cell number or by more than 3% in the proportion of cells.[216] Interpretation of any given plasma HIV-1 RNA reduction depends on the treatment response of the $CD4^+$ cell count. Because of the interaction between viral RNA and $CD4^+$ cell count, changes in both, along with a consideration of the clinical course, are necessary for defining therapeutic response. In an analysis of several clinical studies of primarily nucleoside therapy, for those subjects with no reduction in plasma HIV-1 RNA level, subjects with a reduction in $CD4^+$ cell count had a 30% greater risk of clinical progression over 2 years, compared to those who had an increase in $CD4^+$ cells above pretherapy levels.[181]

Additionally, therapy should provide an improved sense of patient well-being with minimal side effects. In targeting for the lowest plasma viral RNA level, consideration must be given to prior antiretroviral drug exposure, balancing therapy compliance, tolerability of the regimen, and long-term toxicity of the therapy regimen.[4,217]

MONITORING HIV-1 RNA IN PREGNANT WOMEN

Monitoring of viral RNA levels in pregnant women is no different from that for nonpregnant women or men,[3,4] and the natural history of plasma viral RNA during pregnancy is still being characterized. In two relatively small studies, the maternal viral load did not rise during pregnancy.[218,219] However, in a larger cohort study of 198 HIV-1-infected women, plasma HIV-1 RNA levels were higher at 6 months postpartum than during antepartum in many of the women.[220] Although both the plasma viral RNA level and the CD4 cell count are independently predictive of vertical transmission risk, the change in plasma viral RNA level only explains, at most, 50% of the benefit of zidovudine therapy.[221] These data strongly suggest that there is a prophylactic benefit from antiretroviral therapy on vertical transmission. The strong association between vertical transmission and maternal plasma viral RNA level[221,222] indicates that plasma viral RNA levels should be suppressed to <1000 copies/mL and preferably to undetectable, to reduce the risk of vertical transmission during pregnancy to <1%.[223–226] Furthermore, because transmission may occur when plasma HIV-1 RNA is not detectable,[220,221] plasma HIV-1 RNA levels should not be the determining factor when deciding when to use antiretroviral prophylaxis.[3,4] As such, antiretroviral therapy is recommended in all pregnant women, regardless of virologic, immunologic, or clinical parameters for the purpose of preventing mother-to-child transmission.[3,4]

USE OF PLASMA VIRAL RNA TO DEFINE VIROLOGICAL FAILURE

A precise definition of therapeutic failure based on viral RNA level has not been developed. Such a definition should embrace the clinical status of the patient, the $CD4^+$ cell count, and the plasma viral RNA level. The failure of plasma viral RNA to decline by at least 30-fold (1.5 $\log_{10}$) or more from baseline following 4–8 weeks of therapy is generally considered to represent a suboptimal virological response.[4,181] In addition, many clinicians would also consider the inability to achieve undetectable plasma viral RNA by 12–24 weeks of therapy as evidence for therapeutic failure. The consideration of undetectable viral RNA as a benchmark of success is based on the recognition that viral replication in the presence of selective antiretroviral drug pressure could potentially result in the development of drug resistance. However, many patients fail to achieve undetectable viral RNA levels or they experience a rebound in viral RNA after starting antiretroviral therapy.[226,227]

It is important to consider that the relative benefit of a decline in plasma viral RNA is the same, no matter where the pretherapy viral RNA level started, although the pretherapy plasma viral RNA level itself confers an additional, independent risk of disease progression. For example, a decline from 10^5 viral RNA copies/mL of plasma to 10^4 viral RNA copies/mL of plasma represents the same relative 72% reduction (95% CI, 61–81%, $p < 0.001$) in risk of disease progression as a change from 10^4 to 10^3 viral RNA copies/mL.[181] However, each of the two pretherapy plasma viral RNA levels of 10^5 and 10^4 copies/mL confers a different relative hazard of disease progression, after controlling for the baseline $CD4^+$ cell count and therapy assignment. The target of reaching undetectable plasma viral RNA after 12–24 weeks of therapy is also affected by the pretherapy plasma viral RNA level. Achieving a detectable plasma viral RNA level of less than $10^{3.7}$ (5000) copies/mL when starting with 10^6 copies/mL will confer clinical benefit and may be all that is obtainable, given a patient's prior antiretroviral therapy experience.

Viral resistance

It has been somewhat arbitrarily set that any sustainable 0.5 $\log_{10}$ (threefold) rise in plasma viral RNA above the therapy-induced plasma viral RNA nadir, which is not attributable to intercurrent infection, vaccination, incomplete adherence to the antiretroviral therapy regimen, decreased absorption of antiretroviral drugs, altered drug metabolism, drug–drug interactions, or testing methodology, likely

represents viral failure due to the emergence of drug-resistant HIV variants[4,210] or potential superinfection with a new drug-resistant strain of HIV. Although genotypic and phenotypic changes associated with drug resistance in vitro are not always synonymous with clinical drug failure, retrospective and prospective clinical trials on the predictive value of these tests have supported their adjunctive use for selecting the next antiretroviral regimen during virological failure.[4,228] The correct interpretation of viral susceptibility is complicated by the complexity of the mutational patterns, undetected subpopulations of mutant virus, residual effects of prior antiretroviral therapy, and host factors including nonadherence. Moreover, the relationship between adherence and the development of antiretroviral drug resistance is complicated, and the level of adherence that creates the most efficient combination of drug pressure and viral replication to select for resistant virus is unknown.[229] Thus, the clinician should approach the clinical management of patients using viral genotypic or phenotype assays cautiously until definitive, prospective data from clinical trial are available.[173] Until such data are available, the clinical management of when to initiate or change therapy in an HIV-infected patient should be individualized and based primarily on viral RNA level, CD4 cell count, and previous antiretroviral drug history, but not on antiretroviral resistance test results alone.[174]

Discordant viral RNA and CD4 cell responses

The therapeutic response in plasma viral RNA and CD4 cell count may be discordant, with a sustained or continued rise in CD4 cell count despite a rise in viral RNA level on antiretroviral drug therapy.[207,230] This discordance occurs in approximately 14% or more of patients who receive antiretroviral therapy.[181] The discordant response has been associated with a decrease in disease progression, raising questions about the wisdom of changing antiretroviral therapy based solely on the plasma viral RNA response.[226] Many clinical trials provide study patients with the endpoint measurement (i.e., plasma viral RNA level) on a real-time basis. This practice raises serious concerns about the introduction of selection bias and the ability to define a viral RNA-based therapeutic failure. Thus, in the absence of clinical trials data, if the sustained rise in plasma viral RNA while on therapy is to either less than 0.5 $\log_{10}$ above the plasma viral RNA therapy nadir or less than 5000 (3.7 $\log_{10}$) copies/mL, whichever is less, it might be prudent to observe carefully for a further deterioration in $CD4^+$ cell count or clinical progression before considering a change of therapy. A sustained increase in plasma viral RNA that exceeds these criteria should warrant a reassessment of the antiretroviral regimen for adherence and pos sible therapy failure. A more contemporary approach would con sider any sustained detection of plasma viral RNA worthy of a switch in therapy.[4] However, neither approach has received validation by a controlled clinical trial.

CAVEATS FOR THE CLINICAL USE OF HIV-1 RNA TESTING

Uncertainty in measuring HIV-1 RNA level

There is uncertainty in assigning a value to a single plasma viral RNA measurement.[141] This uncertainty arises from specimen handling, the performance characteristics of the assay, the technical variability of the assay, whether the different specimens are tested by batch or real time, and the infected person's natural variation in virus level.[211–213] In total, these factors define, with 95% confidence, a variability in the estimated plasma viral RNA copy number of at least fivefold (0.7 $\log_{10}$) for single RNA measurements. Consequently, a single measurement of plasma viral RNA is associated with a defined range of values above or below the measured value at least 95% of the time (2.5% of the time values may be greater than and 2.5% of the time less than this fivefold range). For example, a person with a plasma viral RNA value of 5,000 copies/mL obtained from a single plasma specimen taken today may have a measured viral RNA value anywhere from 1,000 to 25,000 copies/mL on repeat testing of another blood draw taken within the next few days to weeks, falling within this range 95% of the time.[190]

A rigorous virology quality assurance program has shown that the intra-assay standard deviation for these assays ranges from less than 0.1 to 0.2 $\log_{10}$ HIV-1 RNA copies/mL of plasma.[141, 231] This precision enables the assays to distinguish reliably three- to eightfold changes in plasma viral RNA for batched testing and four- to 19-fold changes for real-time testing. Obviously, the uncertainty in defining the true plasma viral RNA level contributes important *uncertainty* for changing antiretroviral therapy based on a single plasma viral RNA value.

In addition to the above considerations, variability in interpreting absolute plasma viral RNA levels across different clinical studies arises because of the patient population studied, the use of serum or plasma to assess the viral RNA level, different viral RNA assay methods, and different anticoagulants and storage conditions. For example, viral RNA levels are generally one-half log value less for serum than for plasma, depending on the assay method used; bDNA values are generally twofold less than those for RT-PCR; and heparin interferes with the detection of viral RNA by both bDNA and RT-PCR assays but not for NASBA.[141,160]

Thus, some patients could have successful therapy regimens inappropriately changed, based on estimates of plasma viral RNA levels that are associated with considerable uncertainty both in their measurement and in the clinical meaning of the plasma viral RNA value, particularly when the plasma viral RNA and $CD4^+$ cell responses are discordant.[181] This is of particular concern for aggressive therapy management, when decisions to change therapy are based on the quantification of viral RNA near the reliable limit of detection

for an assay. Plasma viral RNA assessments by both the bDNA and the RT-PCR assays are usually concordant for most patients below the level of quantification. However, these assessments will be discordant in approximately 20% of patients, and the decision to either maintain or switch antiviral therapy based on the assay quantification limit will be affected by the choice of the viral RNA assay used.[232]

Adequacy of plasma HIV-1 RNA level alone for explaining the clinical response to therapy

Much still remains to be learned about how the favorable and relatively short-term laboratory responses to potent antiretroviral therapy translate into the long-term survival of the individual infected with HIV-1. However, with current antiretroviral drug regimens, the majority of subjects in clinical trials remain suppressed for up to 6 years or more.[233] Of particular concern, however, is the recovery of infectious virus from the presumably longer-lived resting T lymphocytes after prolonged, potent antiretroviral therapy.[116,117] Nevertheless, with continued suppression of viral replication, and failure to demonstrate the development of genotypic resistance to therapy drugs, the long-term outlook for many patients is encouraging, providing the potent therapies are tolerated and drug regimens continue to become more simplified, which both promote adherence.

The use of plasma viral RNA to clinically monitor HIV-1 infection should be based on the following three critical validation points. First, plasma viral RNA is detected in most infected persons, and the level of plasma viral RNA is associated with disease progression. Second, a decline in plasma viral RNA with therapy is associated with improved clinical outcome, and a rise in plasma viral RNA is associated with clinical progression. Third, the change in plasma viral RNA level completely explains the clinical benefit of antiretroviral therapy.[6] Clearly, fulfillment of these three validation criteria is necessary to completely understand the limitations of plasma viral RNA as a substitute marker for disease progression in clinical trials. The first two criteria for surrogacy have been fulfilled in several clinical studies, and the associations between plasma viral RNA level and disease progression are highly significant statistically.[208,234] On the basis of both natural history and clinical trial studies (mostly from adult-based studies), it is now widely accepted that the lower the plasma viral RNA level, the better the clinical outcome.[181,201]

Importantly, the third criterion has not been completely fulfilled. Change in plasma viral RNA level explains only a portion of the clinical response to therapy (probably less than one-half, but the estimates are very imprecise at this time)[7]; thus, plasma viral RNA is only a partial surrogate marker for clinical outcome.[6,128,121] Although this may seem paradoxical, given fulfillment of the first two validation criteria and the strong association between the change in plasma viral RNA and disease progression, the partial surrogacy of plasma viral RNA for clinical outcome means that other host and virus properties are necessary for a complete understanding of disease progression in the individual patient; presumably, such information may eventually help to better define the individual management of patients in clinical practice.[235]

CONCLUSION

The diagnosis of HIV-1 infection by detecting and confirming the presence of specific antibodies is now augmented by more simple/rapid antibody detection assays. These rapid assays are being used in sexually transmitted disease clinics, in urgent care settings, and at the time of labor and delivery for pregnant women without prior prenatal HIV testing. By providing a more rapid assessment of infection status, clinicians can offer more immediate and thus better HIV-1 counseling for patients.

The application of molecular techniques, such as PCR and other nucleic acid amplification technologies, provides earlier supplementary confirmation for the serologic determination of HIV-1 infection and in particular a more definitive and timely resolution of indeterminate immunoblot results. With repeat specimen collection and testing, the nucleic acid amplification technologies have a defined role for diagnosing HIV infection in the absence of antibody (i.e., acute infection) or in the presence of acquired antibody (e.g., neonatal infection).

The direct quantification of HIV-1 RNA in plasma has revolutionized the clinical management of HIV-1-infected patients over the past several years. However, there are other factors, such as the host's immune status, HLA haplotype, and the viral genotype and phenotype that contribute important prognostic information about disease progression, which are not necessarily captured by a single viral RNA value. Testing for HIV-1 drug resistance has become common for assessing virological failure, although the value of these tests in improving clinical outcomes (i.e., suppression of viral replication and the improvement of CD4 cell count) has not been consistently seen. As such, resistance testing may be helpful in selected clinical cases but must await further definitive clinical trial data before routine testing can be recommended.

71 Psychosocial Aspects of HIV Infection

Carol E. Golin, Anna Scheyett, and Andrew H. Kaplan

INTRODUCTION

Powerful forces shape the experiences of people living with HIV. Perhaps more so than for any medical condition in modern times, HIV disease evokes a strong negative response from society at large as the infection targets groups that are already marginalized. For many people living with HIV infection, the struggles that result from the psychological and social factors associated with the disease are as daunting as the biomedical consequences of ongoing viral replication and immune suppression.

The purpose of this chapter is to help clinicians caring for people living with HIV understand and, where appropriate, address the multiple psychological and social contextual challenges faced by their patients. As noted above, these challenges arise from a wide range of sources including: (1) intrapersonal factors, such as substance abuse, mental illness, or coping skills; (2) interpersonal factors, such as violence and victimization; and (3) factors that act at the community level such as social stigmatization. From the perspective of the HIV clinician, these realities are often important obstacles as the patient attempts to gain access to medical care and adhere to treatment recommendations. Further, as the disease advances from the time of diagnosis through the period of clinical latency to the appearance of opportunistic infections, the nature of these challenges may change. Several lines of evidence support the notion that, for many people living with HIV, achieving important biological outcomes such as maintenance of virologic suppression and prophylaxis of opportunistic infections is critically dependent on addressing these psychosocial factors.

One useful framework for understanding the influence of multiple psychosocial factors that act at several levels is Social Ecological Theory (SET). The SET provides a structure for conceptualizing various determinants of health across intrapersonal, interpersonal, and community levels. In the case of HIV/AIDS, it has been recognized since the earliest days of the epidemic that people belonging to traditionally marginalized groups {men who have sex with men (MSM), injection drug users, African American women, etc.} have been disproportionately represented among those infected. The face of the epidemic is changing as well; increasingly new infections occur among the poor, minorities, and women,[1] particularly in the southeastern United States, where HIV incidence is increasing most rapidly in the United States.[1] Factors such as poverty, stigma, and individual health behavior conspire to produce a context in which group members are at high risk for poor physical and emotional health, as well as violence and victimization. It is important to note that membership in a group that is marginalized either as a consequence of a behavior or through discrimination based on race and/or ethnicity and resultant poverty may have significant effects on important health outcomes. For example, studies have shown that perceived discrimination is associated with higher levels of stress, general psychological distress, depression and substance abuse, and with lower levels of life satisfaction and perceptions of mastery and control.[2,3] Individuals with incomes below the poverty level have a life expectancy that is estimated to be 5.6 years shorter than those not in poverty;[4] across all income levels, the life expectancy of African Americans is approximately 4 years shorter than that of Caucasians.[5] Individuals in poverty have difficulty accessing and paying for medical care,[6] experience food insecurity and resultant medical problems,[7] and often live in neighborhoods with high social disorganization and low social support.[8] Many of these characteristics are also associated with a significantly increased risk of victimization and violence; an interview with low-income mothers found that 83% reported physical or sexual abuse during their lifetimes.[9]

Planning for a patient's HIV care must take these contextual factors into consideration for three primary reasons. First, even before HIV infection, many of these patients are likely to have been in poor health; ongoing risk factors for poor health must be considered when planning HIV treatment. Second, the trust of health-care providers may be lower in these patients because of the stressors and struggles they have experienced.[10] Finally, psychosocial needs resulting from poverty, discrimination, etc. may take priority over HIV care for patients; if not addressed, these needs may

become barriers to patient participation in and adherence to treatment.

In addition to social contextual factors, psychological and behavioral aspects of HIV infection play a role in the course of disease. Patients' emotional response to diagnosis and other stressors, coping styles, and coping skills modify the effects that a person's environment has on his or her course of illness. Behavioral skills, health beliefs, and knowledge, in addition to social circumstances influence patients' abilities to take their medication as prescribed, to disclose their illness to others, and to reduce their risky behaviors.

STIGMA ASSOCIATED WITH LIVING WITH HIV

IMPACT OF STIGMA ON THE LIVES OF PEOPLE LIVING WITH HIV

Many of the challenges faced by people living with HIV, including adherence to medications and limiting risky HIV transmission practices, as well as finding employment and locating housing, may be traced to the stigmatized nature of the disease.[11] Since the beginning of the AIDS epidemic, the societal view of HIV infection has been defined largely by its association with stigmatized and vulnerable groups. The level of stigma directed toward people living with HIV appears to have declined as the etiologic agent and modes of transmission became more clearly defined. However, population-based telephone surveys indicate that about one-quarter of those surveyed reported that people with AIDS "have gotten what they deserve" and that 21.8% believe that people with AIDS do not care if they infect others.[12] Further, beliefs that people with HIV should be legally separated from others and that the names of people living with HIV should be made public so that others could avoid them were endorsed by 12% and 16.3% of the population, respectively.[12]

Several studies indicate that these stigmatizing attitudes have a significant impact on the lives of people with HIV. In one series of 142 patients diagnosed with HIV infection at a sexually transmitted diseases clinic, 4% reported that they had lost their job as a result of the diagnosis and 1% had been asked to move.[13] Concerns about HIV-associated stigma may be associated with a reluctance to receive an HIV test and has emerged as a barrier for adherence to HIV medications.[14,15] Of further concern are data suggesting that the stigma associated with HIV infection represents an obstacle for disclosing one's HIV serostatus to a partner.[16,17] Not only do people living with HIV encounter stigma associated with the disease but family members and caregivers may face discrimination as well. In one study, perceived stigma was a predictor of volunteer burnout for AIDS organization workers, and concerns about stigmatization prevented potential volunteers from working for AIDS organizations.[18]

Interventions to minimize the stigma faced by people living with HIV and it impact have largely rested upon attempts to educate HIV uninfected individuals that the widely held stereotypes regarding people living with HIV are inaccurate.[19] These studies have, in general, involved either information giving, counseling, or direct enforced contact with people living with HIV and have targeted either health-care workers or university students. The interventions have had mixed results in increasing empathy and decreasing negative attitudes toward people living with HIV.[20]

Given the lack of success of these individual-based interventions, the persistence of HIV infection as a stigmatized condition, and the refractory nature of these attitudes, it seems likely that successful interventions require action at the community level. Overall, the goal of these interventions should be to promote the view that people with HIV are community members rather than a dangerous "other." Extensive efforts are required to include and take into account the perspectives of marginalized people living with HIV along with the views of opinion leaders in the larger community. The ability of an individual practitioner to effect change may be limited to modeling behavior by treating their HIV-infected patients with respect. However, by virtue of their standing within a community and their expertise in the management of the disease, clinicians may be in a position to play an important role in changing community attitudes.

HIV TESTING, PSYCHOLOGICAL RESPONSE, AND COPING WITH AN HIV DIAGNOSIS

DECISIONS TO GET TESTED FOR HIV

Early stage HIV disease, from the perspective of the patient, begins with the decision to get tested and unfolds following the receipt of a positive test.[21–27] Thus, HIV testing is one important phase in the continuum of HIV care and treatment. The patients' experience of testing is influenced by the social context in which it occurs. About 35% of Americans have been tested for HIV at some time.[28] Recent studies show that reasons for testing are shifting, and more people are having tests as a part of routine medical care rather than to find out whether they are positive.[28] Furthermore, although there has been a push for earlier testing, people seek testing at different stages of the disease. Several studies have shown that half of the people who test positive for HIV do not perceive themselves to be at risk for HIV or do not suspect they have it.[21,27] Among those who do suspect they may be infected, most seek testing because of symptom development rather than because of a known exposure.[22,27,29] Even in the era of highly active antiretroviral theraphy (HAART), people's anxieties about the receipt of a positive test often cause them to put off getting the test including when they suspect they may have been exposed or infected.[21–25] Most women attending

STD clinics in New York, who were not tested for HIV, did not do so because of their anxiety about the possibility of a positive result.[25] In another study, 48% of subjects who suspected being infected with HIV had waited 1 year or more to get tested.[21] Thirty percent of those who are tested never return for their test results.[28]

HIV testing

Most people who get tested for HIV undergo voluntary counseling and testing (VCT) at a testing center, although about 13% of people become aware of their HIV status through mandatory testing.[28] The current VCT model, based on Centers for Disease Control and Prevention (CDC) guidelines, emphasizes an interactive rather than didactic approach focused on a risk reduction plan that is personalized.[28] Counselors not only provide information about HIV and HIV transmission but also counsel people about their individual risk behaviors, using a client-centered approach.[30] How a person is told about the diagnosis can have an impact on his or her psychological response to the illness.[27,31] While currently it is recommended that all patients *should* receive pre- and posttest counseling at the time of testing, studies indicate that such counseling does not always occur.[27,31] In one study, two-thirds of subjects were not satisfied with the way they were told about their diagnosis[26] although we could find no studies that have assessed this more recently. Patients were more satisfied when they received reassurance and sympathy from the provider and when they received more information about their illness.[26] It is incumbent upon the clinician caring for HIV-infected patients to review information about the disease, its causes, transmission, course, and treatment as well as to counsel patients about their own risks at the first visit, even if the patient has undergone testing elsewhere previously. Of note, while it is currently recommended that counseling be conducted before and after testing, some workers argue that the requirement to provide counseling impedes the use of testing and further promotes a sense of AIDS exceptionalism.[32] Thus, there has been a shift among some groups toward eliminating the requisite to provide counseling at the time of HIV testing in order to increase access to testing.

Recently, researchers have developed methods to cost-effectively test people who are acutely infected with HIV (AHI), i.e., who are in the first 6 weeks following an exposure.[33] However, little is known about the emotional, psychological, or prevention needs of these patients because until recently, they have been difficult to identify. As methods to identify AHI begin to be used more widely and routinely, it will become important to understand the special needs of these patients. Patients with AHI, by definition, have recently engaged in high-risk behavior. Therefore, special opportunities are available in the setting of AHI to counsel patients about risky behavior and to identify others at risk through partner notification, but how best to do this is unstudied.

PSYCHOLOGICAL RESPONSES AND COPING WITH AN HIV DIAGNOSIS

The response to an HIV diagnosis varies from person to person, however, some general trends and a time course have been noted. As an immediate psychological response to a positive diagnosis, within the first 10 weeks, most patients experience increased anxiety, sorrow, and loss to which the clinician must be attentive.[34–36] One study showed that for many patients, the level of distress experienced with a positive result was less than they had anticipated but that they still felt distressed.[37] Once diagnosed, individuals experience more negative life events compared with those testing negative, in particular, break-up of marriages and being neglected or disowned by family members.[38] For a substantial minority of patients, the psychological response to a diagnosis can be quite devastating. In one study in South Africa, 56% of newly diagnosed patients were also diagnosed with depression, dysthymia, PTSD, or alcohol dependency after diagnosis.[36] Men had more substance abuse and women more PTSD.[36] Other studies have shown that between 15% and 30% of patients experience PTSD during the first 6 months of diagnosis with at least 30% of PTSD occurring as a direct result of the diagnosis.[39,40] Severe symptoms of distress are more likely to occur among those who had preexisting history of major depressive disorder, suicidality, social anxiety disorder,[40] or ineffective coping strategies, such as blaming or withdrawal.[34]

While patients generally experience immediate distress from a positive diagnosis, most HIV-infected persons are able to cope effectively with the demands of the infection. Most patients with HIV show flexibility in their use of coping strategies and ultimately achieve high quality of life after an initial phase of sorrow and lack of orientation regarding future life.[34,41,42] Among a national probability sample of nearly 3000 individuals in care for HIV, most made health-promoting changes following diagnosis, such as increased exercise, improved diet, quitting smoking, and reducing substance use. Those more likely to make a change had greater desire for involvement in their medical care and for information and had information-seeking positive coping.[42] One study showed that health-related Internet use by HIV-infected men and women was related to a broader spectrum of health behaviors including HIV treatment adherence, active coping strategies, and indicators of better health.[43]

RECOMMENDATIONS TO ASSIST PATIENTS TO COPE WITH A DIAGNOSIS OF HIV

HIV-infected persons with more effective coping skills are better adjusted to their HIV diagnosis and have a better quality of life.[41,44,45] Spiritual well-being among HIV-infected people is associated with better quality of life, social support, and positive coping strategies and negatively related to perceived stress, uncertainty, psychological distress, and emotional

focused coping.[44] Stress management and coping skills programs can successfully teach more effective coping skills and stress management that improve quality of life among people living with HIV. One Cognitive Behavioral Stress Management Program consisted of 10 weeks of weekly 135-minute structured group-based GET SMART (Group Experienced Therapy for Stress Management and Relaxation Training) program aimed at increasing cognitive and behavioral skills and at increasing social support. Participants had significant improvement in cognitive coping strategies involving positive reframing and acceptance and in social supports involving attachment, alliances, and guidance compared with controls. Improved coping was associated with improvements in anxiety and mood.[46]

DISCLOSURE OF SEROSTATUS

Fueled in part by the observation that as many as one-third of all people living with HIV continue to have unprotected sex, several organizations including the CDC have focused their HIV prevention efforts on limiting the risk behaviors of people who are already infected with HIV. Disclosure of one's HIV status to a sex partner has emerged as one of the cornerstones of these broader attempts to limit HIV transmission; proponents of disclosure suggest that providing information about one's HIV status increases the likelihood that partners will take preventive measures.

Unfortunately, there are often significant consequences that flow directly from revealing an HIV diagnosis. The decision to disclose has the potential to expose people living with HIV infection to HIV-associated stigma and its outcomes including loss of employment, housing, relationships as well as the potential for interpersonal violence. It is also important to note that, in some settings, revealing an HIV diagnosis may also raise questions about whether a partner has participated in other risk behaviors. For some people, a desire to avoid taking on an additional stigmatized identity (e.g., MSM or intravenous drug use [IVDU]) may therefore serve as an additional barrier to HIV serostatus disclosure. Many people living with HIV choose not to disclose their status (for a review, see Ref. 47); it has been estimated that as many as half of all people living with HIV fail to disclose their serostatus to sex partners.[48]

Current published guidelines recommend incorporating HIV prevention efforts, including serostatus disclosure, into clinical care; unfortunately, few studies have rigorously examined approaches to promote discussions of HIV status. Although the available research literature provides clinicians with little guidance about how to encourage patients to disclose their HIV serostatus, several general strategies have been suggested.[49,50] These include expressing empathy for the person disclosing this information, openly discussing the advantages and disadvantages of disclosure with the patient, avoid appeals to moral arguments as part of attempts to influence behavior, and review personal experiences with successful disclosures.

ACCESSING SERVICES

ACCESS TO MEDICAL SERVICES

Although the widespread application of HAART and prophylaxis for opportunistic infections has decreased both the mortality and morbidity associated with HIV infection, the benefits of these treatments are limited to those patients with access to medical care.[51] Studies conducted early in the epidemic, before the availability of combination antiretroviral therapy (ART), identified several variables that were associated with delayed receipt of antiretroviral monotherapy.[52–54] African Americans, women, and injection drug users were all less likely to receive azidothymidine (AZT) therapy and the recommended prophylaxis for opportunistic infections. Of note, several studies have described a more precipitous disease course for HIV-infected members of these groups.[55] However, for patients enrolled in care at an academic center with well-developed care guidelines, no relationship was observed between race, gender, and recreational drug-use and disease progression.[56] These findings support the notion that the differences in outcome reported by other studies reflect differences in use of and access to medical care.

These results have been largely supported by extensive studies conducted during the HAART era, although reports suggest that the differences in access observed earlier in the epidemic are narrowing. A nationally representative sample of people living with HIV receiving medical care demonstrated that African American and Hispanic race/ethnicity as well as IVDU route of HIV exposure and insurance status (Medicare/Medicaid vs. private insurance) were associated with receiving suboptimal care.[57] Patients with lower incomes and less education were also less likely to have received optimal care. It appears that these same groups also experience limited access to clinical trials of new anti-HIV therapies; African Americans, Hispanics, and patients without fee-for-service health insurance are underrepresented among participants in research trials of experimental agents.[58]

For many people living with HIV, limited access to care may reflect resources that are inadequate to meet both the expenses of medical care and subsistence needs. For example, one-third of a sample representative of the people living with HIV in the United States receiving medical care reported going without needed care because of competing subsistence needs.[59] Additional analyses indicate that, for these patients, contact with a case manager decreased the number of unmet needs for housing, home health, emotional counseling, and substance abuse treatment services.[60]

Traditionally, the role of the individual clinician in promoting access to medical care has been limited. However,

the studies cited above suggest that clinicians can assist people living with HIV obtain care in a number of ways. At the level of the clinician-patient interaction, clinicians should keep in mind that a significant number of people delay care or go without it entirely. This may have a profound effect on clinical outcomes and the clinician should remain vigilant to this possibility and open to discussions about strategies to meet both medical and social service needs. To this end, at the level of the clinic, it seems prudent for social service providers to be closely integrated into the clinic setting. Further, given the reported relationship between case management services and better access to care, the routine provision of case managers for patients with limited resources and substantial subsistence needs may be advisable. Finally, clinicians should consider using their expertise and social position to advocate for policies that promote access to care for people living with HIV.

ACCESS TO NONMEDICAL SERVICES

Persons infected with HIV have a wide range of needs beyond medical care. For many individuals struggling with challenges and survival issues such as poverty, homelessness, lack of transportation, and food insecurity, accessing medical treatment becomes a less immediate priority in their lives. Because of their life circumstances, HIV+ individuals may be forced to make difficult choices between meeting immediate needs and medical care, the benefits of which may only be seen over time (see Chapter 20).

Research has shown that a significant number of HIV-infected individuals postpone or go without care in order to meet basic needs. In the HIV Cost and Services Utilization Study (HCSUS) data, analysis showed that nearly 12% of the sample reported going without care in order to pay for food, clothing, or housing, and over 15% reported going without care because they could not afford or access transportation. Experiencing any of these needs resulted in significantly higher chances of visiting an emergency room, never receiving antiretroviral medications, and having low overall self-reported access to care.[61] Similarly, a survey of HIV-infected individuals in the southern United States found that over 27% reported needing help applying for benefits such as Medicaid, 17% reported difficulty with transportation, nearly 27% reported needing emergency housing, and over 27% reported needing emergency food in the past year.[62]

Assistance finding and maintaining stable housing is a particularly important service for individuals with HIV infection. Housing instability is common in this population, with rates as high as 49% reported in some studies.[62] Lack of stable housing and homelessness may have a large impact on health status in persons with HIV infection. In a study of rural HIV-infected patients receipt of housing was positively associated with access to medical care,[63] and a second study demonstrated a positive association between housing stability and general physical health status.[64]

USE OF CASE MANAGEMENT TO IMPROVE ACCESS TO NONMEDICAL SERVICES

Case management has been shown to be an effective intervention to address nonmedical needs in patients with HIV infection. Case managers can refer patients to a range of social services and provide assistance in accessing them. Evaluation of case management programs for persons who are HIV positive have demonstrated effectiveness in meeting psychosocial needs. Case managers have been shown to help integrate and increase access to both formal and informal helping services for patients[65] and for their caregivers[66] and to significantly decrease unmet basic needs.[67] Thus, if medical care for HIV infection is to be successful, a holistic assessment of patient needs and coordinated referrals to case management services and other social services in order to address subsistence issues are essential.

MENTAL HEALTH AND SUBSTANCE ABUSE

OVERVIEW OF MENTAL ILLNESS AND SUBSTANCE ABUSE AMONG PEOPLE LIVING WITH HIV

Substance use and mental health disorders are prevalent psychosocial challenges for individuals infected with HIV. These disorders can create substantial life distress, interfere with treatment adherence, are associated with a worse course of illness, and increase the likelihood of engaging in high-risk behavior for HIV transmission. Thus, identifying and addressing substance use and mental health disorders are essential elements of treatment for HIV-infected patients.

A number of studies have revealed high rates of mental disorders and substance abuse among HIV-positive individuals. The national HCSUS found higher prevalence of mental disorders (48%), substance abuse (19%), and comorbid mental illness and substance abuse (13%) in HIV-infected individuals than documented in the general population (22%, 9.5%, and 3%, respectively).[68] The most common mental disorders identified within the HIV-infected population include depression, severe and persistent mental illnesses such as bipolar disorder and schizophrenia, and posttraumatic stress disorder.[69,70]

Mental illness and HIV

Rates of depression vary widely in studies of HIV+ individuals but are generally higher than in the HIV-negative population, with lifetime prevalences of 30–50%.[71] Some studies suggest gender and sexual orientation differences in rates of depression, with particularly high rates of depression in HIV-infected women compared with their seronegative counterparts[72] and higher rates in HIV-positive homosexual men

compared to HIV-positive heterosexual men.[73] HIV-positive individuals are found to have higher rates of serious mental illnesses such as schizophrenia, with one study showing nearly 6% of HIV-infected individuals diagnosed with schizophrenia.[74] Trauma exposure and resultant posttraumatic stress disorder and symptoms are also more common in individuals with HIV infection. High rates of sexual assault and childhood abuse have been reported in both HIV-positive women and men (up to 68% in some studies); frequently this is part of a pattern of repeated traumatization.[75,76] Rates of posttraumatic stress disorder have been reported to be as high as 42% in HIV-positive populations.[69]

Substance abuse among HIV-infected persons

Substance use disorders are common comorbid conditions with HIV. Lifetime prevalence of alcohol disorders in people who are HIV infected has been reported as high as 60% and lifetime prevalence of drug disorders as high as 56%.[70]

Substance use disorders contribute most directly to HIV transmission through IVDU; up to 2001, 25% of the cumulative cases of AIDS in the United States were due directly to IVDU, and it has been estimated that over 35% of all U.S. cases of AIDS are directly or indirectly attributable to IVDU.[77] Substance use disorders also contribute to HIV transmission indirectly through a number of high-risk behaviors, including decrease of sexual inhibition and poor judgment, trading sex for money or drugs, and inconsistent condom use.[70]

Clearly, unaddressed substance use disorders in a HIV-infected patient increase the risk for ongoing HIV transmission to others. In addition, unaddressed mental health disorders may increase the risk of transmission, particularly in disorders related to trauma. For example, research has shown that individuals with a history of childhood abuse are more likely to engage in unprotected sex, sex with multiple partners, sex work, and drug use than those without trauma histories.[69] Untreated substance use and mental health disorders are also associated with higher rates of nonadherence to antiretroviral therapy. In a sample of individuals in the HCSUS cohort, depression, anxiety, and substance abuse were associated with two times the odds of self-reported nonadherence to HAART,[78] and Ammassari and colleagues[79] found that both depression and IVDU were associated with nonadherence to HAART. Alcohol consumption has also been associated with reduced medication adherence, higher plasma HIV RNA levels, and lower $CD4^+$ cell counts.[80] A study by Tucker and colleagues[81] suggests that nonadherence in individuals with mental and substance use disorders may be mediated by difficulty getting medication and poor fit of medication regimen with lifestyle. It is encouraging that research also indicates that as mental health improves with treatment, adherence to antiretroviral medication also improves.[82]

PHYSIOLOGIC IMPACT OF SUBSTANCE USE AND MENTAL ILLNESS

A final consideration is the physiological impact of substance use and mental health disorders on individuals with HIV infection. Studies in vitro have indicated enhanced HIV replication with alcohol exposure. Alcohol consumption is also associated with decreased levels of a range of immunomodulators.[83] Depression has also been shown to have potent immunologic effects on persons with HIV infection. Depression has been associated with a more rapid decline in $CD4^+$ cell count and more rapid progression to AIDS and death, even controlling for sociodemographic and clinical characteristics. A prospective study of over 700 women with HIV infection found that those with chronic depression had mortality rates twice as high as nondepressed women, even when controlling for sociodemographic, clinical, and treatment factors.[84]

RECOMMENDATIONS TO ADDRESS SUBSTANCE ABUSE AND MENTAL ILLNESS OF PATIENTS WITH HIV

Given these findings, several recommendations can be made for physicians caring for HIV-infected individuals. First, all patients should be regularly screened for substance use and mental health disorders. Identification of depression may be particularly challenging in this population, since a number of symptoms overlap with those of HIV infection, such as poor appetite, weight loss, loss of energy, and insomnia.[82] A standardized screening tool may be useful in identifying these disorders. Whetten and colleagues[85] have developed a simple 13-item substance use and mental disorder screen specifically for HIV-infected patients that has demonstrated good sensitivity and psychometric properties. Risks and challenges faced by specific populations should also be considered during this screening, such as increased rates of depression and abuse in women and stresses related to poverty and discrimination, which may cause or exacerbate depression in minority patients.

Once identified, patients should be referred to mental health and/or substance abuse providers with whom the physician has a collaborative relationship. Treatment should consider both pharmacologic and psychological services, including cognitive behavioral and coping skill interventions. Care must be taken in the prescription of psychopharmacological agents; research indicates that certain antidepressants may interfere with some antiretroviral medications, as may methadone and possibly buprenorphine.[73,83] In all cases, medical and psychosocial treatment should be integrated into a unified plan of care.

VIOLENCE VICTIMIZATION AMONG PEOPLE LIVING WITH HIV

Violence victimization and, in particular, abuse by an intimate partner, is a pervasive experience for many people living with HIV. In part, this reflects the prevalence of violence

in society at large; data collected by the U.S. Bureau of Justice Statistics indicate that as many as 6.5 million men and 5 million women are assaulted each year.[86] Physical assault from an intimate partner is particularly common for women. Women have a five- to eightfold higher risk for intimate partner violence than men, and physical abuse from a spouse or partner is the leading cause of injury for reproductive age women.[87] Several studies have examined the frequency with which people living with HIV experience physical abuse as well as their lifetime risk for abuse.[88–91] Although results have varied with the methods used, these reports indicate that a significant number of people living with HIV describe physical abuse in an intimate relationship during adulthood.[92] In addition to the immediate effects of violence victimization on health, physical abuse may have an indirect but significant impact on HIV care itself. For example, in a population-based study of people living with HIV and receiving medical care, MSM with a history of violence victimization were more likely to visit the emergency department and more likely to go without medical care because of the expense.[93] It has also been suggested that the trauma associated with physical and mental mistreatment may increase the risk for abuse of drugs and alcohol.[94] This, in turn, may complicate attempts to adhere to treatment regimens as well as HIV prevention efforts.

The reported risk factors for physical assault among people living with HIV vary somewhat based on gender and HIV-risk category. As is the case for the overall U.S. population, women with HIV appear to be at greater risk for physical assault from an intimate partner than men.[95] In one population-based survey of HIV-infected people receiving medical care, 20.5% of women, 11.5% of MSM, and 7.5% of men not reporting sex with men indicated that they had been "physically hurt by your partner or someone important to you" since their HIV diagnosis.[95] It is important to note that for this representative sample of people living with HIV, physical assault appeared to be a relatively common feature of their experience independent of their HIV infection. In fact, several studies suggest that while the prevalence of intimate partner violence is quite high among people living with HIV, HIV-infected individuals are at no greater risk for such violence after controlling for other factors, associated with physical assault, such as drug use.[92,96,97]

What is perhaps most striking is the overlap between the variables associated with violence and those associated with acquiring HIV infection. These include homelessness, drug dependence, unemployment, and having multiple sexual partners.[89–93] It has also been noted that increasing age and more advanced HIV disease as measured by lower CD4 counts appear to be protective for physical abuse.[98]

These observations have important implications for clinical care. First, given the prevalence of violence victimization and particularly physical assault in intimate relationships, it seems prudent for clinicians to screen all patients for physical abuse with a focus on those at greatest risk or who show signs of having sustained traumatic injuries consistent with abuse. Further, because violence victimization may be a barrier to adequate treatment response, clinicians should also explore physical abuse as a contributory factor in the setting of treatment failure. Unfortunately, few interventions to reduce physical abuse among people living with HIV have been rigorously tested.

ADHERENCE TO ANTIRETROVIRAL THERAPY (ART)

Adherence to antiretroviral therapy is one behavioral challenge that people living with HIV face in their efforts to obtain optimal treatment of their HIV infection. Available treatment for HIV can dramatically suppress viral load, enhance CD4 counts, and reduce morbidity and mortality related to HIV infection.[99,100] However, if antiretroviral medications are not taken as prescribed, treatment failure as well as drug resistance may ensue.[101–106] Although patients taking antiretrovirals generally achieve higher levels of adherence than do patients on other chronic medical regimens,[101,103,104] ART regimens are complex and lifelong, and, as discussed above, many HIV-infected patients' living situations impose multiple obstacles to obtaining optimal medical care; not surprisingly, a large proportion of patients have difficulty achieving targeted levels of adherence that are quite high.[101,103,104] Consequently, since 2002, the CDC and the United States Department of Health and Human Services (US-DHHS) National Treatment Guidelines[100] have recommended that assessment and promotion of ART adherence become a part of routine care for patients taking ART.

ESTIMATING ADHERENCE TO ART

Practice guidelines recommend that providers assess their patients' adherence routinely. Several studies, however, have demonstrated that, without guidance, providers inaccurately estimate adherence, most often overestimating patient adherence.[107] Often what is perceived as patients' overreporting of adherence reflects differences in patients' and providers' understandings of what was meant by "adherence."[108] On average, patients on ART take 55–80% of prescribed doses although the level varies widely.[101–103,109–111] Providers can improve their adherence assessment by asking open-ended nonjudgmental questions about how ART is taken rather than simply asking the number of doses missed. Brief self-administered patient questionnaires, such as a visual analog scale, also exist to supplement but not substitute information[112] obtained from open-ended inquiries.

FACTORS THAT HINDER AND HELP PATIENTS ADHERE TO ART

Medication adherence is a complex behavior that is influenced by many factors. Some salient issues stand out[101,104,113–118]:

1. Patient factors

   No demographic features have been consistently associated with poor adherence.[104,115,116] However, studies have shown that HIV-infected patients who have more positive attitudes toward ART,[114] better knowledge of their regimen,[119] or greater confidence in their ability to take ART[116] are more adherent. Providers can address patient factors by exploring patients' knowledge and beliefs about the medication, dispelling misconceptions, and clarifying for patients the link between nonadherence and poor outcomes.

   Lower literacy levels,[117] substance abuse[104,114,115,120,121] and psychiatric illness have been linked with poor adherence.[101,104] Active abuse of alcohol and other substances have consistently been shown to be barriers to adherence.[104,114,115,120,121] Some studies have shown that a history of prior intravenous drug use is also associated with worse adherence[115,121] whereas others found no link with prior drug use and others found that recovered intravenous drug users demonstrated better ART adherence.[120] These findings underscore the need for ongoing assessment of substance abuse as well as concurrent alcohol and drug counseling for patients on antiretroviral therapy.

2. Regimen factors

   The more complex the antiretroviral regimens[104,115,120] and the less well it fits with the other daily activities[114,116] the less adherent patients are. Dose frequency (i.e., the number of times per day medications must be taken) appears to be a greater culprit than the total number of pills taken[115] at least partly because patients have particular difficulty with the middle of the day dose.[122] The impact of dosing complexity on adherence can guide clinicians to select medication regimens and delineates a role for adherence aids to help to remind patients of midday doses. Adherence aids (such as pill boxes, medication timers etc.)[115,122,123] can improve adherence although many patients are unaware that such aids exist.[122] Including standardized patient education about adherence aids during ART initiation is a practical way to introduce patients to these potentially valuable interventions.

3. Features of the clinical interaction

   The quality of the provider-patient relationship, including the trust of the patient in the provider and the sensitivity of the physician to patients' needs has been shown to be also associated with ART adherence.[124] Taking the time to establish a good, trusting rapport with patients likely has a beneficial effect on patient outcomes.

4. Social/environmental factors

   The social support[121,125] that patients have available, often related to perceived stigma, as well as other factors in their environment, such as homelessness, competing demands, and chaotic routines have been shown to be associated with worse adherence to AR therapy.[104,122,126] Exploring environmental barriers to adherence and identifying means to overcome such barriers, such as support from friends or family, is a fourth important aspect of addressing adherence.

INTERVENTION TO IMPROVE ADHERENCE

Recent studies had identified effective interventions that improve ART adherence.[104,118,127–129] A Cochrane review of programs to promote ART adherence identified a pharmacist-led education and supportive counseling program that improved adherence to antiretroviral therapy. A recent review of 11 ART adherence interventions reported mixed results but identified successful educational ART adherence programs.[127] These included a psychoeducational adherence program for[118] patients starting new treatment regimens, multidisciplinary team-delivered interventions,[128,129] and an online paging reminder system.[123] Overall, interventions that improved adherence include pharmacist-based adherence clinics; adherence encounters at each visit, often multidisciplinary; reminders; alarms; pagers and timers; patient education aids, including regimen pictures, calendars, stickers; and clinician education aids (e.g., medication guides, pictures, calendars).

RECOMMENDATIONS TO IMPROVE PATIENTS' ADHERENCE TO ART

Based on the existing intervention studies as well as the 2002 guidelines put forth by the CDC and the US-DHHS, we outline below several recommendations to help patients on ART adhere to their regimens (Table 71-1). Guidelines recommend that providers use not only regimen-oriented and patient-related strategies but also specific "clinician and health team" strategies to improve adherence.[100] We also believe that it is important to address social-environmental factors.[115] It is particularly important to spend adequate time when initiating therapy, assessing readiness, and educating patients about the specific requirements of their regimen and assessing their understanding. Because things change in people's lives, monitoring ongoing adherence and intensifying management in periods of low adherence can be particularly useful.[100]

SEXUAL BEHAVIOR

While most new HIV infections are transmitted from people who are unaware of their HIV serostatus, it is estimated that about 45% of new infections occur from persons who know that they are infected.[130] On average, about one-third of people infected with HIV continue to engage in risky sexual

Table 71-1. Recommendations for Addressing Factors That Influence Patients' Adherence to ART

1. Addressing provider factors
- Establish trust
  - talk openly, nonjudgmentally about adherence
  - use a client-centered approach; try to understand things from your patients' perspective
- Teach patients
  - why ART adherence is so important
  - names of their medications
  - reasons for requirements
- Write down
  - names of their medications
  - dosing schedule
  - dosing requirements
  - who to contact for questions

2. Addressing patient factors
- Assess your patient's readiness to adhere before initiation of therapy
  - prior experience taking medications
  - beliefs about ART
  - importance they place on adhering to ART
  - their self-efficacy or confidence that they can adhere to their particular regimen
  - barriers and facilitators they perceive to their taking ART
  - patient rehearsals (e.g., giving jelly beans)
- Screen for and treat conditions that impede adherence
  - depression and other psychiatric illness
  - screen for and treat substance abuse
- Negotiate a concrete treatment plan in relation to daily schedule
- Help the patient develop cues/reminders
- Set and reinforce goals: enhance patients' self-efficacy or confidence by pointing out things they do well

3. Addressing regimen factors
- Involve your patient in the decision-making process regarding which ART regimen to choose
- Assess your patient's preferences for the medication schedule and intake requirements (in relation to food)
- Prepare your patients for potential side effects during initiation
- Anticipate, treat, and manage side effects
- Suggest regimens that are simpler to help patients juggle therapies
- Help the patient develop cues/reminders

4. Addressing social factors
- Recruit family and friends
- Assess need to take medicine in private
- Ask about work, eating, and other patterns
- Ask about weekend routines
- Be familiar with community resources

practices and this proportion may be increasing[131–140]; in some studies, 13–15% have other STDs.[133,141] Pre- and posttest counseling has been shown to be inadequate alone to change risky behavior for HIV-infected persons.[142–146] Recently, a few effective interventions have been identified to help people living with HIV practice safer sex.[142–145,147,148] Because many factors can influence safer sex practices of people living with HIV,[134,136,149–160] successful "prevention with positives" interventions generally use a client-centered, nonjudgmental approach and consider the social context in which sexual relationships take place. Other common elements of successful prevention with positive programs include addressing issues of disclosure, enhancing sexual negotiation /communication skills, taking a holistic view of sexuality,[142–145,147,148,152] and providing transmission risk information (see Chapter 72). Specific guidelines have been developed and published in the *Morbidity and Mortality Weekly Report* (MMWR) to help health professionals incorporate prevention counseling into the routine care of persons living with HIV[161] (see Chapter 72).

END OF LIFE

Increasingly effective pharmacological treatments for HIV disease have resulted in lower mortality rates and less focus on end of life issues than seen in the previous decade.[162] However, HIV disease continues to be a prominent cause of death in adults in the United States; in 2002, HIV disease was one of the top 10 causes of death in adults, with mortality rates of 4.9 per 100,000.[163] Given this, end of life issues are clearly an important area in the psychosocial care of HIV-infected individuals. These issues include discussions between patient and physician about the reality of approaching death and exploration of the patient's preferences in aggressiveness of care, pain management, and location of death. In addition, patient and physician discussions on the creation of an advance directive or "living will" as a way to clearly and legally document preferences, as well as appointment of a health-care proxy through a health-care power of attorney are important issues to be explored.

Despite its importance, studies have demonstrated that a majority of persons with HIV do not discuss end of life care with their physician and do not prepare advance directives or appoint health-care proxies.[164] In addition, physicians and patients may have differing perceptions as to what constitutes an end of life discussion. For example, a study of patient–doctor communication about end of life care found that in 26% of cases patients and physicians disagreed about whether end of life communication had occurred at all.[165]

There are multiple barriers to the discussion of end of life care experienced by both the physician and the patient. Patients may be reluctant to discuss death out of fear or a sense that talking "will bring it (death) closer."[166] Facing death in an era where HIV-infected individuals are living longer may induce feelings of shame and failure or have a particularly tragic quality.[167] For physicians, end of life discussions may be difficult as a result of the characteristics of the patients who are dying. In the post-HAART era, patients who die are often different from those who are doing well. They are often non-adherent, more likely to abuse substances, and more likely to come from a chaotic and deprived environment where HIV is not their primary day-to-day focus. Physician frustration with these patients may make it difficult to establish the trusting relationship needed to discuss end of life issues.[168]

The most extensive and informative study of end of life discussions and preferences in persons with HIV was completed using national survey data from the HCSUS. Wenger and colleagues[169] found that 35% of respondents reported having a conversation with their physicians about end of life care,[169] and that physicians communicated less frequently with black and Latino patients and more frequently with women and people with children. Only 38% of respondents had completed an advance directive; completing an advance directive was more likely if the respondent reported that their physician had discussed the topic with them, if they reported higher social support, and if they were white. When asked about desire for aggressive life-extending care, respondents had widely varied responses; from definitely desiring to extend life irrespective of pain levels (30%) to definitely relieving pain even if this shortened life (32%). These results echo findings from a smaller qualitative study, which found that HIV-infected individuals held widely divergent definitions of a "good death."[170]

Many HIV-infected patients with advanced disease experience pain with high frequency. In studies, physicians have been shown to underestimate and undertreat pain in HIV-infected patients. Reasons for this include doctor's lack of knowledge of pain management, poor communication with patients, and patient concerns regarding addiction to analgesic medication. In addition, higher rates of uncontrolled pain have been noted in minorities and people in poverty.[166] Pain management is an important issue in end of life care and is closely related to decisions around the location of death-wishing to die in the more comfortable setting of home or hospice rather than in hospital. However, access to hospice services is uneven among HIV-infected patients; it has been found that minority and impoverished HIV-infected patients are more likely to have a hospital death and less likely to utilize hospice care than white patients.[166,171] For those patients wishing to die at home, informal home-based care is essential. However, informal supports have been found to be far less frequent for HIV-infected patients than others in hospice, and those family and friends that do provide care seldom receive targeted support and education.[166,172]

Given the findings in the literature, physicians providing end of life care for patients with advanced HIV disease should attend to a number of issues. First and most importantly is the establishment of a trusting relationship with open communication regarding end of life care. Physicians may need to initiate, and in some cases repeatedly broach the subject with patients, discussing care preferences, advance directives, and health-care proxies. In addition, physicians should be aware of racial and cultural differences in openness to initiating these discussions and in care preferences themselves. Careful assessment of pain in advanced HIV disease is important, as is aggressive pain management. Physicians must also consider timely hospice referrals, ensuring that patients can access hospice with time to benefit from services, as well as ensuring that informal helpers involved with end of life care are provided the necessary support and education. Finally, physicians should be aware of their own assumptions and biases around a "good death." Research has demonstrated that patients with HIV disease vary widely in their needs and preferences, and only through honest communication between physician and patient can end of life care needs be defined and implemented.

72 HIV Transmission Prevention in the Context of Care

Samuel W. Dooley and Mark Thrun

INTRODUCTION

HIV and AIDS rates in the United States decreased markedly from the beginning of the epidemic through the early 1990s, due at least in part to adoption of safer sex and drug use practices. However, since that time, new infections have remained stable at approximately 40,000 cases per year, and recent data suggest HIV incidence may be increasing in some subpopulations.[1] From the earliest days of the HIV epidemic, prevention efforts have mainly targeted persons who are at risk for HIV, but not yet infected. However, with the institution of more effective treatment, HIV-positive persons are living longer, and HIV/AIDS prevalence has risen dramatically.[1] Not only are HIV-positive persons living longer and healthier lives; they are also having longer, more active sex lives. Unfortunately, many are engaging in activities that facilitate HIV transmission and are increasingly being diagnosed with sexually transmitted diseases (STDs).[2–10] In addition, rates of primary antiretroviral drug resistance are rising, further suggesting that HIV-infected persons on treatment are engaging in high-risk activities.[11–13] Although prevention efforts should continue for high-risk persons not yet infected, it has become increasingly clear that targeting HIV-positive persons for prevention must be a key strategy for further reducing HIV transmission in this country. Because many HIV-positive persons receive ongoing medical care, health-care settings offer an excellent opportunity to reach them with HIV prevention interventions.

TRENDS IN HIV TRANSMISSION RISK IN THE UNITED STATES

The percentage of men who have sex with men (MSM) who consistently use condoms during sex has decreased over the last several years, and the number reporting multiple sex partners has increased.[14–17] These increases in risk behaviors have been accompanied by increases in the number of MSM recently diagnosed with STDs.[14,18–20] Although STD incidence is considerably less than in the mid-1980s, it is no less concerning: in the 1980s and 1990s, HIV infection rates closely paralleled STD rates; therefore, recent increases in STD rates raise concerns that HIV incidence may also rise.

Numerous surveys have documented relatively high rates of unprotected sex among HIV-infected individuals.[5,7] In fact, rates of unprotected anal sex among gay men in Seattle were higher among those with HIV infection than among those without HIV.[10] In a survey of patients from a Midwest HIV clinic, 22% of 95 HIV-infected participants reported having unprotected anal or vaginal sex or injecting drugs in the past 3 months.[6] Rural populations do not seem to fare any better. In a study of 216 HIV-positive persons from rural sites across the country, 59% of men who reported having anal sex with a man in the last 3 months had never or only rarely used a condom, and 31% of women who had vaginal sex in the last 3 months reported never using a condom.[21] In another study of 277 people living with HIV in rural Wisconsin, only 41% of men and 17% of women reported always using a condom when having sex during the previous 6 months.[22]

HIV-infected individuals in steady relationships with serodiscordant partners do not seem to use condoms more frequently. In a national surveillance project, 21% of 674 HIV-infected MSM who were aware of their infection reported having unprotected anal intercourse with their HIV-negative partner.[23] In a majority (56%) of unprotected intercourse episodes, the HIV-positive partner assumed the insertive role. This pattern is not limited to MSM: in a study of 104 serodiscordant heterosexual couples, 71% of HIV-negative partners reported having had unprotected sex with their infected partner in the last 6 months.[24] Collectively, these data demonstrate that HIV-infected persons are participating in behaviors known to transmit HIV and that this pattern spans gender, race, locale, and sexual preference.

Note: The views and opinions contained in this chapter are those of the authors and should not be interpreted as representing the official policies, either expressed or implied, of the US Centers for Disease Control and Prevention.

Compounding this problem, many new STDs are being diagnosed in HIV-infected persons.[2,10] As early as 1996, in STD clinics that collected information about HIV infection, up to 25% of new gonorrhea cases were coinfected with HIV.[18] More recently, in a report of 57 persons who had new syphilis infections and knew their HIV status, 34 (60%) were coinfected with HIV.[19]

Also of concern are rates of primary antiretroviral drug resistance. Transmission of drug-resistant virus has been observed since the advent of antiretroviral drugs.[25–27] Recent studies, however, suggest that rates of primary antiretroviral drug resistance are high and may be increasing, at least in some parts of the world.[11–13,28–30] Thus, risky behavior among persons in HIV care not only results in transmission of HIV, but also transmission of drug-resistant strains of virus. Given the limited number of antiretroviral drugs currently available, and cross-resistance within classes of agents, the importance of primary resistance cannot be overstated.

Increasing rates of high-risk behavior may be at least partly attributable to the availability of highly active antiretroviral therapy (HAART). In addition to increasing HIV prevalence by increasing survival, HAART allows many persons to have longer, more active sex lives, resulting in more opportunities for high-risk behavior to occur. Furthermore, availability of HAART may decrease the extent to which HIV-positive persons perceive sex as being risky: In one study, persons on HAART were more likely than those not on antiretroviral medications to subsequently be diagnosed with an STD.[31] Since the advent of HAART, there also appears to be a reduction in the perceived risk associated with HIV acquisition among persons not yet infected.[17,32–35]

Ample opportunities for high-risk sex continue to abound. Cross-sectional studies have documented persistence of unprotected sex among frequent visitors to bathhouses, and a significant percentage of MSM practice "bare-backing," the intentional act of having anal intercourse without a condom.[36–38] Also, many persons are seeking sex partners on the Internet.[39–42] In a cross-sectional study of 856 clients from an HIV counseling and testing site, those who found sex partners via the Internet were significantly more likely to report having had an STD, having more total partners, having more partners who were known to be HIV-infected, and having more anal sex.[41]

Knowledge alone does not seem to result in lower rates of risky sex. In a survey of HIV-infected patients, 85% of those reporting unprotected anal or vaginal sex in the last 3 months defined "safe sex" as using a condom.[6] Thus, many HIV-positive persons apparently know how to protect themselves and others, but are not practicing protective behavior.

Several conclusions can be drawn from these and similar studies: (1) a wide spectrum of risk behaviors exists among persons in HIV care, ranging from no transmission risk to ongoing high levels of risk behaviors; (2) risk-taking behaviors appear to span a variety of patient types and care settings; (3) many patients know how to prevent HIV transmission but have difficulty consistently translating this knowledge into safe behavior; and (4) to fully address the epidemic, prevention strategies must include persons already living with HIV.

HIV PREVENTION IN THE HEALTH-CARE SETTING

ROLE OF HEALTH-CARE PROVIDERS IN CHANGING PATIENT BEHAVIOR

Substantial evidence indicates that health-care providers can affect patient behavior in a variety of health areas, including smoking cessation, drug and alcohol dependence, seeking care for mental health issues, and encouraging diet and exercise.[43–51] As many persons living with HIV in the United States have an identified provider, care settings provide an excellent opportunity to promote HIV prevention concepts. Visits to HIV-care providers generally occur several times yearly, affording excellent opportunities for providers to interact with patients, develop trusting relationships, and determine whether or not risk behaviors are occurring. They also provide opportunities to deliver brief prevention messages to all patients and more in-depth risk reduction counseling to patients at risk for transmitting HIV.

Despite the clear need for ongoing prevention efforts with HIV-positive persons, evidence supporting the efficacy of prevention in care, and the convenience of the care setting, many providers have not taken full advantage of the opportunity afforded by clinical visits consequently, incorporating HIV prevention into the care of persons living with HIV has not become standard practice.[33,52] The Gonorrhea Community Action Project undertook a study in 1998 attempting to clarify providers' practices regarding elicitation of sexual histories and barriers to this process.[53] In this study, 208 providers in 121 diverse clinics were interviewed about their opinions and practice patterns regarding elicitation of sexual histories and provision of education and counseling messages to patients. Only 57% of respondents stated that obtaining a sexual history was a routine part of medical care, with even fewer stating they inquire about the patient's prior STD history (34%), sexual orientation (17%), or preferred types of sex (e.g., anal, oral) (15%). When discussing counseling practices, most providers stated that when education was offered, they offered facts about STD transmission (67%), but far fewer offered information on how to prevent an STD (30%), specific STD risk behaviors (17%), or long-term consequences of having an STD (21%).

Other studies of HIV-infected patients and their providers also reveal that providers discuss risk-taking behaviors with their patients infrequently. When 250 HIV-infected men in San Francisco and New York were interviewed about

health-care providers' safer sex messages, 1 in 4 stated their provider had never discussed safe sex with them.[54] Similarly, in a cross-sectional study of 839 diverse patients, including MSM, heterosexuals, women, Latinos, and blacks from six California public HIV clinics, 33% could not recall ever having a discussion about safer sex with their HIV-care provider.[55] From an institutional standpoint, two clinics reached over 90% of their patients with safer sex messages, whereas three clinics reached fewer than 60%. In a third study, among 317 providers asked to rate how frequently they discuss risk reduction related to HIV transmission and substance abuse with their HIV-infected patients, only 37% reported always asking about HIV transmission risk and only 24% asked about substance abuse.[56]

BARRIERS TO PREVENTION IN CARE

There are many possible explanations for low rates of risk assessment and risk-reduction counseling among providers. In one study, the most common barriers to more intensive counseling cited by providers were concerns about the patients' emotional response (42%), lack of time (40%), patients' reluctance to discuss STDs (32%), patients' resistance to changing behavior (31%), and provider discomfort (13%).[53] Another study cited difficulty initiating conversations about STDs, provider discomfort, and a provider-centered rather than patient-centered counseling style.[57] Other studies have identified similar barriers, including perceived lack of time, provider discomfort, concern about inadequate counseling skill, concern about negative patient reaction, and concern that the provider–patient relationship may be harmed by asking questions that could be perceived by patients as judgmental or accusatory.[33,53,58] To facilitate incorporation of prevention into care, these barriers must be addressed.

Given competing demands on clinicians, it is not surprising that the most frequently cited barrier is insufficient time. Yet, most persons in HIV care may have little or no risk for transmitting HIV and do not need in-depth assessment or extensive risk-reduction counseling.[6,23] Indeed, brief risk screening, which need not be a time-consuming process, will reveal that the majority of HIV-infected persons seen in care are not currently having sex or are taking adequate steps to reduce risk and can be classified as having low risk for transmitting HIV to others.[6,23] In fact, when informed of their HIV status, most persons significantly reduce their level of transmission risk when compared to those who have HIV but are unaware of their infection.[59] For these patients, simple acknowledgment of their success in keeping themselves and their partners free from risk may be all the risk discussion need entail.

A minority of persons seen in care will require longer discussion or more in-depth intervention, but even discussions with these patients need not be onerous and time consuming. Patients in HIV care are usually seen multiple times a year and, frequently, significant relationships develop between the patient and the provider; thus, all factors related to risk need not be discussed in one visit. In fact, given the nature of progressive behavior change, it may be advantageous to distribute brief risk discussions over multiple visits. This model is not novel in medicine: patients rarely stop smoking because of a single discussion about the benefits of cessation. Rather, for many patients the conversation must occur repeatedly over many clinic visits. At each interaction, the provider helps the patient move closer to choosing when and how he or she will stop smoking. Brief risk discussions spread over many clinic visits need not take significant time away from other priorities at any single visit.

A second barrier frequently cited by providers is the need to address higher priority issues during clinic visits. Closely related to the barrier of time, this reflects the low priority often placed on prevention in care. Providers usually need to deal with issues of medication compliance, side effects, symptomatic complaints, and discussing laboratory results during the brief medical encounter, often squeezing prevention out of the visit. However, seemingly unrelated risk behaviors—be they HIV transmission risk or poor medication adherence—may be secondary to the same deeper issue. Frequently, different risk behaviors are linked by a common denominator, such as substance abuse or mental health issues, which may need to be addressed before a patient can change his or her behavior. Thus, time spent screening for transmission risk behaviors may uncover important information relevant to other aspects of a patient's care.

Another reason given by providers for not conducting risk discussions more frequently is concern about their own counseling skills and perception that their efforts to change patient behavior are not effective. Frequently, patients are counseled on smoking cessation or excessive alcohol use, only to return with cigarettes in their pocket or intoxicated at subsequent visits. Providers may also feel discomfort talking openly about intimate issues such as sexual behavior. Although counseling is an integral part of medical care, it is a skill in which many clinicians are not well trained. Yet, studies have shown that training can improve clinicians' skill and comfort in counseling about HIV transmission risks, which in turn can lead to patient behavior change.[60,61] Furthermore, these skills can be extended to counseling for other behavioral issues, such as medication adherence. Thus, it is important for providers to become educated about behavior change, specifically behavior change related to reducing patients' risk for transmitting HIV.

Providers often report they do not discuss risk behaviors more often because they fear patients will respond negatively. Considering that risk discussions often focus on intimate behaviors, about which patients may already feel guilty or concerned, patients might feel uncomfortable broaching the topic themselves. Yet many patients would like their providers to initiate these conversations and rely on them doing so.

Finally, it is important to acknowledge that, though reimbursement is occasionally possible through documentation of time spent with the patient, providers are often not directly compensated for risk screening and risk-reduction counseling, be it about HIV transmission, medication compliance, diabetes self-care, or other behavioral issues. Despite lack of direct remuneration, the benefits of risk screening and counseling, from the tangible, such as reduction in STDs, to the intangible, such as improved patient–provider relationships, make these discussions worth the relatively brief amount of time they take.

In spite of these barriers, health-care providers can be effective in helping patients change HIV risk behaviors.[61–63] By delivering general HIV prevention messages to all HIV-positive patients, screening patients for HIV risk behaviors and STDs, providing or facilitating more in-depth assessment, and counseling to patients with identified risk behaviors or STDs, and facilitating partner notification, health-care providers can help patients live healthier, more satisfying lives and reduce their risk for transmitting infection to others.

PREVENTION MESSAGES FOR ALL HIV-POSITIVE PATIENTS

All HIV-positive patients can benefit from brief prevention messages about adopting and maintaining safer behaviors to protect their own health and that of their sex or drug-injection partners. For patients actively engaging in risky behaviors, these messages may be a stimulus to think about changing behaviors; for those trying to reduce risky behaviors, brief prevention messages may provide encouragement; and for patients already practicing safer behaviors, such messages may provide support for maintaining those behaviors.[64,65]

Although some patients are knowledgeable about HIV transmission and prevention, inadequate information and misconceptions about HIV transmission and methods for reducing or eliminating transmission risk remain common.[66–74] Although information alone may be insufficient to produce behavioral change, change is also unlikely to occur in the absence of knowledge.[75] The most reliable strategy for ensuring patients have adequate information is systematically asking all new patients what they know about HIV transmission and prevention, affirming accurate information, correcting misconceptions, and periodically reinforcing this information.

The principal message for all patients is that the most effective way to prevent new HIV infections is to protect noninfected persons from exposure to HIV. For HIV-positive persons, the only certain methods for preventing sexual transmission to noninfected persons are sexual abstinence and limiting sex to partners already infected with HIV, although simply limiting sex to HIV-positive partners does not protect against transmission or acquisition of other STDs or strains of HIV.[76] The only certain means by which HIV-positive persons can prevent injection-related transmission is abstaining from sharing drug-injection paraphernalia (e.g., needles, syringes, cottons, cookers, water). General messages for all patients should include their responsibility for appropriately disclosing HIV serostatus to current and prospective sex and drug-injection partners so that the partners can make informed decisions about their own behaviors.[77–81]

Certain misconceptions about HIV transmission and prevention appear relatively common. For example, many patients believe HIV cannot be transmitted through fellatio; however, the risk for transmission through fellatio, while lower than for other acts, is not zero.[82,83] They may also not appreciate that transmission risk is affected by numerous factors (e.g., coexisting STDs, high viral load) that may substantially increase the risk associated with a specific sexual act.[84–90] Another common misconception is that persons with undetectable viral load cannot transmit infection.[35,73,91–93] While lower viral load is associated with lower risk for transmission, patients with undetectable plasma viral loads may still be able to transmit HIV. In discussing risk with patients, clinicians may identify other locally prevalent misconceptions and knowledge gaps that should be addressed in the general information provided to all patients in that setting.

General messages about preventing HIV transmission should be delivered by patients' primary care providers and can be reinforced by other clinic staff, such as nurses, social workers, medication adherence counselors, case managers, or health educators.[94] These messages can be amplified by designing the clinic or office environment to convey nonjudgmental support for prevention. Information can be provided in multiple formats throughout the clinic; for example, brochures and other educational materials containing prevention messages can be placed at strategic locations; posters encouraging safer sex and drug-use practices and disclosure of HIV serostatus to sex and drug-injection partners can be placed in waiting and examination rooms; and educational videos can be shown in waiting areas. This can set the tone for prevention discussions and prompt patients to begin thinking about their sex and drug-use practices. Providers can then ask patients if they have noticed the posters or read the brochures as a way of introducing risk screening or initiating discussion about risk. Computer-based prevention programs with interactive elements have been used to support prevention messages for other health issues and may be effective for HIV prevention with some patients.[95,96] Condoms should be readily accessible. With other health issues, such as smoking cessation, repeating prevention messages in multiple formats throughout health-care encounters has been found to increase the likelihood that patients will successfully change their behavior.[60,94]

RISK SCREENING

To determine whether a risk discussion is warranted, all patients should be screened for indicators and facilitators of HIV transmission risk. Screening in the clinical setting should include screening for behavioral risk, STDs, and pregnancy.

SCREENING FOR BEHAVIORAL RISK

Behavioral risk screening is a brief process by which providers can identify patients for whom more in-depth diagnostic assessment is needed.[97] Whereas diagnostic assessment is done to confirm and better understand problems in patients already suspected of practicing risky behavior, risk screening is performed in patients who offer no external indication of such behavior. Behavioral risk screening should be repeated periodically, preferably at each routine visit. Questions that do not uncover risk behaviors in one visit may do so in a future visit if a patient's life circumstances or relationships change. In addition, patients may need to develop a certain level of trust with their provider before feeling comfortable disclosing sensitive information.

Behavioral risk screening can be done through various means. Self-administered, written questionnaires, in which patients respond to questions regarding behaviors over recent months, can be completed by patients in waiting rooms, examination rooms, or other clinic areas before they see the provider. This can set the tone for the clinic visit by indicating that prevention is an important part of care. Alternatively, patients can answer questions using computer-assisted screeners that print out results for the provider. Although still in trial stages, some practices have developed software that not only reports HIV risk behavior screening results, but also classifies the patient in terms of readiness to change and gives the provider suggested prevention messages appropriate to the patient's stage of readiness. Screening can also be done face-to-face by medical assistants or nurses while checking patients in for clinic visits. Responses can be recorded, similar to documentation of presenting complaints or reason for the visit, and given to providers before they meet with patients.

For patients with negative screens, providers can deliver simple, brief, supportive messages, reinforcing the patient's safe behaviors. For patients with positive behavioral risk screens, the provider can conduct further assessment by asking more in-depth questions. In either case, these models provide repetition of prevention messages, through both the initial screening and the follow-up discussion with the primary provider, reinforcing the concept of prevention.

Often, the responsibility for behavioral risk screening rests with the primary provider. In this case, providers may incorporate screening into the visit as part of the review of systems or as a separate series of questions. This model exploits the primary provider's role as a behavior change agent and helps emphasize how important the issues addressed by screening questions are to the patient's overall care. This model can also enhance the patient–provider relationship by demonstrating to the patient that the provider is truly concerned about his or her overall well-being.

The effectiveness of behavioral risk screening can be enhanced in several ways. First, providers should help patients understand how behavioral risk screening supports their care—that it is not done to identify "bad" behavior, but rather to better treat the patient. For example, patients engaging in unprotected sex risk not only transmitting HIV to partners, but also acquiring other STDs themselves, which may adversely affect their HIV disease. But this risk will not be identified unless the provider does behavioral risk screening. Screening is also an opportunity to identify and intervene in aspects of patients' lives that may affect care, such as recent change in a relationship, loss of a partner, or homelessness. Providers should convey to the patients that screening questions may help identify significant factors that can impact their health and medical care, and thus are merited in the context of the medical visit.

Second, patients should understand they are not being singled out, but rather that screening questions are routine and asked of all patients. This message can be delivered explicitly at the outset of the interaction, before screening questions are asked, and implicitly by including screening questions naturally in the review of systems.

Third, patients should be assured of confidentiality. Because providers are trained to keep all aspects of medical encounters confidential except under extenuating circumstances, many assume confidentiality need not be discussed explicitly with patients. Yet patients may perceive a difference between questions typically asked in a review of systems, which normally centers on external manifestations of illness, and more personal questions asked in behavioral screening. Patients may worry that their confidentiality will be breached and that disclosure of high-risk behaviors may have negative consequences; thus, providers should explain the conditions of confidentiality to them. Also, patients should be informed if laws or regulations require providers to report specific behaviors to any authority. Patients are more apt to be open in their responses if mutual trust has been established.

Questions used for behavioral risk screening should be sufficiently broad such that most patients with risk behaviors screen positive (Table 72-1). Screening may not identify all patients at risk for transmitting HIV—to do so would require an exhaustive list of questions. Nor is screening intended to reveal the intricacies surrounding, or reasons for, risky behavior. Screening is meant to identify most persons who merit further assessment; it should be brief and to the point. While screening tools for identifying persons at risk for transmitting HIV have been developed, none have been well-validated.

Table 72-1. Key Behavioral Risks to Include in Screening[a]

Behavioral Risks	Strategies to Use for Behavioral Risk Screening	
	Open-Ended Questions	Directed (Close-Ended) Questions
Sexual risk behaviors		
Is the patient sexually active? If so:	"What's been going on with your sex life since your last visit?"	"Since your last appointment, have you had sex with anyone?"
Are any of the patient's sex partners HIV-negative or of unknown HIV status? If so:	"Tell me about the people you've been having sex with."	"Were any of the people you've had sex with HIV-negative, or are you unsure about whether they're infected?"
Does the patient disclose his or her serostatus to sex partners of negative or unknown serostatus?	"How do you feel about letting the people you're having sex with know you're HIV-positive?"	"If you've had sex with someone who's HIV-negative, or you're unsure whether they're infected, did you tell them you're HIV-positive first?"
Does the patient use condoms consistently and correctly for sex with partners of negative or unknown serostatus?	"What have you been doing about using condoms?"	"If you've had sex with someone who's HIV-negative, or you're unsure whether they're infected, did you always use a condom?"
What steps other than using condoms does the patient take to prevent sexual transmission?	"What are your thoughts about giving someone HIV and what else you can do to keep that from happening?"	"Have you been doing anything besides using condoms to keep from passing HIV to your sex partners?"
What is the patient doing to prevent pregnancy?	"What are your thoughts about getting pregnant (or someone you're having sex with getting pregnant)?"	"Are you using birth control pills or anything else to keep from getting pregnant?"
Injection-drug-related risk behaviors		
Is the patient injecting drugs? If so:	"Tell me what you've been doing with drugs since your last visit."	"Since your last appointment, have you shot up any drugs?"
Is the patient sharing injection paraphernalia? If so:	"What are you doing about sharing needles or works?"	"Have you been sharing needles or works with anyone?"
Is the patient sharing paraphernalia with any partners who are HIV negative or of unknown serostatus? If so:	"Tell me about the people you've been sharing needles or works with."	"Were any of the people you've shared needles or works with HIV-negative, or are you unsure about whether they're infected?"
Does the patient disclose his or her serostatus to needle-sharing partners of negative or unknown serostatus?	"How do you feel about letting the people you're sharing needles or works with know you're HIV-positive?"	"If you've shared needles or works with someone who's HIV-negative, or you're unsure whether they're infected, did you tell them you're HIV-positive first?"
Does the patient bleach needles and works before sharing them?	"What have you been doing about cleaning needles and works before sharing them?"	"Are you bleaching the needles and works before you share them?"
What steps other than bleaching needles and works does the patient take to prevent injection-related transmission?	"What are your thoughts about giving someone HIV and what else you can do to keep that from happening?"	"If you've shared with someone who's HIV-negative, or you're unsure whether they're infected, did you use the needles and works after they used them?"

[a]These are the key issues of concern in screening patients for behavioral risks. A positive response in any of these areas should prompt the provider to follow up with more in-depth discussion and assessment.

SCREENING FOR STDs AND PREGNANCY

STDs facilitate both transmission and acquisition of HIV.[85,98–102] Epidemiological studies have found significantly increased risk for HIV transmission from HIV-infected persons with genital ulcer disease and inflammatory STDs that cause urethral or cervical discharge. Treatment of STDs has been found to reduce viral load in genital secretions, which presumably reduces risk for HIV transmission. Therefore, screening should assess for symptoms, signs, and laboratory evidence of STDs. Symptoms such as urethral, vaginal, or anal discharge; ulcerative lesions; testicular, epididymal, lower abdominal and pelvic, anal, or pharyngeal pain; and rash should be elicited. Presence of any symptoms or signs suggestive of STDs should prompt immediate diagnostic evaluation and appropriate treatment.

Because STDs are frequently asymptomatic, routine laboratory screening for STDs should be undertaken.[103,104] Sexually active HIV-positive men and women should be screened for syphilis annually, and regular screening for gonorrhea and chlamydial infection should be strongly considered.[76,103–105] Women should be screened for trichomoniasis annually. Screening should be done at anatomic sites corresponding to an individual's risk behaviors; thus, a man who is the receptive partner for oral sex with other men should be screened for pharyngeal disease.[104] Similarly, a female who has anal sex with her male partner should be screened for rectal disease. The interval between screenings should be reduced for persons at increased risk for STDs (e.g., those reporting multiple sex partners).

Because HIV-positive persons are living longer, healthier lives, unintended pregnancy may become more likely, and many have begun to contemplate intentional pregnancy.[106–108] Therefore, patients should be asked about symptoms and signs of pregnancy, use of contraception to prevent unintentional pregnancy, and consideration of future planned pregnancy. Positive screens should prompt referral to providers with expertise in reproductive health for HIV-positive persons.

TAILORED APPROACHES FOR PATIENTS AT RISK FOR TRANSMITTING HIV INFECTION

Patients at risk for transmitting HIV infection to others, or acquiring new STDs, other HIV variants, or blood-borne infections themselves, require further assessment and intervention. This includes patients identified through risk screening as currently or recently engaging in risky sexual or drug-injection practices; patients who have a current or recent STD; patients interested in pregnancy or at risk for unintentional pregnancy; patients with other characteristics associated with increased likelihood of risky behaviors (e.g., alcohol or other noninjection drug use, dissolution of a long-term relationship), even if their risk screen does not indicate current risky behavior; and patients who express concern to clinicians or other clinic staff. Whether the problem is relatively simple (e.g., inadequate knowledge) or complex (e.g., multiple risky behaviors with complicating comorbidities and significant barriers to change), a similar approach can be used: (1) do a risk assessment to guide the clinical approach to the patient; (2) provide brief, clinician-delivered, educational, and motivational counseling; (3) address comorbidities and contextual factors, directly or through referral; (4) provide referrals for more intensive or supplemental prevention services, if appropriate; and (5) follow up with the patient at subsequent visits.

TARGETED RISK ASSESSMENT AND CLINICAL APPROACH

Assessment of behaviors

Risk assessment is a natural extension of the briefer risk screen. A primary goal of risk assessment is to better understand behaviors patients are engaging in that may affect their risk for transmitting HIV, or for transmitting or acquiring other STDs or blood-borne infections, and may be amenable to change (Table 72-2).[105] This allows providers to focus behavioral change efforts on very specific behaviors relevant to individual patients. Risk assessment should include in-depth inquiry into patients' sexual and drug-injection behaviors. For women of child-bearing age, assessment should include whether they might be pregnant, are interested in becoming pregnant, or are not specifically considering pregnancy but are sexually active and not using reliable contraception, because risk for perinatal HIV transmission is high without appropriate intervention.[106–108] For HIV-positive men with serodiscordant female partners, issues of current or future planned or unplanned pregnancy may be equally important. For both sexual and drug-injection behaviors, inquiry should specifically address both main and casual partners, because behaviors and barriers often differ significantly with the two.[109–117]

Risk assessment is usually accomplished through face-to-face, personalized discussion with the patient. Open-ended questions that avoid simple "yes" or "no" responses may encourage patients to discuss personal risks and associated circumstances, often revealing unsuspected information that might be missed with a more directive style. On the other hand, using directed questions in a more structured style is a relatively rapid method of ensuring that important issues are not overlooked. Neither approach alone has been clearly demonstrated to be more effective, and many clinicians naturally combine the two styles. As with behavioral risk screening, face-to-face discussion can be preceded or supplemented

Table 72-2. Behaviors to Consider in Assessing Risk for HIV Transmission

Sexual Behaviors	Drug-Injection Behaviors
General	Use of new or sterilized paraphernalia
Number of partners	Sharing of paraphernalia
Number or frequency of sex episodes	Other risky injection practices (e.g., "backloading")
HIV serostatus of partner(s)	
Serostatus disclosure to current or prospective partners	Number of paraphernalia-sharing partners
Types of sex acts	Number or frequency of paraphernalia-sharing episodes
Condom use	HIV serostatus of paraphernalia-sharing partners
Other methods used to reduce sexual transmission risk	Serostatus disclosure to current or pro-prospective partners
Barriers to abstinence or condom use	Sterilization of shared paraphernalia
For women of child-bearing age	
Current pregnancy	Distributive vs. receptive sharing
Interest in future pregnancy	Other methods used to reduce injection-related risk
Use of reliable contraception to prevent unintended pregnancy	Barriers to ceasing injection drug use or adopting safer injection practices

with self-administered written or computer-, audio-, or video-assisted questionnaires, which have been found more effective for eliciting self-reports of risky behaviors than face-to-face interview in some situations.[112,118–121]

Assessment of comorbidities and contextual factors

A second goal of risk assessment is to identify comorbidities and contextual factors that may affect patients' HIV transmission risk behaviors. For example, risky behaviors have been found in some studies to be associated with mental illness (e.g., depression), substance abuse and addiction, sexual compulsivity, and history of childhood sexual abuse.[113,117,122–130] Contextual factors, such as relationship issues (e.g., desire for intimacy, fear of rejection, power imbalance, partner conflict or violence; lack of emotional or social support; negative or positive social or cultural influences (e.g., stigma); living situation (e.g., homelessness); or financial insecurity (e.g., need to exchange sex for drugs, money, or other support)[131–144] may also facilitate risky behavior or pose barriers to behavior change.

The circumstances under which risky behaviors occur (e.g., use of alcohol or other drugs before or during sex) may affect judgment and decision-making. Environmental factors may be important facilitators of risky behavior; for example, increased sexual risk has been associated with bathhouses and sex clubs, public sex environments, circuit parties, and "cruising" on the Internet.[36,145–153] Risk assessment should consider these factors.

Assessment of underlying factors

A third goal of risk assessment is to identify psychosocial factors that may underlie a given patient's risk behaviors. Several theories of behavior and behavior change have been applied to understanding HIV risk-taking behavior and collectively have identified a relatively discrete number of factors that appear to directly or indirectly determine a person's behavior: (1) information; (2) skills and abilities (behavioral or physical); (3) external constraints; (4) self-efficacy (belief in one's ability to do something, even under difficult circumstances); (5) attitude (derived from one's beliefs about the consequences of performing a behavior and one's evaluation of whether those consequences have a net positive or negative value); and (6) subjective norms (derived from one's beliefs about what certain important others, such as family, friends, spouse, or partner, think about the behavior and one's motivation to comply with those referent others). A given behavior may be driven by any one or combination of these factors in one individual, but may be driven by very different factors in another individual. Accordingly, the appropriate intervention for these two individuals will likely differ substantially.

Clinical approach

On the basis of risk assessment, clinicians can decide how best to help patients reduce or eliminate risky behaviors or adopt protective behaviors. For patients with multiple risk behaviors, this includes considering which behavior the patient is most ready to change, as stage of change may substantially affect outcome.[64,65] Targeting behaviors the patient is not ready to consider changing will likely lead to failure, and to frustration for both the patient and clinician.[154] Other factors to consider include which of the patient's risk behaviors and underlying issues can be addressed by the clinician during regular medical visits and which might require referral (Table 72-3), as well as the level or intensity of intervention and support needed.[94]

The clinician's role in behavioral risk reduction may vary substantially, depending on time available; clinician skill, interest, and personal bias; type and complexity of contributing factors; availability of other on-site resources (e.g., prevention counselor); and availability and accessibility of off-site resources (e.g., community-based organizations [CBOs] providing HIV risk reduction services). Clinicians can increase the likelihood that patients will receive appropriate prevention-related services by deciding in advance what role(s) they are able and willing to perform and identifying resources to meet other needs. Primary care providers, who have established ongoing relationships with patients, can be particularly influential in patients' efforts to change behavior; therefore, even when referral is chosen as the primary approach, they should remain

Table 72-3. Examples of Which Issues to Address and Which may Require Referral

Issues That Can Often be Addressed by Clinicians and Clinic Support Staff	Issues That Might Require Referral
Lack of knowledge about HIV transmission risks	Need for extensive HIV prevention intervention
Misconceptions about risk of specific types of sexual and drug-use practices	Excessive use of alcohol or recreational drug use
Misconceptions about viral load and HIV transmission	Drug addiction, including injection drug use
How to disclose HIV-seropositive status to a sex partner, family member, or friend	Depression, anger, guilt, fear, or other mental health needs
Importance of using condoms and not exchanging body fluids with partners	Need for social support
Ways to reduce number of sex or drug partners	Sexual compulsivity
Ways to keep condoms accessible	Sexual or physical abuse (victim or perpetrator)
Ways to remember to use comdoms	Desire to have children
How to persuade partners to use condoms	Contraceptive counseling
Ways to obtain support (e.g., financial, emotional) from family, friends, and lovers	Housing or transportation needs
Ways to disinfect injection paraphernalia	Nutritional needs
Ways to obtain clean needles	Financial emergencies
Ways to avoid sharing paraphernalia	Child custody, parole, or other legal matters
Ways to deal with mild psychological distress stemming from situational circumstances	Insurance coverage

actively involved in the risk-reduction process and follow up with patients at subsequent visits.

CLINICIAN-DELIVERED RISK-REDUCTION COUNSELING

Counseling approaches

Clinicians can choose from a variety of counseling approaches, none of which has been clearly demonstrated to be consistently more effective than another. The manner in which a clinician interacts with patients may be at least as important as the specific approach used: counselors providing the same treatment in the same setting may have substantially different outcomes.[155] Several counseling approaches applicable in clinical settings have been described, of which client-centered HIV prevention counseling and various adaptations of motivational interviewing are examples.

Client-centered HIV prevention counseling. Client-centered HIV prevention counseling is an interactive approach that has usually, but not always, been delivered in the context of HIV testing.[156] In the testing context, this approach has traditionally included two steps, one prior to testing and one after testing. In the first session, the counselor and client (1) conduct a personalized risk assessment to help the client identify behaviors that put him or her at risk; (2) explore strategies for reducing the client's personal risk; and (3) identify a single, explicit step for doing so, to which the client commits. In the second session, test results are provided and the counselor and client follow up on the client's progress with the previously-identified risk-reduction step and identify additional, specific, client-appropriate risk reduction steps. Client-centered HIV prevention counseling in the testing context has been studied among HIV-negative, heterosexual, STD clinic patients in a large, randomized, controlled trial with two intervention arms in which clients received either two or four counseling sessions.[63] Compared with clients receiving only didactic information, both intervention arms were associated with significantly higher self-reported condom use and lower rates of subsequent STDs.

Although client-centered HIV prevention counseling was tested among HIV-negative clients, a similar approach may be adaptable for use with HIV-positive patients receiving ongoing care. Important elements recognized by many specialists include (1) in-depth risk assessment; (2) exploration of the details and context of risk behaviors; (3) exploration of successes and challenges associated with previous risk-reduction efforts; (4) support for positive steps already taken; (5) clarification of critical misconceptions; and (6) negotiation of a specific, achievable behavior-change step.[156] Client-centered HIV prevention counseling sessions typically take at least 20 minutes; therefore, they may be more appropriate for delivery by special counselors than for incorporation into a multipurpose medical visit.

Adaptations of motivational interviewing. Many interventions found effective for reducing HIV risk behaviors are probably most appropriate for patients already planning or beginning to take action. Less work has been done on interventions for persons who are not yet aware of, or thinking of changing, a risk behavior, and therefore not seeking help to do so. In encounters with patients seeking care for other problems, clinicians are often uniquely positioned to help patients recognize their problem behaviors and begin thinking about changing them. Motivational counseling approaches aim to increase patients' intrinsic motivation to change and may be particularly appropriate in such circumstances.[157,158]

One such approach is motivational interviewing, which incorporates four general principles: (1) expressing empathy by using reflective listening and acknowledging that ambivalence is normal; (2) developing discrepancy between current behavior and important personal values; (3) "rolling with resistance" by avoiding confrontation and allowing the client to be the primary resource for finding solutions; and (4) supporting self-efficacy by allowing the client to take responsibility for choosing and carrying out change, and by recognizing that the counselor's belief in the client's ability (or inability) to change may have a powerful effect on outcome.[159,160]

The principles and spirit of motivational interviewing seem very applicable to use in medical care settings, but motivational interviewing may involve numerous sessions of considerable duration. Clinicians providing primary medical care to HIV-positive persons frequently see patients repeatedly over time; however, time available for counseling in each visit is generally limited, especially for patients with complex medical problems. Consequently, use of motivational interviewing by clinicians in medical care settings requires adaptation into a briefer format.[158,161,162] An example of such an adaptation is a 5- to 10-minute smoking cessation intervention in which clinicians do a quick assessment of a patient's readiness to change and self-efficacy for doing so, then build the patient's motivation and confidence by encouraging him or her to identify arguments for change or practical steps for accomplishing change.[163] The patient then establishes a specific target for change (if ready to do so), and follow-up plans are made. This model uses an open-ended, client-centered approach, but also has a directive, algorithmic format well-suited to a medical counseling style.[158]

Special considerations. Patients may be at very different stages in terms of their readiness to change risky behaviors.[65] Some may not be aware of their risk or, if aware, not thinking of changing (*pre-contemplation* stage); others may be considering taking steps to reduce or eliminate the risky behavior in the future (*contemplation* stage); and others may have made a commitment to action and taken some small steps toward changing the behavior, but not yet reached the point of

effective action (*preparation* stage). Some may be actively changing their behavior or environment to reduce or eliminate the problem at hand (*action* stage) and others may have already changed their behavior and be working to prevent relapse (*maintenance* stage).

While these stages are often described as a linear sequence, progression through them is not necessarily linear.[65] People typically recycle through various stages multiple times, and relapse is the rule rather than the exception; however, many who relapse are able to recover and proceed in a positive direction. Also, people may be in different stages with different behaviors: a person may not be contemplating changing one risk behavior, but may be successfully maintaining another risk-reduction behavior. Clinicians should try to match prevention messages to the patient's stage of change with respect to the targeted behavior (Figs. 72-1 and 72-2).[164]

Changes in behavior usually occur over time, often in small steps that may not be readily apparent.[65] If success is measured only by immediate, sustained change in the target behavior, it may be difficult to recognize incremental successes that are priming the patient for effective change. This may lead the clinician to question whether brief prevention messages during clinic visits are effective. However, the cumulative impact of brief discussions at each visit can, over time, help patients achieve and maintain safer behaviors.[165] The short-term objective for each interaction is to help the patient advance through the stages of change, ultimately leading to the desired behavior change.

Different patients may respond to different types of messages. For example, some patients may be more motivated by

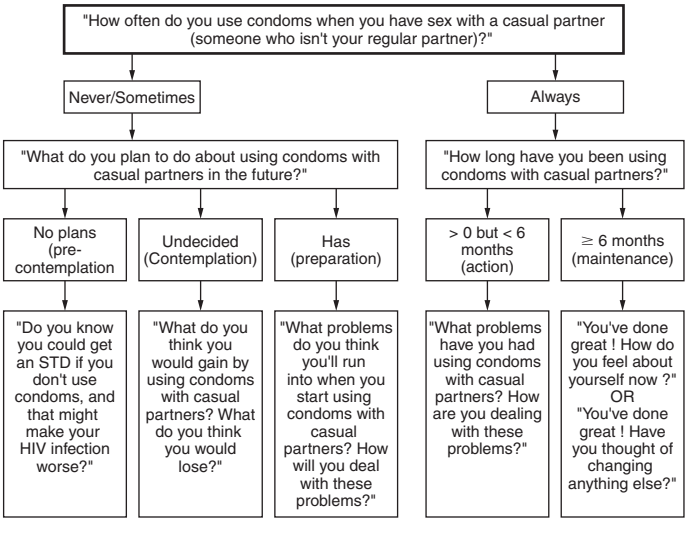

FIGURE 72-1. Example of tailoring messages regarding condom use for sexually-active, HIV-infected persons. (Adapted from Centers for Disease Control and Prevention. Incorporating HIV prevention into the medical care of persons living with HIV: Recommendations of CDC, the Health Resources and Services Administration, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America. *MMWR* 2003; 52(No. RR-12): 1–25.)

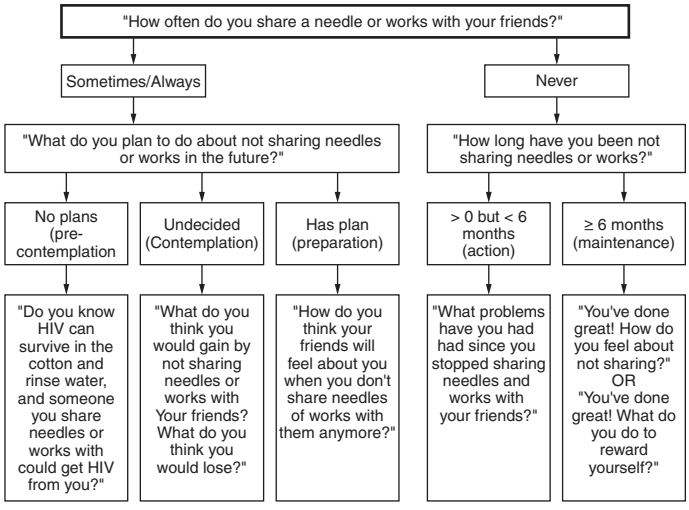

FIGURE 72-2. Example of tailoring messages regarding needle-sharing for HIV-infected persons who continue to inject drugs. (Adapted from Centers for Disease Control and Prevention. Incorporating HIV prevention into the medical care of persons living with HIV: Recommendations of CDC, the Health Resources and Services Administration, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America. *MMWR* 2003; 52(No. RR-12): 1–25.)

altruistic feelings about protecting partners, while others may be more motivated by a sense of self-protection. Patients may also respond differently to whether a message is framed positively ("gain frame") or negatively ("loss frame").[61,166–168] Similarly, counseling may need to be adjusted to a patient's culture, language, sex, sexual orientation, age, or developmental level.[154] Attention to these differences may help the clinician tailor messages to specific patients more effectively.

Success may be more likely if psychosocial factors underlying a patient's behavior are considered, comorbidities and contextual factors are identified, and the clinician's approach is tailored accordingly. Success is also more likely if the target is a very specific behavior (e.g., always use a condom for vaginal sex with casual partners), rather than a broad behavioral goal (e.g., avoid transmitting HIV) or a behavioral category (e.g., practice safer sex; use condoms).[154] Finally, opportunities for developing skills (e.g., correctly putting on a condom, negotiating condom use with a partner) may increase the likelihood of success.[169]

Specific patient strategies for eliminating or reducing transmission risk

A primary objective of clinician-delivered counseling is helping patients identify specific ways to eliminate or reduce HIV transmission risk. The ultimate goal being to eliminate transmission risk, but this may be difficult to achieve in one step. However, HIV-positive persons and their partners can choose among a range of strategies that can at least reduce their risk until elimination of risk is possible. Combining two or more risk reduction strategies may have a multiplicative effect; for example, in a serodiscordant relationship between two men, the risk for the HIV-negative partner becoming infected

during a single sexual act decreases 100-fold if he chooses insertive oral sex rather than receptive anal sex, and another 20-fold by using a condom, yielding an overall 2000-fold reduction in risk.[170]

At a minimum, HIV-positive persons have a responsibility to disclose their serostatus to prospective sex and drug-injection partners, who can then make informed choices about the level of risk they are willing to take.[77–81] HIV-positive individuals have used a variety of strategies to reduce transmission risk. In counseling patients, clinicians should be prepared to discuss these strategies and their potential roles in reducing or eliminating HIV transmission risk.

Sexual risk

Abstinence and partner choice. The only certain methods HIV-positive individuals can use for preventing sexual transmission of HIV to noninfected persons are sexual abstinence and limiting sex to partners known to be infected with HIV already. Limiting sex to already infected partners depends on knowing a partner's infection status with certainty, but people often make assumptions about one another's serostatus based on unreliable criteria, such as age, appearance, or willingness to engage in risky sexual behaviors (e.g., "If he is willing to have risky sex, he must be already infected").[71,171,172] Also, restricting sex to HIV-positive partners does not protect against transmission or acquisition of other STDs unless condoms of latex, polyurethane, or other synthetic materials are used consistently and correctly.[76] Nevertheless, short of abstinence, limiting sex to already-infected partners is the most effective strategy for reducing new HIV infections.[170]

Use of condoms. If serodiscordant partners who are aware of one another's HIV serostatus mutually decide to engage in sex, they should, at a minimum, use condoms made of latex, polyurethane, or other synthetic materials. Meta-analyses of published literature indicate that latex male condoms, used consistently and correctly, substantially reduce, but do not eliminate, risk for HIV transmission.[173,174] A recent National Institutes of Health workshop panel concluded that "always" use of latex male condoms significantly reduces risk for HIV in men and women.[175] One analysis, synthesizing data from a variety of existing studies, concluded that using a condom can provide approximately a 20-fold reduction in the per-act risk of transmission of HIV.[170]

Women unable to become pregnant because of elective sterilization or other medical causes may not use condoms because they are not concerned about unintended conception. These women should be counseled regarding the need to use condoms to reduce risk for transmission of HIV and other STDs.

Choice of sex act and strategic positioning. Numerous studies examining the risk for HIV transmission associated with different sex acts suggest that some sexual behaviors have substantially lower average per-act risk than others; however, studies of transmission risk are subject to many limitations that make determination of absolute risk difficult.[176–190] Also, risk for HIV transmission is affected by a wide variety of factors, such as stage of infection, viral load, antiretroviral therapy (ART), coexisting STDs, male circumcision, menstruation, and patterns of partnering.[85–88,102,115,136,177,179,181–184,191–196] This leads to considerable heterogeneity in per-act risk, with some infections occurring after only a few contacts.[188,189] Thus, risk estimates based on models assuming constant infectivity are unreliable, and estimates of the average per-act risk associated with specific acts could be misleading when applied to a specific person or situation.[176,178,181,186,190] Nevertheless, these studies do allow reasonable estimates of the relative risks of various sex acts, and it is reasonable to conclude that substituting a higher-risk behavior with a relatively lower-risk behavior might further reduce HIV transmission risk when added to condom use (Table 72-4).[170] For example, all other factors being equal, transmission risk is likely reduced, though not eliminated, by choosing oral instead of anal sex, or by the HIV-positive partner assuming the receptive rather than the insertive role, a practice sometimes referred to as "strategic positioning."[197]

Number of sex episodes and number of partners. Although the average absolute per-act risk for HIV transmission is relatively low compared with other STDs, risk for transmission obviously increases as the number of sex episodes increases. The effect of accumulating risk can be considerable; for example, if the per-contact infectivity of unprotected anal intercourse is 0.01, the cumulative risk after 10 episodes is about 10%.[174] Thus, in theory, cumulative transmission risk can be decreased by reducing the number of sex episodes. Interestingly, although some epidemiologic studies of transmission have found a positive association between number of contacts with a given partner and transmission, others have not found such an association.[179–181,188,198] Finally, reducing the number of different partners decreases the number of persons who might become infected, thereby reducing overall transmission in the community, at least in the short term.[199]

STD treatment. Because STDs facilitate HIV transmission and because treatment of STDs appears to reduce this risk.[200] HIV-positive persons can reduce their risk for transmitting HIV by taking steps to prevent other STDs and immediately seeking diagnosis and treatment if they develop STD symptoms.

Withdrawal before ejaculation. Withdrawal before ejaculation has been cited as a strategy used by some MSM and heterosexuals attempting to reduce transmission risk.[72,115,197,201,202] In one longitudinal study of transmission among heterosexual partners, no seroconversions were observed among women in couples that reported nearly always practicing withdrawal, while couples that reported practicing withdrawal in about half of sexual episodes had rate of 7.2% and those that reported rarely or never practicing withdrawal had a

Table 72-4. Estimated Per-Act Relative Risk for a Person Without Human Immunodeficiency Virus Infection Acquiring HIV Infection, Based on Sex Act[a] and Condom Use[b]

Risk Factor	Relative Risk for a Person Without HIV Infection of Acquiring HIV Infection
Sex act	
Insertive fellatio[c]	1
Receptive fellatio[c]	2
Insertive vaginal sex[d]	13
Receptive vaginal sex[d]	20
Insertive anal sex[d]	13
Receptive anal sex[d]	100
Condom use	
Yes[e]	1
No[e]	20

Note: This table quantifies the relative risk for HIV transmission in a way that can help compare the effects of a person's choices of sex act and condom use. It is presented from the point of view of a person without HIV infection and should be used to educate the HIV-infected patient regarding risks for transmission to partners who are not HIV infected or have unknown HIV serostatus. These risks are estimated from available data. Risks can vary depending on several factors, including presence of STDs in either partner and the HIV-infected partner's viral load. In addition, the relative frequency of performance of higher- and lower-risk sex acts will affect risk for transmission.

[a] Data regarding risk for transmission from sharing drug injection equipment are too limited to be included in this table.

Incorporating HIV prevention into the medical care of persons living with HIV: Recommendations of CDC, the Health Resources and Services Administration, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America. *MMWR* 2003; 52(No. RR–12): 1–25.

32.4% rate.[177] However, in a study of seroconverters in a cohort of gay men, believing withdrawal to be safe with regard to HIV transmission was an independent predictor of seroconversion.[201] Although there are hypothetical reasons that withdrawal may be partially protective (e.g., smaller viral dose), there are substantial reasons for withdrawal to fail (e.g., presence of HIV in pre-ejaculatory fluid, failure to withdraw before ejaculation). Adequate data are not available to address this issue or to base estimates of any absolute or relative risk reduction this practice might afford.

Injection-related risk

Substance abuse treatment and abstinence from injection drug use. For injection-related transmission, the only certain means by which HIV-positive persons can prevent transmission to noninfected persons, and avoid other injection-related health risks themselves, is abstaining from injection drug use. However, most injection drug users (IDUs) are not able to sustain long-term abstinence from injecting without substance abuse treatment.[203] There is substantial evidence to support the effectiveness of substance abuse treatment, especially methadone and buprenorphine maintenance, for reducing injection drug use, and several studies have found associations between enrollment in substance abuse treatment and reductions in HIV transmission risk behaviors.[204–211] Thus, for IDUs, referral and entry into substance abuse treatment programs is a key component of HIV prevention.

Refraining from sharing injection paraphernalia. For IDUs unable or unwilling to stop injecting drugs, risk for transmitting HIV to others can be eliminated by not sharing injection equipment (i.e., needles, syringes, cottons, cookers, water).[212] This is best achieved by once-only use of new, sterile syringes, although this approach does not eliminate other health risks to HIV-positive IDUs (e.g., soft tissue abscesses, endocarditis) unless strict aseptic technique is used.[213] Also, this is often not feasible due to difficulty obtaining new, unused syringes, and needles; thus, for IDUs who continue to inject, facilitating access to sterile syringes, needles, and other injection paraphernalia is a critical component of a comprehensive program for reducing transmission of HIV and other bloodborne infections.[214–217] Cohort, case-control, and observational studies indicate that access to sterile syringes through syringe exchange programs (SEPs) reduces HIV transmission risk behavior and HIV seroconversion among IDUs and increases rates of entry into substance abuse treatment programs.[111,218–225] Access to new, sterile syringes can also be increased through physician prescribing and pharmacy programs, although significant barriers to these approaches exist.[226–232] If new, sterile equipment is not available, transmission risk can still be eliminated through use of sterilized equipment used by one person without sharing.

Partner choice. In spite of substantial evidence that substance abuse treatment and SEPs have reduced HIV transmission among IDUs, and that sharing of needles, syringes, and other injection paraphernalia has decreased in at least some areas, sharing remains common among both HIV-negative and

HIV-positive IDUs, especially among close friends, spouses, and sexual partners.[115,116,138,233–240] One recent survey found very high rates of paraphernalia sharing among young suburban and urban IDUs in the Chicago area.[239] Clinicians should continuously work to help patients eliminate this behavior; however, until this goal can be achieved, HIV-positive persons can prevent transmission to noninfected persons by limiting sharing of injection equipment to HIV-positive partners, analogous to sexual serosorting. This strategy clearly has major limitations, including mistaken assumptions about another person's serostatus, and the fact that restricting sharing to HIV-positive partners does not protect against transmission or acquisition of other serious blood-borne infections (e.g., hepatitis B, hepatitis C).[71,171,172,241]

Cleaning injection equipment and other injection practices. If serodiscordant persons who are aware of one another's HIV serostatus mutually decide to share injection paraphernalia, they should, at a minimum, disinfect syringes and all other paraphernalia by boiling or flushing with bleach, and avoid other risky injection practices, such as "backloading" (a process in which drugs are drawn up in one syringe to measure and transfer a portion to a second syringe).[242] This may reduce risk for HIV transmission and has also been associated with lower rates of HCV seroconversion; however, reliable disinfection is difficult to achieve and patients need to understand that this practice is not as safe as using a new, sterile syringe.[213,243–245]

Published studies of injection practices frequently focus on "receptive" needle sharing (i.e., using the syringe or needle after another person has used it), which, for HIV-negative persons, presents the greatest risk.[111,236,239] However, for the HIV-positive person—analogous to the relative risks for receptive and insertive sexual practices—the greatest risk for transmitting HIV is with distributive sharing (i.e., using the needle or other paraphernalia before another person). Thus, if shared paraphernalia are being disinfected between use by two serodiscordant persons, risk for HIV transmission from the infected partner to the noninfected partner may be further reduced if the HIV-positive partner uses the shared equipment after the partner of negative or unknown HIV serostatus.

Number of injection episodes and number of partners. Cumulative transmission risk might be reduced by limiting the number of injection episodes. Also, decreasing the number of injection partners will reduce the number of persons who might become infected. However, as with sexual transmission, these strategies can only be viewed as additions to, not substitutes for, other precautions, such as disinfecting paraphernalia between injectors. Furthermore, from the perspective of the patient's overall health, the most desirable strategy is cessation of injecting or, failing that, once-only use of sterile paraphernalia.

Sexual behaviors. Risky sexual behaviors are also prevalent among IDUs, and a substantial proportion of IDU-related transmission results from unsafe sexual behaviors.[111,138,236,246,247] While focusing on safer drug-use behaviors for IDUs, it is important to also screen for and address unsafe sexual behaviors.[248]

Perinatal transmission risk

Pregnancy prevention. The most reliable approach for preventing perinatal transmission is preventing pregnancy. Sexually active HIV-positive women who are not interested in becoming pregnant should use reliable contraception. It has been noted that some women mistakenly believe hormonal contraception is protective against HIV.[66,67] Women need to understand that, in addition to using reliable contraception to avoid vertical transmission, they must also use condoms to reduce risk for horizontal sexual transmission of HIV or other STDs.[249]

Antiretroviral therapy. It is beyond the scope of this chapter to address perinatal transmission in detail; however for HIV-positive women who are pregnant or desire to become pregnant, risk for perinatal transmission can be substantially reduced by appropriate use of ART during pregnancy and at the time of delivery, delivery by elective cesarean section before onset of labor, administration of ART to infants during the first 6 weeks of life, and avoidance of breast feeding.[250] HIV-positive women who are considering pregnancy, or are already pregnant, should be referred to a reproductive health specialist with expertise in management of HIV-positive patients, as should HIV-negative women who are considering pregnancy with HIV-positive partners.[106–108]

Serostatus disclosure as a risk reduction strategy. HIV prevention efforts often emphasize encouraging HIV-positive persons to disclose their serostatus to current and prospective sex and drug-injection partners.[80,251,252] This practice is based on the assumption that, if serostatus is disclosed, safer behavior will necessarily follow. However, the relationship between disclosure and safer behavior is complex: available studies have generally failed to demonstrate a consistent relationship between serostatus disclosure and safer sex.[171,253–255] In fact, there are substantial disincentives to serostatus disclosure, including stigma, violence from partners and others, and fear of retribution.[134,256–261] In a national probability sample of HIV-infected persons receiving care, 42% of gay or bisexual men, 19% of heterosexual men, and 17% of all women reported any sex without disclosure, and across all groups, 13% of serodiscordant partnerships involved unprotected anal or vaginal sex without disclosure.[80] Nevertheless, partners cannot make fully informed decisions without knowledge of one another's serostatus, and HIV-positive persons need to recognize their responsibility for disclosure of serostatus to current and prospective partners.[77–81]

Adherence to antiretroviral therapy. ART should be initiated only for appropriate clinical indications—not to reduce risk for transmission. Also, since HIV can be detected in the semen, rectal secretions, female genital secretions, and pharynx of HIV-positive patients with undetectable plasma viral loads, clinicians and patients should assume that patients who are on therapy and have undetectable plasma HIV levels can still transmit HIV.[262–266] However, high viral load is a major risk factor for HIV transmission: among untreated patients, risk for heterosexual HIV transmission has been shown to increase approximately 2.5-fold for each 10-fold increase in plasma viral load.[194] Therefore, ART that lowers viral load might reduce risk for sex- and injection-related transmission, as has been demonstrated with perinatal transmission and indirectly suggested for sexual transmission.[267–273] However, consistent reduction of viral load depends on high levels of adherence to antiretroviral regimens, thus efforts at promoting adherence, such as adherence counseling, not only provide substantial clinical benefit to individual patients, but may also reduce the likelihood that the patient will transmit HIV to others.[274] As important as the potential benefit may be, the degree to which ART actually reduces sexual transmission is not known, and this strategy should be considered a supplement to other methods (e.g., condom use), rather than a substitute.

Post-exposure prophylaxis. A discussion of potential HIV prevention strategies would not be complete without addressing nonoccupational postexposure prophylaxis (nPEP) for sexual, injection-drug-related, and other nonoccupational exposures to HIV. In the present context, this is most relevant because of the potential disinhibitory effect the availability of nPEP could have on HIV risk behaviors among both HIV-negative and HIV-positive individuals. Data from animal studies, postnatal prophylaxis in perinatal clinical trials, studies of postexposure prophylaxis for occupational exposures, and observational studies, taken together, suggest that nPEP might reduce risk for infection after nonoccupational exposure in some cases.[270,275–285] On the basis of these data, the United States Public Health Service currently recommends prompt (i.e., within ≤72 hours after exposure) initiation of PEP in carefully defined circumstances of nonoccupational exposure]; however, nPEP is unlikely to prevent infection in all cases, and effectiveness may be hindered by medication side effects, toxicity, or poor adherence to the regimen.[286–292] Therefore, potential availability of nPEP should not be viewed as an acceptable routine strategy for HIV prevention.

■ SUPPLEMENTARY PREVENTION SERVICES

On-site interventions

Some patients require more intensive intervention than most clinicians can provide in the limited time available during regular clinical visits. Also, it has been demonstrated with HIV and other health behaviors (e.g., smoking) that successful behavior change is correlated with the intensity of intervention, and provision of other longer or more intensive interventions in the clinic setting can build upon the primary provider's efforts.[94,169] These interventions are usually beyond what most clinicians have time or expertise to provide, but could be delivered by existing staff (e.g., nurses, social workers, adherence counselors) who receive additional training, or by counselors or other staff hired specifically for that purpose. It may be possible to develop collaborations with CBOs or other agencies, which may be able to provide staff to deliver these interventions on-site at the clinic.

Several multisession interventions in community service organization settings have been found effective at reducing sexual risk behaviors among HIV-positive persons (Table 72-5).[144,293–295] These interventions resemble one another in that each addresses multiple life issues faced by HIV-positive persons, rather than focusing only on transmission risk reduction. Addressing contextual issues may increase the likelihood that patients will be able to make and sustain behavioral changes, in addition to making the intervention more appealing to patients who might otherwise not choose to attend.[169] Three of these interventions use a group format, which gives patients trying to change their behavior an opportunity to interact with, and derive support from, other persons who are struggling with similar issues.[144,293,294] Although these interventions were not tested in health-care settings, they might be suitable for adaptation to the clinical setting if the intervention's core elements are preserved.[296–299]

Prevention case management (PCM) is an intervention that provides ongoing, intensive, one-on-one, client-centered HIV prevention counseling, as well as assistance accessing other services to address issues that affect patients' health and ability to change HIV-related risk-taking behavior.[300] PCM has been widely used with HIV-negative persons at risk for becoming infected and less often with HIV-positive persons; however, its efficacy has not been demonstrated in any rigorously controlled studies. Also, this intervention may be less relevant for many HIV-positive persons, who might benefit from intensive, one-on-one prevention counseling, but already have access to other services through case managers.

For HIV-negative or HIV-status-unknown persons, numerous interventions delivered in health-care settings have been found effective for reducing HIV risk behaviors (Table 72-5).[62,63,301–321] Some of these interventions may be adaptable for use with HIV-positive persons in health-care settings; however, HIV-positive persons face numerous issues that may affect their ability to adopt and maintain safer behaviors, and interventions designed for HIV-negative or HIV-status-unknown persons may not adequately address these issues.

Adapted from Herbst JH, Collins CB, Jr, Kay LS, Crepaz N, Lyles CM, and the HIV/AIDS Prevention Research Synthesis Team. Evidence-based HIV behavioral interventions in the United States identified through a systematic Review, 2000–2004. Poster presented at the 2005 HIV Prevention Leadership Summit, San Francisco, CA, July 31–August 3, 2005.

Off-site interventions

Patients who need additional support can often be referred to services in the community. Several community-based interventions for HIV-positive persons have already been listed and are available in some areas.[144,293,295] For HIV-negative or HIV-status-unknown persons, a number of community-based interventions have been found effective (Table 72-5).[322–336] These interventions may be available through health departments and CBOs in some areas; however, their adaptability for use with HIV-positive persons has not been demonstrated.

For patients who inject illicit drugs, referral to substance abuse treatment (or for those unable or unwilling to cease injection, access to sterile injection paraphernalia) is critical. In addition to the obvious risks of injection drug use, increased risk behavior and HIV transmission, especially among MSM, have been associated with use, before and during sex, of amyl nitrites ("poppers"), alcohol, stimulant drugs (e.g., powder and crack cocaine, methamphetamines), and "party" or "club" drugs, such as Ecstasy (3,4-methylene-dioxy-methamphetamine).[112,149,150,337–340] Individuals using drugs of these types should also be referred for substance abuse treatment.

REFERRAL PROCESSES

Referrals for psychosocial and supplemental prevention services can be critical in addressing prevention needs of HIV-positive persons, but successful referral can be difficult to accomplish. Factors important for successful referral include patients' willingness and ability to accept and complete referrals; patients' self-identified priorities; appropriateness of providers to whom patients are referred, in terms of the patients' culture, language, sex, sexual orientation, age, and developmental level; availability of transportation or child care; compatibility with patients' work schedules; and cost, accessibility, and convenience of services.[156] Successful referral may be more likely if these issues are addressed and if clinicians or other staff help patients schedule appointments and arrange for transportation, child care, and other needs. Knowing about available resources is important: referral guides that list local HIV prevention and supportive social services may be available from health department HIV/AIDS programs (Table 72-6). Clinicians often do not have time or capacity to make all referrals. Case managers or other staff, such as counselors or educators, can help make referrals and help patients complete referrals successfully.

TRAINING

Training can substantially increase the likelihood that behavioral risk reduction interventions will be successful. In a study of providers' efficacy with smoking cessation counseling, 35 resident physicians were randomized to either a training program in which they learned to provide counseling that matched smokers' motivation to quit or a didactic session on management of dyslipidemia.[341] At 12 months, patients cared for by the trained providers were significantly more likely to be abstinent from smoking (13% vs. 5% in the control group).

Providers can also improve their skill at assessing HIV transmission risk. In a study of HIV risk assessment and counseling, 961 providers were randomized to (1) a control group, (2) a group that was sent educational materials via the mail, or (3) a group that was sent the same educational materials and received an office visit from an instructor.[342] A significantly greater percentage of providers in the third

Incorporating HIV prevention into the medical care of persons living with HIV: Recommendations of CDC, the Health Resources and Services Administration, the National Institutes of Health, and the HIV Medicine Association of the Infectious Diseases Society of America. *MMWR* 2003;52(No. RR-12):1–25.

group (mailings plus instructor visit) reported increasing their assessment of patients' sexual histories (76%) than those in the control group (43%) or the group receiving the mailing alone (56%). A similar pattern was noted in the providers self-reported counseling practices. To assess possible reporting bias, equal numbers of providers in each group were evaluated using a standardized patient. Providers in the third group (mailings plus instructor visit) were significantly more likely to counsel the patient on using condoms (99%) than those in the control group (89%) or the mailing alone group (88%). In a study of an intervention to improve providers' HIV and STD assessment and counseling skills, patients seen by providers who received the intervention were significantly more likely than patients seen by providers who did not receive the intervention to have had the provider discuss HIV or STDs (OR 1.6), ask about sexual risk behaviors (OR 1.7), discuss HIV prevention in general (OR 2.4), and discuss personal risk reduction (OR 2.6).[60] These results persisted in follow-up at 38 weeks. Thus, providers appear able to significantly improve their ability to assess and counsel for a variety of risk behaviors, including HIV transmission.

The Partnership for Health (PFH) intervention trial included a 4-hour training for all medical care providers and other staff in participating clinics, with a briefer, reinforcing session provided 1 month after the intervention was initiated.[61] The Options Project intervention trial also involves clinician training, including a 4-hour training session on the protocol and motivational interviewing techniques, a 2-hour workshop on sexual and injection drug use risk behaviors and risk-reduction strategies, and a one-on-one booster session.[343] Training on incorporating HIV prevention into care is also being developed by CDC for general use. Training on many of the other interventions listed in this chapter is available and would be appropriate for designated staff in clinics planning to implement any of these interventions on-site. Information about training can be obtained through CDC-funded STD/HIV prevention training centers (PTCs) (http://depts.washington.edu/nnptc), HRSA-funded AIDS education and training centers (AETCs) (http://www.aids-ed.org), and the Diffusing Effective Behavioral Interventions project (DEBI) (http://www.effectiveinterventions.org).

PARTNER SERVICES AND RELATED ACTIVITIES

PARTNER COUNSELING AND REFERRAL SERVICES

Several studies in geographically diverse areas have found that partner counseling and referral services (PCRS), including partner notification, can be effective for identifying HIV-positive individuals not aware of their infection.[344–350] PCRS provides a valuable service to HIV-positive persons and their sex and drug-injection partners by (a) helping HIV-positive persons ensure that partners are aware of their risk and able to take steps to avoid becoming infected or, if already infected, to avoid infecting others and (b) helping infected partners gain earlier access to medical evaluation, treatment, prevention, and other services.[351,352] Unfortunately, a recent survey of health departments in 22 jurisdictions with HIV reporting found that only 32% of persons with newly-diagnosed HIV infection were interviewed for PCRS.[353] Several studies have found that the majority of HIV counselors and health-care providers support PCRS; however, studies also indicate that many counselors and health-care providers do not refer their HIV-positive patients for PCRS.[354–359]

PCRS includes three main elements: (1) eliciting information from HIV-positive persons about sex and drug-injection partners, (2) notifying partners of their risk, and (3) helping them access HIV counseling and testing services.

PCRS is *voluntary*, in that infected persons decide which partners to identify to the interviewer, and *confidential*, in that partners are not told who reported their name or when the reported exposure occurred, nor is information about partners relayed back to the original patient.[352] In surveys of persons seeking HIV testing, HIV-positive persons, and notified partners, the majority of respondents have supported partner notification.[360–362]

PCRS is most often conducted by health departments, but clinicians can play a key role by referring their HIV-positive patients to the health department for these services. In areas where laws and regulations permit, some clinicians choose to play a more active role by performing parts of PCRS, such as interviewing HIV-positive patients to elicit partner information. If so, this is best done in collaboration with the appropriate health department. Effective partner elicitation takes time and requires considerable motivational skill, which is best learned by specific training. Some studies have indicated patients are more likely to name close partners than more casual partners; clinicians eliciting partner information from patients should be sure to include casual partners, as well.[363–365] Also, while reports regarding PCRS often focus on sex partners, it is important to include drug injection paraphernalia-sharing partners.[351] Because HIV is a chronic condition and new exposures may occur after the original interview, clinicians should periodically inquire whether patients have new sex or drug-injection partners who may benefit from PCRS.

Once partners are identified, they can be notified of their risk by a health department specialist (provider-referral), by the patient (patient- or client-referral), or by the patient and a health-care provider, together (dual-referral).[352] Most health departments offer another option, in which clients have a few days to notify partners; but, if partners have not reported for counseling and testing by an agreed-upon date, they are contacted by a health department specialist (contract-referral).[352] One randomized, controlled trial comparing notification strategies found that notification by health department specialists is substantially more effective than the notification by infected persons.[349]

Some clinicians may wish to take on the responsibility for informing partners. As with partner elicitation, notification requires considerable time, skill, and training. One observational study suggested health department specialists were more successful than physicians in interviewing patients and locating partners.[366] Some reports of partner violence after notification suggest a need for caution[367,368]; however, other studies have found that patients report few adverse reactions.[362,364,367,369,370] When violence does occur, it is often in relationships where violence is already a problem.[370] This emphasizes the importance of assessing potential for violence and, when identified, obtaining expert consultation before proceeding with notification.[352]

SOCIAL NETWORKS

Available evidence suggests the majority of new HIV infections in the United States originate from HIV-positive persons not yet aware of their infection and that most persons greatly reduce risky behaviors upon learning they are infected. Therefore, identifying HIV-positive persons and linking them to medical, prevention, and other services as soon as possible after they become infected is critical to HIV prevention. This is primarily an issue for public health practitioners; however, with relatively little effort, clinicians and medical facilities where HIV-positive persons receive care can help address this problem and reduce transmission in the communities they serve. By asking HIV-positive patients to identify persons in their social networks who may be at risk for HIV and accompany or refer them to HIV counseling and testing sites, clinicians can help reach high-risk persons who might not be reached through other strategies. This strategy has been used in a Los Angeles HIV clinic, a Chicago CBO, and, more recently, in demonstration projects located in seven cities across the country.[369–371] Although more evaluation is needed before this strategy is widely implemented, initial results are promising.

INCORPORATING PREVENTION INTO CARE

SPECIFIC MODELS OF HIV PREVENTION IN CLINICAL SETTINGS

Comprehensive HIV prevention programs for persons living with HIV should be multifaceted. Relatively few models for incorporating theory-based HIV prevention interventions for HIV-positive persons into clinical settings have been described. Three examples are PFH, the Options Project, and the Healthy Living Project (HLP).

PARTNERSHIP FOR HEALTH

PFH is a theory-based, individual-level intervention that is intended to reduce sexual HIV transmission risk behaviors among HIV-positive men and women and is delivered to patients by their regular HIV care providers during routine care visits. This intervention, which requires approximately 3–5 minutes at each visit, emphasizes the importance of a patient–provider team approach to help patients stay healthy and involves discussing safer-sex goals and risk-reduction behaviors; providing general prevention messages to all patients; and delivering brief, tailored prevention messages to high-risk patients. The messages focus on self-protection, partner protection, and serostatus disclosure. A randomized, controlled trial of PFH targeting HIV-positive patients in six California HIV clinics demonstrated that "loss-framed" messages emphasizing positive outcomes that may be missed or

negative outcomes that may occur if the patient engages in unsafe sexual behavior (e.g., "If you don't use condoms, you may get another STD or a strain of HIV that's resistant to the medications you're taking.") were associated with significant reductions in unprotected anal or vaginal intercourse among patients with high baseline risk.[61]

Patients in PFH are given informational brochures and flyers at the reception desk, and posters emphasizing the importance of patient–provider teamwork and providing prevention messages are displayed in waiting and examination rooms. Clinicians use the brochures, informational flyers, and posters to facilitate counseling. Clinician and patient identify specific behavioral goals for the patient, and the provider gives the patient referrals to other appropriate services. At subsequent visits, providers follow up on patients' progress toward their behavioral goals, provide additional counseling, and reinforce patients' healthful behaviors.

THE OPTIONS PROJECT

The Options Project is an individual-level, clinician-delivered intervention aimed at reducing risky sexual and drug-use behaviors among HIV–positive patients. This intervention, based on the Information–Motivation–Behavioral Skills model, involves providing critical information, increasing patients' motivation to change risky behaviors, and developing their behavioral skills for risk reduction (e.g., negotiating condom use).[75] In the Options Project, clinician and patient together assess the patient's sexual and drug-use behaviors, then (1) select a specific behavior to target for change; (2) identify conditions under which the behavior occurs; (3) evaluate the patient's readiness to change the behavior; (4) rate the patient's confidence for changing the behavior; and (5) identify specific strategies for changing the behavior. They negotiate a specific behavior change plan and the clinician gives the patient a written "prescription" for the plan. This intervention requires about 5–10 minutes incorporated into each routine clinic visit and has been found acceptable to providers and patients and feasible in practice; behavioral outcome data are not yet available.

HEALTHY LIVING PROJECT

Healthy Living Project (HLP) is an ongoing randomized trial of a theory-based intervention involving women, heterosexual men, IDUs, and MSM in four urban US sites.[112,372] This multidimensional intervention is intended for use in clinical care settings and addresses three key issues faced by persons living with HIV: stress and coping, transmission risk behavior, and medication adherence. In the intervention trial, HLP is delivered in fifteen 90-minute structured sessions by trained, ethnically diverse facilitators with a wide range of backgrounds, including community-based service providers, social workers, counselors, and doctoral-level therapists. Behavioral outcome data are not yet available from HLP. Because each session is 90-minute long, this intervention is not appropriate for delivery by clinical care providers during routine medical visits; however, it could be delivered by other staff in clinical settings.

CONCLUSION

Stagnating rates of new HIV infection in the United States require a shift in thinking about HIV prevention to a model that includes both persons at risk for acquiring HIV and individuals already infected and at risk for transmitting the disease to others. Medical providers have a unique opportunity to screen HIV-infected patients for risk behaviors, initiate discussions about these risk behaviors, and offer prevention messages and counseling in an ongoing manner in HIV care settings.

Providers should deliver brief prevention messages to all patients. They should use brief screening to open the door to broader discussion about each patient's risk for transmitting HIV and to identify persons for whom more in-depth assessment of risk is necessary. For those with identified behavioral risks, they should conduct further assessment of the risk, including the patient's knowledge about the level of risk posed by the behavior, circumstances surrounding the behavior, and attitudes the patient has about the behavior.

Risk discussions and counseling should be tailored to individual patients. A plan of action should be discussed with the patient and documented in the medical record in order to facilitate follow-up at subsequent visits. Referrals should be made if needed to help facilitate behavior change. All HIV-positive persons should receive PCRS at the time of diagnosis, and subsequently if there are indications that transmission may have occurred to additional partners. This is usually best done by consulting health department staff trained in PCRS.

Structural approaches, such as development of risk screening tools for use by allproviders in the clinic or identification of a prevention counselor may facilitate more rapid adoption of prevention in care by providers and greater acceptance from patients. Resources are available for providers and staff who do not feel they have the comfort or skill level to undertake risk discussions.

ACKNOWLEDGMENTS

The authors would like to thank Mary Spink Neumann, Ph.D., and Charles Collins, Ph.D, for their thoughtful comments on the manuscript.

73 Antiviral Therapy of Human Immunodeficiency Virus Infection

Joseph J. Eron, Jr. and Martin S. Hirsch

Human immunodeficiency virus type 1 (HIV-1) causes a chronic viral illness that results in a gradual destruction in the host immune system manifested primarily as a loss in $CD4^+$ lymphocytes and the occurrence of infections, malignancies, and other signs of immune impairment. The interaction between the infected host and HIV-1 is a complex interplay between viral replication and immune containment. Reduction, and perhaps eventually elimination, of HIV-1 replication is the goal of therapy. Antiretroviral therapy has been shown to improve the clinical course of HIV-1 disease and to result in prolongation of survival. In developed countries, the mortality from HIV-1 disease has dropped dramatically and opportunistic diseases and hospitalizations have decreased substantially. Over the last several years, antiretroviral therapy has become even more effective,[1] and the complex nature of highly active antiretroviral therapy (HAART) has been markedly simplified. The availability of a pill that allows three of the most commonly used antiretroviral agents to be coformulated in a single once daily dose emphasizes this point.

BRIEF OVERVIEW OF THE HIV-1 REPLICATION CYCLE

A retrovirus in the lentivirus subfamily, HIV-1 contains two single-stranded RNA molecules as its genome. The replication cycle of this virus requires attachment to the host-cell membrane (usually by an interaction between the viral envelope glycoprotein gp120 and the host cell $CD4^+$ receptor), engagement of a second receptor on the cell surface, CCR-5 or CXR-4, fusion and entry into cell cytoplasm, followed by uncoating of the viral capsid, reverse transcription of HIV-1 RNA to proviral DNA, which is then transported to the cell nucleus. Once in the nucleus, the double-stranded DNA is integrated into the host chromosome by the HIV-1 integrase enzyme. The provirus can then remain latent and unexpressed, or RNA transcripts can be produced that allow replication to continue. The transcription of full-length HIV-1 RNA depends on interactions between host transcriptional factors (NFKB and others) and the products of viral regulatory genes (e.g., *tat* and *rev*). Once full-length transcripts are formed, they are transported out of the nucleus and translated into proteins. These proteins are processed by proteolytic cleavage, and the envelope protein is glycosylated. The gag, pol, and protease proteins are produced as one polyprotein that requires cleavage by the HIV-1 protease enzyme for appropriate assembly of the HIV-1 nucleocapsid. During the final assembly of the nucleocapsid around the genomic RNA molecules, the viral particle buds from the cell to complete the life cycle.

Any process in the viral replication cycle that can be inhibited in a relatively specific manner is a potential target for antiretroviral therapy. Each of the three steps in HIV entry, attachment of gp120 to $CD4^+$, binding to the chemokine coreceptor, and fusion with the cell membrane, has been successfully inhibited and an antiretroviral effect has been demonstrated.[2–8] Enfuvirtide (ENF, T-20), which inhibits HIV fusion, is used frequently in highly treatment experienced patients.[9,10]

Viral uncoating may be another step at which HIV can be inhibited. The human protein cyclophilin A appears to be used by some HIV-1 isolates in this step prior to reverse transcription, perhaps to prevent cellular degradation of the viral capsid and RNA.[11] Cyclosporine has been shown to inhibit HIV-1 in vitro perhaps by binding to cyclophilin A and interfering with capsid binding. Small molecule analogs of cyclosporine have now been developed that do not bind to calcinerin (avoiding the immunosuppressive effects of cyclosporine), but retain cyclophilin A binding and have anti-HIV effects in vitro.[12]

Reverse transcription has been one of the most successful targets for antiretroviral therapy. Reverse transcriptase inhibitors can be divided into two categories. One class of compounds are analogs to endogenous nucleosides and require phosphorylation to have activity against HIV-1. These are nucleoside and nucleotide analogs, and include zidovudine (ZDV), didanosine (ddI), stavudine (d4T), lamivudine (3TC), abacavir (ABC), tenofovir (TDF), and

emtricitabine (FTC). These compounds when phosphorylated act as competitive inhibitors and chain terminators of the elongating DNA strand produced during reverse transcription. The second class of compounds, collectively known as nonnucleoside reverse transcriptase inhibitors (NNRTI), interacts with the reverse transcriptase in a noncompetitive manner, does not require phosphorylation for activity, and has extremely potent inhibitory activity in vitro. Nevirapine (NVP), delavirdine (DLV), and efavirenz (EFV) are the currently available NNRTI, though additional agents are in development.

The movement of double-stranded HIV-1 DNA from the cellular cytoplasm to the nucleus may require specific nucleotide-binding sequences that interact with a transporter protein. The intracellular steroid receptor may be such a transporter protein, and interaction with the HIV regulatory protein *vpr* may be important in transport.[13] Mifepristone, which is an inhibitor of the steroid receptor, has been shown to have anti-HIV effects in vitro;[14] however, an in vivo proof of principle study showed no activity.[15]

HIV-1 encodes an integrase that allows incorporation of HIV-1 DNA into the host chromosomal DNA. This step is essential for the completion of the replication life cycle of HIV-1. In addition, integration and latent infection of resting $CD4^+$ memory T cells is a substantial barrier for the eradication of HIV-1 infection.[16] HIV-1 encodes three enzymes and while antagonists of RT and protease have been highly successful, inhibitors of HIV integrase that have favorable pharmacokinetics and acceptable preclinical safety profiles have been very difficult to develop. Inhibitors of HIV-1 integrase that rely on inhibition of the strand transfer step of HIV DNA integration into the cellular DNA have now reached clinical trials.[17–20]

Control of transcription and translation of HIV-1 is a complex process that is influenced by cellular proteins and HIV-1 proteins such as *tat* and *rev*. Inhibitors of these HIV-1 proteins offer the promise of high specificity, although, as yet, no compounds with clinical activity have emerged.[21]

HIV-1 proteins require posttranslational modification prior to their incorporation into viable HIV-1 particles. The *gag* structural proteins and enzymes are translated as one polyprotein that must be cleaved into smaller protein components by the HIV-1 protease. Inhibitors of the HIV-1 protease have demonstrated potent in vivo activity[22] that has translated into antiretroviral and clinical efficacy when given in the context of combination therapy.[23–25] More recently, maturation of the gag proteins has also been inhibited in vitro and in vivo by blocking a specific gag cleavage site.[26] Later steps in the HIV-1 life cycle also may be amenable to inhibition, such as viral particle assembly or modification of viral glycoproteins by cellular glycosidases. As further information is gained about the replication cycle of HIV-1, newer or more precise targets for inhibition may be revealed.

HIV DISEASE PATHOGENESIS

Before discussing the clinical evaluation and application of antiviral therapies for HIV-1 infection, it is important to consider disease pathogenesis as it applies to therapeutic strategies. The duration of time from initial infection to onset of the defining symptoms and signs of AIDS can vary greatly, ranging from less than 3 years in some individuals to potentially as long as several decades.

PRIMARY INFECTION

Following exposure to HIV-1, most newly infected individuals experience a high initial level of HIV-1 replication, as measured by plasma HIV-1 RNA, and large numbers of T lymphocytes are infected, especially, it appears, in gut lymphatic tissue.[27–32] HIV-1 rapidly disseminates to multiple body compartments including the gastrointestinal tract, central nervous system, and genital tract.[33] The level of viral replication and viremia is such that many persons experience an acute illness with lymphadenopathy and fever, sometimes accompanied by rash, pharyngitis, or aseptic meningitis.[34] Viral replication results in destruction of host $CD4^+$ cells, with detectable decreases in $CD4^+$ lymphocyte counts in the peripheral blood, occasionally declining to levels seen in later stages of the disease. These individuals may rarely become clinically immunocompromised, such that minor infections (thrush, herpes zoster, vaginal candidiasis) or AIDS-defining opportunistic infections (candida esophagitis, pneumocystis pneumonia) occur during this period. Whether therapeutic intervention during this early period of intense viral replication has either short- or long-term benefit remains an open question.[35] An early study of individuals with acute or early infection treated with only zidovudine was suggestive of a modest effect.[36] Whether other, more potent therapies would result in more profound improvements in $CD4^+$ cell counts and in a delay in the appearance of HIV-1 disease-related symptoms or mortality remains unknown, although recent nonrandomized trials suggest a modest benefit.[37,38] Several small, noncomparative studies suggested that the early therapy preserved HIV-specific immune function, though these benefits seem to wane over time.[39–42]

LYMPH NODE DISSEMINATION AND DISEASE PROGRESSION

Following the primary infection period when HIV-1 is disseminated systemically, the host produces a cellular and humoral immune response that coincides with a marked decrease in HIV-1 replication, as measured by HIV-1 RNA levels in plasma.[43] During this period of clinical quiescence, infected individuals may be completely asymptomatic or have only minor signs or symptoms. This period can vary markedly in length,

though the median time from infection to first AIDS-defining symptom is 8–10 years.[44,45] In most infected individuals, HIV-1 disease progression, involving progressive lymph node destruction and CD4$^+$ cell count decline and ongoing replication of HIV-1, continues to occur during this period. The pace of disease progression is dictated by many factors, both viral and host. HIV RNA levels in plasma vary from individual to individual. Steady state or set point levels are established approximately 6 months following infection and are relatively stable over time. Plasma HIV RNA level correlates with CD4$^+$ cell decline and disease progression in the absence of therapy.[46–49] However, plasma HIV RNA level explains only a small fraction of CD4$^+$ cell decline[50] and after more than two decades of study, the exact mechanisms of CD4$^+$ cell loss are still debated. It is likely multifactorial and includes direct viral killing, apoptosis, and chronic immune activation.[51] A more profound impact of the initial unchecked acute infection on CD4$^+$ cell depletion has recently been postulated.[31,32,52] Host factors also appear to affect disease progression.[53–56]

In most individuals, HIV-1 infection is a very dynamic process, even during the clinically quiescent period, with marked virus replication and CD4$^+$ cell turnover.[57–59] These observations have important implications for the use of antiretroviral therapy. Given the underlying mutation rate of the HIV-1 reverse transcriptase enzyme of approximately one error per 10,000 base pairs,[60] and the replication rate of HIV-1 in the human host, the likelihood of resistance development during suboptimal treatment is high.[61] This likelihood is especially high if single-drug therapies or even combination-drug therapies with only incomplete, modest suppression of HIV-1 replication are used. Hence an overriding goal of antiretroviral therapy is to suppress HIV-1 replication to the greatest extent possible. For most who are infected with HIV-1 disease, progression occurs in the absence of therapy. As peripheral blood CD4$^+$ cell counts diminish, clinical signs and symptoms (e.g., fevers, malaise, weight loss) develop and opportunistic infections or neoplasms may occur.

HIV-1 DISEASE MARKERS: ASSESSING DISEASE PROGRESSION AND ANTIRETROVIRAL THERAPY RESPONSE

Disease staging is important for estimating the prognosis for an individual, as well as for epidemiologic and natural history studies. Disease staging is also an integral part of the clinical study of antiretroviral therapy and the use of antiretroviral and prophylactic therapies in clinical practice. The evaluation of antiretroviral agents relies on the effect of the agent or agents being studied on markers of HIV-1 disease, in particular, plasma HIV-1 RNA levels. Clinical endpoints such as disease progression and death have been used to validate the predictive capacity of surrogate markers both in the absence and presence of antiretroviral therapy and are now rarely used as the primary endpoints in clinical trials of antiretroviral therapy. CD4$^+$ cell counts and HIV RNA levels are used commonly in clinical practice to help clinicians estimate an individual's risk of disease progression prior to and after initiation of the antiretroviral therapy and to monitor the response to the antiretroviral treatment.

CD4$^+$ CELL COUNT

CD4$^+$ cell counts have been used as indicators of disease stage in HIV-1-infected patients for over 20 years. CD4$^+$ cell counts are predictors of disease progression independent of disease duration or clinical symptoms, and can be used in conjunction with clinical symptoms to provide staging for an individual patient or a population of patients, and to compare groups of patients across different studies. The likelihood of specific opportunistic infections is related to the CD4$^+$ cell count.[62,63] In the context of HIV disease progression or response to therapy, the CD4$^+$ count or a change in the CD4$^+$ cell count explains only a fraction of the clinical progression rates or clinical responses to antiretroviral therapy.[64] Including clinical symptoms in the algorithms improves the prognostic value of these observations.[44]

HIV-1 RNA LEVELS IN PLASMA

The ability to measure HIV-1 RNA levels in plasma led to fundamental changes in the understanding of HIV-1 pathogenesis, the prognostication of disease progression, the evaluation of antiretroviral agents, and the understanding of clinical progression in the context of antiretroviral treatment. Many groups have shown that measurement of HIV RNA levels, in conjunction with, and independent of, CD4$^+$ cell counts, markedly improves the ability to predict the rate of disease progression.[47–49,65,66] Individuals with low CD4$^+$ cell counts and high HIV RNA levels progress to AIDS events or death most rapidly, whereas those with low HIV RNA levels and high CD4$^+$ cell counts progress more slowly (Fig. 73-1). Measurement of plasma HIV-1 RNA levels in conjunction with potent antiretroviral therapy led to our understanding of the HIV-1 disease as a very dynamic state, with large numbers of virions produced daily and rapid turnover of infected, activated CD4$^+$ cells with half-lives of the order of 1 to 2 days.[57–59] Taken together, HIV-1 RNA level and CD4$^+$ cell count provide important prognostic information of the likelihood of progression to AIDS in the absence of antiretroviral therapy (Fig. 73-1).

OTHER MARKERS

The combination of HIV RNA levels in plasma and CD4$^+$ cell counts does not explain all the variability in disease progression that occurs from individual to individual. Additional viral factors are also likely have some role. The discovery of

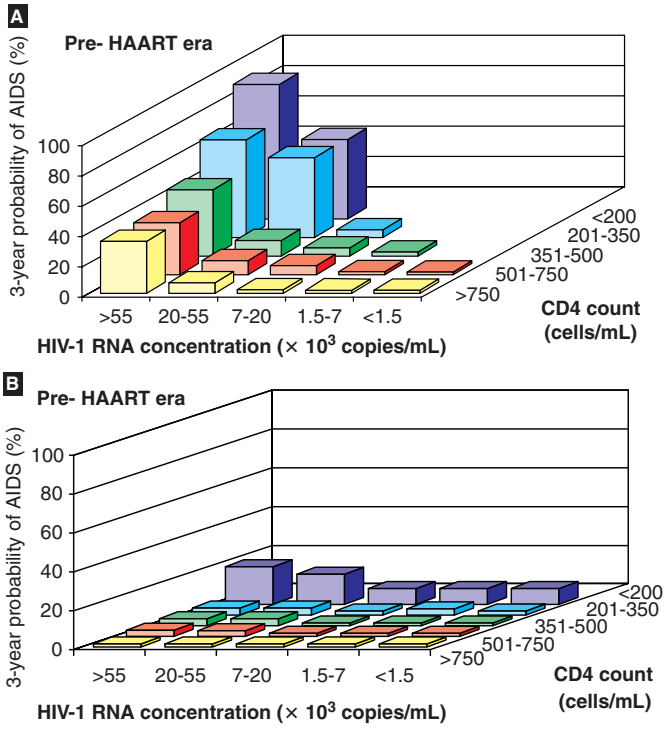

FIGURE 73-1 A. Three-year probability of AIDS by CD4⁺ cell count and HIV-1 RNA level prior to the highly active antiretroviral therapy (HAART) era and in the setting of HAART.[67] **B.** This figure represents a replication of the MACS analysis using data from the ART-Cohort Collaboration based on 5152 drug-naive homosexual men who started HAART between 1996 and 2000 and is a Kaplan Meier estimate of the 3-year probability of AIDS by baseline CD4⁺ cell hour and HIV-1 RNA level prior to antiretroviral therapy in the HAART era.[67]

the second cellular receptors that must be engaged after the virus binds to the CD4⁺ molecule furthered our understanding of HIV pathogenesis.[68,69] Two chemokine receptors, CCR5 and CXCR4, are the major chemokine receptors demonstrated to be used by the virus. HIV-1 variants may use CCR5 or CXCR4 exclusively or they may be dual tropic. An HIV-1-infected individual may have variants that use only CCR5 (R5 variants), primarily CXCR4 (X4 variants), or a mixture of variants, some using CCR5 some CXCR4, and some that can use both receptors.[70] Rarely, infected individuals have only X4 variants. Initially, most individuals are infected with R5-using variants. In some patients, X4 variants or variants that can use both CCR5 and CXCR4 emerge and this emergence is often associated with more rapid CD4⁺ cell decline and clinical progression,[71,72] suggesting that X4 and dual tropic variants may be more pathogenic. In addition, virions lacking a key regulatory gene (*nef*) have been associated with slower disease progression.[73,74] Host genetic factors may play a role in HIV disease progression independent of HIV RNA and CD4⁺ cell counts. Individuals lacking functional CCR5 receptors are much less likely to be infected with HIV-1,[75] and those who are heterozygous for the gene encoding the dysfunctional receptor, generally have HIV disease progress more slowly.[76,77] Evaluation of multiple genetic factors may improve the prognostic value of these assessments. An analysis that included multiple CCR5 genetic polymorphisms and the number of CCR5 ligand genes demonstrated that these host genetic factors are a very strong predictor of HIV disease progression.[55] An individual's HLA type also influences HIV disease progression.[53,78] Simple factors such as an individual's age at the time of infection influence HIV disease progression, likely due in part to decreasing thymic function with increasing age.[79–81] The sex of the individual or HIV-1 acquisition risk category does not appear to affect the rate of disease progression but gender may affect the relationship between CD4⁺ cell count and HIV RNA values and prognosis in the absence of antiretroviral therapy.[82]

PROGNOSTIC MARKERS IN THE CONTEXT OF ANTIRETROVIRAL THERAPY

In the context of initial HAART, CD4⁺ cell counts and plasma HIV-1 RNA levels also are predictive of disease progression. In a landmark paper, Egger and colleagues demonstrated that in treatment-naive individuals who were starting combination antiretroviral therapy, including at least three agents, baseline CD4⁺ cell count remained a strong predictor of overall mortality and progression to AIDS or death (Fig. 73-1).[67] Compared to individuals who began HAART with CD4⁺ cell counts less than 50/mm³ individuals in higher CD4⁺ group strata were progressively less likely to advance to AIDS or die during the observation period. For example, compared to those with CD4⁺ cell counts <50/mm³, individuals with CD4⁺ cell counts between 100–150/mm³ were half as likely to progress and those with CD4⁺ >350 cells/mm³ were approximately six times less likely to have an AIDS event or die. Plasma HIV RNA level prior to initiation of HAART was only predictive of disease progression if the viral load was >100,000 c/mL (Fig. 73-1). These results contrast with earlier studies in the pre-HAART era, when baseline plasma HIV RNA was a strong predictor of disease progression in the setting of non-HAART antiretroviral therapy.[83,84] When the initial therapy is HAART, other independent predictors of disease progression were injection drug use, increasing age, and a previous AIDS-defining illness.[67] These data allow one to estimate an individual's risk of disease progression prior to initiating HAART. Once therapy is initiated, an individual's response to therapy is the overwhelming predictor of subsequent disease progression, trumping pretherapy plasma HIV RNA level and CD4⁺ cell count. In a follow-up study from the Antiretroviral Therapy Cohort Collaboration, Chene and colleagues analyzed the response to HAART by stratifying patients by their CD4⁺ cell counts and HIV RNA levels 6 months after HAART initiation.[85] In this analysis, both on-therapy CD4⁺ cell count and HIV RNA were predictive of subsequent disease progression or death. Over a 3-year follow-up period, the likelihood of AIDS progression or death in individuals in the lowest risk group (HIV RNA <500 q/mL and CD4⁺ cell count >350 cells/mm³) on therapy

was only 2.4%, whereas those who failed to respond ($CD4^+$ <25 cells/mm^3 and HIV RNA >100,000 c/mL) had a greater than 80% probability of further AIDS events or death. Baseline $CD4^+$ cell count and plasma HIV RNA were no longer predictive of outcome when 6 month parameters were included in the model.

SPECIFIC ANTIRETROVIRAL THERAPIES

OVERVIEW

For individuals with HIV-1 infection requiring treatment, a combination of three or more agents (HAART) is the standard of care, both in the developed and the developing world. HAART has had a dramatic effect on survival and AIDS progression in the United States, other developed countries, and in the developing world.[86–88] An important caveat in the treatment of HIV infection is that outcomes for patients improve when care is provided by clinicians with expertise in HIV treatment.[89–91]

CURRENT RECOMMENTATIONS

The current recommendations for initial HIV-1 antiretroviral therapy in the United States are straightforward and relatively consistent between the two main guideline panels, the Department of Health and Human Services (DHHS) Panel on Antiretroviral Guidelines for Adults and Adolescents and the International AIDS Society USA (ISA-USA)[92,93] (Table 73-1). The goal of the therapy is to suppress plasma HIV RNA levels to below the limit of detection, using the most sensitive assay available. For initial therapy, this goal should be possible for nearly all patients who can tolerate and adhere to the treatment.

A summary of recommendations for initial therapy is shown in (Table 73-1). For initial therapy, the DHHS guidelines allow for selection from a variety of preferred regimens. The basic recommendation is to select two nucleoside reverse transcriptase inhibitors (NRTI), one of which is lamivudine (3TC) or emtricitabine (FTC), plus either an NNRTI (efavirenz [EFV] is the preferred agent),[94–96] or a protease inhibitor that is pharmacologically boosted by low-dose ritonavir (lopinavir/ritonavir [LPV/r], fosamprenavir/r, or atazanavir/r are the current preferred protease inhibitors).[25,97] The second NRTI in the preferred regimen is either zidovudine (ZDV) or tenofovir (TDF). Recently, TDF, FTC, and EFV were shown to be superior to ZDV, 3TC, and EFV in a large randomized open-label study.[98] TDF, FTC, and EFV can now be administered together in a single coformulated pill once daily.

Multiple alternatives to these initial preferred regimens are listed in the DHHS guidelines. An important concept is that initial, as well as subsequent regimens should be tailored to the individual patient, taking into account her/his medical conditions, concomitant medications, life style, and social supports. All alternative regimens include FTC or 3TC in first-line therapy. Nevirapine (NVP) is the alternative NNRTI, while there are multiple choices for alternative protease inhibitors (see Table 73-1). Abacavir (ABC) and didanosine (ddI) are considered alternatives to ZDV or TDF. Though the triple NRTI regimen of abacavir/lamivudine/zidovudine has been shown to be inferior to zidovudine/lamivudine and EFV,[95] this triple NRTI regimen, which is available as a fixed-dose combination, is still considered an acceptable therapy in certain clinical situations. Currently there is no evidence that more that three agents (not inclusive of low-dose RTV) are needed for initial treatment of HIV-1 infection, even in settings of high plasma viral load or low $CD4^+$ cell counts.[99,100]

The IAS-USA guidelines for initial therapy are similar to the DHHS guidelines (Table 73-1).[92] Protease Inhibitor choices include LPV/r, saquinavir with low-dose RTV (SQV/r), atazanavir with low-dose RTV (ATV/r), and fosamprenavir with low-dose RTV; the latter has been shown to be comparable to LPV/r in a large randomized comparative trial.[97] These guidelines list three dual nucleoside combinations, TDF/FTC, ZDV/3TC, and ABC/3TC, all of which are available in fixed-dose combinations. Efavirenz and nevirapine are recommended components of initial therapy, though nevirapine has significant limitations on its use because of rash and hepatotoxicity. Women with $CD4^+$ cell counts >250 cells/mm^3 and men with >400 cell/mm^3 should not be given NVP because of potential hepatotoxicity.

Certain combinations of antiretrovirals should be avoided. Stavudine and ZDV are antagonistic in vitro and in vivo.[101,102] Stavudine and ddI lead to substantial serious toxicity such as peripheral neuropathy, lactic acidosis, and pancreatitis.[96,103–106] The combination of TDF and ddI has been associated with declines in $CD4^+$ cell counts, especially if the ddI dose is not appropriately dose reduced[107–111] and in combination with EFV, TDF plus ddI may result in more rapid virologic rebound.[112,113] Therefore, this NRTI combination (even if ddI is appropriately dose adjusted) should not generally be used in initial therapy regimens. Two triple nucleoside combinations, ABC/TDF/3TC and ABC/ddI/3TC, also should not be used as initial therapy because of observed rapid plasma HIV RNA rebounds and emergence of resistance.[114,115]

Combinations of NNRTI have not demonstrated any additional benefits to antiretroviral regimens with only one NNRTI. Combinations of protease inhibitors, especially with RTV-boosting, have been described in many noncomparative studies. While there may be added efficacy benefit in combining two or more PI in treatment-experienced patients with PI-resistant virus, the limited evidence for added activity, the risk of negative pharmacological interactions,[116] and the added regimen complexity suggest that combinations of boosted protease inhibitors should not be used in antiretroviral regimens in treatment-naive patients.

Table 73-1. Preferred and Alternative Regimens for Initial Antiretroviral Therapy as Recommended by the DHHS and IAS-USA guidelines[92,93] An NRTI Combination Plus Either a PI or NNRTI Are Recommended

Class	Medication	Recommendation
NRTI	Tenofovir/emtricitabine[a,b]	Preferred (IAS-USA and DHHS)
	Zidovudine/lamivudine[a,b]	Preferred (IAS-USA and DHHS)
	Abacavir/lamivudine[a,b]	Preferred (IAS-USA) Alternative (DHHS)
	Didanosine and lamivudine or emtricitabine	Alternative (DHHS)
NNRTI	Efavirenz[c]	Preferred (IAS-USA and DHHS)
	Nevirapine[d]	Preferred (IAS-USA) Alternative (DHHS)
PI	Atazanavir plus ritonavir	Preferred (IAS-USA and DHHS)
	Fos-amprenavir plus ritonavir (twice daily)	Preferred (IAS-USA and DHHS)
	Lopinavir/ritonavir[a] (twice daily)	Preferred (IAS-USA and DHHS)
	Saquinavir plus ritonavir	Preferred (IAS-USA)
	Atazanavir[e]	Alternative (DHHS)
	Fos-amprenavir	Alternative (DHHS)
	Fos-amprenavir plus ritonavir (once daily)	Alternative (DHHS)
	Lopinavir/ritonavir[a] (once daily)	Alternative (DHHS)

[a]Fixed-dose combinations (FDC).

[d]Emtricitabine may be used in place of lamivudine and vice versa (not available as FDC).

[c]Efavirenz is not recommended for use in the first trimester of pregnancy or in sexually active women who are not using effective contraception.

[d]Nevirapine should not be initiated in women with $CD4^+$ cell counts >250/mm^3 or men with $CD4^+$ cell counts >400/mm^3.

[e]Atazanavir should be boosted with ritonavir when given with tenofovir.

The nucleoside sparing combination of a protease inhibitor (with or without RTV boosting) plus an NNRTI has been studied most recently in a large comparative trial that also examined EFV and two NRTI and LPV/r and two NRTI. In this study, EFV plus LPV/r had similar antiviral efficacy to EFV, 3TC, and either ZDV, d4T, or TDF.[117] Nucleoside-sparing regimens are not yet recommended for initial therapy in the DHHS or IAS-USA guidelines (Table 73-1).

SPECIFIC CLASSES

Four classes of antiretroviral agents have been studied extensively. These classes are nucleoside analog reverse transcriptase inhibitors, NNRTIs, HIV-1 protease inhibitors, and an inhibitor of the fusion step of HIV-1 entry. Over 20 antiretroviral agents have been approved in the United states for HIV-1 treatment, and several fixed-dose combinations are available.

REVERSE TRANSCRIPTASE INHIBITORS

NUCLEOSIDE AND NUCLEOTIDE ANALOGS

Nucleoside and nucleotide analog reverse transcriptase inhibitors are phosphorylated intracellularly to triphosphorylated active metabolites. They inhibit viral replication by competing with endogenous nucleotides for incorporation into the elongating HIV-1 DNA that is being synthesized from the HIV-1 RNA genome by the viral reverse transcriptase. Once incorporated, these agents terminate chain elongation because the 3′ carbon lacks a hydroxyl group necessary for the addition of additional nucleotides.[118] Some of the toxicity observed with these agents result from their affinity

for human DNA polymerases, though the affinity is less than that for the HIV-1 reverse transcriptase. The relative affinity of these agents for specific human DNA polymerases, in particular mitochondrial DNA polymerase gamma, varies for the different agents and may explain, in part, their differing toxicities. A toxicity associated with the class is lactic acidosis with hepatic steatosis, which may be due to effects on NRTI on mitochondrial function.

Zidovudine

Zidovudine (3′-azido-2′, 3′-dideoxythymidine–ZDV, AZT, or Retrovir and a component of combivir and trizivir) is a thymidine analog with an azido group at the 3′ location of the ribose ring. After triphosphorylation by cellular kinases, it competes with deoxythymidine triphosphate for reverse transcriptase binding and then terminates HIV-1 DNA chain elongation. Zidovudine is well absorbed orally (60–65% bioavailability). The ZDV serum half-life is short (1–1.5 hours), but the intracellular half-life of ZDV-triphosphate may be up to 4 hours[119] and activity may correlate best with intracellular ZDV triphosphate levels.[120] Zidovudine penetrates into the cerebrospinal fluid (CSF) well.[121,122] The current recommended dose is 300 mg twice daily. Zidovudine is metabolized predominantly by the liver via glucuronidation, and its one metabolite does not have antiretroviral activity. Agents that affect glucuronidation may affect ZDV metabolism.[123]

The predominant long-term toxicity of ZDV is hematological, particularly anemia and neutropenia. When ZDV is administered at 600 mg/day to patients with less advanced disease or who are asymptomatic, hematological toxicity occurs less frequently.[98,124] Headache and nausea have been associated with ZDV therapy, though in some controlled trials of combination therapy, these symptoms do not always occur at a substantially greater frequency than with non-ZDV HAART combinations.[98,124] An additional toxicity seen in patients on prolonged ZDV therapy is myopathy, which is usually reversible with discontinuation of therapy.

Zidovudine as monotherapy was the first antiretroviral shown to improve survival in patients with AIDS.[125,126] In combination with 3TC, ZDV was shown to be superior to either drug alone or other nucleoside combinations.[127–129] Most importantly, in combination with 3TC and either NNRTI or protease inhibitors, ZDV has been one of the key components of many efficacious HAART regimens. ZDV along with either 3TC or FTC is a preferred nucleoside when combined with a PI or NNRTI for initial antiretroviral therapy in both the DHHS or IAS-USA guidelines (Table 73-1).[92,93]

Variants of HIV-1 resistant to ZDV have been isolated from many patients receiving ZDV therapy, especially when it was given as monotherapy or in a dual nucleoside combination. Amino acid changes at five separate codons of the HIV-1 reverse transcriptase have been associated with HIV-1 resistance to ZDV, and these mutations are now referred to commonly as thymidine analog mutations or TAMs.[130–133] These mutations lead to substantial cross-resistance to other nucleoside analogs. When ZDV is given in combination with 3TC and either an NNRTI or a boosted protease inhibitor as part of initial therapy, emergence of these TAM mutations is uncommon in virologic failure.[25,98,99,134]

Didanosine

Didanosine (2′ 3′-dideoxyinosine–ddI or Videx) is an adenosine analog that lacks a hydroxyl group at the 3′ location. The active metabolite of ddI is dideoxyadenosine triphosphate (ddATP). Didanosine is absorbed poorly in an acid environment or in the presence of food and is available as an enteric coated formulation[135] or as buffered tablets or solutions. Didanosine should be administered either 30–60 minutes prior to eating or 2 hours after eating,[136] though with the enteric-coated formulation the effect of food on absorption is less.[137] The half-life of ddI in serum ranges from 0.6 to 2.8 hours, and the intracellular half-life of ddATP is 12–24 hours.[138] ddI is administered as 400 mg once daily, with dose adjustments for individuals weighing less than 60 Kg.

The long-term toxicity of ddI may include idiosyncratic pancreatitis, dose-dependent peripheral neuropathy, and less commonly, lactic acidosis.[96,104,106,139–143] With correct dosing and dose adjustment, the incidence of peripheral neuropathy and pancreatitis in large-scale clinical trials of ddI is diminished, especially if the combination of ddI with d4T is avoided. Additional adverse effects of ddI included nausea, bloating, abdominal pain, and diarrhea, though these are much less common with the newer enteric-coated formulation.[135]

As a component of HAART initial therapy, many early ddI studies combined this agent with stavudine (d4T), sometimes with the addition of hydroxyurea.[96,139,144,145] Although in some studies these ddI-containing combinations had similar activity to other HAART regimens,[144] the combination of ddI, d4T, and either EFV or nelfinavir was shown to be inferior to ZDV/3TC/EFV in a large randomized trial.[96] These and similar results coupled with the recognition that ddI/d4T, with or without hydroxyurea, had substantial toxicity, predominantly peripheral neuropathy and pancreatitis,[96,104,106,139–143] have diminished the use of this NRTI combination as a component of HAART, and it is now considered a combination that should be avoided.[93,146] More recently, ddI combined with emtricitabine (FTC) and EFV was shown to be superior to ddI, d4T, and EFV in treatment-naive subjects in a large randomized trial.[147] However, given the potential toxicity of ddI, this combination is considered an alternative 2 NRTI component of HAART, as opposed to a preferred 2 NRTI component (Table 73-1).[93,146] Combinations of ddI with other NRTI such as TDF as a component initial therapy have led to disappointing antiviral responses, perhaps due to a specific interaction between drug-resistance mutations, and should be avoided.[112,113]

Didanosine may have greater utility in treatment experienced patients with some degree of nucleoside analog resistance. Even in the setting of multiple nucleoside analog associated mutations (NAMs) and the M184V mutation associated with 3TC and FTC, didanosine still has clinically relevant activity[148] that may be harnessed in the context of combination second line or salvage therapy. These results have to be tempered somewhat by the demonstration of an interaction between tenofovir (TDF) and ddI that appears to result in diminished $CD4^+$ cell responses even when plasma HIV RNA responses are robust. These effects appear to be most prominent when ddI is given at full dose (400 mg once daily).[107–111] The use of the combination of ddI and TDF in the context of multidrug salvage regimens should always include appropriate ddI dose adjustment and be limited to situations where the potential antiviral activity of the combination outweighs the potential for a less robust $CD4^+$ cell response. Isolates of HIV-1 resistant to ddI have been well described.[149–152] The signature mutation for ddI resistance occurs at RT gene codon 74; however, combinations of other NAM and the M184V mutation also diminish the effectiveness of ddI to some degree.[153,154]

Stavudine

Stavudine (3′-deoxy-2′, 3′-didehydrothymidine–d4T or Zerit) is a thymidine analog with an oral bioavailability of 60–80%, a serum half-life of 1.5–2 hours, and an intracellular half-life as the triphosphate metabolite of 3–4 hours.[155–157] Stavudine is excreted by both renal and nonrenal routes, with approximately 40% of an oral dose excreted unchanged in the urine.[158] The standard dose of d4T is 40 mg twice daily, reduced to 30 mg twice daily in persons who weigh less than 60 kg. No significant drug-drug interactions have been described.

The initial administration of d4T is usually well tolerated. Long-term toxicity includes sensory polyneuropathy, lipoatrophy, lactic acidosis, and increased triglycerides,[94,104,140,159] which may be related to the effect of stavudine and other NRTI on mitochondrial DNA polymerase.[105,160]

Stavudine with lamivudine and either an NNRTI or a ritonavir-enhanced protease inhibitor has been shown to be very effective antiretroviral combination for initial therapy.[25,94,161] When d4T is combined with ddI and an NNRTI or nelfinavir, the regimen is less effective than 3TC or FTC-based therapy.[96,147] Stavudine use is now limited by its metabolic toxicity. Use in the developing world remains considerable because of its inexpensive and convenient generic formulations. However, recent World Health Organization (WHO) Guidelines urge caution in using stavudine as a component of first-line therapy.[162]

Mutations in the reverse transcriptase gene that are specific to d4T resistance have been described but appear uncommon,[163] TAMs, first described as selected for by zidovudine, are also selected for by stavudine,[164] and cross-resistance between stavudine and zidovudine is believed to be extensive.

Lamivudine

Lamivudine (3TC or Epivir) is the (-)enantiomer of the cytosine analog 2′-deoxy-3′-thiacytidine, which contains a sulfur atom in the ribose ring. This compound also lacks a 3′ hydroxyl group. In addition to in vitro activity against HIV-1 and HIV-2, 3TC also inhibits hepatitis B virus (HBV) and has antiviral activity in patients with chronic active hepatitis B.[165–167] Lamivudine has an oral bioavailability of greater than 80% in adults and greater than 60% in children.[168] The serum concentration is unaffected by food, and the intracellular half-life of 3TC triphosphate is 12–18 hours.[169] 3TC is administered either 150 mg twice daily or 300 mg once daily, and is frequently used in fixed dose combinations with zidovudine (Combivir), abacavir (Epzicom),or both (Trizivir). Lamivudine is excreted predominantly by the kidney, and dose reduction is required in patients with moderate-to-severe renal failure.

3TC appears to have relatively limited toxicity. In early studies of 3TC monotherapy, dose-limiting toxicity was not observed. At doses higher than currently recommended, neutropenia was observed in a minority of subjects.[168,170,171] Mild headache may occur with the use of 3TC, but the addition of 3TC to ZDV appeared to show no additional adverse effects than those seen with ZDV alone.[127]

Lamivudine and the similar compound emtricitabine (see below) are the key components of any initial regimen for treatment-naive patients (Table 73-1).[92,93] 3TC with zidovudine, stavudine, abacavir, or TDF in combination with an NNRTI or a ritonavir-enhanced PI has demonstrated consistent efficacy in large comparative trials in treatment-naive patients.[25,94,96–98,161,172]

Resistance of HIV-1 to 3TC develops rapidly in vitro and is common in HIV isolates from patients treated with 3TC who rebound on therapy.[173–175] A single amino acid substitution at codon 184 (methionine to isoleucine or valine; M184V) of the reverse transcriptase results in a 100-to 1000-fold decrease in activity of the drug in vitro. A virus that contains this mutation may also have a decreased replicative capacity,[176] and despite high-level resistance, 3TC has been shown to have a persistent modest effect in vitro.[177] In infected individuals, 3TC clearly has a persistent effect on HIV-1 replication and viral load, even when the M184V mutation is present, and this persistent effect results in blunted $CD4^+$ cell declines.[127,178–180] The 3TC resistance mutation also impacts resistance to other agents. When the M184V mutation is introduced into virions with high-level resistance to ZDV, these virions frequently regain sensitivity to ZDV,[181] and M184V also likely increases susceptibility to stavudine and TDF.[182,183] This mutation results in a low level of cross-resistance to ddI, ddC, and abacavir.[184,185]

Abacavir

Abacavir (ABC; Ziagen) is a carbocyclic 2′-deoxyguanosine nucleoside analogue that undergoes intracellular metabolism by a unique set of intracellular enzymes to a 2′-deoxyguanosine nucleoside analogue that is triphosphorylated (carbovir triphosphate) and inhibits HIV reverse transcriptase via chain termination. Carbovir triphosphate has limited affinity for human DNA polymerases. The bioavailability of abacavir is approximately 80% and its absorption is not affected by food. This drug undergoes hepatic metabolism by several enzymes including alcohol dehydrogenase,[186] though not via the p450 system. The plasma half-life of abacavir is short (<2 hours), though the intracellular half-life of carbovir triphosphate is substantially longer, perhaps >12 hours.[187] Dose modification in individuals with reduced renal function does not appear necessary.

Typical doses of abacavir are either 300 mg twice daily or 600 mg once daily, and abacavir is commonly used in fixed dose combinations with lamivudine (Epzicom) or lamivudine and zidovudine (Trizivir).

Abacavir is generally well tolerated with mild nausea, fatigue, and headache seen in early monotherapy trials. The predominant serious side effect is a hypersensitivity syndrome that usually includes fever and may include rash and gastrointestinal symptoms; respiratory symptoms may also be present. The symptoms tend to worsen with dose and improve rapidly after ABC discontinuation. Severe systemic reactions with hypotension, respiratory failure, and death have occurred when abacavir has been reintroduced in a patient with previous symptoms of hypersensitivity.[188] This syndrome occurs in approximately 5–10% of individuals treated, and appears less common in individuals of African descent. Abacavir hypersensitivity has been associated with the HLA allele B5701.[189,190] Testing for this allele may reduce abacavir hypersensitivity reactions if patients with B5701 avoid use of this agent. However, whether all abacavir hypersensitivity reactions are mediated through this HLA allele is not known, and risk cannot be assumed to be zero in HLA B5701 negative individuals.

Abacavir is a potent nucleoside leading to 1.5 to 1.6 $\log_{10}$ declines in plasma HIV RNA with monotherapy.[191] Abacavir with zidovudine and lamivudine was used commonly as an initial therapy combination when the combination was shown to have similar activity to a combination of indinavir with zidovudine and lamivudine.[192] Use as initial therapy increased when the combination was available as a single fixed dose combination tablet given twice daily. However, a large randomized trial comparing fixed dose combination abacavir/lamivudine/zidovudine to the triple nucleoside combination plus efavirenz or fixed dose combination zidovudine and lamivudine plus efavirez showed inferiority of the three-nucleoside combination.[95] As initial therapy, abacavir is now most commonly used with lamivudine and a third potent agent such as a ritonavir-enhanced protease inhibitor or efavirenz.[97] Abacavir, substituting for a protease inhibitor, has also been used to simplify therapy or reduced toxicity in patients already suppressed on three-drug therapy.[193,194] Abacavir has also been used as a component of therapy in treatment-experienced patients,[195] with such therapy now typically guided by resistance testing.

As monotherapy, abacavir may select for the M184V mutation and also selects for L74V, Y115F, and less commonly, K65R.[196] In the context of combination therapy with lamivudine and zidovudine, M184V is selected and TAMs emerge over time.[95]

Tenofovir

Tenofovir disoproxil fumarate (TDF; Viread) is an acyclic nucleotide analog of adenosine monophosphate, and is converted to tenofovir in vivo and then phosphorylated to tenofovir diphosphate, which is the active form. The intracellular half-life of TDF-DP is greater than 40 hours in resting peripheral blood mononuclear cells and 11 hours in activated PBMC.[197] Bioavailability is 25–40% and is highest in the fed state. There is no liver metabolism and tenofovir is mostly excreted unchanged in the urine. The adult dose is 300 mg daily and tenofovir is also available as a fixed dose combination with emtricitabine (Truvada) (see below) or with emtricitabine and efavirenz (Atripla). Dose reduction is required during decreased renal function, with a decrease to every other day dosing when creatinine clearance falls to less than 50 mL/min. This agent also has activity against HBV.

Tenofovir is generally well tolerated with mild gastrointestinal side effects as the main consequence of therapy. Tenofovir can be nephrotoxic, especially if given at higher than recommended doses and the effect is predominantly one of renal tubular dysfunction that can result in a Fanconi's like syndrome or acute renal failure.[198] However, at currently recommended doses, TDF appears to have limited renal toxicity with very few substantial rises in creatinine observed in randomized trials.[94,98,199] Glomerular filtration rate decreases slightly on TDF-containing regimens, though the clinical significance of this is unclear.[200]

Tenofovir was first studied in treatment-experienced patients and showed modest but consistent activity in patients with NRTI-resistant virus, reducing plasma HIV RNA by 0.5 to 0.7 $\log_{10}$ copies per mL.[199,201] In patients with wild-type virus, tenofovir has substantially more activity.[202] More recently, in combination with emtricitabine or lamivudine and efavirenz, tenofovir has shown substantial and prolonged efficacy in treatment-naive patients.[94,98] The combination of tenofovir, emtricitabine, and efavirenz is now available in as a single once daily pill in the United States, and is one of the most commonly used first-line therapies, endorsed by both the DHHS and IAS-USA guidelines (Table 73-1).[92,93] Tenofovir with 3TC or FTC and a protease inhibitor is also

likely to be very effective in treatment-naive patients, though these combinations have been less well studied.

The signature-resistance mutation for tenofovir is K65R.[203] This mutation arises relatively infrequently when tenofovir is given as part of a potent combination to treatment-naive patients,[94,98] but the overall prevalence of this mutation which leads to cross-resistance with ddI, abacavir, 3TC, FTC, and probably stavudine, is increasing in the population of treated patients. Viruses with K65R mutation are hypersusceptible to ZDV in vitro.[204] TAMs and the multi-nucleoside resistance mutations at codon 69 (insertions) also affect tenofovir activity, though some activity remains against many viruses that have TAMs.[183,205] The K65R mutation reverses some of the effects of TAMs, and the ability for these mutations to coexist on the same virus may be limited.[206] The presence of the M184V mutation tends to modestly increase susceptibility to tenofovir.[203]

Emtricitabine

Emtricitabine (FTC; SP Emtriva) is a pyrimidine nucleoside analog with activity against HIV-1, HIV-2, and HBV that has a chemical structure, a *cis* enatiomer of 2′, 3′-dideoxy-5-fluoro-3′-thiacytidine, very similar to that of lamivudine (3TC). These two agents have very similar activity. FTC may have greater short-term antiviral activity and has a longer plasma and intracellular half-life than 3TC.[207] FTC has good oral bioavailability not affected by food. FTC is cleared by the kidney and must be dose adjusted in patients with decreased creatinine clearance. The standard adult dose is 200 mg daily, and this agent is coformulated with tenofovir (Truvada) and with tenofovir and efavirenz (Atripla).

Emtricitabine is well tolerated with mild nausea, headache, and abdominal pain reported in a minority of subjects in clinical studies. FTC is occasionally associated with skin discoloration, which appears to be more common in blacks and may predominantly affect the palms, soles, and nails.

Emtricitabine has potent activity in combination with two other antiretroviral agents in treatment-naive patients. This drug has been shown to be superior to stavudine when given with ddI and efavirenz, and when combined with tenofovir and efavirenz had superior efficacy to zidovudine, lamivudine, and efavirenz.[98,147] This agent is now a common component of initial therapy regimens (Table 73-1).

Like lamivudine, the signature-resistance mutation is at codon 184 with a switch from methionine to isoleucine or most commonly valine. This mutation occurs frequently in patients who have virologic rebound on either emtricitabine or lamivudine, though when emtricitabine is given with tenofovir and efavirenz emergence of this mutation with rebound in plasma HIV RNA may be somewhat less likely.

NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

Nonnucleoside reverse transcriptase inhibitors are noncompetitive inhibitors of the HIV-1 reverse transcriptase that bind tightly and specifically to the HIV-1 reverse transcriptase (RT)[208,209]; some have very potent in vitro activity.[210] Resistance to NNRTI emerges rapidly in vitro and in vivo if viral replication is not fully suppressed.[211,212] However, these agents are very efficacious in combination with other agents, especially in patients who are naive to antiretroviral therapy. There are three NNRTI approved for clinical use in the United States and Europe—nevirapine, delavirdine, and efavirenz, though delavirdine, is not commonly used.

NEVIRAPINE

The pharmacokinetics of nevirapine (NVP or Virammune) are favorable with rapid, nearly complete absorption, and a long half-life that supports twice-daily dosing.[213] Many clinicians also use nevirapine once daily. The predominant adverse effect of nevirapine is the incidence of rash, which occurs in approximately 30% of treated subjects. Some rashes may be severe, and Stevens-Johnson syndrome has been observed. Because there is autoinduction of nevirapine metabolism, a dose-escalation strategy from 200 mg daily to 400 mg daily reduces the incidence of rash. Nevirapine is also associated with a hypersensitivity syndrome, which includes fever, rash, and hepatotoxicity.[214] This syndrome has resulted in liver failure and death in some individuals, and women and men with a more intact immune system are at a greater risk. Nevirapine should not be given to women with $CD4^+$ cell counts greater than 250/mm^3 or men with $CD4^+$ >400 cells/mm^3 or HIV-uninfected individuals as postexposure prophylaxis(PEP).

Nevirapine in combination with 3TC and stavudine has similar activity in treatment-naive patients to efavirenz given with the same two nucleosides in a large randomized study.[161] There was greater hepatotoxicity when nevirapine was given once daily, though the nevirapine-containing regimens had a more favorable effect on lipids.[215] Nevirapine appears safe during pregnancy and therefore may be a reasonable choice for initial therapy in women of child-bearing potential provided $CD4^+$ cell counts are less than 250/mm^3. Nevirapine also has limited central nervous system side effects. Data are limited on the combination of nevirapine with the two commonly used fixed dose combination nucleosides, tenofovir/emtricitabine, and abacavir/lamivudine.

Resistance develops rapidly to NVP, and characteristic mutations in the *RT* gene have been described.[211,216] The appearance of resistance is associated with a rapid loss of antiretroviral activity. Even single doses of nevirapine rapidly select for resistance mutations and these mutations may persist for months following a single dose.[217,218] Nevirapine is an

inducer of the p450 enzyme system and may increase metabolism of other medications metabolized by this system, including HIV-1 protease inhibitors.

DELAVIRDINE

Delavirdine (DLV or Rescriptor) is an NNRTI with potent activity against a broad range of HIV-1 variants in vitro.[219] However, the pharmacokinetics of delavirdine require dosing three times daily limiting the utility of this medication. Unlike nevirapine and efavirenz, delavirdine inhibits cytochrome p450 enzyme isoform 3A4 and may result in increased levels of medications metabolized by this enzyme.

EFAVIRENZ

Efavirenz (EFV or Sustiva) has a similar mechanism of action to nevirapine and delavirdine despite a unique chemical structure.[220] This agent is highly potent despite substantial protein binding. Efavirenz is well absorbed orally and has a prolonged half-life of 40–55 hours with long-term administration allowing once daily dosing. The standard dose is 600 mg daily. Efavirenz is metabolized by the p450 system in the liver (CYP3A4 and CYP2B6) and is also an inducer of the p450 system. Common central nervous system side effects include sleep disturbances and vivid dreams; rashes are also common though severe rash is rare. Liver function abnormalities may also occur. In most studies of efavirenz therapy in treatment-naive patients, total cholesterol, LDL cholesterol, and HDL cholesterol all rose moderately.

Efavirenz is now a cornerstone of initial antiretroviral therapy. An array of randomized comparative studies that have combined efavirenz with lamivudine or emtricitabine and either zidovudine, stavudine, tenofovir, or abacavir have demonstrated that efavirenz-containing regimens achieve the highest virologic suppression rates in treatment-naive subjects of any antiretroviral therapy combinations studied.[94–96,98,99,117,124,221–223] In these trials, approximately 75% of individuals treated with efavirenz, lamivudine, or emtricitabine, and another nucleoside achieved plasma HIV RNA levels less than 50 c/mL at 48 weeks or longer. In one study, 69% of subjects treated with efavirenz, lamivudine, and stavudine and 73% treated with efavirenz, lamivudine, and tenofovir had HIV RNA levels <50 c/mL at 144 weeks in an analysis where all missing values were considered virologic failures.[94] Efavirenz is also a useful agent in later therapy regimens if a patient has not been exposed to NNRTI-based therapy. A history of previous treatment with an NNRTI-based regimen that resulted in virologic failure limits the usefulness of efavirenz in treatment-experienced patients, likely due to NNRTI resistance, whether that resistance can be detected by standard assays or not.[195]

As with other NNRTI, resistance to efavirenz emerges rapidly in most individuals whose virus is not suppressed, or who have a rebound of HIV replication while on therapy. While the number of virologic failures in the studies outlined above is typically small, the majority of those who fail and undergo resistance testing have had virus with NNRTI resistance (summarized in Ref. 222).[94,95,98] While K103N is the most common resistance mutation selected by efavirenz-based regimens, other mutations may be selected (examples include V106M, Y188C/L, or G190A/S/E/Q).

PROTEASE INHIBITORS

Like other retroviruses, HIV-1 expresses the products of its *gag* and *pol* genes as a single precursor polyprotein that must be cleaved by the HIV-encoded protease in order to produce infectious viral particles. The amino acid cleavage sites for the HIV-1 aspartyl protease are specific and not similar to cleavage sites of human host proteases. Currently available protease inhibitors bind to the active site of the enzyme and are competitive inhibitors of the HIV-1 protease with K_i in the 1.0 n*M* range.

The HIV-1 protease is an enzyme that tolerates marked variability in amino acid sequence while still retaining function. Polymorphism has been shown to exist at almost half of the amino acid positions of this 99 amino acid homodimer. Some of these amino acid substitutions also emerge during protease-inhibitor administration in vitro and in vivo and are thought to contribute to resistance to protease inhibitors. Therefore, many individuals who are treated with protease inhibitors already have HIV-1 variants with amino acid substitutions that may contribute to protease inhibitor resistance once therapy is instituted.

SAQUINAVIR

Saquinavir (SQV, Invirase) is a peptidomimetic HIV-1 and HIV-2 protease inhibitor with in vitro activity in the nanomolar range. Saquinavir has a bioavailability of approximately 4% when given with a high-fat meal and substantially lower when given in the fasting state, due in part to first-pass metabolism by p450 3A4 enzymes in the intestinal wall and liver. Therefore, in order to be maximally effective, saquinavir must be given with the potent p450 inhibitor, ritonavir (see below) in order to achieve adequate levels. When given with ritonavir, saquinavir trough concentrations are increased substantially. Recommended dosing is either 1000-mg saquinavir plus 100-mg ritonavir twice daily,[224] or 1500-mg (or 1600-mg) saquinavir and 100-mg ritonavir once daily.[225] Because of multiple changes in the formulation of saquinavir over time, limited data are available at these doses. Adverse gastrointestinal effects can occur with saquinavir, but these symptoms are usually mild and infrequently result in treatment discontinuation, and are difficult to disentangle from the side effects of coadministered ritonavir.

Despite the fact that saquinavir was one of the first protease inhibitors introduced, there are very few studies that help guide use with the current formulation given with low-dose ritonavir. In a large randomized study comparing lopinavir/ritonavir to saquinavir boosted by ritonavir, each with nucleoside analogs, the proportion of patients with treatment failure was significantly higher on the saquinavir arm. Most treatment failures were due to discontinuation of saquinavir and ritonavir.[226] The interpretation of this trial is muddied by the fact that the patient population enrolled in the trial did not belong to one treatment group but instead was composed of subjects naive to therapy, subjects suppressed on therapy, and subjects who had failed previous antiretroviral therapy.

Resistance of HIV-1 to saquinavir has been demonstrated both in vitro and in vivo. Resistant isolates selected by saquinavir contain protease gene mutations at either codon 48 or codon 90 or both. Mutations that are associated with saquinavir resistance have been demonstrated in 30–50% of subjects treated with saquinavir, with the mutation at codon 90 occurring most commonly. Other primary protease-inhibitor mutations may also be selected.[227]

INDINAVIR

Indinavir (IDV; Crixivan) is a hydroxyaminopentane amide compound that is a potent inhibitor of the HIV-1 protease enzyme with a K_i of 0.34 n*M* 228 and nanomolar activity in tissue culture. This agent is not highly protein bound and has a short half-life, requiring three times daily dosing (800 mg)on an empty stomach. Like saquinavir, indinavir concentrations are substantially increased by low-dose ritonavir, and indinavir 800 mg with either 100 mg or 200 mg of ritonavir twice daily have been studied and used in clinical practice.[229–232] There are several adverse events associated with indinavir therapy. The most common serious side effect is nephrolithiasis, which occurs in approximately 2–5% of patients[233] and is due to precipitation of indinavir in the renal collecting system. Although less common, indinavir can lead to frank renal dysfunction. Indinavir is associated with increases in cholesterol and insulin resistance and may be associated with abdominal lipo-accumulation. Indinavir is also associated with skin changes and alopecia. Rises in indirect bilirubin are seen frequently, but are of little clinical consequence.

Indinavir with zidovudine and lamivudine was the combination of antiretrovirals that first showed the potential to suppress HIV replication to below detectable limits in the majority of treated patients.[233] Suppression of replication to below detectable limits was also associated with a very durable response in this small original study.[234] Indinavir in combination with zidovudine and lamivudine was also shown to be superior to zidovudine and lamivudine in reducing progression to AIDS/death.[235] Introduction of newer agents coupled with thrice daily dosing, fluid requirement, and adverse events limit indinavir use. Combination with low-dose ritonavir improves convenience substantially, but does not diminish and may actually increase adverse effects.

Viral variants resistant to indinavir have been isolated from patients in whom viral replication was not suppressed.[236] The establishment of high-level resistance requires multiple mutations in the protease gene, and these mutations appear to be acquired serially over time. An array of mutations is associated with indinavir resistance, with mutations at codons 46, 82, and 84 being characteristic.[227] Many viral variants with high-level resistance to indinavir are cross-resistant to several other protease inhibitors.

RITONAVIR

Ritonavir (RTV; Norvir) is a peptidomimetic protease inhibitor active in vitro that improved survival when added as a single agent to nucleoside antiretroviral therapy in patients with very advanced disease.[24] Full-dose ritonavir (600 mg twice daily) is so poorly tolerated, however, that this dose is almost never used. Instead, ritonavir's potent inhibition of p450 3A4 binding is what makes it one of the most commonly prescribed antiretrovirals today, at doses that have limited antiviral activity themselves, but that substantially enhance the concentrations of coadministered protease inhibitors. Higher doses of ritonavir are associated with substantial gastrointestinal side effects and perioral paresthesias. Some patients have similar side effects at the doses used for boosting of other PI (100 mg or 200 mg), once or twice daily, but this is typically a small minority of patients. Triglyceride levels increase with ritonavir, even at lower doses. Elevations in hepatic transaminases have also been more commonly associated with ritonavir-containing regimens at higher doses of ritonavir, especially in patients with hepatitis B or C coinfection.[237] At lower doses used in boosting, ritonavir-containing regimens appear to have no additional risk of hepatic toxicity compared to other PI-containing combinations.[238]

Because ritonavir is both an inducer and inhibitor of the human liver p450 cytochrome system, multiple drug–drug interactions exist. These interactions must be carefully considered when using this agent even at lower doses.

Resistance of HIV-1 to ritonavir has been well documented, both in vitro and in vivo,[239,240] with mutations at codons 82 and 54 occurring in a number of variants. Viruses with high-level resistance to ritonavir typically have cross-resistance to indinavir and lopinavir.

NELFINAVIR

Nelfinavir (NFV; Viracept) is a potent inhibitor of HIV-1 in vitro at low nanomolar concentrations.[241] This agent has an oral bioavailability of 17–47% in animals[242] and absorption is improved when given with food. The current recommended

dose is 1250 mg twice daily. The predominant side effect of nelfinavir is diarrhea, with approximately 15% of patients having substantial diarrhea in clinical studies.[25,243] Frequencies of other nelfinavir-associated adverse events such as increased lipids, nausea, and elevated liver transaminanses appear similar to other protease inhibitors. Nelfinavir, like other protease inhibitors, has the potential for drug-drug interactions with other medications that undergo hepatic p450 metabolism.

Because of its activity, relatively good tolerability, and twice daily dosing, nelfinavir became a common component of initial antiretroviral therapy. However, in comparative studies against EFV or lopinavir/ritonavir (each medication given with lamivudine and either zidovudine or stavudine), nelfinavir-containing regimens were inferior as measured by suppression of HIV replication.[25,96] Consequently, nelfinavir is recommended as an acceptable but not preferred agent for first-line therapy in most guidelines.[92,93] Some clinicians find nelfinavir useful in women of child-bearing potential and in pregnant women.

Resistance to nelfinavir usually occurs via selection of one of two initial mutations, either D30N or L90M, each of which can occur with secondary mutations.[244] The D30N mutation occurs more commonly, at least in individuals infected with subtype B virus and virus with this mutation have limited cross-resistance to other protease inhibitors.[245,246] The L90M mutation is associated with more broad cross-resistance.

LOPINAVIR/RITONAVIR

Lopinavir (LPV) is a C2 symmetrical peptidomimetic inhibitor of HIV-1 protease, and is available only in a form coformulated with ritonavir (LPV/r; Kaletra). Ritonavir inhibits the metabolism of lopinavir, resulting in high levels of the compound. Lopinavir is highly protein bound (98–99%), and when given with ritonavir has a half-life of 5–6 hours. Both lopinavir and ritonavir are metabolized by cytochrome P-450 enzymes, and the combination also inhibits several hepatic enzymes and induces the levels of others. Thus, drug–drug interactions are common between lopinavir/ritonavir and a variety of other agents, and these interactions must be considered when using this combination. A tablet formulation has replaced previously used capsule formulations, allowing a lower pill burden and potentially fewer adverse effects. Each tablet contains 200 mg lopinavir and 50 mg ritonavir, and the current recommended dose is two tablets (400/100 mg) twice daily. Once daily dosing (800/200 mg) is possible in treatment-naive patients. Lopinavir/ritonavir may be taken with or without food, and the tablet does not require refrigeration. The predominant toxicities are gastrointestinal (diarrhea, nausea) and hyperlipidemia, particularly hypertriglyceridemia.

Several clinical trials have demonstrated potent antiretroviral activity when lopinavir/ritonavir is combined with two NRTIs. In one pivotal trial, lopinavir/ritonavir was shown to be superior to nelfinavir (both combined with stavudine and lamivudine) in maintaining undetectable viral loads over 48 weeks.[25] In this study, no evidence of genotypic or phenotypic resistance to protease inhibitors was observed in lopinavir/ritonavir-treated subjects who did not attain or failed to maintain undetectable viral levels (<400 copies/mL), whereas 45% of such subjects in the nelfinavir arm developed PI resistance.[244] Although very uncommon, HIV-1 protease mutation I47A confers high-level resistance to lopinavir (>100-fold), and may be the primary resistance mutation to this agent; this mutation confers cross-resistance to amprenavir [the active metabolite of fos-amprenavir (see below)], while enhancing susceptibility to saquinavir.[247]

Lopinavir/ritonavir-containing regimens are now recommended by many for initial therapy of treatment-naive patients, as well as for individuals with previous treatment and little PI resistance (<5 protease-inhibitor resistance mutations).[92,93]

FOSAMPRENAVIR

Fosamprenavir calcium (fosAPV;Lexiva) is a prodrug of the protease-inhibitor amprenavir[248] and is available at a strength of 700 mg, equivalent to 600 mg of amprenavir. Ritonavir boosts fosamprenavir's half-life, making once daily dosing possible in treatment-naive individuals at a dose of 1400 mg of fosamprenavir with 200 mg of ritonavir; in treatment-experienced patients, fosamprenavir/ritonavir should be taken twice daily (fosamprenavir 700 mg, ritonavir 100 mg twice daily). Fosamprenavir without ritonavir is also given twice daily (1400 mg twice daily), but is not as widely used.

Adverse effects include nausea, vomiting, perioral paresthesias, and rash. Rash occurs in approximately 19% of treated patients, but is generally mild or moderate, and often the drug can be continued during the rash or restarted later. Severe skin rashes, including Stevens-Johnson syndrome, however, have also been described.

Clinical trials have compared three drug regimens including fosamprenavir alone or fosamprenavir boosted with ritonavir to similar regimens containing nelfinavir;[243,249] these studies showed similar or greater suppression in the fosamprenavir arms, particularly in subjects with pretreatment plasma viral loads >100,000 copies/mL. A more recent open-label trial compared lopinavir/ritonavir with fosamprenavir/ritonavir, each administered with the coformulation of abacavir/lamivudine[97]; this noninferiority trial in 878 treatment-naive subjects showed comparable suppression of plasma HIV RNA and increases in $CD4^+$ cell counts, with similar adverse event profiles in the two arms over 48 weeks.

Although resistance profiles have been observed similar to those seen in patients taking amprenavir (e.g., I54L/M, V32I, I47V, M46I, and I50V),[250] very little resistance was

observed in large trials employing three drug regimens including fosamprenavir/ritonavir.[97]

ATAZANAVIR

Atazanavir (ATV; Reyetaz) is an azapeptide inhibitor of HIV-1 protease. Administration with food enhances bioavailability and reduces pharmacokinetic variability. Atazanavir is highly protein bound and has a half-life of approximately 7 hours. It is metabolized by the cytochrome 450 enzyme CYP3A4, and administration with ritonavir boosts concentrations up to 10–fold.[251] The recommended dose when used without ritonavir in treatment-naive patients is 400 mg once daily, and for treatment-experienced patients it is recommended that atazanavir 300 mg be taken with ritonavir 100 mg once daily. This dose is also used in treatment-naive patients.

The principal observed adverse effect with atazanavir is indirect hyperbilirubinemia without accompanying liver function abnormalities; this may lead to jaundice and scleral icterus. Diarrhea and nausea may also occur. Atazanavir use has been associated with ECG PR prolongation, and the drug should be used cautiously in patients with cardiac conduction abnormalities. Importantly, atazanavir appears to have fewer adverse effects on lipid profiles than other available protease inhibitors,[252] and thus is becoming a popular choice in initial therapy regimens.

Early studies compared atazanvir-based regimens to either efavirenz or nelfinavir-based regimens, and showed comparability to both in antiretroviral-naive patients after 48 weeks.[253,254] In treatment-experienced subjects, atazanavir plus ritonavir showed comparable efficacy and safety when compared with lopinavir/ritonavir over 96 weeks; moreover, there were reductions in total cholesterol and fasting triglycerides and improved gastrointestinal tolerability in the atazanavir/ritonavir group.[255,256]

The I50L protease mutation confers resistance to atazanvir but increases susceptibility to many other protease inhibitors.[257] Resistance to atazanavir in treatment-experienced patients is also associated with protease mutations M46I/L, G73S/A/C, I84V, and L90M; fewer than 30% of individuals with these mutations will respond to atazanavir/ritonavir.[258,259]

TIPRANAVIR

Tipranavir (TPV; Aptivus) is a nonpeptidic protease inhibitor of HIV-1 belonging to the class of 4-hydroxy-5, 6-dihydro-2-pyrone sulfonamides. Because absorption is limited, tipranavir is administered with ritonavir (500 mg tipravir/200 mg ritonavir twice daily). It is highly protein bound and is metabolized primarily by hepatic CYP 3A4 mechanisms. Its half-life is 5.5–6.0 hours. Tipranavir and ritonavir together have multiple effects on cytochrome p450 enzymes and transport proteins such as p-glycoprotein. Complex drug–drug interactions are possible and should be carefully considered when initiating this combination (reviewed in Ref. 260).

The most frequent toxicities of tipranavir are gastrointestinal (nausea, diarrhea). Liver enzyme abnormalities may occur, and severe liver inflammation has been observed, particularly in individuals with chronic HBV or HCV infection or with liver enzyme elevations at the onset of therapy. Marked elevations of cholesterol and/or triglycerides are also seen in some patients.[261] Fatal and nonfatal intracranial hemorrhages have been observed in patients receiving tipranavir/ritonavir; no pattern of abnormal coagulation function was observed in such patients, though in vitro data suggest that tipranavir may have antiplatelet activity. Rash occurs in 8–14% of patients, and since tipranavir contains a sulfa moiety, it should be used with caution in individuals with sulfonamide allergies.

Tipranavir/ritonavir has activity against many viruses resistant to other protease inhibitors. The combination has been evaluated primarily in patients in whom other regimens have failed.[261] The RESIST 1 and II trials compared tipranavir/ritonavir with other comparator ritonavir-boosted protease inhibitors, each combined with optimized background regimens. Subjects receiving tipranavir/ritonavir had greater reductions in plasma HIV-1 RNA, greater $CD4^+$ cell rises, and longer median times to treatment failure than the comparator arm. In this heavily treated population, responses were best if more than two active drugs were in the regimen, particularly if one of them was enfuvirtide (see below). Thus, tipranavir/ritonavir-containing regimens are used primarily in individuals in whom other protease-inhibitor regimens are no longer effective.

In vitro resistance to tipranavir can be generated, with mutations appearing in the following order: 33F, 84V, 45I, 13V, 32I, 82L, 36I, 71V, 10F, and 54V/T. In clinical trials, the most commonly observed substitutions observed were L33V/I/F, V82T, and I84V. A tipranavir mutation score has been developed consisting of 16 protease positions and 21 mutations (10V, 13V, 20M/R/V, 33F, 35G, 36I, 43T, 46L, 47V, 54A/M/V, 58E, 69K, 74P, 82L/T, 83D, and 84V); HIV isolates displaying increasing numbers of these mutations have decreased susceptibility to tipranavir.[262] Cross-resistance with other approved protease inhibitors is modest, and viruses with single primary mutations generally are sensitive to tipranavir, with the exception of I84V and V82L or T.[263]

DARUNAVIR

Darunavir (DRV; Prezista; TMC-114) is an HIV-1 protease inhibitor that received accelerated approval from the US FDA in 2006 for use in combination with ritonavir (600 mg darunavir/100 mg ritonavir twice daily) by adults with

advanced HIV infection. This protease inhibitor has currently been best studied in treatment-experienced patients who have HIV strains resistant to other protease inhibitors. Darunavir should be taken with food, which increases Cmax and AUC by 30%. The drug is 95% bound to plasma proteins, and its half-life when combined with ritonavir is 15 hours. It is metabolized in the liver, primarily by CYP3A4.

The most common side effects of darunavir have included diarrhea, nausea, and headache. Rash, ranging from mild to serious, occurs in approximately 7%. Elevations in liver enzymes, amylase, and lipids, particularly triglycerides, were similar to those of comparator protease inhibitors in clinical trials. Darunavir contains a sulfa moiety and, thus, should be used cautiously in patients who have sulfonamide allergies.

Two randomized controlled trials (POWER 1 and II) compared the safety and effectiveness of a darunavir/ritonavir-based combination with other ritonavir-boosted protease inhibitor combinations in subjects with extensive prior treatment with antiretroviral drugs; all subjects in these trials had resistance to other protease inhibitors and were given optimized background regimens with the assistance of resistance testing. At 24 weeks, the darunavir group showed substantially better virologic responses than the comparator group,[264,265] and these differences were sustained to 48 weeks.[266]

The resistance profile of darunavir has not been characterized fully. Several protease mutations, including V11I, V32I, L33F, I47V, I50V, I54L/M, G73S, L76V, I84V, and L89V, are associated with decreased responses to darunavir. When three or more mutations are present at baseline, the probability of treatment failure increases.[267]

ENTRY INHIBITORS

The interaction of HIV-1 with the $CD4^+$ cell membrane involves several specific interactions between the virus and the host and is, therefore, an important target for antiretroviral therapy. First, there is a specific interaction between the HIV envelope protein, gp120, and the $CD4^+$ molecule. This interaction is followed by a conformational change in gp120, allowing this protein to bind to the chemokine coreceptor (CCR5 or CXCR4). Finally, the HIV envelope fuses with the cell membrane via a structural change in the gp41 envelope protein.[5]

Antiretroviral agents are being developed to target each of the steps outlined above, though only one, enfuvirtide, is currently available for clinical use.

FUSION OF THE HIV ENVELOPE WITH THE CELL MEMBRANE

HIV-1 fusion with the $CD4^+$ cell is a multistep process that we are beginning to understand more clearly.[5] The HIV-1 envelope complex of gp120/gp41 is an oligomeric protein, most likely a trimer of three noncovalently bound gp120/gp41 molecules. At some point after gp120 binds to the $CD4^+$ molecule, the gp41 molecule extends its N-terminal end or fusion peptide into the cell membrane. At this point, gp41 undergoes a folding process pulling the HIV-1 membrane into close proximity to the cell membrane and allowing fusion of the membranes in a thermodynamically favorable protein–protein interaction. Enfuvirtide has an amino acid sequence identical to one region in the gp41 molecule allowing it to bind in a hydrophobic groove preventing folding of the gp41 molecule and fusion of the two lipid membranes.

ENFUVIRTIDE

Enfuvirtide (ENF, T-20, Fuzeon) is a 36-amino-acid peptide with a sequence that corresponds exactly to a region of HIV-1 envelope protein gp41. This agent is active in vitro against a wide variety of HIV-1 variants, including variants that use the CXCR4 chemokine receptor (X4), the CCR5 receptor (R5), and dual-tropic viruses. Because ENF is a peptide molecule, like insulin, it cannot be administered orally, and must be administered by a parenteral route. The standard dose is 90 mg twice daily delivered by subcutaneous injection.

The major adverse event with enfuvirtide is injection-site reactions.[268] These reactions occur in almost all patients, are typically mild, but usually result in pruritic subcutaneous nodules, although larger painful inflammatory nodules are occasionally observed. In phase III trials, approximately 3% discontinued treatment because of local reactions. Rarely, allergic reactions can occur. Also in the phase III clinical trials, the use of enfuvirtide was also associated with pneumonias, including typical bacterial pneumonia.[268] The pathophysiology of this association is not understood; however, respiratory symptoms in an individual on enfuvirtide should be investigated thoroughly.

Enfuvirtide will have activity against viruses resistant to agents from the RT and protease inhibitor classes. This fact, coupled with the fact that it is delivered by injection, results in enfuvirtide being used predominantly in moderately to highly treatment-experienced patients. Two parallel phase III studies of enfuvirtide, conducted in almost 1000 patients with extensive prior treatment experience, demonstrated that enfuvirtide added substantial antiretroviral activity to an optimized regimen of multiple agents selected on the basis of resistance testing.[9,10] $CD4^+$ cell responses were also substantially better. Enfuvirtide is probably most useful when combined with one or more agents with substantial activity against a patient's HIV-1. Most recently, this approach has been demonstrated with the newer protease inhibitors, tipranavir and darunavir.[261,266]

Mutations in the region of gp41 at which enfuvirtide binds result in decreased binding of enfuvirtide.[269,270] If combination therapy with enfuvirtide does not suppress

HIV-1 replication to below the limit of detection, resistance to enfuvirtide emerges relatively rapidly.

NEW ANTIRETROVIRAL AGENTS IN LATE-STAGE DEVELOPMENT

There are several agents in three classes in late-stage development, i.e., phase III studies that are nearing primary endpoints and early access programs that are opening in the United States and other developed nations.

Etravirine (TMC 125) is an NNRTI that has in vitro and in vivo activity against viruses resistant to the currently available NNRTI.[271] In short-term phase IIa studies, this agent was extremely active against wild-type virus and retained activity over a 7-day course against viruses resistant to EFV and/or NVP.[272,273] More recently etravirine has been shown to add antiretroviral activity in the setting of late-stage salvage therapy in patients resistant to NNRTI and with three or more primary PI mutations. With rising rates of transmitted NNRTI resistance, this agent may also find utility in earlier stages of HIV treatment. To date, toxicity of this compound has been fairly limited though rash has certainly been observed. The dose of etravirine is 200 mg orally twice daily and will likely be used in later lines of therapy in NNRTI-experienced patients.

An integrase inhibitor, MK 0518 (raltegravir), is also in late-stage development and is widely available in the United States via early access programs. This stand-transfer nhibitor is very potent in vitro, active against viruses resistant to other classes and has demonstrated very potent short-term activity in treatment-naive patients.[274] In a phase II comparative study in treatment-naive patients, MK 0518 combined with tenofovir and emtricitabine had similar response rates over 24 weeks as efavirenz plus the same two NRTI.[19] Fewer adverse events were seen in the MK 0518 treated patients. In highly treatment experienced patients, MK 0518 was vastly superior to placebo when combined with an optimized background regimen in a randomized phase II study.[20] Approximately 65% of patients had HIV RNA levels <50 c/mL at 24 weeks. Adverse event rates were similar to placebo. MK 0518 is metabolized by glucuronidation and has limited interactions with other antiretrovirals and medications metabolized by p450 system. The dose of MK 0518 is 400 mg orally twice daily and also will likely be used, at least initially, in later lines of therapy. A second integrase inhibitor, GS 9137 (elvitegravir), is in early stages of development, has similar potency as MK 0518, requires only once daily dosing but must be given with ritonavir, and has pharmacokinetic interactions with protease inhibitors and NNRTI.[275]

A third class of new agents is the CCR5 antagonist. Two agents, maraviroc and vicriviroc, are in later stages of development, though only maraviroc has begun initial phase III studies. These agents are active again viruses that use CCR5 (R5 viruses) and appear to have no clear antiviral activity in individuals who have HIV-1 that use CXCR4 or both receptors (so-called X4 or dual-mixed virus populations).[7] In a phase II study in highly treatment experienced patients with R5 virus vicriviroc had substantial activity over 24 weeks (approximately 2.0 log10 declines in plasma HIV-1 RNA from baseline).[276] Marviroc is expected to have similar activity. How these agents will be used and whether there will be long-term consequences or adverse events based on their mechanism of action are unknown.

PATIENT MANAGEMENT CONSIDERATIONS

WHEN TO START THERAPY

Current treatment guidelines allow for substantial clinical judgment in the timing of initiation of antiretroviral therapy in treatment-naive individuals in the developed world setting (Table 73-2). DHHS, IAS-USA, and WHO guidelines are consistent in recommending antiretroviral therapy for any individual with symptomatic HIV/AIDS or with a $CD4^+$ cell count $\leq$200 cells/mm^3. In fact, waiting to initiate therapy until $CD4^+$ cell counts are <200 cell/mm^3 results in substantially inferior clinical outcomes (AIDS events and death) in the analyses of multiple clinical cohort studies, even when controlling for lead-time and other biases.[67,277] Unfortunately, many patients present for care with $CD4^+$ cell counts <200 cells/mm^3 or with clinical AIDS diagnoses.[278]

In the United States and other developed countries, guidelines are less directive for patients who have $CD4^+$ cell counts >200 cells/mm^3 (Table 73-2). For individuals with $CD4^+$ cell counts between 201 and 350/mm^3, current guidelines favor therapy initiation. Some cohort data suggest that initiation of therapy in this group results in a favorable clinical outcome, but the evidence is not consistent or overwhelming.[67] Most agree that therapy should be initiated prior to a $CD4^+$ cell count of 200 cells/mm^3; however, the precise $CD4^+$ cell threshold for initiating therapy has not been established. Individuals who initiate HAART at higher $CD4^+$ cell counts are more likely to survive AIDS-free longer. However, significant differences in AIDS-free survival between populations of patients started at $CD4^+$ between 200 and 350 cell/mm^3 and patients started with $CD4^+$ >350 cells/mm^3 have not been consistently seen, though differences have been observed in some studies, particularly in patients with higher viral loads.[277,279] The movement to delay the start of therapy until $CD4^+$ cell counts approached 200/mm^3 was predominantly driven by antiretroviral side effects, especially metabolic and body shape

Table 73-2. Recommendations on Initiation of Antiretroviral Therapy in Treatment-Naive Adult and Adolescent Patients[a] with Chronic HIV Infection

Clinical Staging	Recommendation
Symptomatic	
AIDS-defining illness or severe symptoms	Initiate antiretroviral therapy
Asymptomatic	
$CD4^+$ <200 cells/mm^3	Initiate antiretroviral therapy
$CD4^+$ >200 ≤350 cells/mm^3	Offer treatment (DHHS) Consider treatment (IAS-USA)
$CD4^+$ >350 ≤500 cells/mm^3 HIV RNA >100,000 c/mL	Most clinicians defer; some recommend treatment (DHHS) Consider treatment[b] (IAS-USA)
HIV RNA <100,000 c/mL	Defer therapy (DHHS) Generally not recommended (IAS-USA)
$CD4^+$ >500 cells/mm^3[c]	Generally not recommended (IAS-USA)

[a]Men and non-pregnant women.

[b]IAS-USA guidelines also recommend considering thearpy if there is rapid $CD4^+$ cell decline.

[c]This $CD4^+$ cell stratum not listed separately in DHHS Guidelines.

Adapted from Hammer SM, Saag MS, Schechter M, et al. Treatment for adult HIV infection: 2006 recommendations of the International AIDS Society–USA panel. *JAMA* 2006; 296: 827–843; Panel on Clinical Practices for the Treatment of HIV Infection, DHHS guidelines, 2006.

changes, coupled with concern that patients would be at greater risk for accumulating resistant HIV-1. More recently, therapy has become much simpler, with initial regimens that are composed of only one or two pills daily. In addition, metabolic side effects are much better understood, and newer regimens are less likely to cause lipoatrophy, lipoaccumulation, peripheral neuropathy, insulin resistance, or marked hyperlipidemia. Also, potent initial therapies are very successful, and even individuals with virologic failure on initial treatment are very unlikely to have viruses exhibiting broad cross-class resistance.[280] Logical arguments for earlier initiation of therapy have been made,[281] and many clinicians favor initiation of antiretroviral therapy when $CD4^+$ cell counts are at or above 350/mm^3.

WHEN TO SWITCH THERAPY

In clinical trials, the vast majority of patients receiving initial antiretroviral therapy have plasma HIV RNA levels that fall to and remain below detectable limits for 3 years or more.[94,234,282] While results in clinical cohorts have not been as robust, proportions of treated patients who have HIV RNA levels suppressed below the limit of detection have been increasing. However, for those patients on initial or subsequent regimens who have persistent detectable HIV-1 RNA or a rebound in plasma HIV RNA to above detectable limits, the precise time to switch to a new regimen has not been clearly defined. Typically, patients with relatively low levels of HIV RNA (<10,000 copies/mL) have stable $CD4^+$ cell counts and do not show signs of clinical progression. A declining $CD4^+$ cell count or a return of HIV/AIDS signs and symptoms would be a strong indication for changing antiretroviral therapy. If however the only indication that therapy is "failing" is a reproducibly detectable HIV RNA level, then altering therapy is based on clinical opinion and limited objective data. Factors that impact the decision include:

1. Assessment of adherence to the current regimen. Intermittent or partial adherence is a likely cause of persistent or recurrent viremia in a patient on a potent regimen with limited previous antiretroviral resistance. Altering therapy in a patient who is struggling with adherence is unlikely to lead to the desired therapeutic response.
2. Treatment options available. No matter how many previous regimens a patient has experienced, the goal of antiretroviral therapy should be to suppress HIV replication to below detectable limits. Therefore, if a regimen can be constructed that contains more than two active agents, a

Table 73-3. Recommendations for Resistance Testing

Clinical Scenario	Comments[d]
Antiretroviral-naive individual[a]	
Acute infection	Optimal time to detect transmitted drug resistance will influence drug choices if therapy is instituted
Recent infection	Earlier testing increases likelihood that transmitted resistant variants will be detected
Chronic infection (>2 yr)	Transmitted resistant variants may be seen in 5–15%; minority variants may not be detected
Antiretroviral-experienced individuals	
Suboptimal suppression following therapy initiation[b]	Minority resistant variants may emerge rapidly with the selective pressure of treatment
Virologic failure[c]	Will help maximize the number of active agents in a new regimen; Minimal resistance might suggest poor drug exposure or problems with adherence
Following ART discontinuation	Superior replication of wild-type virus occurs within 4–8 weeks; resistance testing after drug discontinuation may be misleading and is not recommended
Pregnancy	A pregnant woman with detectable plasma HIV RNA should have resistance testing regardless of treatment history

[a]Genotype resistance testing may be optimal in this setting as some mutations that are clear markers of transmitted resistance may have little or no effect on phenotype.

[b]There is no precise definition but plasma HIV RNA level should fall by approximately 2 $\log_{10}$ (100-fold) in 4 weeks.

[c]In patients with complex treatment history, a combination of genotype and phenotype resistance testing may be most helpful.

[d]Resistance testing is most likely to be successful if plasma HIV RNA level is >500–1000 c/mL.

Adopted from Hammer SM, Saag MS, Schechter M, et al. Treatment for adult HIV infection: 2006 recommendations of the International AIDS Society-USA panel. *JAMA* 2006; 296: 827–843; Hirsch MS, Brun-Vezinet F, Clotet B, Conway B, et al. Antiretroviral drug resistance testing in adults infected with human immunodeficiency virus type 1: 2003 recommendations of an International AIDS Society-USA Panel. *Clin Infect Dis* 2003; 37: 113–128.

change in therapy is typically recommended. Determining "active" agents is done through a careful treatment history and resistance testing[283] (Table 73-3). Medications from a class to which the patient is naive are likely to have the most activity.

3. Clinical status. Patients with advanced disease, such as those with a low $CD4^+$ cell count or ongoing AIDS diagnosis, may need to switch therapy even if a regimen with more than two active agents cannot be constructed.
4. Resistance risk. Ongoing viral replication in the presence of antiretroviral drugs will result in emergence of resistance over time.
5. The speed at which new mutations emerge depends on the strength of the selective pressure, the number of mutations required for the virus to "achieve" resistance, and the relative fitness of the resistance variant. In general, single mutations that result in high levels of resistance emerge rapidly and can lead to accumulation of further resistance mutations. Patients on initial regimens are typically switched earlier following confirmed detectable HIV replication than those patients who already have HIV variants with substantial resistance mutation, as viruses in patients with fewer mutations tend to accumulate resistance mutations more rapidly.[284]

Varied opinions exist on whether to switch patients who have low-level viremia (plasma HIV RNA levels in the 50–1000 c/mL), especially in patients who are tolerating their treatment and have high, stable, or even rising $CD4^+$ cell counts. Clinicians need to balance the risk of selection of

resistance mutations with the risks of any new therapy. Patients with treatment options that are very likely to be effective and are relatively uncomplicated may be served by changing therapy rapidly once HIV-1 replication is reproducibly detected and adherence and toxicity issues are addressed.

SALVAGE/RESCUE THERAPY

Highly treatment experienced patients with HIV-1 variants resistance to multiple agents present a common treatment challenge to clinicians. Many of these patients received non-HAART prior to receiving HAART, or they began therapy with less potent HAART regimens.[280] In addition, transmission of multiple drug-resistant variants has been well documented.[285,286] The ultimate goal of antiretroviral therapy is to preserve the long-term health of the infected individual. For most patients, this goal is likely to be achieved by suppression of HIV-1 replication to below detectable limits. Until recently, the goal of full virologic suppression was not possible for patients with highly resistant virus because the goal was unattainable or the number and combinations of ARV required was difficult to adhere to, poorly tolerated, and marginally successful. However, with the introduction of multiple new agents with activity against resistant variants, such as enfuvirtide, darunavir, and tipranavir, and the promise of new agents now in later stages of development, treatment guidelines now state that the goal of antiretroviral therapy in moderate to highly experienced patients is to suppress HIV-1 replication to below the limits of detection in blood plasma.[92,93] If at least two new agents anticipated to have a high level of activity can be combined with additional agents with partial activity, then the likelihood that a highly treatment experienced patient will achieve a plasma HIV RNA below the limit of detection appears to be above 40%, and has been as high as 60–70% in studies of darunavir/ritonavir.[109,261,264,266,268]

For an individual patient, knowing whether there are two or more active agents to which the patient's virus is susceptible, requires substantial clinical acumen. Advice of an expert HIV clinician may be particularly valuable. Treatment history is very important, and resistance testing is standard in this setting (Table 73-3).[283] Antiretroviral drug prescribing information for the newer agents now routinely includes data on resistance and response, and this information may be particularly helpful for the newer protease inhibitors, darunavir and tipranavir. HIV-1 variants with high-level resistance to these agents are uncommon but can occur and, therefore, activity of either of these medications in highly treatment experienced patients should not be assumed. Fortunately, many variants that are resistant to one of these two agents may not be resistant to the other. In general, an antiretroviral agent from a class of drugs to which the patient is naive is likely to have activity, though this activity can be quickly lost if the rest of the regimen has limited antiretroviral activity. Most experts would include nucleoside analogs in most salvage regimens. NRTI may have residual activity against viruses with resistance, perhaps by compromising fitness of the virus or via residual direct antiretroviral activity.[179,180,287] Much of this activity may be attributed to lamivudine (3TC).[178] Information about when newer drugs will become available, either through expanded access programs or via regulatory agency approval, is essential for treatment decision making in the highly treatment experienced patient. If a new agent is likely to become available soon, postponing a change in therapy may be the best decision, assuming that the patient is not in serious clinical danger.

TREATMENT INTERRUPTIONS

Interruptions of antiretroviral treatment have been proposed as a strategy to address several clinical issues in different treatment situations. Current evidence, however, suggests that once an individual has HIV replication suppressed on therapy, that person needs life-long therapy. Treatment interruptions have been proposed as a way to address treatment fatigue and a way to avoid toxicity and conserve resources particularly in developing world settings. Two recent large randomized studies, one in resource rich countries and another in a resource poor setting, demonstrated that $CD4^+$ cell count guided treatment interruptions, with therapy restarted when $CD4^+$ counts fell to 250/mm^3, significantly increased the risk of serious HIV/AIDS-related clinical events; in the developed world study, the cumulative risk of non-AIDS complications such as cardiovascular events, and liver and kidney failure was also significantly higher.[288,289] Other strategies including fixed interval interruptions or $CD4^+$ cell count guided interruptions with a higher $CD4^+$ threshold are under study.[290]

A second proposed use for therapy interruption was in advanced patients with highly resistant virus who do not have HIV replication suppressed as measured by plasma HIV RNA levels. The hypothesis was that therapy interruption would allow outgrowth of wild-type virus that would then be more responsive to combination salvage antiretroviral therapy. This strategy also failed in several clinical trials.[291–294] In two of the trials, not only were treatment responses no better following interruption compared to therapy switch without interruption, but there were increased clinical events in the group of patients who were randomized to interruption.[292–294]

A third proposed use of treatment interruptions is in individuals with HIV replication suppressed on therapy. In this scenario, individuals undergo treatment interruptions to allow HIV to replicate and stimulate HIV-specific

immune responses, in a sense immunizing the patient. Therapy is then restarted and this cycle may be repeated several times. Ultimately antiretroviral treatment is stopped and viral set point is then examined. Multiple studies have investigated this approach, though few were randomized. In acutely infected patients treated with antiretrovirals very early after infection, this strategy was thought to have the greatest chance of success, as preservation of some HIV-1-specific immune responses could be demonstrated.[295] In this population, initial results were encouraging but long-term sustained suppression of HIV replication off therapy was not observed.[41,42] In a recent randomized trial in chronically infected patients, significant differences in viral replication parameters were observed following strategic treatment interruptions compared to patient maintained on continuous therapy when both groups stopped therapy.[296] These results suggest that some measure of immune control can be induced; however, these responses appear modest, and more effective, safer strategies are needed. Notably in the same study, immunization with a canary pox HIV-1 vaccine had no effect on viral kinetics or set point.

Given the disappointing results in clinical trials evaluating each of the treatment interruption strategies, treatment interruptions in successfully treated patients should be discouraged. Even in patients who have incomplete suppression of their HIV replication and advanced immunosuppression, maintaining antiretroviral treatment is associated with better survival and fewer AIDS events. In clinical practice, however, patients will stop therapy either because of toxicity, treatment fatigue, mental illness, substance abuse, or other factors. If a clinician is aware that a patient is going to stop therapy, then careful follow-up with $CD4^+$ cell count monitoring should be arranged. In addition, if a patient is on an NNRTI plus nucleoside (with or without other agents), the NNRTI should probably be stopped first, given the different half-lives between the two classes of drugs. The optimal timing of discontinuation is not known, but several studies have used 7 days between stopping efavirenz or nevirapine and stopping the nucleoside analogs.

SPECIAL CONSIDERATIONS

TRANSMISSION OF RESISTANT VIRUS

Drug-resistant HIV-1 variants can be transmitted from an infected individual to their sexual partners, while sharing needles, or during mother-to-child transmission(MTCT). Many groups around the world have attempted to quantify the prevalence of transmitted resistance in different locations.[297–302] Primary resistance (transmission of virus with at least one resistance-associated mutation) has a prevalence of 5–15%, depending on the population and how specific mutations are scored. Some resistance mutations such as those at RT codon 215 and NNRTI resistance mutations appear more commonly. Others, such as the 3TC resistance mutation M184V, which is highly prevalent in treatment-experienced patients, is uncommonly seen in patients with primary or transmitted resistance. Most treatment guidelines recommend resistance testing for treatment-naive patients when they enter care, especially if they are within a few years of acquiring the infection (Table 73-3). Any resistance mutation in this setting should raise concern, as other mutations may have been transmitted but reverted to the wild-type over time.

ANTIRETROVIRAL THERAPY IN THE DEVELOPING WORLD

A full discussion of antiretroviral therapy in the developing world is beyond the scope of this text, although some basic principles can be discussed. Recent WHO guidelines provide more detailed information.[162] Because of the very large numbers of individuals that must be treated, as well as cost concerns, a public-health approach to antiretroviral therapy may be necessary.[303] In such an approach, virtually all patients are treated with the same regimen and that regimen is usually selected based on a balance among antiviral activity, cost, convenience, toxicity, and availability.[304] In early years, a fixed-dose combination of nevirapine, lamivudine, and stavudine was the mainstay of treatment for much of the developing world. This approach has been effective, though the limited monitoring available may result in substantial selection of resistant variants.[305] In addition, the toxicities of stavudine in resource poor settings are considerable, just as they were in more resource-rich settings. Treatment guidelines from the WHO have been recently updated and encourage alternatives to stavudine, when possible.[162] Recommendations also include beginning antiretroviral therapy at or above a $CD4^+$ cell count of 200 cells/mm^3 in asymptomatic patients, not waiting until the $CD4^+$ cell count is less than 200/mm^3 (Table 73-4). The progress in the roll out of antiretroviral therapy to many developing countries has been remarkable. However, without effective prevention strategies, infections will likely continue to outstrip our ability to provide sustained antiretroviral therapy to all those who need it.

MOTHER TO CHILD TRANSMISSION

In the developed world, interruption of MTCT focuses on suppression of HIV-1 replication in the pregnant woman using standard combination antiretroviral therapy (HAART)

Table 73-4. Recommendations on Initiation of Antiretroviral Therapy in Treatment-Naive Adult and Adolescent Patients with Chronic HIV Infection in Resource Limited Settings

$CD4^+$ Criteria	Recommendation
<200 cells/mm^3	Treat irrespective of clinical stage
200–350 cells/mm^3	
Stage 4 disease and some stage 3 (e.g., TB)	Initiate antiretroviral therapy
All other individual	Consider treatment and initiate before $CD4^+$ cell count drops bellow 200/mm^3
>350 cells/mm^3	Do not initiate therapy

Adapted from World Health Organization. *Antiretroviral Therapy for HIV Infection in Adults and Adolescents in Resources-Limited Settings: Towards Universal Access Recommendations for a Public Health Approach,* 2006.

guided, in many situations, with resistance testing (Table 73-3). Many clinicians would include zidovudine in the combination because of older efficacy data[306] and considerable experience with this agent, and avoid efavirenz because of the risk of teratogenicity. Given that nevirapine should be avoided in women with $CD4^+$ cell counts greater than 250/mm^3, many MTCT regimens are protease inhibitor-containing regimens. Women who do not meet guidelines for treatment based on clinical status ($CD4^+$ cell count, plasma HIV RNA level, and/or clinical symptoms) may discontinue therapy after delivery. HIV-1-infected women in developed countries should not breast feed their infants regardless of treatment status.

Full discussion of MTCT in the developing world setting is beyond the scope of this text.[307,308] Single-dose nevirapine decreases vertical transmission substantially, is cost-effective, and can be implemented on a large scale.[309] However, this strategy selects for nevirapine resistance in a substantial proportion of the women,[217,218] and this may have an impact on subsequent NNRTI-based therapy.[310] Strategies to decrease selection of resistant virus in the mother are under investigation.[311]

ANTIRETROVIRAL DRUGS FOR PREVENTION

There are three ways antiretroviral therapy can be used to prevent transmission of HIV: by treatment of the infected individual, as preexposure prophylaxis (PrEP) or as PEP. This topic has been extensively reviewed.[312]

The belief that ART treatment of the infected subject can interrupt transmission to discordant sexual partners comes from the well-recognized relationship between the viral load and horizontal transmission probability[313] and the experiences with HAART and MTCT. In addition, recent observational studies have noted greatly reduced transmission of HIV in discordant couples where a partner has started ART.[314]

The belief that ART can prevent HIV acquisition before or after exposure stems from extensive experiments with nonhuman primates. Tenofovir provided to macaques shortly before or within 72 hours after exposure reduces the probability of HIV transmission.[315] However, more recent work with tenofovir–emtricidaine suggests that the latter combination is more reliable in the macaque model.[316]

Careful consideration of antiviral therapy for PEP has, de facto, become the standard of care in many settings and has been the subject of intense, worldwide policy formation. In all cases, therapy must be based on risk assessment, be started emergently, and use ART combinations that recognize the possibility of de novo resistance, toxicity, and adherence, and in some cases genital tract pharmacology.

Percutaneous exposure to blood from an infected individual carries an approximately 0.3% chance of seroconversion.[317] Mucous membrane exposure to HIV-1-infected blood or other body fluids conveys less risk.[318] The use of antiretroviral therapy as postexposure prophylactic therapy is now accepted standard of care for blood or specific body fluid exposures in the health-care setting. PEP following sexual exposure remains controversial. CDC recommendations for the PEP of occupational exposures to HIV are summarized in Table 73-5.[318] Some experts, including the authors, would strongly consider three-drug therapy in any setting in which PEP is being offered. The optimal duration for administration of PEP is unknown. Four weeks of therapy is recommended. PEP should begin as soon as possible after exposure, though the interval between exposure and initiation of PEP at which PEP is no longer effective is unknown.

Table 73-5. Recommendations for HIV Postexposure Prophylaxis

Percutaneous

	Infection Status of the Sources			
Exposure type	**HIV class 1 (low viral load)**	**HIV class 2 (AIDS, high viral load, resistant virus)**	**Unknown HIV Status[c]**	**Unknown Sources (e.g., needle box)**
Less severe (solid needle or superficial injury)	Two-drug PEP[a]	≥Three-drug PEP[b]	No PEP; consider two-drug PEP if source had HIV risk factors	No PEP: consider two-drug PEP if exposure HIV-infected source is likely
More severe (hollow bore, deep puncture, visible blood, needle used in artery or vein)	≥Three-drug PEP	≥Three-drug PEP	No PEP; consider two-drug PEP if source had HIV risk factors	No PEP: consider two-drug PEP if exposure to HIV-infected source is likely

Mucous Membrane and nonintact skin

Exposure type	**HIV class 1 (low viral load)**	**HIV class 2 (AIDS, high viral load, resistant virus)**	**Unknown HIV Status[c]**	**Unknown Sources (e.g., needle box)**
Small volume (few drops)	Consider two-drug PEP	Two-drug PEP	Generally no PEP warranted	Generally no PEP warranted
Large volume (e.g., major blood splash)	Two-drug PEP	≥Three-drug PEP	No PEP; consider two-drug PEP if source had HIV risk factors	No PEP: consider two-drug PEP if exposure to HIV-infected source is likely

[a]Two-drug PEP consists of two NRTI one of which is either lamivudine or emtricitabine; the preferred other is either zidovudine or tenofovir all at standard doses.

[b]Three-drug PEP consists of the NRTI combinations listed above plus lopinavir/ritonavir at standard doses. Alternatives include atazanavir RTV, fosamprenavir RTV, Indinavir with or without RTV, Saquinavir RTV, nelfinavir, efavirenz.

[c]If the source patient is found to be HIV negative PEP should stop.

Note: If the source patient has resistant virus or a complex treatment history, PEP should NOT be delayed but expert opinion should be sought and the PEP regimen may be tailored to the viral variants likely to be present in the source. Resistance testing of the source virus may be useful, though not recommended by the CDC. PEP should NOT be delayed for results of resistance, viral load, or HIV testing from the source patient.

74 Preventing Opportunistic Infections Among HIV-Infected Persons

Jonathan E. Kaplan and Henry Masur

The natural history of untreated infection with the human immunodeficiency virus (HIV) is characterized by an inexorable decline in host immunity, culminating in the appearance of opportunistic infections (OIs) that define the acquired immunodeficiency syndrome (AIDS). In the early years of the AIDS epidemic, before treatment was available, the average time from acquisition of HIV infection to development of AIDS was estimated to be 8–11 years.[1]

The circulating $CD4^+$ T lymphocyte count is the best indicator of current susceptibility to OIs and to short-term prognosis. Because of the relationship between the $CD4^+$ T lymphocyte count and the risk of OI, this parameter is the standard indicator for when specific chemoprophylactic regimens should be initiated. For example, *Pneumocystis jiroveci* pneumonia (PCP) generally occurs when the $CD4^+$ T lymphocyte count is below 200 cells/mm,[3] and prophylaxis against PCP is recommended for persons with $CD4^+$ T lymphocyte counts below this level. Disseminated *Mycobacterium avium* complex (MAC) disease generally occurs at CD4 counts less than 50 cells/mm^3 (Fig. 74-1).

Chemoprophylaxis against PCP was recommended for adults and adolescents in 1989[2] and for HIV-exposed/infected children in 1991.[3] Prophylaxis against MAC was recommended in 1994.[4] The USPHS/IDSA Guidelines for the prevention of OIs in HIV-infected persons, which includes recommendations for chemoprophylactic, vaccine, and behavioral interventions, were first published in 1995,[5] were revised in 1997, 1999, and 2002,[6–8] and are undergoing further revision at the time of this writing.

The most significant intervention against OIs has been combination antiretroviral therapy (ART), introduced (as triple drug therapy) in 1995. Following the introduction of triple drug ART, incidence of all major OIs dropped markedly, including many for which specific prophylaxis and treatment were unavailable (Fig. 74-2). This effect was so pronounced that the incremental benefit of chemoprophylaxis and other prevention measures in persons on ART could be reasonably questioned. However, in one study, survival benefits of PCP and MAC prophylaxis and pneumococcal vaccination in AIDS patients were demonstrated even in the presence of ART.[9] Furthermore, low $CD4^+$ T lymphocyte counts indicate immediate risk of OI, whereas the benefits of ART are only gradually accrued over a 3–6-month period.[10] Therefore, chemoprophylaxis against OIs continues to be recommended based on $CD4^+$ T lymphocyte count regardless of ART treatment, although many such regimens can be discontinued when $CD4^+$ T lymphocyte counts increase in persons successfully treated with ART.[8]

Prevention of OIs in HIV-infected persons begins with the diagnosis of HIV. It is sobering that PCP, a preventable infection in HIV-infected persons, continues to occur and remains one of the most common AIDS-presenting illnesses, even in the era in which most AIDS cases are diagnosed immunologically, based on a $CD4^+$ T lymphocyte count less than 200 cells/mm^3.[11] In an analysis of cases of PCP reported in CDC's Adult and Adolescent Spectrum of Disease Project, 43% of cases of PCP occurred in persons previously undiagnosed with HIV or otherwise not in care (Fig. 74-3). Of the estimated 1,100,000 HIV-infected persons in the United States, about 1/4 are thought to be unaware of their HIV status.[12] Therefore, counseling and testing of persons at risk for HIV are critical for OI prevention, as well as for preventing transmission of HIV to others. HIV testing should be offered to persons with identifiable behavioral risk factors for HIV (men who have sex with men, injecting drug users, and persons with multiple sex partners) and persons with medical conditions suggestive of HIV infection.[11] In addition, all pregnant women should be tested for HIV.[11]

This chapter summarizes important interventions for preventing OIs in HIV-infected persons; these recommendations apply to both persons taking and not taking ART. For the sake of brevity, not all materials presented in the USPHS/IDSA guidelines for preventing OIs in HIV-infected persons are included here. However, as in the USPHS/IDSA guidelines, recommendations are divided into those for preventing exposure to OI pathogens, those for preventing first episodes of OI, and those for preventing disease recurrence. Chemoprophylaxis and vaccination recommendations included in the USPHS/IDSA

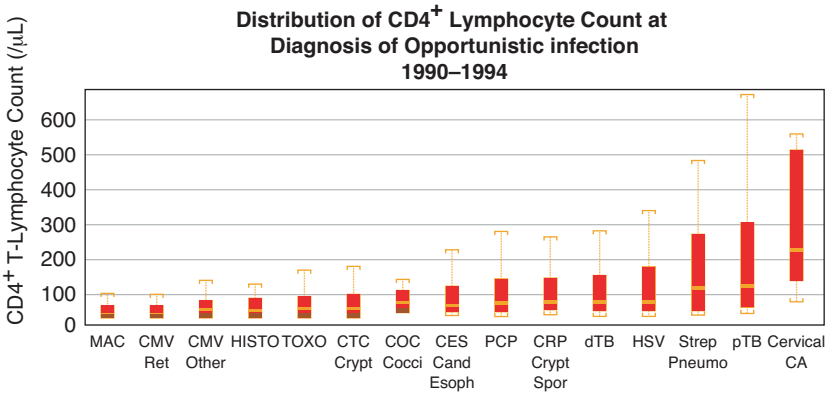

FIGURE 74-1. Distribution of CD4+ lymphocyte counts at diagnosis of opportunistic infection, 11 U.S. cities, 1990–1994. Source: Adult and Adolescent Spectrum of HIV Disease Project, Centers for Disease Control and Prevention. The bar represents the median CD4+ value; the box, the interquartile (25–75%) range; and the brackets, the range of values, excluding outliers. MAC = disseminated *Mycobacterium avium* complex; CMV = cytomegalovirus; HISTO = histoplasmosis; TOXO = toxoplasmosis; CTC = cryptococcosis; COC = coccidioidomycosis; CES = Candida esophagitis; PCP = *Pneumocystis jiroveci* pneumonia; CRP= cryptosporidiosis; dTB = disseminated tuberculosis; HSV = disseminated herpes simplex virus; CA = cancer.

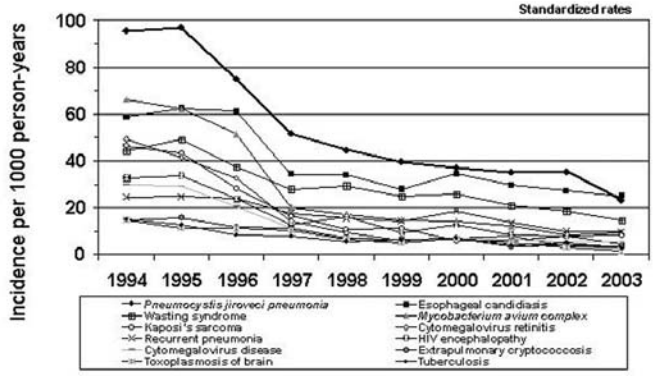

FIGURE 74-2. Annual trends in the 12 most common incident opportunistic illnesses, Adult and Adolescent Spectrum of HIV Disease Project, 1994–2003. Incidence rates are standardized to the population of AIDS cases reported nationally by CD4 count, age, sex, race, HIV risk mode, and birth origin.

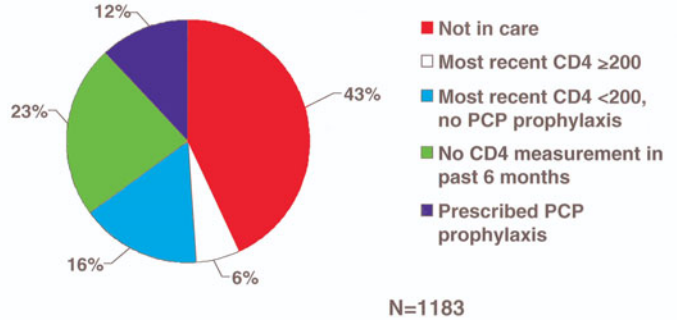

FIGURE 74-3. Classification of cases of *Pneumocystis jiroveci* pneumonia, Adult and Adolescent Spectrum of HIV Disease Project, 2000–2003.

guidelines, including those for discontinuing prophylaxis in patients whose CD4+ T lymphocyte counts have increased in response to ART, are included (Tables 74-1 to 74-3).

PNEUMOCYSTIS JIROVECI PNEUMONIA (PCP)

PREVENTING EXPOSURE

Although an environmental source may exist, *P. jiroveci* infection appears to be spread primarily from human to human. Thus, preventing exposure to humans, who are excreting the organism, would be a logical method to avoid disease. However, almost all humans appear to be infected during the first few years of life,[13–15] and it is not clear how often disease occurs due to reactivation of a latent focus of infection versus recent acquisition of a new strain.[16–18] Given these uncertainties, it is reasonable to isolate susceptible patients from individuals known to have PCP. However, whether such isolation would prevent transmission of *P. jiroveci* and prevent cases of PCP is unknown.

PREVENTING DISEASE

Chemotherapy has been proven to prevent PCP and to prolong survival for HIV-infected patients. Patients with CD4+ T cell counts <200 cells/mm^3 or <14% are known to be susceptible.[19–21] Risk increases with decreasing CD4+ T lymphocyte count. In addition, patients with a history of PCP and patients who have had oropharyngeal candidiasis should be offered prophylaxis regardless of their CD4+ T lymphocyte count.[19,20]

About 10–15% of cases of PCP occur in patients with CD4+ T lymphocyte counts >200 cells/mm^3.[19] Some but not all of these patients would have been eligible for PCP prophylaxis due to history of oral candidiasis. However, prophylaxis is not recommended for these patients in general because a very large number of patients would require prophylaxis in order to prevent a small number of cases of PCP.

Other risk factors for PCP include a previous episode of pneumonia of any type, unexplained weight loss, high HIV viral load, positive plasma CMV PCR, history of AIDS-defining illness, and rapid decline in CD4+ T lymphocyte count.[20]

Trimethoprim-sulfamethoxazole (TMP-SMX) is the prophylactic agent of choice.[2,22–25] TMP-SMX is more effective than other agents and is reasonably well tolerated. Patients may develop nausea and vomiting, rash, pruritis, hepatitis, anemia, leucopenia, or thrombocytopenia due to this agent. However, these complications are rarely life threatening. Chemopro-phylaxis can often be continued despite these toxicities.

Table 74-1. Prophylaxis to Prevent First Episode of Opportunistic Disease Among Adults and Adolescents Infected with HIV

Pathogen	Indication	Preventive Regimen	
		First Choice	Alternative
I. Strongly recommended as standard of care			
Pneumocystis jiroveci	$CD4^+$ count of <200/μL or oropharyngeal candidiasis	Trimethoprim-sulfamethoxazole (TMP-SMZ), 1 double-strength tablet (DS) by mouth, daily or TMP-SMZ, 1 single-strength tablet (SS) by mouth daily	Dapsone, 50 mg by mouth, twice daily or 100 mg by mouth daily; dapsone, 50 mg by mouth daily plus pyrimethamine, 50 mg by mouth weekly plus leucovorin, 25 mg by mouth weekly; dapsone, 200 mg by mouth plus pyrimethamine, 75 mg by mouth plus leucovorin, 25 mg by mouth weekly; aerosolized pentamidine, 300 mg monthly via Respirgard II™ nebulizer (manufactured by Marquest, Englewood, Colorado); atovaquone, 1500 mg by mouth daily; TMP-SMZ, 1 DS by mouth three times weekly
Mycobacterium tuberculosis, Isoniazid-sensitive	Positive test for latent *M. tuberculosis* infection (tuberculin skin test or interferon-gamma release assay), or prior positive test without treatment, or contact with person with active tuberculosis, regardless of latent *M. tuberculosis* test result	Isoniazid, 300 mg by mouth plus pyridoxine, 50 mg by mouth daily for 9 mo or isoniazid, 900 mg by mouth plus pyridox Ine, 100 mg by mouth, twice weekly for 9 mo	Rifampin, 600 mg by mouth daily for 4 mo or rifabutin 300 mg by mouth daily for 4 mo;
Isoniazid-resistant	Same as previous pathogen; increased probability of exposure to isoniazid-resistant tuberculosis	Rifampin, 600 mg by mouth daily for 4 mo or rifabutin, 300 mg by mouth daily for 4 mo	
Multidrug-resistant (isoniazid and rifampin)	Same as previous pathogen; increased probability of exposure to multidrug-resistant tuberculosis	Choice of drugs requires consultation with public health authorities; depends on susceptibility of isolate from source patient	
Toxoplasma gondii	Immunoglobulin G (μgG) antibody to Toxoplasma and $CD4^+$ count of <100/μL	TMP-SMZ, 1 DS by mouth daily	TMP-SMZ, 1 SS by mouth daily; dapsone, 50 mg by mouth daily plus pyrimethamine, 50 mg

(*Continued*)

Table 74-1. (*Continued*)

Pathogen	Indication	Preventive Regimen	
		First Choice	Alternative
			by mouth weekly plus leucovorin, 25 mg by mouth weekly; dapsone, 200 mg by mouth plus pyrimethamine, 75 mg by mouth plus leucovorin, 25 mg by mouth weekly; atovaquone, 1500 mg by mouth daily with or without pyrimethamine, 25 mg by mouth daily plus leucovorin, 10 mg by mouth daily
Mycobacterium avium complex	$CD4^+$ count of <50/μL	Azithromycin, 1200 mg by mouth weekly or clarithromycin, 500 mg by mouth twice daily	Rifabutin, 300 mg by mouth daily; azithromycin, 1200 mg by mouth weekly plus rifabutin, 300 mg by mouth daily
Varicella-zoster virus (VZV)	Substantial exposure to chickenpox or shingles for patients who have no history of either condition or, if available, negative antibody to VZV	Varicella-zoster immune globulin (VZIG), 5 vials (1.25 mL each) intramuscularly, administered <96 h after exposure, ideally in <48 h	–
II. Usually recommended			
Streptococcus pneumoniae	$CD4^+$ count of >200/μL	23-valent polysaccharide vaccine, 0.5 mL intramuscularly	–
Hepatitis B virus	All susceptible patients (i.e., antihepatitis B core antigen-negative)	Hepatitis B vaccine: 3 doses	–
Influenza virus	All patients (annually, before influenza season)	Inactivated trivalent influenza virus vaccine: one annual dose (0.5 mL) intramuscularly	Oseltamivir, 75 mg by mouth daily (influenza A or B); Rimantadine, 100 mg by mouth twice daily; or amantadine, 100 mg by mouth twice daily (influenza A only)
Hepatitis A virus	All susceptible patients at increased risk for hepatitis A infection (i.e., antihepatitis A virus-negative) (e.g., illegal drug users, men who have sex with men, hemophiliacs) or patients with chronic liver disease, including chronic hepatitis B or C	Hepatitis A vaccine: two doses	–

Table 74-1. (*Continued*)

Pathogen	Indication	Preventive Regimen	
		First Choice	Alternative
III. Evidence for efficacy but not routinely indicated			
Bacteria	Neutropenia	Granulocyte-colony-stimulating factor (G-CSF), 5–10 µg/kg body weight subcutaneously daily for 2–4 wks or granulocyte-macrophage colony-stimulating factor (GM-CSF), 250 µg/m2 subcutaneously for 2–4 wks	–
Cryptococcus neoformans	$CD4^+$ count of <50/µL	Fluconazole, 100–200 mg by mouth daily	Itraconazole capsule, 200 mg by mouth daily
Histoplasma capsulatum	$CD4^+$ count of <100/µL, endemic geographic area	Itraconazole capsule, 200 mg by mouth daily	–

Table 74-2. Prophylaxis to Prevent Recurrence of Opportunistic Disease After Chemotherapy for Acute Disease Among Adults and Adolescents Infected with HIV

Pathogen	Indication	Preventive Regimen	
		First Choice	Alternative
I. Recommended as standard of case			
Pneumocystis jiroveci	Prior *P. jiroveci* pneumonia (PCP)	Trimethoprim-sulfamethoxazole (TMP-SMZ), 1 double-strength tablet (DS) by mouth daily; TMP-SMZ 1 single-strength tablet (SS) by mouth daily	Dapsone, 50 mg by mouth twice daily or 100 mg by mouth daily; dapsone, 50 mg by mouth daily plus pyrimethamine, 50 mg by mouth weekly plus leucovorin, 25 mg by mouth weekly; dapsone, 200 mg by mouth plus pyrimethamine, 75 mg by mouth plus leucovorin, 25 mg by mouth weekly; aerosolized pentamidine, 300 mg every month via Respirgard II™ nebulizer (manufactured by Marquest, Englewood, Colorado); atovaquone, 1500 mg by mouth daily; TMP-SMZ, 1 DS by mouth 3 times weekly

(*Continued*)

Table 74-2. (*Continued*)

Pathogen	Indication	Preventive Regimen	
		First Choice	Alternative
Toxoplasma gondii	Prior toxoplasmic encephalitis	Sulfadiazine, 500–1000 mg by mouth 4 times daily plus pyrimethamine, 25–50 mg by mouth daily plus leucovorin, 10–25 mg by mouth daily	Clindamycin, 300–450 mg by mouth every 6–8 h plus pyrimethamine, 25–50 mg by mouth daily plus leucovorin 10–25 mg by mouth daily; atovaquone, 750 mg by mouth every 6–12 h with or without pyrimethamine, 25 mg by mouth daily plus leucovorin, 10 mg by mouth daily
Mycobacterium avium complex	Documented disseminated disease	Clarithromycin, 500 mg by mouth twice daily plus ethambutol, 15 mg/kg body weight by mouth daily with or without rifabutin, 300 mg by mouth daily	Azithromycin, 500 mg by mouth daily plus ethambutol, 15 mg/kg body weight by mouth daily with or without rifabutin, 300 mg by mouth daily
Cytomegalovirus	Prior retinitis	Valganciclovir 900 mg by mouth daily; or ganciclovir sustained-release implant every 6–9 months with or without oral valganciclovir	Ganciclovir, 5–6 mg/kg body weight/day intravenously 5–7 d weekly; foscarnet, 90–120 mg/kg body weight intravenously daily; cidofovir, 5 mg/kg body weight intravenously every other week with probenecid 2 gm by mouth 3 h before the dose followed by 1 gm by mouth 2 h after the dose, and 1 gm by mouth 8 h after the dose (total of 4 gm); or fomivirsen 1 vial (330 µg) injected into the vitreous, then repeated every 2–4 wk
Cryptococcus neoformans	Documented disease	Fluconazole, 200 mg by mouth daily	Amphotericin B, 0.6–1.0 mg/kg body weight intravenously weekly–3 times weekly; itraconazole, 200-mg capsule by mouth daily
Histoplasma capsulatum	Documented disease	Itraconazole capsule, 200 mg by mouth twice daily	Amphotericin B, 1.0 mg/kg body weight intravenously weekly
Coccidioides immitis	Documented disease	Fluconazole, 400 mg by mouth daily	Amphotericin B, 1.0 mg/kg body weight intravenously weekly; itraconazole, 200-mg capsule by mouth twice daily
Salmonella species, (nontyphi)	Bacteremia	Ciprofloxacin, 500 mg by mouth twice daily for >2 mo	Antibiotic chemoprophylaxis with another active agent

(*Continued*)

Table 74-2. (*Continued*)

Pathogen	Indication	Preventive Regimen	
		First Choice	Alternative
II. Recommended only if subsequent episodes are frequent or severe			
Herpes simplex virus	Frequent/severe recurrences	Valacyclovir, 500 mg by mouth twice daily; or famciclovir, 250 mg by mouth twice daily	Acyclovir, 200 mg by mouth 3 times daily or 400 mg by mouth twice daily;
Candida (oropharyngeal or vaginal)	Frequent or severe recurrences	Fluconazole, 100–200 mg by mouth daily	Itraconazole solution, 200 mg by mouth daily
Candida (esophageal)	Frequent or severe recurrences	Fluconazole, 100–200 mg by mouth daily	Itraconazole solution, 200 mg by mouth daily

Table 74-3. Criteria for Starting, Discontinuing, and Restarting Opportunistic Infection Prophylaxis for Adults with HIV

Opportunistic Illness	Criteria for Initiating Primary Prophylaxis	Criteria for Discontinuing Primary Prophylaxis	Criteria for Restarting Primary Prophylaxis	Criteria for Initiating Secondary Prophylaxis	Criteria for Discontinuing Secondary Prophylaxis	Criteria for Restarting Secondary Prophylaxis
Pneumocystis jiroveci pneumonia	$CD4^+$ count of <200 cells/μL or oropharyngeal Candida	$CD4^+$ count of >200 cells/μL for ≥ 3 mo	$CD4^+$ count of < 200 cells/μL	Prior *Pneumocystis jiroveci* pneumonia	$CD4^+$ count of >200 cells/μL for ≥ 3 mo	$CD4^+$ count of <200 cells/μL
Toxoplasmosis	Immunoglobulin G (igG) antibody to Toxoplasma and $CD4^+$ count of <100 cells/μL	$CD4^+$ count of >200 cells/μL for ≥ 3 mo	$CD4^+$ count of <100–200 cells/μL	Prior toxoplasmic encephalitis	$CD4^+$ count of >200 cells/μL sustained (e.g., ≥ 6 mo) and completed initial therapy and asymptomatic for Toxoplasma	$CD4^+$ count of <200 cells/μL
Disseminated *Mycobacterium avium* complex (MAC)	$CD4^+$ count of <50 cells/μL	$CD4^+$ count of >100 cells/μL for ≥3 mo	$CD4^+$ count of <50–100 cells/μL	Documented disseminated disease	$CD4^+$ count of >100 cells/μL sustained (e.g., ≥ 6 mo) and completed 12 mo of MAC therapy and asymptomatic for MAC	$CD4^+$ count of <100 cells/μL

(*Continued*)

Table 74-3. (*Continued*)

Opportunistic Illness	Criteria for Initiating Primary Prophylaxis	Criteria for Discontinuing Primary Prophylaxis	Criteria for Restarting Primary Prophylaxis	Criteria for Initiating Secondary Prophylaxis	Criteria for Discontinuing Secondary Prophylaxis	Criteria for Restarting Secondary Prophylaxis
Cryptococcosis		Not applicable	Not applicable	Documented disease	$CD4^+$ count of >100–200 cells/μL sustained (e.g., ≥ 6 mo) and completed initial therapy and asymptomatic for cryptococcosis	$CD4^+$ count of <100–200 cells/μL
Histoplasmosis		Not applicable	Not applicable	Documented disease	No criteria recommended for stopping	Not applicable
Coccidioidomycosis		Not applicable	Not applicable	Documented disease	No criteria recommended for stopping	Not applicable
Cytomegalovirus retinitis		Not applicable	Not applicable	Documented retinitis	$CD4^+$ count of >100–150 cells/μL sustained (e.g, ≥6 mo) and no evidence of active disease; regular ophthalmic examination	$CD4^+$ count of <100–150 cells/μL

One double strength tablet daily is the preferred regimen.[8] However, one single strength tablet daily and one double strength tablet two or three times weekly are also effective.[24,25] The double strength tablet regimen is effective against *Toxoplasma gondii*[26] and bacterial respiratory pathogens[22,27] and is probably more effective than one single strength tablet daily. However, the higher dose regimen is probably not as well tolerated.

If patients do not tolerate TMP-SMX and the toxicity is not life threatening, the drug can often be successfully reintroduced by a gradual dose escalation. Oral regimens for desensitization have been published.[28,29]

Dapsone and dapsone plus pyrimethamine are alternatives to TMP-SMX that have a high degree of efficacy.[22,30,31] However, 70% of patients with hypersensitivity to TMP-SMX will have a hypersensitivity response to dapsone as well. Aerosolized pentamidine[23] and atovaquone[32,33] are also reasonable alternatives. Atovaquone is expensive and absorption depends on food intake. Aerosolized pentamidine requires a specialized facility for administration, and the coughing induced has the potential to spread concurrent respiratory pathogens.

Breakthroughs of PCP occur primarily in patients who are nonadherent with $CD4^+$ T lymphocyte counts <50 cells/mm^3 and patients receiving a regimen other than TMP-SMX.[21,34]

Prophylaxis against PCP can be safely discontinued if patients demonstrate a $CD4^+$ T lymphocyte response to ART with a count rising to >200 cells/mm^3 for at least 3 months.[8,35–43] If the $CD4^+$ T lymphocyte count subsequently falls below this level, prophylaxis should be reinstituted.

PREVENTING RELAPSE/RECURRENCE

Secondary prophylaxis, or chronic maintenance therapy, should be continued for life in patients with HIV infection who have survived an episode of PCP unless they initiate ART and their $CD4^+$ T lymphocyte count increases to >200 cells/mm^3 for ≥3 months.[8,41] Numerous studies have demonstrated that

the risk of acquiring PCP in such patients is extremely low. However, if the $CD4^+$ T lymphocyte count falls below 200 cells/mm^3 again due to failure of ART or nonadherence, PCP prophylaxis should be reinitiated.

TOXOPLASMIC ENCEPHALITIS

PREVENTING EXPOSURE

T. gondii is transmitted to humans via ingestion of inadequately cooked meat or by inadvertent ingestion of cat feces.[44,45] About 20% of individuals in the United States are infected with Toxoplasma compared to much higher prevalence in other countries; in Europe and certain developing countries, 60–80% of adult populations are infected.[46–48] Most disease in humans appears to be due to reactivation of latent infection, although some cases appear to be due to acute, adult-acquired infection.

Patients with HIV infection can modify their behavior to reduce the risk of exposure to Toxoplasma. Eating meat that is fully cooked and avoiding contact with felines that are at risk for infection, i.e., those that eat uncooked meat, or are allowed to hunt small rodents outside, are potential strategies. Felines transmit Toxoplasma to humans via their feces. Toxoplasma oocysts in the feces become infectious after several days and can persist in dried feces for many months.[44] Transmission may occur when a cat litter box is emptied, during which time the oocysts may contaminate hands and be ingested or may be aerosolized and inhaled. Therefore, having another person dispose of the cat litter, emptying the litter box daily, and wearing gloves may reduce the risk of exposure.

PREVENTING DISEASE

HIV-infected individuals should be tested for IgG antibody to Toxoplasma.[8] Individuals who are seropositive, i.e., those who have evidence of chronic infection, are candidates for chemoprophylaxis when their $CD4^+$ T lymphocyte counts fall below 100 cells/mm^3. There are virtually no well-documented cases of toxoplasmosis occurring in seronegative patients when the serology is performed in a reference laboratory. It must be pointed out, however, that some laboratories use relatively insensitive assays, and thus cases have been well documented where routine testing revealed a negative IgG test result.[49]

The chemoprophylaxis of choice for IgG seropositive individuals with a $CD4^+$ T lymphocyte count <100 cells/mm^3 is TMP-SMX. One double strength tablet daily is recommended. There is less evidence supporting the use of a single strength tablet. Dapsone-pyrimethamine is an effective alternative.[30,31] Atovaquone, with or without pyrimethamine, may also be effective.

From a practical perspective, the decision about Toxoplasma prophylaxis will be largely influenced by the decision regarding PCP prophylaxis, which is triggered at a higher $CD4^+$ T cell count. However, clinicians should recognize that one of the disadvantages of aerosolized pentamidine is its lack of activity against toxoplasmosis.[22,26]

Prophylaxis against toxoplasmosis can be safely discontinued if patients demonstrate a $CD4^+$ T lymphocyte response to ART with a count rising to >200 cells/mm^3 for at least 3 months.[8,50,51] If the $CD4^+$ T lymphocyte count subsequently falls below 100 cells/mm^3, prophylaxis should be reinstituted.

PREVENTING RELAPSE/RECURRENCE

Secondary prophylaxis, or chronic maintenance therapy for toxoplasmosis should be continued for life unless the patient demonstrates immunologic response to ART.[8] If a patient has received at least 6 weeks of antitoxoplasma therapy, the lesions are stable and the $CD4^+$ T lymphocyte count has increased to >200/mm^3 for at least 6 months, chronic maintenance therapy can be discontinued.[8] Some clinicians would not stop therapy until the lesion disappears on MRI, but in some patients scarring and distorted anatomy persist indefinitely. If the $CD4^+$ T lymphocyte count subsequently falls below 200 cells/μL prophylaxis should be reinstituted.

CRYPTOSPORIDIOSIS

PREVENTING EXPOSURE

Cryptosporidiosis is a common worldwide intestinal parasite that is spread by fecal-oral spread from human to human or animal to human.[52–56] This spread can occur by direct contact or via contaminated water.[57,58] Children in day care centers are one reservoir. Cats and dogs, especially young ones, can also be infected and spread this parasite via their feces. There have been large outbreaks of cryptosporidiosis associated with public drinking water.[59] Outbreaks have also been associated with water parks, presumably because babies defecated into the water, and the parasites survived despite routine chlorination.[60,61] Sexual contact, especially contact involving rectal intercourse, is also a mode of spread of this organism.

Patients with HIV can reduce their likelihood of acquiring cryptosporidia by avoiding contact with kittens and puppies, especially those from commercial breeders, or those that have been stray. Avoiding diapering infants who have been in childcare, or using gloves and handwashing after such exposure should also help reduce risk. Patients should also take precautions to avoid fecal exposure during anal intercourse.

HIV-infected patients should also be aware that surface water, and many municipal water supplies can be contaminated with Cryptosporidium. However, there is insufficient evidence to recommend that patients avoid swimming or avoid drinking municipal water except in outbreak situations.

PREVENTING DISEASE AND RELAPSE/RECURRENCE

No drug is known to be effective for preventing disease or for preventing recurrence. Some data have suggested that either rifabutin or clarithromycin, when used to prevent MAC disease, will also reduce the incidence of cryptosporidiosis.[62,63] However, these data are not convincing enough to warrant recommending these drugs for this purpose.

MICROSPORIDIOSIS

PREVENTING EXPOSURE

Microsporidiosis, due to several different species of microsporidia, is thought to be acquired by exposure to infected animals or humans, especially via their stool.[64–67] However, the routes of transmission have not been well defined.

PREVENTING DISEASE AND RELAPSE/RECURRENCE

Chemoprophylaxis is not recommended for microsporidiosis. No drug is known to be effective against *Enterocytozoon bieneusi,* the most frequent microsporidial cause of diarrhea. Albendazole and fumagillin appear to be effective against other species of microsporidia,[68,69] but whether chemoprophylaxis provides any benefit is unknown.

When patients have been successfully treated for microsporidial disease, it would be logical to continue the effective drug as long as the $CD4^+$ T lymphocyte count is below 100 cells/mm^3, but there are no data confirming the efficacy or safety of such an approach.

TUBERCULOSIS

PREVENTING EXPOSURE

Since *Mycobacterium tuberculosis* causes disease exclusively in humans, and since patient populations at high risk for tuberculosis can be identified, there are strategies that logically could reduce exposure to *M. tuberculosis*.[70–75] Employment on a pulmonary service in a hospital, or work in correctional facilities, with the homeless, or with certain immigrant populations could place patients at high risk for exposure to *M. tuberculosis*. Patients can be counseled regarding the risks of such activities and the feasibility of using masks to prevent transmission in such settings.

PREVENTING DISEASE

When HIV infection is first recognized, patients should be tested for *M. tuberculosis* infection using a tuberculin skin test (TST) or one of the new *in-vitro* assays that determine interferon (IFN) - gamma release in response to peptides move specific for *M. tuberculosis.*[8,76–78] Testing should be repeated annually if the patient has a significant risk of exposure to TB. Consideration should also be given to repeating the test if the initial test was performed when the patient was profoundly immunosuppressed, i.e., $CD4^+$ T lymphocyte count <200 cells/mm^3, and the patient has had a substantial increase in $CD4^+$ T lymphocyte count due to ART.

All HIV-infected persons who have a positive test for *M. tuberculosis* infection should undergo chest radiography and clinical evaluation to rule out active TB.[8] HIV-infected persons who have symptoms suggestive of TB should promptly undergo chest radiography and clinical evaluation regardless of their *M. tuberculosis* infection test result.

All HIV-infected persons, regardless of age, who have a positive test for *M. tuberculosis* infection but have no evidence of active TB and no history of treatment for active or latent TB should be treated for latent TB infection.[8,79,80] Isoniazid daily or twice weekly for 9 months is the preferred regimen. A 4 month course of rifampin or rifabutin can also be used.[8,80,81] The combination of rifampin plus pyrazinamide for 2 months has been shown to provide benefit, but severe hepatotoxicity and death have been observed in some HIV-uninfected patients who received this regimen.[82] Therefore, it should not be used.

Rifampin and rifabutin both have substantial p450 cytochrome enzyme interactions.[80] They must be used with caution when concurrent drugs are administered to avoid increased toxicity or reduced efficacy of either the rifamycin or the other drugs.

PREVENTING RELAPSE/RECURRENCE

Tuberculosis is unusual among HIV-associated OIs in that it rarely recurs after completion of a full course of therapy, if the organism was sensitive to the chemotherapeutic agents used. Thus, after successful completion of therapy, chronic maintenance therapy is not necessary.

DISSEMINATED MYCOBACTERIUM AVIUM COMPLEX INFECTION

PREVENTING EXPOSURE

Mycobacterium avium-intracellulare is ubiquitous in dust, dirt, and in animals.[83,84] Thus, it is not feasible to avoid exposure to this organism. Most humans have been exposed. It is not certain how often active disease is due to endogenous flora that were previously acquired, and how often disease is due to a recently acquired infection.

PREVENTING DISEASE

Adults and adolescents who have HIV infection should receive chemoprophylaxis against disseminated MAC

disease if they have a CD4+ T lymphocyte count of <50 cells/mm^3.[4,8] Clarithromycin[85–87] or azithromycin[87] are the preferred prophylactic agents. The combination of azithromycin with rifabutin is more effective than azithromycin alone; however, the additional cost, increased occurrence of adverse effects, potential for drug interactions, and absence of a difference in survival when compared with azithromycin alone do not warrant a routine recommendation for this regimen.[87] In addition to their preventive activity for MAC disease, clarithromycin and azithromycin each confer protection against respiratory bacterial infections.

If clarithromycin or azithromycin cannot be tolerated, rifabutin is an alternative prophylactic agent for MAC disease, although rifabutin-associated drug interactions make this agent difficult to use.[85,88] Before prophylaxis is initiated, disseminated MAC disease should be ruled out by clinical assessment, which might include obtaining a blood culture for MAC if warranted. Because treatment with rifabutin could result in rifampin resistance among persons who have active TB, active TB should also be excluded before rifabutin is used for prophylaxis.

Primary MAC prophylaxis should be discontinued among adult and adolescent patients who have responded to ART with an increase in CD4+ T lymphocyte counts to >100 cells/mm^3 for ≥3 months.[8,89] Two substantial randomized, placebo controlled trials and observational data have demonstrated that such patients can discontinue primary prophylaxis with minimal risk of developing MAC.[90,91] If the CD4+ count subsequently falls below 50–100 cells/mm^3, prophylaxis should be reinstituted.

■ PREVENTING RELAPSE/RECURRENCE

Patients with disseminated MAC disease should receive lifelong secondary prophylaxis (chronic maintenance therapy), unless immune reconstitution occurs as a result of ART.[8] Patients are at low risk for recurrence of MAC when they have completed a course of >12 months of treatment for MAC, remain asymptomatic with respect to MAC signs and symptoms, and have a sustained increase (e.g., >6 months) in their CD4+ T lymphocyte counts to >100 cells/mm^3 after ART.[92] Secondary prophylaxis should be reintroduced if the CD4+ T lymphocyte count decreases to <100 cells/mm^3.

BACTERIAL RESPIRATORY INFECTIONS

■ PREVENTING DISEASE

Adults and adolescents who have a CD4+ T lymphocyte count of ≥200 cells/mm^3 should be administered a single dose of 23-valent polysaccharide pneumococcal vaccine (PPV) if they have not received this vaccine during the previous 5 years.[93–96] One randomized placebo-controlled trial of PPV in Africa paradoxically demonstrated an increase in pneumonia among vaccinated subjects.[97] However, multiple observational studies in the United States have not identified increased risk associated with vaccination and have demonstrated benefit in persons with CD4+ T lymphocyte counts >200 cells/mm^3.[93–96] The majority of HIV specialists believe that the potential benefit of pneumococcal vaccination in the United States outweighs the risk. Immunization may also be considered for patients with CD4+ T lymphocyte counts of <200 cells/mm^3, although clinical evidence has not confirmed efficacy. Revaccination can be considered for patients who were initially immunized when their CD4+ T lymphocyte counts were <200 cells/mm^3 and whose CD4+ counts have increased to >200 cells/mm^3 in response to ART. The recommendation to vaccinate is increasingly pertinent because of the increasing incidence of invasive infections with drug-resistant (including TMP-SMZ-, macrolide-, and ß-lactam-resistant) strains of *Streptococcus pneumoniae.*

The duration of the protective effect of primary pneumococcal vaccination is unknown. Periodic revaccination should be considered, perhaps every 5 years.[95] However, no evidence confirms clinical benefit from revaccination.

TMP-SMX, when administered daily for PCP prophylaxis, reduces the frequency of bacterial respiratory infections. This should be considered in selecting an agent for PCP prophylaxis.[22] However, indiscriminate use of this drug (when not indicated for PCP prophylaxis or other specific reasons) might promote development of TMP-SMX-resistant organisms. Thus, TMP-SMX should not be prescribed solely to prevent bacterial respiratory infection. Similarly, clarithromycin administered daily[86] and azithromycin administered weekly[87] for MAC prophylaxis might be effective in preventing bacterial respiratory infections; this should be considered in selecting an agent for prophylaxis against MAC disease. However, these drugs also should not be prescribed solely for preventing bacterial respiratory infection.

■ PREVENTING RELAPSE/RECURRENCE

Secondary prophylaxis (chronic maintenance therapy) after successful completion of antibiotic treatment for bacterial respiratory tract infections is not indicated, although administration of antibiotic chemoprophylaxis to HIV-infected patients who have frequent recurrences of serious bacterial respiratory infections might be considered.

The most effective method to prevent bacterial pneumonia in HIV-infected patients is probably optimization of ART. Annual influenza vaccine might be useful in preventing pneumococcal superinfection of influenza.[8]

BACTERIAL ENTERIC INFECTIONS

PREVENTING EXPOSURE

HIV-infected patients can reduce the risk of exposure to many enteric pathogens by avoiding certain high-risk food items. These include raw or undercooked poultry, raw eggs, raw seafood, and unpasteurized dairy products. Cross contamination is another route of infection that can be avoided through good food hygiene practices.

Animals can also be vectors for enteric bacterial pathogens. Kittens and puppies less than 6 months of age, stray animals, and animals from commercial breeders can all pose enhanced risk for transmitting enteric organisms. Pet reptiles, chicks, and ducks can also transmit such bacteria.

HIV-infected travelers to areas with poor sanitation need to be especially cautious about ingesting potentially contaminated food or water. HIV-infected patients need to consider carefully the likelihood of enteric infection when deciding whether to travel and should be aware of what medical resources will be available.

PREVENTING DISEASE

Preventive antibacterial agents are not recommended chronically to reduce the acquisition of enteric bacterial infections. While prophylactic antibacterial agents would be expected to be effective for short-term protection, they are associated with obvious toxicities. Chronic administration of antibiotics also promotes the development of antibiotic resistant flora.

PREVENTING RELAPSE/RECURRENCE

HIV-infected patients with Salmonella bacteremia have a high likelihood of relapse. Such patients should receive long-term prophylaxis with an active antibacterial agent. Whether such therapy needs to be continued lifelong is unknown.

BARTONELLOSIS

PREVENTING EXPOSURE

Among the multiple species of Bartonella, *B. henselae* and *B. quintana* are the most common causes of human disease among patients with HIV infection. *B. henselae* causes long-lasting infection in felines.[98–101] Cat fleas, and probably cat scratches, bites, and licks can transmit this infection.[102–104] Cats less than 1 year of age are more likely to be infected than older cats.

B. quintana is transmitted by lice.[105,106] Homeless individuals are the patients most often recognized with disease caused by this organism.[107,108] Improved hygiene should reduce the likelihood of infection.

PREVENTING DISEASE

Antibacterial prophylaxis for these infections is not recommended.

PREVENTING RELAPSE/RECURRENCE

Following therapy for acute Bartonella infection, patients should receive secondary prophylaxis (chronic maintenance therapy). Therapy with erythromycin, azithromycin, or doxycycline should be considered.[109–111] There are no large studies that clearly define the optimal length of secondary prophylaxis, or the relationship of $CD4^+$ T lymphocyte count to relapse.

CANDIDIASIS

PREVENTING EXPOSURE

Candida are ubiquitous in the environment.[112–114] All humans are colonized with these organisms. Thus, prevention of acquisition of Candida is not likely to be a successful strategy for reducing the incidence of Candida disease. However, in health-care settings, fluconazole resistant Candida are likely to be common, and using barrier precautions to reduce superinfection of patients would seem to be a reasonable strategy.

PREVENTING DISEASE

Primary chemoprophylaxis with fluconazole is effective for reducing the frequency of candidiasis and cryptococcosis.[115,116] However, chronic administration of fluconazole is expensive and is associated with toxicities and drug interactions and it promotes the development of azole resistant yeast. In addition, Candida almost never cause invasive disease. Mucosal candidiasis can be readily treated in most cases. Thus, the majority of clinicians would not recommend primary drug prophylaxis for candidiasis.

PREVENTING RELAPSE/RECURRENCE

Chronic maintenance therapy following resolution of acute candidiasis is not recommended by most experts for the same reasons that primary prophylaxis is not usually advocated.[8] However, some recommend secondary prophylaxis for several months following an episode of candida esophagitis. There may be other patients in whom relapses are so frequent or so severe that chronic therapy could be considered. In such a case, fluconazole or itraconazole would be reasonable options to consider. However, since azoles are cytochrome p450 inhibitors, drug interactions must be considered. In addition, the emergence of azole resistant Candida is a particular concern.

CRYPTOCOCCOSIS

PREVENTING EXPOSURE

Cryptococcus neoformans is present in bird feces.[117–119] However, there is no strategy known to be effective for avoiding exposure to this organism.

PREVENTING DISEASE

Primary prophylaxis with fluconazole or itraconazole is effective for reducing the incidence of cryptococcosis.[115] However, as discussed above for candidiasis, most experts would not recommend primary prophylaxis solely to prevent cryptococcosis. First, the incidence of cryptococcosis is not high in most settings. Second, cryptococcal disease can be readily treated if it occurs. Third, no survival benefit has been demonstrated for prophylaxis against this disease.

Clinical disease could theoretically be prevented by screening patients periodically with serum cryptococcal antigen testing and treating CRAG+ persons before symptoms develop.[120] However, the likelihood of this test being positive in asymptomatic patients is low and the efficacy of such a strategy has not been demonstrated.

PREVENTING RELAPSE/RECURRENCE

Patients who have completed an initial course of therapy for cryptococcosis have a high likelihood of recurrence unless ART results in immune reconstitution. Thus, maintenance therapy with fluconazole is recommended for life unless the patient has successfully completed initial therapy, is asymptomatic, and the $CD4^+$ T lymphocyte count has increased to >100–200 cells/mm^3 for at least 6 months on ART.[8,121–123] If the $CD4^+$ count subsequently falls to below these levels, secondary prophylaxis should be reinstituted.

HISTOPLASMOSIS

PREVENTING EXPOSURE

Acquisition of histoplasmosis can be associated with certain high-risk activities that involve exposure to bird feces, including chicken feces.[124] Thus, working in chicken coops, or disturbing soil below bird-roosting sites, or cleaning areas where birds have roosted are all high-risk activities.

PREVENTING DISEASE

Routine skin testing with histoplasmin and serologic testing for Histoplasma antibody or antigen in histoplasmosis-endemic areas are not predictive of disease and also are not generally available. Data from a prospective randomized controlled trial indicate that itraconazole can reduce the frequency of histoplasmosis among patients who have advanced HIV infection and who live in histoplasmosis-endemic areas.[125] However, no survival benefit was observed among persons receiving itraconazole. Nevertheless, prophylaxis with itraconazole can be considered for patients with $CD4^+$ T lymphocyte counts <100 cells/mm^3 who are at high risk because of occupational exposure or who reside in a community with a hyperendemic rate of histoplasmosis (≥10 cases/100 patient-years).

PREVENTING RELAPSE/RECURRENCE

Patients who have completed an initial course of therapy for histoplasmosis are at high risk of recurrence unless they receive chronic maintenance therapy. Itraconazole is the drug of choice.[8,126,127] Some exerts would use tablets because that is the preparation used in most trials that have demonstrated efficacy. Others would use the oral formulation since it is better absorbed. However, better absorption is associated with increased toxicity, especially nausea and vomiting. Some specialists advocate measuring serum levels of itraconazole: free itraconazole levels of 1 mg/mL or free plus hydroxylated metabolite of 2 g/mL are considered sufficient. Patients whose $CD4^+$ T lymphocyte count has increased to >100 cells/mm^3 on ART may be able to discontinue maintenance therapy, but the number of persons in whom prophylaxis has been discontinued is too small to allow recommending this approach with confidence.[127]

COCCIDIOIDOMYCOSIS

PREVENTING EXPOSURE

Coccidiodes is transmitted by aerosolization of spores of *Coccidioides immitis*. In endemic areas, activities that increase risk include those related to exposure to dust and soil, e.g., working in building excavation sites, farming, and gardening.[128–130] Dust storms are also likely to be associated with acquiring infection.

Prior infection can be assessed by the coccidioidin skin test. However, this skin test is not predictive of disease and therefore is not generally recommended. Serologic tests can also identify infection but they are not sufficiently useful to warrant routine use.

PREVENTING DISEASE

Primary chemoprophylaxis is not recommended for coccidioidomycosis.

PREVENTING RELAPSE/RECURRENCE

After completing therapy for coccidioidomycosis, patients should receive life long therapy with either fluconazole or

itraconazole.[8,131] Patients who have a CD4+ T lymphocyte count >100 cells/mm^3 may be able to discontinue their azole therapy, but the number of patients in whom treatment has been discontinued is too small to recommend this approach.

CYTOMEGALOVIRUS DISEASE

PREVENTING EXPOSURE

CMV can be acquired by sexual contact, by exposure to oral secretions, or via blood transfusion. In the United States, 60–70% of the population has been infected.[132] Almost all patients who are HIV-infected also have latent infection with CMV.[133] The use of barrier contraception can prevent infection or reinfection with CMV.

PREVENTING DISEASE

Oral ganciclovir has been shown to be effective for preventing the development of CMV disease in patients with CD4+ T lymphocyte counts <50 cells/mm^3.[134,135] However, oral ganciclovir is associated with toxicity, especially marrow suppression, is expensive and may induce development of ganciclovir-resistant CMV. In addition, the drug is no longer commercially available.

Oral ganciclovir has been replaced by oral valganciclovir, which attains higher serum levels than oral ganciclovir. These higher serum levels are associated with higher rates of adverse events. Thus, oral valganciclovir, while likely to be effective for prophylaxis, is not recommended.[8]

Acyclovir is not effective for prophylaxis against CMV. The optimal approach to prevent severe sequelae of CMV disease is to recognize manifestations early and to institute appropriate treatment.

PREVENTING RELAPSE/RECURRENCE

After induction therapy, secondary prophylaxis (i.e., chronic maintenance therapy) is recommended for life,[8] unless patients generate a CD4+ T lymphocyte count >100–150 cells/mm^3 for 6 months on ART and have stable disease.[136–141] Regimens effective for chronic suppression include oral valganciclovir, parenteral or oral ganciclovir, parenteral foscarnet, combined parenteral ganciclovir and foscarnet, parenteral cidofovir, and (for retinitis only) ganciclovir administration through intraocular implant or repetitive intravitreous injections of fomivirsen.[142–146]

Repetitive intravitreous injections of ganciclovir, foscarnet, and cidofovir have been effective for secondary prophylaxis of CMV retinitis in uncontrolled case series. However, clinicians should recognize that local therapy does not provide systemic protection or protection for the contralateral eye.

If chronic maintenance therapy is stopped, patients should be followed carefully by an experienced ophthalmologist. If the lesion is near the optic disk, some clinicians would be reluctant to discontinue it.

Chronic maintenance therapy is not routinely recommended for gastrointestinal disease but should be considered if a relapse occurs. There are few data about the need for chronic maintenance therapy following the infrequent cases of CMV pneumonia.

HERPES SIMPLEX VIRUS DISEASE

PREVENTING EXPOSURE

HIV-infected patients can acquire herpes simplex via sexual intercourse. Thus, latex condoms should be used to prevent exposure to HSV and other STIs and to prevent transmission of HIV to others. Patients should also avoid contact with obvious orolabial or genital HSV lesions.

PREVENTING DISEASE

Primary prophylaxis with acyclovir after exposure to HSV or to prevent an initial episode of HSV[147] is not recommended. Prompt therapy of acute episodes with acyclovir is preferred.

PREVENTING RELAPSE/RECURRENCE

Since HSV rarely disseminates, the preferred strategy for treating recurrent HSV is to treat episodes when they occur. However, chronic therapy with acyclovir will reduce recurrences of disease. If episodes are frequent or severe, chronic suppressive therapy is a logical strategy provided the virus is acyclovir-sensitive. Famciclovir and valacyclovir can also be used and have the advantage of more convenient dosing schedules.[148–151]

VARICELLA-ZOSTER VIRUS DISEASE

PREVENTING EXPOSURE

HIV-infected persons who are seronegative for varicella-zoster virus (VZV) can acquire VZV by aerosol spread from an individual with primary varicella or disseminated zoster. Patients with dermatomal zoster can also transmit varicella via infected scabs.

If an HIV-infected patient is seronegative for varicella, immunization of household contacts is a useful strategy to reduce the likelihood that varicella infection will be introduced into the household.

PREVENTING DISEASE

Patients who are exposed to varicella zoster and who are VZV-seronegative should receive zoster immune globulin within 96 hours of exposure. Alternatively, patients might receive acyclovir, which can be given during the window of likely disease occurrence, i.e., from day 10 to day 20 in most patients. However, there is little evidence that either zoster immune globulin or acyclovir is effective in preventing VZV in HIV-infected persons.

Varicella vaccine contains live, attenuated virus. The safety of this vaccine in HIV-infected patients is not well studied at any $CD4^+$ T cell count. Thus, the use of this vaccine in HIV-infected patients is not recommended.[8]

PREVENTING RELAPSE/RECURRENCE

Secondary prophylaxis to prevent the recurrence of zoster is not routinely indicated. However, if recurrences are frequent or severe, chronic therapy with acyclovir, famciclovir, or valacylovir would be reasonable, but efficacy of these regimens has not been demonstrated in HIV-infected persons.

HCV INFECTION

PREVENTING EXPOSURE

In the United States, Hepatitis C virus (HCV) is transmitted primarily via injection drug use.[152] A small percent of infections may be transmitted sexually and for another small segment the route is unknown.[153–155] Thus, any intervention that can prevent injection drug use could be expected to reduce the incidence of HCV infection in HIV-infected persons. Since HCV is a blood-borne pathogen, any other practice that results in exposure to blood could potentially transmit HCV. Thus, tattooing or body piercing, if performed with unsterile equipment, could result in exposure to HCV.

PREVENTING DISEASE

Current guidelines recommend that all HIV-infected patients be screened for hepatitis C.[8] Knowledge of HCV status is important for interpreting liver function test abnormalities, i.e., deciding whether such abnormal test results are due to antiretroviral drugs, other chemotherapeutic agents, or HCV. Such testing is also important for clinicians to determine whether further diagnostic studies are warranted to determine the severity of HCV disease and the need for therapeutic intervention.

Persons coinfected with HCV and HIV should be advised not to drink excessive amounts of alcohol; avoiding alcohol altogether might be prudent because whether even occasional alcohol use increases the incidence of cirrhosis among HCV-infected persons is unclear.

Patients coinfected with HCV and HIV who are susceptible to Hepatitis A virus (HAV) (i.e., lack antibody to HAV) should be vaccinated against hepatitis A, since hepatitis A can cause particularly severe disease in HCV-infected persons.[8]

HIV-infected persons should also be screened for hepatitis B coinfection.[8] Seronegative persons should receive hepatitis B vaccine.

PREVENTING RELAPSE/RECURRENCE

For patients who have had a virologic and histologic response to therapy for hepatitis C, the optimal duration of therapy is unknown. Therefore, no recommendations are available for chronic maintenance therapy in this setting.[156,157]

75 Clinical Management of HIV Infection: Management of Opportunistic Infections

Catherine F. Decker and Henry Masur

INTRODUCTION

The widespread use of potent antiretroviral therapy (ART) and chemoprophylaxis for opportunistic infections (OIs) has resulted in a marked reduction of most OIs in human immunodeficiency virus (HIV) infected persons.[1–4] However, OIs continue to occur in both patients who are not receiving medical care and in patients who receive aggressive medical management.[5]

The persistence of OIs in the United States is due to several factors. Many persons remain unaware of their HIV diagnosis and do not receive ART or appropriate prophylaxis against OIs. Until access to care becomes more available in the United States, and until HIV testing and awareness improves, this population will continue to present with OIs as their initial indication of HIV infection. In addition, only a minority of those receiving ART will achieve and remain virologically suppressed.[6] With ART being or becoming ineffective in some patients, long-term virological failure will cause progression of disease, and hence will increase the risk for OIs. These patients benefit from OI prophylactic strategies. Clinicians need to be cognizant of the value of such prophylaxis while they focus on optimizing ART.

DIAGNOSIS OF OPPORTUNISTIC INFECTIONS

When patients present with new symptoms or signs, clinicians are faced with the decision: should the physician attempt to establish a specific diagnosis, or treat the patient empirically. Such a decision depends on the resources available, the potential severity of the syndrome, and the certainty the clinician has that the correct causative process can be identified by either presumptively or specifically. For instance, for a patient presenting with dysphagia, white oral plaques, and a $CD4^+$ T-cell count below 100 cells/μL, the pathogen is almost always azole Candida, and the disease is rarely life-threatening. Thus, empiric therapy with fluconazole would be a reasonable approach. Alternately, a patient with a similar $CD4^+$ T-cell count and respiratory failure with diffuse pulmonary infiltrates could have a wide variety of infectious and noninfectious processes causing respiratory failure. A specific diagnosis would be more urgent to be certain that the correct causative process was being treated.

Clinicians must be cognizant that HIV-infected patients can develop non-OIs. OIs are defined as those that occur with increased frequency or increased severity. HIV-infected patients are at risk of such infections regardless of their $CD4^+$ T lymphocyte cell counts. For instance, pneumococcal respiratory infections and tuberculosis occur with increased incidence at all $CD4^+$ T lymphocyte cell counts. However, as the $CD4^+$ T lymphocyte cell count declines, the incidence and severity of OIs increase. In addition to the opportunistic processes, HIV-infected patients are also susceptible to community and hospital acquired pathogens that are not opportunistic. For instance, they can develop pneumonia due to *Legionella*, *Influenza*, or *Acinetobacter*. The issue to recognize is that non-OIs and other disease processes both occur and must be appropriately diagnosed and treated. This is especially relevant when HIV-infected patients have other risk factors such as advanced age, substance abuse, tobacco use, or environmental exposures.

When an HIV-infected patient presents, clinicians are often tempted to treat the patient empirically. This may well be appropriate, especially if the syndrome is not severe and the clinician is reasonably confident of the pathologic diagnosis. However, opportunistic processes can present in typical and atypical manners. Inadequately treated processes can progress rapidly and unnecessary drugs can produce preventable toxicity. Thus, establishing specific diagnoses to assure that treatment is appropriate remains an important strategy in dealing with this patient population.

ART: SHOULD IT BE INITIATED OR CONTINUED IN PATIENTS WITH OPPORTUNISTIC INFECTIONS?

When an OI is diagnosed, clinicians are often faced with the question as to whether or not ART should be started or continued. For patients not currently on ART and who have an

acute OI, there is a rational reason to consider starting ART. ART may increase immune function if the virus is susceptible to available drugs. Such therapy might hasten resolution of the syndrome and prevent other HIV-related complications from occurring. Thus, such therapy is an attractive option. There are a number of disadvantages to starting therapy. ART drugs are almost all oral; thus, patients with acute OIs may not be able to predictably absorb oral drugs if they are critically ill, or if they have gastrointestinal dysfunction. If serum levels of ART are suboptimal, HIV viral resistance may be promoted. Therefore, initiating ART when patients are acutely ill and unable to reliably take and absorb drugs may have serious long-term consequences relevant related to the success of ART.

If ART is absorbed, drug interactions with concurrent agents may substantially alter ART pharmacokinetics. Patients with acute OIs are often receiving multiple drugs to treat the OI and to treat concurrent and related problems. Thus, serum levels of either the antiretroviral agent, or the anti-infective, may be excessively high, promoting toxicity, or excessively low, reducing efficacy.

It is also important to note that when toxicities such as rashes or liver function abnormalities occur in patients with acute OIs, it will be difficult to determine if these are due to the OI, the recently introduced ART agents, or the drugs used to manage the OI. Thus, most clinicians would opt not to initiate ART unless there is a compelling reason such as a lack of alternative treatment of the OI, as might be the case with progressive multifocal leukoencephalopathy, cryptosporidiosis, or disease due to *Enterocytozoan bieneusi*.

The potential for immune reconstitution syndrome (IRIS) is another factor to consider when determining whether or not to initiate ART. IRIS occurs within days, weeks, or months of starting ART. As the viral load falls, even before the $CD4^+$ T lymphocyte cell count rises, generalized and nonspecific immune activation decreases, and specific immune responses augment. In some patients, especially those with low $CD4^+$ T lymphocyte cell counts and high viral loads who have a prompt response to ART, immunologic reactions can occur at sites of latent or active infection. Thus, for a patient who has never been symptomatic, and who is starting ART solely because of laboratory markers, clinical manifestations may occur at the site of a sequestered, clinically silent infection such as a fungal or mycobacterial focus. Focal lymphadenopathy, an inflammatory lung nodule or infiltrate, or dysfunction at some other organ can thus occur. These syndromes have been most often described in association with active or latent mycobacterial or fungal disease, but can occur with a wide variety of infectious and apparently noninfectious entities.

For patients with active infection, such as pulmonary tuberculosis, pneumocystosis, or cryptococcal meningitis, initiation of ART can be associated with exacerbation of the clinically apparent disease. This may be undesirable for patients who already have significant organ dysfunction; it can even be life-threatening. Patients may manifest new clinical findings related to the causative organism. Patients with apparent pulmonary tuberculosis may develop worsening pulmonary disease or pericarditis or meningitis due to augmented inflammatory response at sites that had been clinically silent.

Patients who start ART after recovering from an OI may experience a flare in their apparently cured disease. Patients who have been successfully treated for CMV retinitis, for example, usually experience a flare in inflammation in their vitreous. This flare can be asymptomatic, or can obscure their vision. Patients who have been treated for tuberculosis or cryptococcal meningitis also have frequently been reported with such syndromes: adenopathy, fever, or focal organ dysfunction can develop and be mild or life-threatening.

How often these IRIS syndromes occur is not certain. Their frequency depends on host factors, such as the viral load and $CD4^+$ T cell count at the time ART was initiated. The frequency of IRIS syndromes also depends on environmental factors: such syndromes are more common in areas endemic for tuberculosis or cryptococcosis than in areas where these diseases are unusual. There are many anecdotal reports and small series of these occurrences. How often they occur and what factors are predictive need further study. How to manage such syndromes has also not been clearly defined; nonsteroidal agents, corticosteroids, and ARV withdrawal have been used, but no guidelines currently exist to define when such interventions are appropriate.

An ongoing randomized controlled trial has been initiated within the Adult AIDS Clinical Trials Group comparing outcomes between ART-naive patients who start ART immediately after presentation with an acute OI, and patients who start ART at least 4 weeks after the OI has resolved. This trial should help identify the factors supporting early or delayed initiation of antiretrovirals. Current recommendations for treatment of common HIV-associated OIs are summarized in Table 75-1, which is modified from current CDC guidelines.

PNEUMOCYSTIS JIROVECI

Pneumocystis pneumonia (PCP), which is caused by *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*), remains a frequent initial manifestation of HIV infection.[4,7] *P. jiroveci* is a fungus that appears to be ubiquitous in the environment.[8] The taxonomy has been modified; *P. carinii* refers to the species that infects rodents, and *P. jiroveci* is the species that infects humans. Serologic data in the United States indicates that most humans become subclinically infected with *P. jiroveci* in childhood.[9] There is emerging literature suggesting that primary infection and reinfections may be associated with clinical symptoms, including sudden

Table 75-1. Treatment of AIDS-Associated Opportunistic Infections in Adults

Opportunistic Infections	Preferred Therapy and Duration	Alternative Therapy	Other Options/Issues
Pneumocystis jiroveci Pneumonia (PCP)	*Acute therapy:* • Trimethoprim-Sulfamethoxazole (TMP/SMX): [15–20 mg TMP and 75–100 mg SMX]/kg/day IV given q6h or q8h (AI); or • Same daily dose of TMP/SMX PO in 3 divided doses (AI); or • TMP-SMX DS 2 tablets 3 times a day (AI) Total duration = 21 days (AII) *Chronic maintenance therapy* (secondary prophylaxis): First choice • Trimethoprim-sulfamethoxazole (TMP-SMX) 1 double-strength tablet (DS) PO QD (AI); or • TMP-SMX 1 single-strength tablet (SS) PO QD (AI) Alternatives • Dapsone 50 mg PO twice daily or 100 mg PO daily (BI); or • Dapsone 50 mg PO daily plus pyrimethamine 50 mg PO weekly plus leucovorin 25 mg PO weekly (BI); or • Dapsone 200 mg PO plus pyrimethamine 75 mg PO plus leucovorin 25 mg PO weekly (BI); aerosolized pentamidine 300 mg every month via Respirgard II™ nebulizer (manufactured by Marquest, Englewood, Colorado) (BI); or • Atovaquone 1500 mg PO daily (BI): or • TMP-SMZ 1 DS PO 3 times weekly (CI)	*For severe PCP:* Pentamidine 4 mg/kg IV QD infused over at least 60 minutes (AI), some experts reduce dose to 3 mg/kg IV QD because of toxicities (BI) *For mild-to-moderate PCP:* • Dapsone 100 mg PO QD and TMP 15 mg/kg/day PO (3 divided dose) (BI); or • Primaquine 15–30 mg (base) PO QD and Clindamycin 600–900 mg IV q6h to q8h or Clindamycin 300–450 mg PO q6h to q8h (BI); or • Atovaquone 750 mg PO BID with food (BI); or • Trimetrexate 45 mg/m^2 or 1.2 mg/kg IV QD with leucovorin 20 mg/m^2 or 0.5 mg/kg IV or PO q6h (leucovorin must be continued for 3 days after the last trimetrexate dose) (B1); addition of dapsone or sulfamethoxazole or sulfadiazine might improve efficacy (CIII)	Indications for corticosteroids (AI): PaO_2 <70 mm Hg at room air; or alveolar-arterial O_2 gradient >35 mm Hg Prednisone doses (beginning as early as possible and within 72 hours of PCP therapy) (AI): 40 mg BID days 1–5, 40 mg QD days 6–10, then 20 mg QD days 11–21 IV methylprednisolone can be given as 75% of prednisone dose Chronic maintenance therapy (secondary prophylaxis) should be discontinued if CD4$^+$ T lymphocyte count increases in response to ART from <200 to >200 cells/μL for ≥3 months (AI)
Toxoplasma gondii encephalitis	*Acute therapy:* Pyrimethamine 200 mg POx1, then 50 mg (<60 kg) to 75 mg (≥60 kg) PO QD and Sulfadiazine 1000 (<60 kg) to 1500 mg (≥60 kg) PO q6h + Leucovorin 10–20 mg PO QD (can increase up to 50 mg or higher) (AI)	• Pyrimethamine (leucovorin)* and Clindamycin 600 mg IV or PO q6h (AI); or • TMP-SMX (5 mg/kg TMP and 25 mg/kg SMX) IV or PO BID (BI); or • Atovaquone 1500 mg PO BID with meals (or nutritional supplement)	Adjunctive corticosteroids (e.g., dexamethasone) should be given when clinically indicated for treatment of mass effect attributed to focal lesions or associated edema (BIII) and discontinued as soon as clinically feasible

(*Continued*)

Table 75-1. (*Continued*)

Opportunistic Infections	Preferred Therapy and Duration	Alternative Therapy	Other Options/Issues
	Total duration for acute therapy is at least 6 weeks (BII) *Chronic maintenance therapy:* (Secondary Prophylaxis) *First choice:* • Sulfadiazine 500–1000 mg PO 4 times daily plus pyrimethamine 25–50 mg PO daily plus leucovorin 10–25 mg PO daily (AI)- *Second choice:* • Clindamycin 300–450 mg PO every 6–8 hours plus pyrimethamine 25–50 mg PO daily plus leucovorin 10–25 PO daily (BI); or • Atovaquone 750 mg PO every 6–12 hours with or without pyrimethamine 25 mg PO daily plus leucovorin 10 mg PO daily (CIII)	and Pyrimethamine (leucovorin)* (BII); or • Atovaquone 1500 mg PO BID with meals (or nutritional supplement) and Sulfadiazine 1000–1500 mg PO q6h (BII); or • Atovaquone 1500 mg PO BID with meals (BII); or • Pyrimethamine (leucovorin)* and Azithromycin 900–1200 mg PO QD (BII) *For severely ill patients who cannot take oral meds:* TMP-SMX IV and Pyrimethamine PO (CIII) For other regimens with limited experience (CIII), see text.	Anticonvulsants should be administered to patients with a history of seizures (AIII) *Secondary prophylaxis may be discontinued if:* free of TE signs and symptoms; and sustained $CD4^+$ T lymphocyte count of >200 cells/μL for ≥6 months of ART (CIII)
Cryptosporidosis	Symptomatic treatment of diarrhea (AIII) Effective ART therapy (to increase $CD4^+$ count to >100 cells/μL) can result in complete, sustained clinical, microbiological and histologic resolution of HIV-associated cryptosporidiosis (AII)	Nitazoxanide 500 mg PO BID Paromomycin 25–35 mg/kg PO in 2 to 4 divided doses	Supportive care including hydration, nutritional support
Microsporidiosis	Initiate or optimize ART with immune reconstitution to CD4 >100 cells/μL (AII) *For disseminated (not ocular) and intestinal infection attributed to microsporidia other than Enterocytozoon bienuesi:* • Albendazole 400 mg PO BID (AII), continue until CD4 >200 cells/μL (AIII) *For ocular infection:* • Fumidil B 3 mg/mL in saline (final conc. is fumagillin 70 μg/ml) eye drops continued indefinitely (not available in U.S.) (BII) and Albendazole 400 mg PO BID for management of systemic infection (BIII)	*Disseminated disease:* Itraconazole 400 mg PO QD and Albendazole for disseminated disease attributed to *Trachipleistophora* or *Brachiola* (CIII)	Fluid support in patients with diarrhea resulting in severe dehydration (AIII) Nutritional supplement for patients with severe malnutrition and wasting (AIII) Treatment for ocular infection should be continued indefinitely (BIII). With immune reconstitution, it is possible that this treatment can be discontinued (CIII). Chronic maintenance therapy may be discontinued if patients (CIII): • Remain asymptomatic with regards to signs and symptoms of microsporidiosis;

Table 75-1. (*Continued*)

	For gastrointestinal infections caused by Enterocytozoon bienuesi: • Fumagillin 60 mg PO QD (not available in U.S.) (BII)		• Sustained $CD4^+$ T-lymphocyte counts >200 cells/μL for ≥6 months on ART
Mycobacterium tuberculosis (MTB)	**For drug-sensitive MTB** *Initial phase (8 weeks) (AI):* Isoniazid (INH) 5 mg/kg (max: 300 mg) PO QD and [Rifampin 10 mg/kg (max: 600 mg) PO QD or Rifabutin 300 mg PO QD (or dose adjusted based on concomitant meds[3])] and Pyrazinamide (PZA) (dose based on wt%) PO QD and Ethambutol (EMB) (dose based on wt%) PO QD *Continuation phase (18 weeks) (AI):* • INH 5 mg/kg (max: 300 mg) PO QD and [Rifampin 10 mg/kg (max: 600 mg) or Rifabutin 300 mg PO QD]; or • INH15 mg/kg (max 900 mg) PO BIW or TIW + [Rifampin 10 mg/kg (max: 600 mg) or Rifabutin 300 mg PO or TIW] In patients with delayed clinical or microbiological response to initial therapy (e.g., sputum culture (+) after 2 months or if cavitary pulmonary lesions are present), total duration up to 9 months (BII)	**Treatment for drug-resistant MTB:** *Resistant to INH:* • discontinue INH (and streptomycin, if used) • Rifamycin, PZA, and EMB for 6 months (BII); or Rifamycin and EMB for 12 months (preferably with PZA during at least first 2 months) (BII) *Resistant to rifamycin:* • INH and PZA and EMB and a fluoroquinolone (e.g., levofloxacin 500 mg/day) for 2 months, followed by 10–16 additional months with INH and EMB and fluoroquinolone (BIII) *Multidrug resistant (MDR) TB, i.e., both INH and rifamycin resistant:* • Therapy should be individualized based on resistance pattern and with close consultation with experienced specialist (AIII) **TB treatment in patients with liver disease** *If AST ≥3 times normal before treatment initiation:* • Standard therapy with frequent monitoring; or • Rifamycin and EMB and PZA for 6 months • INH and rifamycin and EMB for 2 months, then INH and rifamycin for 7 months (BII) *For patients with severe liver disease:* • Rifamycin and EMB for 12 months (preferably with another agent such as fluoroquinolone for first 2 months) (CII)	Treatment by Directly Observed Therapy (DOT) is strongly recommended for all HIV patients (AII). Rifabutin has less drug interaction potential and can be used in place of rifampin Rifapentine given once weekly can result in development of resistance, it is not recommended in HIV patients (EI) Twice weekly intermittent regimen containing rifamycin might lead to rifamycin resistance, particularly in advanced HIV patients with CD4 cell count <100 cells/μL; in this situation, therapy must be given as daily or 3 times weekly For paradoxical reaction that is not severe—may be treated with nonsteroidal anti-inflammatory drugs (NSAIDs) without change in TB or HIV medications (BIII)

(*Continued*)

Table 75-1. (*Continued*)

Opportunistic Infections	Preferred Therapy and Duration	Alternative Therapy	Other Options/Issues
Mycobacterium avium complex disease	*At least 2 drugs as initial therapy*: Clarithromycin 500 mg PO BID (AI) and Ethambutol 15 mg/kg PO QD (AI) Consider adding third drug for patients with advanced immunosuppression (CD4 <50), high mycobacterial loads, or in the absence of effective ART: Rifabutin 300 mg PO QD (AI) (dosage may be adjusted based on drug-drug interactions) (CIII) Duration (Chronic Maintenance Therapy): Lifelong therapy unless in patients with sustained immune recovery on ART (AII). *Chronic maintenance therapy*: (Secondary Prophylaxis) *First choice:* • Clarithromycin 500 mg PO twice daily (AI) plus ethambutol 15 mg/kg PO daily (AII); with or without rifabutin 300 mg PO daily (CI) *Second choice:* • Azithromycin 500 mg PO daily (AII) plus ethambutol 15 mg mg/kg body weight PO daily (AII); with or without rifabtuin 300 mg PO daily (CI)	*Alternative to clarithromycin:* Azithromycin 500–600 mg PO QD (AII) *Alternative third or fourth drug for patients with more severe symptoms or disseminated disease* (CIII): • Ciprofloxacin 500–750 mg PO BID; or • Levofloxacin 500 mg PO QD; or • Amikacin 10–15 mg/kg IV QD	NSAIDs may be used for patients who experience moderate to severe symptoms attributed to ART-associated immune reconstitution syndrome (CIII) If symptoms persist, short term (4–8 weeks of systemic corticosteroid (20–40 mg of prednisone) can be used (CIII). Maintenance therapy can be discontinued in patients who (BII): • completed ≥12 months therapy, and • remain asymptomatic, and • have sustained (≥6 months) CD4 count >100 cells/μL
Bacterial pneumonia	*Empiric therapy (targeting towards Streptococcus pneumoniae and Hemophilus influenzae):* • Extended spectrum cephalosporin (e.g., cefotaxime, or ceftriaxone) (AIII); or • Fluoroquinolone with enhanced activity against pneumococcus (e,g, gatifloxacin, levofloxacin, or moxifloxacin) (AIII) *Empiric therapy in patients with severe illness:* • Extended-spectrum cephalosporin and a macrolide (AIII)	*For high-level penicillin-resistant isolates (MIC ≥4.0 μg/mL):* • Consider adding vancomycin or a fluoroquinolone (CIII) • *Empiric therapy in patients with severe immunodeficiency (CD4≤100), a known history of previous pseudomonas infection, bronchiectasis, or relative or absolute neutropenia) (BIII):* Broaden empiric coverage to include antimicrobials with activities against *P. aeruginosa* and other gram-negative bacilli, e.g. ceftazidime, cefepime, piperacillin-	Patients with $CD4^+$ T-lymphocyte count of ≥200 cells/μL should receive a single dose of 23-valent polysaccharide pneumococcal vaccine (if not received during the preceding 5 years) (BII) Yearly influenza vaccine–might be useful in preventing pneumococcal superinfection after influenza respiratory infection (BII) Antibiotic prophylaxis may be considered in patients with

Table 75-1. (*Continued*)

		tazobactam, a carbepenem, high dose ciprofloxacin or levofloxacin • If ceftazidime or ciprofloxacin is used, addition of another antibacterial with optimal coverage for gram-positive infection is recommended	frequent recurrences (CIII)–caution should be taken for the risks for developing drug resistance and drug toxicities
Salmonellosis	*Salmonella gastroenteritis:* • Ciprofloxacin 500–750 mg PO BID (or 400 mg IV BID) (AIII) *Duration:* • Mild gastroenteritis without bacteremia: 7–14 days (BIII) • Advanced HIV (CD4 < 200) and/or bacteremia: at least 4–6 weeks (BIII) *Chronic Suppressive Therapy:* • For patients with *Salmonella* bacteremia–ciprofloxacin 500 mg PO BID (BII). Should be given for ≥2 months or until ART-induced immune reconstitution (BIII)	• TMP-SMX PO or IV (BIII) • Third generation cephalosporin such as ceftriaxone (IV) or cefotaxime (IV) (BIII)	Treatment is recommended in HIV patients because of high risk for bacteremia in this population (BIII) Newer fluoroquinolones (e.g., levofloxacin, gatifloxacin, or moxifloxacin) might also be effective (BIII)
Campylobacter jejuni infections	*For mild disease*: might withhold therapy unless symptoms persist for several days Optimal therapy: not well defined; options include: • ciprofloxacin 500 mg PO BID (BIII); or • azithromycin 500 mg PO QD (BIII) *Consider addition of an aminoglycoside in bacteremic patients (CIII) *Duration:* • Mild to moderate disease: 7 days • Bacteremia: at least 2 weeks		There is an increasing rate of quinolone resistance Antimicrobial therapy should be modified based on susceptibility reports Role of aminoglycoside is unclear
Shigellosis	Fluoroquinolone IV or PO for 3–7 days (AIII) Duration for bacteremia: 14 days (AIII)	• TMP-SMX DS 1 tab PO BID for 3–7 days; or (BIII) • Azithromycin 500 mg PO on day 1, then 250 mg PO QD for 4 days (BIII) Duration for bacteremia: 14 days (AIII)	Therapy is indicated both to shorten the duration of illness and to prevent spread of infection (AIII) Shigella infections acquired outside of U.S. have high rates of TMP-SMX resistance

(*Continued*)

Table 75-1. (*Continued*)

Opportunistic Infections	Preferred Therapy and Duration	Alternative Therapy	Other Options/Issues
Bartonella infections	*Non-CNS infections* • Erythromycin 500 mg PO QID (or IV at same dose if unable to take PO) (AII); or • Doxycycline 100 mg PO or IV q12h (AII) *CNS infections:* • Doxycycline 100 mg PO or IV q12h (AIII) *Duration:* At least 3 months (AII) Life-long therapy for patients with relapse (AIII)	• Azithromycin 600 mg PO QD (BII) • Clarithromycin 500 mg PO BID (BII) • Fluoroquinolones have variable activity in case reports and in vitro—may be considered as alternative (CIII)	
Treponema pallidum infection (syphilis)	*Early stage (primary, secondary, and early latent Syphilis)*: • Benzathine penicillin G 2.4 MIU IM for 1 (AII) *Late-latent disease (≥1yr or of unknown duration, without CNS involvement)* • Benzathine penicillin G 2.4 MIU IM weekly for 3 doses (AIII) *Late-stage (Aortitis and gummata)* • Infectious diseases consultation (AIII) *Neurosyphilis (CNS involvement including otic and ocular disease)* • Aqueous crystalline penicillin G 3–4 MIU IV q4h or total dose by continuous IV infusion for 10–14 days (AII) +/- Benzathine penicillin G 2.4 MIU IM weekly for 3 after completion of IV therapy (CIII)	*Early stage (primary, secondary, and early latent syphilis) treatment with close clinical monitoring* (BIII): • Doxycycline 100 mg PO BID for 14 days; or • Ceftriaxone 1 g IM or IV QD for 8–10 days; or • Azithromycin 2 g PO for 1 dose *Late-latent disease (without CNS involvement):* • Doxycycline 100 mg PO BID for 28 days (BIII) *Neurosyphilis:* • Procaine penicillin 2.4 MIU IM QD and Probenecid 500 mg PO QID for 10–14 days (BII) +/- Benzathine penicillin G 2.4 MIU IM weekly for 3 after completion of above (CIII); or • *For* penicillin *allergic pts:* Ceftriaxone 2 grams IM or IV QD for 10–14 days (CIII)	Desensitization to penicillin might be a better option than ceftriaxone in penicillin allergic patients with neurosyphilis (BIII) Combination of procaine penicillin and probenecid is not recommended for patients with history of sulfa allergy because these patients might be at risk for hypersensitivity reactions to probenecid
Candidiasis (mucosal)	*Oropharyngeal candidiasis:* *Initial episodes (7–14 day treatment):* • Fluconazole 100 mg PO QD (AI); or • Itraconazole oral solution 200 mg PO QD (AI); or • Clotrimazole troches 10 mg PO 5 times daily (BII); or	*Fluconazole-refractory oropharyngeal candidiasis:* • Itraconazole oral solution ≥200 mg PO QD (BII); or • Amphotericin B suspension 100 mg/mL (not available in U.S.)–1 mL PO QID (CIII); or • Amphotericin B deoxycholate 0.3 mg/kg IV QD (BII); or	*Suppressive therapy–generally not recommended (DIII) unless patients have frequent or severe recurrences* • Oropharyngeal candidiasis - fluconazole or itraconazole oral solution may be considered (CI).

Table 75-1. (*Continued*)

	• Nystatin suspension 4–6 mL QID or 1–2 flavored pastilles 4–5 times daily (BII) *Esophageal candidiasis (14–21 days):* • Fluconazole 100 mg (up to 400 mg) PO or IV QD (AI); or • Itraconazole oral solution 200 mg PO QD(AI) • Voriconazle 200 mg Po BID (AII) • Caspofungin 50 mg IV qd (AII) *Vulvovaginitis:* • Topical azoles (clotrimazole, butoconazole, miconazole, tionazole, or terconazole) for 3–7 days (AII) • Topical nystatin for 14 days (AII) • Oral Itraconazole 200 mg BID for 1 day or 200 mg QD for 3 days (AII) • Oral Fluconazole 150 mg for 1 dose (AII)	• Caspofungin 50 mg IV qD (BIII) • Voriconazole 200 mg PO or IV BID (CIII) *Fluconazole-refractory esophageal candidiasis:* • Caspofungin 50 mg QD (BIII); or • Voriconazole 200 mg PO or IV BID (CIII) • Amphotericin B 0.3–0.7 mg/kg IV QD (BII); or • Amphotericin liposomal or lipid complex 3–5 mg/kg IV QD (BII)	• Vulvovaginal candidiasis: daily topical azole for recurrent cases (CII) • Esophageal Candidiasis-fluconazole 100–200 mg daily (BI). Chronic or prolong use of azoles might promote development of resistance.
Cryptococcus neoformans meningitis	*Acute infection:* • Amphotericin B deoxycholate 0.7 mg/kg IV QD ± flucytosine 25 mg/kg PO QID for 2 weeks (AI); or • Liposomal Amphotericin B 4 mg/kg IV QD ± flucytosine 25 mg/kg PO QID for 2 weeks (AI) *Consolidation therapy:* • Fluconazole 400 mg PO QD for 8 weeks or until CSF cultures are sterile (AI) *Maintenance Therapy:* • Fluconazole 200 mg PO QD; lifelong unless immune reconstitution as a result of ART (AI)	*Acute infection (alternative):* • Amphotericin B 0.7 mg/kg/day IV for 2 weeks (BI); or • Fluconazole 400–800 mg/day (PO or IV) for less severe disease • Fluconazole 400–800 mg/day (PO or IV) and flucytosine 25 mg/kg PO QID for 4–6 weeks (BII) *Consolidation therapy (alternative):* • Itraconazole 200 mg PO BID (BI) *Maintenance therapy (alternative):* • Amphotericin B 1 mg/kg IV per week–for patients with multiple relapse on azole(s) or intolerant of azole(s) (CI); or • Itraconazole 200 mg PO QD–for patients intolerance of or failed fluconazole (BI)	Repeated lumbar puncture might be indicated as adjunctive therapy for patients with increased intracranial pressure (AII). Discontinuation of antifungal therapy can be considered in patients who remain asymptomatic, with $CD4^+$ T-lymphocyte count >100–200 cells/μL for ≥6 months (CIII) Some might consider performing a lumbar puncture before discontinuation of maintenance therapy
Histoplasma capsulatum infections	**Severe disseminated:** *Acute phase (3–10 days or until clinically improved):* • Amphotericin B deoxycholate 0.7 mg/kg IV QD (AI); or • Liposomal amphotericin B 4 mg/kg IV QD (AI)	**Severe disseminated:** *Acute phase (alternative):* • Itraconazole 400 mg IV QD (BIII) *Continuation phase alternatives:* • Itraconazole oral solution (BIII) • Fluconazole 800 mg QD (CII)	Acute pulmonary histoplasmosis in HIV-1 infected patients with $CD4^+$ T-lymphocyte count >500 cells/μL might require no therapy (AIII).

(*Continued*)

Table 75-1. (*Continued*)

Opportunistic Infections	Preferred Therapy and Duration	Alternative Therapy	Other Options/Issues (AIII).
	Continuation phase (12 weeks): • Itraconazole 200 mg cap PO BID (AII) Less severe disseminated: • Itraconazole 200 mg cap PO TID for 3 days, then 200 mg PO BID for 12 weeks (AII) Meningitis: • Amphotericin B deoxycholate or liposomal for 12–16 weeks (AII) *Maintenance therapy (Chronic suppression):* • Itraconazole 200 mg cap PO QD (AI)	**Mild disseminated:** • Fluconazole 800 mg PO QD (CII)	Some experts would consider discontinuation of antifungal therapy (CIII) in patients who are: • in remission • serum and urine histoplasma antigen , 4 units • completed 1 year itraconazole • CD4 cells count > 150 cells/μL
Coccidiodomycosis	**Nonmeningeal infection**: *Acute phase (diffuse pulmonary or disseminated disease):* • Amphotericin B deoxycholate 0.5–1.0 mg/kg IV QD continue until clinical improvement, usually 500–1000 mg total dose (AII) *Acute phase (milder disease):* • Fluconazole 400–800 mg PO QD (BIII); or • Itraconazole 200 mg PO BID (BIII) Meningeal Infections: • Fluconazole 400–800 mg IV or PO QD (AII) *Chronic Suppressive Therapy* • Fluconazole 400 mg PO QD (AII); or • Itraconazole 200 mg capsule PO BID (AII)	**Nonmeningeal infection:** *Acute phase (diffuse pulmonary or disseminated disease):* • Some experts add azole to amphotericin B therapy (BIII) **Meningeal infections:** • Intrathecal Amphoterin B (CIII)	Not enough data to recommend discontinuation of chronic suppressive therapy at this point.
Invasive aspergillosis	Voriconazole 400 mg IV or PO q12h for 2 days, then 200 mg q12h (AIII) **Duration of therapy:** based on clinical response	• Amphotericin B deoxycholate 1 mg/kg/day IV (AIII); or • Lipid formulations of amphotericin B 5 mg/kg/day IV (AIII) • Voriconazole and caspofungin (CIII)	Not enough data to recommend chronic suppression or maintenance therapy (CIII)

Table 75-1. (*Continued*)

Cytomegalovirus (CMV) disease	**CMV retinitis:** *For immediate sight-threatening lesions:* Ganciclovir (GCV) intraocular implant and valganciclovir 900 mg PO QD (AI) *For peripheral lesions:* Valganciclovir 900 mg PO BID for 14–21 days, then 900 mg PO QD (AII) *Chronic maintenance therapy* (secondary prophylaxis): First choice: • Valganciclovir 900 mg by mouth daily (BI) • Foscarnet 90–120 mg/kg body weight intravenously daily (AI); or Second choice: • Cidofovir 5 mg/kg body weight intravenously every other week with probenecid 2 g by mouth 3 hours before the dose followed by 1 g by mouth 2 hours after the dose, and 1 g by mouth 8 hours after the dose (total of 4 g) (AI); or • Fomivirsen 1 vial (330 μg) injected into the vitreous, then repeated every 2–4 weeks (AI); or **CMV esophagitis or colitis:** • Ganciclovir IV or Foscarnet IV for 21–28 days or until signs and symptoms have resolved (BII); oral valganciclovir may be used if symptoms are not severe enough to interfere with oral absorption (BII) • Maintenance therapy is generally not necessary, but should be considered after relapses (BII) **CMV pneumonitis:** • Treatment should be considered in patients with histologic evidence of CMV pneumonitis and who do not respond to treatment of other pathogens (AIII)	**CMV retinitis:** • Ganciclovir 5 mg/kg IV q12h for 14–21 days, then 5 mg/kg IV QD (AI); or • Ganciclovir 5 mg/kg IV q12h for 14–21 days, then Valganciclovir 900 mg PO QD (AI); or • Foscarnet 60 mg/kg IV q8h or 90 mg/kg IV q12h for 14–21 days, then 90–120 mg/kg IV q24h (AI); or • Cidofovir 5 mg/kg IV for 2 weeks, then 5 mg/kg every other weeks; each dose should be given with IV saline hydration and oral probenecid (AI); or • Repeated intravitreal injections with fomivirsen (for relapses only, not as initial therapy) (AI)	Choice of initial therapy for CMV retinitis should be individualized, based on location and severity of the lesion(s), level of immunosuppression, and other factors such as concomitant medications and ability to adhere to treatment (AIII) Initial therapy in patients with CMV retinitis, esophagitis, colitis, and pneumonitis should include optimization of ART (BIII) Some experts suggest delaying ART in patients with CMV neurological disease due to concerns of worsening of condition as a result of immune recovery inflammatory reaction (CIII) Preemptive treatment of patients with CMV viremia without evidence of organ involvement is generally not recommended (DIII). Maintenance therapy for CMV retinitis can be safely discontinued in patients with inactive disease and sustained $CD4^+$ T-lymphocyte (>100–150 cells/mm^3 for ≥6 months); consultation with ophthalmologist is advised (BII) Patients with CMV retinitis who discontinued maintenance therapy should undergo regular eye examination for early detection of relapse (AIII). Immune recovery uveitis (IRU) might develop in the setting of immune reconstitution. Treatment of IRU: periocular corticosteroid or short courses of systemic steroid.

(*Continued*)

Table 75-1. (*Continued*)

Opportunistic Infections	Preferred Therapy and Duration	Alternative Therapy	Other Options/Issues
	• The role of maintenance therapy is not yet established (CIII). **CMV neurological disease:** • GCV IV and Foscarnet IV continue until symptomatic improvement (BII) • Maintenance therapy should be continued for life (AI)		Because of its poor oral bioavailability and with the availability of valganciclovir, oral ganciclovir should not be used (DIII).
Herpes simplex virus (HSV) disease	*Orolabial lesions and Initial or recurrent genital HSV:* Famciclovir 500 mg PO BID or Valaciclovir 1 g PO BID or Acyclovir 400 mg PO TID for 7 days (AII) *Moderate-to-severe mucocutaneous HSV infections:* • Initial therapy Acyclovir 5 mg/kg IV q8h (AII) • After lesions began to regress, change to Famciclovir 500 mg PO BID or Valacyclovir 1 g PO BID or Acyclovir 400 mg PO TID. (AII) Continue therapy until lesions have completely healed *HSV keratitis:* • Trifluridine 1% ophthalmic solution, one drop onto the cornea every 2 hours, not to exceed 9 drops per day, for no longer than 21 days (AII) *HSV Encephalitis:* • Acyclovir 10 mg/kg IV q8h for 14–21 days (AII)	*Acyclovir-resistant HSV:* • Foscarnet 120–200 mg/kg/day IV in 2–3 divided doses until clinical response (AI) • Cidofovir 5 mg/kg IV weekly until clinical response (AI) *Alternative for acyclovir-resistant HSV infections:* • Topical trifluridine • Topical cidofovir *Note*: Both of the above preparations are not commercially available. Extemporaneous compounding of these topical products can be prepared using trifluridine ophthalmic solution and cidofovir for intravenous administration	Chronic suppressive therapy with oral acyclovir, famciclovir, or valacyclovir may be indicated in patients with frequent or severe recurrences.
Varicella zoster virus (VZV) disease	*Primary VZV infection (chicken pox):* • Acyclovir 10 mg/kg IV q8h for 7–10 days (AII) • Switch to oral therapy (Acyclovir 800 mg PO QID or Valacyclovir 1g TID or Famciclovir 500 mg TID) after defervescent if there is no evidence of visceral involvement (AII) *Local dermatomal herpes zoster:* • Famciclovir 500 mg or Valacyclovir 1 g PO TID for 7–10 days (AII)		Corticosteroids for dermatomal zoster are not recommended (DIII)

Table 75-1. (*Continued*)

	Extensive cutaneous lesion or visceral involvement: • Acyclovir 10 mg/kg IV q8h, continue until cutaneous and visceral disease clearly resolved (AIII)
	Progressive Outer Retinal Necrosis (PORN): • Acyclovir IV 10 mg/kg q8h and Foscarnet 60 mg/kg IV q8h (AIII)

infant death syndrome and exacerbation of chronic obstructive lung disease.[10–12]

Pneumocystis is probably transmitted by respiratory spread from human to human. There is speculation that asymptomatic individuals can transmit infection and that disease can occur either due to reactivation of latent infection, or acquisition of a new strain. Thus, all episodes of PCP may not be due to reactivation of latent disease, but may represent reinfection with the same or a different strain of the organism.[13,14]

Before the widespread use of ART and primary PCP prophylaxis, PCP occurred in 70–90% of patients with HIV infection.[15] Approximately 90% of cases occurred among patients with $CD4^+$ T lymphocyte cell counts <200 cells/μL.[4,16] The current $CD4^+$ T lymphocyte cell count continues to be the major determinant of susceptibility. The nadir $CD4^+$ T lymphocyte cell count is not a major factor for determining susceptibility.[3,17] Thus decisions regarding differential diagnosis and the need for chemoprophylaxis should be made on the basis of the current count. HIV viral load is also a risk factor for PCP. However, most decisions are made based on the $CD4^+$ T lymphocyte cell count. A substantial number of cases of PCP in the United States continue to occur among patients who are not aware of their HIV infection. A significant number also occur among patients who are aware of their infection but are not receiving care.[7,18]

Pneumocystis has an unusual tropism for the lung. The biologic basis of this tropism is not understood. However, from a clinical perspective, *P. jiroveci* rarely causes clinical disease outside the lungs. If patients are systematically imaged, lesions in the liver, spleen, and kidneys, that can resolve with therapy, can be identified, and thus appear to be due to pneumocystis. There are reports of occasional cases of pneumocystis involving the eye, ear, liver, spleen, kidney, and lymph nodes.[19–21] Cases of disseminated disease with abundant organisms in multiple capillary beds have been described.[22] Many but not all of these cases occurred in patients receiving aerosolized pentamidine prophylaxis.[19–22] Thus, these cases were purported to be related to high drug concentrations in the lung, with limited drug in other organs. Whether disseminated disease is truly more common among patients receiving aerosol pentamidine prophylaxis, or whether reporting bias has overrepresented such cases, is not clear.

Patients with pneumocystis present with fever, shortness of breath, and dyspnea. There is nothing specific for PCP as opposed to other pulmonary processes in the presentation. The cough is usually nonproductive, or productive of scant amounts of watery sputum. The shortness of breath typically presents slowly, progressing over many days or weeks. There is usually no chest pain or hemoptysis. A substernal "catching" on deep inspiration can often be elicited.[23,24] The onset is typically more indolent than the presentation of PCP in patients immunosuppressed by virtue of corticosteroids or antineoplastic chemotherapy.

Physical examination is often unrevealing, except for fever and tachypnea. Routine laboratory testing is also unremarkable except for nonspecific elevations of serum lactate dehydrogenase.[25] Hypoxemia may range from mild-moderate (room air arterial oxygen [pO_2] of >70 mm Hg or alveolar-arterial O_2 difference [A-a] DO_2 <35 mm Hg) to moderate-to-severe levels (pO_2 <70 mm Hg or [A-a] DO_2 >35 mm Hg). Patient and health-care provider education can enable cases to be identified earlier in their natural history, before patients have severe symptoms, and at a time when their likelihood of responding to therapy is greatest.

The typical chest radiograph is one of diffuse and symmetrical bilateral increased interstitial markings.[26–30] When patients are identified early, before symptoms are severe, the chest radiograph may be normal, although a high-resolution

CT scan will show diffuse interstitial infiltrates. As disease progresses, interstitial infiltrates become apparent, followed by diffuse alveolar involvement. Pleural effusions, lymphadenopathy, and cavities are unusual unless another pathogenic process is present. Pneumatocoeles, however, are quite characteristic. When they are subpleural and rupture, pneumothorax can develop.

P. jiroveci pneumonia can present with "atypical" radiographs; asymmetric involvement, upper lobe disease, lobar infiltrates, and nodules are among the presentations that have been described. Thus, imaging cannot confirm the diagnosis of PCP, and therefore, a microbiologic diagnosis should be established.

Because *P. jiroveci* cannot be routinely cultivated, definitive diagnosis requires the demonstration of cysts or trophozoites within tissue or body fluids. Organisms are recognized via colorimetric or immunofluorescent stains. The development of monoclonal antibodies provides a rapid, sensitive, and easy-to-perform immunofluorescence assay, which is more sensitive than conventional staining.[31,32] Organisms can almost always be identified in bronchoalveolar lavage. At many institutions, induced sputum also has a very high sensitivity; over 90% of diagnoses can be established in patients with HIV or other immunodeficiencies.[31,32]

PCR has been developed for diagnosis by research laboratories. For bronchoalveolar lavage, sputum, or oral rinses, PCR can be very sensitive and quite specific.[33] A negative PCR test is an extremely sensitive method for excluding PCP. A positive PCR can represent true disease, or subclinical infection. A quantitative test can provide better specificity than a qualitative assay. Serologic assays to diagnose PCP have been studied, but are not yet clinically useful.

Trimethoprim–sulfamethoxazole (TMP–SMX) is the agent of choice for the initial treatment of acute PCP.[34,35] Parenteral pentamidine is the alternative choice for patients with severe disease. TMP–SMX is as effective as parenteral pentamidine but is less toxic. Atovaquone, clindamycin–primaquine, and dapsone–pyrimethamine are reasonable options for patients with mild disease. For patients with moderate or severe disease, parenteral trimetrexate can also be used.

Patient outcome depends on host, microbiologic, and therapeutic factors.[35,36] Patients have a better prognosis if therapy is started before disease is severe, and if their immunologic status is relatively preserved. Patients without severe underlying lung disease, and patients without serious concurrent disease processes, also have better prognoses.

Oral outpatient therapy with TMP–SMX is highly effective among patients with mild-to-moderate disease.[37–39] In many series, survival for patients with mild-to-moderate disease is >90–95%. As noted above, patients with mild disease can be treated successfully with other oral regimens, including dapsone plus pyrimethamine, atovaquone, and clindamycin plus primaquine. Parenteral pentamidine and parenteral trimetrexate are options for patients with more severe disease.

TMP–SMX is associated with a high frequency of adverse effects. Pruritis, nausea, rash, leukopenia, hepatitis, and nephritis have commonly been reported.[35,37–41] Mild adverse events do not necessarily require discontinuation of TMP–SMX. Often these toxicities can be watched carefully, or managed symptomatically while therapy is completed. In the past, all pneumocystis organisms were presumed to be sensitive to TMP–SMX. However, no assay was available to determine if this were true. More recently, both the target enzymes for sulfa and for trimethoprim have been sequenced from human isolates. Mutations associated with resistance to sulfa drugs have been documented.[42] There are conflicting reports in case series as to whether or not these mutations are associated with poorer outcome when TMP–SMX is used for therapy.[43,44] Patients who develop PCP despite TMP–SMX prophylaxis are usually effectively treated with standard doses of TMP–SMX. This suggests that at least some cases of resistance involve low level reduction in drug activity, and that such resistance can be overcome with high doses. Whether such resistance will become more difficult to overcome as TMP–SMX exposure continues, remains to be determined.

Intravenous pentamidine is the most effective alternative to TMP–SMX.[34] This drug can only be given parenterally for therapy, as aerosol pentamidine is not sufficiently effective for acute therapy to be a recommended regimen. Intravenous pentamidine can be associated with substantial toxicities, including renal dysfunction, pancreatitis, and hyper and hypoglycemia.[35,40] Patients also become hypoglycemic at unpredictable times, either early during the course or weeks after the final dose. Patients may then become hyperglycemic due to destruction of pancreatic beta cells.

Trimethoprim–dapsone is as effective as TMP–SMX, but the dapsone probably has a 50% cross reactivity with sulfonamides.[39] Primaquine–clindamycin is effective for mild-to-moderate disease; however, primaquine is only available as oral preparation and is associated with rash and G-6-PD associated hemolysis.[45,46] Atovaquone is less effective than TMP–SMX for mild disease, but is very well tolerated.[38] Absorption can be an issue in patients unable to ingest high fat foods.[38] Trimetrexate with leucovorin is less effective than TMP–SMX, but can be used if TMP–SMX is not tolerated and an intravenous therapy is needed.[47]

Moderate-to-severe disease (pretherapy pO_2 <70 mm Hg on room air) should be treated with adjunctive corticosteroids in addition to the specific anti-*Pneumocystis* regimen. The use of adjunctive corticosteroids substantially decreases morbidity and improves survival for patients with moderate-to-severe disease.[34,48] Use of corticosteroids is not recommended if the diagnosis of PCP is not promptly confirmed. However, it should be intuitively obvious that patients with moderate-to-severe disease should have a specific diagnosis

established to ascertain that the correct causative process is being treated.

Therapy for PCP is usually continued for 21 days. However, no trial has demonstrated superiority of 21 days over 14 days. Moreover, patients with severe disease are often treated for more than 21 days if their response is slow, or is incomplete, after 21 days of therapy.

As noted above, many authorities recommend delaying the initiation of ART until the completion of anti-PCP therapy, given the possibility of IRIS that may complicate the treatment of PCP.[49] For patients with severe hypoxemia, such an IRIS can precipitate respiratory failure. The initiation of ART can also complicate the management of toxicities. For instance, when skin rash or abnormal liver function tests develop, it may be difficult to determine which drug was most likely to cause the toxicity.

All patients who have survived an episode of PCP should receive lifelong secondary prophylaxis unless ART is initiated and their $CD4^+$ T lymphocyte cell count persists above 200cells/μL.[50] TMP–SMX is the drug of choice for both primary and secondary prophylaxis. If patients do not tolerate TMP–SMX and the toxicity is not life-threatening, an oral desensitization regimen can be useful for permitting patients to tolerate the drug. For patients who are intolerant of TMP–SMX,[51–53] dapsone, atovaquone or aerosolized pentamidine may be used with a high degree of efficacy.[50]

PROTOZOAL INFECTIONS

Toxoplasma gondii

Toxoplasma gondii, an intracellular coccidian protozoan, causes zoonosis. Primary infection occurs after eating undercooked or raw meat containing tissue cysts, or via ingestion of oocysts that have been shed in cat feces. Transmission of the organism does not occur via person-to-person contact. Primary infection is usually asymptomatic in immunocompetent hosts. Clinical disease occurs when hosts are immunosuppressed years after their primary infection.

Seroprevalence indicating chronic, latent disease varies geographically, with seroprevalence being 75–90% in Africa and European countries, but 15% in the United States.[34,50,54] In the pre-ART era, of those HIV-infected patients who where seropositive for toxoplasma, 50% would develop clinical toxoplasmosis.[55] The incidence of clinical disease has decreased substantially since the introduction of ART and the use of prophylaxis in those who were seropositive for *T. gondii.* Clinical toxoplasmosis rarely occurs until the $CD4^+$ T lymphocyte cell count falls below 100 cells/μL.[55–58]

The predominant clinical presentation of toxoplasmosis among AIDS patients is a focal mass lesion of the central nervous system. Patients may present with headache, confusion, seizure, or motor weakness. Patients are often not febrile. Disease outside the central nervous system is unusual, but cases involving the gastrointestinal tract, lung, heart, kidney, and eye have been reported.[58]

Cerebral toxoplasmosis is usually established presumptively by the presence of an enhancing central nervous tract lesion on CAT scan or MRI scan, and response to therapy.[34,58,59] Positron emission tomography (PET) or single-photon emission computed tomography (SPECT) scanning might be helpful in distinguishing between toxoplasmosis and primary central nervous system lymphoma.[60,61] However, literature correlating PET or SPECT imaging with pathology or definitive response to anti-toxoplasma therapy is sparse.

Serology can be very helpful in establishing the diagnosis. HIV-infected patients with toxoplasmosis are almost always seropositive for anti-toxoplasma IgG antibodies when testing is done at a reference laboratory. The absence of IgG antibody makes a diagnosis of toxoplasmosis highly unlikely. Anti-toxoplasma IgM antibodies are usually absent; thus, this test is not helpful diagnostically.[58] The use of polymerase chain reaction (PCR) in the cerebrospinal fluid (CSF) for the detection of *T. gondii* has a low sensitivity and is available from a few reference laboratories.[62,63]

The definitive diagnosis of toxoplasmic encephalitis (TE) requires the demonstration of organism on brain tissue via brain biopsy. Brain biopsy is generally reserved for patients failing to respond to therapy or for patients in whom an alternative diagnosis is likely from the clinical presentation. In a patient with a compatible $CD4^+$ T lymphocyte cell count and a presumptive radiologic diagnosis, it is appropriate to begin empirical treatment for toxoplasmosis, especially if the patient is known to be seropositive for toxoplasma infection and not receiving anti-toxoplasma prophylaxis. CSF testing for antibody or for PCR positivity can be helpful.[62–64] However, these tests and their interpretation are not standardized. A biopsy is indicated if there is no clinical and radiographical improvement in 10–14 days.[34,55,58]

The preferred treatment for toxoplasmosis is the synergistic combination of pyrimethamine and sulfadiazine plus leucovorin. The latter is used to offset hematologic effects of pyrimethamine.[34,55,65] In those who are unable to tolerate this regimen, the preferred alternative regimen is pyrimethamine plus clindamycin and leucovorin, which appears to have comparable efficacy.[34,55,65] Other agents that have shown efficacy include dapsone, atovaquone, and azithromycin, all of which should probably be administered with pyrimethamine, based on limited experience.[58,66,67]

Acute therapy should be continued until the clinical abnormalities and radiologic lesions show no additional signs of improvement. Most clinicians would continue therapy for at least 6 weeks.

Adjunctive corticosteroids can be used if patients are symptomatic and there are radiologic signs of brain edema or mass effect. Anticonvulsants should only be administered to patients with seizure activity and should not be given prophylactically.[34]

Patients who have successfully completed a 6-week course of induction therapy should receive lifelong secondary prophylaxis, unless, through the use of ART immune reconstitution, their $CD4^+$ T lymphocyte cell counts increase to >200 cells/μL for greater than 6 months, and the patients have maintained virologic suppression.[34,68–70]

Cryptosporidiosis

Cryptosporidia are coccidian protozoa that infect the small bowel mucosa. In immunocompromised patients, the large bowel, the biliary-pancreatic tree, and occasionally the respiratory tract can also be involved. There are several zoonotic species found in feces of cattle and domestic pets, and that contaminate rural and urban water supplies, all of which can infect humans despite standard chlorination.[71] Person-to-person transmission can occur, especially among men who engage in oral–anal sex, and among individuals who work in day-care centers, or whose children spend time in day-care centers. Exposure to cryptosporidia can occur in day-care centers during diapering, or due to fecal contamination of environmental sources.

In immunocompetent hosts, infection generally leads to a mild, self-limited disease, in contrast to patients with AIDS who develop a persistent chronic enteritis of variable severity. The most common presentation of cryptosporidiosis is acute or subacute onset of profuse nonbloody diarrhea, which can be associated with nausea, vomiting, crampy lower abdominal pain, and fever. Severe disease occurs primarily in those with $CD4^+$ T lymphocyte cell counts less than 100 cells/μL.[72,73] Since the wide availability of ART, the incidence of cryptosporidiosis has decreased.

Diagnosis of cryptosporidiosis is based on identification of oocysts on direct microscopic evaluation of stool, intestinal biopsy, or other fluids or tissues. Oocysts also can be detected by direct immunofluorescent or enzyme-linked immunosorbent assays.[72–74]

No drugs specifically used against cryptosporidiosis are clearly effective. However, ART with immune reconstitution (an increase in $CD4^+$ T lymphocyte cell counts to >100cells/μL) has been associated with complete resolution of cryptosporidiosis.[34,75,76] Therefore, optimizing ART to achieve full virologic suppression is essential.

Paromomycin, a nonabsorbable aminoglycoside has been used, but a controlled trial of this drug failed to show benefit compared to placebo.[34,77,78] Combination therapy with paromomycin and azithromycin appeared to show some clinical benefit in a single study, but patients rarely have had microbiologic cure.[79] Nitazoxanide has some efficacy in HIV-uninfected children, but evidence of efficacy in patients with HIV infection has been unimpressive.[80] Aggressive fluid support, antimotility agents, and total parenteral nutrition can be helpful management tools.[34]

Microsporidia

Microsporidia organisms are obligate spore-forming intracellular protists, related to fungi in taxonomy. They are ubiquitous in nature, likely zoonotic and waterborne in origin.[81,82] There are five major genera that have been identified as human pathogens including *Enterocytozoon*, *Septata*, *Nosema*, *Encephalitzoon,* and *Pleistophora*. The incidence of microsporidiosis has declined dramatically with the widespread use of ART. Those at risk have $CD4^+$ T lymphocyte cell counts <100 cells/μL.[82]

Like cryptosporidiosis, the most common manifestation of microsporidiosis is diarrheal illness. However, encephalitis, ocular infections, sinusitis, myositis, and disseminated infection have been reported.[82–86] Manifestations differ for each microsporidial species.

Enterocytozoon bieneusi is the most commonly recognized enteric pathogen responsible for approximately 90% of human infection and is associated with malabsorption, diarrhea, and cholangitis. It is important to recognize which species of microsporidium is causing disease, since response to therapy differs dramatically among species.

Diagnosis of microsporidiosis is made by modified trichrome staining of the stool or by light and electron microscopy of small bowel biopsies.[74,85] ART is the only specific intervention, which is effective. ART with immune restoration (increase of $CD4^+$ T lymphocyte count >100 cells/μL) can be associated with a resolution of symptoms in microsporidiosis.[87,88] Patients with severe diarrhea may not absorb ART efficiently, and thus may not have an optimal immunologic or virologic response. Short of ART, no specific treatment is consistently effective against *E. bieneusi*, the most common cause of microsporidial diarrhea.[86–89]

For other types of microsporidiosis, albendazole can be effective for initial therapy of intestinal and disseminated (not ocular) microsporidiosis caused by microsporidia other than *E. bieneusi*.[90,91] Fumagillin has been reported to also be effective when used as an oral or a topical agent; however, fumagillin is not available in the United States.[92]

Isospora belli and Cyclospora

Isosporiasis is a disease caused by the coccidian protozoa *Isospora belli*, which is commonly found in the tropical and subtropical climates. It is endemic in AIDS patients in Haiti and Africa. Isospora causes disease in the proximal small intestine leading to a severe diarrheal illness.[93] Diagnosis is made by identifying acid-fast oval oocysts in stool specimens. The disease is effectively treated with TMP–SMX. Pyrimethamine or ciprofloxacin may also be effective.[94] Lifelong maintenance therapy is necessary to prevent relapses in AIDS patients, unless immune restoration occurs due to ART. Immune restoration with ART is associated with more rapid resolution of symptoms and less frequent relapses.[34]

Cyclospora infection in HIV-infected patients is similar to isosporiasis in that it is common in the tropics, responds to treatment with TMP–SMX,[95–98] and has a high-resolution rate with immune reconstitution due to ART.[50] *Cyclospora* are waterborne, and disease occurs predominately in the summer months. Outbreaks have been reported due to fruits or vegetables imported into the United States. Clinically, watery diarrhea is present with cramping, fatigue, and weight loss.[95,97,98] Diagnosis is made by identifying acid-fast organisms in stool samples. Therapy with TMP–SMX or possibly ciprofloxacin appears to be effective.

FUNGAL INFECTIONS

Candida species

For patients with HIV disease, Candida predominantly causes mucosal disease. Invasive disease is unusual: when it occurs it is associated with other risk factors such as intravascular catheters or intravenous substance abuse.[99] Candidiasis most often manifests as oral thrush, esophagitis, or vulvovaginitis in patients with HIV infection. The majority of infections are caused by *Candida albicans*. However, the widespread use of fluconazole has been accompanied by a gradual emergence of nonalbicans *Candida* species, such as *C. glabrata* and *C. krusei*.[100,101] These organisms are often azole resistant and can cause fluconazole refractory mucosal candidiasis in patients with advanced AIDS.[99,102–109]

The occurrence of oropharyngeal or esophageal candidiasis in patients with no prior AIDS manifestations is recognized as an indicator of clinical progression and immune suppression: this alone is an indication for primary PCP prophylaxis regardless of $CD4^+$ T lymphocyte count. Vulvovaginitis, in contrast, occurs in patients at all $CD4^+$ T lymphocyte cell counts and may be unusually frequent in patients with HIV, especially those with low $CD4^+$ T lymphocyte cell counts.[34] Some of these cases occur at $CD4^+$ T lymphocyte cell counts >200 cells/μL. However, most cases occur in patients with $CD4^+$ T lymphocyte cell counts <200 cells/μL.[98,105]

Oropharyngeal candidiasis presents with white plaques, having a very characteristic appearance, on the buccal mucosa and tongue. Scrapings of lesions can be diagnostic if much yeast is seen. Esophagitis usually presents with dysphagia, odynophagia, or retrosternal discomfort. Because *Candida* is a much more likely cause of these symptoms than any other pathogen, an empiric course of antifungal therapy is usually reasonable. Odynaphagia is said to be more characteristic of CMV esophagitis than candida esophagitis, but in practice, this distinction often does not hold up. Endoscopy for diagnosis is indicated only if there is no response to a 7–10 day course of empiric therapy.[107]

Topical clotrimazole or nystatin can be effective for mild oral candidiasis. Both are well tolerated and inexpensive. Many clinicians and patients prefer oral fluconazole or itraconazole. Oral azole therapy is also effective for esophagitis or vaginitis. Voriconazole is also effective, but there is no strong reason to prefer voriconazole over fluconazole or itraconazole in most cases. Caspofungin or micafungin are also effective, but these agents are only available as intravenous preparation, and are thus used only for refractory cases. An amphotericin B preparation could also be used for refractory cases.

Effective ART reduces the frequency of occurrence of mucosal candidiasis[34] Secondary prophylaxis is generally not given to prevent recurrences, unless the recurrences are particularly frequent or severe. Prophylaxis is not recommended because of the cost, inconvenience, and potential drug interactions of fluconazole, as well as the potential for chronic prophylaxis to promote the occurrence of azole-resistant strains.[34]

Cryptococcus neoformans

Before the advent of ART, cryptococcosis occurred in 5–10% of patients with HIV infection in North America.[110–113] Pigeon and other bird droppings are most often considered the environmental source. The incidence has declined dramatically with the use of ART, and the majority of cases are seen in patients with $CD4^+$ T lymphocyte cell counts <50 cells/μL.[111]

Meningitis is the most common clinical manifestation, although pulmonary and disseminated disease is well described.[112] Meningitis typically presents subtly with fatigue and headache. Meningismus is present in only 22% and fever is present in 65% of the patients. Thus, subtle presentations should be watched for. Extrameningeal disease can present as pneumonia with fever and cough, as disseminated disease with skin lesions, and as fever with severe malaise. Diagnosis of cryptococcosis is established by the presence of the organism on stain or culture, or by detection of cryptococcal antigen in the serum, CSF, or less often, some other tissue or fluid such as bone marrow, bronchoalveolar lavage fluid, or lymph node.[112,114] Clinicians suspicious of cryptococcal disease will typically obtain a serum cryptococcal antigen, blood cultures for fungus, and spinal fluid for culture and antigen determination.

The recommended initial treatment for acute disease is intravenous amphotericin B in preference to fluconazole.[34,111,114–119] The addition of flucytosine does not appear to offer a significant benefit or improve immediate outcome in the setting of AIDS, but does appear to be associated with decreased risk for relapse.[34,116,119] Lipid formulations of amphotericin B also appear to be effective.[116,117]

The availability of oral azole antifungal agents has led to several studies evaluating these as alternatives to amphotericin in the initial treatment of cryptococcal meningitis. The greatest experience has been with fluconazole, which has a high bioavailability, and adequate CSF levels are readily

attained. Fluconazole has been found to be effective; however, it has been associated with a higher mortality in the first 2 weeks of treatment and a longer time to attain a negative CSF culture as compared with amphotericin.[34,115,116] Itraconazole is not an appropriate choice for initial management due to low penetration of the blood–brain barrier. Azole therapy should almost never be used as the sole therapy before at least 2 weeks of amphotericin B has been given.

Increased intracranial pressure can cause clinical deterioration. In such cases, the CSF opening pressure is usually >200 mm H_2O.[120] In one large clinical trial, 93% of deaths occurring in the first 2 weeks were associated with increased intracranial pressure.[118] The intervention for reducing symptomatic elevated intracranial pressure is repeated daily lumbar punctures. CSF shunting may also be considered.[34] Corticosteroid therapy is not known to be beneficial.

After a 2-week period of successful induction therapy, consolidation therapy should be initiated with fluconazole administered for 8 weeks.[111,114,121] Some clinicians would advocate repeating the lumbar puncture after 8 weeks to assess the sterility of the CSF. Fluconazole maintenance therapy is recommended following the 8-week course. Maintenance treatment for cryptococcal disease is lifelong, unless immune reconstitution occurs as a consequence of ART.[34]

Histoplasma capsulatum

Histoplasma capsulatum is a dimorphic fungus that grows as a mold in soil contaminated by bat or bird excreta. Primary infection occurs when microconidia are inhaled into the lungs, where they grow as the pathogenic yeast phase. Histoplasmosis occurs in 2–5% of patients with AIDS. Most cases occur in the Midwest and Puerto Rico.[34,122,123] In areas where the disease is not endemic, it most often occurs among those who have previously lived in an endemic area. Disease may occur due to either primary infection or reactivation.[122–124] Clinical disease does not usually occur until the $CD4^+$ T lymphocyte cell count is below 150 cells/μL.

Patients typically present with pulmonary disease or with fever. Patients with higher $CD4^+$ T lymphocyte cell counts may have localized pulmonary infiltrates. Patients with $CD4^+$ T lymphocyte cell counts below 100 cells/μL have diffuse pulmonary disease, or a sepsis-like syndrome. A severe sepsis syndrome with hypotension and multiorgan system dysfunction is seen in 10% of cases; this is referred to as progressive disseminated histoplasmosis. Febrile patients may have a prolonged syndrome with fever and weight loss. Hepatosplenomegaly may also be present. Other less common presentations include central nervous system, gastrointestinal, chorioretinitis, and cutaneous manifestations.

Diagnosis of histoplasmosis is established either by recovery of the organism in culture or by visualization in histopathologic specimens.[124,125] Fungal stain of blood smears or tissues might yield a rapid diagnosis, but the sensitivity is <50%. Detection of *Histoplasma* polysaccharide antigen in blood or urine is a sensitive method for rapid diagnosis of disseminated histoplasmosis, but insensitive for localized pulmonary infection. Levels of *Histoplasma* antigen decline with therapy and increase with relapse, providing a useful tool for monitoring the response to therapy.[124]

The initial treatment for histoplasmosis should be intravenous amphotericin B.[34,126,127] Either the deoxycholate or liposomal formulation can be used. This should induce remission in 85–90% of patients. Liposomal amphotericin B (AmBisome) is better tolerated than the deoxycholate preparation.[126] Liposomal amphotericin is preferred in patients with severe or moderately severe disseminated histoplasmosis. Itraconazole can be used for mild disease.[127] Chronic maintenance therapy should be continued for life, unless ART results in immune reconstitution.[34]

Coccidioides immitis

Coccidiomycosis is endemic to the deserts of the southwestern United States, Mexico, and Central America. The incidence of disease in endemic areas ranged from 2% to 5% in the pre-ART era. Increased risk is associated with extensive exposure to disturbed soil, as might be seen with gardening, farming, or excavations.[34,128,129] Active disease may represent either reactivation of latent disease or recently acquired primary infection. Coccidiomycosis in HIV-infected patients usually occurs in those with a $CD4^+$ T lymphocyte cell count <250 cells/μL and a previous diagnosis of AIDS.[128,129]

The most common clinical presentation in HIV-infected patients is diffuse pulmonary disease, which presents as cough, fever, night sweats, fatigue, and weight loss. The chest radiograph typically shows a diffuse reticulonodular infiltrate. Disseminated extrapulmonary disease manifests as generalized lymphadenopathy, skin nodules, cutaneous ulcers, peritonitis, liver lesions, and osteomyelitis.[128] Definitive diagnosis is based on culture of the organism from sputum, bronchoalveolar lavage fluid or tissue, or demonstration of spherules on histopathology. Blood cultures are rarely positive. IgG antibody is positive in the majority of cases, but antibody does not identify acute versus chronic disease.

For nonmeningeal pulmonary or disseminated disease, amphotericin B is the preferred initial therapy.[34,130–132] It should be continued until clinical improvement is observed, which usually requires a total of 1–2.5 g. Fluconazole or itraconazole might be appropriate alternatives for patients with mild disease. Coccidioidal meningitis should be treated with fluconazole, which has been reported to be successful in approximately 80% of patients.[131] Lifelong suppressive therapy should be administered with daily fluconazole. Some clinicians recommend stopping therapy for patients with $CD4^+$ T cell responses to levels ≥200 cells/μL after prolonged therapy, but the safety of such an approach is not well established for all forms of coccidiomycosis in this patient population.

Itraconazole could also be used for suppression of non-meningeal disease.[130–132]

CYTOMEGALOVIRUS INFECTIONS

In the pre-ART era, disease due to reactivation of latent cytomegalovirus (CMV) infection affected 40% of AIDS patients.[34,133] Incidence of new cases of CMV end-organ disease has decreased substantially.[34] End-organ disease caused by CMV occurs among persons with $CD4^+$ T lymphocyte cell counts <50 cell/μL, who are either not receiving ART or have failed to respond to ART.[34,133–136]

The majority of patients with HIV infection are seropositive for CMV, with highest rates among men that have sex with men (rates up to 95%) and intravenous drug users. In patients whose only risk factor is heterosexual contact, the rate may be substantially less. Most CMV disease is caused by reactivation of latent disease, but primary infection or reinfection may be responsible for some cases. The most common manifestation of end-organ disease is retinitis, although colitis, esophagitis, and neurological disease are also well recognized. CMV pneumonitis is a rare occurrence.[133–136]

The diagnosis of CMV retinitis is based on characteristic ophthalmologic findings. Diagnosis of CMV esophagitis or colitis is based on histopathologic demonstration of characteristic intranuclear and intracytoplasmic inclusions. Neurologic disease is diagnosed based on either brain biopsy or PCR testing of CSF.

CMV can be detected in blood by culture or PCR.[135] CMV can also be found by culture or PCR in urine, other body fluids, and various tissues. However, the presence of CMV by culture or PCR does not necessarily imply that CMV is the cause of disease. The demonstration of CMV inclusion bodies in cytologic preparations or in tissue may not necessarily indicate that CMV is causing disease and should be treated. CMV involvement can be focal; thus, disease may be missed even when large pieces of tissue are sampled. Alternatively, a few CMV inclusion bodies can be seen even when this virus is not the true cause of the predominant pathologic process.

CMV retinitis requires immediate treatment, especially when the fovea or optic disk is threatened. Without appropriate care, CMV retinitis will progress rapidly and produce substantial visual loss. There are five FDA-approved treatments for CMV retinitis: intravenous ganciclovir, oral valganciclovir, intravenous foscarnet, intravenous cidofovir, and an ocular device containing ganciclovir.[34,133–136]

The choice of initial therapy for CMV retinitis should be based on the location and severity of lesions, the patient's ability to adhere to a regimen, and the level of underlying immune suppression.[34,134] Oral valganciclovir has become the preferred therapy for treatment of patients with peripheral lesions that are not immediately sight-threatening. This regimen is preferred due to the ease of administration and lack of surgical or catheter-associated complications.[34] Drug resistance can occur among patients receiving long-term therapy and can contribute to relapses.

Adverse effects of ganciclovir and valganciclovir include neutropenia, thrombocytopenia, and nausea. Some patients require G-CSF in order to maintain their white blood count while receiving ganciclovir or valganciclovir. Foscarnet and cidofovir are associated with nephrotoxicity and chelation of cations.

For patients who have had CMV retinitis, the initiation of ART can be associated with flares in ocular disease.[137–139] Within days or weeks of initiating ART, patients may experience inflammation in their posterior or anterior chamber, along with a decrease in visual acuity. Even in patients who do not note a change in acuity, fluorescein angiography can demonstrate capillary inflammation and leak. It is not clear if this is associated with the presence of live virus, or whether this can occur due to the presence of CMV antigen alone. Patients are often treated with periocular corticosteroids or short courses of systemic steroids.[137–139] However, the optimal therapeutic approach to this syndrome is not clear.

Discontinuing secondary prophylaxis (chronic maintenance therapy) should be considered for patients with a sustained (>6 months) increase in $CD4^+$ T lymphocyte cell counts >100–150 cells/μL in response to ART. Regular ophthalmologic monitoring for early evidence of relapse and for immune recovery uveitis should continue.[34,137–141]

Herpes simplex virus

Herpes simplex virus (HSV), types 1 and 2, cause mucocutaneous involvement of the orolabial, genital, anorectal, and esophageal areas. Disseminated disease is extremely unusual, even in patients with very advanced disease.[34,142]

Approximately 95% of HIV-infected persons are seropositive for either HSV-1 or HSV-2.[142] Infection and reactivation disease can occur at any time during the course of HIV disease, but the most severe and chronic manifestations occur at $CD4^+$ T lymphocyte cell counts below 100 cells/μL.

The diagnosis of HSV infection is often made empirically on the basis of characteristic vesicular lesions. Definitive diagnosis may be readily attained by HSV antigen testing, Tzanck smear, or viral culture. When lesions are atypical, or do not respond to empiric courses of acyclovir or valaciclovir or famcyclovir, such definitive diagnosis, and susceptibility testing, is appropriate.

Severe mucocutaneous HSV lesions are best treated initially with intravenous acyclovir.[143,144] Patients may be switched to oral therapy after the lesions have begun to regress. Oral therapy may be used for less severe disease; several agents are effective, including oral acyclovir, famcyclovir, or valaciclovir. Intravenous acyclovir is usually well tolerated, but may occasionally cause renal impairment or

CNS toxicity.[34] Treatment failure related to viral resistance should be suspected if lesions do not indicate signs of resolution within 7–10 days.[34,143] If the thymidine kinase enzyme has mutated, the treatment of choice is intravenous foscarnet. If the mutation is in the polymerase, the virus may be resistant to ganciclovir, foscarnet, and cidofovir. For such resistant virus, topical cidofovir and topical trifluridine have been successfully used.

Varicella-zoster virus

Varicella-zoster virus (VZV) can cause primary disease in patients with HIV. Clinical chicken pox can be a severe and even fatal disseminated viral process in this patient population. However, most patients develop reactivation disease, which manifests as dermatomal zoster. Unlike some other immunosuppressed populations, patients with HIV infection rarely develop disseminated zoster.

The incidence of VZV is 15–25 times greater in HIV-infected persons than in the general population, and 3–7 times greater than among the elderly. VZV can occur at any $CD4^+$ T lymphocyte cell count and may be the initial presentation of HIV.

There are some rare manifestations of VZV to be aware of. For patients with higher $CD4^+$ T lymphocyte cell counts, acute retinal necrosis can occur. For patients with lower $CD4^+$ T lymphocyte cell counts, peripheral outer retinal necrosis can occur. Therapy for the former is sometimes successful with acyclovir; therapy for the latter is rarely successful. Combination therapy with ganciclovir plus foscarnet is often used. Zoster ophalmicus can also occur, as can a variety of neurologic lesions, including carotid artery intimate involvement and stroke.

Diagnosis is based on characteristic appearance of the lesions. Cutaneous vesicles can be scraped, and a definitive diagnosis can be made on the basis of characteristic multinucleated giant cells, or the detection of antigen or the isolation of the virus.

The treatment for dermatomal zoster depends on the extent and severity of the episode. In severe cases, when more than one dermatome or the ophthalmic division of the trigeminal nerve is involved, or disseminated disease is present, the treatment should be intravenous acyclovir for 7–14 days or longer if the clinical response is slow. Localized VZV can be treated with oral famcyclovir or valaciclovir until lesions are crusted.[34] Adjunctive corticosteroid therapy to prevent post-herpetic neuralgia is not recommended for HIV-infected patients. Acyclovir-resistant VZV can occur in patients already receiving acyclovir. Foscarnet should be used in these patients.[34,144] Maintenance regimens following acute therapy are not indicated. Dermatomal VZV may recur, but recurrences are rarely frequent enough to warrant chronic therapy.

BACTERIAL INFECTIONS

Mycobacterium tuberculosis

Mycobacterium tuberculosis (MTB) infection in HIV-infected patients is not common in the United States, but HIV-infected patients do have a disproportionate incidence of the disease.[145–151] Progression to disease among those with latent TB infection is more likely to occur in HIV-infected patients than in HIV-uninfected persons.[150] HIV-uninfected persons with a positive tuberculin skin test (TST) have a 5–10% lifetime risk for developing TB, compared with a 7–10% annual risk in the HIV-infected patient with a positive TST.[34,151,152] TST of >5 mm to a standard purified protein derivative (PPD) is considered positive in HIV-infected patients. A negative test is not useful for ruling out tuberculosis infection due to the frequency of anergy, especially in patients with low $CD4^+$ T lymphocyte cell counts.[34,153] Patients with TB have higher HIV viral loads and a more rapid progression of their HIV illness than comparable HIV-infected patients without TB.[151]

In the developing world, the concurrence rates of TB and HIV can be impressively high. In the United States, the majority of HIV-infected patients with tuberculosis are immigrants.[146–148] Tuberculosis in the United States is also characteristically seen in native-born individuals who have been incarcerated or who have abused intravenous drugs.

MTB occurs among those with HIV infection at all $CD4^+$ T lymphocyte cell counts. Clinical manifestations depend on the degree of immunosuppression. Patients with $CD4^+$ T lymphocyte cell counts >200 cells/μL have manifestations that are not substantially different from HIV-uninfected patients. Those with $CD4^+$ T lymphocyte cell counts <200 cells/μL are more likely to have atypical infiltrates (lower lobes, unilateral, or military) and often have extrapulmonary and/or disseminated disease.[150,151,154,155]

Active tuberculosis may be the presenting manifestation of HIV infection. The clinical and radiographic presentation depends on the degree of immunosuppression.[150,151,154,155] Patients with higher $CD4^+$ T lymphocyte cell counts tend to have upper lobe disease with cavities, in contrast to those with lower $CD4^+$ T lymphocyte cell counts, who develop lower lobe disease and adenopathy. Extrapulmonary disease may occur in up to 60% of the cases and virtually all organ systems can be affected, from adenitis to meningeal involvement. Histopathological findings are also affected by the degree of immunosuppression. Patients with relatively intact immune function have typical granulomatous inflammation associated with TB disease. With advanced immunosuppression, granulomas become poorly formed or can be completely absent.[154,155]

Diagnosis of tuberculosis is based on identifying the acid-fast organisms in any clinical specimen. Such specimens can include sputum, bronchoalveolar lavage, lung

biopsy, blood, bone marrow, CSF, or urine. HIV-infected patients are more likely than uninfected persons to have negative smears, probably because cavities, which produce huge organism loads, do not usually occur at low $CD4^+$ T lymphocyte cell counts.[155–157] Nucleic-acid amplification tests are useful for providing rapid identification of *M. tuberculosis* from sputum smear-positive specimens.[158–160] The specificity of this test is close to 100%. The sensitivity is not 100% however, especially when smear-negative specimens are probed.

Mycobacterial blood cultures can be useful, even in patients who appear to have localized pulmonary disease.[161–163] Blood should be inoculated into special mycobacterial media, or into isolator tubes and then plated on an appropriate solid medium. If acid-fast organisms are present on smear of any clinical specimen, *M. tuberculosis* should be routinely considered as part of the differential diagnosis. Clinicians often assume that a mycobacterium is *M. avium*, only to discover that it is really MTB after multiple healthcare workers have been exposed, and after ineffective therapy has been given for months.

Culture of *M. tuberculosis* requires 10–21 days to detect growth using radiometric techniques. The time to positivity depends on the size of the inoculum and the specific MTB strain involved. Identification is rapid once adequate growth occurs, when gene probe techniques are used. Drug susceptibility tests can also be available in 10–21 days.

Treatment of HIV-related TB should follow the general guidelines developed for TB treatment among uninfected persons.[34,152] Directly observed therapy (DOT) is strongly recommended. Treatment of drug-susceptible TB in HIV-infected patients should include the use of a 6-month regimen consisting of an initial phase of isoniazid (INH), rifampin (RIF) or rifabutin, pyrazinamide (PZA), and ethambutol (EMB) given for 2 months, followed by INH plus RIF (or rifabutin) for 4 months for susceptible organisms.[34] The optimal duration of therapy for HIV-related TB is 6 months if patients defervesce promptly and are smear negative by the end of 2 months of therapy.[34] DOT should be administered at least 3 times weekly. Fewer observed administrations have been associated with an unacceptable therapy failure rate, especially among patients with $CD4^+$ T lymphocyte cell counts <100 cells/μL.[34,152,164–168]

Antituberculous therapy is a major challenge to administer to patients with HIV infection.[169,170] The first issue to address is whether ART should be instituted when patients with tuberculosis are found to have HIV infection. Most authorities would wait for at least 2 months, although data proving that to be the most effective strategy is limited. If patients are started on ART before a minimum of 2 months of anti-tuberculous therapy, there is a major risk they will develop an IRIS. Such syndromes may include mild exacerbation of the initial lesions, flares at new sites, or fever and hypotension. Such syndromes appear to occur with less frequency if TB has been treated for at least 2 months.

Anti-tuberculous drugs have many toxicities that overlap with HIV disease and with toxicities emanating from the ART. These overlapping toxicities can be exceedingly difficult to manage. Drug interactions are also a significant problem, especially with the rifamycins, which are potent inducers of cytochrome p450 metabolic enzymes.[34] Rifabutin is a less potent inducer than rifampin.[34] Several sources document drug doses to be used when anti-tuberculous and anti-HIV therapies must be administered simultaneously.[34]

Mycobacterium avium complex

Mycobacterium avium complex (MAC) is a ubiquitous organism found in the environment, including water, food, and soil. The mode of transmission of MAC is thought to be through ingestion, inhalation, or inoculation through the respiratory or gastrointestinal tract portals of entry.[152,171–175] Colonization appears to occur before dissemination. Household or close contacts of those with MAC disease do not appear to be at increased risk for experiencing disease, and person-to-person transmission is unlikely.[171–175]

Disseminated MAC is rarely seen until the $CD4^+$ T lymphocyte cell count falls below 50 cells/μL. In the absence of effective ART and chemoprophylaxis in those with $CD4^+$ T lymphocyte cell counts <50 cells/μL, the incidence of disseminated MAC ranges from 20% to 40% in the United States and Western Europe.[152,171–175] Colonization appears to occur before dissemination. Household or close contacts of those with MAC disease do not appear to be at increased risk for experiencing disease, and person-to-person transmission is unlikely.[171–175] For reasons that are not clear, MAC has not been commonly recognized in developing countries where MTB is common.

Fever, fatigue, night sweats, weight loss, abdominal pain, and diarrhea are the most common clinical manifestations of disseminated MAC. Elevations of alkaline phosphatase levels and severe anemia are characteristically present. Hepatosplenomegaly or lymphadenopathy may be seen by physical examination or by imaging techniques.

IRIS, characterized by focal lymphadenitis and fever, can be seen in response to ART. Immune reconstitution can be difficult to distinguish clinically from active infection. Patients with immune reconstitution are not expected to be bacteremic.

Definitive diagnosis of localized or disseminated MAC is based on the isolation of MAC from blood, bone marrow, or other normally sterile body tissue or fluid.[172–177] Cultures of sputum or stool are diagnostically unhelpful because a positive result may indicate colonization rather than invasive disease.

Disseminated MAC disease requires lifelong therapy with combination chemotherapy, unless immune restoration

occurs. Clarithromycin plus ethambutol is the preferred regimen. This combination is associated with a rapid clearance of MAC from the blood.[176,177] Azithromycin plus ethambutol is also effective; azithromycin appears to cause fewer drug interactions than clarithromycin.

Some clinicians add rifabutin as a third agent to treat disseminated MAC. However, there is not consistent evidence that triple therapy enhances survival, and thus most clinicians do not use triple therapy, especially since the addition of a rifampin alters the pharmacokinetics of many drugs.[34,178–180]

Duration of therapy should be lifelong in the absence of effective ART. For patients who are started on ART, become asymptomatic, and have a robust $CD4^+$ T cell response ($CD4^+$ T lymphocyte count >100 cells/μL for at least 6 months), 12 months of treatment appears to be sufficient.[34,178–180]

When MAC becomes resistant to clarithromycin, treatment is usually unsuccessful. Rifabutin, quinolones, linezolid, and amikacin have activity against most strains of MAC. However, unless ART can substantially augment $CD4^+$ T cell counts, the prognosis has been poor so far using various combinations of these drugs with in vitro activity.

Secondary prophylaxis may be discontinued if the $CD4^+$ T lymphocyte cell count increases to >100 cells for >3 months. It should be reinstituted if the $CD4^+$ T lymphocyte cell count falls below 100 cells.[34,181,182]

Bacterial pneumonia

Bacterial pneumonia is one of the most common causes of HIV-related morbidity.[34,183,184] Compared to HIV-uninfected controls, HIV-infected patients have a five times greater risk of developing bacterial pneumonia and a higher rate of sinusitis and bronchitis, and the risk increases as the $CD4^+$ T lymphocyte cell count decreases.[183] In addition, intravenous drug abusers have a higher incidence of pneumonia. Among patients with lower $CD4^+$ T lymphocyte cell counts, cigarette smoking has been associated with an increased incidence of infections.

Streptococcus pneumoniae and *Haemophilus influenzae* are the most common causes of bacterial respiratory infections.[183–185] Oxacillin-resistant *Staphylococcus aureus* and *Pseudomonas aeruginosa* are also probably overrepresented.

Infection with *S. pneumoniae* is 150–300 times more common among HIV-infected patients than age-matched HIV-uninfected controls.[186] Its incidence has declined since the introduction of HAART.[187] Recurrent pneumococcal pneumonia with the same or unrelated serotype has been frequently observed.[186]

There is nothing unusual about the diagnosis or treatment of bacterial processes compared to HIV-uninfected patients. Prevention of infections due to *S. pneumoniae* with the 23-valent polysaccharide vaccine is currently recommended for all HIV-infected patients.[188] Antibody responses decrease as HIV disease progresses. The durability of antibody response is also likely to be diminished. There is no evidence that the 7-valent polysaccharide vaccine provides additional benefit. Influenza vaccine is also useful for reducing the incidence of post-influenza bacterial pneumonias. PCP prophylaxis with TMP–SMX has been shown to provide some protection against bacterial infections. Further, the use of MAC prophylaxis with azithromycin decreases the incidence of bacterial infections. Effective ART reduces the incidence of bacterial infections.[34]

Bartonella

In AIDS patients, *Bartonella* spp. are the etiologic agents of bacillary angiomatosis. This syndrome can be caused by *Bartonella henselae*, which is transmitted by fleas and by cats, and by *Bartonella quintana*, which is transmitted by lice. Thus, *B. quintana* is generally a disease of the homeless, while *B. henselae* is usually, but not invariably, linked to cats.

Bacillary angiomatosis often occurs late in HIV infection in patients with $CD4^+$ T lymphocyte cell counts of <50 cell/μL.[189,190] Bacillary angiomatosis presents with subcutaneous and cutaneous vascular lesions that often appear similar to the lesions of Kaposi's sarcoma. Patients are almost invariably febrile with fatigue and anemia. Lesions often occur in the head and neck region, although they can be found in lymph nodes, bone, brain, and mucosal surfaces. Histopathologically, vascular proliferation can be seen. Organisms can be visualized by Warthin-Starry staining. Organisms can also be found in lesions of peliosis hepatis, although these are histopathologically different from cutaneous lesions; peliosis is by definition large, blood-filled spaces. Splenic lesions may occur with areas of fibrosis in the presence of organisms.

Bartonella sp. can be isolated from blood using lysis centrifugation, but organisms are difficult to isolate from tissue unless an enriched medium is used.[188–190] Erythromycin and doxycycline have been used successfully to treat bacillary angiomatosis, peliosis hepatis, bacteremia, and osteomyelitis. Erythromycin is generally considered the drug of choice, although azithromycin has also been used successfully.

OPPORTUNISTIC INFECTIONS OF SPECIAL GEOGRAPHIC INTEREST

The OIs that manifest are a reflection of their immune defect, as well as the pathogens they have been exposed to. As physicians see more and more immigrants, they must remember that certain diseases uncommon in the United States may require diagnosis and therapy. Thus, leishmaniasis, trypanosomiasis, isosporiasis, and penicilliosis may require special diagnostic techniques and must be considered in differential diagnoses.

76 AIDS-Related Malignancies

Patricia A. Cornett and Paul Volberding

OVERVIEW

Individuals with HIV infection have an increased risk of certain cancers. These HIV associated malignancies include Kaposi's sarcoma, non-Hodgkin's lymphoma (NHL), and cervical cancer; these three cancers have been designated by the Centers for Disease Control as AIDs defining diagnoses.[1] Other HIV-associated malignancies such as anal cell cancer,[2,3] Hodgkin's disease,[4] squamous cell carcinomas, lung cancer, testicular seminoma, and soft-tissue sarcomas have been shown to occur at a higher rate in HIV infected individuals.[5–7] At least some of these HIV-associated malignancies, particularly those linked to immunosuppression,[8] have the common link to, if not causative role of, an oncogenic virus. It is noteworthy, though, that the most common cancers seen in non-HIV-infected individuals such as prostate, breast, lung, and colon, occur at approximately the same rate as in HIV-infected individuals and individuals must be appropriately screened for these cancers. With the introduction of highly active antiretroviral therapy (HAART) in the mid to later 90s, incidence of many of the HIV-related malignancies has declined. Still, two malignancies, Kaposi's sarcoma and NHL, continue to occur at greater frequencies in HIV-infected patients and when they occur in this population, both malignancies have unique characteristics and special management considerations.

KAPOSI'S SARCOMA

EPIDEMIOLOGY

Kaposi's sarcoma was first recognized and described by Moritz Kaposi in the late 1800s. It was rare in the United States before 1981, particularly in healthy young adults. When it did occur, it generally afflicted elderly men of Ashkenazi Jewish descent, most often affecting the feet and lower extremities. This variant, now referred to as classic KS, had an indolent course and was not associated with a known immune deficiency. Classic KS can be seen occasionally in gay men who remain HIV-negative.[9] Well before the AIDS epidemic, KS was known to be a common malignancy in Central Africa, where some of its variants were seen to be aggressive and infiltrating even in children and young adults without immune deficiencies.[10–12] This form of Kaposi's sarcoma has been termed endemic KS.

In the early 1970s, KS was reported to be associated with iatrogenic immune suppression, generally in the setting of organ transplantation. It had been reported most commonly in renal allograft recipients as well as in patients treated for various autoimmune diseases with corticosteroids.[13,14]

In 1982, a cluster of cases of KS was reported in homosexual men.[15,16] It was subsequently demonstrated that KS was much more common in homosexual men with AIDS than in heterosexual AIDS patients.[17,18] At its peak incidence, KS was the initial AIDS diagnosis in 30% of HIV-infected gay men.[19] The incidence has declined in the HAART era; recent data shows an incidence of 0.7 cases per 100 patient years compared to 4.1 cases per 100 patient years in the pre-HAART era.[20] This decline in incidence is likely not only related to HAART but also to the adoption of safer sexual practices in gay men.

Risk factors for developing KS in HIV-positive patients include the detection of the virus, human herpes virus-8 (HHV-8) in the blood of patients, and the HHV-8 viral load[21] as well as declining CD4 counts and increasing duration of HIV infection.

PATHOGENESIS

Based on the epidemiology of AIDS-related KS, a sexually transmitted coinfection had long been suspected[22–24]; in 1994, a newly recognized herpes virus, HHV-8, was discovered within KS lesions.[25] HHV-8 is found in endothelial spindle cells[26,27] of all types of KS including classic KS, African or endemic KS, transplant-associated KS, and AIDS-related KS.[28] The virus can also be found in peripheral blood mononuclear cells in many KS patients. In one population based study, the coinfection of HIV and HHV-8 resulted in a

10-year probability of the development of KS of 49%.[29] The HHV-8 virus is also associated with rare lymphoproliferative diseases most often seen in HIV-infected individuals, including Castleman's disease and a subtype of NHL known as primary effusion lymphoma (PEL).[30]

The virus can be transmitted in a number of different ways. Transmission occurs by blood and by semen but these routes are relatively inefficient. The most efficient mechanism for transmission is through saliva.[31]

The mechanism by which HHV-8 causes KS lesions is complex. The tumor, microscopically composed of spindle shaped cells, typically arises synchronously in multiple sites. These tumor cells are derived from lymphatic endothelial cells[32] that are infected with the HSV-8 virus. Viral genes, showing some homology with corresponding human genes and likely interacting with the HIV tat protein, produce cytokines with angiogenic properties.[33] Cell cycle controls and apoptosis mechanisms are altered resulting in cellular proliferation. Some evidence supports KS being a monoclonal process,[34] although it may be a polyclonal proliferative process in other cases, especially in the initial phases of the disease process.

NATURAL HISTORY

The natural history of AIDS-related KS is variable. The disease can manifest at a wide range of CD4 counts but becomes more common as the CD4 count drops. Although an occasional patient will have a spontaneous remission or long interval without disease progression, others have a rapid progression. Patients with limited KS and no symptoms suggesting other underlying infectious disease (e.g., fevers, night sweats, weight loss) do reasonably well. More often, however, in the setting of uncontrolled HIV infection, KS progresses rapidly.

The clinical course of the newly diagnosed KS patient is difficult to predict, but several factors are associated with disease progression and shorter survival: previous opportunistic infections, night sweats, fever, weight loss, anemia, elevated erythrocyte sedimentation rate, a low helper to suppresser T-cell ratio, an absolute helper-cell count of less than 100 cells/mm^3, and gastrointestinal (GI) or pulmonary lesions.[35,36] Patients with the best prognosis have only a few small nodular lesions, no previous serious infections, and no recent weight loss, fevers, or night sweats. Neither the site of cutaneous involvement nor the presence or absence of lymph node involvement appears to be particularly important prognostically. Visceral KS, however, does imply a poor prognosis. The AIDS Clinical Trials Group Oncology Committee has devised a staging system for patients with Kaposi's sarcoma with the intent of risk stratification; however, in the HAART era, the staging system is less successful as a prognostic tool and recommendations for revision have been proposed.[37] Specifically, with HAART, the importance of CD4 as a prognostic factor is eliminated whereas tumor extent, HIV associated symptoms and complications are better predictors of survival. The use of HAART has also impacted the natural history of the disease; an analysis of the Multicenter AIDS Cohort study demonstrated a reduction in the risk of death of 81% in patients with KS receiving HAART.[38]

CLINICAL MANIFESTATIONS

Most patients with AIDS-related KS have subcutaneous tumor nodules or lymphatic involvement.[39–41] Cutaneous lesions are typically pigmented red or purple, even early in the disease process. They are usually palpable, painless, and nonpruritic. Occasionally, surrounding ecchymosis is apparent, especially in the cases of rapidly progressing disease. Lesions typically appear on the face and in the oral cavity or on the feet and lower legs, although they may affect almost any site. KS frequently involves the plantar surfaces of the foot but rarely the palm. Other notable sites of disease include the tip of the nose, the region behind the ear, the conjunctiva, and the penis. Vascular sites devoid of lymphatic vasculature, such as the retina, rarely if ever develop KS. Lesions tend to be circular, but those on the back or around the neck can be linear, apparently following cutaneous lymphatic drainage patterns.

Exophytic tumor masses rarely occur in AIDS-related KS, but when they do they can ulcerate, bleed, and when present on the feet, be painful. With advanced disease, plaques of coalesced lesions are common, especially over the medial aspect of the inner thigh. Inactive, previously treated KS lesions may fade entirely but more commonly leave a permanent pigmentation due to hemosiderin-laden macrophages that have engulfed extravasated erythrocytes.

Lymphedema is a common sequela of AIDS-related KS, is often striking, and is most typically seen in the face, where it causes disfiguration and potentially physical obstruction of vision and hearing. Involvement of the lower extremities is also common, with associated upper thigh, scrotal, and penile edema, which can be rapidly progressive and debilitating. In any location, lymphedema may be out of proportion to the extent of cutaneous tumors, reflecting obliteration of small cutaneous lymphatics. Once lymphedema is extensive it can be difficult to reverse even with effective chemotherapy, and many would advocate for early treatment of KS to prevent this complication.

Up to one-third of patients with AIDS-related KS have oral involvement at the time of diagnosis. KS lesions in the oral cavity commonly affect the mucosa of the hard and soft palate and less commonly the posterior pharyngeal wall or the tonsillar pillars.[42]

Visceral involvement is common in AIDS-related KS. Almost any organ can be involved, although central nervous

system (CNS) involvement is exceedingly rare.[43] The GI tract is affected in as many as 50% of patients, even early in the course of the disease.[44] GI involvement is often an incidental finding because it is most often asymptomatic. It can, however, produce obstructive symptoms, bleeding, and malabsorption. Pulmonary involvement tends to be progressive and can be rapidly fatal without treatment. A dry cough, intermittent hemoptysis, dyspnea, fevers, and an abnormal chest radiograph are typical.[45] Lymphadenopathic or visceral KS may occur in the absence of cutaneous manifestations.

DIAGNOSIS

KS lesions are generally readily recognizable but, irrespective of risk group or clinical appearance, a biopsy should be performed to establish the histologic diagnosis. The differential diagnosis of KS includes other pigmented processes such as bacillary angiomatosis, dermatofibromas, granuloma annulare, insect bite reactions, pyogenic granuloma, stasis dermatitis, and cutaneous lymphoma. The biopsy can be performed at any site, but skin is most convenient. A small punch biopsy (2–4 mm) is usually adequate, but it is helpful to include unaffected adjacent skin in the punch specimen. Enlarged peripheral lymph nodes can also be biopsied. Aspiration cytology has also been used to diagnose KS.

If a biopsy shows KS in a patient without previously established HIV infection, a serologic test is necessary. Patients with a positive test are diagnosed with AIDS, no matter what their CD4 count is. If the serologic test is negative, the KS is not considered to be AIDS-related, even if the patient is a member of an AIDS risk group.

In the initial evaluation of a KS patient, tumor extent should be determined by a complete skin examination. The oral cavity should also be carefully examined. However, clinically important visceral KS can occur in the absence of cutaneous or oral manifestations in approximately 15% of cases. If unexplained GI or pulmonary symptoms are present, endoscopy should be performed. The classic appearance of small submucosal vascular nodules establishes the diagnosis of visceral KS. Biopsies are diagnostic in only a minority of cases of GI KS because the tumors are generally submucosal, but biopsy specimens may exclude other diagnoses. Endobronchial biopsy is discouraged because of the risk of hemorrhage.

In all KS patients, associated symptoms such as fevers, night sweats, and weight loss should be recorded and immunologic status, including CD4 cell count and HIV viral load, assessed.

THERAPY

When to initiate therapy and the choice of therapy for AIDS-related KS are problematic for several reasons. (1) The natural history of KS is highly variable and thus unpredictable.[46] (2) Because of advances in HIV treatment, affected patients are living longer and may therefore have a more protracted course of KS. (3) Use of cytotoxic chemotherapy may impair cellular immunity and thus increase the risk of opportunistic infections. Other acute or cumulative toxicities include myelosuppression, allergic reaction, neuropathy, pulmonary fibrosis, and other risks depending on the agent used. (4) With initiation of HAART, lesions may regress without the use of cytotoxic chemotherapy.[47] Concurrent initiation of HAART and chemotherapy may make the response rate of drugs used in clinical trials somewhat difficult to interpret. (5) Even though the AIDS Clinical Trials Group staging system and tumor response criteria have led to better standardization among trials,[48] the clinical benefits obtained by patients are sometimes not well documented by these criteria, and the criteria may now not be as reliable as in the pre-HAART era when the criteria system was devised.[47] (6) Finally, therapeutic drug studies that have used different response criteria are difficult to compare.

When to initiate treatment must be decided on a patient-by-patient basis. Even disease that does not appear to be medically complicated may raise difficult issues for the patient because KS may be so recognizable and socially stigmatizing. When treatment is initiated and disease activity increases, the treatment alternatives are to maximize the dose and frequency of the agent being used or to change to a new agent. When the disease is quiescent, the alternatives are to use a tolerable agent intermittently or to discontinue therapy until a clear progression is seen.

Therapeutic approaches may be classified as local or systemic. The disease is often systemic even if the manifestations seen are only localized, but patients with indolent disease activity and a limited number of lesions may be managed with local therapy for long periods. In general, treatment is considered palliative and patients' desires for improved quality of life should be balanced against the toxicities and risks of therapy.

LOCAL THERAPY

Surgery, cryotherapy, intralesional chemotherapy, and laser therapy

Several effective local control methods can be used for small, superficial, discrete cutaneous lesions. Although surgery is often used to biopsy lesions, in general, it should not be a routine choice for treatment due to problems with local recurrences around the wound site despite attempts at wide excisions. Cryotherapy with liquid nitrogen, easily performed in the office setting, can be effective for small, superficial lesions. Its use in dark skinned individuals can result in noticeable hypopigmented skin due to destruction of

melanocytes. Topical application of topical 9-cis-retinoic acid (0.1% gel) has been shown to have responses in up to 41% of patients; side effects include local irritation and erythema.[49] Intralesional administration of vinblastine causes necrosis of the KS, often accompanied by several days of pain, but the result may be cosmetically satisfactory and possibly long-lasting.

Other local treatments include laser therapy and photofrin photodynamic therapy. Laser therapy can be very effective in controlling often painful mouth lesions and results in less morbidity and improved outcomes than other forms of local treatment.[50]

Radiation therapy

Radiation therapy is very useful in managing AIDS-related KS, particularly if the tumor has associated symptoms such as pain, bleeding, or edema.[51–53] Superficial lesions are best treated with a low-energy electron beam, which only penetrates a short distance into tissues, sparing deeper structures. Facial lesions, especially those on the nose or eyelid, can be successfully treated this way, with good cosmetic results. Larger, plaque-like areas of disease or areas with considerable edema may require coverage with megavoltage photons. Even with low doses, brawny induration in the radiation field can develop, and radiation recall resulting in skin erythema over the radiation field and even skin necrosis can occur when the patient moves on to systemic chemotherapy with anthracyclines. Optimal dosing and fractionation regimens will vary depending upon tumor size and location of the tumor as well as goals of therapy. A single treatment at low dose (8–12 Gy) produces a complete response in approximately 50% of lesions so treated with almost 100% of patients experiencing symptomatic improvement, but the duration of response is often shorter than if higher doses are given over a protracted course.[54]

SYSTEMIC THERAPY

Chemotherapy

Many older chemotherapy agents including vinblastine, vincristine, bleomycin, doxorubin, and etoposide have been studied, either alone or in combination, as therapy for KS. However, conventional chemotherapy has rarely produced durable remissions and has been associated with significant acute and chronic toxicity. For AIDS patients battling a number of chronic symptoms or intermittent infections, chemotherapy toxicity was often an excessive burden. Therefore, the goal of therapy was palliation of symptoms, and systemic chemotherapy was reserved for intermittent use during exacerbations of KS. Combination regimens, although intended to produce quick and sustained responses in the most symptomatic patients, have largely been supplanted by better-tolerated single agents such as liposomal anthracyclines and paclitaxel. Liposomal doxorubicin (Doxil) and liposomal daunorubicin (DaunoXome) are encapsulated anthracylines that are approved as single agents for the treatment of advanced KS. In a large randomized trial, Doxil produced a response rate nearly twice that of a combination of doxorubicin (Adriamycin), bleomycin, and vinblastine (ABV).[55] In a similar study, a fourth of patients responded to either DaunoXome or ABV, but DaunoXome use was associated with a trend toward more opportunistic infections.[56] Even with long-term use of these liposomal anthracyclines, cardiotoxicity and other cumulative toxicity have not been seen. Mild myelosuppression is the most common side effect and generally develops after several cycles. The usual dose of Doxil is 20 $\mu g/m^2$ every 3 weeks or DaunoXome 40–60 $\mu g/m^2$ every 2–3 weeks, each given intravenously over 30 minutes.

Paclitaxel (Taxol) appears to have significant amount of activity.[57] It is approved as second-line treatment of KS and is frequently used for patients whose disease has progressed during therapy with liposomal anthracyclines. Two dosing schedules have activity, 100 $\mu g/m^2$ every 2 weeks and 135 $\mu g/m^2$ every 3 weeks. Side effects such as hair loss, myelosuppression, and neuropathy make it less appealing for some HIV-infected patients.

Biologic agents and investigational therapies

Since the association between HHV-8 and KS was identified, there has been attempts to treat the underlying herpes viral infection or molecular pathways. One study has shown that the incidence of KS can be reduced by the antiviral agent ganciclovir but to date, antiviral drugs have not been shown to significantly affect established KS lesions.[58]

Alpha-interferon is active against KS, especially in those patients with relatively well-preserved immune systems as measured by their CD4 counts.[59] It is also one of the few agents that have been able to induce durable remissions, albeit in a minority of patients. Although neutropenia may develop, alpha-interferon has immune-enhancing and antiviral properties, in addition to its antineoplastic and antiangiogenic effects. The major drawbacks are that it requires daily subcutaneous injections and is associated with toxicity such as a flu-like syndrome. In addition, responses occur up to 6–8 weeks or more following initiation of therapy. Antiretroviral therapy should be given with alpha-interferon as older studies demonstrated that response rates appeared to be higher when an antiretroviral drug was given with alpha-interferon. Doses generally used are 4–18 million units by subcutaneous injection daily as a single agent; doses of 1–10 million units when combined with newer antiretrovirals are currently being studied.

As the histologic manifestation of Kaposi's sarcoma is characterized by vascular proliferation; drugs targeted at inhibiting angiogenesis are being explored in studies. Thalidomide has shown some promise[60]; other antiangiogenesis drugs

such as bevacizumab and sorafenib are being evaluated in clinical trials.

Summary of treatment guidelines

HAART, with either local therapy, alpha-interferon, watchful waiting or experimental agents are all reasonable approaches to the patient with limited disease or an indolent disease course. Effective control of HIV should be the first step.

Patients with associated B-symptoms (fevers, sweats, weight loss), edema, symptomatic visceral disease, or the rapid appearance of a number of new lesions should receive effective systemic therapy. Reasonable options include alpha-interferon or chemotherapy with Doxil, DaunoXome, or Taxol. Doxil has become the most frequently used agent, followed by taxol if control is inadequate with Doxil.

As durable remissions are possible, periodic trials off chemotherapy should be allowed to determine which patients may discontinue chemotherapy. More often, patients will require ongoing or intermittent chemotherapy to maintain the benefits that they achieved. However, any residual pigmentation, which may be permanent, needs to be distinguished from ongoing KS disease. Close observation during any period off chemotherapy, looking for progressive disease, may be the only way to determine if ongoing chemotherapy is still required.

NON-HODGKIN'S LYMPHOMA

Since the first cases of high-grade NHL were reported in the early 1980s,[61–63] many reports of aggressive lymphoma in patients at risk for AIDS have been published. In June 1985, the CDC amended its case definition of AIDS to include patients with high-grade, B-cell NHL in the setting of documented HIV infection.[1]

NHL IN IMMUNODEFICIENT NON-HIV-INFECTED POPULATIONS

It has been recognized for more than 30 years that in patients with congenital immune deficiency in which there is impaired cell-mediated immunity, such as the Wiskott-Aldrich syndrome, the incidence of cancer is up to 100 times greater than expected and malignant lymphomas comprise the majority of these malignancies.[64] Patients typically have marked generalized lymphadenopathy for several years before the diagnosis of lymphoma,[65] and lymph node biopsies can often initially show a pattern of reactive hyperplasia, as they do in renal transplant patients receiving immunosuppressive medications.[66,67] Overall, renal transplant patients have a 35-fold increased risk of developing NHL, often in unusual sites.[68]

In one-third of patients with NHL associated with renal transplantation, the disease is confined to the CNS.[69] Lymphoproliferative disease may appear as a relatively benign polyclonal proliferation in renal transplant patients or as an invasive and aggressive monoclonal large-cell NHL.[65] An etiologic role for Epstein-Barr virus (EBV) is supported by serologic studies as well as the finding of multiple copies of the EBV virus within the tumor cells. Lymphoproliferation occurs when the host immune response is unable to control the proliferation of the EBV infected B cells.

NHL IN AIDS

EPIDEMIOLOGY

NHL in HIV-infected patients has many similarities to NHL seen in transplant patients. The rate of NHL among HIV-infected persons is about 200-fold greater than that in the general population and is fairly uniform throughout all HIV exposure risk groups.[70] The incidence of primary central nervous system lymphoma (PCNSL) is 1000-fold higher than that seen in the general population. The risk of lymphoma increases with the severity as well as the duration of immunosuppression. Although HAART has decreased the incidence of lymphoma by about 50%,[71] it is anticipated that the number of cases will rise as other AIDS-related complications are controlled and patient survival is prolonged.

PATHOGENESIS

The pathogenesis of AIDS-related NHL is complex.[72,73] The same regulatory dysfunction seen in the lymphoproliferative disorders of transplant patients likely plays a similar role in AIDS related NHL. A state of chronic B-cell stimulation evidenced by polyclonal hypergammaglobulinemia and follicular (B-cell) hyperplasia typifies HIV infection. One-third of patients diagnosed with NHL have histories of persistent generalized lymphadenopathy. HIV appears to induce the production of a host of cytokines or growth factors that serve to induce a state of ongoing B-cell activation, differentiation, and proliferation. In the context of impaired T-cell immunity, ongoing EBV infection can drive polyclonal B-cell activation. EBV nuclear antigen (EBNA) has been identified in 40–50% of AIDS related lymphomas, and most patients have shown evidence of previous EBV infection. Virtually all PCNSLs contain EBV. The inherent genetic instability of EBV-infected and immortalized B-cell clones eventually leads to c-*myc* gene rearrangement, resulting in the emergence of a fully transformed, EBV-containing monoclonal B-cell lymphoma. AIDS-related NHL does not infrequently carry c-*myc* rearrangements in the absence of EBV. A variety of other chromosomal translocations involving oncogenes have been described in AIDS-related NHLs, and multiple alternative molecular pathways likely contribute to lymphomagenesis in the setting of HIV.[74] In summary, major contributing

factors for the development of lymphomas in HIV-infected individuals are the HIV induced immunosuppression, chronic antigenic stimulation, cytokine overproduction, and eventually genetic alterations in c-*myc, bcl*-6, *ras*, and/or p53.

CLINICAL MANIFESTATIONS

Systemic NHL comprises approximately 80% of all AIDS-related NHLs; the other 20% are confined to the CNS. The vast majority of systemic lymphomas are diffuse large B-cell (DLBCL), intermediate- or high-grade DLBCL, typically presenting with advanced disease and involving extranodal sites.

In 1984, Ziegler et al. reported a retrospective, multiinstitutional study of 90 homosexual men with HIV-associated NHL.[61] Of 77 patients diagnosed antemortem, 33 had a prodrome of generalized lymphadenopathy, 15 had previous opportunistic infections, and 9 had KS before NHL developed. All but two patients had evidence of extranodal disease; 42% of patients had CNS disease, and 33% had bone marrow involvement. Meningeal infiltration developed in two-thirds of patients by the time of death. The GI tract has become the most common extranodal site of involvement since CNS prophylaxis with intrathecal chemotherapy became standard practice. However, virtually any organ site may be infiltrated with NHL. The lungs and liver are also common sites.

Patients presenting with ascites or with pleural or pericardial effusions will be diagnosed with PELs, which is a subtype of DLBCL. This subtype of AIDS related lymphoma accounts for approximately 1–5% of lymphomas in HIV-infected persons.[75] PEL is especially aggressive and is associated with resistance or only partial responses to chemotherapy resulting in relatively poor overall survival in the range of 6–9 months. Malignant cells universally contain HHV-8, often in conjunction with EBV.

DLBCL confined to the CNS or PCNSL should be considered in any patient belonging to a risk group for AIDS who shows focal neurologic findings or has more nonspecific symptoms such as confusionor memory loss. Brain involvement tends to be multifocal. Most patients have late stage HIV disease with CD4 counts less than 50/mm^3. Survival is poor with a median survival of about 4 months.[76] With the use of HAART, the incidence of PCNSL has fallen considerably from the pre-HAART era.[77]

DIAGNOSIS

The diagnosis is often elusive because patient presentation can be so variable. Fevers and declining functional status, signs of organ compromise due to NHL infiltration, or the onset of asymmetric lymphadenopathy are common presentations. The differential diagnosis includes opportunistic infections, other malignancies such as KS, or benign lymphadenopathy. Fine needle aspiration with flow cytometry is appropriate for peripheral or accessible intra-abdominal masses and can often make the diagnosis, but additional tissue may be required to confirm the diagnosis. The major histologic subtypes by the WHO classification are diffuse large B-cell lymphoma (DLBCL) and Burkitt's lymphoma. PELs are best diagnosed by fluid sampling with flow cytometry of the cells. Suspected PCNSL should be biopsied if possible.

THERAPY

AIDs-related lymphomas in the pre-HAART era were difficult to treat. Standards treatment commonly used in HIV-patients frequently caused more immunosuppression and increased the risk of death due to opportunistic infections. More than a decade ago, Ziegler and colleagues[61] reported that morbidity and mortality appeared to be directly related to the degree of previous HIV-related illness. Patients who were asymptomatic at the time of diagnosis showed the best treatment results. Only two of 21 patients with a previous AIDS diagnosis remained alive and well. Thirty-eight of 66 evaluable patients had died, half from progressive lymphoma and half from opportunistic infections.

Much has changed over the last 2 decades largely due to HAART and also in part due to work in identifying tolerable regimens for HIV-positive patients on HAART. In the pre-HAART era, important prognostic features such as CD4 count and existing prior AIDS diagnosis were important prognostic components, differing from factors important in non-HIV infected lymphoma patients.

The poor outcomes in these patients prompted the use of attenuated doses of combination chemotherapy. Levine and colleagues initiated this approach with a study of low dose m-BACOD (methotrexate, calcium leucovorin, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone).[76] This led to a large multi-institutional trial, conducted in the pre-HAART era, of standard-dose m-BACOD versus low-dose m-BACOD.[77] This trial demonstrated a median survival in both arms of approximately 8 months, with less than 20% of patients surviving longterm. No subgroup could be identified in whom standard-dose therapy was more beneficial. In a similar attempt to identify a tolerable but more effective regimen, the Eastern Cooperative Oncology Group (ECOG) performed a phase II trial in patients with HIV-associated lymphoma evaluating infusional therapy with cyclophosphamide, doxorubicin, and etoposide.[78] Of note, this trial had approximately equal numbers of patients receiving HAART and no HAART; this allowed investigators to assess the effect of HAART on outcomes. Although complete remission rates were similar between the HAART and no-HAART groups (44% vs. 47%, respectfully), survival favored the HAART group with 47% of patients alive compared to only 30% of patients receiving no HAART.

Rituximab (humanized anti-CD20 antibody) has emerged as a standard component of all $CD20^+$ lymphomas in HIV^- patients following demonstration in the randomized Groupe d'Etude de Lymphome de l'Adulte (GELA) study in patients over 60 years of age showing a survival benefit in patients treated with CHOP chemotherapy plus rituximab versus patients treated with CHOP alone.[79] However, the same clear benefit has not yet been demonstrated for HIV-infected patients. In an AMC sponsored randomized trial in HIV-infected patients with NHL looking at CHOP with or without rituximab, there was no difference in survival between the two groups but a significant increase in deaths associated with bacterial infections in the rituximab group of 14% versus 2% in the CHOP alone arm.[80] Sixty percent of the deaths were seen in patients with CD4 counts less than $50/m^3$. Some have advocated that rituximab should be used in HIV-infected lymphoma patients with careful attention to supportive medical care and early intervention for infectious complications.[81]

The prognosis for patients with PCNSL is extremely poor.[82,83] Most will die with recurrent disease within 1 year. Radiation therapy is the standard treatment approach, although combination chemotherapy followed by radiation can be used in patients with adequate immune function. There is evidence that the use of HAART along with antineoplastic treatment can improve survival.[84]

In summary, treatment of AIDS-related lymphoma will almost always offer at least palliation of cancer-related symptoms and clearly improves survival compared with no therapy at all. Patients treated with HAART and relatively preserved immune function will fare better with standard cytotoxic chemotherapy. Although the prognosis for patients with AIDS-related lymphoma has improved substantially, the outcome is still less favorable for these patients when compared to non-HIV infected patients. Further narrowing of this gap awaits identification of better tolerated and more effective regimens along with advances in HIV treatment.

77 Management of Neurological Disease in HIV-1 Infection

Kevin Robertson and Colin Hall

Early in the human immunodeficiency virus type 1 (HIV) epidemic, it was recognized that neurologic disease occurred in up to 70% of infected patients, often with disastrous consequences.[1,2] Neurologic opportunistic infections such as cytomegalovirus (CMV), progressive multifocal leukoencephalopathy, cryptococcal meningitis, toxoplasmosis, and central nervous system (CNS) neoplasms, primarily lymphoma, were very frequent before the era of highly active antiretroviral therapy (HAART), and are still highly prevalent in resource-limited settings.[3–6] Treatment of these diseases is covered elsewhere in this book. In this chapter, we will concentrate on nervous system diseases that appear to be the result of HIV alone. They include a clinically unique dementing process that has been called HIV-associated dementia (HAD) or AIDS dementia complex (ADC) and a milder clinical impairment labeled minor cognitive motor dysfunction (MCMD), myelopathy, peripheral neuropathy, and myopathy.[7–18] With the advent of HAART, there has been a dramatic decline in the incidence of dementia in the developed world, although, since effective treatment has resulted in increased survival, the relative prevalence has not yet shown a clear decline.[19–21] The incidence and prevalence of HIV-related neurological disorders in resource-limited settings where the majority of the disease burden remains have yet to be characterized.[22,23] HIV is known to cross the blood–brain barrier by way of trafficking lymphocytes within the first days of infection and to remain sequestered in the CNS, particularly in microglial cells throughout the course of the infection.[24–26] An acute but generally mild and self-limiting meningoencephalitis may occur at that time, but neurological signs and symptoms generally do not occur until many years later, usually in conjunction with severe immune compromise.[26–28] We will describe the different presentations and their treatment individually, but it should be remembered that these conditions frequently occur concomitantly.

DEMENTIA

From the earliest stages of the HIV epidemic, it has been recognized that some patients developed severe and progressive intellectual dysfunction that had a rather unique clinical presentation.[29] Recognizing that this condition usually involved more than cognitive loss, Price and colleagues labeled this as ADC.[5,30] The American Academy of Neurology later suggested the term HAD.[31] The terms are used interchangeably. HIV encephalopathy and AIDS dementia are also terms in common usage.[5,30] Patients without dementia but with mild and often subclinical cognitive dysfunction have been labeled as having MCMD.[31]

HIV-ASSOCIATED DEMENTIA

Incidence and prevalence

Before effective antiretroviral (ARV) therapy was available, HAD was reported in up to one-third of infected patients,[1,13] with an annual incidence rate of between 3.5% and 14%.[32,33] The vast majority was severely immune compromised with peripheral CD4 lymphocyte counts below 200 cells/μL, and many had other manifestations of AIDS including lymphadenopathy, wasting, and a history of AIDS-related opportunistic infections and/or cancers. Other risk factors include increasing age, intravenous (IV) drug use, and lower hemoglobin levels.[33–36] The CDC reported 2.8% of patients presented with HAD, and a large European study found HAD in 4.5% of patients at the time of AIDS diagnosis.[35,37] With the availability of effective ARVs, there has been a marked reduction in the incidence of HAD in the developed world.[38] ADC was seen in 39% of patients in the Netherlands before zidovudine treatment, and 6% after with a later study by the same group showing a 7.5% prevalence.[39] The incidence in the United States is reported as now being less than 1%.[40] In the developed world, almost all those presenting with classical HAD are either HAART-naive or have severely inadequate viral control. As could be expected with the greatly increased longevity associated with treatment, the prevalence of HAD has not yet shown a comparable decline, and has been reported as high as 15%. The incidence and prevalence likely remain high in resource-poor settings, but accurate figures are not currently available.[19–21]

Clinical findings

HAD is somewhat unique in its constellation of symptoms and signs, which generally include cognitive, behavioral, and motor dysfunction (see Table 77-1). Untreated, the condition generally starts insidiously but progresses over weeks or months to a profound and devastating dementia affecting all spheres of function. Early cognitive findings include forgetfulness, lack of concentration, and loss of interest in activities that may be mistaken for depression. This progresses to flattening of affect and inability to understand written materials, maintain conversation, and cope with activities of daily living. A common late feature is progressive slowing of cognitive and motor responses to where the patient may take many seconds to offer an answer to the simplest questions. Behavioral changes may include delusions, hallucinations, irrational actions, and at times mania. There is almost always an associated decline in motor function. Early signs may include mild clumsiness and unsteadiness on rapid turns. Gait difficulty may progress to require a cane and eventually wheelchair. There may be increasing limb incoordination, loss of facial expression, paucity of movement, and motor weakness.[1,13] Movement disorders including myoclonus, tremor, and other parkinsonian features may accompany HAD, and may also occur in nondemented patients, even as the first manifestation of AIDS.[41] The deep tendon reflexes are increased although the ankle jerks in particular may be suppressed if there is concomitant neuropathy. The plantar responses may be extensor, along with prevalent prominent jaw jerk and frontal release signs including snout and grasp responses. Sphincter disturbances are common. Untreated patients who do not first expire from intercurrent infection or other causes progress to become mute, unresponsive, and bed bound with urinary and fecal incontinence.

Table 77-1. Early Symptoms of the AIDS Dementia Complex Seen in 44 Patients

Symptoms		Number of Patients (%)
Cognitive		29 (66%)
	Forgetfulness	17 (39%)
	Loss of concentration	11 (25%)
	Confusion	10 (23%)
	Slowness of thought	8 (18%)
Motor		20 (45%)
	Loss of balance	15 (34%)
	Leg weakness	9 (20%)
	Deterioration of handwriting	4 (14%)
Behavioral		17 (39%)
	Apathy, social withdrawal	16 (36%)
	Dysphoric mood	5 (11%)
	Organic psychosis	2 (4%)
	Regressed behavior	1 (2%)

Clinical research criteria (see Table 77-2) for the diagnosis of HAD include a combination of motor symptoms, cognitive symptoms, and changes in activities of daily living and function in the absence of other confounding neurological or psychiatric disease.[11,13,42] The Memorial Sloan Kettering (MSK) ADC staging system (see Table 77-3), developed by Price, Brew, and Sidtis, has proven useful in characterizing the severity of the dementia in research studies, and is also helpful in the general clinical setting.[14] At Stage 0, patients have no functional disability and normal cognitive-motor functioning. In Stage 0.5 (*equivocal/minimal*), patients have some signs or symptoms consistent with ADC, but do not have functional deficits. In Stage 1, mild impairments of cognition and motor function exist that lead to functional deficits such that the patients cannot engage in their usual activities, but can still perform the less demanding aspects of work. In Stage 2, moderate impairments of cognitive motor functioning exist, and normal work becomes impossible. Stage 3 shows marked slowing, difficulty with conversation and personal events, and inability to walk unaided. In Stage 4, the patient is nearly vegetative, with little or no spontaneous language or responsiveness, paraplegia, and double incontinence.[14,15]

HIV-ASSOCIATED MINOR COGNITIVE MOTOR DISORDER

Early cohort studies of HIV-infected patients showed that subjects who did not meet the criteria for dementia often had less severe cognitive dysfunction, and this was more prevalent than in matched control subjects. In 1991, an American Academy of Neurology working group developed the term MCMD to describe this entity.[43] While patients with HAD have clear abnormalities that disrupt work ability and activities of daily living, those with MCMD have either no clear impairment or difficulty with only the most demanding tasks. The bedside mental status examination is generally within normal limits, and more specific and demanding neuropsychological tests are required to establish the diagnosis. Nonetheless, the presence of MCMD does predict difficulties, including in work performance and driving. Before HAART, it also had predictive value in the development of HAD.

Table 77-2. HIV-Associated Dementia Diagnosis

Confirmed

1. Acquired cognitive/motor dysfunction for at least 1 month causing impairment of work or activities of daily living (verifiable by report of other), not attributable solely to severe systemic illness or medication adverse effects

2. Abnormalities from at least two of the following categories:

a. Motor abnormality–for example, slowed rapid movements, release signs, abnormal gait, limb incoordination, diffuse hyperreflexia, hypertonia, or weakness

b. Behavioral abnormality–for example, change in personality with apathy, inertia, irritability, and/or emotional lability or new onset of impaired judgment characterized by socially inappropriate behavior or disinhibition

c. Cognitive abnormality in two or more domains of memory, judgment, flexibility, visual, constructional difficulties, reaction time, speed of mental processing, attention, and/or concentration as determined by appropriate neuropsychological testing

3. No other etiology confirmed by MRI/CT scan, negative CSF cryptococcal antigen or CSF CMV PCR: exclude active CNS opportunistic infections or malignancy, active psychiatric disorders, active alcohol or substance use, or substance withdrawal

Probable

1. Acquired cognitive/motor dysfunction for at least 1 month causing impairment of work or activities of daily living, not attributable solely to severe systemic illness or medication adverse effects

2. Abnormalities from at least two of the following categories:

a. Motor abnormality–for example, slowed rapid movements, release signs, abnormal gait, limb incoordination, diffuse hyperreflexia, hypertonia, or weakness

b. Behavioral abnormality–for example, change in personality with apathy, inertia, irritability, and/or emotional lability or new onset of impaired judgment characterized by socially inappropriate behavior or disinhibition

c. Cognitive abnormality in two or more domains of memory, judgment, flexibility, visual, constructional difficulties, reaction time, speed of mental processing, attention, and/or concentration as determined by appropriate neuropsychological testing

3. Tests for other possible etiology (active CNS opportunistic infections or malignancy, active psychiatric disorders, active alcohol or substance abuse, or substance withdrawal) are not completed, results are not available, or results do not exclude other CNS processes

Possible

1. Acquired cognitive/motor dysfunction for at least 1 month causing impairment of work or activities of daily living, not attributable solely to severe systemic illness or medication adverse effects

2. Other possible CNS processes cannot be excluded (active CNS opportunistic infections or malignancy, active psychiatric disorders, active alcohol or substance abuse, or substance withdrawal)

Source: Modified from Appendix 60: Diagnoses Appendix. 2004, AIDS Clinical Trials Group.

However, it is not clear that HAD represents the progression of MCMD, or whether different mechanisms may be responsible for the two conditions. It is not established that MCMD responds to any treatment other than optimal treatment for the underlying HIV infection.

Pathology

The changes resulting from HIV-1 infection in the brain first and most profoundly involve the white matter and subcortical gray matter.[1] Early autopsy series reported neuropathological abnormalities in over 90% of brains, 33% of spinal cords, and up to 100% of peripheral nerves of AIDS patients, many of whom had not shown overt neurological disease. Changes in the brain include myelin pallor, formation of microglial nodules, rarification and vacuolation of white matter, and inflammatory changes that include multinucleated giant cells. While the presence of multinucleated giant cells does correlate with dementia, they are only present in a quarter of demented patients.[1,42,44,45]

Pathogenesis

HIV-1 DNA, RNA, and viral antigen are found in macrophages, microglial cells, and multinucleated giant cells in the CNS, particularly in white matter and deep gray matter structures, indicating productive viral infection in these cells.[46–49] Vascular endothelial cells also show evidence of HIV infection.[49,50] However, astrocytes do not show productive infection,[51–53] and there has not been convincing evidence of direct infection of neurons.[47,54] Despite this, neuronal loss is common, starting in the clinically asymptomatic stages and progressing with advancing disease. Studies have found loss of up to 50% of cortical neurons in AIDS patients, both demented and nondemented.[55–60] It has been therefore proposed that neuronal death is the result of secondary indirect

Table 77-3. Staging Scheme for the AIDS Dementia Complex

ADC Stage	Characteristics
Stage 0 (normal)	Normal cognitive and motor function
Stage 0.5 (equivocal)	Either minimal or equivocal symptoms of cognitive or motor dysfunction characteristic of ADC or mild signs (snout response, slowed extremity movements) but without impairment of work or capacity to perform activities of daily living; gait and strength normal
Stage 1 (mild)	Unequivocal evidence (symptoms, signs, neuropsychological test performance) of functional, intellectual, or motor impairment characteristic of ADC, but able to perform all but the more demanding aspects of work or ADL; can walk without assistance
Stage 2 (moderate)	Cannot work or maintain the more demanding aspects of daily life, but able to perform basic activities of self-care; ambulatory but may require single prop
Stage 3 (severe)	Major intellectual incapacity (cannot follow news or personal events, cannot sustain complex conversation, considerable slowing of all output) or motor disability (cannot walk unassisted, requiring walker or personal support, usually with slowing and clumsiness of arms as well)
Stage 4 (end stage)	Nearly vegetative; intellectual and social comprehension and responses are at a rudimentary level; nearly or absolutely mute; paraparetic or paraplegic with double incontinence

Source: Modified from Sidtis JJ, Price RW. Early HIV-1 infection and the AIDS dementia complex. *Neurology* 1990; 40(2): 323–326.

mechanisms. In vitro models suggest that macrophages and microglia are upregulated by HIV-1 infection to release substances that may act both directly and indirectly through upregulation of astrocytes to give neuronal apoptosis.[61–65] While the exact mechanism is not established, a wide array of proposed toxins have been postulated, including the viral gene products *gp120*,[66–68] *tat*,[69–71], *nef*,[51] and *rev*,[51] cell-derived toxins such as quinolinic acid,[72,73] and cytokines including tumor necrosis factor alpha (TNF-α),[74–76] eicosanoids,[74,77] platelet-activating factor,[78] and nitric oxide.[79,80] Glutamate receptors, voltage-dependent calcium channels, or both have been implicated as the final common pathway, leading to increases in intracellular calcium concentrations and neuronal injury or death, and agents blocking these effects have been shown to protect neurons exposed to HIV in culture.[79,81–83] Other studies have suggested that while cellular death is related to calcium influx, the final pathway may not be glutamate mediated.[84]

Diagnosis

While the clinical presentation in the late stages is quite typical, HAD remains a diagnosis of exclusion, to be considered when patients present with cognitive changes, particularly in association with motor and/or behavioral abnormalities. Individuals with HAD show impaired performance on neuropsychological tests that target motor function, attention and concentration, speed of information processing, and visuospatial performance.[15,31,85] However these tests, while sensitive, are not specific to HIV.[15] It is necessary to rule out opportunistic infection or neoplasm of the brain, encephalopathy due to other end organ failure, medication effects, and psychogenic states. Complaints of cognitive disturbance, particularly in the earlier stages of infection, may result from anxiety or depression.[86] Toxoplasmosis CMV encephalopathy,[87–89] seen commonly in the early epidemic and once considered as the cause of HAD, is now rare but cognitive changes still occur with other viral infections, including progressive multifocal leukoencephalopathy[90] and herpes infections[91] toxoplasmosis,[92–94] cryptococcosis,[95] syphilis,[96] tuberculosis and lymphoma should be considered, as well as a number of less common infectious agents. Medications that affect CNS function should be considered. While ARVs do not usually cause significant intellectual changes, efavirenz may elicit mood change, irritability, and sleep disturbance, particularly in the first few months of treatment.[97]

Cerebrospinal fluid (CSF) examination and neuroimaging are particularly helpful in the differential diagnosis of HAD. If there is any suspicion of a mass lesion in the brain, it is prudent to perform computerized tomography (CT) or magnetic resonance imaging (MRI) before lumbar puncture. While neuroimaging is of most value in excluding alternative infectious and neoplastic causes of dementia, MRI is more sensitive than CT in this respect, although it should be noted that some viral infections, cryptococcosis, and even lymphoma may present without obvious neuroimaging changes. A typical pattern in advanced HAD is of diffuse brain atrophy with

patchy changes in white matter that may fluctuate over time. However, both CT and MRI may show considerable brain atrophy, even in the asymptomatic stages of infection with no intellectual dysfunction, and white matter changes may not be obvious, even with HAD.[13,98–103]

Attempts to identify a reliable surrogate marker for HAD in the CSF have been largely unsatisfactory. Absolute levels of CSF HIV RNA and comparisons with blood levels have not proven reliable indicators. Studies on patients before the availability of HAART indicated a relationship between CSF HIV-1 RNA viral load and dementia severity.[104,105] CSF viral load correlated with cognitive scores, and CSF viral load greater than 10,000 copies per milliliter (cps/mL) correlated both with severity of dementia[106] and with the likelihood of abnormalities on neuroimaging.[107] However, patients undergoing HAART treatment do not show a clear correlation between CSF viral load and nervous system dysfunction.[45,108] While data from the MACS suggest that a CSF beta-2-microglobulin concentration of >3.8 mg/dL in a CSF specimen with a normal WBC count is specific for the diagnosis of HAD, and p24 antigen and neopterin are also elevated in dementia, none of these has proven sensitive enough to have value in the clinical setting.[109–116] There is also evidence that the utility of these markers has been further reduced in the HAART era.

While conventional CSF analysis is useful in excluding opportunistic infections of the CNS, it must be realized that CSF abnormalities are frequent in HIV-infected patients without any signs of neurological disease.[117–119] These include increased WBC, particularly mononuclear, count, increased protein, the presence of oligoclonal bands, and blood–brain barrier compromise. A high granulocyte cell count and hypoglychorracia, on the other hand, are likely to indicate intercurrent infection. Identification of viral antigen by using polymerase chain reaction (PCR) has greatly increased the value of CSF evaluation. Positivity for JC virus, herpes viruses, and CMV, while not highly sensitive, has very high specificity for active nervous system disease caused by these agents, and PCR for Epstein Barr virus is almost 100% positive in the presence of CNS lymphoma.[87–91,120]

Recent efforts have been made to address the diagnostic criteria and definitions of HIV-related neurological disease, especially with changes some have noted in the presentation of neurological disease in the HAART era. An NIMH/NINDS panel found that some modification of the prior AAN criteria was needed. Among other changes, the panel recommended that an *asymptomatic neurocognitive impairment* category be added to the existing diagnostic schema to describe impaired performance on testing without substantial functional impact.[121]

Treatment

Zidovudine is the only single agent that has undergone double-blind placebo-controlled randomized trial for efficacy in the treatment of HAD.[122] There was evidence of efficacy, but experience soon showed that the beneficial effects were quite limited in both degree and duration.[123–127] However, while little is described on the effectiveness of individual agents, there is a great deal of evidence that effective systemic HAART therapy has led to a reduction in the incidence of ADC.[128–130] There is also strong anecdotal evidence of improvement, often dramatic, in demented individuals following the institution of effective HAART. The standard of care for dementia is therefore to optimize viral suppression using HAART. This approach is particularly likely to be beneficial in patients who are HAART naive or who have had a protracted period off medication. In fact, such patients comprise the vast majority of those who now present with dementia. There is also evidence that cognitive function is improved by effective viral suppression, even in patients who do not show evidence of dementia.[130]

The exact mechanism behind this therapeutic effect is not known. ARVs have poor penetration into the CNS, particularly protease inhibitors which are highly protein bound in plasma and are a substrate of the P-glycoprotein efflux mechanism which limits entry.[131,132] This has led to speculation that virus may become sequestered in the CNS, increasing the likelihood of the development of resistant virus behind the blood–brain barrier, and maintaining the propensity for neurological disease even in the face of adequate systemic treatment.[133,134] Another complication could be reseeding of the systemic compartment with resistant virus from the CNS.[134] It should be stressed that, although there is evidence that virus in the CNS compartment can show different mutations from those in the systemic compartment in individual patients, there is no reliable evidence that this affects the likelihood or intensity of neurological disease.[133–135] However, it has raised the possibility that ARV regimens with higher CNS penetration may provide increased protection from neurological disease (see Table 77-4 for comparative CNS penetration of ARVs). Although earlier retrospective reports found no difference,[130,136] recent studies have suggested improved neurological outcome in high over low CNS penetrant regimens.[130,137–139] So, there is mounting evidence to support the use of ARVs known to have higher CNS penetrance, especially in patients showing evidence of CNS dysfunction.[136,140–142] Higher CNS penetrating regimens have been associated with reduced CSF viral load, and improved cognitive functioning.[143,144]

Based on the premise that neuronal loss is a secondary effect rather than a direct result of viral infection, a number of agents have been tested for their neuroprotective effects in HAD. Early phase two trials with medications available by prescription include the anti-oxidant selegiline,[145,146] and the calcium channel antagonist nimodipine.[147] Although each demonstrated a trend for improvement in individual aspects of the extensive neuropsychological battery used in testing, neither showed significant benefit. Other agents continue to be studied, but none can yet be recommended.

Table 77-4. CNS Penetration/Efficacy

High	**NRTI**	ZDV	ABV			
	NNRTI	NVP	DLV			
	PI	ATV-r	APV-r	f-APV-r	IDV-r	LPV-r
Medium	**NRTI**	3TC	FTC	D4T		
	NNRTI	EFV				
	PI	APV	f-APV	ATV	IDV	
Low	**NRTI**	TFV	DDI	DDC		
	PI	NFV	SQV	SQV-r	RTV	TPV-r
	FI	T20				

Note: High, medium, low denote level of penetration/efficacy within the CNS.

NRTI, nucleoside reverse transcription inhibitors; NNRTI, non-nucleoside reverse transcription inhibitors; PI, protease inhibitors; FI, fusion inhibitors. The suffix r refers to ritonavir boosting.

Eighth Conference on Retroviruses and Opportunistic Infections, 2001. Robertson K, Parsons T, Robertson W, Hall CD. Antiretroviral CNS Penetration and Neurocognitive Outcomes. HIV Infection and the Central Nervous System, Developed and Resource Limited Settings, Frascati, Italy, 2005.

Other adjunctive therapies that can be considered in treatment include antidepressants, psychostimulants to counter some of the psychomotor, attention and speed of processing symptoms,[148] and antipsychotics to treat delusional or hallucinatory symptoms. Behavioral techniques that focus on compensation for lost abilities in early dementia and on providing a structured environment in late dementia may be helpful.[149,150] Clinical trials of other adunctive therapies such as nimodipine, memantine, and lexipafant have not been very successful. Trials of selegiline have just completed, and upcoming trials of minocycline are planned after promise in SIV model has been demonstrated.

Course

Before the availability of ARV medication, dementia was generally rapidly progressive with survival ranging from 6 to 8 months.[33,35,39] Zidovudine, the first available ARV, was shown in a controlled study to have benefit in reversing some symptoms of HAD, and the incidence of dementia in studied populations declined with the availability of the nucleoside reverse transcript inhibitors as a group. With the availability of HAART, there has been a marked improvement in both the incidence of dementia and the prognosis for recovery, as described above.

DEMYELINATING DISEASE

Although it is not unusual to have MRI evidence of white matter disease in late stage AIDS, particularly with dementia, there have been a number of reported cases of multiple-sclerosis-like illness with more prominent demyelination and with no evidence of opportunistic viral or other infections of the brain. The initial reports were of patients early in the course of infection,[151,152] but later descriptions were in more advanced disease.[153,154] It has been suggested that a severe form associated with dementia and death may be the result of immune restoration inflammatory syndrome.[155] There have been no formal studies of treatment for this condition, but a tapering course of corticosteroids has provided temporary improvement in one of our patients.

HIV-1 MYELOPATHY

Clinical presentation

Early descriptions of HIV-infected cohorts included patients who had clear evidence of spinal cord involvement.[29,156,157] Patients with HIV myelopathy develop symptoms that are predominantly in the lower limbs. These include weakness, spasticity of tone in the legs with increased reflexes, extensor plantar responses, sensory loss that particularly involves joint position and vibration sense, sexual dysfunction, and sphincter disturbance. In untreated patients, the course is generally of subacute or chronic decline, with progressive loss of gait and eventual wheelchair confinement. On occasion, this presents as a pure myelopathy with no evidence of other nervous system involvement. However, the clinical picture is often much more complicated by concomitant evidence of brain and/or

peripheral nerve involvement. These patients may have cognitive dysfunction and frontal release signs such as snout, grasp and palmomental responses and an increased jaw jerk due to brain involvement, or hyperreflexia at the knees with suppressed ankle reflexes due to peripheral neuropathy. It may not be clinically possible to distinguish the different areas involved. An abnormal spinal component of lower limb sensory evoked potentials may suggest spinal cord involvement, but there is not a close correlation between this and symptomatic spinal disease.[157]

Pathology

The autopsy findings associated with HIV myelopathy show prominent vacuolation in the white matter, particularly in the dorsal and lateral columns, and most prominently in the thoracic spinal cord.[2,158] As with the brain, there is no clear evidence that spinal cord neurons are directly infected by HIV.[159–161] The degree of pathological change not only correlates with the degree of clinical dysfunction but also with the presence of dementia, suggesting that a similar process could be involved in both the processes.[160,162]

Differential diagnosis

In the HAART era, clinical HIV myelopathy has become rare, and it is particularly important to rule out other potential causes of spinal cord dysfunction. Opportunistic infections to consider include herpes simplex,[162,163] varicella-zoster virus,[164,165] CMV,[166–169] *Toxoplasma gondii*,[170–173] mycobacteria,[174] and syphilis.[175] Compression of the cord due to degenerative disease and tumor must also be ruled out. Evaluation should include MRI of the cord and CSF studies, including appropriate PCR evaluations.

Treatment

There is no defined treatment for HIV myelopathy, but the marked decline associated with HAART suggests that effective ARV therapy should be the goal. The pathological changes are similar to those seen with Vitamin B12 deficiency, and while there is no clear evidence of efficacy, it is prudent to ensure adequate B12 levels.[157,160,161,176]

PERIPHERAL NEUROPATHY

In the developed world, and probably globally, neuropathy is the commonest neurological manifestation of HIV infection, and may be due to a number of different pathological processes.[177]

Opportunistic infections that may result in neuropathy include varicella-zoster, hepatitis C and its treatment, human T-lymphotropic virus type 1, CMV and rarely toxoplasma, syphilis, or cryptococcus. Some neuropathies are immune mediated. The commonest form, however, is a primarily painful distal sensory polyneuropathy (DSPN), generally occurring in late disease. A clinically similar neuropathy is associated with ARV medications.

IMMUNE-MEDIATED NEUROPATHIES

These generally occur in the clinically asymptomatic and early symptomatic stages of HIV infection, when the immune system is still able to mount a vigorous response.[178]

Clinical presentation

Cranial nerve and more rarely individual peripheral nerve palsies may occur very early in the course of infection. The commonest is of the facial nerve.[3,8,9,11] This is generally self-limiting. While no formal studies have been performed, it may be treated over 1–2 weeks with a tapering course of high-dose steroids, as this has reduced morbidity in traditional Bell's palsy. As Bell's palsy has been associated with herpes simplex infection, acyclovir or valacyclovir may also be given.[179–182]

An acute inflammatory demyelinating polyneuropathy (AIDP) indistinguishable from Guillian-Barre syndrome (GBS) may also occur. This generally presents as a rapidly progressive primarily motor neuropathy, most commonly but not always starting in the lower limbs and like GBS can lead to quadriparesis with respiratory failure over days or even hours.[183–189] Some patients will progress to or develop de novo a more slowly progressive chronic inflammatory demyelinating polyneuropathy form (CIDP).[29,184,190–193] Generally there is weakness, sensory symptoms that may be more prominent than actual sensory loss, and loss of reflexes. The CSF will show elevated protein after the first few days.[29,184] Unlike non-HIV-related inflammatory neuropathies, there may be CSF pleocytosis.[29,184] Nerve conduction studies will generally be compatible with a demyelinating neuropathy, but axonal forms have also been described.[29] Treatment with either plasma exchange, starting with three infusions per week for 2 weeks, or IV immunoglobulin, 2 g/kg infused as 400 mg/kg/day for 5 days, is generally effective in both the forms, but may need prolonged repetitions in CIDP. CIDP is also often responsive to corticosteroids, although these carry the risk of further immune compromise.[29,191]

There have also been isolated reports of biopsy-confirmed vasculitic mononeuritis and mononeuritis multiplex, some with response to immunoglobulins or corticosteroids.[29,191–193]

A rapidly ascending paralysis similar to GBS but associated with lactic acidosis and exposure to nucleoside reverse transcriptase inhibitors has also been reported. This entity remains poorly defined but has been suggested to be the result of mitochondrial toxicity.[194–196]

Facial palsy and peripheral neuropathy may also be seen as part of the diffuse infiltrative lymphocytosis syndrome resulting from persistent CD8 hyperlymphocytosis.[197] Corticosteroids may have efficacy in severe cases.

DISTAL SYMMETRIC SENSORY POLYNEUROPATHY

Distal symmetric sensory polyneuropathy (DSP) is the commonest nervous system manifestation of HIV infection in the developed world, affecting about a third of patients with advanced disease.[9,17,190,192,193] The incidence and prevalence of DSP in resource-poor settings is not well characterized, but initial studies have similar prevalence as in the developed world.[198,199]

Pathologically it is a "dying back" axonal neuropathy, first affecting the distal branches of the longest nerves, then progressing proximally.[191] As with the CNS, there is no evidence that HIV infects or replicates in peripheral neurons, and the condition is likely due to an indirect process, with activated macrophages causing neuronal death by liberating cytokines and/or other toxic products.[9,18,65,200–203] Nutritional factors have also been postulated as having a role.[17,18,76]

Clinical presentation

DSP has a characteristic clinical presentation with paresthesia numbness aching and/or burning in the toes progressing to the feet over weeks to months.[7,17] There is variable objective sensory loss and generally loss of ankle reflexes or at least depression when compared to knee reflexes. Pain may be very severe, greatly impairing quality of life. Motor loss is usually absent or mild. Autonomic neuropathic features may occur late in the course.

Diagnosis

While electrodiagnostic studies and sural nerve biopsy may indicate an axonal neuropathy,[17,18] this remains primarily a diagnosis based on history and clinical examination.[204,205]

Treatment

The effect of HAART on the incidence and prevalence of DSP is not clear,[7,126,127] but it appears prudent to attempt effective viral suppression. If patients are on an ARV regimen that contains a "d-drug" including ddI, ddC, or D4T, then it is possible that these ARVs could be responsible for the neuropathy symptoms. The symptoms and signs of DSP are indistinguishable from those reported with exposure to the nucleoside reverse transcriptase inhibitors ddI, d4T, and ddC, particularly in combination, and reduction or withdrawal of these medications may need to be considered.[206–211] Although, it does appear that if a patient can tolerate d-drug therapy initially without development of neuropathy, the majority can safely tolerate this regimen for longer term treatment.[212]

Treatment is otherwise aimed at control of pain and usually involves the sequential trial of systemic agents including gabapentin,[213,214] lamotrigine,[215] valproic acid,[216] carbamazepine, and tricyclic antidepressants.[217] Topical lidocaine or capsacin may also be helpful.[218–220] Some patients require chronic narcotic use, but this is of limited effectiveness.

Differential diagnosis

As noted above, toxic side effects of the NRTI's ddi, ddC, and D4T, and some ARVs, are indistinguishable from DSP. Reduction or withdrawal of these medications may need to be considered to determine if the symptoms are due to the toxic side effects of the d-drugs or from HIV.[206–211] Alcohol can lead to neuropathy symptoms similar to HIV DSP, and an assessment of alcohol should be considered. Correction of deficiencies of nutritional factors such as vitamin B12[176] and withdrawal of other potentially neurotoxic medications should also be considered.

MYOPATHY

Nonspecific myalgias are common in HIV infection.[221] A usually noninflammatory myopathy, generally but not always associated with diffuse wasting, or "slim disease" is frequently associated with late-stage untreated or inadequately treated HIV infection, and probably results from a combination of poor nutritional intake and cachexia related to upregulation of proinflammatory cytokines.[222,223] Small uncontrolled studies have suggested that corticosteroids or anabolic steroids may result in clinical improvement,[16,223,224] but the most important therapy is adequate viral suppression.

Otherwise, disease of muscle is less commonly encountered than other neurological complications of HIV infection. However, myopathy may still present at any stage.[223,225] HIV-associated polymyositis is generally indistinguishable from that disease in non-HIV-infected patients in presentation and response to treatment.[226] Subacute progressive proximal muscle weakness, often with myalgias, is accompanied by elevation in serum creatine kinase level, electromyographic changes compatible with inflammatory myopathy, and muscle biopsy showing perivascular and endomysial inflammatory infiltration with necrosis and regeneration of individual fibers.[221–225] The pathology is believed to be immune mediated, and the disease generally responds to the same forms of immune modulation that are of benefit in non-HIV-infected patients, although there are no controlled clinical studies of treatment.[227] Prednisone at a starting dose of 1 g/kg and tapered over weeks according to response may provide rapid symptomatic relief, although it does raise concerns of further immune compromise.[226,228] Methotrexate starting at a weekly dose of 7.5 mg, azathioprine, or mycophenolate mofetil may be used as single therapy or added in cases of steroid failure. IV immunoglobulin 2 mg/kg given over a 5-day course may give excellent clinical improvement without the danger of further immune compromise, but this will generally require repeated infusions titrated to response, and/or combination

with immunosuppressant drugs. Steroid-responsive polymyositis may also present in the course of HAART-related immune restoration syndrome[229] and diffuse infiltrative lymphocytosis syndrome.[202,226]

Rare reports of other apparently immune-mediated muscle disorders have been described. One was a case of inclusion body myositis with typical clinical and pathological findings.[230] A painless myopathy responsive to prednisone and associated with nemaline rods on biopsy has also been described.[231,232] There are rare reports of myasthenia gravis with or without antibodies to acetylcholine receptors in association with HIV infection, and it can be assumed that this too is in some way related to immune upregulation.[233,234]
